Attempt to Resolve **4,4′-Dicarboxy-1,1′-dianthraquinoyl with** Quinine.—A mixture of 5.02 g. (0.01 mole) of 4,4′-dicarboxy-1,1′-dianthraquinoyl, 3.24 g. (0.01 mole) of quinine and 200 cc. of chloroform was refluxed for sixty hours. The mixture was then cooled and the insoluble material was removed by filtration. This material consisted of the quinine salt, since the weight was 8.26 g. It had an unsharp melting point starting at 210°. The salt is insoluble in benzene, p-cymene, acetone, gasoline, chloroform, alcohol, nitrobenzene, ethyl acetate and ether. The extraction of 3 g. of salt with 2 liters of hot p-cymene gave about 0.1 g. of salt, the acid from which gave no rotation in 0.1 N sodium hydroxide. Pyridine was found to decompose the salt. An attempt was then made to solubilize the salt by forming the mono-quinine mono-sodium salt. To a suspension of 4 g. of the mono-quinine salt of 4,4′-dicarboxyl-1,1′-dianthraquinoyl in 400 cc. of water was added slowly 47 cc. of 0.108 *N* sodium hydroxide solution (1 equiv.). The mixture was warmed for six hours at 80° and filtered from 2.6 g. of insoluble material. The insoluble material was again combined with the filtrate and warmed for twelve hours at 80°. The amount of insoluble material was again 2.6 g. The material was found to be the diquinine salt, for upon hydrolysis one equivalent of acid and two equivalents of quinine were obtained. The soluble portion was found to consist chiefly of the disodium salt. It gave no rotation in aqueous or pyridine solution.

Summary

1. 4,4′-Dicarboxy-1,1′-dianthraquinoyl and its di-*l*-menthyl ester have been prepared. Only one di-*l*-menthyl ester was obtained.

DEGUELIN. II. RELATIONSHIPS BETWEEN DEGUELIN AND ROTENONE

BY E. P. CLARK

RECEIVED APRIL 18, 1931 PUBLISHED JUNE 8, 1931

Recently[1] attention has been directed to a relationship between deguelin and rotenone in ,which the following facts were involved. Upon mild oxidation rotenone is converted to dehydrorotenone, $C_{23}H_{20}O_6$, which when boiled with alcoholic potassium hydroxide and zinc dust yields an hydroxp acid, $C_{23}H_{24}O_8$.[2] When this acid is oxidized in alkaline solution with hydrogen peroxide, the molecule is ruptured, and derric acid, $C_{12}H_{14}O_7$,[3] is obtained. Derric acid contains the two methoxyl groups originally in rotenone and represents one-half of the rotenone molecule.

In an analogous manner deguelin is oxidized with potassium ferricyanide to dehydrodeguelin, $C_{23}H_{20}O_6$,[4] which upon boiling with alcoholic potassium hydroxide yields a phenolic monocarboxylic acid, $C_{23}H_{24}O_8$, known as deguelic acid. When this acid is oxidized with hydrogen peroxide, as was the acid from dehydrorotenone, it also yields derric acid.

It thus follows that in deguelin as in rotenone derric acid constitutes one-half of the molecule, and hence the structural differences between deguelin and rotenone must be sought either in the second half of the molecule or in the linkages between the two parts.

Another set of experiments showing the same relationship has been performed more recently. Takei, Miyajima and Ono[5] described an acid, $C_{11}H_{12}O_7$, which they called risic acid (Rissaure). The compound was obtained by permanganate oxidation of the hydroxy acid, $C_{23}H_{24}O_8$, derived from dehydrorotenone through the action of alcoholic alkali. LaForge and Smith[6] originally obtained this acid by permanganate oxidation of derric acid, and as derric acid is a part of the deguelin molecule, risic acid should be expected as an oxidation product of deguelic acid. This experiment was performed, and risic acid was obtained, having the properties recorded for it by the Japanese investigators.

The purpose of the present report is to record the experimental data obtained in establishing the relationship mentioned above and also to describe some experiments the results of which show that these two insecticides are even more closely related than was demonstrated in the first instance.

Dehydrodeguelin was catalytically reduced with hydrogen to dihydro-

dehydrodeguelin, $C_{23}H_{22}O_6$. This material was found to be identical with the compound recently described by Haller[7] as dehydro-β-dihydrorotenone. Mild oxidation of dihydrodehydrodeguelin with chromic acid under the conditions described in the experimental part yielded oxydehydrodeguelin, $C_{23}H_{20}O_8$. Dihydrodehydrodeguelin when treated with alcoholic alkali in the manner by which deguelic acid was obtained from dehydrodeguelin yielded dihydrodeguelic acid, $C_{23}H_{26}O_8$. The same substance was also prepared by catalytically reducing deguelic acid. This reduced deguelic acid was found to be identical with the compound described by Haller as dehydrodihydroxy-β-dihydrorotenoic acid.[7]

When dihydrodeguelic acid was subjected to alkaline oxidation with hydrogen peroxide, the yield of derric acid was essentially the same as that given by deguelic acid.

In the first communication of this series[4] it was shown that deguelic acid reverts to dehydrodeguelin when an attempt is made to acetylate the phenolic hydroxyl group in the acid with acetic anhydride and sodium acetate. However, it has been found that if the acid is treated with a large excess of acetic anhydride in pyridine, a monoacetyldeguelic acid is formed which no longer gives a phenolic reaction with ferric chloride.

The reactions under discussion are summarized diagrammatically in Chart I.

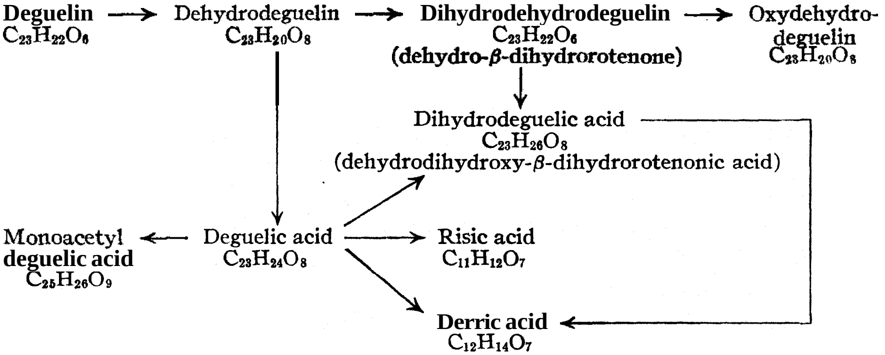

CHART I—DERIVATIVES OF DEGUELIN

The observations just recorded show that there exist structural relationships common to the entire molecule of both rotenone and deguelin. However, the information now available is so fragmentary that it seems best to present the facts now at hand and await further developments before attempts at correlation are made.

Experimental

Derric Acid from Deguelic Acid.—An aqueous solution of 2 g. of deguelic acid in 25 cc. of 5% potassium hydroxide solution, warmed to 60°, was treated portionwise with

---

[7] Haller, THIS JOURNAL, 53, 733 (1931).

6 cc. of 30% hydrogen peroxide. After the reagent was added the mixture was gently boiled until foaming ceased The liquid was then cooled, acidified with sulfuric acid and thoroughly extracted with ether. The extract was dried with sodium sulfate, concentrated to 20 cc. and allowed to crystallize. After several hours 0.5 g. of derric acid separated. This was removed from the mother liquor, washed with a small quantity of ether and dried. Its melting point was 167–168°.

The acid was recrystallized from boiling n-butyl ether, from which it separated as colorless rods and needles that melted at 168° (corr.).

The crystals had both straight and inclined extinction and positive elongation: η_α, 1.525 (on rods crosswise showing straight extinction); η_β, 1.565 (common on fragments not extinguishing sharply); and η_γ, 1.640 (usually on irregular-shaped fragments).[8]

These properties are the same as those possessed by derric acid prepared according to the directions of LaForge and Smith[3] from rotenone and recrystallized from n-butyl ether.

Risic Acid from Deguelic Acid.—Two grams of deguelic acid, dissolved in 40 cc. of 1% potassium hydroxide was treated portionwise with a warm aqueous solution of 15 g. of potassium permanganate. After the reaction was completed, the liquid was filtered from the manganese dioxide and concentrated to 15 cc. The solution was then acidified with sulfuric acid and allowed to crystallize. The yield was 0.25 g. or 21%. Recrystallization of the acid from boiling n-butyl alcohol yielded colorless sheathes of fine needles and rods which melted at 256° with decomposition. A sample of the acid which Dr. LaForge obtained by the oxidation of derric acid had the same melting point upon recrystallization from n-butyl alcohol, and a mixture of the two acids showed no melting point depression.

Dihydrodeguelic Acid from Deguelic Acid.—A solution of 2 g. of deguelic acid in 100 cc. of alcohol was reduced at atmospheric pressure with hydrogen and the platinum catalyst of Voorhees and Adams.[9] After the reaction was completed the solution was filtered and heated to boiling. An equal volume of hot matcr was then added. As the solution cooled long colorless needles separated. These began to soften at 70° and melted at 80°, apparently with the loss of vapor. Upon further heating the melt solidified and then remelted at 144°. When the acid was recrystallized from boiling n-butyl ether, it separated as colorless rods showing inclined extinction and having a melting point of 147° (corr.); η_α, 1.490; η_β, indeterminate and η_γ, higher than 1.740. It also possesses two intermediate indices, η_ι, 1.605, and η_ι' 1.740, which are useful diagnostic values.

Anal. Calcd. for $C_{23}H_{26}O_8$: C, 64.17; H, 6.09; OCH_3 (2), 14.4. Found (material recryst. from butyl ether): C, 64.13; H, 6.24; OCH_3, 14.6.

Dihydrodeguelic acid and the compound described by Haller[7] as dehydrodihydroxy-β-dihydrorotenonic acid were shown to be identical when it was found that both materials possess the same optical properties and melting point and that when the two substances were mixed no melting point depression occurred.

Derric Acid from Dihydrodeguelic Acid.—Two grams of dihydrodeguelic acid was treated with alkali and hydrogen peroxide according to the directions given before for the preparation of derric acid from deguelic acid. The yield of crystalline product was 0.55 g. This material, recrystallized from n-butyl ether, had a melting point of 167–168° and it showed no depression of the melting point when mixed with derric acid. It also had the optical properties that are characteristic of derric acid.

---

[8] The optical data recorded in this communication were determined by George L. Keenan of the Food and Drug Administration of the U. S. Department of Agriculture. Appreciation is gratefully acknowledged for this coöperation.

[9] Voorhees and Adams, THIS JOURNAL, 44, 1397 (1922).

Monoacetyldeguelic Acid.—Two grams of deguelic acid was dissolved in 12 cc. of pyridine, and the solution was treated with 16 cc. of acetic anhydride. The mixture was allowed to stand at room temperature for three hours, and then one volume of acetic acid and four volumes of water were added. The liquid was made acid to Congo red with 10% sulfuric acid and set aside to crystallize. The yield was 1.85 g. The material was recrystallized by dissolving it in acetic acid and adding hot water until a slight turbidity was produced. Upon standing the acetyl derivative separated as colorless crystals which melted at 128–129°. It gave no color reaction with ferric chloride as did the free acid.

For analysis it was necessary to heat the material to its melting point in a high vacuum to remove an indefinite quantity of solvent which could not be completely eliminated otherwise.

Anal. Calcd. for $C_{25}H_{26}O_9$: C, 63.82; H, 5.57; OCH_3 (2), 13.2. Found: C, 63.85; H, 5.6; OCH_3, 13.1.

Dihydrodehydrodeguelin.—Five grams of dehydrodeguelin dissolved in 200 cc. of hot acetic acid was reduced at atmospheric pressure and approximately 75° with hydrogen and the platinum catalyst of Voorhees and Adams.[9] After the reaction was completed and the solution cooled to room temperature, a product crystallized from the acetic acid. This was removed by filtration, and dissolved in 40 cc. of chloroform. The solution was filtered through norit, again heated to boiling, and five volumes of boiling ethanol was then added. Crystallization began at once, yielding 1.9 g. of long yellow rods and needles which melted at 267". Their extinction was inclined and in convergent polarized light (crossed nicols) biaxial interference figures were common. 2E was small and the double refraction was very strong. The only index of refraction determinable was the minimum value η_α, 1.498; η_γ is greater than 1.74

A comparison of dihydrodehydrodeguelin and the compound **dehydro-β-dihydro**rotenone described by Haller showed the two substances to be identical, as their melting points and optical properties were the same, and when the two substances were mixed the melting point was not depressed.

Anal. Calcd. for $C_{23}H_{22}O_6$: C, 70.03; H, 5.63; OCH_3 (2), 15.7. Found: C, 69.86; H, 5.79; OCH_3, 15.5.

Oxydehydrodeguelin.—Two grams of dihydrodehydrodeguelin dissolved in the minimum quantity of boiling acetic acid was oxidized with 15 cc. of a 10% acetic acid solution of crystalline sodium dichromate. The mixture was allowed to stand until the next day. The oxydehydrodeguelin was then removed by filtration. The yield was 0.36 g. It was recrystallized by dissolving 0.3 g. of the crystals in 20 cc. of boiling chloroform and adding to the solution 60 cc. of boiling ethanol. The substance melted at 303°, and the yield was almost quantitative. It consisted of small yellow needles and rods with square ends. The extinction was straight, and the elongation was negative. Only faint partial biaxial interference figures were shown in convergent polarized light (crossed nicols); η_α, 1.490 (frequently shown lengthwise on rods), η_β, 1.595 (crosswise), and η_γ, >1.740.

Anal. Calcd. for $C_{23}H_{20}O_8$: C, 65.08; H, 4.75; OCH_3 *(2)* 14.6. Found: C, 64.81; H, 4.85; OCH_3, 14.2.

Dihydrodeguelic Acid from **Dihydrodehydrodeguelin.**—A mixture of 0.5 g. of dihydrodehydrodeguelin, 1 g. of zinc dust, 12 cc. of ethanol and 3 cc. of a 50% aqueous potassium hydroxide solution was refluxed for thirty minutes. The reaction mixture was cooled by the addition of crushed ice and diluted with water to a volume of 75 cc. The zinc was removed by decantation, and the alkaline solution was made acid to Congo red with sulfuric acid. The acid solution was extracted with ether, The ethereal extract was dried over sodium sulfate and evaporated to dryness. The residue was dissolved in hot n-butyl ether. Upon cooling 0.36 g. of dihydrodeguelic acid separated which had the properties recorded for the acid obtained by catalytically reducing deguelic acid.

Summary

1. Derric and risic acids have been obtained from deguelic acid by methods analogous to those used in preparing these acids from derivatives of rotenone. This shows that in degueiin as in rotenone, derric acid constitutes one-half of the molecule.
2. Reduction of dehydrodeguelin yields dihydrodehydrodeguelin, which is identical with dehydro-β-dihydrorotenone.
3. Upon treatment with alcoholic alkali, dihydrodehydrodeguelin gives dihydrodeguelic acid. This acid is also obtained by catalytically reducing deguelic acid.
4. Dihydrodeguelic acid has been found to be identical with dehydrodihydroxy-β-dihydrorotenonic acid described by Haller.
5. These facts show that there exist structural relationships common to the entire molecule of both rotenone and deguelin.

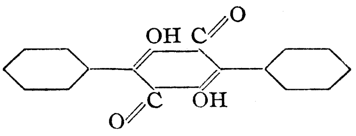
THE SYNTHESIS OF POLYPORIC ACID AND ATROMENTIN DIMETHYL ETHER

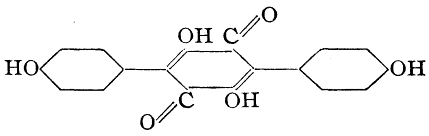
BY P. R. SHILDNECK[1] AND ROGER ADAMS

RECEIVED APRIL 21, 1931 PUBLISHED JUNE 8, 1931

Two of the important coloring matters found in fungi are polyporic acid (I) obtained from *Polyporous nidulans* and atromentin (II) from *Paxillus atrotomentosus*. Kogl[2] determined the structures of these two compounds to be derivatives of diphenylquinone.



I



II

Moreover, he synthesized each of these compounds in two ways. The first method was that devised by Fichter.[3] For the polyporic acid, ethyl phenylacetate and ethyl oxalate[2] were condensed together with sodium;

---

[1] This communication is an abstract of a portion of a thesis submitted by P. R. Shildneck in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[2] Kogl, Ann., 447, 78 (1926).

[3] Fichter, *ibid.*, 361, 363 (1908).

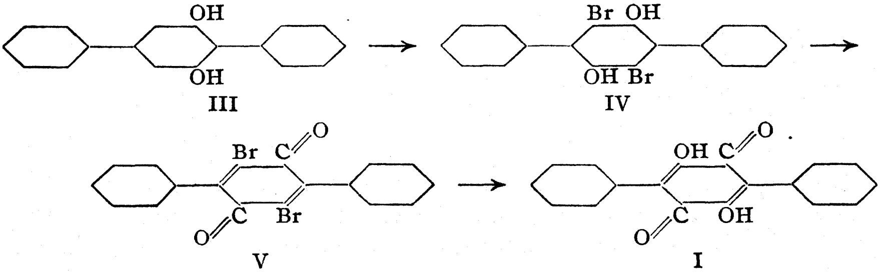
for the atromentin, ethyl *p*-methoxyphenylacetate and ethyl oxalate.[4] Although sufficient product in each case was obtained to characterize the compounds and to form one or two derivatives, the yields were extremely poor, as they amounted only to about one per cent. of the theoretical.

Kogl used a second method of synthesis also which consisted in preparing diphenylquinone or p-hydroxyphenylquinone by the method of Pummerer[5] and then in introducing methoxyls adjacent to the carbonyl groups of the quinone by heating with zinc chloride in methyl alcohol. Upon demethylation of the ethers the two natural coloring matters were obtained Even by this procedure, however, the introduction of the methoxyl groups resulted in such low yields that these syntheses may be considered valuable only so far as the identification of structure is concerned.

During recent work on substituted diphenylquinones in connection with the stereochemistry of diphenylbenzenes, it was noticed that diaryldibromoquinones were easily hydrolyzed to the corresponding hydroxy derivatives. This procedure has now been applied to the synthesis of polyporic acid and atromentin dimethyl ether with the result that the compounds were prepared with ease in excellent yields.

Diphenylhydroquinone (III) was prepared by the general procedure of Pummerer but with such changes in detail as to increase the yield seven-fold to about 65%. This was then brominated to diphenyldibromohydroquinone (IV) and the latter oxidized to diphenyldibromoquinone (V). Upon hydrolysis of this product, the corresponding dihydroxyquinone was obtained which was polyporic acid (I). Each of the steps involved in the process just mentioned resulted in yields of 90% or better.

Acetylation of the diphenyldihydroxyquinone gave an acetyl derivative which analyzed correctly for the diacetate and agreed as to melting point with the diacetylpolyporic acid prepared by Kögl.[3] The corresponding diacetylhydroquinone and tetraacetate were also prepared.



III → IV → V → I

In a similar manner anisole was condensed with quinone to dianisylhydroquinone (VI). Upon treatment with bromine in glacial acetic

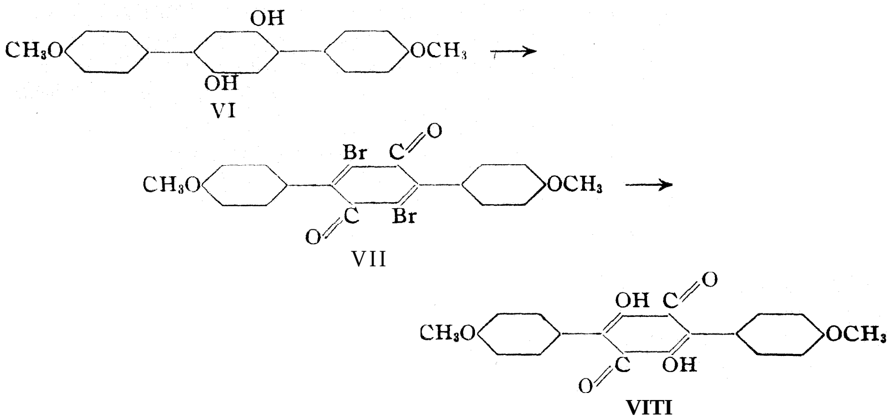
[5] Pummerer and Prell, *Ber.*, 55, 3108 (1922).

acid, bromination and oxidation took place simultaneously and di-(p-methoxyphenyl)-dibromoquinone (VII) was produced. This in turn was hydrolyzed with aqueous sodium hydroxide to the dimethyl ether of atromentin (VIII).



Experimental

2,5-Diphenylquinone.—To a suspension of 300 g. of finely powdered anhydrous aluminum chloride in 500 cc. of dry benzene in a 2-liter three-necked flask equipped with a mechanical stirrer, 500-cc. separatory funnel, thermometer and reflux condenser was slowly added with stirring a solution of 100 g. of pure benzoquinone in 1000 cc. of dry benzene. Heat was evolved and the rate of addition was regulated to maintain the reaction mixture at a temperature of 35–40°. The addition required two to three hours. Stirring was continued for five hours thereafter and the temperature allowed to drop to that of the room.

The reaction product was decomposed by pouring it slowly onto a mechanically-stirred mixture of 2 kg. of ice and 250 cc. of concentrated hydrochloric acid. Stirring was continued until a light brown emulsion was formed and no lumps of undecomposed material remained. The benzene was removed by steam distillation. The residual light brown solid was definitely granular and was readily separated by filtration. It was washed with hot water and air-dried. The yield of dry material was 140 g., green in color and obviously a mixture of quinones, hydroquinones and quinhydrones.

To obtain the yellow crystalline diphenylquinone, the crude reaction product was oxidized carefully in a hot glacial acetic acid solution with chromic acid, but since any excess chromic acid over that required to oxidize hydroquinones and quinhydrones in the crude product to the quinone state will rapidly oxidize the terphenyl molecule to benzoic acid, it was necessary to determine beforehand the amount of chromic acid to be used per unit weight of the crude material. This was carried out as follows.

Three 1-g. samples of the crude product were accurately weighed out and placed in 50-cc. Erlenmeyer flasks. To the first flask was added 0.100 g. of chromic acid; to the second 0.133 g. and to the third 0.150 g. To each flask was then added 25 cc. of glacial acetic acid. Each was heated to boiling for two to three minutes and filtered hot. The first filtrate was a definite mixture of yellow quinone plates and dark green quinhydrone needles; the second showed only yellow plates of the quinone at first but the dark colored quinhydrone crystallized later as a fringe around the upper edge of the solution, and the third filtrate exhibited only the yellow plates of the quinone even on long standing.

The remaining 137 g. of crude product was placed in a 5-liter round-bottomed flask with 3 liters of glacial acetic acid and 21 g. of chromic acid and rapidly heated to boiling. The solution was immediately filtered through a large fluted filter, the filtrate cooled for two to three hours under the tap and then filtered through a Büchner funnel. The mat of yellow flakes was washed first with water, then with 150 cc. of 50% ethyl alcohol. The yield of air-dried material amounted to 51 g. and it melted at 210–212° (corr.). It was pure enough to be used for further preparations. A single recrystallization from either benzene or glacial acetic acid yielded the pure substance melting constantly at 214° (corr.). An additional 7 g. of pure material was obtainable from the mother liquors, bringing the total yield up to 58 g. (72%).

2,5-Diphenylhydroquinone (II).—In a 1-liter round-bottomed flask was placed a mixture of 500 cc. of glacial acetic acid, 25 g. of diphenylquinone and 50 g. of powdered zinc. The mixture was stirred for one hour without external heating and then refluxed for thirty minutes. The solution was filtered hot and the solid material on the filter washed with two 50-cc. portions of warm glacial acetic acid, the washings being added to the filtrate. The filtrate was transferred to a 3-liter round-bottomed flask equipped with a reflux condenser and heated to boiling. Hot water was added slowly through the condenser until the white hydroquinone crystallized from the boiling solution. A few hundred cc. more of water may be slowly added if desired to complete the precipitation of the product and the filtrate then cooled. It was filtered and the product washed with hot water. The pale straw-colored air-dried material amounted to 23 g. and was sufficiently pure to be used for the next step. A single recrystallization from either chloroform or dilute ethyl alcohol yielded white needles melting constantly at 225° (corr.).

2,5-Diphenyl-3,6-dibromohydroquinone (IV).—To a 1-liter three-necked flask, equipped with a mechanical stirrer, thermometer, 125-cc separatory funnel and outlet tube, was added 400 cc. of chloroform and 20 g. of diphenylhydroquinone. The stirrer was started and the contents of the flask cooled to 10° by external cooling. Through the separatory funnel was then added rapidly a solution of 39 g. of bromine in 50 cc. of chloroform. At first a heavy dark crystalline precipitate, presumably the quinhydrone, appeared which later dissolved to a clear orange solution. The solution was stirred for eight hours at room temperature.

The solvent was removed under reduced pressure, avoiding a temperature above 30°. The light yellow solid remaining was refluxed with 1500 cc. of 95% ethyl alcohol and 20 g. of stannous chloride until a clear pale yellow solution was obtained. Dilute hydrochloric acid (6 N) was added slowly to the boiling solution until needles of the white hydroquinone appeared. The solution was chilled to 0° and filtered. The mat of white needles was washed with 6 N hydrochloric acid, followed by hot water and then air-dried; yield, 29 g. (90%).

The product as obtained was quite pure. A single recrystallization from 95% ethyl alcohol yielded long, slender white needles melting constantly at 237° (corr.).

Anal. (Parr bomb). Calcd. for $C_{18}H_{12}O_2Br_2$: Br, 38.10. Found: Br, 38.44.

2,5-Diphenyl-3,6-dibromoquinone (V).—A mixture of 25 g. of the diphenyldibromohydroquinone, 1 liter of 95% ethyl alcohol and 15 g. of benzoquinone was refluxed for one-half hour. The mixture was cooled and filtered. The orange crystalline quinone was washed free of benzoquinone on the filter with cold alcohol and air-dried; yield, 21 g. The product crystallized from *n*-butyl alcohol in slender orange needles melting constantly at 224°.

Anal. (Parr bomb). Calcd. for $C_{18}H_{10}O_2Br_2$: Br, 38.23. Found: Br, 38.03.

2,5-Diphenyl-3,6-dihydroxyquinone (I).—A mixture of 20 g. of the diphenyldibromoquinone, 1 liter of methyl alcohol and 1 liter of 10% sodium hydroxide solution was stirred mechanically for two hours at 40–50°. The purple solution was filtered and acidified with concentrated hydrochloric acid. One liter of water was added and the volume of solution reduced to one-half by evaporation on a hot-plate. This boiling and concentrating served to coagulate the brown precipitate material and to remove a considerable amount of alcohol, all of which aided subsequent filtration. The filtered product after washing and drying amounted to 13 g. (92%).

The product may be crystallized from toluene––1.4 g. in 630 cc. of boiling toluene yielded 1.1 g. of bronze-colored plates melting with sublimation at 305° (obs.)—or purified through the diacetate as described below.

Anal. (Crystallized from toluene.) Calcd. for $C_{18}H_{12}O_4$: C, 73.85; H, 4.14 Found: C, 73.61, 73.50; H, 4.11, 4.19.

2,5-Diphenyl-3,6-diacetoxyquinone.—A mixture of 10 g. of the dihydroxyquinone, 150 cc. of pyridine and 150 cc. of acetic anhydride was refluxed for two minutes and then poured with stirring into a mixture of 1500 cc. of water and 250 cc. of concentrated hydrochloric acid. The light yellow solid was filtered, washed and dried; yield, 11.5 g. (quantitative). A single recrystallization from benzene yielded yellow needles melting constantly at 215° (corr.).

Anal. Calcd. for $C_{22}H_{16}O_6$; C, 70.18; H, 4.29. Found: C, 70.09; H, 4.30.

Hydrolysis of the **Diacetoxyquinone.**—A solution of 5 g. of the diacetoxy derivative in 150 cc. of glacial acetic acid was heated to boiling under a reflux condenser. Through the condenser was added 40 cc. of 6 N hydrochloric acid and refluxing continued for thirty minutes. The hydroxyquinone crystallized from the boiling solution in bronze-colored flakes. If the mixture was cooled before filtering, the recovery of material was nearly quantitative — 4.2 g. The product melted at 305° (obs.) with sublimation and was otherwise identical with that obtained by crystallization from toluene.

2,5-Diphenyl-3,6-diacetoxyhydroquinone.—A solution of 3.35 g. of the diacetoxyquinone and 7 g. of stannous chloride in 200 cc. of acetone was gently refluxed for ten to fifteen minutes. The original yellow solution was almost completely decolorized. Through the condenser was added 25 cc. of 6 N hydrochloric acid and heating continued for two to three minutes. The flask was removed, 200 cc. of 3 *N* hydrochloric acid added at once and the solution immediately cooled to 15–20°; yield of slender white needles, 3.2 g. Two crystallizations from n-butyl alcohol gave a white product consisting of minute needles and melting constantly at 246° (corr.).

Anal. Calcd. for $C_{22}H_{18}O_6$: C, 69.81; H, 4.80. Found: C, 70.10; H, 4.95.

2,5-Diphenyl-1,3,4,6-tetraacetoxybenzene.—Acetylation of 2 g. of the diacetoxyhydroquinone with pyridine and acetic anhydride in the usual manner gave a quantitative yield of the crude material (2.45 g.). Two crystallizations from n-butyl alcohol yielded minute white needles melting constantly at 267–268° (corr.).

Anal. Calcd. for $C_{26}H_{22}O_8$: C, 67.50; H, 4.80. Found: C, 67.33; H, 4.79.

2,5-Di(*p*-methoxyphenyl)-hydroquinone, VI.—The corresponding quinone was prepared from benzoquinone and anisole according to the directions of Pummerer and Prell.[5] The hydroquinone was obtained by reduction with stannous chloride and hydrochloric acid in acetone solution.

A mixture of 20 g. of the dianisylquinone, 40 g. of stannous chloride and 600 cc. of acetone was stirred for one hour at room temperature. Heat developed, the red quinone disappeared and the resulting bluish-green solution deposited small lustrous white plates of the hydroquinone. If cooled to 0° and allowed to stand for two to three hours, the yield of practically pure product was 16–17 g. A single recrystallization from acetone containing a trace of stannous chloride and hydrochloric acid yielded a pure white product melting constantly at 210° (corr.).

2,5-Di-(*p*-methoxyphenyl)-3,6-dibromoquinone, VII.—A solution of 8.5 g. of dianisylhydroquinone in 4.5 liters of glacial acetic acid was prepared by gentle heating and stirring on the steam-bath. The warm solution was cooled to 25". To this was added with stirring a solution of 17 g. of bromine in 100 cc. of glacial acetic over a period of one hour. The red solution was slowly stirred for forty-eight hours during which time a small crop of dark reddish-brown needles separated. (The dianisylquinone, produced by oxidation with bromine of the hydroquinone in cold glacial acetic acid solution, separates in bright red silky needles easily distinguished from the darker colored brominated product.) Stirring was then discontinued and the solution allowed to stand at 15" or a few degrees lower for three to four days. The needles were filtered off and washed with cold methyl alcohol; yield 5.7 g. Three crystallizations from glacial acetic acid, using 125 cc. per gram of substance, gave a reddish-brown product melting with decomposition constantly at 282–283° (corr.).

Anal. Calcd. for $C_{20}H_{14}O_4Br_2$: Br, 33.44; C, 50.21; H, 2.95. Found: Br, 33.75; C, 50.66; H, 3.12.

This substance crystallized unchanged in m. p. or appearance from acetic anhydfide, pyridine, or a mixture of the two.

2,5-Di-(*p*-methoxyphenyl)-3,6-dihydroxyquinone (Atromentin Dimethyl Ether), VIII.—A mixture of 1.7 g. of the dibromodianisylquinone in a solution consisting of 170 cc. of methyl alcohol and 170 g. of 10% sodium hydroxide was stirred at room temperature for forty-eight hours. The dibromoquinone was nearly completely replaced by the purple sodium salt of the corresponding dihydroxyquinone. The mixture was filtered and the filtrate, being nearly colorless, was set aside. The sodium salt was separated from the unreacted starting material on the filter by pouring repeatedly over it 500 cc. of cold water. The permanganate-colored filtrate was acidified with acetic acid and heated to boiling. The brown flocculent precipitate was filtered with gentle suction and washed with hot water. It was redissolved on the filter with 500 cc. of cold 2% sodium hydroxide, reprecipitated with acetic acid, filtered, washed and dried as before; yield of air-dried material 1.0 g. (80%). Two crystallizations from toluene, using 500 cc. of toluene per gram of substance, gave minute, glistening, bronze-colored plates melting with decomposition constantly at 297–298° (corr.) and free of halogen.

Anal. Calcd. for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58. Found: C, 67.65, 67.72; H, 4.66, 4.60.

2,5-Di-(*p*-(*n*)-butoxyphenyl)-quinone.—To a solution of 10.8 g. of benzoquinone and 15 g. of n-butyl phenyl ether in 150 cc. of dry carbon disulfide maintained at 0–5° with an ice-bath, 27 g. of anhydrous aluminum chloride was slowly added with vigorous stirring. The addition required about thirty minutes and the mixture was stirred for four hours longer. The reaction mixture was decomposed by pouring onto ice and dilute hydrochloric acid. The carbon disulfide was steam distilled out and the residual black solid material crystallized from 1 liter of n-butyl alcohol to which was previously added 2 g. of norite and 3 g. of benzoquinone; yield of yellow flakes, 4 g. Recrystallization from 50 cc. of toluene gave 3.2 g. of similar crystals melting constantly at 173° (corr.).

Anal. Calcd. for $C_{26}H_{28}O_4$: C, 77.18; H, 6.98. Found: C. 77.02; H, 6.99.

Summary

1. Polyporic acid and atromentin dimethyl ether have been prepared by new procedures in excellent yields.

2. Diphenylquinone from the condensation of benzene and quinone was reduced to diphenylhydroquinone. This was in turn brominated to diphenyldibromohydroquinone and the latter, after oxidation to the

corresponding quinone, was hydrolyzed to diphenyldihydroxyquinone (polyporic acid).

3. In a similar manner atromentin dimethyl ether was produced from dianisylquinone, the condensation product of anisole and quinone.

ACTION OF AROMATIC ALCOHOLS ON AROMATIC COMPOUNDS IN THE PRESENCE OF ALUMINUM CHLORIDE. VII. CONDENSATION OF BENZYL ALCOHOL WXTH PARA-CRESOL

BY R. C. HUSTON AND W. C. LEWIS

RECEIVED APRIL 22, 1931 PUBLISHED JUNE 8, 1931

Para-cresol and benzyl alcohol in the molecular ratio of 2 to 1 dissolved in petroleum ether and treated with **0.5** mole of aluminum chloride gave a condensation product which upon fractional distillation yielded *35%* of crude mono and 36% of crude dibenzylated p-cresol. When the reactants were used in the ratio of **3** to 1, with the same amount of aluminum chloride. the yields were **53** and 30%, respectively. Crystallization of the monobenzylated *p*-cresol from petroleum ether in the cold gave transparent needles melting at 35–36°. The dibenzylated p-cresol did not crystallize.

These compounds were found to agree in properties with those prepared by Claisen[1] by the action of benzyl chloride on the sodium salt of p-cresol in toluene, except that he did not obtain the monobenzyl derivative in crystal form.

The 2-benzyl-4-methylphenol was easily soluble in dilute potassium hydroxide and when treated with the calculated amount of benzoyl chloride gave the ester. **As** was anticipated, the 2,6-dibenzyl-4-methylphenol was not soluble, even in strong potassium hydroxide, but formed a solid. This, however, treated with benzoyl chloride reacted to produce the ester.

Bromination of 2-benzyl-4-methylphenol in chloroform gave 2-benzyl-4-methyl-6-bromophenol. This configuration **was** proved by preparing the **same** compound by benzylating 4-methyl-6-bromophenol by the Claisen reaction. In addition a small amount of 4-methyl-6-bromophenyl benzyl ether was obtained,

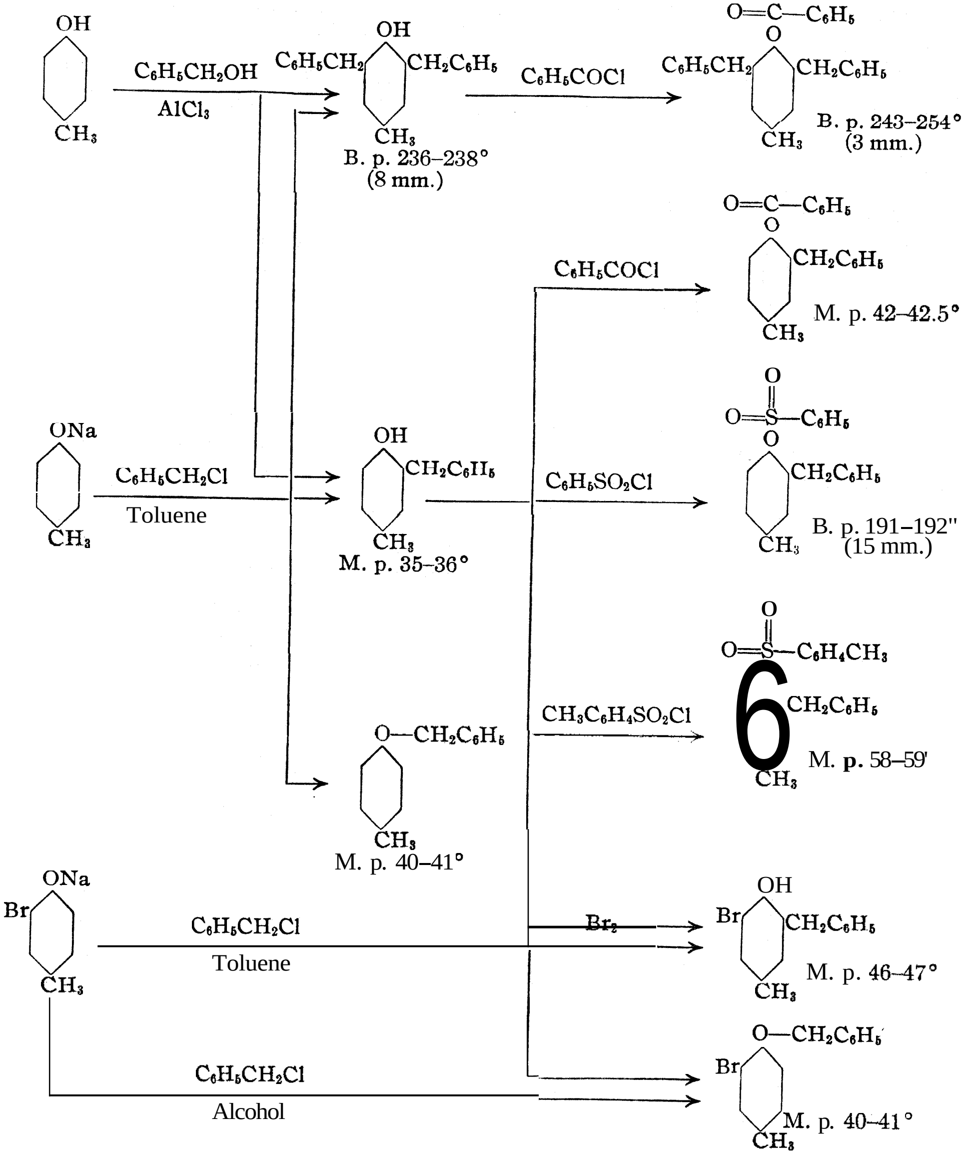
The monobenzylated p-cresol **was** further characterized by preparing benzene sulfonic and toluene sulfonic esters by the pyridine method.

Experimental

Benzyl Alcohol and *p*-Cresol with Aluminum Chloride.—A mixture of 108 g. of p-cresol, 54 g. of benzyl alcohol and 75 g. of petroleum ether (40–60°) was placed in a tall cylinder and stirred mechanically while adding 33 g. of anhydrous aluminum chloride in small portions over a period of one hour. The temperature was kept below 30".

---

[1] Claisen, *Ann.*, 442,210 (1925).



Hydrogen chloride gas was freely evolved. The mixture was allowed to stand overnight and then decomposed with ice and a little hydrochloric acid. The white oily product was extracted with ether. After distilling off the ether the residue was fractionated at 10 mm. The third fractionation gave:

Up to 100°	61.5 g. (*p*-cresol)
165–185°	34.0 g.
185–250°	25.5 g.

The 165–185° fraction crystallized when seeded and placed in the cold. Recrystallization from petroleum ether gave transparent, prismatic crystals that melted at 35–36°.

Anal. Subs., 0.1508: CO_2, 0.4695; H_2O, 0.0980. Calcd. for $C_{14}H_{14}O$: C, 84.8; H, 7.12. Found: C, 84.93; H, 7.27.

From the 185–250° fraction there was isolated a portion which boiled at 236–238° (8 mm). This was a viscous liquid that did not crystallize, and was assumed to be 2,6-dibenzyl-4-methylphenol.

Anal. Subs., 0.1732: CO_2, 0.5553; H_2O, 0.1068. Calcd. for $C_{21}H_{20}O$: C, 87.45; H, 6.99. Found: C, 87.41; H, 6.63.

Preparation of **2-Benzyl-4-methylphenol, 2,6-Dibenzyl-4-methylphenol** and **4-Methylphenyl Benzyl** Ether by the Claisen Method.—Using half molar quantities of p-cresol, sodium and benzyl chloride in three runs gave an average of 40 g. of 2-benzyl-4-methylphenol, m. p. 35–36°, and 11.8 g. of 2,6-dibenzyl-4-methylphenol, b. p. 236–238° (8 mm.). The petroleum ether extract from the above condensations gave an average of 6 g. of 4-methylphenyl benzyl ether, recrystallized from alcohol, m. p. 40–41°.

Preparation of Benzoyl Esters.—Employing the Schotten–Baumann reaction, 21 g. of 2-benzyl-4-methylphenol, 6.97 g. of potassium hydroxide in 20 cc. of water and 14.82 g. of benzoyl chloride gave a white oil which boiled at 205–206° (5 mm.). After long standing, it crystallized. Recrystallization from alcohol gave transparent plates, m. p. 42–42.5°.

Anal. Subs., 0.1008: CO_2, 0.3056; H_2O, 0.0541. Calcd. for $C_{21}H_{18}O_2$: C, 83.4; H, 6.0. Found: C, 83.33; H, 6.03.

The 2,6-dibenzyl-4-methylphenol was treated with strong (50%) potassium hydroxide. The resulting solid was filtered off and treated with the calculated amount of benzoyl chloride. Heat was evolved and a yellowish oil was formed which was washed with dilute alkali and water, b. p. 243–245 (6 mm.).

Anal. Subs., 0.2300: CO_2, 0.7200; H_2O, 0.1342. Calcd. for $C_{28}H_{24}O_2$: C, 85.67; H, 6.168. Found: C, 85.35; H, 6.43.

Preparation of Sulfonyl Esters.—By the pyridine method, 5 g. of 2-benzyl-4-methylphenol, 12.5 g. of pyridine and 4.5 g. of benzene sulfonyl chloride gave a viscous yellowish-red liquid, that boiled at 190–192° (2 mm.) and did not solidify.

Anal. Subs., 0.1029: $BaSO_4$, 0.0739. Calcd. for $C_{20}H_{18}SO_3$: S, 9.47. Found: S, 9.86.

By the same method, 5 g. of 2-benzyl-4-methylphenol, 12.5 g. of pyridine and 4.8 g. of toluene sulfonyl chloride gave a crystalline product. Recrystallization from petroleum ether gave transparent rhombohedra, m. p. 58–59°.

Anal. Subs., 0.1000 g.: $BaSO_4$, 0.0676. Calcd. for $C_{21}H_{20}SO_3$: S, 9.1. Found: S, 9.28.

Preparation of the Monobromo Derivative.—Addition of the calculated weight of bromine to 15 g. of 2-benzyl-4-methylphenol dissolved in chloroform produced 2-benzyl-4-methyl-6-bromophenol. Crystallization from about 85% alcohol gave a white silky felt-like product melting at 46–47°.

Anal. Subs., 0.1000: cc. of 0.1 N $AgNO_3$, 3.6. Calcd. for $C_{14}H_{13}OBr$: Br, 28.84. Found: 28.771.

One-half mole of 6-bromo-p-cresol dissolved in toluene and treated with sodium and benzyl chloride by the Claisen method gave a product identical in crystal form and melting point with that obtained by brominating 2-benzyl-4-methylphenol.

From the petroleum ether extract in the above condensation there was isolated a small amount of 4-methyl-6-bromophenyl benzyl ether. Crystallization from strong alcohol gave transparent rhombohedra, m. p. 40–41°.

Anal. Subs., 0.1015: cc. of 0.1 *N* $AgNO_3$, 3.68. Calcd. for $C_{14}H_{13}OBr$: Br, 28.84. Found: Br, 29.03.

Summary

Para-cresol was benzylated by both the Claisen and the aluminum chloride methods and the yields were compared.

Bromination of 2-benzyl-4-methylphenol gave 6-bromo-2-benzyl-4-methylphenol, which was also prepared from 6-bromo-4-methylphenol by the Claisen reaction.

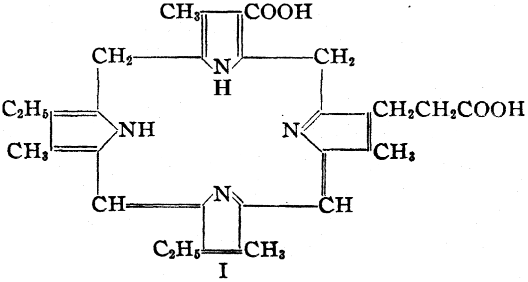
STUDIES IN THE CHLOROPHYLL SERIES. V. THE STRUCTURE OF CHLOROPHYLL A

BY J. B. CONANT, EMMA M. DIETZ, C. F. BAILEY AND S. E. KAMERLING

RECEIVED APRIL 23, 1931 PUBLISHED JUNE 8, 1931

The experiments reported in the fourth paper of this series[1] indicated that chlorophyll a and the closely related compound phaeophorbide a contained the grouping $-\mathrm{CHOH}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-\mathrm{O}-$. In allomerization or "phase test saponification," we supposed that this structure was transformed into the a-ketonic acid grouping which was subsequently easily removed as potassium oxalate by boiling the compounds with alkali. The resulting simple chlorin, chlorin *f*, was thus to be regarded as a partially hydrogenated rhodoporphyrin. It was uncertain whether the two hydrogen atoms which were removed from the secondary alcohol group were transferred to some other molecule or intra-molecularly to a pyrrole ring. A further study[2] has shown that the first alternative is correct and that the dehydrogenating agent is oxygen of the air. The structure of chlorin f is therefore that of a dihydrorhodoporphyrin (I); this formula replaces



I

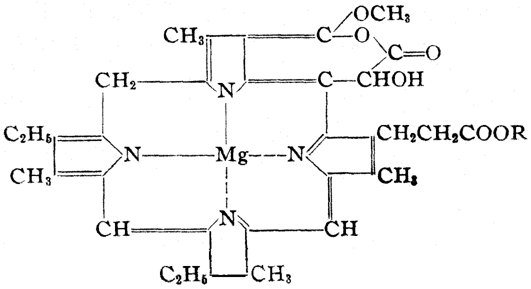
[1] THIS JOURNAL, 53, 359 (1931). For other papers of this series see *ibid.*, 51, 3668 (1929); 52, 1233, 3013 (1930).

[2] A brief statement of these results was given in a letter to the editor, THIS JOURNAL, 53, 1615 (1931). The corresponding experiments are recorded in this present paper except for the study of the phase test, which will form a separate paper by Miss C. C. Steele.

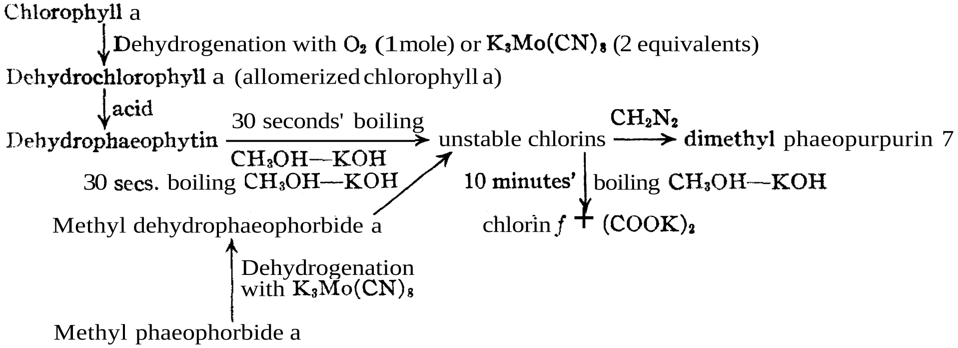
the one given in our previous paper. The position of the double linkages is arbitrary and many tautomeric modifications of Formula I may be written. The quantitative dehydrogenation of this simple chlorin is now being studied in order to throw more light on such problems.

We are now in a position to write a structural formula for chlorophyll *a* with some assurance. Such a formula is given below (II) R = phytyl, and the recent evidence is summarized in the accompanying diagram.



II

The corresponding formulas for methyl phaeophorbide *a* and phaeophorbide *a* are obtained by letting R = CH_3 and H, respectively, and substituting two hydrogen atoms for the magnesium atom.[3]



We may briefly review the arguments for Formula II for chlorophyll *a* and related compounds. The skeleton structure of chlorin *f* follows from its easy conversion to rhodoporphyrin (paper IV) whose structure has been established by Fischer by synthesis. From the above diagram it is clear that the nucleus of dehydrochlorophyll *a* is chlorin *f* plus the oxalic acid grouping; this agrees in the number of carbon atoms with the analyses of methyl phaeophorbide, etc. (paper III, p. 3016). Two mole-

[3] The distinction indicated by the heavy and dotted lines from the magnesium is only useful in showing that two hydrogen atoms are replaced by the metal; there is no reason, of course, to believe that there is a real difference between any of the four coordinate links.

cules of potassium molybdicyanide (a powerful oxidizing agent) are involved in the dehydrogenation of chlorophyll *a* (or methyl phaeophorbide *a*). This fact, together with the formation of potassium oxalate on alkaline decomposition of the dehydro compounds, shows the presence of an esterified or otherwise masked a-hydroxy acid group in the original molecule. The methoxyl group of chlorophyll *a* is attached to the β-position of a pyrrole ring because the transformations described in the fourth paper yielded a monomethyl ester of chlorin f which, unlike chlorin f itself (a dibasic acid), does not readily lose carbon dioxide on heating. The well-known relationship of chlorophyll *a* to phaeophorbide *a* shows that the phytyl group is attached to the acid group which is free in the latter compound. This is the propionic acid residue since on pyrolysis of phaeophorbide *a* this acid group is not eliminated as carbon dioxide (paper I).

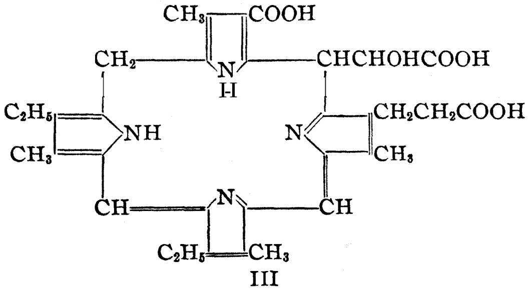
The position of the $-\mathrm{CHOH}-\mathrm{C}\genfrac{}{}{0pt}{}{\diagup\!\!\diagup\mathrm{O}}{\diagdown\mathrm{OH}}$ group and the masking of its acidic hydrogen remain to be considered. The latter necessity arises from the fact that phaeophytin *a* and methyl phaeophorbide *a* are only di-esters although they contain three potential carboxyl groups The analyses of methyl phaeophorbide *a* indicate six oxygen atoms; the masking of one carboxyl group as a lactam (but not as a lactone) or as an anhydride (as shown in Formula II) is consistent with these analyses. The second alternative seems preferable to us because on pyrolysis phaeophorbide *a* loses carbon dioxide and methyl alcohol, the methoxyl group being destroyed (see experimental portion of this paper). This points to a close interconnection of the masked carboxyl group and the carboxyl group in the β-position of the pyrrole ring, the propionic acid group being free. We therefore write Formula II, placing the CH_2 link arbitrarily, there being at present no direct evidence in regard to this portion of the molecule.[4]

The analyses of chlorin e correspond to Formula III, as do its transformations into pyrochlorin e described in the last paper. It is rapidly oxidized by potassium molybdicyanide (two equivalents are involved)

---

[4] Since this paper was sent to the editor, an article by Fischer, Moldenhauer and Süs [*Ann.*, 486, 107 (1931)] has appeared on the same subject. These authors write a structural formula for chlorophyll *a* (largely based on their investigation of phylloerythyrin) which is very different from the one proposed in the present paper. The chief differences are as follows: they consider the chlorophyll nucleus to be an oxidized porphyrin ring instead of a partially reduced porphyrin as we have postulated; they write a five-membered carbon ring joining one pyrrole ring to the bridge, a tertiary hydroxyl (instead of a secondary in our formula) and the phytyl and methyl groups in different positions. Without going into a long discussion of this new paper, we can only say that we do not believe that the formula for chlorophyll *a* there proposed is capable of explaining the dehydrogenation reactions and certain other transformations described in this and our previous papers.

and like all a-hydroxy acids loses carbon dioxide during the oxidation.[6] The resulting chlorin (designated hereafter as chlorin *k*) gives a monomethyl ester on treatment with diazomethane. Presumably the aldehydic group formed by the oxidation has closed a lactone ring with a carboxyl group. The further transformations of chlorin k will be reported in detail in a later paper. The trimethyl ester of chlorin e (formed by the action of diazomethane) unlike the parent compound is not oxidized by potassium molybdicyanide. This fact together with the analyses, which show a loss of water during the esterification, indicate a lactone formation between a carboxyl and the hydroxyl of the $—CHOHCOOCH_3$ group; enolization would account for the ability to form a trimethoxyl derivative.



III

The unstable chlorins appear to be a tribasic acid and its monomethyl ester corresponding to the removal of the two hydrogen atoms of the CHOH group of chlorin *e*. (They are chlorin f + $—\overset{O}{\overset{\|}{C}}—COOH$.) The nature of their transformation into the phaeopurpurins has not yet been established with certainty and a discussion of the structure of the latter will be postponed. Although they are important as a method of characterizing the dehydro series, the details of their structure are not involved in the evidence which leads to Formula II for chlorophyll a. As would be expected, the phaeopurpurins and methyl dehydrophaeophorbide are not oxidized by potassium molybdicyanide. It may be mentioned that methyl phaeophorbide b is more rapidly oxidized than the corresponding *a* compound. A study of the b series from the point of view presented in this paper is now in progress.

Methyl dehydrophaeophorbide *a* is a crystalline compound which can be purified and studied in the usual way; it differs only slightly in its visible absorption spectrum from the unoxidized compound. However, in the near ultraviolet there is considerable difference (Fig. 1). In studying chlorophyll a itself we have been forced to use spectroscopic methods and chemical transformations since the amount of material at

---

[6] It may be noted that phaeophorbide *a* (a free acid) on oxidation does not lose carbon dioxide but behaves exactly like its methyl ester. This is additional proof that the phytyl group is not on the bridge carboxyl.

our disposal was small and the compounds containing the phytyl group crystallize with difficulty. The absorption spectra in the near ultraviolet of the compounds are given in Fig. 2. It will be seen that the dehydrochlorophylls prepared with oxygen (allomerization) or with molybdicyanide are identical (curve B) and differ from chlorophyll a (curve A) as methyl dehydrophaeophorbide differs from methyl phaeophorbide. However, there is a difference in the absorption spectrum of dehydrochlorophyll *a* in the visible according to whether oxygen or molybdicyanide is used in the preparation. This difference amounts to some 40 Å. in the position of the band at 662 mμ and the same amount of shift at 530 mμ is found in the corresponding dehydrophaeophytins. The com-

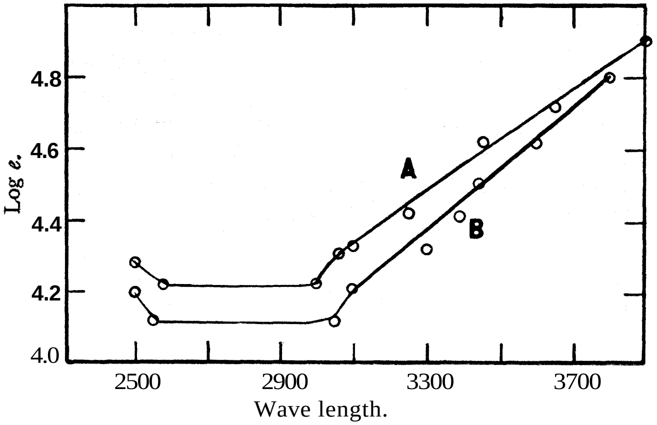


Fig. 1.—Log extinction coefficient–wave length curves for: A, methyl phaeophorbide *a*; B, methyl dehydrophaeophorbide *a*.

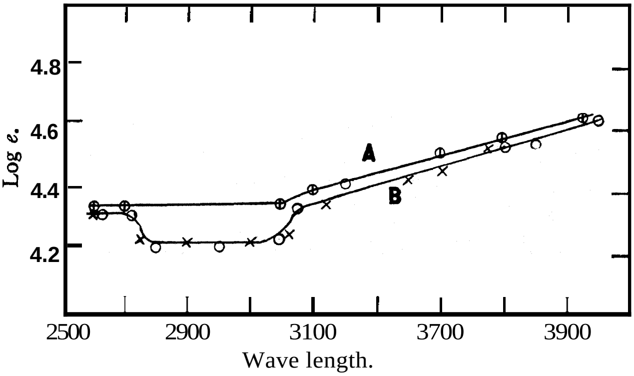

Fig. 2.—Log extinction coefficient–wavelength curves for: A, chlorophyll a; B, X X X, allomerized chlorophyll a; ○○⊖, dehydrochlorophyll a.

pound prepared with oxygen is the one which resembles dehydrophaeophorbide in regard to the position of this one band which represents a shift from phaeophorbide *a* itself. Since the chemical transformations of the two dehydrochlorophylls are the same, and they are both formed by the removal of two hydrogen atoms, any difference between them must he slight. We cannot be certain at present whether we are dealing with a subtle isomeric shift or the presence of an impurity in the material made with molybdicyanide.

The possible significance of the easily oxidized group $-\mathrm{CHOHC}\overset{\mathrm{O}}{/\!\!/}-$ in chlorophyll from the point of view of photosynthesis has been discussed in a brief note[6] and will be considered in more detail in a later paper of this series.

We are indebted to Miss Helen F. Hawes for carrying out the microanalyses reported in this paper.

Experimental

Quantitative Dehydrogenation Experiments with Potassium Molybdicyanide.—The molybdicyanide reagent was freshly prepared before each set of experiments as follows:[7] 5 cc. of 0.06 M $K_4Mo(CN)_8$ and 0.7 cc. of glacial acetic acid were mixed and approximately 0.1 *N* potassium permanganate added drop by drop until present in very slight excess; the mixture was then made up to a total volume of 10 cc. In each experiment approximately 10^{-5} mole of compound (accurately weighed) was dissolved in 5 cc. of acetone containing enough anhydrous pyridine to be molar with respect to this base. One cc. of the molybdicyanide reagent was then added, the time noted and the mixture made up to 10 cc. with more molar pyridine in acetone. Definite samples (1 cc. or 0.7 cc.) were withdrawn from the reaction mixture from time to time, diluted with 5-fold aqueous acetate buffer solution and the molybdicyanide content determined by electrometric titration with 0.001 M $K_4Fe(CN)_6$ using a micro-buret and a very small titration vessel. The end-point is very sharp even at these high dilutions and the accuracy is determined by the error in sampling (about ±5%). With each set of experiments a "control experiment" was carried out, by introducing 1 cc. of the same reagent into the pyridine–acetone solution, making the volume exactly 10 cc. and withdrawing a sample at the same time as the samples were withdrawn from the various reaction mixtures. There was very little change in the control titration even after twenty-four hours but it was deemed best to correct for this change by taking the extent of reduction of the molybdicyanide as being the difference between the "control titration" and the titration of the reaction mixture. A typical experiment was as follows: 4.97 mg. of methyl phaeophorbide a plus 1 cc. of molybdicyanide reagent (prepared as described above, approximately 0.03 M) in molar pyridine in acetone with a total volume of 10 cc.; the control was exactly like the experiment but the methyl phaeophorbide *a* was omitted. The titrations of 0.7-cc. samples with 0.001 M $K_4Fe(CN)_6$ were as follows: 20 min. control 1.65 cc., reaction 1.42, diff. 0.23; 90 min. control 1.65 cc., reaction 1.30, diff. 0.35; 390 min. control 1.65 cc., reaction 0.75, diff. 0.90; 1400 min. control 1.49 cc., reaction 0.50, diff. 1.04; since the 4.97 mg. of methyl phaeophorbide a is 8×10^{-6}

---

[6] Conant, Dietz and Kamerling, Science, 73, 1888 (1931).

[7] For the use of molybdicyanide in organic reactions, see Conant and Pratt, THIS JOURNAL, 48, 3229 (1926).

mole, two equivalents of oxidizing agent is 16×10^{-6} mole for the whole sample or 1.12 cc. for a 0.7-cc. sample. The extent of the reaction is thus 93% based on two equivalents after 1400 min., with an increase of only 13% in the last 1000 min.; the limit is clearly two equivalents per mole within the experimental error. To save space the other quantitative experiments may be summarized by giving the extent of the reaction based on two equivalents at each time: ***chlorophyll a:*** 12 min. 67%; 60 min. 87%; 400 min. 110%; ***chlorin e:*** 30 min., 90%; 90 min., 96%; 390 min., 95%; 600 min., 99%; ***methyl phaeophorbide b:*** 30 min., 35%; 90 min., 66%; 390 min., 102%; 1400 min., 125%; ***dimethyl phaeopurpurin 7*:** none in 390 minutes; ***trimethyl ester chlorin e:*** none in 1400 minutes. In all these experiments at least three moles of reagent per mole of substance was employed. The rates are roughly reproducible if all the conditions are kept rigidly constant. The potassium molybdocyanide crystallizes on the sides of the container during the reaction since it is much less soluble than the molybdicyanide in acetone. This separation of the reduced reagent probably helps to keep the reaction proceeding at a definite pace as the oxidation potential of the solution is thus kept high throughout the experiment.

The Dehydrogenation of Chlorophyll a

(a) With Molybdicyanide.—Twenty-five milligrams of pure chlorophyll *a* were dehydrogenated as follows: 5 cc. of approximately 0.03 M $K_3Mo(CN)_8$ (prepared freshly as described above) was diluted with a molar pyridine solution in acetone to exactly 50 cc. Five cc. of this mixture was kept as the control and the 25 mg. of chlorophyll *a* added to the remainder (45 cc.); 0.7-cc. samples of the mixture and the control were titrated for oxidizing power with 0.001 M $K_4Fe(CN)_6$ as described above; after 400 minutes the titration corresponded to slightly more than 100%, compared with about 90% at the end of one hour. The mixture was then poured into water, extracted with ether and the ether layer repeatedly washed with water to remove pyridine and inorganic salts. The ether layer was finally dried over sodium sulfate and evaporated to dryness in *vacuo* leaving the dehydrochlorophyll as an amorphous wax. A solution of this in alcohol showed the following spectrum in the visible: principal absorption 678.5–653.0; weak absorption centers 615,568,531; E.A. 444. The ultraviolet extinction coefficient curve is given as B (circles) in Fig. 2. On removal of the magnesium by shaking an ethereal solution of this dehydrochlorophyll with dilute hydrochloric acid, a solution of dehydrophaeophytin was obtained which showed the following spectrum in the visible: I, 681.7–653.1; II, 615–604; III, 538.9–529.5; IV, 509.0–490.0; E.A., 439; Order I, IV, III, II. The hot rapid saponification of this dehydrophaeophytin by the usual Willstatter procedure (30 sec. with 35% methyl alcoholic potassium hydroxide) yielded no chlorin *e* but gave the unstable chlorins which were identified by conversion to dimethyl phaeopurpurin 7 with diazomethane (ether and acid spectrum identification). In another experiment, 7 mg. of pure chlorophyll *a* was dehydrogenated in the same manner as just described and the magnesium removed with acid. The resulting dehydrophaeophytin (as an amorphous wax) was treated with boiling methyl alcoholic potassium hydroxide (35%) and boiled for three minutes under a reflux. The reaction mixture was worked up in the usual way, being first methylated with diazomethane and then carefully acid fractionated. No chlorin e ester was obtained; the major product was identified spectroscopically in acid and ether as chlorin *f* ester. This was judged to be about 50% of the total; the other product was a porphyrin of acid number lower than 10. (The acid number of dimethyl chlorin *f* is 13.)

(b) With Oxygen (Allomerization).—The oxygen absorption during allomerization was demonstrated by using a modified Warburg apparatus.[8] A number of experiments

---

[8] Hyde and Scherp, THIS JOURNAL, 52,3359 (1930).

were carried out, of which the following is typical. Pure chlorophyll ***a*** (9.03 mg., 0.01 millimole) was dissolved in 10 cc. of absolute ethyl alcohol (prepared by distillation from magnesium ethylate) and the solution immediately placed in one of the bottles of the absorption apparatus; the other bottle contained the corresponding amount of pure solvent. The apparatus was placed in a water-bath at 25° and shaken continuously; pressure readings were taken from time to time and the number of moles of gas absorbed calculated from a previously determined factor (1 cm. of manometer liquid = 0.0017 millimole of gas). The course of the reaction is indicated by the following figures, which give the millimoles of gas absorbed at different times: 1 hr., 0.0017; **3.3** hrs., 0.0037, 7.5 hrs., 0.0053; 31 hrs., 0.0088; 46 hrs., 0.0099. The reaction clearly proceeds at a progressively diminishing rate as illustrated by the fact that the rate in 10^{-6} mole per hr. is 1.7 for the first hour, 0.4 for the 3.3–7.5-hr. period and 0.075 for the period between the last readings. The limit is clearly one mole of oxygen per mole of chlorophyll, corresponding to the reaction chlorophyll ***a*** $+ O_2 \longrightarrow$ dehydrochlorophyll a $+ H_2O_2$.

As Willstatter emphasized, the rate of the process of allomerization is very sensitive to impurities. Since we now know that allomerization is a kind of autoxidation, this sensitivity to positive and negative catalysts is not surprising. We are planning a thorough study of this interesting problem. For the present, we may note that among the variables are the water content and the alkalinity. By using an amount of barium hydroxide corresponding to a 0.01 M solution, the rate of oxygen absorption was greatly accelerated. As would be expected dehydrochlorophyll prepared by the use of potassium molybdicyanide did not absorb any oxygen even after twenty hours of shaking.

The absorption spectrum in the visible of dehydrochlorophyll *a* prepared by the use of oxygen was as follows: principal absorption, 672.8–641; weak absorption centers, 608, 568, 528; E. A., 442. The corresponding dehydrophaeophytin spectrum **was** as follows: (identical with methyl dehydrophaeophorbide): I, 683.7–653.5; II, 6.16–604.5; 111,535.6–526.5; IV, 508.6–488.9; E. A. 436; Order: I, IV, III, II.

The ultraviolet absorption curve is given as B (crosses) in Fig. 2. The transformation of dehydrochlorophyll prepared with oxygen (*i. e.*, allomerized chlorophyll) into the unstable chlorins was described in the fourth paper.

Preparation of Methyl Dehydrophaeophorbide a.—A typical preparation was as follows. A solution of 2 g. of potassium molybdocyanide in a mixture of 120 cc. of water and 12 cc. of glacial acetic acid was oxidized with 0.1 M potassium permanganate solution, and the excess of oxidizing agent destroyed with a few milligrams of the reduced salt. The resulting yellow solution was mixed with 600 cc. of acetone and 80 cc. of dry pyridine, and the amorphous brown precipitate which formed was filtered out. Acetone was added to bring the total volume to 900 cc. and 25 cc. was removed at this point as a control for subsequent titration. Six hundred milligrams of methyl phaeophorbide ***a*** was then added and the solution shaken for several minutes. Titration of samples showed the reduction of 50% of two equivalents of oxidizing agent after one hour and 20% more than two equivalents after nineteen hours.

The solution was then filtered and one-third of the solvent was removed with a water pump at room temperature. The remaining solution was added to 3 liters of ether and the resulting olive-green ether solution was washed thoroughly with a total of ***3*** liters of water. The washings were a dark olive-brown in color and were thick with scum. This was filtered off and dissolved in a chloroform–acetone mixture, poured into ether and fractionated separately. Usually, the aqueous washings contained considerable material in colloidal form, which settled out only after standing several hours, preferably in the presence of sodium chloride or hydrochloric acid. Before acid fractionation, the alkali–soluble material was removed with 0.05 M potassium hydroxide. The fractionation **was** carried out with 500-cc. extracts of cooled acid, each being washed with two

500-cc. portions of ether. Five extracts of 14% hydrochloric acid removed some phaeopurpurin 7 and olive-brown material, which on standing for several days changed somewhat further, but not completely, into phaeopurpurin 7. The remaining solution was extracted exhaustively with eight 500-cc. portions of 17% acid, then with one of 18% acid,

The 16–17% fraction was estimated to contain 155 mg. by comparison with a standard solution in a Zeiss comparison spectroscope. After washing with alkali and concentrating the solution, 95 mg. crystallized. The homogeneity of the product was shown by its spectrum and by hot rapid saponification which yielded only the unstable chlorins, which were identified by conversion into dimethyl phaeopurpurin 7 with diazomethane.

Approximately 150 mg. of scum was obtained per gram of methyl phaeophorbide a used. This could not be avoided even by taking the solution to dryness in a vacuum desiccator and adding a pyridine solution of the residue to ether. The first 14% extracts were rose-brown in color and showed a marked phaeopurpurin 7 spectrum though they were alkali-insoluble. The material rendered alkali-soluble by acid hydrolysis during fractionation was converted by diazomethane to equal quantities of dimethyl phaeopurpurin 7 and methyl dehydrophaeophorbide a.

The purity of the various crops of crystals of methyl dehydrophaeophorbide a is best tested by examining the products of hot rapid saponification. As described by Willstatter, unchanged methyl phaeophorbide a goes mainly to chlorin e under these circumstances although some oxidation by the air seems unavoidable. However, dehydrophaeophorbide a, which is in the oxidized series, forms no chlorin e but goes to unstable chlorins, which on methylation with diazomethane yield dimethyl phaeopurpurin 7. The detection of chlorin lines in the spectrum of the 8% fraction of methylated saponification products probably indicates from 10–25% of methyl phaeophorbide a in the starting material. The absence of chlorin lines in the spectrum of the 8% fraction probably indicates that the fraction of unoxidized methyl phaeophorbide a is below 10%. The experimental conditions are as follows, and aim to exclude air oxidation of the sensitive methyl phaeophorbide a. Five milligrams of solid is warmed in a silver crucible with 0.1 cc. of dry pyridine, 7 cc. of boiling 35% potassium hydroxide in methyl alcohol is added and the boiling continued over a free flame for thirty seconds. The intensely green alkaline solution is washed into a separatory funnel and the product transferred by acidification to 75 cc. of ether. The aqueous layer is shaken with fresh ether to remove more completely the strongly basic chlorins. The combined ether solutions are washed, dried with sodium sulfate and treated with an ethereal solution of diazomethane.

An instantaneous change in color and spectrum occurs if unstable chlorins are present. Acid fractionation is carried out as usual. With unoxidized material, 8% hydrochloric acid extracts most of the product, namely, chlorin e ester. In the oxidized series, the main product, dimethyl phaeopurpurin 7, is removed by 11% acid, although there is always some chlorin *f* ester of slightly higher acid number, which results through further saponification of the unstable chlorins.

Methyl Dehydrophaeophorbide a.—This substance was recrystallized for analysis from acetone–methyl alcohol. Black iridescent plates with irregular corners formed slowly. In thin layers they appear red-brown by transmitted light. The acid number is 16.5 and the color in acid solution is the same green-blue as that of methyl phaeophorbide a. The ether solution, however, is a much brighter green than that of the unoxidized compound and the solubility is greater. A "mixed solubility" test proved more satisfactory than mixed melting points to show the difference between the two. This is carried out by preparing in small test-tubes thoroughly saturated solutions of each of the two substances in question and of their mixture. If the two samples are identical, the three solutions should show the same shade and intensity of color. If different substances are actually present, the solution containing the mixture will be as concentrated as the sum of the other two, and its color will be a blend of theirs. Such a comparison indicated methyl dehydrophaeophorbide *a* and the unoxidized compound to be distinct individuals. When a dilute ether solution of methyl dehydrophaeophorbide *a* is treated with concentrated methyl alcoholic potassium hydroxide (phase test), only an uncertain. fleeting, light yellow precedes the green color; under the same conditions methyl phaeophorbide *a* gives a strong yellow persisting for several seconds. The material sinters at 260–265°.

The spectrum in ether differs from that of methyl phaeophorbide *a* by a shift of about 40 Å. in the position of the narrow green band at 530: (1 mg. in 30 cc. of ether) I, 690.5–650; II, 618–603; III, 565---556; IV, 536–524.5; V, 512.4–485; E. A., 444. Order: I, V, IV, II, III. The spectrum in 19% acid: I, 690442; II, 615---603; III, 584.5–569; IV, 538–523; E. A., 454. Order: I, III, IV, II.

Anal. Calcd. for $C_{36}H_{36}O_6N_4$: C, 69.7; H, 5.8; N, 9.0; OCH_3, 10.0. Found: C, 68.65, 68.48, 68.30; H, 6.28, 6.28, 6.34; N, 8 88, 8.62; OCH_3, 8.65, 8.99; ash, 0.34, 0.40.

Hot Quick Saponification of Methyl Dehydrophaeophorbide a.—The identification of phaeopurpurin 7 and its decomposition product, chlorin *f*, and the complete absence of chlorin e among the products of this reaction offer strong chemical evidence for the homogeneity of the methyl dehydrophaeophorbide *a* employed and for its relation to the oxidized series. To 165 mg. of methyl dehydrophaeophorbide *a* warmed with one cc. of pyridine in a silver crucible, was added 20 cc. of boiling 35% potassium hydroxide in methyl alcohol. The boiling was continued over a free flame for thirty seconds and the intense green solution was diluted with water and transferred to two liters of ether. The olive-green ether solution was dried and methylated with diazomethane. It was acid-fractionated into an 8–11% fraction containing mainly dimethyl phaeopurpurin 7, and a 12–14% fraction which was mainly dimethyl chlorin f. Careful refractionation and concentration of the resulting solutions gave 30 mg. and 55 mg., respectively, of well-formed crystals of each of the two products. These were identified spectroscopically in acid and ether solutions and by mixed melting points with known samples.

In another experiment with 100 mg. of methyl dehydrophaeophorbide *a* the alkaline solution was boiled for ten minutes under reflux in order to achieve a more complete conversion to chlorin f and potassium oxalate. The yields were 45 mg. of chlorin f and 7 mg. of calcium oxalate isolated in the usual way. One hundred milligrams of methyl phaeophorbide *a* under similar treatment yielded 55 mg. of chlorin *e*, 5 mg. of chlorin *f*, and 1.7 mg. of calcium oxalate. The last two are degradation products of the oxidized series and their presence here must be due to unavoidable oxidation even during the rapid hot saponification or else to the presence of a small fraction of methyl dehydrophaeophorbide in the original methyl phaeophorbide a. A phase test saponification of methyl dehydrophaeophorbide *a* follows a parallel course to that of methyl phaeophorbide *a*, with the formation of the same unstable chlorins as intermediates and dimethyl phaeopurpurin 7 as the product of methylation. The yield of crystalline dimethyl phaeopurpurin 7 was 65 mg. from 137 mg. of methyl dehydrophaeophorbide *a*. The identity of the product was tested by acid and ether spectra and by a mixed melting point with an authentic sample.

Preparation of Chlorin f.—A more efficient and less laborious method of preparing this compound from methyl phaeophorbide *a* follows from our present knowledge of the chemical steps involved. By bubbling oxygen through a solution of methyl phaeophorbide *a* in concentrated methyl alcoholic potassium hydroxide at 0°, oxidation was accomplished before appreciable hydrolysis to chlorin e could take place. The same alkaline solution was then rapidly heated to boiling and refluxed for ten minutes in order to effect the decomposition to potassium oxalate and chlorin f. As a precaution against the usual oxidation of chlorin f to a porphyrin in the hot saponification, nitrogen was bubbled through the solution both before and during the heating. The details are as follows. To a solution of 2 g. of methyl phaeophorbide *a* in 10 cc. of pyridine was added 250 cc. of 25% potassium hydroxide in methyl alcohol which had previously been cooled to 0° and saturated with oxygen for fifteen minutes. The intense green solution was kept at 0° and stirred by an oxygen stream for thirty minutes. Nitrogen was then passed through for twenty-five minutes after which the solution was quickly brought to the boiling point with a free flame and boiled vigorously under reflux for ten minutes in the nitrogen atmosphere. The product was cooled rapidly and diluted with one liter of water. The green alkaline solution was acidified in the presence of 4.5 liters of ether and transferred (there was some formation of scum). The olive-green ether solution was extracted as described in paper IV, the only two products being a porphyrin with an acid number of 5–6 and chlorin *f*, which is removed by 11% acid. No chlorin e could be detected when the temperature was kept low. The yield of crystalline product (isolated as the dimethyl ester after treatment with diazomethane) was 970 mg.

Conversion of the Unstable Chlorins to Chlorin f and Potassium Oxalate.—The unstable chlorins cannot be isolated from an ether solution but are stable in concentrated alkali. They are readily prepared from methyl phaeophorbide *a* in methyl alcoholic potassium hydroxide as was described in the preparation of chlorin f. An experiment was performed to demonstrate that potassium oxalate was the other product of the reaction which forms chlorin f. The calcium oxalate was precipitated and titrated with standard permanganate solution as previously described (paper IV). The yield from 400 mg. of methyl phaeophorbide *a* was 150 mg. of chlorin f and 37 mg. of calcium oxalate.

Chlorin k.—A typical preparation of this compound by the oxidation of chlorin *e* with molybdicyanide was as follows: 500 mg. of chlorine was added to a filtered oxidizing mixture which was made from 1.66 g. of potassium molybdocyanide in 100 cc. of 10% acetic acid oxidized with a slight excess of permanganate and 500 cc. of molar pyridine in acetone, the total volume being brought to exactly 750 cc. by the addition of water. A sample was removed as a control before the addition of chlorin e. After five hours at room temperature the reaction mixture was worked up in the usual way with water and ether; titration had previously shown that about 85% of two equivalents of oxidizing agent had been reduced. A "colorimetric comparison" in a Zeiss comparison spectroscope with chlorin f as an assumed standard showed little or no destruction of the organic colored material. The ether solution after repeated washing with water was fractionated with 9 and 14% hydrochloric acid; the lower fraction, which was small, was discarded. The 14% portion was carefully refractionated; the 13 and 14% portions were combined, transferred to ether and the solution concentrated and a small amount of petroleum ether added. The product crystallized with a steel-blue luster. The yield was 109 mg. (24%). The acid number is between 11 and 12; the color in ether is olive-green and in acid, blue. The spectrum in ether: I, 685–644.5; II, 615---613.5–601; III, 561---553; IV, 535.3–522.5; V, 510.5–483; E. A., 437. Order: I, V, IV, II, III. The spectrum in 13% hydrochloric acid: I, 682–630; II, 611–602; III, 582–571; IV, 535–522; E. A. 447. Order: I, IV, III, II.

Anal. Calcd. for $C_{33}H_{34}O_4N_4$: C, 72.0; H, 6.2; N, 10.18. Calcd. for $C_{33}H_{36}O_5N_4$: C, 69.7; H, 6.3; N, 9.86. Found: C, 71.6, 71.4; H, 6.64, 6.55; N, 10.5, 9.7, 10.2.

Chlorin k Monomethyl Ester.—Chlorin k was esterified in ether solution with diazomethane. The ester was crystallized from ether–petroleum ether. The melting point was 145–147° with some decomposition. The spectrum in ether and acid was identical with that of free chlorin k. The acid number was 13.

Anal. Calcd. for $C_{34}H_{36}O_4N_4$: C, 72.3; H, 6.4; N, 9.93; OCH_3, 5.5. Found: C, 71.4, 71.6; H, 6.5, 6.8; N, 9.66, 9.46; OCH_3, 4.5, 5.0, 6.2.

Evolution of Carbon Dioxide from Chlorin e on Oxidation.—An experiment exactly similar to that described under the preparation of chlorin k was carried out in a flask connected with an inlet tube for purified nitrogen and an outlet tube passing through an empty bottle set in a freezing mixture and then into barium hydroxide solution. Nitrogen was passed through the apparatus with the oxidizing mixture in place for three hours before adding the chlorin *e*; there was no trace of barium carbonate visible. After adding the chlorin e the gas stream was continued and in seven minutes time a cloudiness was observed in the barium hydroxide solution. After five hours, the heavy precipitate of barium carbonate which had formed rapidly during the first hour, was filtered, dried at 110° and weighed. It weighed 90 mg. (56% of the theoreticai amount of one mole of carbon dioxide per mole of chlorin *e*).

Further Experiments on the Pyrolysis of Methyl Phaeophorbide *a*.—In our first report of the preparation of pyrophaeophorbide *a* and methyl pyrophaeophorbide *a* (paper I), the fact that a methoxyl group was involved in the decomposition was overlooked due to the failure to carry out a methoxyl determination on the pyro compounds. The complete analysis of the two pyro compounds reported in Table I of the third paper of this series (p. 3016) showed that not only was carbon dioxide eliminated but methyl alcohol or formaldehyde was split out of the molecule. To test for the presence of these substances the gases evolved in the pyrolysis of 300 mg. of methyl phaeophorbide *a* in boiling diphenyl were passed into 5 cc. of distilled water, a current of nitrogen being used to sweep through the products. The aqueous solution gave a definite aldehyde test with decolorized fuchsine solution (Schiff's reagent) and with Tollens' reagent. The presence of methyl alcohol was demonstrated by the usual procedure of repeatedly introducing a heated bright copper wire and subsequently applying the aldehyde test, which is greatly increased by this treatment. The possibility that the methoxyl group of phaeophorbide *a* might have been eliminated as methane during the pyrolysis was investigated by using carbon dioxide to sweep the volatile products into a buret filled with potassium hydroxide solution. Half a millimole of methyl phaeophorbide *a* yielded only 1.75 cc. of gas which was shown by combustion analysis to be 63% carbon monoxide, 13% inert (probably nitrogen from air) and 23% methane, corresponding to a total of 0.4 cc. = 0.02 of millimole (in a duplicate experiment the methane was found to be 0.5 cc.). The actual yield of crystalline pyro compound was five times this amount. The possibility of a shift of the methoxyl group from oxygen to nitrogen during pyrolysis was also considered and the pyro compounds were tested for N-methyl groups by Pregl's quantitative method; no such groups were found, however.

Summary

1. The process of allomerization has been shown to be a process of dehydrogenation by atmospheric oxygen.

2. Chlorophyll *a* and methyl phaeophorbide *a* may be dehydrogenated by potassium molybdicyanide, two equivalents of reagent being involved. The dehydro compounds on rapid saponification yield no chlorin e but only the unstable chlorins which on longer boiling with alkali yield chlorin *f* and potassium oxalate.

3 Chlorin e is oxidized by potassium molybdicyanide with loss of carbon dioxide.

4. A structural formula for chlorophyll *a* has been proposed based on the experiments reported in this and previous papers of this series.

THE PARTITION PRINCIPLE AS APPLIED TO THE STRUCTURES OF ENOLIC SODIUM DERIVATIVES OF 1,3-DIKETONES AND BETA-KETO ESTERS

BY ARTHUR MICHAEL AND JOHN ROSS

RECEIVED MAY 6, 1931 PUBLISHED JUNE 8, 1931

The partition principle of Thomsen[1] was based upon the distribution of an insufficient amount of base for complete neutralization between two acids. This principle was extended to the course of organic reactions,[2] and was verified experimentally with a number of typical organic reactions.[3] Accordingly, the distribution of the sodium in a compound capable of reacting in more than one enolic form would be expected to follow the partition law, and the ratio of the amounts of the sodium enolates should stand to one another in a definite relation to the avidities of the corresponding enolic structures.

Geuther[4] represented the structures of acetoacetic ester and the sodium derivative by $CH_3C(OH)=CHCOOEt$ and $CH_3C(ONa)=CHCOOEt$ and although this conception was accepted by Claisen, Nef and other chemists, the commonly accepted view was that of FranMand[6] and J. Wislicenus[6] who considered the formulas CH_3COCH_2COOEt and CH_3-$COCHNaCOOEt$, respectively, to represent these compounds. In 1888 it was shown,' theoretically and experimentally, that the chemical relations of these substances could be explained only from the keto structure CH_3CO-CH_2COOEt for the ester and the*enol structure $CH_3C(ONa)=CH$-$COOEt$ (I), for the sodium derivative. However, it was emphasized[8] that a solution of the sodium compound should also contain some of the isomeric derivative $CH_3COCH=C(ONa)OEt$ (11), since malonic ester yields an enolate, and the formula of acetoacetic ester may be derived from that of malonic ester by replacing one of the carbethoxy groups of the former by the more negative acetyl group; further, that the relative amount of (I) should largely exceed that of (11), since acetyl is a much more negative radical than carbethoxyl.

This view is supported by the fact that along with the main product

of the action of chlorocarbonic ester upon the sodium enol acetoacetic ester, *viz.*, $CH_3C(OCOOEt){=}CHCOOEt$ (III),[9] some of the isomeric $CH_3COCH(COOEt)_2$ (IV) is formed.[10] Since it has not been possible to convert the O-carbethoxy ester (III) into the enolic sodium derivative of (IV),[12] it would appear that (III) and (IV) are formed from the corresponding sodium derivatives I and II.

A reagent that would react with equal velocity with each of the above sodium enol derivatives to give stable products derived from the structures of the corresponding enols could be used to demonstrate the existence of such sodium enolic compounds, and the relative amounts should be in direct relation to the avidities of the enol structures; but no reagent is known that entirely fulfils these ideal conditions. In certain reactions, such as the above example of the sodium enol derivatives of acetoacetic ester, chlorocarbonic ester is the best reagent available but the proportions even in this case can only be accepted qualitatively.

J. Wislicenus[13] showed that the time required for complete reaction in alcoholic solution with a series of alkyl iodides was greater for sodium enol acetoacetic ester than for the a-ethyl derivative, and much greater than for sodium enol malonic ester. A comparison of the rates of reaction at 25° of methyl iodide and ethyl bromide with sodium enol malonic ester and sodium enol acetoacetic ester is given in the curves, which very clearly show that the reaction velocity with both of these alkyl halides is much greater for sodium enol malonic ester than for sodium enol acetoacetic ester.

The alkyl halide was added to an alcoholic solution of the sodium enol malonic ester and sodium enol acetoacetic ester prepared by adding the esters to the alcoholic solution of sodium ethoxide. At certain intervals, samples of the reaction mixture were removed by a pipet, immediately added to an excess of cold dilute hydrochloric acid, and the excess of acid titrated with alkali. The error due to formation of neutral sodium salts of carboxylic acids was probably small under these conditions.

The above reactions were carried out with approximately 2 *N* solutions, this being the concentration usually employed for alkylation of sodium enol derivatives of this type. For comparison, the curve for the rate of reaction between the alkyl halides and sodium ethoxide in alcohol is placed alongside the curves for sodium enol acetoacetic and malonic esters. The reaction with methyl iodide in all cases proceeds very rapidly

with these concentrations, and it was impossible in the case of malonic ester to prevent a small rise of temperature. With ethyl bromide the reaction velocity could be examined more accurately. It should be noticed that half the sodium had reacted with ethyl bromide within thirty minutes in the case of sodium enol malonic ester, and within eighteen hours in the case of sodium enol acetoacetic ester. The curves for the reactions between the alkyl halides and sodium ethoxide are of interest. With methyl iodide the reaction velocity of sodium ethoxide is less than for sodium enol acetoacetic ester, but with ethyl bromide the reverse relation exists. It is apparent, therefore, that using an alcoholic solution of sodium enol acetoacetate, a larger percentage yield of alkyl derivative will be obtainable with methyl iodide than with ethyl bromide.

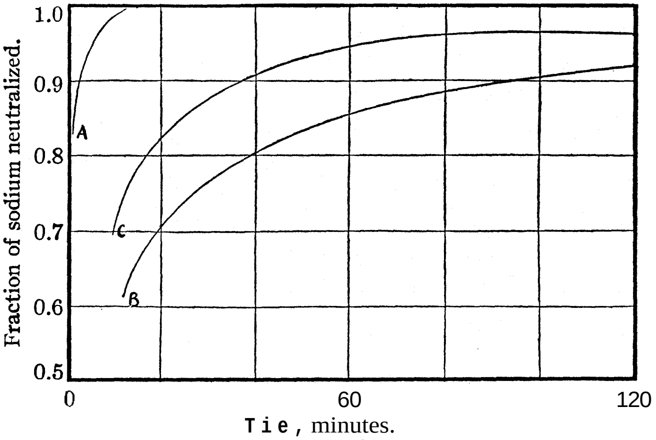

Fig. 1.—A, CH_3I + NaOEt + $CH_2(COOEt)_2$.
B, CH_3I + NaOEt + C_2H_5OH.
C, CH_3I + NaOEt + CH_3COCH_2COOEt.

When the reaction of methyl iodide (1 mole) with an alcoholic solution of equimolecular amounts of sodium ethoxide, acetoacetic and malonic esters was carried out at 0°, the product was found to consist of 6% methylmalonic ester and 70% methylacetoacetic ester. Under the same conditions using ethyl bromide, the product contained 30% ethylmalonic ester and only a trace of ethylacetoacetic ester. Therefore, using methyl iodide, the main reaction resulted in alkylation of acetoacetic ester, while with ethyl bromide, the main reaction was the alkylation of malonic ester.

These results and those of Wislicenus agree with the conclusion that the velocity relations in the action of alkyl halide upon the sodium derivatives of organic compounds depend upon the free positive chemical energy of the sodium in the respective compounds.[14] Thus, while methyl

iodide replaces readily the sodium in sodium enol acetoacetic ester, by methyl, it does so with greater difficulty with sodium enol formylacetoacetic ester;[15] it can substitute the sodium of the sodium derivative of the more acidic enol oxalacetic ester only at a higher temperature (100°), and then with a poor yield;[16] and the well neutralized sodium of sodium enol nitromethane, or that of any neutral organic salt, cannot be replaced by methyl in this way.

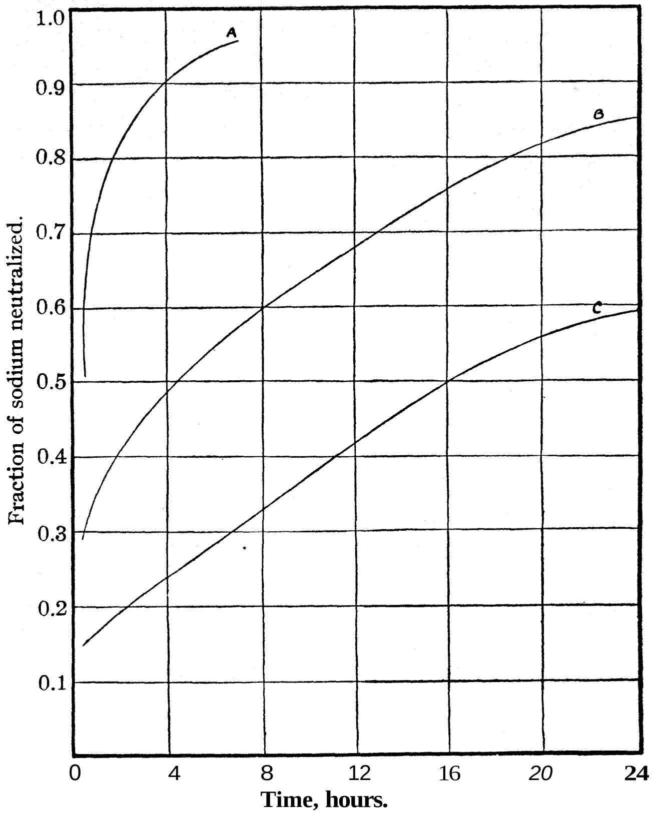

Fig. 2.—A, $C_2H_5Br + NaOEt + CH_2(COOEt)_2$.

C, $C_2H_5Br + NaOEt + CH_3COCH_2COOEt$.

Since enol acetoacetic ester is decidedly more acidic than enol malonic ester, the distribution of the sodium in the above mixture must have been largely at the acetoacetic ester residue and, as there is a relatively small difference in the reaction velocity of methyl iodide toward the two sodium derivatives, the presence of the much larger mass of sodium enol aceto-

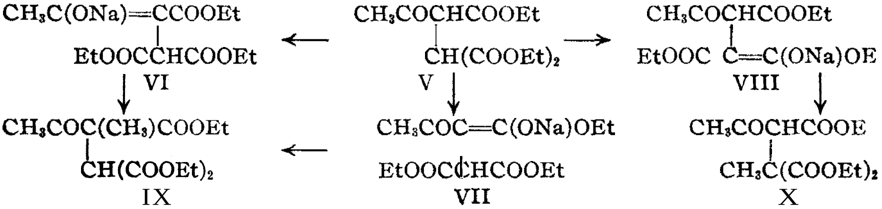
[15] Michael, Ber., 38, 2098 (1905).

[16] Wislicenus and Arnold, Ann., 246,336 (1888).

acetic ester mainly determined the proportions of the reaction products. It follows from the greater percentage of ethylation of the malonic than of the acetoacetic enolate with the use of the much less reactive ethyl bromide, that a transference of sodium from sodium enol acetoacetic ester to malonic ester must occur during the reaction. This conclusion evidently conforms with the partition principle.

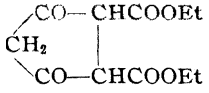
The methylation of a-acetyl-a'-carbethoxysuccinic ester (V) through its enolic sodium derivative was then examined to ascertain whether a partition of sodium among the possible enolic forms of this ester could be proved by use of methyl iodide as a reagent. The ester (V) should be capable of forming three structural sodium derivatives (VI), (VII) and (VIII). Upon alkylation (VI) and (VII) would give the same α-acetyl-a-methyl-a'-carbethoxysuccinic ester (IX), and the sodium derivative (VIII) would give the isomeric α-acetyl-α′-methyl-α′-carbethoxysuccinic ester (X).



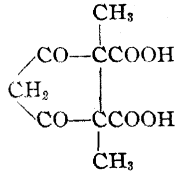
Treating the alcoholic solution of the sodium derivative of ester (V) with methyl iodide at 0° gave mainly α-acetyl-α′-methyl-α′-carbethoxysuccinic ester and no evidence of the formation of the isomeric ester (IX) could be obtained. Methylation therefore occurred at the malonic residue in preference to the acetoacetic residue, notwithstanding that there must have been a larger amount of sodium at the latter group in the original solution of sodium enolates. This result showed the much greater reactivity of the malonic enolate group compared with the acetoacetic enolate group.

In the original solution the sodium enol derivative (VI) should preponderate; there should also be a certain amount of the enolate (VII) together with a much smaller proportion of (VIII). In the structures (VI) and (VII) a greater neutralization of the sodium is realized, being directly derived from the enol forms of acetoacetic ester, as well as being indirectly under the influence of the negative malonic residue. In structure (VIII) the sodium is directly attached to the enolic malonic residue and is only under the indirect spatial influence of the enol acetoacetic residue. Evidently, the sodium atoms of Formulas (VI) and (VII) are relatively neutral compared with the sodium in (VIII). The experiment showed that the reaction occurred at the malonic enolate group, and that the enolates (VI) and (VII) are practically inert toward methyl iodide under the experimental conditions The entrance of the methyl group at the malonic residue proves that methyl iodide cannot be used to ascertain the position of the sodium in the sodium derivatives of esters of the mixed type (V).

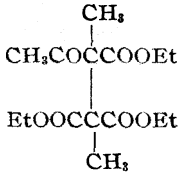
The structure of the methylated ester (X) was determined by saponification with barium hydroxide, when a mixture of α-methyl-α-carboxysuccinate was obtained together with α-methyl-α-carboxy levulinate There *was* also formed a small amount of the salt of 1,2-dimethylcyclopenta-3,5-dione-1,2-dicarboxylic acid (XII). It was shown that ester (V) readily forms the sodium derivative of cyclopenta-3,5-dione-1,2-dicarboxylic ester (XI) when treated with sodium ethoxide. It is not possible, therefore, to state whether this acid arose through methylation of the cyclic diketo ester (XI) or by cyclization of the dimethylated ester (XIII).



XI

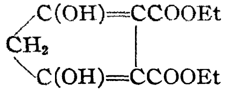


XII

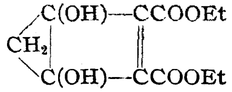


XIII

The formation of the pentacyclic keto ester (XI) from the open-chain keto ester (V) is analogous to the formation of 5-phenyldihydroresorcinol-4-carboxylic ester from the addition product of sodium enol acetoacetic ester to cinnamic ester[17] or from the addition product of sodium enol malonic ester to benzalacetone.[18] When ester (V) was treated in ether solution with alcoholic sodium ethoxide, two isomeric cyclic keto esters were obtained, a liquid and a solid, m. p. 86°. The liquid keto ester gave a deep blue color with alcoholic ferric chloride and was probably the mono enolic form of structure (XI). The solid isomer gave no coloration with ferric chloride, and may be derived by rearrangement of the di-enolic structure (XIV). This may be related to the phenomenon termed "intra-annular tautomerism," assumed in this type of compound by Farmer, Ingold and Thorpe,[19] in which case it would be represented by the structure (XV).



XIV



XV

The structure of benzoylacetone has been in the past the subject of many physical and chemical investigations, but the direction of enolization

---

[17] Michael, *Am Chem. J.*, 9,117 (1887); *J. prakt. Chem.*, *35,353* (1887).

[18] **Vorlandrr,** *Ber* , **27,** 2053 (1 *894)*; Michael, *ibid.*, 27,2126 (1894).

has not yet been decisively established. Since the results of earlier investigations upon the constitution of enols have been summarized by Scheiber and Herold,[20] only brief references that are relevant to the structure of benzoylacetone need be made here.

The magnetic rotation,[21,22] and molecular refraction[22] indicate that benzoylacetone has the enol structure (XVI).

$C_6H_5C(OH){=}CHCOCH_3$ XVI

$C_6H_5COCH{=}C(OH)CH_3$ XVII

$C_6H_5C(OH){=}C{=}C(OH)CH_3$ XVIII

$C_6H_5COCH_2COCH_3$ XIX

The parachor of benzoylacetone[23] is very close in value to a calculation based upon an open-chain diketone structure (XIX) and this agrees with the results obtained from examination of the reaction with tertiary amines.[24]

The bromine titration method of K. H. Meyer[25] led him to conclude that benzoylacetone in alcohol solution exists as 94–98% of a mono-enol in reversible equilibrium with the diketone. The method evidently cannot decide between structures (XVI) and (XVII), but Meyer favored the structure (XVI) since he considered that the physical investigations as well as the results of the bromine titration of keto–enols in general showed that the benzoyl group has a greater enolizing capacity than the acetyl. Scheiber and Herold found that ozonization of benzoylacetone gave chiefly benzoic acid (97.5% of the theoretical) and carbon dioxide, and the formation of some methylglyoxal was proved through the osazone. These chemical results therefore also point to the structure (XVI) for benzoylacetone, although they do not exclude the presence of the isomeric enol (XVII) and of the di-enol (XVIII). The ozone addition is a slow process, and if one of the mono-enolic isomers adds much faster than the other, and the isomers are in a state of rapid reversible equilibrium, then the process may proceed mainly in one direction. The results obtained by the method would not then express correctly the quantitative relations between the mono-enolic forms.

On the other hand, Claisen[26] considered that the fission of benzoylacetone by the action of alkali into acetophenone and acetate, and the

reactions of benzoylacetone with ammonia, aniline or hydroxylamine to give, respectively, $C_6H_5COCH{=}C(NH_2)CH_3$, $C_6H_5COCH{=}C(NHC_6H_5)CH_3$ and 3,5-methylphenylisoxazole (XXII), indicated greater reactivity at the acetyl group, and consequently Claisen suggested structure (XVII) as possibly representing benzoylacetone.

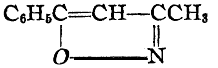
It would be expected from the partition principle that a solution of sodium enol benzoylacetone would contain sodium derivatives (XX and XXI), corresponding to the enolic structures (XVI and XVII).

$C_6H_5C(ONa){=}CHCOCH_3$
XX

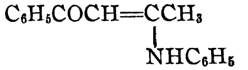
$C_6H_5COCH{=}C(ONa)CH_3$
XXI

In the hope of obtaining some information regarding the structure of the sodium derivative, the action of chlorocarbonic ester upon sodium enol benzoylacetone was studied.

The sodium derivative was prepared by adding an ether solution of the benzoylacetone to an ether suspension of sodium ethoxide prepared by Brühl's method. Chlorocarbonic methyl ester was added gradually and the reaction allowed to proceed in the cold. Approximately 85% of a substitution product was obtained. This was found to consist of two isomeric O-carbomethoxy keto esters, one a crystalline solid, melting at 57°, and the other a liquid, boiling at 164° (2 mm.). The solid ester showed no sign of changing into the liquid isomer when heated slightly above its melting point for forty-eight hours; but, on fractionation of the liquid 0-ester, varying amounts of the solid 0-ester could be frozen out of the first and last fractions, although the liquid keto ester could be kept indefinitely at ordinary temperature without any indication of changing into the solid form. Each 0-ester gave benzoylacetone when treated with aqueous ammonia or aqueous hydroxylamine in the cold. With hydroxylamine acetate in the cold, each gave some 3-methyl-5-phenylisoxazole (XXII) and, with aniline, in ether solution, theoretical yields of the anilido derivative (XXIII).



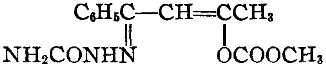
XXII



$C_6H_5COCH{=}\underset{\displaystyle NHC_6H_5}{\underset{|}{C}}CH_3$
XXIII

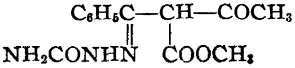
These reactions involving the elimination of the carbomethoxy group are of little value as evidence of the structures of the carbomethoxy compounds. It was found that benzoylacetone under like conditions gave the same products and there was no means of finding out whether condensation preceded or followed the elimination of the carbomethoxyl.

With semicarbazide acetate, the 0-esters showed a difference in behavior. The solid ester gave in the cold a semicarbazone derivative of benzoylacetoacetate (XXV) together with a semicarbazone derivative of the O-ester (XXIV). The latter could be converted into (XXV) by treatment with dilute acids when migration occurred of the —$COOCH_3$ group from the oxygen to the carbon atom



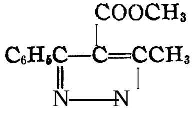
$$\begin{array}{lcl} & C_6H_5C{-}CH{=}CCH_3 & \\ & \| \qquad\quad | & \\ NH_2CONHN & & OCOOCH_3 \end{array}$$

XXIV



$$\begin{array}{lcl} & C_6H_5C{-}CH{-}COCH_3 & \\ & \| \qquad | & \\ NH_2CONHN & & COOCH_3 \end{array}$$

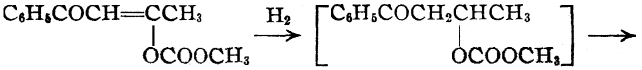
XXV



XXVI

The final product of the reaction in dilute acetic acid solution was the pyrazole derivative (XXVI). A definite product could not be isolated from the liquid 0-ester upon similar treatment with the semicarbazide acetate solution.

When the solid 0-ester was treated in methyl alcohol solution with hydrogen in the presence of platinum oxide catalyst,[27] it was found that two molecular equivalents of hydrogen were rapidly absorbed, producing *n*-propyl phenyl ketone. The addition must therefore proceed at the unsaturated carbon group and may be considered to take place as follows



$$\underset{\text{XXVII}}{\begin{array}{l} C_6H_5COCH{=}CCH_3 \\ \qquad\qquad\quad | \\ \qquad\qquad OCOOCH_3 \end{array}} \xrightarrow{H_2} \underset{\text{XXVIII}}{\left[\begin{array}{l} C_6H_5COCH_2CHCH_3 \\ \qquad\qquad\qquad | \\ \qquad\qquad OCOOCH_3 \end{array}\right]} \longrightarrow$$

$$\underset{\text{XXIX}}{C_6H_5COCH{=}CHCH_3} + HOCOCH_3 \xrightarrow{H_2} \underset{\text{XXX}}{C_6H_5COCH_2CH_2CH_3}$$

The rate of absorption did not show any marked decrease after the absorption of the first molecular equivalent of hydrogen, so that it may be supposed that the saturated carbonic ester derivative (XXVIII) was unstable and decomposed relatively rapidly to give phenyl propenyl ketone and acid carbonic methyl ester. The phenyl propenyl ketone (XXIX) would be reduced readily to the saturated ketone (XXX).

When treated with hydrogen under the same conditions, the liquid 0-ester gave as readily phenyl n-propyl ketone in almost quantitative yield.

Benzoylacetone similarly treated was reduced to give 1-phenylbutane-1,3-diol (XXXI).

$$\underset{\text{XXXI}}{C_6H_5CH(OH)CH_2CH(OH)CH_3}$$

This was obtained as a liquid distilling at 130° *(2* mm.) without decomposition. It gives a diacetate upon acetylation in pyridine. Franke and Kohn[28] obtained a 1-phenylbutane-1,3-diol melting at 73° by the action

---

[27] **Adams.** "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 92.

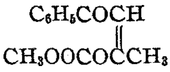
[28] Franke and Kohn, *Monatsh.*, **27, 1115** (1906).

of phenylmagnesium iodide upon acetaldol melting at 73°. Bauer[28a] by the action of sodium and alcohol. on benzoylacetone obtained some 1-phenylbutane-1,3-diol, a liquid of b. p. 168° (13 mm.), and Kubota and Hayashi[28b] by the action of hydrogen on benzoylacetone at 105° in the presence of copper catalyst, obtained, among other products, some of this diol. Whether our material is identical or stereomeric with the compounds obtained by these authors, can only be decided by further examination.

Since benzoylacetone is thus ruled out as a common intermediate in the reduction of the isomeric 0-esters, and since each of the 0-esters gives the same saturated ketone, it must be concluded that these two O-esters are related to one another as stereomers with configurations as follows

$$\begin{array}{l} C_6H_5COCH \\ \qquad\| \\ CH_3COCOOCH_3 \end{array}$$

XXXII



$$\begin{array}{r} C_6H_5COCH \\ \| \qquad \\ CH_3OOCOCCH_3 \end{array}$$

XXXIII

It also follows that in this reaction with the chlorocarbonic ester, the sodium enol benzoylacetone reacts (at least to 85%) as though it had the structure (XXI) and that the enolate consisted of a mixture of stereomeric sodium compounds. Such a result agrees with the partition principle since the sodium compounds would be derived from stereomeric enols of different acidity. The above results also raise the question of the stereochemical homogeneity of the corresponding free mono-en01 of benzoyl acetone.

In view of these results, it was of interest to examine the action of chlorocarbonic ester upon sodium enol dibenzoylmethane. When the sodium derivative was prepared, using an ether suspension of sodium methoxide as in the experiment with benzoylacetone, it was found that over 90% of the dibenzoylmethane was recovered unchanged after treatment with chlorocarbonic ester. Better results were obtained when the sodium derivative was prepared directly from pulverized sodium and dibenzoylmethane in ether solution. A yield of 7% of O-carbethoxy derivative (XXXV), together with some dibenzoylmethane, was obtained, but the main product was a thick sirup of undetermined composition that could not be distilled nor crystallized. It is possible that the method of preparing the sodium derivative resulted in a partial reduction of the dibenzoylmethane or produced some complex compound of high molecular weight.

$C_6H_5COCH{=}C(ONa)C_6H_5$

XXXIV

$$\begin{array}{l} C_6H_5COCH{=}CC_6H_5 \\ \qquad\qquad\quad | \\ \qquad\qquad\quad OCOOCH_3 \end{array}$$

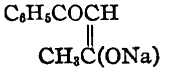
[28a] Bauer, *Compt. rend.*, 154, **1093 (1911).**

[28b] Kubota and Hayashi, Bull. *Chem. Soc. Japan*, **1,** 14 (1926).

In another experiment the sodium derivative was prepared using an ether solution of dibenzoylmethane and finely powdered sodamide. The solid sodium derivative was filtered off and washed free of ammonia with ether, before the addition of the chlorocarbonic ester; 50% of dibenzoylmethane was recovered, and 30% of the O-ester melting at 90° together with 20% of liquid material which possibly contained a stereomeric O-ester was obtained.

These experiments show the greater difficulty of replacing by carbomethoxyl the sodium of an enol group adjacent to a phenyl than to the methyl group.

Since benzoyl is a more negative radical than acetyl (the dissociation values, K, of acetic and benzoic acids are 0.0063 and 0.0018, respectively), it is evident that the sodium in the structure $C_6H_5C(ONa){=}CHCOCH_3$ should be better neutralized than in the structure $C_6H_5COCH{=}C(ONa)CH_3$. The isomeric enolic benzoylacetones are definitely acidic compounds, and the sodium in the first derivative should be considerably better neutralized and therefore less reactive than the sodium in the second structure, a conclusion supported by the relative difficulty of obtaining an O-carbethoxy derivative of dibenzoylmethane. The facile action of chlorocarbonic ester upon sodium enol benzoylacetone and upon sodium enol acetylacetone[29] has proved the greater reactivity of the sodium in the $C_6H_5COCH{=}C(ONa)CH_3$ than in the $C_6H_5C(ONa){=}CHCOCH_3$ structure. It has also shown that in the first structure the sodium is partitioned between the stereo structures (XXXVI) and (XXXVII), of which the latter enolate should preponderate.



$$\begin{array}{l} C_6H_5COCH \\ \qquad\;\; \| \\ \;\; CH_3C(ONa) \end{array}$$

$$\begin{array}{l} C_6H_5COCH \\ \qquad\;\; \| \\ (NaO)CCH_3 \end{array}$$

XXXVII

For comparison with the results of the experiments upon the action of semicarbazide acetate upon the keto esters above, the action of semicarbazide upon benzoylacetone was reexamined. Posner[30] stated that semicarbazide does not react with benzoylacetone in the cold, but with molecular amounts of semicarbazide hydrochloride at 60°, sodium acetate and benzoylacetone, he obtained 3,5-methylphenylpyrazole-1-carboxamide (XXXIX).

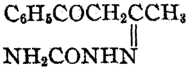
Using semicarbazide or semicarbazide acetate in alcoholic solution at 0°, it was found that pyrazole ring formation could be avoided. The monosemicarbazone (XXXVIII) is readily formed and with excess of semicarbazide a disemicarbazone is formed. Treatment of the monosemicarbazone in alcoholic solution with a small amount of acetic acid

---

[29] Claisen, Ann., 277, 176 (1893).

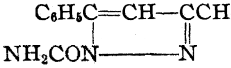
[30] Posner, Ber., 34, 3983 (1901).

or hydrochloric acid gave the 3,5-methylphenylpyrazole-1-carboxamide, which on warming or standing in acid solution readily hydrolyzed with loss of carbon dioxide to give the 3,5-methylphenylpyrazole (XL).

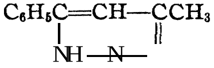


$C_6H_5COCH_2C(=NNHCONH_2)CH_3$

XXXVIII



XXXIX



XL

Accordingly, semicarbazide acetate in acid solution or semicarbazide hydrochloride with benzoylacetone gave directly mainly 3,5-methylphenylpyrazole together with some 3,5-methylphenylpyrazole-1-carboxamide.

The physical properties of benzoylacetone indicate that it exists mainly as $C_6H_5C(OH){=}CHCOCH_3$ (XVI). Since benzoyl is decidedly more negative than acetyl, the sodium derivative should consist largely of $C_6H_5C(ONa){=}CHCOCH_3$ (XX), yet the sodium derivative with chlorocarbonic methyl ester yields only stereomeric forms of $C_6H_5COCH{=}C(OCOOCH_3)CH_3$ which are formed from $C_6H_5COCH{=}C(ONa)CH_3$ (XXI), since benzoylacetone with alkali should give mainly a mixture containing much of (XX) and little of (XXI), and fluxing with it should result in a mixture of benzoate and acetone, with much less acetate and acetophenone. However, acetate and acetophenone are the sole or at least the main products of the decomposition. With typical carbonyl reagents, *e.* g., ammonia, hydroxylamine, phenylhydrazine and semicarbazide, benzoylacetone yields primarily derivatives by replacement of the 0-atoms of the carbonyl group of the acetyl radical,[31] and the introduced group then acts on the C-atoms of the —C(OH)=CH— group to form cyclic derivatives, or with a further quantity of the reagent yield products involving the enolic group. Physical investigation supports structure (XVI), while chemical investigation points unmistakably to $C_6H_5COCH{=}C(OH)CH_3$ (XVII). How may these opposing results be reconciled?

In sodium derivatives (XX) and (XXI), the metal in (XX) must be decidedly more neutralized than that in (XXI); sufficiently in the former that $ClCOOCH_3$ acted upon it slowly or not at all. The energetic reaction therefore extended only to (XXI), which is reformed progressively followed by introduction of the carbomethoxyl group. The course of alkali fission of (XX) and (XXI) depends upon the reaction mechanism of the

[31] This behavior led Claisen [Ber., 59, 146 (1926), footnote 10] to believe that the position of the enolic group in benzoylacetone is open to question, and Scheiber and Nerold [*Ann.*, 405, 318 (1914)] considered that the formation of acetophenone and acetate by alkali fission favors the structure $C_6H_5COCH{=}C(ONa)CH_3$ for the sodium derivative. The statement is not tenable that this view finds support in the easy synthesis of sodium enol benzoylacetate from acetophenone and ethyl acetate compared with the difficulty and poor yields encountered when it is attempted to prepare it from ethyl benzoate and acetone. The second reaction would depend upon the formation of sodium enol acetone, which appears in such small amount in the action of sodium upon acetone that its formation can hardly be considered as definitely established.

process. Carbonyl derivatives that do not form enolates with alkali react primarily by addition of the alkali to the carbonyl group to form the group —C(OM)OH—. The slightly neutralized energy of the alkali in this complex loosens the affinity of the C-atom to the directly attached C-atoms[32] and cleavage occurs between the C-atoms by hydrolysis. The rupture should take place at the carbon linkage which is most weakened by the positive influence of the alkali atom. In fluxing enolates (XX) and (XXI) with alkali, similar intermediate products should be formed by addition of water at the unsaturated carbon system and as the alkali atom in the addition product from (XXI) is decidedly less neutralized than in that from (XX), disruption of the carbon chain takes place with the (XXI) compound, thus

$$C_6H_5CO—CH{=}C(ONa)CH_3 + H_2O \rightarrow C_6H_5COCH_2C(ONa,OH)CH_3 \rightarrow C_6H_5COCH_3 + CH_3COONa$$

Finally, the course of the reaction of benzoylacetone with carbonyl reagents depends upon whether they add more facilely to the carbonyl or to the —C(OH)=C— group. This relationship may vary with the chemical character of the radicals in direct union with these groups. The course of the above reactions is therefore *prima facie* evidence that with the benzoylacetone structure (XVI) they act much more readily on the carbonyl than on the enolic group. Direct experimental confirmation of this is found in the action of hydroxylamine upon the isomeric keto ethers $C_6H_5COCH{=}C(OC_2H_5)CH_3$ and $C_6H_5C(OC_2H_5){=}CHCOCH_3$ since in each case the O of the carbonyl group is replaced by the hydroxylamine residue.[33]

There is no doubt that the principles developed in the examination of the above reactions can be applied to problems concerning compounds of this or similar types where the partition principle is involved.

Experimental

A. Reaction Velocity of Sodium Enolates with Methyl Iodide and Ethyl Bromide.—To a solution of 2–3 g. of sodium in 50 cc. of absolute alcohol 13 g. of acetoacetic ester was added; 14.5 g. of methyl iodide was added to the cold solution of the enolate and after mixing thoroughly was placed in a thermostat at 25°. At known intervals 10 cc. of this mixture was removed with a pipet and run into 50 cc. of 0.5 N hydrochloric acid cooled in ice. The excess acid was then titrated with standard caustic soda using phenolphthalein as indicator. Thus as the reaction proceeded, it was possible to measure the amount of sodium that had been neutralized by the alkyl halide.

Similar experiments were made using (a) malonic ester, (b) an equal volume of alcohol in the place of the acetoacetic ester. Also a series of experiments was carried out using ethyl bromide in the place of methyl iodide. The results are summarized in Curves I and II.

Reaction between Alkyl Halide and a Mixture of NaOEt, $CH_2(COOEt)_2$ and CH_3-

---

[32] Michael, THIS JOURNAL, 32, 997 (1910); Michael and Ross, *ibid.*, 52, 4601 (1930).

[33] Claisen, *Ber.*, 59, 148 (1926).

$COCH_2COOEt$ in Alcohol Solution.—A mixture of 32.5 g. of acetoacetic ester with 40 g. of malonic ester was added to a solution of 5 75 g. of sodium in absolute alcohol. After standing for one hour, 36 g. of methyl iodide was added and the mixture stood in ice water for twelve hours. The product was then mixed with 500 cc. of water containing a small amount of acetic acid and the neutral esters extracted with ether, dried and the ether removed upon the water-bath.

The cold esters were then shaken with successive portions of 5% caustic potash (40 g. in 800 cc. of water). Toward the end of this extraction the amount of ester became so small that it was necessary to take it up in a small volume of ether. The ester that remained in ether solution was washed with water, dried, distilled and weighed as methyl malonic ester;[34] the yield was 2.5 g. or 6% of the possible yield calculated upon complete methylation of malonic ester.

The aqueous alcoholic extract was left overnight cooled in water in order to complete saponification. Using the procedure described by Michael and Wolgast,[35] the solution was acidified and after refluxing for two hours, the volatile ketones distilled off. The aqueous ketone distilled was saturated with salt and the ketones taken up in ether, separated, dried and distilled up an 8-inch Vigreux fractionating column. The fraction distilling at 76–77.5°, after separation from alcohol by the sodium bisulfite compound, was weighed as pure ethyl methyl ketone; yield, 12 g (70%) The semicarbazone gave large prisms, melting at 148° without recrystallization.[36]

A similar experiment was carried out using ethyl bromide in the place of ethyl iodide, allowing the reaction mixture to stand for seven days and using the same method as above for the separation of the products: 12 g. of ethylmalonic ester (30%) and 3 g. of methyl propyl ketone (16%), b. p. 101–102°, were obtained. The semicarbazone melted at 110°.[37] These results may be summarized as follows

	Yield of alkylacetoacetic ester, %	Yield of alkylmalonic ester, %
CH_3I	70	6
C_2H_5Br[38]	trace	30

B. Methylation of Sodium Enol α-Acetyl-α'-carbethoxysuccinic Ester.—a-Acetyl-*α'-carbethoxysuccinic* ester was prepared by the action of sodium enol acetoacetic ester on chloromalonic ester[38a]: 33 g. of acetoacetic ester was added to 5.75 g. of pulverized so-

---

[35] Michael and Wolgast. Ber., 42,3176 (1909).

[36] Robinson, J. Chem. *Soc.*, 109,1044 (1916), gives m. p. 148°.

[37] Michael, THIS JOURNAL, 41,419 (1919)

[38] It is significant to note in comparison with this result that the products of complete reaction at *25* of 26 g. of acetoacetic ester, sodium ethoxide (from 4.6 g. of sodium in 100 cc. of alcohol), and 22 g. of ethyl bromide contain approximately 40% ethylacetoacetic ester and 10% di-ethylacetoacetic ester. It is apparent that when an alkyl halide acts upon a sodium enolate with equal or less velocity than it does upon alcoholic sodium ethoxide, it is evidently not advisable to carry out the reaction in alcoholic solution.

[38a] Gault and Klees [Bull. *soc.* chim , 39, 1000 (1926)] by the action of chloroacetoacetic ester upon sodium enol malonic ester obtained among other products a liquid of b. p. 170–175° (15 mm.), which they considered to be α-acetyl-α'-carbethoxy succinic ester. By the action of sodium enol acetoacetic ester upon chloromalonic ester they obtained a solid compound m p. 34" which they regard as the keto form of a-acetyl-a'-carbethoxysuccinic ester. However, the solid they describe is very close in its properties to α,α'-di-aceto-succinic ester (α_3 form, m p. 32") and we propose to examine this point in another communication

dium suspended in ether and the mixture allowed to stand overnight, when the formation of the sodium derivative was complete; 49 g. of chloromalonic ester was added and the mixture warmed gently on the water-bath for one hour. After cooling, the excess of alkali was neutralized by dilute acetic acid and the neutral product was washed with 10% sodium carbonate, dried and fractionated: 40 g. of material distilling at 60–120° (15 mm.) was apparently unchanged acetoacetic and chloromalonic esters; 20 g. distilling at 140–160° (5 mm.) consisted of a-acetyl-a-carbethoxysuccinic ester. A higher boiling fraction 160–200° (5 mm.) (10 g.) partially solidified; the solid was ethanetetracarboxylic ester.[39]

The a-acetyl-a'-carbethoxysuccinic ester was refractionated and obtained as a colorless oil, b. p. 147" (5 mm.), which gave a deep red color with alcoholic ferric chloride; yield, 25%.

Anal. Calcd. for $C_{13}H_{20}O_7$: C, 54.16; H, 6.94. Found: C, 53.95; H, 6.79.

It readily gave a semicarbazone, m. p. 76°.

Anal. Calcd. for $C_{14}H_{23}O_6N_3$: C, 48.70; H, 6.67. Found: C, 48.53; H, 6.90.

Methylation.—To a cold solution of 2.3 g. of sodium in 30 cc. of ethyl alcohol, 28.8 g. of a-acetyl-a'-carbethoxysuccinic ester was added. After the mixture had stood for two hours, 18 g of methyl iodide was added and the mixture left overnight cooled in ice water. The product was diluted with ether and washed with dilute acetic acid, then with aqueous sodium carbonate and dried and fractionated.

There was obtained 27 g. of ester, b. p. 144–152° (2 mm.), which gave a deep red color with alcoholic ferric chloride. Saponification with barium hydroxide showed that the product consisted almost entirely of **a-acetyl-a'-methyl-a'-carhoxysuccinic** ester.

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.62; H, 7.28. Found: C, 55.03; H, 7.40.

Saponification with Barium Hydroxide.—Five grams of the above methylated ester, b. p. 144–152" (5 mm.), was boiled for four hours with a slight excess of 8% barium hydroxide solution. The product was cooled and the precipitate of barium salts filtered off, washed with ether, decomposed with hydrochloric acid in the cold and the organic acid extracted with ether. A sirupy acid was obtained which from chloroform-ligroin solution slowly deposited crystals (m. p. 158°). This solid acid (0.7 g.) on recrystallization melted at 166" with decomposition and analysis indicated that it had the composition $C_6H_8O_6$. The mixed melting point with a sample of a-methyl-a-carboxysuccinic acid (m. p. 170°) was not lowered. The latter acid was prepared from chloromalonic ester and sodium enol methylmalonic ester.[40] Moreover, upon heating a portion of this acid at 175° for fifteen minutes, methylsuccinic acid was obtained, melting at 111° after recrystallization, and shown to be identical, by mixed melting point, with methylsuccinic acid.

The remaining sirupy acid which could not be obtained in crystalline form was heated at 150° for fifteen minutes and a product obtained that distilled at 155° (5 mm.). This was then shown to be α-methyllevulinic acid by direct comparison and by a mixed melting point of the semicarbazone (m. p. 191°). No indication could be found of the presence of β-methyllevulinic acid in the decomposition product.

The filtrate from the insoluble barium salts was evaporated on the water-bath to a small bulk and the acid extracted with ether after acidifying. On concentration of the ether solution, the acid separated as glittering plates. It was recrystallized from ace-

---

[39] It seems probable that in the alcoholic solution some chloromalonic ester was reduced to malonic ester, from which the necessary sodium enol malonic ester was formed that reacted with unchanged chloro ester to give the tetracarboxylic ester.

[40] Bischoff and Kuhlberg, *Ber.*, 23, 635 (1918); Blaise and Gault, Bull. *soc. chim.*, [4] 9,460 (1912).

tone and melted at 295–300° with sublimation It gave no color with alcoholic ferric chloride. Analysis agrees with the formula of 4,5-dimethylcyclopentane-1,3-dione-4,5-dicarboxylic acid; yield, 0.5 g.

Anal. Calcd. for $C_9H_{10}O_6$: C, 50.47; H, 4.67. Found: C, 50.29; H, 4.63.

α-Methyl-α-carboxylevulinic ester was prepared by the condensation of bromoacetone with sodium enol methylmalonic ester in alcohol solution. A yield of 50% was obtained and the keto ester distilled at 133° (5 mm.).

Anal. Calcd. for $C_{11}H_{18}O_5$: C, 57.40; H. 7.83. Found: C, 57 15; H, 8.0.

This ester readily gave a sernicarbazone, m. p. 102°.

Anal. Calcd. for $C_{12}H_{21}O_5N_3$: C, 50.18; H, 7.32. Found: C, 49.95; H, 7.47.

α-Methyl-α-carboxylevulinic acid was obtained as a sirup through saponification of the above ester with barium hydroxide. Upon distillation, it gave a-methyllevulinic acid, b. p. 160° (5 mm.), which was characterized by the sernicarbazone, m. p. 191°.[41]

The Action of Sodium Ethoxide upon α-Acetyl-α-carbethoxysuccinic Ester.—To a suspension of sodium ethoxide prepared from 1.2 g. of pulverized sodium and **23** g. of ethyl alcohol in ether, 14 g. of the above ester was added and the mixture warmed for two hours upon the water-bath. The mixture was cooled and added to 40 cc. of water containing 4 g. of acetic acid, and extracted with ether. The ether solution was washed with sodium carbonate and a considerable amount of acid material removed. The acid fraction was acidified and the acid recovered as a thick sirup which, however, did not crystallize. The neutral ester was distilled and 9 g. of ester, b. p. 150–155° (2 mm.) was obtained which partially crystallized upon standing. The solid ester was filtered off and crystallized from ether–ligroin mixture. It melted at 86° and gave no coloration with alcoholic ferric chloride. It may have the bicyclic structure (XV).

Anal. Calcd. for $C_{11}H_{14}O_6$: C, 54.55; H, 5.79. Found: C, 54.91; H, 5.37.

The liquid ester, b. p. 149° (2 mm.), gave a deep blue color with alcoholic ferric chloride and because of this fact was tentatively ascribed the structure (XIV).

Anal. Calcd. for $C_{11}H_{14}O_6$: C, 54.55; H, 5.79. Found: C, 54.86; H, 5.60.

This liquid ester readily gave a di-semicarbazone melting at 220° and which crystallized in plates from dilute alcohol.

Anal. Calcd. for $C_{13}H_{20}O_6N_6$: C, 43.54; H, 5.62. Found: C, 43.84; H, 6.1.

With equimolecular quantities of semicarbazide acetate this ester gave a compound of m. p. 76°, crystallizing in large prisms from ether. From analysis it would appear to be a bicyclic pyrazole derivative

Anal. Calcd. for $C_{11}H_{14}O_4N_2$: C, 52 39; H, 5.56. Found: C, 52.42; H, 6 10.

C. Action of Chlorocarbonic Methyl Ester upon Sodium Derivatievs of **Enol Benzoyl** Acetone.—Sodium methoxide was prepared by adding 8.0 g. of methyl alcohol to a suspension of 5.7 g. of pulverized sodium in ether, and standing for twelve hours at room temperature. An ether solution of 40.5 g. of berizoylacetone was added and to the sodium derivative thus obtained as a fine yellow suspension, 24 g. of methyl chlorocarbonate diluted with ether was gradually added to the cooled material. The mixture stood for twelve hours although most of the reaction was completed at the end of one hour. The ethereal mixture reacted slightly alkaline and was washed first with dilute acetic acid and then several times with 10% sodium carbonate, followed by water, and was dried with calcium chloride. The ether was removed on the water-bath and residue distilled up to 150° (3 mm.). A small quantity of unchanged benzoylacetone separated which had not been extracted by the sodium carbonate. On cooling 27 g. of solid keto ester, m. p. 57°, separated out as large needles, leaving 11.5 g. of a

---

[41] *Cf* March, *Comfit. rend.*, 134,180; *Ann. chim* , [7]**26, 323** (1902).

liquid keto ester which on redistillation boiled at 164° (2 mm.). Approximately 5.7 g. of benzoylacetone was recovered, so that the 85% of benzoylacetone that had reacted gave a ratio of nine parts of solid to four parts of liquid keto ester.

Solid Keto Ester.—This crystallized in long, colorless needles from a mixture of ether and ligroin, m. p. 57°. It gave no coloration with alcoholic ferric chloride.

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.46; H, 5.45. Found: C, 65.30; H, 5.63.

Liquid Keto Ester.—This was purified by two fractional distillations and freezing out of the solid isomer. It was noticed that after distillation the solid isomer always appeared in the first and last fractions, which made it probable that the liquid ester was converted into the solid isomer upon heating to the boiling point temperature. A sample after keeping for six months at ordinary temperature showed no sign of changing into the solid form. The ester is a slightly yellow, highly refractive liquid which gave a deep red color with alcoholic ferric chloride, and boils at 164" (2 mm.).

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.46; H, 5.45. Found: C, 65.60; H, 5.70.

Behavior Toward Semicarbazide and Salts

(a) Solid Keto Ester.—Using semicarbazide hydrochloride with an excess of sodium acetate in the cold gave the same results as free semicarbazide. An equivalent amount of the reagent in each case was added gradually to an alcoholic solution of the ester, cooling, and from 2.2 g. of the keto ester an immediate precipitation of 0.6 g. of a finely crystalline solid appeared, m. p. 166". After several hours, large crystals of a slightly yellow solid, m. p. 183° (1.5 g.), were deposited, and after several days, 0.3 g. of a white solid, m. p. 202°.

Semicarbazone, m. p. **166°.**—This recrystallized from aqueous alcohol as fine plates, which gave a deep blue color with alcoholic ferric chloride. This fact, with the analysis, suggests that it is a semicarbazone of benzoylacetoacetate of structure (XXV).

Anal. Calcd. for $C_{13}H_{15}O_4N_3$: C, 56.31; H, 5.54. Found: C, 56.35; H, 5.7.

Semicarbazone m. p. 183° crystallized in slightly yellow prisms from dilute alcohol It was the main product of the reaction, gave no color with alcoholic ferric chloride and was apparently the semicarbazone of the O-carbomethoxy keto ester. An alcoholic solution of this semicarbazone containing a small amount of acetic acid when warmed to 50° for a few minutes becomes colorless and upon cooling quantitatively deposits the semicarbazone of benzoylacetoacetate, m. p. 166". The small quantity of acetic acid apparently causes migration of the carbomethoxyl group from oxygen to the methylene carbon atom.

Anal. Calcd. for $C_{13}H_{15}O_4N_3$: C, 56.31; H, 5.54; Found: C, 56.42; H, 5.63.

Semicarbazone m. p. 202° crystallized in needles from dilute alcohol. The analysis pointed to a condensation product of keto ester with more than two molecules of semicarbazide.

Anal. Found: C, 34.7; H, 4.94.

Semicarbazide hydrochloride with an equivalent weight of sodium acetate in the cold reacted as follows: 2.2 g. of keto ester was mixed in the cold with an aqueous solution of 1.1 g. of semicarbazide hydrochloride and 1.3 g. of sodium acetate. There was an immediate precipitation of 0.6 g. of the solid semicarbazone of benzoylacetoacetate, m. p. 166°. None of the semicarbazone of the O-carbomethoxy keto ester, m. p. 183°, was formed. After seven days an oil separated which solidified on cooling. This crystallized from ligroin in large prisms, m. p. 62°. It gave no color with alcohclic ferric chloride. Analysis showed that it was 3,5-methylphenylpyrazole-4-carboxylic (methyl ester).

Anal. Calcd. for $C_{12}H_{12}O_2N_2$: C, 66 66; H, 5.55, N, 12.96. Found: C, 66.7; H, 5.28; N, 13.2.

(b) On Liquid Keto Ester.—No definite products could be isolated.

Action of Aqueous Ammonia.—This reagent added to an alcoholic solution of each of the isomeric O-esters caused decomposition in each case, benzoylacetone crystallizing out in about one hour.

Action of **Hydroxylamine.**—An aqueous solution of the free amine reacted on the solid keto ester in methyl alcohol solution in the same way as aqueous ammonia above. After half an hour, crystals of benzoylacetone were deposited. With hydroxylamine acetate, a 50% yield of 3-methyl-5-phenylisoxazole was obtained from the solid and also from the liquid carbomethoxy ester.

Action of Aniline.—To an ether solution of the solid ester, an equivalent quantity of freshly distilled aniline dissolved in ether was added. The anil of benzoylacetone $C_6H_5COCH{=}C(NHC_6H_5)CH_3$, m. p. 110°, crystallized out as deep yellow prisms after standing at room temperature for about three days. The isomeric esters gave the same product, the liquid 0-ester apparently showing slightly greater reaction velocity. Benzoylacetone with aniline in ether solution after standing several days at room temperature gives the same product.[42]

Action of Potassium Carbonate.—To a solution of 8.8 g. of solid keto ester in methyl acetate, 4.0 g. of dry potassium carbonate was added, and the mixture boiled on the water-bath for four hours. The solution was filtered from the solid potassium carbonate, washed with water and dried. Upon concentration 7.0 g. of unchanged solid ester crystallized out. There remained a small amount of material in the mother liquor which proved to be henzoylacetone. A small amount of benzoylacetone was also obtained upon acidifying the potassium carbonate residue; 80% of the solid ester was recovered unchanged and approximately 15% of benzoylacetone was obtained. No indication of benzoylacetoacetic ester was found.

Reduction.—The method described by Adams[43] was used. A solution of 8.8 g. of the solid keto ester (m. p. 57°) in methyl alcohol, to which 0.2 g. of the platinum oxide catalyst was added, was shaken in an atmosphere of pure hydrogen. A total volume of 1750 cc. of hydrogen (1.8 molecular equivalents) was rapidly taken up and then absorption ceased. The absorption curve showed no significant change in the rate of absorption at the point where one molecular equivalent of hydrogen was taken up, so that it was necessary to proceed until hydrogenation was complete under the conditions used.

The solution was filtered, shaken with activated charcoal and the reaction product distilled after removal of the methyl alcohol. It boiled at 117° (8 mm.) as a colorless liquid with a characteristic odor.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.07; H, 8.11. Found: C, 80.72; H, 8.30.

This ketone readily gave a semicarbazone with alcoholic sodium acetate solution of semicarbazide hydrochloride, which crystallized in fine needles, melting at 188°.

Anal. Calcd. for $C_{11}H_{15}ON_3$: C, 64.39; H, 7.32. Found: C, 64.62; H, 7.50.

A mixed melting point showed this semicarbazone to be identical with the semicarbazone of n-propyl phenyl ketone, which was prepared from butyryl chloride and benzene.[44]

When similarly treated with hydrogen, the liquid keto ester also gave n-propyl

phenyl ketone. The rate of absorption of hydrogen was slightly more rapid than with the solid keto ester. The saturated ketone was identified through the semicarbazonc, m. p. 188°.[44b]

Catalytic Reduction of **Benzoylacetone.**—Benzoylacetone was carefully purified by recrystallization from methyl alcohol; 8.0 g. of benzoylacetone in 100 cc. of methyl alcohol was treated with hydrogen in the same manner as in preceding experiments; 1950 cc. of hydrogen was rapidly absorbed. The methyl alcohol was removed under reduced pressure and the product distilled. There was obtained 7.5 g. of **1-phenylbutane-1,3-diol,** b. p. 129–131" (2 mm.). It was a fragrant smelling oil which at this pressure distilled without decomposition, and gave no color with femc chloride immediately, but upon standing the solution developed a red coloration, possibly due to oxidation to benzoylacetone.

Anal. Calcd. for $C_{10}H_{14}O_2$: C. 72.25; H, 8.43. Found: C, 71.96; H, 8.13.

Addition of acetyl chloride to a pyridine solution of the above diol gave a diacetate, b. p. 140° (2 mm.), a colorless oil.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.20; H, 7.23. Found: C, 67.53; H, 7.6.

D. Action of Chlorocarbonic Methyl Ester upon Sodium **Enol Dibenzoylmethane.**—To a suspension of 3.3 g. of pulverized sodium in ether, 32 g. of dibenzoylmethane in ethereal solution was gradually added, and the mixture left overnight cooled in ice water. To the fine yellow mass of the anhydrous sodium derivative, 13.5 g. of chlorocarbonate methyl ester, diluted with ether was gradually added. The mixture did not rise in temperature and so was left at room temperature for twelve hours. The product was washed with water, then with sodium carbonate solution, dried and the ether distilled off on the water-bath. As the product decomposed on distillation *in vacuo,* it was therefore heated at 100° (10 mm.) to remove any lower boiling substance. The residual sirup was dissolved in a mixture of ether and ligroin and permitted to crystallize by slow evaporation in a desiccator over paraffin wax. After some unchanged dibenzoylmethane (12 g.) crystallized out, a crystalline solid of m. p. 90° separated. This was recrystallized from a mixture of ether and ligroin. This solid gave no color with alcoholic ferric chloride and is the O-carbomethoxy derivative of dibenzoylmethane; yield, 3 g.

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.35; H, 4.85. Found C, 72.60; H, 5.04.

There remained 15 g. of sirup of undetermined composition. In another experiment the sodium derivative was prepared from powdered sodamide. The solid sodium enol dibenzoylmethane being filtered off and washed with dry ether, and treated as described above, a 30% yield of the O-carbomethoxy derivative, m. p. 90°, was obtained together with 20% of the sirupy liquid product.

E. Action of Semicarbazide and its Salts on Benzoylacetone

In the Presence of Excess Sodium Acetate.—An excess of semicarbazide hydrochloride (2.2 g.) was dissolved with 3.0 g. of sodium acetate in a minimum of cold water and the solution added to 3.2 g. of benzoylacetone dissolved in cold alcohol. After standing for an hour, at room temperature, large prisms were deposited but the reaction took about two days for completion. Upon recrystallization from dilute alcohol, the substance (3.8 g.) melted at 127–128° and was the monosemicarbazone of benzoylacetone. It gave a deep green color with alcoholic ferric chloride.

Anal. Calcd. for $C_{11}H_{13}O_2N_3$: C, 60.28; H, 6.12; N, 19.18. Found: C, 60.12; H, 6.04; N, 19.05.

Free **Semicarbazide.**—An equivalent quantity of 2.4 N caustic soda was added to a cold solution of semicarbazide hydrochloride, and this solution mixed in the cold with an alcoholic solution of benzoylacetone. The above monosemicarbazone was obtained in almost the theoretical yield.

Semicarbazide Hydrochloride.—Two and two-tenths grams of semicarbazide hydrochloride dissolved in a minimum of water was added in the cold to 3.2 g. of benzoylacetone in alcohol. After several minutes the solution became warm, a few bubbles of gas were evolved, and it was therefore cooled in water. Some long needle-shaped crystals were deposited (0.1 g., melting at 161°) which proved to be 3,5-methylphenylpyrazole-1-carboxamide. Later a flocculent mass (1.3 g.) separated. Upon dilution of the reaction liquid, some unchanged benzoylacetone was obtained. The flocculent material crystallized from a mixture of ethyl acetate and ligroin as large prisms, melting at 121–122°. Analysis and reactions showed this to be 3,5-methylphenylpyrazole. It was found to be identical with a sample prepared from hydrazine and benzoylacetone.[46]

Anal. Calcd. for $C_{10}H_{10}N_2$: C, 75.95; H, 6.33; N, 17.72. Found: C, 75.72; H, 6.50; N, 18.0.

Action of Semicarbazide Acetate at 60°.—Two and two-tenths grams of semicarbazide hydrochloride was dissolved with 2.7 g. of sodium acetate in the minimum of water and the solution added to 3.2 g. of benzoylacetone in alcohol. The mixture was warmed in a water-bath at 60° for half an hour. The main product was 3,5-methylphenylpyrazole together with a small amount of 3,5-methylphenylpyrazole-1-carboxamide.

Action of Two Molecules of Semicarbazide on Benzoylacetone.—Two and two-tenths grams of semicarbazide hydrochloride was dissolved with 3.0 g of sodium acetate in a minimum of water and the solution added to 1.6 g. of benzoylacetone in alcohol. On standing for one hour in the cold, fine needle crystals of the disemicarbazone were deposited, melting at 242°.

Anal. Calcd. for $C_{12}H_{16}O_2N_6$: N, 30.43. Found: N, 30.80.

Action of Acids on Benzoylacetone Monosemicarbazone.—The pure monosemicarbazone, m. p. 128°, can be recrystallized from boiling aqueous alcohol without showing any signs of change or decomposition. However, when warmed to 60° in the presence of acetic or of hydrochloric acids (equivalent quantity), it readily undergoes ring formation to give a mixture of 3,5-methylphenylpyrazole-1-carboxamide and 3,5-methylphenylpyrazole of varying proportions. The substances are easily separated, the carboxamide crystallizes out as long needles before the pyrazole is deposited. The 3,5-methylphenylpyrazole-1-carboxamide must be carefully freed from traces of acid before recrystallization, as otherwise it readily undergoes hydrolysis, losing carbon dioxide to give the 3.5-methylphenylpyrazole.

Anal. Calcd. for $C_{11}H_{11}ON_3$: C, 65.67; H, 5.47; N, 20.9. Found: C, 65.42; H, 5.63; N, 21.0.

Summary

1. The reaction velocities of sodium enol acetoacetic ester, sodium enol malonic ester and sodium ethoxide in alcohol solution with methyl iodide and ethyl bromide are compared.

2. The products of the reactions in alcoholic solution between sodium ethoxide, acetoacetic ester and malonic ester and (a) methyl iodide and (b) ethyl bromide are determined quantitatively and the course of the reactions explained.

---

[46] Sjollema, *Ann.*, 279, 268 (1894); Posner, *Ber.*, 34, 3983 (1901); and Moureu and Brachin, Hull. *soc. chim.*, [3] 31, 172 (1904), give m. p. 127°.

3. The results of the methylation of sodium enol α-acetyl-α'-carbethoxysuccinic ester is interpreted in the light of the above experiments.

4. The formation of carbomethoxy derivatives from chlorocarbonic methyl ester and sodium enol benzoylacetone in stereomeric forms is proved and its bearing upon the structure of sodium enol benzoylacetone discussed.

5. The products of the reaction between benzoylacetone and semicarbazide are described.

6. The structure of enol benzoylacetone is discussed and an explanation offered of the apparent discrepancy between the results of physical and chemical investigations.

7. The above experiments are interpreted in the light of the partition principle as applied to organic reactions, subject to the reaction velocities and reactivities of the groups involved.

CONVERSE MEMORIAL LABORATORY
CAMBRIDGE, MASSACHUSETTS

NOTES

Trichloromethylcyclopentanol-1.—The condensation of chloroform with ketones to give tertiary trichloro alcohols has been limited to acetone[1] and methyl ethyl ketone.[2] Other ketones have been tried but unsatisfactory results have been obtained in every case where a ketone of more than four carbon atoms was used.[3]

In view of the fact that this condensation reaction seemed to be limited to the two lowest members of the series of aliphatic ketones, it was decided to try two of the alicyclic type. Cyclopentanone and cyclohexanone were used and the procedure followed was essentially that described by Willgerodt.

Nine parts of cyclopentanone was mixed with thirteen parts of chloroform and six parts by weight of powdered potassium hydroxide was added over a period of several hours with constant stirring. A vigorous reaction sets in unless the mixture is kept well cooled by surrounding the reaction vessel with ice. When all of the potassium hydroxide had been added, it was allowed to stand for six days at 0–10°, being stirred occasionally. The residue was then filtered off and washed with ether. The combined filtrate and washings, after being neutralized with dilute hydrochloric acid, were washed with water and dried over anhydrous sodium sulfate. Distillation was carried out at atmospheric pressure until all of the ether, unreacted chloroform and cyclopentanone were removed. When the

[2] Ekeley and Klemme, THIS JOURNAL, **46**, 1252 (1924).

[3] Howard, *ibid.*, **48**, 774 (1926).

temperature reached 140°, decomposition set in so the residual oil was steam distilled. This distillate was then treated with sodium bisulfite solution to remove traces of ketone, taken up in ether and again dried over anhydrous sodium sulfate. On fractional distillation under vacuum no definite product was obtained; it was therefore decided to treat the mixture with bromine water so that the boiling point of unsaturated impurities, formed by condensation of the ketone with itself, would be raised sufficiently to facilitate the separation. A fraction was collected which on further purification distilled at 102--102.5" at 10 mm. The yield was about 3.0% based on the total ketone used or 9.1% calculated on the amount reacting. The unsaturated impurity which has a boiling point so near that of the alcohol is cyclopentylidene-cyclopentanone.

Trichloromethylcyclopentanol-1 is a colorless oily liquid, insoluble in water, but soluble in ether, benzene, chloroform, carbon disulfide, carbon tetrachloride and glacial acetic acid; specific gravity, 1.3690^{25}_{4}; n^{25}_{D} 1.5066.

Anal. Calcd. for $C_6H_9OCl_3$: Cl, 52 29. Found: Cl, 52.03, 51.82. Mol *wt* (in benzene). Theoretical, 203.4. Found: 201.O, 205.9.

In an attempt to react chloroform and cyclohexanone by the above method, qualitative tests indicated that a small amount of the alcohol derivative was formed but apparently the tendency for this ketone to condense with itself is somewhat stronger than that of the cyclopentanone. A yield of about 15% of cyclohexylidene-cyclohexanone was obtained which was identified by means of the semicarbazone.[4] Approximately 75% did not react and apparently the remainder formed higher condensation products.

THE CRYSTAL STRUCTURES OF ELECTRODEPOSITED ALLOYS. SILVER-CADMIUM

Sir:

The crystal structures of silver–cadmium alloys, ranging in composition from 20% Cd to 96% Cd, have been obtained from x-ray diffraction data. The alloys were deposited at room temperature according to the method of Stout [Preprint No. *29,* Trans. ***Am. Electrochem. Soc.,*** *59* (1931)], using a current density of one ampere.

In general, the structures of the alloys are quite different from those of thermal alloys of corresponding composition which have been brought to equilibrium before examination. The alloys prepared under equilibrium conditions [Astrand and Westgren, ***Z. anorg. allgem. Chem.,*** **175,** 90 (1928)] show the following phases.

Percentage Cd	
0–44	**α–solid solution of Cd in Ag**
44–49	$\alpha + \beta$
49–51	**β–C_2Cl type cubic lattice. 8'–close-packed hexagonal lattice, similar to a, obtained when β is heated above 400° and suitably quenched. It differs from ϵ in axial ratio**
51–57	$\beta + \gamma$
57–66	**γ–body-centered cubic lattice**
66–69	γ + a
69–83	**ϵ–close-packed hexagonal lattice**
83–95	$\epsilon + \eta$
95–100	**η–solid solution of Ag in Cd**

Westgren notes that β should also be formed at high temperatures in the **γ-range** but his attempts to produce it by heating the y-phase failed

The electrodeposited alloys show the following structures: (1) 40% Cd—contains the α, β' and γ phases and may contain the β phase; (2) 46–75% Cd—only the ϵ phase is deposited. The crystals show a preferred orientation with respect to the base metal, and this orientation differs with the composition; (3) 89–96% Cd—the ϵ and η phases are deposited.

Our results do not agree with microscopic data recently published by Fink and Gerapostolou [Metal *Ind.* (N. Y.), 28, 519, 562 (1930)].

It is evident that under the conditions of deposition used in these experiments the r-phase is produced throughout the greater part of the range, and is apparently a metastable phase at least through the approximate range 46–66% of Cd. This is consistent with the behavior of some pure metals, which are known to be electrodeposited in metastable forms.

It is important to know how the conditions of deposition affect the crystal structure of an alloy of any given composition, since hardness and other physical properties depend upon the structure.

We are at present investigating (1) the effect of current density and temperature on crystal structure, the composition of the deposit remaining constant; (2) the recrystallization temperatures of Cd–Ag alloys.

EXPLOSION DURING THE CATALYTIC REDUCTION OF NITROANISOLE IN THE LIQUID PHASE

Sir:

Brown, Etzel and Henke [*J.* Phys. Chem., **32,** 631–635 (1928)] quantitatively reduced a number of nitro compounds in the liquid phase at about 215°, under a hydrogen pressure of about 500 lb. per sq. in., using a nickel catalyst. The reduction could be made either without a solvent or with benzene and ethyl alcohol. Their work was done on small quantities (about 5 g.) of material, in a shaking autoclave maintained at the desired temperature by immersion in an oil-bath.

The writer attempted to apply this method to the reduction of *o*-nitroanisole. As no danger was anticipated, the work was done on a technical scale, using 400 g. of the nitro compound. A shaking autoclave of steel was used, of about 3000 cc. total capacity, heated electrically. The first experiment was made using benzene as a solvent, with a nickel catalyst, and gave approximately a 50% yield of amine. In the next, the solvent was omitted and the catalyst was carefully prepared to give a very active product; 250 g. of nickel nitrate was ignited at 400°, and then heated for three hours in a muffle at 560°. The oxide was reduced in the autoclave under a stream of hydrogen at a temperature of 280–300°. Four hundred grams of the nitroanisole, freshly distilled, was then added and hydrogen was passed in to a pressure of 500 lb. At a temperature of 250°, with shaking, the hydrogen was rapidly taken up, and the pressure dropped in about fifteen minutes to 250 lb. It then began to rise rapidly, and reached a total of 500 **lb.** in about five minutes. In thirty seconds more the pressure jumped to 1000 lb. The writer then opened the needle valve on the autoclave in the hope of relieving the pressure. Gas and liquid shot out of the valve, and an instant later the autoclave exploded with great violence.

The autoclave, a steel shell three-sixteenths of an inch thick by about fifteen inches long and six inches in diameter, failed by splitting open on one side. Before use, it had been tested to 1500 lb. pressure. The detonation was of sufficient violence to blow out all the windows of the laboratory and shake a large concrete building.

The explosion could not have been caused by any mixture of hydrogen and oxygen in the autoclave, as the autoclave had been thoroughly swept out with hydrogen during the reduction of the catalyst. As was indicated by the initial pressure drop, reduction was taking place very satisfactorily. It seems probable that the explosion was caused by decomposition of the nitro compound itself, possibly by auto-oxidation, or possibly by rapid oxidation by the nitro body of an intermediate product of the reduction. This may have been induced by the catalyst, which was evidently quite vigorous, and it may have been aided by local high temperature attained by the rapid reduction. In the original work of Brown, Etzel and Henke, such dangers as these were eliminated by the small scale on which they worked and by the adequate cooling afforded by the oil-bath.

The purpose of this note is to call the attention of other investigators to the dangers of this type of reduction when carried out on other than a very small scale.

THE RAMAN SPECTRA OF FORMALDEHYDE, TRIOXYMETHYLENE, ETHYLENE GLYCOL, AND OF SOME VISCOUS LIQUIDS

Sir:

The Raman spectrum of a 37% solution of formaldehyde in water consists of at least nine lines corresponding to frequencies, expressed in wave numbers of 802, 909, 1055, 1285, 1479, 2840, 2915, 3015 and 3087. Trioxymethylene gives modified lines corresponding to 497, 579, 674, 908, 1050, 1232, 1285, 1376, 1477 and 1527 wave numbers. Ethylene glycol gives lines corresponding to 341, 491, 526, 869, 1040, 1274, 1460, 2725, 2874, 2948, 3048 and 3131 wave numbers. Except for a fairly consistent shift toward the higher frequencies, of about 25 wave numbers, the stronger Raman lines from the aldehyde solution correspond both in intensity and in distribution to those from ethylene glycol. No lines are found typical of the C=O linkage (1675–1725) for formaldehyde. On the other hand, the line at 1050 typical of C–O is fairly strong. These observations would seem to indicate the formation of methylene glycol by formaldehyde in aqueous solution. This is compatible with the observations of Auerbach and Barschall [Chem. *Zentr.*, II, 1081 (1905)] and Walker [J. *Phys.* Chem., 35, 1104 (1931)], who came to the same conclusion from cryoscopic and vapor pressure measurements. The absence of frequencies less than 800 wave numbers indicates that the concentration of higher polymers in a solution of this concentration must be small. The absence of a modified line in the 1675–1725 region for the trioxymethylene and the presence of a line corresponding to the C–O linkage may be due to the formation of a trimer in the manner suggested by Venkateswaren and Bhagavantam [*Proc.* Roy. *Soc.* (London), **128,** 260 (1930)] for paraldehyde. The presence of only three frequencies below 900 wave numbers may indicate that the polymer consists of not more than three aldehyde units. Lines corresponding to C–H linkage for the trioxymethylene are very weak and as yet have not been definitely identified.

That strong continuous Raman spectra may be a property common to viscous liquids has received some substantiation from the Raman spectra of sodium silicate, orthophosphoric acid, potassium hydrogen phosphite and ethylene glycol solutions. The continuous spectra decrease on dilution and on temperature elevation. This behavior is similar to that observed with glycerin by Venkateswaren [Indian *Journal* Phys., **3,** 105 (1928)]. This phenomenon may possibly owe its origin to intermolecular attraction, the continuous spectra arising from the probability of a large number of energy levels. The Raman spectrum of α-chloronaphthalene consists of 16 lines and shows some similarities to that of chlorobenzene and naphthalene.

A detailed account of these experiments will be communicated later.

THE IONIZATION CONSTANT OF ACETIC ACID

Sir:

We have obtained a precise value of the ionization constant of acetic acid at 25° from the results of new conductance measurements, made in this Laboratory, on acetic acid, hydrochloric acid, sodium chloride and sodium acetate at low concentrations (the lowest in each case being about 0.00003 N). The principles underlying the computations are essentially those which have been outlined by one of the undersigned [MacInnes, THIS JOURNAL, **48,** 2068 **(1926)**]. The calculations take account of the change of the mobilities of the ions as required by the Debye–Hückel–Onsager theory and of the ion activities as predicted by the Debye–Hückel theory. The computations, which involve a short series of approximations, consist in estimating the proportion of ions at each acetic acid concentration by comparing the measured equivalent conductance with that of completely dissociated acetic acid, A„ at the same ion concentration. Values of A, are found by using Kohlrausch's law of independent ion migration, which is valid at the low ion concentrations involved. Applying the mass action law to the resulting degrees of dissociation we find a series of "constants," K', which, to obtain the thermodynamic ionization K, must be multiplied by the product of the ionic activity coefficients, γ^2.

It is noteworthy that to obtain a true constant the activity coefficients required are exactly those given by the Debye–Hückel theory in its limiting form

$$-\log \gamma^2 = 2 \times 0.5065 \sqrt{C_i}$$

in which C_i is the ion concentration. The results for the more dilute solutions are given in Table I.

TABLE I

RESULTS FOR THE MORE DILUTE SOLUTIONS

Concentration, equivalents per liter $\times 10^3$	Ion concn., C_i $\times 10^3$	K' $\times 10^5$	γ^2	h $\times 10^5$
0.028014	0.015092	1.7620	0.9910	1 747
.15321	.044005	1 7733	.9846	1.740
.21844	,054096	1.7766	.9830	1.746
1.0283	,12714	1.7937	9741	1 747
1.3638	.14779	1 7961	.9721	1 746
2.4139	.19992	1.8053	.9776	1.747
3.4407	.24069	1.8104	.9645	1 746
5.9115	.31895	1.8189	.9592	1.745
9.8421	.41517	1.8285	.9536	1.744

Although extraordinarily constant in the range given, at higher concentrations there is a decrease in the value of K. This variation is due to several effects which may for the present be lumped together as "effect of the medium." The bearing of this value of K on the PH scale will be discussed later and full accounts of these researches will shortly be submitted to THIS JOURNAL.

THE DIRECT REACTION BETWEEN OXYGEN AND ETHYLENE

Sir:

The direct reaction between oxygen and ethylene is of general theoretical and technical interest. Study of the reaction in this Laboratory has shown that the slow non-explosive thermal reaction is complex. Two compounds have been found to be formed in the reaction whose presence has not been demonstrated before; these compounds are ethylene oxide and dioxymethyl peroxide,[1] $CH_2OHOOCH_2OH$. Investigation of the reaction at temperatures from 300 to 525° under widely different conditions has shown that the two principal primary reactions are the formation of ethylene oxide and of formaldehyde. The other reaction products, dioxymethyl peroxide, acetaldehyde, formic acid, the oxides of carbon, hydrogen and water are formed in a step-wise sequence[2] of follow reactions. At temperatures above 500° the thermal polymerization of ethylene becomes an important reaction even in the presence of appreciable amounts of oxygen and inert gases.[3]

The velocity of reaction is proportional to the cube of the ethylene concentration and is almost independent of oxygen, as has been shown by Thompson and Hinshelwood.[4] Comparison of the rates of reaction in packed and unpacked vessels shows that the reaction is mainly homogeneous. The reaction has an induction period which decreases with increase in temperature. It appears that the reaction follows a chain mechanism though it is necessary to assume that the chains can be both continued and stopped by the surface of the vessel.

Evidence of the formation of hydrogen peroxide as a reaction product has been obtained.

A full account of this work will appear shortly.

INTERATOMIC FORCES IN BINARY LIQUID ALLOYS. QUANTITATIVE DETERMINATION FROM THERMODYNAMIC DATA

Sir:

It is generally agreed that the attractive force between non-polar molecules varies inversely as some high power (*e.* g., the 9th) of the distance. Langmuir [This JOURNAL, **38**,2246 (1916)] has emphasized that the forces holding together such molecules are acting almost wholly between molecules *in contact* and that, as a very good approximation, all forces acting at greater distances may be neglected. The quantitative treatment of the properties of liquids in terms of power laws of force involves great mathematical difficulties when one attempts to consider molecules of irregular shape. Langmuir has shown that the problem may be greatly simplified

[4] Thompson and Hinshelwood, *Proc. Roy. Soc.* (London), A118, 170 (1928).

by regarding these van der Waals forces as coming into play between molecules only at the areas of contact. By using the concepts of surface area of individual molecules, and of interfacial energy for the contact surfaces, and assuming random orientation, he has developed through the Boltzmann equation ["Colloid Symposium Monograph," **3,** *48* (1925)] an expression for the deviation of activities from Raoult's law in binary liquid mixtures. So far as I know this relation has never been tested in binary liquid alloys where the situation is much simpler than in the cases of the organic mixtures discussed by Smyth and Engel [THIS JOURNAL, **51,** 2646 (1929)]. The equation is $\ln a_1/N_1 = \beta^2 S_1 \lambda/kT$ or $\ln a_2/N_2 = \alpha^2 S_2 \lambda/kT$, where $a = p/p^\circ$, p being the partial vapor pressure, p° the vapor pressure of the pure liquid, N the mole fraction, S the surface area per molecule, λ the energy per sq. cm. of interface between the two kinds of molecules, k the Boltzmann constant, T the absolute temperature and a and β are the surface fractions of the two components in the solution defined by $\alpha = N_1S_1/(N_1S_1 + N_2S_2)$ and $\beta = N_2S_2/(N_1S_1 + N_2S_2)$. The activity a may also be evaluated from electromotive forces of concentration cells. The ordinary molecular volume V which equals molecular weight/density, must be multiplied by 0.76 to take account of cubic or hexagonal close packing in the liquid, and divided by the Avogadro number to get the effective volume of a single molecule, v $= 4/3nr^3$. From this $S = 4nr^2$.

The thermodynamic data presented herewith are based upon electromotive force measurements of N. W. Taylor [This JOURNAL, **45,** *2884* (1923)] and of Hildebrand and Sharma [ibid., 51, *467* (1929)]; density values from Hogness [ibid., **43,** *1621 (1921)*] have been used.

INTERFACIAL ENERGIES BETWEEN METAL ATOMS IN LIQUID ALLOYS

System	Temp., t	Component 1	Component 2	Log a/N $N = 0$	$S \times 10^{16}$, sq. cm.	λ Ergs/sq. cm.
Zn–Cd	540°	Zn		0.490	25.8	48.8
Zn–Cd	540°		Cd	.615	32.8	48.2
Cd–Pb	544°	Cd		.480	32.8	37.7
Cd–Pb	544°		Pb	.582	40.6	37.0
Cd–Sn	544°	Cd		.246	32.8	19.4
Cd–Sn	544°		Sn	.270	37.3	18.7
Tl–Sn	352°	Tl		.444	37.6	23.4
Tl–Sn	352°		Sn	.44	36.7	23.9
Zn–Sn	539°	Zn		.240	25.8	23.9
Zn–Sn	539°		Sn	.60	37.3	41.3

The test of the Langmuir equation lies in a comparison of the two λ values calculated for each system from log a/N and S of each component independently. For all systems except zinc–tin the agreement is good to **3%.** Since the log a_2/N_2 values for the second component of each system were evaluated by the Duhem relation they are themselves uncertain to 1 or *2%.* They are somewhat smaller than the values given in my original paper which were based upon an incorrect extrapolation. The system zinc–tin is certainly abnormal as I pointed out in my original paper in 1923. In this case influences are present which inhibit random orientation of the molecules.

The Hildebrand equation for "Regular Solutions" RT In $a_1/N_1 = bN_2^2$ or R T In $a_2/N_2 = bN_1^2$ can be strictly true only when the two components have the same surface area per molecule. S_{Tl} exceeds S_{Sn} by only 2%, and this is the reason for the result found by Hildebrand and Sharma that "so far as the variation with N is concerned, this system corresponds perfectly to the definition of a regular system given by the senior author" (THIS JOURNAL, 51, 66 (1929)].

The evidence presented thus lends support to Langmuir's equation and to the assumptions upon which it is based.

More extensive data and a fuller treatment of this problem will be presented in a later publication.

RADIOCHEMICAL EQUILIBRIUM IN AMMONIA SYNTHESIS

Sir:

The attempt to calculate chemical equilibrium or a steady state attained by alpha radiation from the known yield per ion pair of the two opposing non-thermal reactions was first made for the synthesis and decomposition of water [Lind, *Trans.* Am. *Electrochem. Soc.*, 34, 214 (1918)]. The case for ammonia is much more suitable since the system remains entirely homogeneous. The decomposition of ammonia has been measured by Wourtzel [Le Radium, **11,** 342 (1919)]. The yield in synthesis was determined in a flow system by Lind and Bardwell [THIS JOURNAL, **50,** 745 (1928)] to lie in the range $+M_{\mathrm{NH_3}}/N_{(\mathrm{N_2} + \mathrm{H_2})} = 0.2\text{–}0.3$. Choosing 0.2 as the most probable value of $+M/N$ and the round number 1.0 (from Wourtzel) for the decomposition $(-M/N)$, Lind and Bardwell calculated that the equilibrium (at 25°) would be $(1.0/1 + 0.2) = 83.3\%$ decomposition, corresponding to *9.09%* NH_3 by volume.

Later Ponsaert [Bull. *soc.* chim. Belg., **38,** 110 (1929)] redetermined the yield for synthesis as ***0.32*** and taking 1.08 from Wourtzel for decomposition calculated equilibrium at 13.5% NH_3 by volume. The actual equilibrium has now been experimentally determined by D'Olieslager and Jungers [Bull. *soc.* chim. Belg., **40,** 75 (1931)] as only *4.7%* NH_3 by volume.

In calculating the equilibrium from the yields at the beginning of the opposing reactions where back-reaction is negligible, it has been assumed that the mechanisms of the two reactions at equilibrium are independent of each other in their intermediate steps. If this were true, it would require a value of $+M/N$ in synthesis of only 0.11 in order to give a steady state at 4.7% NH_3. That the value for synthesis cannot be so low has been shown above. It therefore appears that the intermediate steps are not independent and that there must be an exchange of activation energy in the direction to produce additional decomposition.

The principal object of this communication is to point out that the shift of equilibrium from that predicted is in the right direction to be accounted for by an exchange of ionization from the elemental ions H_2^+ (16 volts) or N_2^+ (17 volts) to give NH_3^+ (11 volts). Such transfer of ionization would favor decomposition at the expense of synthesis, assuming always that H_2^+ and N_2^+ in some way cause synthesis and that NH_3^+ causes decomposition.

This same type and direction of shift may be general in other similar reactions in gaseous phase, since the larger molecules will usually have a lower ionization potential than either of its components.

An effort is being made to test this hypothesis quantitatively for ammonia by means of a complete kinetic equation which should fit the kinetics of either reaction and the equilibrium.

THE IONIC NATURE OF THE HYDROGEN BOND

Sir:

In a recent paper, Linus Pauling [This journal, 53, 1367 (1931)] has pointed out that the hydrogen bond postulated by Huggins, Latimer and Rodebush is to be expected only of molecules having ionic characteristics and that the bond itself is ionic. The evidence that is offered by Pauling is for the most part chemical, and it might be profitable to examine the question in the light of physical data not considered by him.

Work on the Raman effect [in particular Krishnamurti, ***Nature,*** 125, 892 (1930)] has indicated that Raman lines are to be expected with atomic bonds (*i. e.*, shared electron pairs) rather than with ionic linkages. The reason for this is obscure; but at least in solutions it may be due in many cases to the magnitude of the energy states involved in the various types of molecules or "resistant groups." Raman data on the association of liquids (such as H_2O, NH_3 and SO_3) are inconclusive so far as offering information about the character of this bond. It might be possible to decide this question from the sharpness of the lines. However, in all of the work that has been done on the Raman effect of hydrates and solutions no lines have been reported that may be interpreted as showing an "atomic vibration" of the water "molecule" with respect to the metal ion. A literal application of the older conception of this bond demands that there be such lines. The observed state of affairs is to be expected on the basis of Pauling's suggestion. Furthermore, if the hydrogen ion is connected to the water molecule by means of a shared electron pair in the oxonium ion, we would expect a Raman spectrum characteristic of the latter ion. This would mean that all solutions of acids would have lines in common. An examination of the data for nitric, hydrochloric and sulfuric acids shows that this is not the case.

Another interesting example is the ammonium ion. In solution this ion has no observable Raman lines. This indicates not only that the hydrogen ion connects itself to the ammonia molecule through an ionic linkage, but that in doing so it causes the other bonds to become ionic. It is entirely possible that the case of the oxonium ion is parallel, and that each hydrogen is connected to the oxygen through an ionic linkage.

As investigations in solutions are inherently under adverse conditions, the bond may actually be intermediate in character. At least the evidence indicates quite strongly that it is not of the extreme electron pair type formerly assumed.

THE CARBON–HALOGEN BOND AS RELATED TO RAMAN SPECTRA

Sir:

The purpose of the work described here was to determine the variation of the characteristics of the bond between carbon and another atom as the length and structure of the hydrocarbon chain is varied. The frequency which corresponds to the carbon–bromine bond in methyl bromide is 1.808×10^{13} per second, but in longer normal chains this is reduced to a constant value of 1.688×10^{13}. In an iso compound or in the presence of a double bond, this is reduced to about 1.61×10^{13}. These frequencies are of considerable interest, since in the simple theory they are supposed to be equal to the frequencies of the carbon–bromine bond in these compounds.

What is sometimes called the "strength of a bond" may be represented by the force constant, which for the carbon–carbon single bond is about 5×10^5 dynes per cm. The values for the carbon–halogen bond do not seem to have been calculated for monohalogens. They are given in Table I.

The force constant (a) is calculated in the ordinary way, and it is considered that the methyl group vibrates as a unit with respect to the halogen atom. In (b) a slight, somewhat arbitrary allowance has been made for the fact that this is not strictly true.

TABLE I

VALUES FOR THE CARBON–HALOGEN BOND

Compound	Wave number, cm.$^{-1}$	Frequency per second $\times 10^{-13}$	Force constant $\times 10^{-5}$ dynes *a*	*b*	Amplitude $\times 10^{10}$ cm. $n = 0$	$n = 1$
CH_3Cl[1]	712	2.135	3.14	3.02	6.7	11.6
CH_3Br[2]	603	1.808	2.70	2.60	6.65	11.5
CH_3I[2]	534	1.601	2.25	2.17	6.9	11.9

The force constants decrease from the chloride to the iodide, in somewhat the same way as the corresponding energies of dissociation. Those given in Column *(a)* are much smaller than the values of the single bonds listed by Dadieu and Kohlrausch,[1] which are (in 10^5 dynes per cm.) equal to 4.31 for *C–C* in ethane, *4.96* for C–O in methyl alcohol, and 4.89 for C–N in methylamine.

That the frequencies chosen in Table I are those characteristic of the carbon–halogen bond is shown by work on various bromides. These are listed in Table II.

TABLE II

CHARACTERISTIC WAVE NUMBERS FOR THE CARBON–BROMINE BOND IN ORGANIC BROMIDES

CH_3Br	603 (2)	$(CH_3)_2CH(CH_2)_2Br$	564
C_2H_5Br	586 (2)	$(CH_3)_2CHBr$	540
n-C_3H_7Br	563	$C_2H_5CHBrCH_3$	537
n-C_4H_9Br	563	$(CH_3)_3CBr$	538
n-$C_5H_{11}Br$	564	$CH_2:CHCH_2Br$	535
		$(CH_2)_2CHCH_2Br$	572

The remarkable fact revealed by these data is that the frequency of the carbon–bromine bond is constant in normal compounds with the exception of methyl bromide, and that it is the same for an iso compound provided the side chain is sufficiently distant from the bromine. However, an adjacent side chain, attachment to a secondary or a tertiary carbon atom, or the double bond of an adjacent unsaturated group as in allyl bromide, in all the given cases lowers the wave number from 563.5 to about 537 cm.$^{-1}$. Thus the carbon–bromine bond seems considerably weaker in this latter class of compounds (with the exception of isobutyl bromide).

It is apparent from the constant value of the wave number for the normal compounds that *the organic radical cannot vibrate as a whole with respect to the bromine atom,* for such an assumption leads to an absurd value for the force constant.

On the basis of the assumption that the effective mass of the methyl group with respect to the vibration toward bromine is 14.4 atomic weight units, the force constant for methyl bromide is 2.60×10^5 dyne/cm.

---

[1] Wave number determined by Dadieu and Kohlrausch, J. *Opt. Soc. Am.*, 5, 297 (1931).

[2] Wave number determined by Cleeton and Dufford, *Phys. Rev.*, 37, 365 (1931).

(or 2.70 if CH_3 vibrates as a single unit of mass 15). If now the amyl group vibrates as a unit the force constant for amyl bromide would be 7.0×10^5 dyne/cm., or more than two and a half times larger than for methyl bromide. This is much too large.

If the force constant in all of the normal bromides is assumed to be constant and equal to 2.60×10^5 dyne/cm., the effective mass of the portion of the hydrocarbon chain which vibrates (with respect to the bromine) is 17. This indicates that the CH_2 group adjacent to the bromine possesses most of the mass which is effective. That is, the CH_2 group vibrates, but its effective mass is increased by the constraint due to its union with the rest of the hydrocarbon chain, and is influenced by the vibration of this part of the molecule.

The writers have determined the frequencies of the Raman lines of nine organic bromides. These give a large number of characteristic frequency differences as, for example, 1639 cm.$^{-1}$ for the double bond of allyl bromide, but only the values characteristic of the carbon-bromine and other carbon–halogen bonds can be discussed here. The variation in the wave number corresponding to this bond is usually not more than one unit of wave number for any one compound, and the maximum variation for any compound is two units.

The equation for the force constant (k) is

$$\nu_0 = \omega_0 \, (n' - n'') = \frac{1}{2\pi} \left(\frac{k}{\mu}\right)^{1/2} (n' - n'')$$

in which n represents a quantum number, μ the mutual mass, ν_0 the fundamental frequency of the radiation, and ω_0 the fundamental mechanical frequency. A further discussion will be presented in the final paper.

PREPARATION OF UNSYMMETRICAL DIALKYL ETHYLENE DERIVATIVES

Sir:

The recent description of the preparation of α,β-unsaturated ethers by Lauer and Spielman [This journal, 53, 1533 (1931)] makes possible an extension of our nuclear synthesis of olefins [*ibid.*, 52, 3396 (1930); 53, 1505 (1931)] to include the unsymmetrical dialkyl derivatives of ethylene. The essential steps in the process are clearly represented by the scheme.

$$CH_2{=}C(R)OEt + Br_2 \longrightarrow CH_2Br{-}CBr(R)OEt \qquad (1)$$

$$CH_2Br{-}CBr(R)OEt + R'MgBr \longrightarrow CH_2Br{-}C(R')(R)OEt + MgBr_2 \qquad (2)$$

$$CH_2Br{-}C(R')(R)OEt + Zn(Alc) \longrightarrow CH_2{=}C(R')R + EtOZnBr \qquad (3)$$

Three hexenes have been prepared by this method, with the physical constants indicated.

THE DECOMPOSITION OF SODIUM AZIDE BY CONTROLLED ELECTRON BOMBARDMENT

Sir:

The decomposition of solid sodium azide has been achieved by subjecting a thin film to bombardment by electrons of known velocity. The reaction was carried out in a high vacuum using an oxide filament as the source of electrons and suitable electrodes for controlling the velocity. Impacts in the gas phase were shown to be absent. The nitrogen resulting from the decomposition was detected and measured by an ionization manometer. The gas evolved was shown to be nitrogen by critical impact measurements. Rate curves taken at various electron velocities gave a sharp intercept on the voltage axis, setting the minimum potential at 12 ± 1 volts. The rate curves showed discontinuities in the region of the critical potentials of nitrogen, thus affording additional proof of the nature of the gas. At no time was any thermal decomposition observed, nor any effect at or below 11.5 volts.

These measurements are being continued with slightly improved technique. The photochemical decomposition is being studied as well and will be the subject of a later communication.

NEW BOOKS

Qualitative Chemical Analysis. BY HERMAN T. BRISCOE, Professor of Chemistry, Indiana University. The D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, 1931. v + 279 pp. Illustrated. 14.5 X 22.5 cm. Price, $2.25.

This book is typical of the Qualitative Analysis text that should be in general use in colleges. Not only are the theoretical principles underlying all analytical operations fully and clearly dealt with, but, to quote the author's own words, "proper correlation between theory and practice" is preserved throughout. The reviewer would have liked a fuller treatment of some topics like complex ions and amphoteric hydroxides and the addition of other important ones like the "salt effect," occlusion, perhaps buffer solutions and the modern method of expressing hydrogen-ion concentrations, which are not treated at all. The reviewer criticizes also the comparatively extended discussion on atomic structure, a rapidly shifting field, which has no particular place in a course in Qualitative Analysis. The Bohr atom was abandoned by Bohr himself years ago and physicists are agreed that a mechanical representation of atomic structure is, at the time of writing this review, an impossibility. The student should have been warned that some solubility products, as for example those of the sulfides, should be taken with a grain of salt. Hydrolysis, oxidation and reduction are very well treated. The laboratory separations, although perhaps not as rigid as those of A. A. Noyes, are generally satisfactory and accompanied by excellent notes in which constant application is made of the principles taught in the theoretical part, a rare accomplishment in the average run of textbooks on Qualitative Analysis.

The book is well printed and bound, free from typographical errors, the diagrams are well drawn and to the point and the reviewer feels he can recommend the book to those desiring to teach a modern course in Qualitative Analysis.

J. ENRIQUE ZANETTI

Tables annuelles de constantes et données numériques de chimie, de physique, de biologie et de technologie. (Annual Tables of Constants and Numerical Data Chemical, Physical, Biological and Technological.) Published under the auspices of the International Research Council and the International Union of Pure and Applied Chemistry by the International Committee appointed by the Seventh Congress of Applied Chemistry (London, June 2, 1909). Table des Matières des Volumes I à V. Années 1910 à 1922. (Table of Contents of Volumes I–V, 1910–1922.) Edited by G. KRAVTZOFF. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1930. lxiii + 382 pp. 22.5 X 28 cm.

As the number of volumes of Annual Tables has increased, it has become correspondingly laborious to search through them for quantitative data published during recent years pertaining to any particular subject. In the future, this labor will be considerably lessened by the use of the

General Index—the first volume of which has now appeared, covering the years 1910 to 1922.

This first volume contains an Introduction explaining the use of the Index, and a list of the French abbreviations. The latter are, however, for the most part self-evident and practically international. Next comes an Analytical Index, which is substantially a very complete table of contents. This is followed by an Alphabetical Index in French; but German, English and Italian translations have been inserted where advantageous, followed by the French equivalent. Finally, there is a Formula Index, which constitutes the bulk of the whole volume. In it, the chemical elements are arranged according to a system similar to that adopted by the new edition of the Gmelin–Kraut handbook, in which the non-metals come first, then carbon, and finally the metals arranged alphabetically according to their symbols.

A second volume of the Index is promised for 1933, covering the years 1923–1930 (Volumes VI to X). Thereafter, it is planned to issue a volume of the Index at five-year intervals. When this schedule has been attained, the labor of consulting the Annual Tables will be still further diminished. Nevertheless, in order to cover the data published during any preceding twenty years, it will still be necessary to inspect three or four volumes of the Index and two to six of the current volumes of the Annual Tables. The only method of lessening this somewhat formidable task would apparently be first to make each five-year volume of the Index cumulative, say for fifteen years, and second to decrease the lag in the appearance of these volumes behind the corresponding volumes of the Annual Tables. These remedies would, however, doubtless entail considerable additional expense.

This Index, even though it may not in the future afford the greatest possible measure of convenience, is nevertheless of very ,great value in rendering more available the unique collection of data in the Annual Tables.

ARTHUR B. LAMB

The Principles of Quantum Mechanics. By P. A. M. DIRAC, **Fellow of** St. John's **College, Cambridge. The Oxford University Press, 114 Fifth Avenue,** New York, 1930. **x + 257 pp.** 16 × **24 cm.**

The spirit and the character of this book may perhaps be best expressed by two sentences taken from it. "The new theories, if one looks apart from their mathematical setting, are built up from physical concepts which cannot be explained in terms of things previously known to the student, which cannot even be adequately explained in words at all." "The only object of theoretical physics is to calculate results that can be compared with experiment, and it is quite unnecessary that any satisfying description of the whole course of the phenomena should be given." From these quotations (though, in the last analysis, they must be seen to be entirely correct) it would be at once inferred that this is not a book for the beginner who wishes to learn quantum mechanics; and, indeed, it is rather directed to the experienced student of that subject, who wishes to study its logical foundations.

Though there is a sort of preview of the physical ideas involved in the first chapter, in general, the method of the book consists in the development of a purely abstract algebra to which the physical results are then "hung on" as representations. The reviewer is not convinced that this is necessary for a logical presentation of the theory, and it has the disadvantage that it greatly increases the difficulty of reading the book, since one has to learn two notations and the connections between them. Nevertheless, any book which presents the ideas of one who has had such a role in the development of the subject will be received with great interest, especially as most of his original work is there presented in connected form.

Having laid the foundations of the subject, the author proceeds to discuss many of its most important applications. This section of the book can be read only after thorough mastery of the ideas and notations of the first part. The last chapter treats of the relativistic theory of the spinning electron, and the author's recent work on the proton.

OSCAR K. RICE

The Quantum Theory. By FRITZ REICHE, Principal of Physics at the University of Breslau. Translated by H. S. HATFIELD, B.Sc., Ph.D., and HENRY L. BROSE, **M.A.** E. P. Dutton and Co., Inc., 286–302 Fourth Ave., New York, 1931. viii + 218 pages. 15 figs. 12.5 × 19.5 cm. Price, $2.10.

The original German edition appeared in 1920 and its English edition in 1922. The present English edition is identically the same as the 1922 edition except for the addition of a chapter of 24 pages and 64 notes and references. The preface states: "A few alterations have been made in the earlier pages. Chapter IX has been renamed. A table of contents and useful formulae and a bibliography have been added." In the new chapter the attempt is made to sketch the development of the quantum mechanics from the status of the theory in 1923. The material touched upon includes the Compton effect, de Broglie waves, Schrodinger's, Heisenberg's and Dirac's contributions to quantum mechanics, electron spin, Bose–Einstein statistics, Fermi–Dirac statistics, Raman effect among other items and finally the "Outlook of Atomic Theory in 1930"; all this in a twenty-four page chapter plus four and one-half pages of "Notes and References." The reader moderately well acquainted with the present-day status of quantum mechanics will hardly recognize in the new material more than a brief synopsis of topics while the student approaching the subject de novo will find the new chapter incomprehensible.

F. G. KEYES

Lehrbuch der Metallkunde des Eisens und der Nichteisenmetalle. (Textbook of Metal Science of Iron and the Non-Ferrous Metals.) By DR. PHIL. FRANZ SAUERWALD, Professor at the Technical High School of Breslau. Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1929. xvi + 462 pp. 399 figs. 16 × 23.5 cm. Price. RM. 29.

In writing this book the author has had three aims: first, a developed synthesis of the whole range of the science of metals, avoiding the necessity of referring the reader to many books on various special subjects with corresponding lack of correlation; second, to stimulate readers to ask and answer their own questions through the problems discussed; and third, to present the results of the author's investigations and those of his colleagues. Somewhat more than half of the book is devoted to the general science of the metallic state, alloys, and consideration of technical manufacturing processes. The remainder is concerned with the fundamental properties of iron, cast iron, steel and the non-ferrous metals. There are a number of unusual features in this work which alone should commend the book to all physical metallurgists. Among these may be mentioned the properties of metals in the liquid and gaseous states, a thorough fundamental treatment of the mechanical properties of metals, rates of reaction and diffusion, the properties of liquid alloys, technical corrosion and means for combating it, the measurement of shrinkage during solidification, and statistical methods in plant investigations. Throughout the work one finds the direct application of physical-chemical laws to metallurgical problems. One feels that the author has been substantially successful in his aims and that here is a book which every progressive physical metallurgist will wish to have in his reference library.

R. H. ABORN

Quantitative Clinical Chemistry. Vol. I. Interpretations. By JOHN P. PETERS, M.D., M.A., Professor of Internal Medicine, Yale University School of Medicine, and DONALD D. VAN SLYKE, Ph.D., Sc.D., Member of the Rockefeller Institute for Medical Research. The Williams and Wilkins Company, Mt. Royal and Guilford Aves., Baltimore, Maryland, 1931. xvi + 1264 pp. 124 figs. 15 × 23.5 cm. Price $12.00.

This huge volume probably would not be interesting to many readers of THIS JOURNAL, but it should prove valuable as a reference book to clinicians. It gives a very impressive picture of the extent to which chemistry, especially analytical chemistry, is being applied in the study of diseases. Clinical chemistry is by far the most baffling field of biochemistry, and for this reason, as well as for certain other reasons, very little of its literature can be accepted without reservation until it has been repeatedly confirmed. It is therefore rather doubtful whether the fields covered by this book actually merit so large a volume, and whether it would not have been better to defer the inclusion of many observations, with their references, to later editions. The cautious reader should certainly be prepared for the probability that hundreds of original papers cited as authority for statements occurring in the book will turn out to be erroneous or misleading.

The arrangement of the material is different from what one finds in other books on clinical chemistry and is, on the whole, to be commended. There are no chapters on the chemistry of any body fluid or tissue. The headings of the twenty-one chapters into which the book is divided are as follows: Total Metabolism; Carbohydrates; Lipoids; Nan-protein Nitrogen and Nitrogen Metabolism; Urea; Ammonia; Amino Acids; Uric Acid; Creatine and Creatinine; Total Organic Acids, Lactic Acid and Ketones; Phenols; Hemoglobin; Proteins of the Blood Plasma, Urine and other Body Fluids; The Volume of the Circulating Blood; Total Base, Sodium and Potassium; Calcium; Magnesium; Carbonic Acid and Acid-Base Balance; Chlorides; Phosphorus; Sulfur. This predominantly chemical arrangement of the material has worked out very well, and it is easy to find any information contained in the book. The index is excellent.

For so large a book the text in some chapters is surprisingly meager. Chapter III, for example, on the lipoids, has over 10 pages of bibliography to only 26 pages of text. And what there is of text in this chapter is not altogether to be commended. The oxidations of the fatty acids, if touched upon at all, should have been described in more detail. The discussion of the digestion and absorption of fat is not only too brief, but is also antiquated and misleading. The essence of the subject as given, page 230, is represented by the following brief paragraph: "It was long believed that emulsified free fats could be directly absorbed; but the studies of Munk (151) conclusively proved that this was not the case and that only emulsified fatty acids could be absorbed."

It may not be possible to deny flatly that either neutral fats or fatty acids are absorbed in the form of emulsions, but Munk's quaint paper, of 1880, proved only that fatty material is absorbed about equally well whether given in the form of fats or as fatty acids. Pflüger's dictum that solution rather than emulsification is a necessary prerequisite for absorption has lost nothing in probability with the passing of time. Pflüger is not mentioned either in the text or in the bibliography.

One curious slip of the pen was found in this chapter, page 229: "Because of its choline content cholesterol has been considered as the source of bile acids."

While a slight tendency toward one-sidedness and partiality is to be detected in many other chapters, the book as a whole will prove an almost inexhaustible mine of information to the large and constantly increasing number of persons who are doing or trying to do research in the field of clinical chemistry.

OTTO FOLIN

Die Riechstoffe und ihre Derivate. (Perfumes and their Derivatives.) Edited by ALFRED WAGNER, Editor of *Die Riechstoffindustrie,* with the cooperation of ALFONS M. BURGER and F. ELZE. Part I, Aldehydes of the Aliphatic Series; Part II, Aldehydes of the Alicyclic Series; Part III, Aromatic Hydroxyaldehydes with Saturated Side Chains–Dihydroxyaldehydes—Aromatic Ether Hydroxyaldehydes with Saturated and Unsaturated Side Chains—Aroxylaldehydes; Part IV, List of Patents—Index of Patents—Author Index and Alphabetical Subject Index. A. Hartleben's Verlag, Singerstrasse 12, Vienna, 1, Austria, 1929, 1930, 1931 1431 pp. 17 X 26 cm.

This volume in the large Hartleben project on perfumes and their derivatives naturally deals primarily with aldehydes that have some actual or potential interest in connection with perfumes. In reality this interest is conceived broadly and nearly all aliphatic and alicyclic aldehydes, as well as a large number of aromatic representatives are passed in review.

Beginning with an excellent introductory chapter containing general methods of preparation and general reactions, the authors continue with the "practical part" in which the aldehydes are considered, one by one, and end with a transcript of patents which constitutes approximately a fourth of the entire volume.

In general, the description of an individual aldehyde contains an account of its history, a discussion of its structure, a complete list of sources and methods of preparation, a review of methods for its detection and quantitative estimation and extensive summaries of its derivatives. All of these matters, which may be regarded as essential to a complete description, are presented with the utmost thoroughness, and supported by innumerable references. One marvels at the patience with which this material has been accumulated and the skill with which it has been tabulated.

But one wonders also on what principles this volume has been organized, and for what manner of reader. Structural formulas of the aldehydes are followed by equally detailed formulas of oximes, hydrazones, semicarbazones which drag their tiresome lengths across the page. Descriptions of aldehydes are immersed in minute accounts of substances which add little to the picture, like cumol, cuminic alcohol, cuminic acid, para cymol and terephthalic acid in connection with cuminic aldehyde. Moreover, the authors insert a number of long papers which are printed verbatim, from periodicals that are so readily accessible as the "Berichte" and "Liebig's Annalen."

It may appear ungracious to protest that a volume offers too much, but the increasing and frequently unnecessary length of many modern treatises makes them too expensive for the individual and it seems unfortunate that a volume which, like this one, contains so much of value should be available only in those libraries in which it is not necessary to count the cost.

VOL. 53 JULY, 1931 No. 7

THE RADIOACTIVE CONSTANTS AS OF 1930. REPORT OF THE INTERNATIONAL RADIUM-STANDARDS COMMISSION[1,2]

BY M. CURIE, A. DEBIERNE, A. S. EVE, H. GEIGER, O. HAHN, S. C. LIND, ST. MEYER, E. RUTHERFORD AND E. SCHWEIDLER

RECEIVED JUNE 13, 1931 PUBLISHED JULY 8, 1931

Following the reorganization of the International Union of Chemistry and of the International Atomic Weights Commission, the need has arisen for the publication of special Tables of the Radioactive Constants.

This responsibility has been assumed by the International Radium-Standards Commission chosen in Brussels in 1910, which has expressed its willingness to cooperate with the International Union.

Besides the members of the Committee, the following have taken part as experts: J. Chadwick, I. Joliot-Curie, K. W. F. Kohlrausch, A. F. Kovarik, L. W. McKeehan, L. Meitner and H. Schlundt, to whom it is desired to express especial obligations.

The following report will also be published simultaneously in the *Physikalische* Zeitschrift, Review of Modern Physics, Philosophical Magazine and Journal Physique *et le* Radium.

General Remarks on Symbols and Terms

The symbols are provisionally retained as used in the texts of St. Meyer–E. Schweidler, F. Kohlrausch, and E. Rutherford, J. Chadwick and C. D. Ellis, as well as in the Physikalische Zeitschrift, 19, 30 (1918); Zeitschrift fur *Elektrochemie*, 24, 36 (1918); and Jahrb. Rad. u. *Elektr.*, 19,344 (1923).

For the three radioactive gases the use of the terms radon (Rn), thoron (Tn), and actinon (An) is recommended (*Z.* anorg. Chem., 103, 79 (1918)), and as general term for elements of atomic number 86 the retention of the word "emanations" (Em) for the three isotopes. The words emanate, emanating power, etc., are retained.

---

[1] To facilitate desirable changes and additions in subsequent years it is requested that data, notes and suggestions be sent to: Prof. Dr. Stefan Meyer, Institut für Radiumforschung, Boltzmanngasse 3, IX Vienna, Austria.

[2] A summary of literature on decay constants and ranges and on absorption coefficients is to be published in other versions of this report, to appear in the July issue of the *Physikalische Zeitschrift* and of the *Review* of Modern *Physics.*

The designation "radio-lead" is restricted to the natural radioactive mixture of lead isotopes in minerals and is not used to designate RaD.

RaG, ThD and AcD shall be called uranium-lead, thorium-lead and actinium-lead, respectively. The mixture of RaG and AcD will also be designated uranium-lead.

Instead of the designation "Isotopic Weight" (Poids isotopique) as used in the earlier "Tables internationales des éléments radioactifs" for the whole numbered atomic weights or the number of hydrogen nuclei, the word "Proton number" is proposed.

Symbols:

UI, UX_1, UX_2, UII, Io, Ra, Rn, RaA, RaB, RaC′, RaC″, RaD, RaE, RaF=Po, RaG, UY, UZ.
Th, $MsTh_1$, $MsTh_2$, RdTh, ThX, Tn, ThA, ThB, ThC′, ThC″, ThD.
AcU, Pa, Ac, RdAc, AcX, An, AcA, AcB, AcC, AcC′, AcC , AcD.
Pa is for protactinium (not Proto-actinium).
Em is the joint symbol for Rn, Tn and An.

The following report contains: I, Basic Values; II, Units; III, Constants.

II. Chemical Units

The chemical atomic weights and quantitative relations are based on O = 16.0000. The discovery of the oxygen isotopes O^{18} and O^{17} in the estimated proportions: $O^{16}:O^{17}:O^{18} = 10{,}000:1:8$ requires a sharper definition.

In contrast to the chemical definition, O = 16.0000 for the isotopic mixture, it is proposed for questions of atomic structure and radioactivity in the sense of Aston's measurements to choose $O^{16} = 16.0000$.

For the isotopic mixture in the ratios (very uncertain) given above, O = 16.0017, R. Mecke and W. H. J. Childs (*Z.* Physik, 68, 362 (1931), estimate O = 16.0035 ± 0.0003).

Corresponding to $O^{16} = 16.0000$, other values are

H = 1.0078 (Aston)	absolute.	$1\ 662 \cdot 10^{-24}$ g.
He = 4.00216 (Aston)	absolute:	$6.599_4 \cdot 10^{-24}$ g
m_0 of $O^{16}/16.00 = 1.00000$	absolute:	$1.6490 \cdot 10^{-24}$ g.
m_0 (proton) = 1.0072	absolute:	$1.661 \cdot 10^{-24}$ g
m_0 (alpha) = 4.00106	absolute:	$6\ 598 \cdot 10^{-24}$ g.
m_0 (electron) = 0.000548 for $e/m_0 = 5.2765 \cdot 10^{17}$ E. S. U.	absolute:	$9.040 \cdot 10^{-28}$ g.

Avogadro's Number

$L = Fc/e = 6.0644 \cdot 10^{23}$ mol.$^{-1}$ for $e = 4.770 \cdot 10^{-10}$
$= 6.0265 \cdot 10^{23}$ mol.$^{-1}$ for $e = 4.80 \cdot 10^{-10}$
1 Year = 365.24223 days = $3.155693 \cdot 10^{7}$ sec.
1 Sec. = $3.168876 \cdot 10^{-8}$ yr.

Derived Values

$\beta = v/c$ $c^2 = 8.988004 \cdot 10^{20}$

$$\eta = \frac{1}{\sqrt{1 - \beta^2}}$$

$m = m_0\eta$ $2e = 9.540 \cdot 10^{-10}$
$m_0c^2 = 5.9303 \cdot 10^{-3}$ for a-particles
$m_0c^2 = 8.1207 \cdot 10^{-7}$ for $e/m_0 = 5.276_5 \cdot 10^{17}$ E. S. U./g. for @-particles
$m_0c^2/{}^2e = 6.2162 \cdot 10^{6}$ for a-particles
$m_0c^2/e = 1.7034 \cdot 10^{3}$ for $e/m_0 = 5.276_5 \cdot 10^{17}$ E. S. U./g. for @-particles

Kinetic energy $E = m_0 c^2 (\eta - 1)$ for a-particles: $E = 5.9303\cdot 10^{-3} (\eta - 1)$ erg.
Kinetic energy in volt-electrons for @-particles: $E = 8.1252\cdot 10^{-7} (\eta - 1)$ *erg.*
Velocity in equiv. volts $P = 299.80E/2e = 3.1426\cdot 10^{11}E$ for or-particles
$P = 299.80E/e = 6.2851\cdot 10^{11}E$ for β-particles

Product of the magnetic field strength and the radius of curvature of the path:

$$\log R = (m_0c^2/2e)\eta\beta = 6.2162\cdot 10^{6}\,\eta\beta \text{ for a-particles}$$
$$\log R = (m_0c^2/e)\eta\beta = 1.7034\cdot 10^{3}\,\eta\beta \text{ for } \beta\text{-particles}$$
$$\lambda = hc/E = 1.9628\cdot 10^{-16}/E \text{ for } h = 6.547\cdot 10^{-27}$$
$$\lambda = hc/E = 1.9637\cdot 10^{-16}/E \text{ for } h = 6.55\cdot 10^{-27}$$

Z = number of a-particles emitted per second from 1 g. of Ra

Note.—The chief source of error lies in the value for the radium equivalent of the preparation (e. g., of RaC). This arises from the decay curve of RaB–RaC. The standardization is not exact to 0.5 because the standards are not more accurate than this and on account of the different shapes of standard and unknown the comparison involves further inaccuracy. Moreover, in the washing of the preparation with alcohol to remove residual radon, RaB is dissolved in excess of RaC [Mitt. Ra. *Inst.,* No. 254; ***Wien*** Ber., 139, 231 (1930)]. The theoretical curve is thereby disturbed in the first part of the decay of the preparation so that differences of 1% in the value of active deposit result. This error would cause a minimal value of Z. Use of the value $\mathbf{3.7\cdot 10^{10}}$ is recommended in accord with lit. (9).

Ratio **Ra:U** in Old Unaltered Minerals

Earlier Literature: St. Meyer–E. Schweidler, "**Radioaktivität,**" 1927, *398,* pp. **404–406,** Lit. Nr. *7.22.23.*

V. Chlopin and M. A. **Paswick,** *Akad. Leningrad (1928)* (Russian). (In samples from the same location values varying due to chemical changes are found from *2.18* to $\mathbf{4.17\cdot 10^{-7}}$. Compare also Lind and Whittemore, THIS JOURNAL, *36,2066 (1914).*

The recommended value is $\mathbf{Ra/U = 3.4\cdot 10^{-7}}$; $\mathbf{U/Ra = 2.94\cdot 10^{6}}$.

Basic Values for the Calculation of the Number of Ion Pairs Produced by One α-Particle

$k = k_0R^{2/3}$ and calculation of velocity from $v^3 = a_0R_0$

All data refer to $0°$ and 760 mm.

As basis for k_0: $Zk = 8.18\cdot10^{15}$ (Meyer and Schweidler, "Radioaktivität," 1927, p. 189), and $Z = 3.7\cdot10^{10}$

For RaC′: $R_0 = 6.58$ cm. (see table of ranges)

$k = 8.18\cdot10^{15}/3\ 7\cdot10^{10} = ko\ 6.58^{2/3}$ $\quad k_0 = 6.296\cdot10^4$

Based on $R_0 = 6.60$ and $Z = 3.72\cdot10^{10}$ $\quad k_0 = 6.253\cdot10^4$

Based on $R_0 = 6.60$ and $Z = 3.70\cdot10^{10}$ $\quad k_0 = 6.283\cdot10^4$

Recommended: $k_0 = 6.3\cdot10^4$

For a_0, different values are obtained according to the choice of RaC′, ThC′ or Po as reference. This may mean that the relation $v^3 = aR$ is not exact and that the definition of the range (Geiger–Henderson) as the intercept of the descending straight line of the Bragg's curve with the abscissa has no theoretical basis.

For RaC′	$R_0 = 6.58$	$v = 1.022\cdot10^9$	$a_0 = 1.0790\cdot10^{27}$	$a_0^{1/3} = 1.026.109$
For ThC′	$R_0 = 8.168$	$v = 2.054\cdot10^9$	$a_0 = 1.0609\cdot10^{27}$	$a_0^{1/3} = 1.020\cdot10^9$
For Po	$R_0 = 3.67$	$v = 1.593\cdot10^9$	$a_0 = 1.1015\cdot10^{27}$	$a_0^{1/3} = 1.032\cdot10^9$
		Recommended:	$a_0 = 1.08\cdot10^{27}$	$a_0^{1/3} = 1.026\cdot10^9$

which differ only slightly from the constants in use

For [3] $R_0 = 6.60$ $\quad v = 1.922\cdot10^9$ $\quad a_0 = 1.0758\cdot10^{27}$ [4] $a_0^{1/3} = 1.0246\cdot10^9$

(Meyer–Schweidler, p. 629)

Radium content is expressed gravimetrically in grams or mg. of elemental radium, regardless of its state of chemical combination. However, it is always desirable to know the total weight and nature of the compound, with reference to Ra concentration.

Radon (Radium Emanation)

1 Curie is the quantity of Rn in equilibrium with 1 g. Ra

1 Curie Rn has the volume 0.66 cu. mm. at 0° and 760 mm.

1 Curie (Rn without decay products) can with complete utilization of the a-particles maintain by its ionization of air a saturation current of $2.75\cdot10^4$ E.S.U. (0.92 milliampere)

Sub-units are millicurie, microcurie, etc. For the Rn content of waters and gases the sub-unit milli-microcurie (10^{-9}) is frequently used.

1 Eman $= 10^{-10}$ curie per liter (10^{-13} curie/cc.) is a term used since 1921 for the Rn content of the atmosphere as a concentration unit.

1 Mache Unit (1 M. E.) is a concentration unit referred to the Rn content of 1 liter of water or gas, etc. It is that quantity of Rn per liter which without decay products and with complete utilization of the α-particles

---

[3] The basic value 6.60 was the mean of the values of G. H. Henderson, *Phil. Mag.*, [6] 42, 538 (1921), 6.592, and of H. Geiger, *Z. Physik*, 8, 45 (1921), 6.608. To R_0 the corresponding value at 15° is $R_{15} = 6.963$ cm.

[4] See Rutherford, Chadwick and Ellis, Ref. (9), p. 86.

can maintain by its ionization of a ira saturation current of 10^{-3} E. S. U. 1 M. E. corresponds to $3.64 \cdot 10^{-10}$ curie/liter = 3.64 Eman.

It is recommended to extend the use of the term curie to the equilibrium quantity of any decay product of radium. One must then specify the element, as 1 curie Rn, for example. The Commission does not favor its extension to members outside the Ra family.

On the other hand, the unit quantity of any radioactive element may be expressed in terms of the mass equivalent to 1 g. of Ra with respect to the effects of the rays or to the number of atoms decaying per second.

In the latter sense one defines: 1 mg. of Ra equivalent as that quantity of any radioactive element for which the number of atoms decaying per second is the same as that for 1 mg. of Ra ($3.7 \cdot 10^7$ atoms/sec.).

Since, however, the determination of the number of atoms decaying per second can seldom be made directly, the number will much more frequently be obtained indirectly from radiation effects.

Polonium.—"1 Curie Po" = that amount which, equivalent to 1 gram of Ra, emits $3.7 \cdot 10^{10}$ a-particles per sec. "1 Curie Po" = quantity in radioactive equilibrium with'1 gram of Ra, $2.24 \cdot 10^{-4}$ g. Po.

That quantity of Po whose a-radiation directed to one side only is fully utilized to ionize air and which can support a current of 1 E. S. U. corresponds to $1.68 \cdot 10^{-10}$ g. of Po or $0.75 \cdot 10^{-6}$ curie of Po. 1 Curie of polonium would in the utilization of its rays in all directions support a saturation current in air of $2.66 \cdot 10^6$ E. S. U. 1 Microcurie of Po (one sided radiation) = 1.33 E. S. U.

Mesothorium.—"1 mg. MsTh" usually signifies the y-ray equivalent of 1 mg. of Ra–RaC, compared after absorption by 5 mm. of lead. This definition is for many reasons (dependence on the age of the preparation and on the experimental conditions (see Meyer–Schweidler, 1927, pp. 496–497)), inexact and open to criticism. All determinations of content of Ra, Rn, MsTh, Po, etc., must be exactly dated, of course.

III. Radioactive Constants[2]

. General Remarks

For U_I it is to be noted that the calculation is made on the basis $Z = 3.70 \cdot 10^{10}\ \alpha/\text{sec.}$; $Ra/U = 3.40 \cdot 10^{-7}$; Avogadro No. = $6.064 \cdot 10^{23}$, with no account taken of the branching of the Ac Series. A correction for this would be so dependent on the value of T assumed for AcU that it would have little significance at present. In any case, however, the values given above are for T and τ upper and for λ lower limits.

For UX_1, the lowest value $T = 23.8$ (1) is mentioned as well as the one preferred by the Commission.

In the Table for R, v, k (Range, Velocity, Ion Production) the directly observed values are denoted by +. The calculation of the other values far v and k was made by using the basic values denoted ++, with the data for k_0 and a_0 given on page 2441.

U_{II} gives according to the ranges of Laurence improbably low values for T (5). Direct determination (50) gives T = $3.4 \cdot 10^5$ years in good agreement with the range determinations of Hoffman–Ziegert (42). The adoption of $3 \cdot 10^5$ years is recommended.

Rn The two best determinations made recently, W. Bothe, *Z. Physik,* 16, 226 (1923), T = 3.825 ± 0.003 days, and I. Curie and C. Chamié, Compt. *rend.,* **178,** 1808 (1924); *J. phys.,* [6] 5,328 (1924), T = 3.823 ± 0.002 days, agree within the limits of experimental error. During the first day, their differences in Rn decay by the hour are scarcely noticeable in the fourth place.

For *T* = 3.823 days extended tables have been published by C. Chamié, M. Cailliet and G. Fournier [Paris, Gauthier-Villars, **1930**].

Radium E

Earlier accepted value	4.85 days	Recommended: *T* = 5.0 days, and T = 4.9 days
L. Bastings, *Phil. Mag.,* **48,** 1075 (1924)	4.985 days	
G. Fournier, *Compt. rend.,* 181, 502 (1925)	4.86 days	
L. F. Curtiss, *Phys. Rev.,* **27,** *672* (1926)	5.07 days	
J. P. McHutchison, *J. Phys.* Chem., **30,** 925 (1926)	4.87 days	

For RaC′: see Lit. (15), (16), (16a) in *Physik. Z.*, July, 1931.

For ThC′: Mme. Curie has recently calculated from the Geiger–Nuttall Law: λ = about 10^9 sec.$^{-1}$. In view of the great uncertainty attaching to the values for ThC′, O. Hahn and L. Meitner propose to be content with the statement: T = 10^{-6} sec.

AcC″: A. F. Kovarik points out that 150 curves are found to give T = 4.71 min., while Albrecht has only 9 curves for T = 4.76 min. Both values are given in the table.

Remarks on "Range" and "Ion Production."—Comparison of the results of different investigations shows that the ranges are not defined with sufficient sharpness to justify the use of three decimal places. Limitation to two places is therefore proposed.

In general, the values of H. Geiger [Z. *Physik,* 8, 45 (1921)] supplemented by those of G. H. Henderson [*Phil. Mag.*, [16] 42, 538 (1921)] and the later values (Lit. 41) are the ones used in the following. For U_{II} see the note on page 2443. For RaC′ Mmes. M. Curie and I. Joliot-Curie have made the following summary

	R_{15}	**Recommended**
H. Geiger, *Z. Physik*, 8, 45 (1921)	6.971	
G. H. Henderson, Phil. Mag., 42, 538 (1921)	6.953	6.95 or
I. Curie and F. Béhounek, J. *Phys. Rad.*, 7,125 (1926)	6.96	6.96
G. I. Harper and E. Salaman, Proc. Roy. *Soc.* (London), 127, 175 (1930)	6.94	

Since the basic value for RaC′ which has been used up to the present (cf. page 2441) is the mean of the values of Geiger and of Henderson, $R_0 = 6.600$ or $R_{15} = 6.963$, it appears advisable to retain it and to round off R_{15} as 6.96.

There is no agreement yet on the range of a-particles of ThC. Both values $R_{15} = 4.78$ and 4.72 are, therefore, reported.

For the discussion of ranges refer especially to the measurements of S. Rosenblum, *Compt.* rend., 190, 1124 (1930), and the sections in Rutherford, Chadwick and Ellis (51), page 82, et *seq.*, and the table on page 86. If one is content with two decimal places for the velocity, then the relation $v^3 = aR$ gives sufficient accuracy for the normal ranges.

The basic value for ion production by a-particles is that for RaC′: k = 2.2·10⁵ (cf. page 2441).

For the velocity of α-particles from ThC Rutherford, Chadwick and Ellis (51) choose $1.701 \cdot 10^9$ cm./sec., while Mmes. M. Curie and I. Joliot-Curie propose $1.698 \cdot 10^9$ cm./sec.

Absorption Coefficients for β- and γ-Rays.—Beta and gamma rays are at present best characterized by their spectra. An extensive reproduction of such spectra would exceed the limits of these first tables issued by the Radium-Standards Commission.

The following summaries are cited

L. Meitner, "Handbuch der Physik," by H. Geiger and K. Scheel, Bd. XXII, 1926; St Meyer and E. Schweidler, "Radioaktivitat," Teubner, 1927; K. W. F. Kohlrausch, "Radioaktivitat," Bd. XV, Handb. d. Experimentalphysik, W. Wien and F. Harms, 1928; A. F. Kovarik and L. M. McKeehan, "Radioactivity," Bull. of the National Research Council, Nr. 51, Washington, 1929; I. Joliot-Curie, "Données numériques de Radioactivité, Tables annuelles de constantes et donneés numériques," Paris, 1930; E. Rutherford, J. Chadwick and C. D. Ellis, "Radiations from Radioactive Substances," Cambridge, England, 1930.

The absorption coefficients (μ) are in the expression $I = I_0e^{-\mu x}$, somewhat deficiently defined, but for practical measurements and for radioactive identification they constitute very useful data and are therefore given in the following table, as well as the velocity limits for β-rays. μ/ρ is the mass absorption coefficient (ρ = density); D = thickness for half absorption, $0.69315/\mu$. All data refer to aluminum as absorbing material.

A NEW FORM OF BUBBLE COUNTER FOR MEASUREMENT OF GAS EVOLUTION

BY E. A. BUDGE

RECEIVED MAY 15, 1930 PUBLISHED JULY 8, 1931

The measurement of the volume of gas evolved during the progress of a reaction in which a gas is one of the products is a well-known method of measuring reaction velocity coefficients. The estimation of the rate of evolution of the gas by timing evolution of gas bubbles of uniform volume is a very attractive experimental method, and if the counting can be performed automatically the method becomes almost ideal. Various appliances to carry out bubble-counting of this kind have been described in the literature at various times. For instance, Bose[1] has used such a method in his studies of photosynthesis.

During an investigation on the rate of decomposition of hydrogen peroxide in the presence of hydrochloric acid, the author was led to devise an apparatus which proved quite useful for the purpose. The starting point was a simple apparatus which was in use in England.[2] In this apparatus, however, the bubbles were formed at the mouth of a bell-shaped tube immersed mouth-downward in a vessel of water. It was found that this form of bubbler was unsatisfactory, as the volume of the bubbles was not constant under varying rates of bubbling and over long periods. Finally the author devised the form of apparatus shown in Fig. 1.

In this figure, A shows the top of the reaction flask, from which the gas to be measured (in this case oxygen) is being evolved. The gas passes by way of the rubber connection B and the tube C to the bubbler D, which is immersed in the water of the thermostat. The gas issues from D in distinct bubbles of constant size. This constancy of size is ensured by the U-shaped bend of capillary tubing which is so fused on that the change of internal diameter shall be as sudden as possible. On account of the surface tension of the water in the capillary tube, the meniscus does not leave it; the bubble breaks off when the gas–water interface has reached F and the interface immediately retreats to E. The volume of the bubble is therefore rigidly defined by the dimensions of this capillary in comparison with the total volume of gas space in the apparatus. Each time a bubble breaks away there is a diminution in the pressure of the gas enclosed in the apparatus. This variation of pressure causes an oscillation in the level of the mercury in the U-shaped tube G, and this oscillation is made to operate an electrical make-and-break by means of a platinum wire H sealed through the lowest part of the U and another platinum wire J so arranged that the mercury in rising will make contact with it. When a bubble breaks away from D and the gas–water interface moves smartly from F to E, the sudden fall of pressure causes the mercury in G to fall rapidly away from the platinum wire J and thus break the circuit. In this circuit is a 2-volt battery, a regulating resistance and a relay. This relay switches on and off a stronger current fur-

---

[1] Bose, "The Physiology of Photo-synthesis," Longmans, 1924, p. 21.

[2] *School Science Review, 4, 139 (1923).* (A more detailed description which was referred to in this review could not be traced.)

nished by a 60-volt battery which operates a counter such as is used for counting telephone calls. The make and break of this higher-voltage circuit is through a pair of arc light carbons, one of which is furnished with a screw adjustment. By this means fouling of the contacts owing to sparking is rendered innocuous. There are a few further points worth mentioning with regard to the low-voltage contact G. A large part of the U-tube of G is made of capillary tubing in order to render the contact "dead beat" in its action by damping out oscillations of the mercury column which might lead to false contacts. A few drops of distilled water are placed above each mercury surface in G to act as a lubricant and prevent sticking of the mercury. To minimize sparking when contact with the wire J is broken, a condenser is placed in parallel with this gap. The absolute elimination of sparking at this contact is desirable, as it results in fouling of the contact and uncertain counting during the course of a long run. This sparking causes a brownish cloud, presumably finely divided mercury, to form in the water. This can be removed by flushing out the widened portion of the tube with distilled water from a wash bottle with a fine jet. If the surface of the mercury becomes covered with a scum, this is removed by adding a trace of nitric acid to the water by touching it with a platinum wire that has been dipped in dilute nitric acid. If this is done, the wide tube must soon afterward be well flushed out with water, as otherwise a deposit of mercurous nitrate will soon put the contact out of action. Contact was found to be more certain when the platinum wire J was connected to the positive pole of the cell, owing to the well-known effect of the nature of the charge of a mercury surface on its surface tension. As the mercury rises toward J its potential is negative toward the water and in consequence the increase of surface tension tends to depress the meniscus; but as soon as the mercury touches the wire J, this negative potential becomes zero. In consequence the surface tension decreases and the resulting small rise of the mercury meniscus renders contact certain and the mercury appears to adhere to the wire. When the mercury meniscus is jerked away from the wire as a bubble breaks away at D, the depression of the meniscus, due to the increased surface tension, effectively prevents any second contact. This phenomenon was found to be a very important protection against the effects of chance vibration. The point needing most attention, however, is the preservation of a bright clean surface at the mercury meniscus by the prevention of sparking. This calls for a small current at the contact J and a sensitive relay. The clicking of the counter could be heard even in an adjacent room and, although this is rather trying to the nerves over a long period, one subconsciously listens to the clicks and soon learns to appreciate the slightest variation from regular working, which gives timely warning of any incipient trouble at the contact.

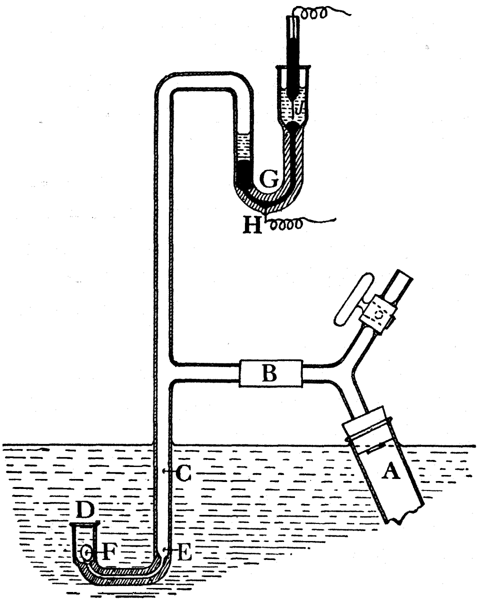

Fig. 1.—Diagrammatic view of the bubble counter.

For testing the equality of the volume of the bubbles a useful accessory is a piece of capillary tube of suitable internal diameter, which is placed horizontally against a scale and calibrated by a mercury thread in the usual manner. One end of this capillary is bent vertically downward and expanded into a bell-shaped mouth. This dips below the water in the bath and enables a single bubble to be caught. The other end of the capillary is also bent downward and carries a stopcock. When the tube is filled with water, it acts as a siphon and by opening the stopcock the bubble caught in the bell may be brought to a convenient place in the tube for measurement of its volume.

A serious limitation on the usefulness of the apparatus lies in the necessity for the constancy of the total volume of gas in the tubes of the counter and any apparatus to which it is connected. Also this gas volume must not be too large or a series of bubbles is formed at each emission instead of a single one. A gradual change in this gas volume can be allowed for by measuring the volume of the bubbles at various times by means of the accessory capillary tube; but, where this gas volume is not subject to change, the apparatus is very convenient for such purposes as the measurement of reaction velocity by gas evolution, since both the total volume of gas evolved and also the rate of evolution of the gas are easily obtained by readings of the dial.

The author desires to express his sincere thanks to Professor E. J. Hartung for the generous manner in which he has made available facilities for carrying out this work and for his very helpful criticism and advice.

INACCURACY IN THE DETERMINATION OF MERCURY BY DIRECT PRECIPITATION AS MERCURIC SULFIDE FROM ACID SOLUTION[1]

BY E. P. FENIMORE AND E. C. WAGNER

RECEIVED NOVEMBER 18, 1930 PUBLISHED JULY 8, 1931

The direct precipitation of mercury as sulfide from acid solution is a procedure whose accuracy has for many years remained apparently unquestioned.[2]

---

[1] This paper is constructed from a portion of the doctorate thesis of Edward P. Fenimore, University of Pennsylvania, 1929.

[2] Fresenius–Cohn, "Quantitative Chemical Analysis," John Wiley and Sons, Inc.. New York, 1903, Vol. I, p. 366; Rüdisüle, "Nachweis, Bestimmung und Trennung der chemischen Elemente," Drechsel, Bern, 1913, Vol. II, p. 412; Treadwell–Hall, "Analytical Chemistry," John Wiley and Sons, Inc., New York, 1924, Vol. II, 6th ed., p. 172.

It was planned to use this method for control purposes in the development of a new distillation procedure (to be described in a later paper) for determination of mercury in organic compounds. Trials with known amounts of mercury, however, yielded results which were too high. Continued study confirmed this unexpected finding, and showed the sulfide to be contaminated, *e. g.*, with chlorine, the impurity being greater in the presence of dissolved salts in quantity.

Experimental

The concentration of mercury was in all trials less than 0.1 g. per 100 cc. Precipitations were made in Erlenmeyer flasks, hydrogen sulfide being introduced under slight pressure at room temperature. The washed precipitates were extracted for one to two hours in a Wiley apparatus; a second extraction was found to be without effect. The Gooch crucibles were prepared with thick mats of fine asbestos, with underlying disks of filter paper.[3]

Each crucible was conditioned by passing through it a solution whose composition, etc., duplicated that of the liquid to be filtered in the analysis; these wash-liquids, however, contained no hydrogen sulfide. This treatment was repeated until it was certain, after drying at 100–105°, that the weight was constant within 0.0001 g.

The materials analyzed were two specimens of mercuric chloride and one of precipitated oxide, all of determined purity.

Results obtained with various conditions of precipitation are given in Table I.

TABLE I

ANALYTICAL RESULTS

Conditions	Mercury taken, g.	Mercuric sulfide, g.	Mercury found, g.	Error. g.
1 Precipitation from solution about **0.2** N in HCl, and free from salts	0.36378	0.42275	0.36449	+0.0007

	1122	.1347	.1161	+ .0039

Discussion

The average error of the first eight trials, made under conditions most favorable to accuracy, was +0.34%. The larger error (about 1%) in series 2 will affect gravimetric results by White's method, though it may in practice be compensated by loss of mercury during the decomposition or by loss in weight of Gooch crucibles not properly conditioned. Presence of iodide or of salts in excess (series 3, 4, 5) increased the positive error markedly. The unfavorable effect of iodide was reported by Wegelius and Kilpi,[4] and several methods to avoid its interference have been proposed, including the solution of the impure sulfide in sodium sulfide and reprecipitation by Volhard's method.[5]

The Volhard procedure, when applied to solutions which contain only the mercury salt and at most the salts from neutralization of a little acid, has been established as accurate. Trials by Rauschenbach[6] yielded results only 0.06% low. One of the writers (W.) has tested the method in comparison with the thiocyanate titration, with several electrolytic methods,[7] and against purified mercuric chloride, results by the several methods being practically identical.

Some of the sulfide precipitates of series 1 were in part removed from the crucibles, ignited with lime and tested for chlorine. A considerable contamination was shown (9.8 mg. of AgCl); a blank on the lime, etc., was negative.

An explanation for the lack of purity of mercuric sulfide precipitated from acid solution is suggested by the intermediate "compounds" whose

visible formation is a feature of the precipitation. The mechanism of mercuric sulfide formation was studied by Smith and Semon,[8] who concluded that five consecutive reactions are involved. The intermediate compounds were represented to be (1) $[Hg(SH)_2 \cdot Hg]X_2$, (2) $[HgSHg]X_2$, (3) $[Hg(SHg)_2]X_2$, (4) $[Hg(SHg)_2](SH)_2$. It is clear that pure mercuric sulfide will result only if none of these intermediate compounds survives.

There must be considered also the ability of mercuric sulfide to combine with or adsorb other molecules. Striking evidence of this was provided by qualitative tests[9] in which freshly precipitated and well-washed mercuric sulfide was introduced into solutions of mercuric chloride, sulfate, nitrate and acetate, and the mixtures well shaken and filtered, the filtrates in every case being free from mercury. During the precipitation of mercury by hydrogen sulfide the newly formed sulfide would probably be especially active in this way. The success of Volhard's method in the absence of salts in excess may be due to the circumstance that sulfide formation requires only transposition of $[SHgS]Na_2$ to the ammonium compound, which on heating decomposes irreversibly due to escape of ammonia and hydrogen sulfide.

Summary

The direct precipitation of mercuric sulfide from acid solution by hydrogen sulfide yields an impure product which is too heavy. In the presence of salts in excess, and of iodide, the positive error is increased. These effects appear to be due to the ability of precipitated mercuric sulfide to cause co-precipitation of other molecules, and perhaps to the nature of the mechanism by which the sulfide is formed. Volhard's procedure is accurate when applied to solutions which contain the mercury salt and not much else, but presence of salts in quantity, and especially of iodide, leads also to high results.

THE ABSORPTION SPECTRA OF COBALTOUS COMPOUNDS. III. THE PYRIDINE AND QUINOLINE COMPLEXES AND SOLUTIONS

BY WALLACE R. BRODE

RECEIVED JANUARY 9, 1931 PUBLISHED JULY 8, 1931

In the earlier papers of this series[1,2] the absorption spectra of cobaltous chloride, bromide and iodide, in solution in the corresponding halogen acids, were measured (Fig. 1). The data presented in these papers showed the cobalt and halogen atoms to be definitely bound together. The change in molecular weight in going from chloride to bromide to iodide caused a proportional shift in the position of the absorption band. No attempt was made to distinguish between the effect produced by the solvent and that produced by the halogen in combination with the cobalt, since each halide was measured in solution in the corresponding halogen acid. By an application of composite curve analysis,[3] the absorption bands were found to be resolvable into a series of component bands of multiple integral frequency. The same series of multiples appeared in the analysis of the absorption band of each of the cobalt halides, but the frequency of any given component band was different, as was also the frequency interval, between the component bands, for the chloride, bromide and iodide.

A discussion of the various theories concerning the color changes of cobalt solutions and molecular configuration of cobalt halides will not be undertaken until additional data have been obtained. However, certain more important papers bearing on the experimental work involved must of necessity be considered. A good review of much of the literature on this subject is to be found in a recent paper by Bassett.[4] Hantzsch[5] has shown, in a study of the absorption spectra of cobalt chloride in pyridine, that the color change from pink to blue, caused by the application of heat to the pyridine solution, is similar to that of an aqueous solution of cobalt chloride. The absorption spectrum of the blue pyridine solution indicated the possible existence of a composite curve, similar to that shown in the case of cobalt chloride in hydrochloric acid. A preliminary examination of the absorption spectra of hot solutions of cobalt chloride, cobalt bromide and cobalt iodide, in pyridine, made by Dr. R. A. Morton and the author[6] at the University of Liverpool, gave the results similar

to those indicated in Fig. 2. These results were only qualitative in nature, due to the relatively high temperatures required to produce a reasonable concentration, particularly for the iodide salt. Recent observations on these cobaltous halides in quinoline (Fig. 2) have given quantitative data, since the blue solutions are stable at room temperature, so that solutions of a definite concentration of the cobalt halide can be easily measured at a constant temperature. Although there is a marked difference in the molecular weight and other physical properties of the two solvents, pyridine and quinoline, absorption bands of nearly identical shape and frequency were obtained for each of the three halides. This would indicate an absence of solvent effect and the probability that neither pyridine nor quinoline is directly bound to the cobalt. On the other hand, the change in shape and frequency position of the absorption bands with a change of the halogen would indicate that there must be a direct connection between the cobalt and the halogen atoms.

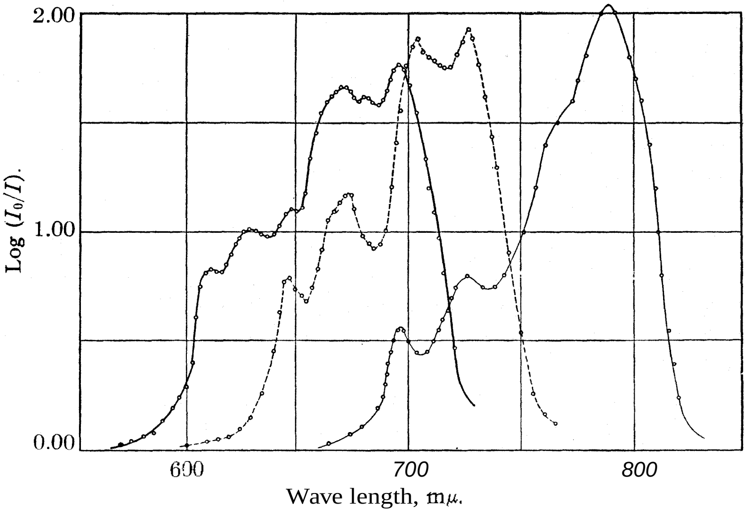

Fig. 1.—The absorption spectra of cobaltous halides in their corresponding halogen acids: ——, $CoCl_2$ in HCl; - - - - - -, $CoBr_2$ in HBr; —○—, CoI_2 in HI.

When one compares the absorption spectra of the cobaltous halides in pyridine solution with those of the same salts in concentrated halogen acids one notes a marked difference. The shift in the position of the. absorption band toward the red end of the spectrum as one goes from chloride to bromide to iodide is much greater in acid solution than in the pyridine or quinoline solution. It will also be noted that for any given halide as, for example, the chloride, the absorption band in acid solution is of lower frequency than for the same salt in pyridine or quinoline.

These larger differences in frequency and the general displacement to lower frequency values in acid solution may be attributed to either of the following causes: (a) to the direct combination of the cobalt atom with a greater number of halogen atoms, or (b) to the effect of the solvent medium which in the acid solution is different for each salt studied.

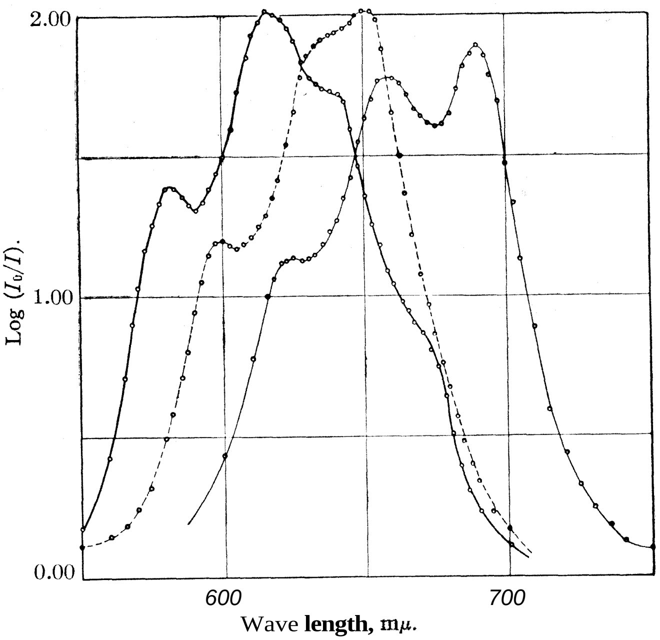

Fig. 2.—The absorption spectra of cobaltous halides in quinoline: ———, $CoCl_2$; - - - - - -, $CoBr_2$; ———, CoI_2. (Identical or nearly identical curves were obtained from cobalt quinolinium halides in quinoline and cobalt halides and cobalt pyridinium halides in pyridine.)

From the above observations it would seem that one has to deal here with two distinct systems of vibrations:[7] that characteristic of the acid solution and that characteristic of solution in an organic base such as pyridine or quinoline. In the present state of our knowledge of these composite absorption bands it is not possible to say whether the differences between the two series of absorption bands are due to a change in the component members. When the data from the halogen acid series (which will be referred to as the "HX" system) and the pyridine–quinoline series (which will be referred to as the "Py–Q" system) are compared on a

---

[7] For purposes of comparison and discussion, a system will be defined as an electronic configuration which produces a series of absorption bands that remain similar in shape and multiple relations even though the mass of the molecule may be changed, *i. e.*, by a change from Cl to Br to I.

frequency scale in place of the wave length scale as used in this paper, it will be noted that either of the above possibilities would be supported by the data.

In a recent article Percival and Wardlaw[8] have described the preparation of cobalt pyridinium and cobalt quinolinium halides, to which they have assigned a constitution involving the $CoCl_4''$ ion. The blue cobalt solutions have been associated by many writers with the possible existence of this ion in solution. The above-mentioned compounds are, however, among the first to be isolated in which such a group has been formulated for a solid substance. The general method of preparation of these compounds was to mix in an alcoholic solution, pyridine (or quinoline) hydrochloride (bromide or iodide) with an equimolecular amount of the corre-

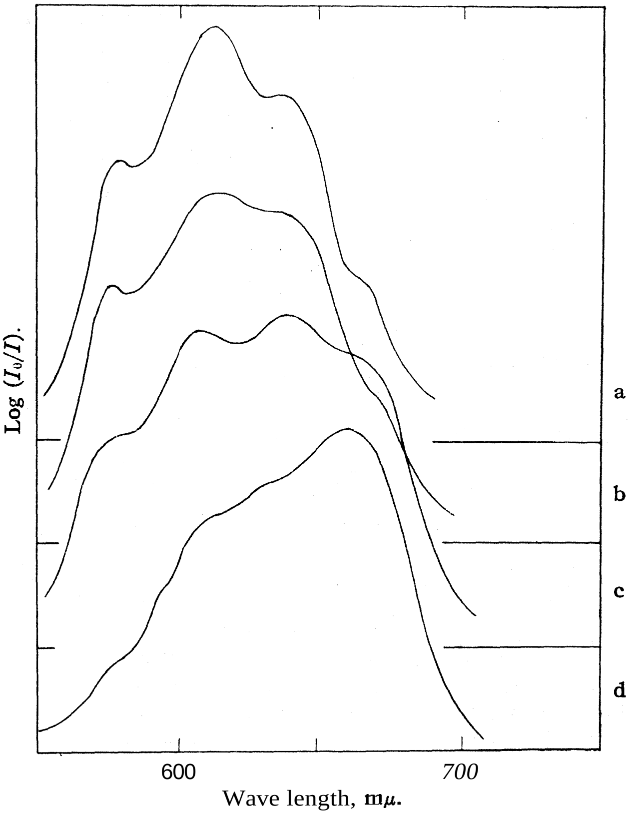

Fig. 3.—(a) The absorption spectra of cobaltous chloride–pyridine complex ($CoPy_2Cl_2$) in $CHCl_3$; (b) $CoPy_2Cl_2$ in $CHCl_3$ + C_2H_5OH; (c) $CoPy_2Cl_2$ in C_2H_5OH; (d) $(PyH)_2CoCl_4$ (cobaltous pyridinium chloride) in C_2H_5OH.

[8] Percival and Wardlaw, *J. Chem. Soc.*, 1505 (1929).

sponding cobaltous halide. The cobalt pyridinium (or quinolinium) halide formed by this reaction was filtered off and recrystallized from alcohol. All of these compounds crystallized with ease from alcohol, yielding needle-shaped crystals in the case of the pyridine derivatives and plates in the case of the quinoline derivatives. Because of the possibility of confusion of these compounds with those described in the following paragraph, analyses were made on these complexes and the results of Percival and Wardlaw were confirmed.

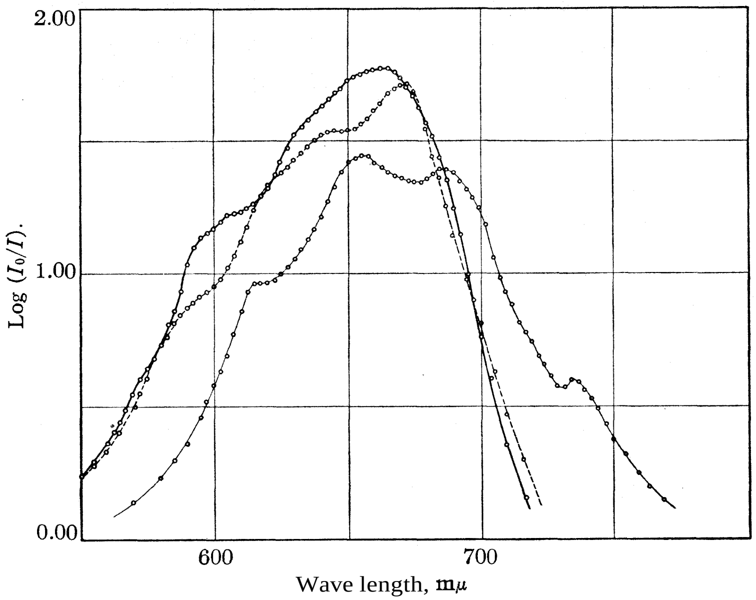

Fig. 4.—The absorption spectra of cobalt quinolinium halogen complexes ($(QH)_2CoX_4$) in absolute ethyl alcohol: X = Cl, ———; Br, - - - - -; and I, ———. The cobalt pyridinium complexes gave identical curves.

Percival and Wardlaw did not refer to the work of Hantzsch,[5] Reitzenstein[9] or Grossmann,[10] who prepared similar compounds by the interaction of cobaltous halides with pyridine or quinoline in alcohol solution. These authors have assigned formulas of the general type $Co(C_5H_5N)_2X_2$ and $Co(C_9H_7N)_2X_2$ to such compounds. The relation between these cobalt halogen complexes may well be represented by the equation

$$\underset{(I)}{CoPy_2Cl_2} + (2HCl) \rightleftharpoons \underset{(II)}{CoCl_2\cdot Py_2\cdot 2HCl} \rightleftharpoons \underbrace{CoCl_2 + 2Py\cdot HCl}_{(III)}$$

According to Percival and Wardlaw the formula for compound (II) should be written as $(PyH)_2CoCl_4$. Since compounds of both types (I)

---

[9] Reitzenstein, *Ann.*, 282, 275 (1894).

[10] Grossmann, *Ber.*, 37, 1256 (1904).

and (II) can be recrystallized from alcohol solutions without change in composition and since both give blue solutions, a study of their absorption spectra should offer valuable information with regard to the nature of these complexes. The cobalt chloride–pyridine complex (Compound I) gave in alcohol an absorption spectrum quite similar to the absorption spectrum of cobalt chloride in pyridine (Fig. **3**). While the band intensities of the former did not exactly correspond with those (Fig. 2) of cobalt chloride in pyridine or quinoline, their frequency positions were the same, and it was further shown that the band intensities could be altered without changing the position of the bands by the use of other solvents such as ligroin and chloroform. In these latter solvents there is a general sharpening of the bands while in alcohol there seems to have been a broadening and flattening of the bands. The same effects were noted in a study of the absorption spectra of the quinoline complex, which, though of a markedly different color from the pyridine complex in the crystalline state, gave an almost identical absorption spectrum in alcohol solution.

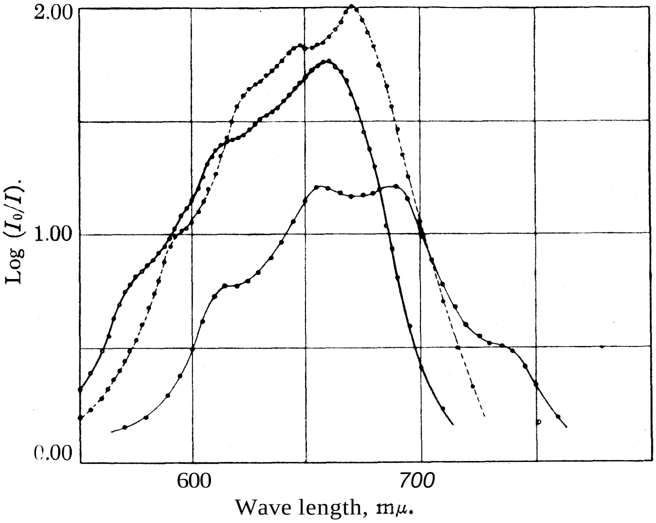

Fig. 5.—The absorption spectra of cobaltous halides in ethyl alcohol: Cl, ——; Br, ------; and I, —·—

The absorption spectra of the cobaltous pyridinium and quinolinium chlorides (11), bromides and iodides (Fig. 4) in alcohol were quite different from the absorption spectra of the corresponding cobalt halides in pyridine and quinoline. A comparison of the curves of these pyridinium and quinolinium complexes in alcohol with those of the corresponding cobalt halides in alcohol (Fig. 5) showed that for the same halogen nearly identical absorption spectra were obtained. These facts suggest a reaction similar to that indicated from (II) to (III) in the above equation, and that the cobalt halide absorption spectrum in alcohol was not influenced by the pyridinium or quinolinium chloride present. An exact analysis of the curves is not possible due to the broad flat nature of the component portions of the alcohol bands. There is some question as to whether there is a distinct alcohol system of absorption, similar to the "HX" and "Py–Q" systems or whether the curve (Fig. 4) is formed by an equilibrium between the "HX" and "Py–Q" systems. The addition of very small amounts of quinoline to a solution of cobalt chloride in alcohol produces the absorption spectra characteristic of cobalt chloride in quinoline, (Fig. 7), and in a like manner the addition of small amounts of hydrochloric acid and lithium chloride to the neutral alcohol solution of cobalt chloride produces absorption spectra which are characteristic of cobalt chloride in hydrochloric acid (Fig. 6). Gróh[11] made a study of this latter reaction and concluded that the alcohol solution of cobalt chloride contained equimolecular amounts of Co^{++} and $CoCl_4''$ ions and that the change in color on addition of the halogen containing salt such as lithium chloride is due to an increase in the concentration of the $CoCl_4''$ ion with a corresponding decrease in the amount of the Co^{++} ion, the latter ion being responsible for the pink color of cobalt solutions. The data here presented would seem to indicate a change in the nature of the blue absorption spectrum rather than a mere intensification of the alcohol bands, and hence does not support Gróh's proposed mechanism. As another example of difference of intensity of components of the same system under different conditions, the changes in intensities of the 595 mμ and 695 mμ bands are worth noting.

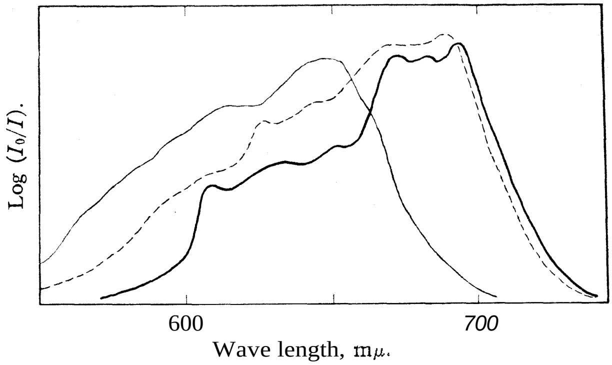

Fig. 6.—The absorption spectra of $CoCl_2$; in concentrated HCl, ———; in a 3% solution of LiCl in alcohol, - - - - - -; and in ethyl alcohol, ———.

---

[11] Gróh, Z. *anorg.* Chem., 162,321 (1927); 146,305 (1925).

The addition of small amounts of halogen ions, either as quinolinium chloride or free hydrochloric acid, had no apparent effect on the absorption bands of cobaltous chloride in quinoline. Also, the addition of quinolinium chloride to the alcohol solution of cobalt chloride had no effect on the absorption band, indicating that all of the cobalt ions have the same amount of halogen.

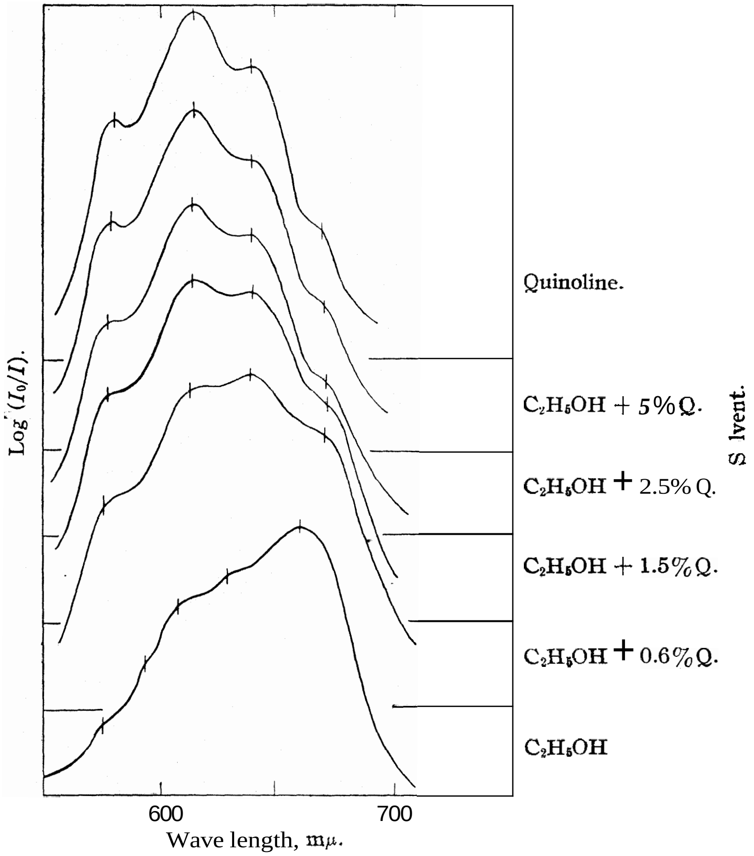

Fig. 7.—The change from the alcohol absorption to the "Py–Q" system of absorption caused by the addition of quinoline to a solution of $CoCl_2$ in ethyl alcohol.

If the alcohol solutions are to be considered as representing an intermediate or equilibrium state between the "HX" and "Py–Q" systems, then it should be possible to go directly from one system to another by the addition of one solvent to a cobalt solution of the other. A few of the curves obtained from nearly fifty solutions of varying concentration of hydrochloric acid and quinoline are presented in Fig. 8. These curves were selected to show representative conditions and transition stages.

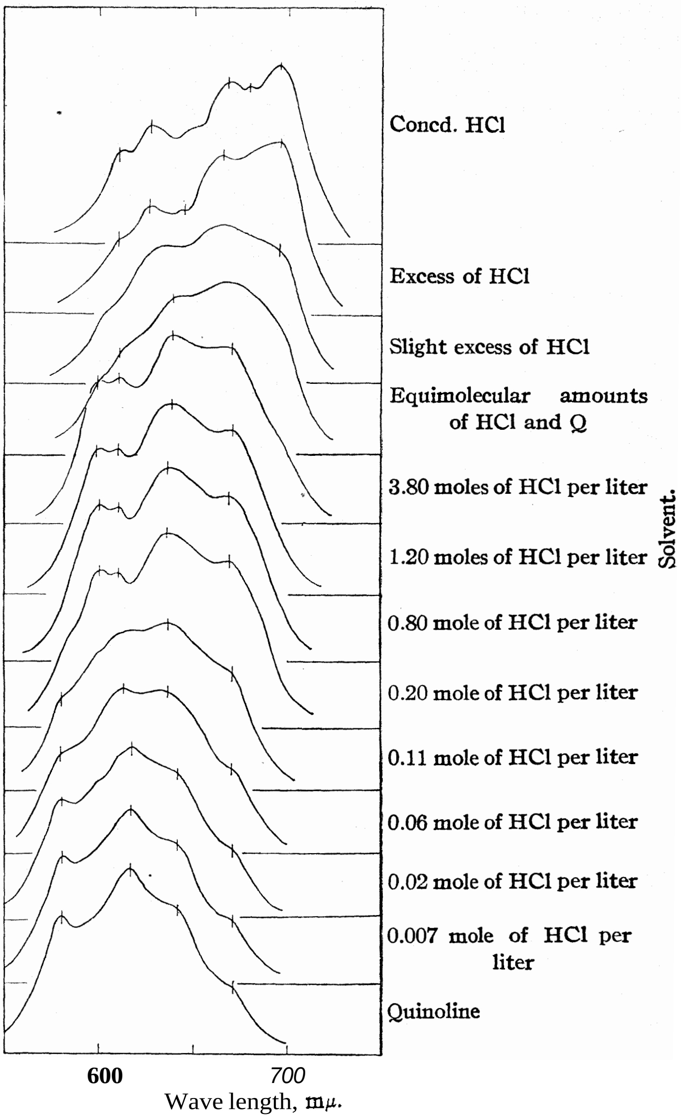

Fig. 8.—The change from the "Py–Q system, through the "intermediate" system to the "HX" system, caused by the addition of HCl to a solution of $CoCl_2$ in quinoline. (The curves in this figure are only a few of the some fifty curves, observed at various Q–HCl concentrations. They have been chosen to show characteristic stages or transition points in the change of the absorption systems. The concentration of $CoCl_2$ in all solutions was approximately 0.0043 mole per liter.)

Over a considerable concentration range there is no apparent effect on the general nature of this intermediate absorption band, and only after a concentration of acid in excess of the quinoline is reached do the " HX or acid system bands appear. While the intermediate band obtained in this "HX"–"Py–Q" equilibrium is not identical with the alcohol band, the close similarity in position and shape, allowing for some solvent effect, would argue for the existence of an "intermediate" system of absorption as well as for the "HX" and "Py–Q" systems.

Experimental

The observations recorded in the figures in this paper, with the exception of Fig. 1, were made on a Bausch and Lomb spectrophotometer which was equipped with a modified DuBoscq colorimeter attachment which permitted the use of all glass cells and the rapid variation of cell thickness by changing the position of the glass plungers. The data are recorded in wave length values expressed in millimicrons (meters $\times 10^{-9}$), as abscissa and in extinction coefficients, expressed as log I_0/I, as ordinates.

Cobalt chloride was prepared by dissolving cobalt carbonate in C. P. hydrochloric acid, recrystallizing from water and drying at 120° in the presence of dry hydrogen chloride. The anhydrous cobalt chloride was kept at 100° in a closed container until used. The sample was analyzed and checked for both cobalt and halogen. The cobalt was determined by the sulfate fusion method and the halogen by the standard silver chloride method.

A convenient means of determining the amount of cobalt present in any sample was to evaporate the solution to a small volume or to dryness and make up to the original volume with concentrated hydrochloric acid. The presence of such impurities as quinolinium hydrochloride, sulfates, nitrates or other halides in small amounts were shown by experiment to have no influence on the absorption bands of the hydrochloric acid solution. The hydrochloric acid solutions follow Beer's law throughout a wide concentration range. Because of its general shape, location and intensity, the band at 625 mμ was chosen for reference purposes (Fig. 1).

The molecular extinction coefficient for cobalt chloride in concentrated hydrochloric acid was found to be **335.5** at $\lambda = 625$ mμ and this value was used to determine the cobalt content of other solutions. In compounds where the halogen content might vary, such as the pyridine and quinoline complexes, separate halogen determinatious were made to insure that the correct compound was being used. The earlier data on the halogen acid solutions[1] were obtained from weighed samples of the supposed hexa hydrate. From the above analyses it is shown that the water content was not as supposed, so that the data as published represent the absorption of 0.7225 g. of the anhydrous cobaltous chloride per liter (Fig. 1).

Summary

A spectrophotometric study has been made of cobalt chloride, cobalt bromide and cobalt iodide dissolved in pyridine and quinoline, and the relation between the data observed and those previously presented on the corresponding acid solutions has been discussed. Although the data of this paper are in contradiction to some of the data and theories published or offered by others on the nature of cobalt colors, no attempt has been made to explain the actual constitution of the cobalt complexes. Discussion on this point is reserved for a later paper which will be presented after the publication of the cobalt alkaline solution data.

1. Evidence has been presented to substantiate the existence of three absorption systems in blue cobalt solutions, namely, the halogen acid system, the pyridine–quinoline system and a possible intermediate system.

2. The fact that the cobalt halides gave identical absorption spectra in both pyridine and quinoline supports the theory that the cobalt atom is not directly connected to the pyridine or quinoline molecule, since with the markedly different molecular weights of pyridine and quinoline, one would expect a shift in the absorption bands or a change in the component intensities with such a change in molecular weight. On the other hand, the nature of the holding or partial valence forces in complexes may be such that the effects produced would be too small to observe.

3. The change in frequency of the absorption bands with a change of halogen in the pyridine–quinoline system is similar to that previously observed in the halogen acid system, but of smaller magnitude, indicating a possible cobalt complex involving fewer halogen ions and more ions common to all three compounds.

4. Cobalt pyridinium and quinolinium halogen complexes give in alcohol the same absorption spectra as the pure cobalt halide in alcohol, indicating the non-existence of pyridinium or quinolinium complexes in the alcohol solution.

5. By a change of solvents it has been possible to alter the intensity of components of absorption bands without shifting their frequency position. If identical band positions but different extinction coefficient values are to be taken as indication of equilibrium isomers,[12] then the data presented on the absorption spectra of the cobalt quinoline and pyridine chloride complexes in alcohol and in chloroform would support the contention of Hantzsch[5] that isomeric forms of these complexes can exist.

AN ANHYDROUS DISTILLATION METHOD FOR THE DETERMINATION OF CERTAIN METALS IN ORGANIC COMPOUNDS. I. THE DETERMINATION OF MERCURY1

BY E. P. FENIMORE AND E. C. WAGNER

RECEIVED JANUARY 31, 1931 PUBLISHED JULY 8, 1931

In the method described below, the sample is decomposed by concentrated sulfuric acid and ammonium (potassium) persulfate in a special apparatus, and mercury is distilled out as chloride by passing a stream of hydrogen chloride and heating to the temperature of distillation of the sulfuric acid (external temperature about 260–310°). The mercuric chloride is collected in water, and is determined by an adaptation of Jamieson's iodate method. Presence of chlorine or bromine introduces no difficulty, but that of iodine necessitates certain changes in the procedure. The method is believed to be general.

It appears that no similar procedure has been described. The volatilization of certain metals as anhydrous halides is employed in the analysis of minerals which are advantageously decomposed by heating in a stream of chlorine, carbon tetrachloride, etc. The wet distillation of metallic chlorides volatile with steam is familiar in the case of arsenic, and Biltz[2] separated arsenic, antimony and tin in this way. Strecker and Riedemann[3] observed mercuric chloride to pass over in part with arsenic, and upon this fact Strecker and Conradt[4] based a procedure for quantitative (though relatively slow) distillation of mercury in steam containing hydrochloric and hydrobromic acids.

In the elaboration of a complete procedure including the decomposition and anhydrous distillation outlined above, it was necessary finally to determine mercury in a solution containing hydrochloric and sulfuric acids and sulfur dioxide, or the salts formed by their neutralization. The nature of the solution excluded Volhard's thiocyanate titration. The iodimetric method of Rupp[5] yielded in five trials with pure mercuric chloride results which were concordant but somewhat high. Isolation of mercury as metal by excess stannous chloride, the washed globules being dissolved in nitric acid and titrated with thiocyanate,[6] was subjected to trial,

[6] The method of Krieckhaus: Low, "Technical Methods of Ore Analysis," John Wiley and Sons, Inc., New York, 1922, 9th ed., p. 159.

a filter being used to retain floating particles of mercury otherwise lost during the washing by decantation. Results were satisfactory when the quantity of mercury was 0.2–0.3 g. (average error, −0.1%), but with 0.1 g. or less of mercury the results were barely acceptable or considerably too low.[7]

Determination of mercury as sulfide by precipitation with hydrogen sulfide was found to yield high results. With dilute solutions of mercuric chloride about 0.03 normal in hydrochloric acid the errors averaged +0.34%, and in presence of salts the errors were larger. This matter is discussed in another paper.[8]

The iodate method of Jamieson,[9] in which mercury is precipitated as $ZnHg(SCN)_4$, which is titrated with standard iodate solution in presence of hydrochloric acid, was found to be satisfactory, the small errors averaging 0.0001 g. For precipitation from the solution obtained in the distillation method, an increase in the concentration of the precipitating reagent was found necessary. The accuracy under the conditions adopted was nearly as high as that of the original method. For comparison purposes the method of White was adopted.[10] The sample, in warm (not hot) concentrated sulfuric acid, was decomposed by addition of powdered permanganate in small portions, the diluted liquid cleared by chlorine-free hydrogen peroxide, and the mercury titrated with thiocyanate solution standardized under the same conditions against pure mercury metal. Tests of this procedure, using pure (99.98%) mercuric acetate, and sucrose to provide oxidizable matter, showed it to be satisfactory, results for mercury averaging 0.04% low. This comparison method is not applicable to compounds which contain halogen, presence of which both increases danger of loss of mercury during the rather vigorous decomposition and excludes the convenient thiocyanate titration.

Distillation Method for Determination of Mercury in Organic Compounds.—The complete apparatus is illustrated in the figure.

1. Decomposition **and** Distillation.—Receiver M contains about 20 cc. of water, and the trap N about 5 cc. Stopcock P is closed. Tube p extends just to the surface of the water in M, and the latter is supported in a beaker of cold water.

---

[7] Willard and Boldyreff, THIS JOURNAL, 52, 569 (1930), determined mercury gravimetrically as metal following reduction by stannous chloride, and, using quantities of mercury never less than 0.14 gram, found it necessary to apply an additive correction of 0.0010 g.

[9] Jamieson, *J. Ind. Eng. Chem.* 11, 296 (1919); "Volumetric Iodate Methods," The Chemical Catalog Co., Inc., New York, 1926, p. 42.

[10] White, THIS JOURNAL, 42, 2350 (1920). The method of Eschka, in the modification described by Whitmore ("Organic Compounds of Mercury," The Chemical Catalog Co., Inc., New York, 1921, p. 365), proved to be somewhat uncertain. The lime method is cumbersome and inclined to yield low results, and the modification by Bouton and Duschak [U. S. Bur. Mines Technical Paper No. 227, 1920] for mineral analysis has *not* been developed for use with organic mercury compounds.

The sample, containing not more than **0.15** g. of mercury, is weighed in a small glass cup, introduced into the decomposition flask G, and dissolved in **4–5** cc. of fuming sulfuric acid, with warming if necessary. To the cooled liquid is added **10** g. of powdered ammonium persulfate (or 12 g. of potassium persulfate), and then **15** cc. of concd. sulfuric acid is introduced in such way as to wash off any powder adhering to the ground surface H.[11] The decomposition flask is put in place, funnel F is charged with **5** cc. of concd. sulfuric acid, and connections are made as shown in the figure.

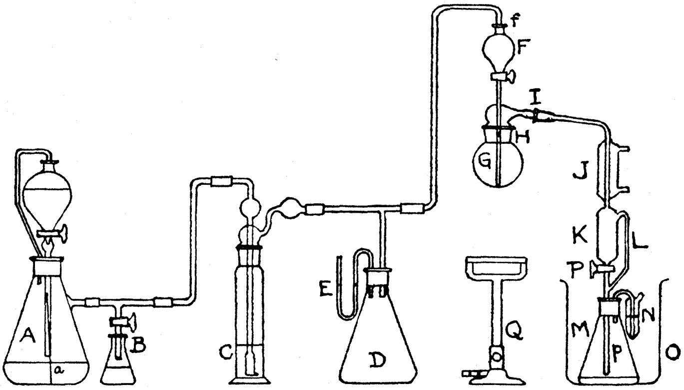

Fig. **1.—A,** HCl generator; NH_4Cl and concd. HCl in flask, concd. H_2SO_4 in funnel. Rod *a* causes acid to enter steadily and not by drops; B, pressure release; flask contains water; C, concd. H_2SO_4 drier and bubble-counter; D, safety flask; E, manometer (concd. HCl); F, funnel of **25** cc. capacity; G, decomposition flask of **100** cc. capacity; H and I, ground joints; J, water condenser; K, reservoir of 6–7 cc. capacity; L, vapor by-pass; M, receiver, capacity **150** cc.; N, trap, capacity **15** cc.; O, cooling bath; Q, ring burner.

Flask G is heated cautiously until oxidation starts, shown by gentle effervescence, and decomposition is completed by judicious heating, with occasional cooling if necessary. When active bubbling ceases, the stopcock F is opened, a stream of hydrogen chloride *(2* or **3** bubbles per second) is started, and the flask is heated rapidly until sulfuric acid distils. Mercuric chloride volatilizes in part far below its boiling point, collecting at first in the upper parts of the flask. As the temperature rises the mercuric chloride passes over rapidly, and eventually most of it is washed into reservoir K by the sulfuric acid which distils. When 5–6 cc. of acid has collected in K, the heating is stopped, the stream of hydrogen chloride is checked, and the apparatus separated at I, the receiving unit being kept assembled.

For compounds which decompose normally the operations just described can be completed in less than thirty minutes. There should be no odor of hydrogen chloride, as the generator sketched permits good control of the gas stream, and as absorption of hydrogen chloride in M is complete.

---

[11] If the substance is too actively attacked by the oxidizing mixture to permit addition of all the persulfate at one time, the sample is treated with **5** cc. of fuming acid and **10** cc. of concd. sulfuric acid, and persulfate is added in small portions while cooling the (open) flask. The ground surface is then rinsed with 5 cc. of concd. sulfuric acid, and the analysis continued as described above.

2. Determination of Mercury in Absence of Iodine. (a) Precipitation of Zinc Mercuric Thiocyanate.—The acid in K is allowed to enter M by drops, regulated by the stopcock, the flask being rotated and cooled during the addition. The parts JKL are washed out partially with water (about 10 cc.) introduced at I. Tube p is thrust to the bottom of the flask, a rubber tube is attached to the outlet of the trap, and the acid liquid is forced up into JKL by gentle blowing, and is then allowed to recede. This is repeated several times, to dissolve any lumps of mercuric salt adhering to the glass. The flask M is disconnected and the associated parts washed with numerous small portions of water. If the foregoing operations have been completed properly, the volume at this point will be about 60 cc., and should not exceed 80 cc

To oxidize sulfur dioxide, fresh bromine water is added (or, if the volume already approaches the stated maximum, vapors from the mouth of a bromine bottle are "poured" into the flask) until a yellow color persists. The solution is neutralized with pure sodium hydroxide, added as a saturated solution and with cooling until the yellow color disappears. The liquid is then barely acidified with hydrochloric acid (yellow color), and an excess of 5 cc. of 6 N hydrochloric acid is added.[12]

To the cold solution, whose volume should not exceed 100 cc., there is added 25 cc of the stronger Jamieson reagent (a filtered solution containing 73 g. of $ZnSO_4 \cdot 7H_2O$ and 125 g. of KSCN per liter), the liquid is mixed and allowed to stand for thirty minutes or longer. The precipitate is filtered with gentle suction on a 9-cm. paper supported by a filter cone. The flask is rinsed with wash liquid (2 cc. of the stronger Jamieson reagent in 450 cc. of water), and precipitate and filter paper are washed five or six times with the same liquid.

(b) Titration.—The filter paper and precipitate are put into a 250-cc. glass-stoppered Erlenmeyer flask, treated with 45 cc. of cold hydrochloric acid (1 volume of water and 3.5 volumes of concd. acid) and 6–7 cc. of chloroform, and titration with standard potassium iodate solution (about 25 g. per liter, standardized as suggested below) is begun at once, with continual rotation of the flask. After the color has become pale, titration is continued cautiously, with shaking of the stoppered flask after each addition, until the last tint in the chloroform is just discharged. The end-point is very sharp.

Standardization of Iodate Solution.—If pure iodate is used the solution will have almost exactly the theoretical mercury equivalent ($Hg \approx 6KIO_3$). It seems better, however, to standardize the solution against pure mercury or mercuric salt by the Jamieson procedure. For this purpose the mercuric solution is acidified with 5 cc. of 6 N hydrochloric acid, diluted to 50 cc., precipitated with 25 cc. of Jamieson's reagent (the weaker reagent, see paragraph 3), and the filtration and titration conducted as outlined above.

Accuracy tests of the distillation procedure applied to pure mercuric chloride arc summarized in Table I.

---

[12] The small excess of free bromine is later reduced by the thiocyanate.

Results for organic mercury compounds are given in Table III. An analysis can be completed in less than two hours.

3. Determination of Mercury in the Presence of Iodine.—Most of the iodine volatilizes before mercuric chloride does so in quantity. The formation of mercuric iodide in the receivers makes it necessary to wash them out with potassium iodide solution. The mercury then cannot be precipitated by Jamieson's reagent. It is therefore first separated as metal by addition of zinc dust, excess of zinc dissolved in dilute hydrochloric acid, mercury and residual zinc dissolved in nitric acid, and mercury precipitated by Jamieson's original method. The procedure is as follows.

After the distillation, reservoir K is emptied into M, 10 cc. of 10% potassium iodide solution introduced at I, and liquid from M forced up into JKL and held there until all mercuric iodide has dissolved. These parts and the trap are washed with water as described in 2(a). The volume of the liquid should be about 75 cc.

To oxidize sulfur dioxide a strong solution of iodine in potassium iodide is added until the color persists. One gram of zinc dust is suspended in a little water and added in small portions to the solution. The flask is covered, and when evolution of hydrogen moderates (five to ten minutes) the amalgam, excess zinc, and a small brown precipitate (apparently mercuric sulfide) are filtered with suction on a glass filtering crucible (30 cc.), and washed well with water. The crucible is placed upright in a 150-cc. beaker, and 25 cc. of 6 N hydrochloric acid added (about 5 cc. in the beaker and 20 cc. in the filtering crucible). The beaker is covered and the acid warmed (not boiled) until the amalgam is reduced to a small mass, stiff in consistency and mossy in appearance. If this treatment is continued until the amalgam becomes liquid, and especially if the acid is boiled, there is danger of loss of mercury. The filtering crucible is replaced in its holder, the acid drawn through, and filter and amalgam washed well with water. The lump of amalgam is dropped into flask M, and the filtering crucible is replaced in its holder, with flask M beneath as receiver. The crucible is treated with several cc. of strong bromine water (no suction), and then with about 2 cc. of hot concd. nitric acid. This treatment dissolves any particles of amalgam and also the small dark precipitate. After a minute the liquid is drawn through the filter, which is treated with several successive portions of hot concd. nitric acid, using in all about 5 cc. of nitric acid. The filter is finally washed with two small portions (1–2 cc.) of water. The flask is warmed until the amalgam dissolves, the solution diluted to about 25 cc. and cooled. Bromine water is added until the color persists.

The liquid is neutralized with strong sodium hydroxide solution, and acidified with 2 cc. of 6 N hydrochloric acid; an acidity much higher than this may lead to interaction of nitric acid and thiocyanate during the precipitation. The solution is cooled, diluted to 50 cc., and mercury precipitated by addition of 25 cc. of Jamieson's reagent (29 g.

4. Analytical Results for Some Organic Mercury Compounds.—Results by the new method, in comparison with those obtained by the comparison method, are shown in Table III.

Comments.—The use of potassium dichromate for the oxidation gave satisfactory decompositions, but it was found impossible to distil out all the mercury as chloride, retention by anhydrous chromic sulfate seeming to occur. The use of persulfate and concd. sulfuric acid for decomposition of organic samples was apparently new at the time this work was first described (1929), though several chemists had earlier used persulfate with water or dilute sulfuric acid.[13] Recently Thompson and Oakdale[14] applied persulfate and fuming sulfuric acid in the determination of halogens in organic compounds by a modification of the Baubigny–Chavanne–Robertson method.

In presence of iodine, the preliminary displacement of mercury from the distillate liquid requires zinc dust. Qualitative trials showed that 1 g. of finely granular zinc was ineffective, whereas half as much zinc dust added as a suspension removed mercury completely in a few minutes.

The principal impurities in the zinc dust were iron (0.03%) and lead (0.1%). As these metals are concentrated in the zinc amalgam during the hydrochloric acid treatment, their effects upon results by Jamieson's method were studied. Iron yielded of course a strongly colored solution, and the precipitate was tinted, but the effect of even ten times the iron present in 1 g. of zinc dust was nil. In the presence of lead the precipitate was yellow-tinted, as it was in analyses following separation of mercury by zinc, and a positive error rather regularly entered the results. No relationship could be established between the quantity of lead and the magnitude of the error, although the color of the precipitate deepened as the quantity of lead was increased. .These results, however, indicate the advisability of using zinc dust as free as possible of impurities.

The trap N is probably not essential, no evidence of presence of mercury in it having been obtained.

Acknowledgment is made to Dr. H. S. Lukens and to Dr. W. M. McNabb for helpful suggestions.

Summary

In the method described for determination of mercury in organic compounds the sample is decomposed by persulfate and concentrated sulfuric acid, mercury is distilled out as chloride by heating in a stream of hydrogen chloride, and is precipitated as zinc mercuric thiocyanate and determined by iodate titration. In presence of iodine, mercury in the distillate liquid is

[14] Thompson and Oakdale, THIS JOURNAL, 52, 1195 (1930).

first precipitated by zinc dust, excess zinc dissolved in hydrochloric acid, the residual amalgam dissolved, and mercury determined by the iodate method.

Trials of the procedure with a variety of compounds and in presence of halogens and of sulfur showed it to be apparently of general applicability. The method has the advantage that in presence of halogens it eliminates the danger (which otherwise attends decompositions by acid agents) of loss of mercury by volatilization.

Presence of iodine prolongs the analysis, but in its absence the method is at least as rapid as others of comparable accuracy and applicability.

STUDIES IN THE RARE EARTHS. I. THE PREPARATION OF THE BROMATES OF CERIUM GROUP RARE EARTHS

BY J. ALLEN HARRIS[1]

RECEIVED FEBRUARY 6, 1931 PUBLISHED JULY 8, 1931

Historical

The method of separating the rare earth elements that proved successful in permitting of the concentration of illinium was a fractional crystallization of samarium rich fractions obtained from a double magnesium nitrate series of rare earths, as the bromates, the cerium, lanthanum and praseodymium having been removed completely prior to the conversion to the double magnesium nitrate. This latter crystallization permitted of the separation of the bulk of the neodymium from the remaining elements but experience seems to prove that in such a series the illinium concentrates with the neodymium, rendering its detection difficult, the order of solubility of these salts being such that we have an increase with increasing atomic weight.[2]

From such a study, then, it would appear to be most advantageous to submit the original material to a preliminary, rather than to a subsequent crystallization as the bromates. The serial order of solubilities would then become, erbium, lanthanum, yttrium, holmium, praseodymium, dysprosium, neodymium, terbium, illinium, gadolinium, samarium, and europium (least soluble), thus permitting of a more efficient separation of the illinium and neodymium.[2,3]

Introduction

The standard method of preparing the bromate is that of James, and was used extensively by him in his classical work on the yttrium group earths.

---

[1] National Research Fellow.

[2] Harris with Hopkins, THIS JOURNAL, 48, 1585 (1926).

[3] James, *ibid.*, 48, 2871 (1926).

The dried earth oxalates are mixed to the consistency of a thin paste with concentrated sulfuric acid, warmed to expel excess of acid, and finally heated strongly to convert to the anhydrous sulfates. These, on cooling, are pulverized and sifted, with constant stirring, into ice water; care being necessary to prevent the formation of a basic salt. This solution is then added a little at a time to a saturated solution of freshly precipitated barium bromate in a large steam heated evaporating dish equipped with a mechanical stirrer, care being taken to ensure the presence of excess barium in the solution. On final addition of the sulfate, the precipitated barium sulfate is removed by filtration and the solution of rare earth bromates crystallized by evaporation.

This method, while extremely annoying, in that it involves the evolution of copious fumes of oxides of sulfur over a considerable period, due to the decomposition of the acid by the oxalate radical, yields anhydrous sulfates of the yttrium group earths, even when considerable amounts of neodymium are present, which dissolve to a neutral solution, fairly readily when added slowly to large volumes of ice water.

It has been the experience of the writer, however, that when all of the members of the cerium group earths (with the exception of cerium) are present, together with certain of the yttrium group earths, it is almost impossible to remove the last traces of acid from the more basic members, without decomposing the sulfates of the less basic earths. If decomposition takes place, these basic salts will not dissolve. On the other hand, if any trace of acid is permitted to remain, although ready solution is effected, total decomposition of the bromates during final concentration of the solution invariably results.

At the suggestion of Professor Georges Urbain, of the Sorbonne, the following method was developed, and has been used extensively by the writer with excellent results, affording sulfates of the cerium group earths that are readily soluble in water, even at room temperature, yielding solutions that are neutral although considerable amounts of lanthanum be present.

Procedure

The dried earth oxalates are ignited to the oxides, weighed and the amount of sulfuric acid necessary for their conversion to the sulfates calculated, measured out and diluted considerably. After thorough moistening of the oxides with water to permit of ready penetration by the acid, the acid is added very slowly in small portions, the liquor being allowed to reach neutrality before subsequent addition. When the point is reached at which the solution shows little or no tendency to become neutral, the mixture is transferred to a hot-plate, and warmed until neutralization is again effected. The process of addition is continued until all of the acid has been added.

If upon final addition the liquor again attains neutrality, a little more dilute acid is added, so that a feebly acidic solution is maintained over the sulfate residue. The mixture is then allowed to evaporate slowly on the hot-plate and when thoroughly dry the sulfates may be removed, pulverized and then heated strongly to remove any excess acid. The evolution of fumes is thus reduced to a minimum, and when the anhydrous sulfates are obtained, as evidenced by cessation of evolution of the oxides of sulfur, they are quickly transferred to a dry and previously weighed container, roughly weighed, and transferred while still hot to a bell jar which is immediately evacuated.

From the weight of the sulfates, the amount of water necessary for their solution is calculated and measured into a large conical precipitation flask. When cool, the sulfates are taken in small portions from the bell jar and sprinkled with vigorous stirring into the water, where they dissolve very readily. In this manner it is possible to obtain a concentrated solution of the sulfates, containing no basic salts, which is neutral to litmus. The solution may now be transferred to an evaporating dish and gently evaporated until crystals begin to form at the edges of the container.

If the barium bromate solution is prepared in advance, so as to contain quantities of salt sufficient to precipitate the sulfate ion, the conversion to the bromates may be effected in the minimum of time and with small volumes of solution.

In conclusion the writer wishes to express his appreciation to the International Education Board and the National Research Council for furnishing funds to permit of the writer's working with Professor Urbain, to whom the writer is also deeply grateful.

Summary

Difficulty is experienced when attempting to prepare a neutral solution of cerium group rare earth sulfates, by igniting the oxalates with sulfuric acid, and dissolving the residue in ice water.

A method is outlined for the preparation of concentrated neutral solutions of these sulfates, by the conversion of the oxides to the sulfates and dissolving in water at room temperatures.

This method eliminates waste of sulfuric acid, annoying prolonged evolution of fumes, the use of ice water, loss of time required in conversion to the bromate and subsequent evaporation of large volumes of solution.

A KINETIC STUDY OF SOME REACTIONS OF DIAZOACETIC ESTER IN BENZENE SOLUTION

BY J. N. BRÖNSTED AND R. P. BELL

RECEIVED MARCH 12, 1931 PUBLISHED JULY 8, 1931

1. Introduction

In the extended theory of acid and basic catalysis[1] the effect of acids in accelerating chemical reactions is looked upon as due to a direct interaction between the molecules reacting and the molecule of the catalyzing acid. In a basic medium like water the catalysis produced by the addition of an acid A may be a compound effect of both A and the hydrogen ion "formed by dissociation." In non-basic media where no protolytic[2] reaction with acids is possible, acid catalysis ought to be of a simpler character.

With the purpose of broadening the foundation of the extended theory we have in the present investigations studied several reactions of diazoacetic ester in benzene solutions. The reaction of this substance with water in the presence of acids according to the equation

$$CHN_2COOC_2H_5 + H_2O \longrightarrow CH_2OHCOOC_2H_5 + N_2 \qquad (1)$$

has long been known as an example of hydrogen-ion catalysis, and kinetic measurements of this reaction have been extensively used as a method for determining hydrogen-ion concentration in aqueous solutions. Provided that the solutions are so dilute that salt effects can be neglected, the velocity of reaction (1) is directly proportional to the concentration of "hydrogen ion," which in aqueous solutions is actually H_3O^+. It has been shown[3] that the reaction has a large linear salt effect. Similarly, when various alcohols are used as solvents, the velocity of the reaction

$$CHN_2COOC_2H_5 + ROH \longrightarrow CH_2ORCOOC_2H_5 + N_2 \qquad (2)$$

is determined by the concentration of the solvated hydrion, though in these media, where the dielectric constant is much less than that of water, primary salt effects are much higher, and are of importance even at low concentrations.'

In the presence of some acids, *e. g.*, the halogen acids and nitric acid, a side reaction takes place.[4]

$$CHN_2COOC_2H_5 + HX \longrightarrow CH_2XCOOC_2H_5 + N_2 \qquad (3)$$

The velocity of this reaction is in aqueous solution proportional to the concentrations of both the hydrogen ion and the anion of the acid. Ex-

amination of the data of Bredig and Ripley[4] and those of Lachs[6] shows that the salt effect is in this case "exponential" in type, as would be expected for a reaction involving two charged molecules[6] and that also numerically there is a fair agreement with the theoretical formula for such a reaction.

Thus in water and the alcohols it appears that acid catalysis in the general sense[7] is at the most very small compared with catalysis by the solvated hydrion. Hantzsch[8] has found an increase of catalytic activity with increasing concentration for the halogen acids in aqueous solution, which he attributes to catalysis by the undissociated molecules. However, in drawing this conclusion, no account has been taken of the fact that the change of acid concentration causes a very considerable change of medium. In fact, if the primary salt effect found at low concentrations[3] is assumed to be linear up to the high acid concentrations used by Hantzsch, it is sufficient to account approximately for the increase of catalytic power observed. Furthermore, the reaction of diazoacetic ester with the halogen acids is complex (see equations (1) and **(3)** above) and the hypothesis of Hantzsch, that the initial stage in the reaction with acid determining the velocity of the reaction is the same in each case, is a pure assumption. Snethlage[9] considers that his results in ethyl alcohol solution show catalysis by the undissociated picric acid molecule, but this view has been shown to be inconclusive owing to the presence of an unknown, but probably large, secondary salt effect.[1]

In aprotic solvents, unable to solvate the free hydrogen ion, acids will not be ionized, and any phenomena of acid catalysis observed must be attributed to acid molecules in general. It is in fact well known that many organic reactions are powerfully catalyzed by solutions of acids in "inert" solvents.[10] The rearrangement of diazoamino compounds in basic solvents, which has been studied extensively by Goldschmidt[11] and his co-workers, probably constitutes an example of general acid catalysis, though it is possible to attribute at least a part of the catalysis to ions such as C_6H_5-NH_3^+, which in these solvents are nothing more than solvated hydrions. In the case of diazoacetic ester, there will not in general be any possibility

of reaction with the solvent itself in such a case, but it is possible to study the reaction of the ester with the acid added, or with a third substance. Such a study is of interest from two main points of view: (a) the catalytic properties of acid molecules in inert solvents, and (b) the molecular state of carboxylic acids in such solvents.

The only previous work on the kinetics of reactions. with diazoacetic ester in non-dissociating solvents is that of Hantzsch[12] with a variety of acids and solvents. These investigations, however, are not of such a character as to permit of any conclusion regarding the nature or mechanism of the reaction. Hantzsch considers that the reactivity of any acid toward diazoacetic ester is a measure of its "strength," but as has been pointed out by v. Halban[13] this is not allowable, since we are considering a different chemical reaction in each case, and not the same reaction catalyzed by different acids. Even admitting Hantzsch's unproved and improbable assumption that the first step, and that which determines the velocity, is the formation of a diazonium salt, it would not justify the relation proposed between reaction velocity and acid strength in any ordinary sense of this word.

The present investigation deals exclusively with benzene solutions. The reaction of diazoacetic ester has been studied with the following acids: monochloroacetic, dichloroacetic, iodoacetic, nitroacetic, formic, α-bromopropionic, α,β-dibromopropionic and picric.

Measurements have also been made for acid mixtures, and for the rate of reaction of diazoacetic ester with phenol, catalyzed by these acids.

2. Materials

Unless otherwise stated, the products used were of "zur Analyse" grade from Merck or Kahlbaum.

Benzene was allowed to stand for periods ranging from two weeks to several months over phosphorus pentoxide, and was finally refluxed and distilled over fresh phosphorus pentoxide in an all-glass apparatus. It was stored in a container protected by mercury seals and phosphorus pentoxide tubes, and when making up a solution only dried air came in contact with the solution and the stock of benzene. All solutions when made were kept in a desiccator.

Monochloroacetic acid was recrystallized from pure benzene, and dried in vacuo over sulfuric acid.

Dichloroacetic acid was redistilled, and the fraction boiling at 191–192.5° was used.

α,β-Dibromopropionic acid was recrystallized from ligroin, and dried in vacuo over sulfuric acid.

α-Bromopropionic acid was purified by partial freezing, and dried in vacuo over sulfuric acid.

---

[13] V. Halban, Z. *Elektrochem.*, 29,434 (1923).

Iodoacetic acid was prepared by the method of Abderhalden and Guggenheim.[14] It was recrystallized from a mixture of one volume of benzene and six volumes of ligroin, and dried in vacuo over sulfuric acid, The acid and its solutions were kept in the dark.

Nitroacetic acid was prepared according to the directions given by Steinkopf[15] and Pedersen.[16] It was recrystallized from chloroform. Only freshly made samples were used.

Formic and picric acids were used without further purification.

Phenol was dried in vacuo over sulfuric acid and kept in the dark.

A test of the purity of the acids was afforded by titration of the stock solutions, which were prepared from weighed amounts of acid. The figures thus obtained corresponded to a purity of 99% or better.

Diazoacetic ester was prepared from a 20% alcoholic solution. The alcohol was removed by standing in a vacuum desiccator over sulfuric acid until the weight had fallen to 5% of its original value. The purity of the product thus obtained was tested by measuring the volume of nitrogen evolved when a weighed amount of the ester reacted in a $N/20$ aqueous solution of perchloric acid. The values obtained for various samples ranged between *97.8* and *99.1%* purity. A further check on the purity, which also served as a test of the simple nature of the reaction between diazoacetic ester and monochloroacetic acid, was as follows. A weighed amount of ester was allowed to react with a known excess of monochloroacetic acid in benzene at room temperature. After standing for some weeks (it being known from kinetic measurements that this period corresponded to practically complete reaction), the solution was poured into water and the residual monochloroacetic acid immediately titrated with alkali. The values obtained for the amount of acid which had reacted were 95–98% of the values calculated from the weight of ester taken.

The ester was not kept as such, but was immediately dissolved in **pure** benzene to give a stock solution about $N/10$ volume normally. These solutions were perfectly stable over long periods, as was shown by the fact that the volume of nitrogen obtained **from** a given amount of solution remained appreciably constant for at least several months.

3. Measurements

The reactions were followed by measuring the pressure of the nitrogen evolved in a closed system. The apparatus used is shown in Fig. 1. The reacting solution (volume 20 cc.) was contained in the flask **A** (volume 40 cc.) which was in a thermostat at 15 ± 0.01°. The flask was shaken to and fro mechanically with an amplitude of about 2 cm., and the rate of shaking was maintained constant by a centrifugal regulator. It was connected by the flexible glass tubing B to the mercury manometer C. The reaction flask was closed by an unlubricated ground cap D, sealed with mercury, and the vacuum side of the manometer by a mercury seal E. At F was a porous plug of gypsum, as described by Prytz.[17] The tube G served to introduce mercury into the manometer, and was afterward sealed off.

The method of carrying out an experiment was as follows. The required

acid solution was introduced into A by means of pipets protected by calcium chloride tubes, standard solutions of known strength being employed. The diazoacetic ester solution was introduced by a small pipet, D immediately closed, the shaking started, and the apparatus evacuated through H for two to four minutes with a good water suction pump, the taps J and K being open. (On account of the high vapor pressure of benzene, the use of a better pump is unnecessary at this stage.) J and K were then closed and the mercury caused to rise in the manometer by introducing a little air through F. This was effected by pushing a small plug of cotton wool (which contains sufficient air entangled) through the mercury above F, and pressing it upon the upper surface of the gypsum. J and K were then opened, and the right-hand side of the manometer evacuated with a Cenco Hyvac oil-pump. Finally, J was closed and mercury allowed to rise in the seal E by admitting a little air through K.

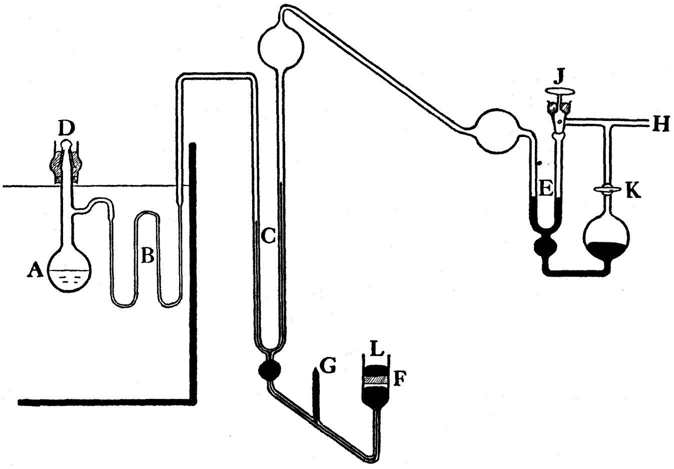

Fig. 1.

The apparatuses were mounted in pairs on a common shaking mechanism. The pressure was measured at intervals by reading the heights in the two manometer limbs, correct to 0.01 cm., using small lenses. The total pressure change for the reaction of 0.0002 gram molecule of ester was about 48 mm. of mercury.

The chief possibility of a systematic error in the results lies in the presence of dissolved gases in the benzene solutions which are probably not completely removed by the short period of evacuation employed. This probably accounts for an occasional irregularity observed in the first few readings, but a steady state appeared to be rapidly reached. A longer period of evacuation is inadvisable, owing to the possibility of appreciable alteration in the concentration of the solutions by the evaporation of benzene. The mutual concordance of the results obtained with periods of evacuation varying from two to four minutes shows that no appreciable error from this source is present. Since the vapor pressure of benzene at 15° changes by about 3 mm. for 1° temperature change, temperature fluctuations of more than 0.03° will affect the manometer reading. A control of ±0.01° is therefore adequate.

4. Calculation of Velocity Constants

All concentrations are expressed as gram formula weights per liter of solution at 15°. The concentration of ester present in most experiments was 0.0075-0.011 N. In a few experiments with acid concentrations less than 0.1 N, the ester concentration was about 0.005 N, and in the experiments with the two most dilute solutions of dichloroacetic acid, about 0.0025 N. Thus the ester concentration was in no case more than 8% of that of the other reactant, and in most cases considerably less, so that the course of an experiment may be expected to follow fairly closely the monomolecular law. This was in fact found to be the case, and all velocity constants given have been calculated by the method of Guggenheim.[18] In three experiments with monochloroacetic acid, an end-point was measured experimentally and used to calculate the constants in the usual manner. The same values were obtained as by Guggenheim's method. The number of readings taken in one experiment was 40–60. In calculating the constant decadic logarithms were used, *i. e.*, the constants given in the tables are

$$k_1 = \frac{d \log_{10} c}{dt}$$

the unit of time being the minute.

5. Results for Carboxylic Acids

The acids which were studied over a large range of concentrations were monochloroacetic, dichloroacetic, α,β-dibromopropionic and α-bromopropionic. Most experiments employed benzene purified as described above, but a few, marked *, were made with Merck's benzene "zur Analyse," which had not been further treated. No difference was detectable between the two sets of results.

Since the concentration of acid never changed by more than 8% during the course of the experiment, and usually by much less, we have taken the monomolecular velocity constant (k_1) to refer to the mean of the initial and final concentrations of acid (c).

It is at once obvious from the figures that in no case is the reaction velocity even approximately proportional to the concentration of acid. As may be seen from Figs. 2 and 3, the velocity in the range of concentrations considered is more nearly proportional to the square of the concentra-

tion, and we have found that the results are expressed within the experimental error by equations of the form

$$k_1 = \alpha c^2 + \beta c \qquad (4)$$

where a and β are constants for each acid. The only exceptions to this relation are the results for the two most dilute solutions of dibromopropionic acid, which do not agree with the equation representing the remainder of the results for this acid. The values of a and @ in equation (4) were determined by plotting k_1/c against c and measuring the slope and intercept of the straight line thus obtained. The values are as given in Table II.

It has previously been found by Nernst and Hohmann[19] that the re-

action velocity of amylene with various carboxylic acids in both amylene and benzene solutions is also proportional to the square of the acid concentration. They explain this relation by assuming that the velocity is proportional to the concentration of double molecules, which are in equilibrium with a much greater concentration of single molecules. It is doubtful whether this view is correct for amylene solutions and it is certainly untenable both for the benzene solutions employed by Nernst and Hohmann, and for those studied in the present work, since cryoscopic molecular weight determinations show the acids to be present almost entirely as double molecules at the concentrations concerned.[20] We must therefore conclude that the reaction with diazoacetic ester (and probably also with amylene) is kinetically of the second order with respect to the double molecules, which may thus be said to catalyze their own reaction. This conception is further supported by the results given later for the reaction of mixtures of acids.

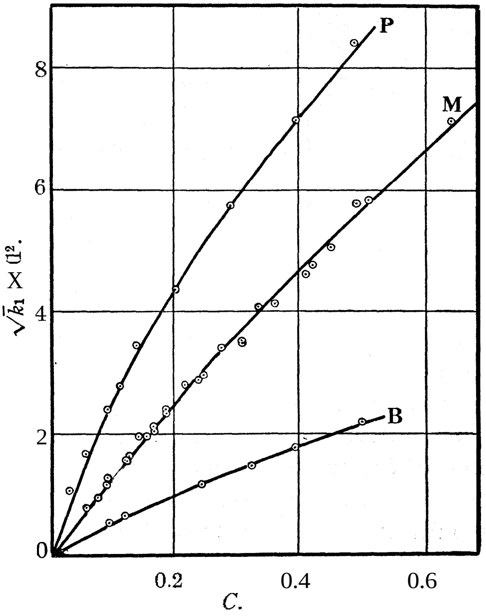

Fig. 2.—B, α-bromopropionic acid; M, monochloroacetic acid; P, α,β-dibromopropionic acid.

Goldschmidt has previously found[21] that the reaction of carboxylic acids with aniline to give anilides in aniline solution is of the second order with respect to the acid, and has termed these reactions "autocatalytic." In the case of aniline as a solvent the state of affairs may be more complex than in benzene solutions, owing to the formation of the anilinium ion,

which may have catalytic properties. The same applies to the self-esterification of di- and trichloroacetic acids in alcohol solution, which has also been found by Goldschmidt[22] to be a second order reaction, though in this case it seems probable that the catalytic agent is the acid molecule itself, since the addition of di- and trichloroacetates causes but little diminution in catalytic power.

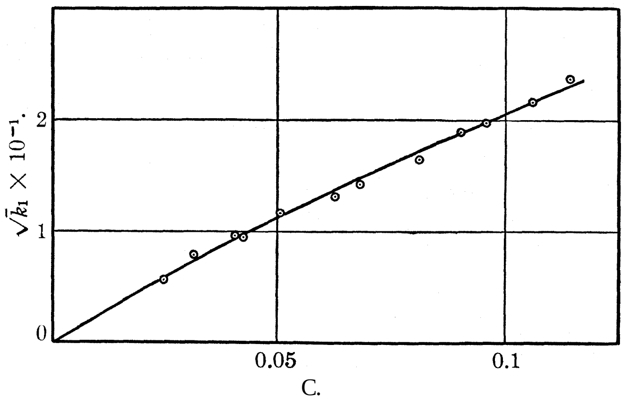

Fig. 3.—Dichloroacetic acid.

If the partial conversion of double molecules into single molecules leads to an increase in reaction velocity, we have a qualitative explanation of the form of equation (4), though it is impossible at present to give a fully quantitative interpretation. In the presence of two species of acid molecules there are theoretically four possible catalytic reactions, two of which are practically indistinguishable. On this basis of classical kinetics we should expect the total velocity to be given by an equation of the type

$$k_1 = a_1[(\mathrm{HA})_2]^2 + a_2[\mathrm{HA}]^2 + a_3[\mathrm{HA}][(\mathrm{HA})_2] \qquad (5)$$

where a_1, a_2 and a_3 are constants. For small concentrations of such molecules and values of a_1, % and a_3 of the same order of magnitude the member containing a_2 would tend to vanish. The experimental accuracy is however not sufficient to make the equation thus appearing distinguishable from equation (4). It is possible that the lack of agreement with equation (4) shown by the two most dilute solutions of α,β-dibromopropionic acid is due to the fact that a considerable fraction of the acid is present as single molecules. (Cryoscopic measurements show[20] that this acid is much less completely associated than monochloroacetic acid at the same concentrations.)

If the equilibrium between double and single molecules can be expressed by the simple mass law equation

$$\frac{[\mathrm{HA}]^2}{[(\mathrm{HA})_2]} = K \qquad (6)$$

---

[22] Goldschmidt, *Ber.*, 29, 2212 (1896); *Z. Elektrochem.*, 15, 4 (1909); *cf.* also Michael and Wolgast, *Ber.*, 42, 3161 (1909); Kailan, *Monatsh.*, 29, 805 (1908).

we have for nearly complete association

$$[\mathrm{HA}] = \sqrt{\frac{Kc}{2}} \qquad [(\mathrm{HA})_2] = \frac{c}{2}$$

and equation (6) becomes

$$k_1 = \frac{a_1}{4}c^2 + \frac{a_2}{2}Kc + \frac{a_3}{2}\sqrt{\frac{K}{2}}\,c^{3/2} \tag{7}$$

What evidence there is, however, goes to show that equation (6) does not hold for carboxylic acids in inert solvents: in other words that the mass action law is not strictly applicable for such solutions. Previous attempts to calculate an association "constant" have not been successful[23] and calculations on the basis of the cryoscopic data of Peterson and Rodebush[24] for very dilute benzene solutions of acetic acid give no constant value for K in equation (7). The results of partition experiments are often quoted as evidence for a simple mass law equilibrium between single and double molecules but it has been found by Szyszkowski[25] that the presence of hydrated molecules invalidates the usual treatment of these results, and it has been recently shown[26] that Szyszkowski's method of correcting this treatment is based on false assumptions.

There is, however, nothing very surprising in the failure of such solutions to obey the gas laws. It seems to be the general view that such deviations are principally confined to ionic solutions, where they are caused by interionic forces. It is necessary, however, also to take into consideration the interaction of dipole fields, which in solvents of low dielectric constant are considerable and can lead to departures from simple behavior in just the same manner as interionic forces. In the case of a dipole gas, the magnitude of this effect has been evaluated quantitatively by Falkenhagen[27] and shown to agree with experiment for several gases. In benzene solution one would expect the double molecule to be more "normal" than the single molecule and thus the constant K to increase with increasing dilution. Recent work of Briegleb,[28] however, seems to show that not only the single carboxylic acid molecules, but also the double ones, have fairly large dipole moments, which introduces some uncertainty in the above conclusion.

Side by side with this departure from simple thermodynamic behavior, we must also anticipate a kinetic "dipole effect" (analogously to kinetic salt effect), so that the constants a_1, a_2 and a_3 of equation (6) are probably not strictly constant over a large range of concentrations. An example

of this type of effect is afforded by the results of Bugarsky[29] on the velocity of the reaction between alcohol and bromine in inert solvents. Bugarsky interprets the abnormalities observed by assuming an equilibrium between double and single alcohol molecules governed by the mass, only the double molecules reacting with bromine. Apart from the improbability of the last assumption, cryoscopic measurements show that the activity coefficient of alcohol in inert solvents changes in a manner which cannot be explained by the simple equilibrium

$$2C_2H_5OH \rightleftharpoons (C_2H_5OH)_2$$

and it seems more reasonable to consider such solutions as containing only single molecules, which show an abnormal thermodynamic behavior owing to the strong inter-dipole forces. Bugarsky's results then appear as a consequence of the corresponding kinetic abnormality of these molecules.

These considerations of deviations from simple behavior leave unaffected the main conclusions, *i.* e., (a) that the reaction is mainly a second order reaction involving two double molecules, and (b) that the values of α in equation (4) and Table II represent at least approximately the specific reaction velocities of the double molecules.

It may be noted that the values of α increase in the same order as the electrolytic dissociation constants in water.

6. Results for Picric Acid

These results are given separately in Table III, since they differ fundamentally from those for the carboxylic acids.

TABLE III

RESULTS FOR PICRIC ACID

c	0.068	0.083	0.104	0.136
$k_1 \times 10^5$	2.93	3.68	5.33	6.60

Owing to the limited solubility of picric acid, it was not possible to study more concentrated solutions. The results are plotted in Fig. 4, from which it is seen that the reaction velocity is directly proportional to the concentration, not to its square. Picric acid also differs from the carboxylic acids in not forming double molecules, but it is strange that such a strong acid should not show "self-catalysis," particularly as it will be shown later that it is capable of catalyzing the reactions of monochloroacetic acid and of phenol with the ester. It is of course possible that a catalyzed reaction is present with picric acid alone, but is obscured by a faster non-catalyzed reaction.

7. Results for Mixtures of Acids

If two different acids are present together in the same solution, we have the added possibility of what one may term a cross-catalysis, *i.* e., that each

---

[29] Bugarsky, *Z. physik. Chem.*, 71, 705 (1910).

acid may catalyze the reaction of the other. Thus if the molecules of each acid remain unchanged by mixing, we should expect a total reaction velocity greater than the sum of velocities for the two acids when present separately at the same concentrations. Actually we must anticipate, in the case of the carboxylic acids, the formation of a new species of complex double molecules (cf. Szyszkowski's results on the solubility of mixtures of acids in benzene).[25] Since the number of possible catalytic reactions is thus still further increased, this will in general give rise to a further increase of reaction velocity, though it may in some cases give a decrease if the two acids concerned have very widely differing reactivities, but are present in comparable amounts.

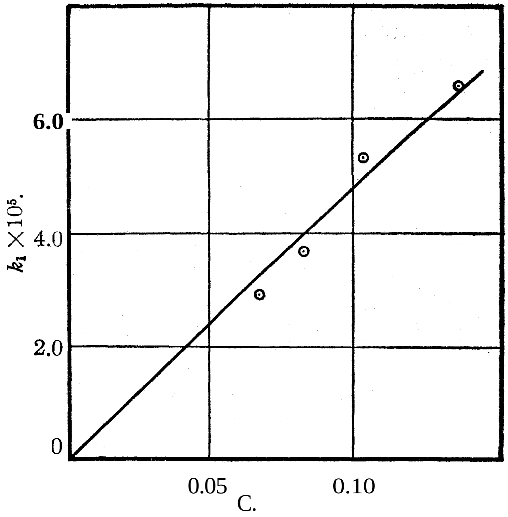

Fig. 4.—Picric acid.

The experimental results for acid mixtures are given in Table IV. As for single acids, the concentrations given are the mean of the initial and final concentrations, the latter differing at the most by a few per cent.

.298	.0950	.0284	17.38	11.96	.45	4.97

For the three acid pairs (d), (f) and (g) an increase of velocity is found, and it is seen from Figs. 5 and 6 that this increase is roughly proportional to the product of the acid concentrations, as would be expected if the effects of cross-association can be neglected. For the acid pairs (a) and (e) the effect is a reduction. For this last pair, dichloroacetic and α-bromopropionic acids, the dichloroacetic acid concentration was the same in each experiment, and in Fig. 7 the percentage reduction is plotted against the concentration of a-bromopropionic acid. It is seen that at high concentrations the reduction tends to a constant value. Since the velocity attributable to the reaction of the a-bromopropionic acid is only a small fraction of the total velocity, this constant value can be interpreted as corresponding to a total conversion of dichloroacetic acid molecules into complex double molecules. For the acid pairs (b) and (c), the effect observed is small, and is probably compounded of both the above influences.

8. Acid Catalysis in the Reaction of Alcohol and Phenol

When the two acids react simultaneously with diazoacetic ester, it is impossible from measurements of the nitrogen evolved to deduce the velocities of the separate reactions involved. Such measurements cannot therefore be used to compare the catalytic activities of different acids for the same reaction. This may however be possible if we can find a suitable substance of low acidity whose reaction with the ester is catalyzed by acids. The catalyzing acid will itself react simultaneously but this can be corrected for on the assumption that its reaction velocity is unaffected by the presence of the second substance.

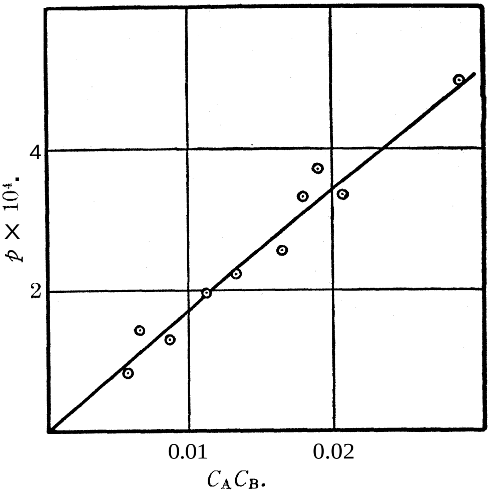

Fig. 5.—Monochloroacetic + picric acids.

The first substance tried was ethyl alcohol, which is known to react according to the equation

$$CHN_2COOC_2H_5 + C_2H_5OH \longrightarrow C_2H_5OCH_2COOC_2H_5 + N_2$$

which reaction is catalyzed by solvated hydrogen ions in aqueous and alcoholic solutions. Experiments in benzene solution with mixtures of mono-

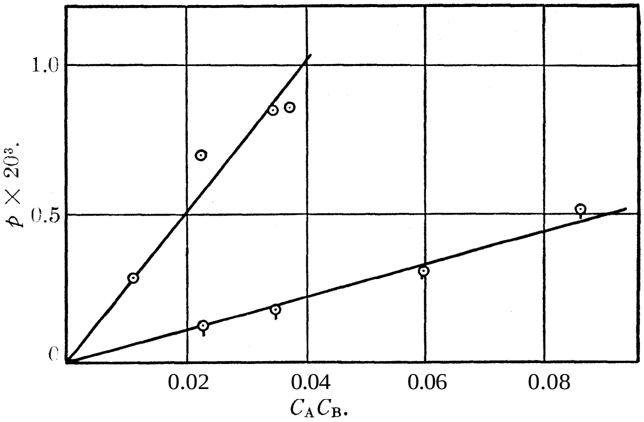

Fig. 6.—⊙, α,β-Dibromopropionic + monochloroacetic acids; ♀, monochloroacetic + a-bromopropionic acids.

chloroacetic acid and alcohol showed, however, that alcohol caused a very large decrease in velocity instead of the expected increase. The figures given in Table V were obtained.

TABLE V

c_1 = concentration of monochloroacetic acid; c_2 = concentration of alcohol

c_1	0.220	0.220	0.220
c_2	0	0.685	1.10
$k_1 \times 10^5$	67.0	2.6	1.3

There is thus present some complicating effect, possibly due to association of the alcohol and acid molecules.

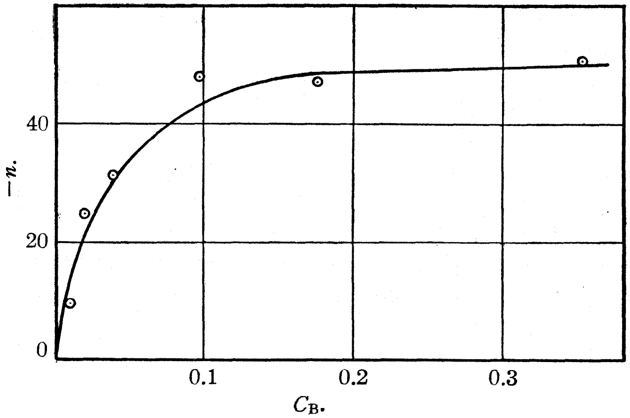

Fig. 7.—Dichloroacetic + α-bromopropionic acids.

A few experiments were also carried out to test whether the presence of small quantities of water would have any appreciable effect on the results obtained (Table VI).

TABLE VI

c_1 = concentration of acid; c_2 = concentration of water; k_1' = velocity constant in absence of water

Monochloroacetic Acid

c_1	c_2	$k_1 \times 10^4$	$k_1' \times 10^4$
0.141	0.043	3.92	3.03
.184	.056	5.70	5.50

Dichloroacetic Acid

c_1	c_2	$k_1 \times 10^4$	$k_1' \times 10^4$
0.0524	0.043	95.4	135

It is seen that the effect is sometimes positive and sometimes negative, but that it is small enough to exclude any uncertainty in the experimental results due to the presence of traces of water.

With benzene solutions of picric acid, however, the addition of alcohol gives rise to an increase in velocity, which must be attributed to the reaction of alcohol with the ester. The results are given in Table VII, the concentrations being as usual the mean of the initial and final values.

TABLE VII

c_A = concentration of picric acid; c_B = concentration of alcohol; k_1 = observed velocity constant, k_A = velocity constant for picric acid alone; $p = k_1 - k_A$

c_A	c_B	$k_1 \times 10^4$	$k_A \times 10^4$	$p \times 10^4$	c_Ac_B
0.0495	0.685	1.94	0.24	1.70	0.0344
.070	.685	2.70	.33	2.37	.0480
.105	.685	3.80	.50	3.30	.0719
.140	.685	5.60	.67	4.93	.0960
.140	1.03	8.40	.67	7.73	.144

It is seen from Fig. 8 that p is directly proportional to c_Ac_B, which is what we should expect for the catalyzed reaction of the alcohol. A single experiment with picric acid + butyl alcohol gave an increase almost identical with that for ethyl alcohol.

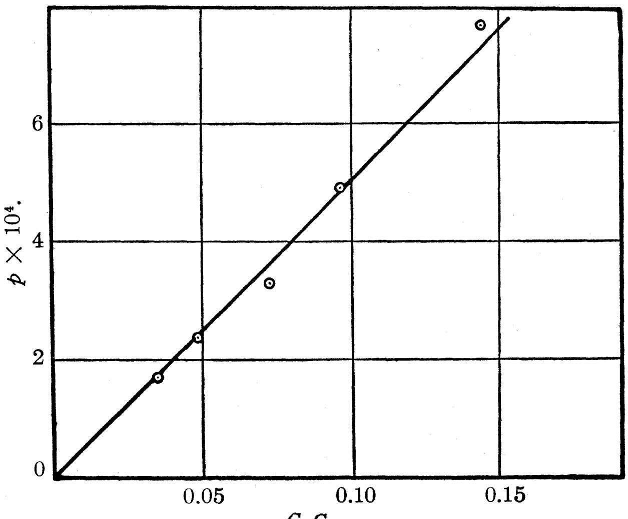

Fig. 8.—Picric acid + ethyl alcohol.

The addition of phenol was next tried, and was found to give an increase of velocity with all the acids studied. This increase we attribute to the reaction

$$CHN_2COOC_2H_5 + C_6H_5OH \longrightarrow C_6H_5OCH_2COOC_2H_5 + N_2 \qquad (8)$$

catalyzed by the acid present. We have not been able to find any reference to the formation of phenoxyacetic ethyl ester by this reaction, but the corresponding reaction of diazomethane

$$CH_2N_2 + C_6H_5OH \longrightarrow C_6H_5OCH_3 + N_2$$

takes place readily. Since phenoxyacetic ester is a liquid boiling at 250°, and will be accompanied by the products of reaction of the acid itself (which are not reported in Beilstein, but which probably have similar boiling points), we have not attempted to isolate the products of reaction. The chief evidence that the increase of velocity is due to reaction (8) is afforded by the kinetic measurements themselves.

Preliminary experiments showed that phenol alone gave no measurable reaction with diazoacetic ester in benzene solution. The most extensive experiments were carried out with monochloroacetic acid, and are given in Table VIII. The concentrations of both phenol and acid are the mean of initial and final concentrations differing by, at the most, a few per cent.

TABLE VIII

c_A = concentration of acid; c_B = concentration of phenol; k_1 = observed velocity constant; k_A = calculated velocity constant for acid alone; $p = k_1 - k_A$

Monochloroacetic Acid (A) + Phenol (B)

c_A	c_B	$k_1 \times 10^4$	$k_A \times 10^4$	$p \times 10^4$	c_Ac_B
0.216	0.085	7.90	6.57	1.33	0.0184
.0778	.426	2.02	0.96	1.06	.0331
.0930	.426	3.02	1.46	1.56	.0396
.217	.256	9.50	6.60	2.90	.0555
.155	.426	6.21	3.46	2.75	.0660
.217	.426	10.90	6.70	4.20	.0924
.218	.597	12.90	6.63	6.27	.130
.312	.426	19.65	12.76	6.89	.133

It is seen from Fig. 9 that the velocity of the catalyzed reaction can be represented by the equation

$$p = lc_Ac_B \tag{9}$$

where "l" is a constant. For the same reasons as those given in section (5), we must conclude that "l" is at least approximately the catalytic constant for the double monochloroacetic molecule. "Medium effects" and effects due to the presence of single molecules cannot be detected within the limits of accuracy obtained. A single experiment with o-chlorophenol + monochloroacetic acid gave a value of p only slightly greater than with phenol.

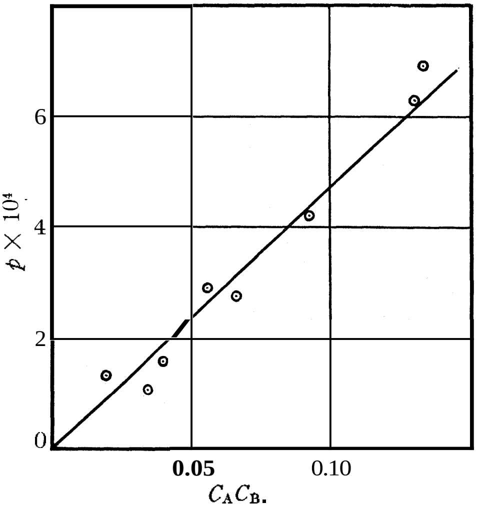

Fig. 9.—Monochloroacetic acid + phenol.

We have not tested equation (9) extensively for any other acids, but have preferred to carry out a few experiments for a number of different acids, and to calculate the values of "l" assuming equation (9) to hold. Even if the values so obtained are only provisional, a comparison for acids of widely varying strength is of great interest. Table IX contains such results, the notation being the same as that employed in Table VIII.

For α,β-dibromopropionic acid the values of k_A are obtained from the curve in Fig. 2. For iodoacetic and formic acids these values were obtained by carrying out an experiment without phenol. For these two acids approximate values have been calculated for the specific reaction velocities of the double molecules α by assuming that

$$k_A = \alpha c_A^2 \tag{10}$$

TABLE IX

Iodoacetic Acid (A) + Phenol (B)

.106	.426	9.03	5.04	3.99	.0452

$l = 8.4 \times 10^{-4}$

With dichloroacetic acid it was found that the addition of phenol to solutions of 0.05–0.1 normality caused no measurable change of velocity. However, by decreasing the acid concentration greatly, while keeping the phenol concentration fairly high, the phenol reaction became the predominant one, as was shown by the fact that the course of these reactions was strictly monomolecular, in spite of the fact that the acid concentration was smaller than that of the ester. Experiments were carried out with constant acid concentration and varying phenol concentration, and the total reaction velocity plotted against c_Ac_B. The slope of the best straight line thus obtained was taken as the catalytic constant.

A similar procedure was adopted for nitroacetic acid, which is too little soluble in benzene to measure at high concentrations (Table X).

TABLE X

Dichloroacetic Acid (A) + Phenol (B)

c_A	c_B	$k_1 \times 10^5$	$c_Ac_B \times 10^4$
0.00204	0.171	9.1	3.49

.00720	.426	25.2	3.07
.00720	.426	18.8	3.07

$l = 5.8 \times 10^{-2}$

In Table XI are collected for each acid the values of α, the specific reactivity of the double molecules, l, the catalytic constant, and K_d, the electrolytic dissociation constant in aqueous solution. Unless a reference is given, the values of this last constant are taken from Landolt–Bornstein "Tabellen" (5th Auflage and Erster Ergänzungsband). The values of α marked * are only approximate, being taken from Table IX and equation (10).

TABLE XI

VALUES OF CONSTANTS

Acid	a	1	$\log_{10} l$	K_{dl}	$\log_{10} K_{dl}$.
Formic	8.0 X 10^{-3}*	1 6 X 10^{-3}	$\bar{3}$ 204	1.77 X 10^{-4}	$\bar{4}$ 248[30]
Iodoacetic	2 0 × 10^{-3}*	1 4 X 10^{-3}	$\bar{3}$ 146	7.5 X 10^{-4}	$\bar{4}$.875
a-Bromopropionic	1 58 × 10^{-3}	.....	...	1.08 × 10^{-3}	$\bar{3}$033
Monochloroacetic	1 20 X 10^{-2}	4 7 X 10^{-3}	$\bar{3}$.672	1.41 X 10^{-3}	$\bar{3}$ 149[31]
α,β-Dibromopropionic	2.35 X 10^{-2}	8 5 X 10^{-3}	$\bar{3}$.929	6.7 X 10^{-3}	$\bar{3}$.826
Nitroacetic	. ...	5.8 X 10^{-2}	$\bar{2}$.763	2.1 X 10^{-2}	$\bar{2}$.322[32]
Dichloroacetic	3 34	1.0 X 10^{-1}	$\bar{1}$.000	5 X 10^{-2}	$\bar{2}$.700
(Picric	....	8 4 X 10^{-4}	...	1.6 X 10^{-1})	.....

It appears from Fig. 10 that there is an approximate agreement with the reaction previously derived[33]

$$l = G_1K_d^x \qquad (11)$$

---

[30] Harned and Owen, THIS JOURNAL, 52,5079 (1930).

[31] Grove, *ibid.*, 52, 1405 (1930).

[32] Pedersen, *Trans.* Faraday *Soc.*, 23, 316 (1927).

[33] Bronsted, Chem. *Rev.*, 5,312 (1928).

which has been shown to hold in aqueous solution in several cases.[34] In this case the exponent x has the value approximately unity. It must be remarked that while the catalytic constants refer to double acid molecules, the dissociation constants refer to single ones. This may explain why the catalytic value for picric acid (which exists as single molecules in benzene solutions) is very much lower than that predicted from equation (11), though we should expect the catalytic constants of the single carboxylic acid molecules to be still higher than those of the double ones. It is more probable that the abnormality of picric acid in this respect is connected with the fact that in a solvent of low dielectric constant the influence of the rest of the acid molecule will be much greater than in water, and thus equation (11) may only hold for acids of the same chemical type. It may be significant in this connection that for the carboxylic acids, the widest deviations are shown by formic and α,β-dibromopropionic acids, while the four substituted acetic acids show good mutual agreement.

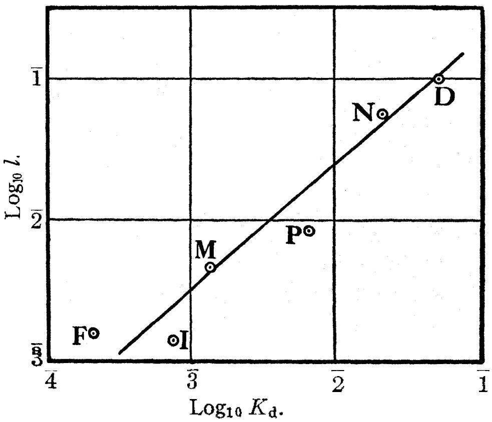

Fig. 10.—F, Formic; I, iodoacetic; M, monochloroacetic; P, α,β-dibromopropionic; N, nitroacetic; D, dichloroacetic.

According to modern views of the acid–base function, the cation of a weak base such as pyridine is also an acid, and we should anticipate that such ions would show catalysis in the reaction of phenol with diazoacetic ester. It was found, however, that a 0.0225 N solution of pyridinium trichloroacetate showed no measurable catalytic effect. It is possible that this represents an extreme case of the influence of electric type in solvents of low dielectric constant.

Summary

1. This paper contains a kinetic study of the reaction of diazoacetic ethyl ester with several substances in benzene solution. The reactions were followed by measuring the pressure of the nitrogen evolved.

2. In solutions of one or more carboxylic acids, the reaction consists of the replacement of the N_2 group by an acid molecule. The velocity of the reactions was found to be expressible by the equation

$$k_1 = \alpha c^2 + \beta c$$

---

[34] Bronsted and Pedersen, *Z. physik. Chem.*, 108, 13 (1924); Rronsted and Duus, *ibid.*, **117**, 229 (1925); Bronsted and Guggenheim, THIS JOURNAL, 49, 2554 (1927); Bronsted and Wynne-Jones, *Trans. Faraday Soc.*, **25**, 59 (1929).

c being the concentration of the acid, and α and β constants characteristic for the individual acids. The velocity increases with increasing acid strength.

This empirical equation is compatible with the assumption that the addition of an acid molecule is catalyzed by the presence of acid molecules of the same or different kind, taking into account the progressive dissociation of double acid molecules into single molecules as the dilution increases. The reaction can be considered as a case of general acid catalysis.

3. The velocity of addition of picric acid is directly proportional to its concentration.

4. The velocity of addition of phenol to diazoacetic ester is strongly catalyzed by the presence of carboxylic acids, the catalytic effect increasing with increasing acid strength. The equation

$$l = GK^x$$

which has previously been shown to hold true for general acid catalysis in aqueous solution also applies approximately in the presence case, the exponent x having the limiting value of unity. Picric acid is much less active than required by the above equation.

THE DETERMINATION OF CALCIUM BY ALKALIMETRIC TITRATION. I

BY CYRUS H. FISKE AND ELLIOTT T. ADAMS

RECEIVED MARCH 24, 1931 PUBLISHED JULY 8, 1931

Among the possible volumetric methods for the determination of small amounts of calcium, after precipitation as the oxalate, alkalimetric titration of the oxide should have certain definite advantages over oxidation with permanganate, which is now used almost exclusively for this purpose. The end-point in the titration of pure calcium oxide is so sharp that, if no errors are introduced in the precipitation and washing of the calcium oxalate or in its subsequent conversion to the oxide, a method based upon this principle should be accurate to 0.002 mg. of calcium. The permanganate titration method, on the other hand, according to the most extensive investigation so far published,[1] is subject to an error of 0.006–0.008 mg. in the analysis of samples containing between 0.2 and 0.5 mg. of calcium.

Of the various objections that have been raised against the determination of small amounts of calcium by permanganate oxidation of the oxalate precipitate, only two appear to be of much importance. These are (1) the fact that the precipitate must be washed with water (or dilute ammonia), in which its solubility is appreciable, and (2) the mechanical loss involved in centrifuging the calcium oxalate, which except perhaps in

---

[1] Van Slyke and Sendroy, *J. Biol. Chem.*, 84, 217 (1929).

the case of fluids containing protein tends to float on the surface of the liquid. The necessity of washing with a liquid in which the precipitate is noticeably soluble has led to the introduction of a wide variety of empirical procedures which, whether by design or not, tend to compensate for the loss of calcium oxalate by leaving behind a little of the precipitating agent,[2] but methods in which the balancing of errors is so large a factor can hardly be expected to give identical results in the hands of every analyst. The mechanical loss of calcium oxalate can be avoided to a large extent by removing the supernatant fluid with a siphon, but apparently this device does not in practice lead to greater accuracy, probably because it is incompatible with the use of strictly uniform technique in washing the precipitate.

In the determination of calcium by titration of the oxide it is possible to avoid the weak points of the permanganate procedure and at the same time to retain the features of the standard gravimetric methods upon which their accuracy rests: *viz.*, (1) separation of the calcium oxalate by filtration, and (2) washing with ammonium oxalate solution, in which the solubility of the precipitate is practically nil. Jansen[3] has proposed a method of this kind for quantities of calcium in the neighborhood of 1 mg., but reports errors of at least 0.008 mg. in the analysis of known solutions. In other hands this method has given still less satisfactory results,[4] and is now rarely used. It is not in the ordinary sense a micro method, but a combination of standard textbook procedures designed for the analysis of samples containing 50 or 100 mg. of calcium and used without essential modification for the determination of much smaller quantities. The filter paper, for example, is out of all proportion to the size of the precipitate, and its presence materially complicates the subsequent steps of the analysis.[5]

Suction filtration on a small mat of paper pulp[6] is one way in which this defect might be overcome. Some risk of loss, however, is involved in the transfer of a very small precipitate from a filter of this type, by purely mechanical means, to the platinum dish in which it is to be ignited. The

---

[4] *Cf.* Heubner and Rona, *Biochem.* Z., 135,248 (1923).

[5] Ignition of the calcium oxalate to carbonate has likewise been suggested, as a means whereby the precipitate may be separated by centrifugation, and the ignition and titration subsequently carried out without transferring the material [Lebermann, *Munch. med. Wochenschrift,* 71, 1392 (1924); Trevan and Bainbridge, *Biochem.* **J.**, 20, 423 (1926)]. The objections to centrifugation, already mentioned, limit the usefulness of this procedure. Furthermore, the difficulty of dissolving the carbonate in hydrochloric acid is so great that Trevan and Bainbridge recommend phosphoric acid in its place, and hence are forced to use an end-point which is by no means sharp. Hendriks, who appears to have subjected this method to a much closer scrutiny than its originators, finds it far from accurate [*ibid.,* 23,1206 (1929)].

[6] See, for example, Fiske, J. *Biol. Chem.,* 46,288 (1921).

alternative procedure of transferring the precipitate dissolved in nitric acid has been tried repeatedly, but the results obtained by titrating the residue left after evaporating the nitric acid solution and igniting have not been satisfactory. Apparently the oxide formed by the decomposition of fused calcium nitrate is so compact that it will not dissolve readily in a moderate excess of standard acid, or else the product is not pure calcium oxide. In any event reconversion of the nitrate to oxalate before ignition is an effective remedy, which at the same time considerably diminishes the total time required for the analysis and brings the error regularly within the anticipated limit (Table I). If the dried calcium nitrate is evaporated with a few drops of a solution of oxalic acid, the oxide formed by ignition of the final residue is much less compact, and dissolves in the course of a few minutes even if the excess of acid added is not more than 0.1 cc. of 0.02 N. The undissolved particles of oxide are, moreover, intensely stained by the indicator (methyl red), so that no difficulty is experienced in deciding when solution is complete.

Experimental

Solutions of calcium nitrate were prepared by dissolving calcium carbonate (Kahlbaum's "zur Analyse") in a slight excess of nitric acid. Accurately measured samples of these solutions were evaporated to dryness on the water-bath in a small platinum dish. The dry calcium nitrate residue was treated with 0.5 cc. of *2.5%* oxalic acid (base-free), and the contents of the dish were again evaporated to dryness and then carefully ignited over a micro-burner. The cooled residue in each instance was dissolved in an excess of standard hydrochloric acid (0.02 or 0.1 *N*, according to the amount of calcium present), added 1 cc. at a time from a calibrated Ostwald pipet, and the solution was titrated back to the turning point of methyl red with 0.02 N sodium hydroxide (free from carbonate and silicate) from a calibrated micro-buret of 5 cc. capacity with 0.02 cc. graduations. Toward the end of the titration the alkali was added in 0.005 cc. portions.

TABLE I

TITRATION OF CALCIUM OXIDE

0.5 cc. of 2.5% **oxalic acid was used to convert the calcium nitrate to the** oxalate **before ignition.**

Calcium present, mg.	Calcium found, mg.	Error, %	Calcium present, mg.	Calcium found, mg.	Error, %
0.200	0.202	+1.0	1.000	1.000	0
0.200	0.198	−1.0	1.000	1.002	+0 2
0.200	0.198	−1.0	1.990	1.986	−0.2
1.000	1.000	0	1.990	1.990	0

Summary

A method is described for converting calcium nitrate to the oxide in a form which can be readily analyzed by alkalimetric titration. Since small

calcium oxalate precipitates, which have been separated by filtration and washed with ammonium oxalate solution, can thus be transferred to a platinum dish with the aid of nitric acid before conversion to the oxide, certain defects inherent in the customary perrnanganate oxidation methods can be avoided.

ADSORPTION BY SILICA FROM NON-AQUEOUS BINARY SYSTEMS OVER THE ENTIRE CONCENTRATION RANGE

BY F. E. BARTELL, G. H. SCHEFFLER AND C. K. SLOAN[1]

RECEIVED APRIL 2, 1931 PUBLISHED JULY 8, 1931

An interferometric method for measurement of adsorption by carbon from binary organic liquid systems was described in earlier papers from this Laboratory.[2] It was shown that, in every case investigated, the curve representing adsorption over the entire concentration range was S-shaped. The component having the higher adhesion tension against carbon was adsorbed to the greater extent. The component of lower adhesion tension was, however, preferentially adsorbed if present in sufficiently low concentration. An equation was derived which was based on the assumption that adsorption of each component of a binary liquid system follows the Freundlich equation. The equation $H\Delta x/m = ax^n(1 - x) - b(1 - x)^d x$ thus obtained was used to calculate the preferential adsorption over the concentration range.[3]

It is quite well known that carbon adsorbs better from aqueous solutions than from organic liquids, while silica adsorbs better from organic liquids.[4] Carbon has been shown to have a high adhesion tension against non-polar organic liquids and a relatively low adhesion tension against certain polar organic liquids and water;[5] the converse is true for silica.[6] From

[3] The symbols used in this paper are the same as those of earlier papers

H = total number of millimoles in the solution
x = mole fraction solute at equilibrium
Δx = mole fraction change due to adsorption
m = weight of adsorbent
c_0 = initial concentration
c = final concentration
Δc = change in concentration due to adsorption
N = total weight (in grams) of solution
a, n, d and b are constants

previous investigations in this Laboratory it has been shown that, other factors being equal, adsorption should be greatest from that liquid which has the lowest adhesion tension against a given solid adsorbent. This explains why adsorption by carbon should be greater from an aqueous solution, and why adsorption by silica should be greater from organic liquids. In the present work the interferometric method was used to determine concentration changes which occurred during the process of adsorption. Binary organic liquid systems were used with silica as the adsorbent. The results obtained are compared with those previously obtained with carbon. The experimental procedure employed was that described by Bartell and Sloan.[2]

Preparation of Silica.—The silica used was prepared by a method similar to that which had previously been used in this Laboratory.[7] A sodium silicate solution of 1.02 specific gravity was treated with concentrated hydrochloric acid in the presence of nickel nitrate. The silica gel thus formed was allowed to synerize slowly. The resulting brownish-black material was digested in conductivity water to remove nickel nitrate. This gel was then heated to 260° for two hours and again digested in conductivity water. After the nickel salt had been removed in this manner, the "silica gel" (about 15 g. per batch) was heated at 1000° for four minutes in order further to dehydrate it. At this stage the "silica" was perfectly white. It was next allowed to cool in dry nitrogen and then transferred to flasks also filled with dry nitrogen. A sufficient quantity of the "silica" was prepared to insure that uniform samples might be used throughout the course of the work.

Purification of Liquids.—Standard methods were employed for the purification of the liquids. Each liquid, after preliminary treatment, was distilled through a tall fractionating column with a large area of cooling surface. The middle fractions only were used. The liquid systems investigated were: (1) ethyl carbonate–benzene, (2) ethyl alcohol–benzene, (3) ethyl carbonate–dimethylaniline, and (4) ethyl carbonate–methyl benzoate.

Results

Adsorption from the System Ethyl Carbonate–Benzene.—The adsorption data obtained for this system when plotted give an S-shaped curve. This curve is shown in Fig. 1. Ethyl carbonate was preferentially adsorbed until a concentration of 0.68 mole fraction of it was reached. Beyond this concentration benzene was preferentially adsorbed. The values of the constants were determined by the method used by Bartell and Sloan.[2] The equation representing the adsorption over the entire concentration range for the above system is

$$H\Delta x/m = 7.603\,(x)^{0.574}(1 - x) - 8.1798(1 - x)^{0.982}\,(x)$$

Adsorption from the System Ethyl Alcohol–Benzene.—The results obtained with the system ethyl alcohol–benzene give an S-shaped curve, as shown in Fig. 2. Ethyl alcohol in this system is highly adsorbed at a low concentration of this component. Preferential adsorption of benzene is indicated at high alcohol concentrations.

The data obtained for the system alcohol–benzene are given in Table II. The equation representing the adsorption of this system is

$$H\Delta x/m = 8.8105\,(x)^{0.227}\,(1 - x) - 4.664\,(1 - x)^{0.615}\,(x)$$

For purposes of comparison, data obtained with carbon as an adsorbent[2] are plotted also in Fig. 2.

Adsorption from the System Ethyl Carbonate–Dimethylaniline.—In the system ethyl carbonate–dimethylaniline, preferential adsorption of each component is noted over some part of the concentration range.

in Table IV. The adsorption data obtained for this system are represented by the equation

$$H\Delta x/m = 0.8479(x)^{0.591}(1-x) - 0.1619(1-x)^{0.246}(x)$$

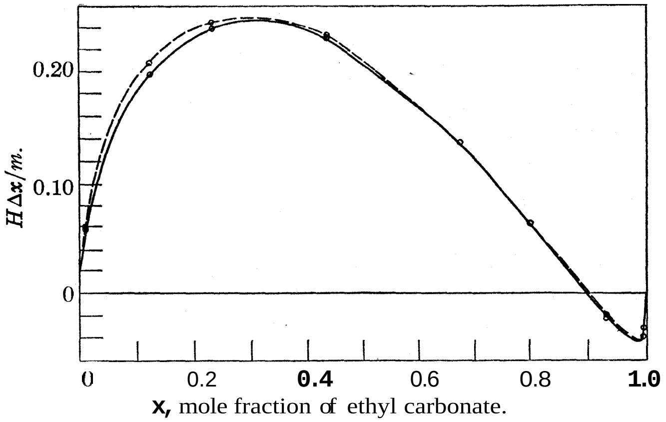

Fig. 4.—Experimental points, — — — — —; $0.8479(x)^{0.591}(1-x) - 0.1619(1-x)^{0.2462}(x)$, ————. Adsorption of ethyl carbonate from methyl benzoate.

Discussion

The interferometric method had previously been used for the determination of the extent of preferential adsorption by carbon, of the components of binary non-aqueous systems over the entire range of concentration.[2] In each case investigated an S-shaped adsorption curve was obtained.

It was noted that the component having the higher adhesion tension against the carbon was preferentially adsorbed over the greater portion of the concentration range.

In the present investigation the same method was employed for the measurement of concentration changes during adsorption, but in this work silica was used as the adsorbent. It was found, as in the earlier investigation, that the component having the higher adhesion tension against the solid was preferentially adsorbed over the greater portion of the concentration range.

In general, it may be stated that the order of increasing adhesion tension values of a series of liquids against carbon is the reverse of the order of increasing values against silica. It must accordingly follow that the order of decreasing interfacial tension values of a series of liquids against carbon is the reverse of the decreasing interfacial tension values of this series of liquids against silica. One would be justified in expecting that the adsorption effects obtained with carbon would be different, in fact, practically the reverse, of the effects obtained with silica. Our results indicate that if one obtains adsorption values for a binary liquid system over the concentration range for carbon, one can by means of the adsorption curve predict with a fair degree of accuracy the degree of preferential adsorption to be expected at the different concentrations, when silica is used as adsorbent. Each adsorbent will tend to give an S-shaped adsorption curve. The one curve will tend to be the inverted and reverse form of the other. In Fig. 2 are plotted curves showing preferential adsorption values for benzene and for ethyl alcohol adsorbed with carbon and with silica. When carbon was used as the adsorbent, the non-polar liquid benzene was much more highly adsorbed than was the polar liquid alcohol; also, benzene was preferentially adsorbed over the greater portion of the concentration range.[2] With silica as adsorbent, the alcohol was more highly adsorbed than was benzene and it was also preferentially adsorbed over a greater portion of the concentration range.

Zero preferential adsorption with carbon comes at a concentration of approximately 0.2 mole fraction of alcohol, and with silica at a concentration of approximately 0.82 mole fraction of alcohol. At zero preferential adsorption both components are adsorbed, but they are adsorbed in the same proportions as represented by the concentration of the bulk of the solution.

Summary

1. In a study of the adsorption by silica from non-aqueous binary systems over the entire concentration range the interferometric method was used to measure changes in concentration of solutions.
2. In each system investigated an S-shaped adsorption curve was obtained. Over some portion of the concentration range each of the components was preferentially adsorbed.
3. The adsorption curve obtained with silica as adsorbent is very nearly the inverted and reverse form of that obtained with carbon for the same binary liquid system.
4. That component having the higher adhesion tension against the solid is preferentially adsorbed over the greater portion of the concentration range.
5. The Freundlich equation when so modified as to express the measure of adsorption in terms of change in concentration, as

$$H\Delta x/m = ax^{*}(1 - x) - b(1 - x)^{d}x$$

was found to express the adsorption as determined over the entire range of concentration.

ADSORPTION BY SILICA AND CARBON FROM BINARY ORGANIC LIQUID MIXTURES OVER THE ENTIRE CONCENTRATION RANGE

BY F. E. BARTELL AND GEORGE H. SCHEFFLER[1]

RECEIVED APRIL 4, 1931 PUBLISHED JULY 8, 1931

Several different investigators have used different adsorbates, constituting an homologous series, in their studies of adsorption with silica.[2] A variety of solvents have been used in such work, but measurements

---

[1] The material presented in this paper is from a dissertation submitted by George H. Scheffler to the Graduate School of the University of Michigan, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1930. This paper was presented at a meeting of the Colloid Division of the American Chemical Society at Cincinnati, September, 1930.

[2] Bartell and Fu, *J. Phys. Chem.*, 33, 680 (1929); Holmes and McKelvey, *ibid.*, **32,** 1522 (1928); Th. Sabolitschka, *Pharm. Z.*, **74,** 382 (1929).

have been carried out only over a limited range of concentration. The adsorbate components have usually been the fatty acids, since for these the change in concentration due to adsorption can be determined by ordinary analytical methods.

In general the results have shown that, in the different homologous series studied, adsorption from an organic solvent is positive. This is to be expected as it is known that, other factors being equal, the greater adsorption is obtained of that component which has the higher adhesion tension against the adsorbent. The adhesion tension values of the fatty acids against silica are greater than are those of the solvents used. The fatty acids, accordingly, should be preferentially adsorbed. It has been found that for the fatty acid series the adsorption is decreased as the molecular weight of the fatty acid adsorbate is increased. Since the adhesion tension values of the different fatty acids against silica are similar, the difference in degrees of adsorption is probably due to the increasing solubility tendency of the adsorbate as its hydrocarbon chain is increased.

Because of the similarity in chemical constitution of the saturated monobasic alcohols and the fatty acids it seems reasonable to expect that the order of adsorption of an homologous series of the saturated monobasic alcohols by silica from benzene should be similar to that obtained for the fatty acids from benzene. The solubility tendencies of the alcohols in benzene should increase as their molecular weights increase. This tendency then should result in a lower adsorption of the higher alcohols from benzene.

If carbon be employed as the adsorbent for the alcohol systems instead of silica, the amount of adsorption of the alcohols should be much less, for the adhesion tension values of the alcohols against carbon are lower than the adhesion tension values against silica and, also, the adhesion tension values of the alcohols against carbon are lower than the adhesion tension of benzene against carbon. In fact, it should be expected that the preferential adsorption tendency with carbon, when considered for different concentrations extending over the entire concentration range, would be just about opposite to that with silica.

Neither volumetric nor gravimetric methods are suitable for measuring the changes in concentration of alcohols due to adsorption. Such changes were therefore measured by interferometric analysis. This method was found to be satisfactory for the determination of the slight concentration changes involved in the adsorption from the systems studied.[3] The accuracy of the method is high for the entire range of concentration.

Preparation of Materials.—The silica was prepared as described in a previous paper.[4] A large quantity was prepared in order that all the samples used should have identical properties.

---

[3] Bartell and Sloan, THIS JOURNAL, 51, 1637 (1929).

[4] Bartell, Scheffler and Sloan, *ibid.*, 53,2501 (1931).

The carbon was a purified ash-free blood charcoal.[5] It was activated by heating for twenty minutes in a muffle furnace at a temperature of 1000°. It was cooled in dry air and was transferred directly to the adsorption flasks.

Standard methods were employed in the purification of the liquids. The middle fractions only were used in this work.

Results

The results obtained are indicated in the curves presented herewith. In order to conserve space, tables of data are not given. In Fig. 1 are given curves for the different alcohol–benzene systems with silica. In Fig. 2 are given the curves for the different alcohol–benzene systems with carbon. The modified Freundlich equation $H\Delta x/m = ax^n(1 - x) - b(1 - x)^d x$ was found to apply to all of these systems. The equations applicable to each system are:

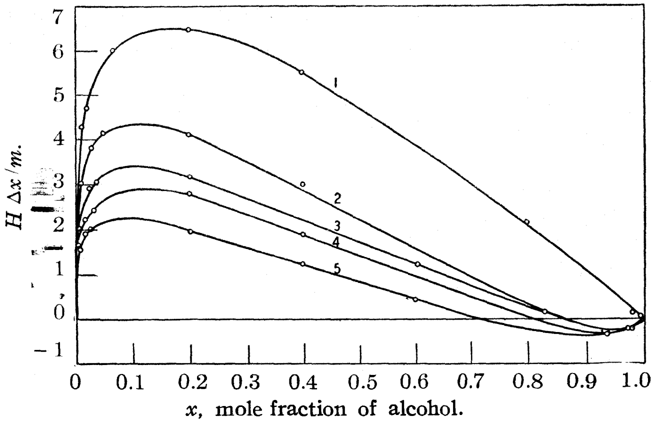

Fig. 1.—Adsorption by silica, alcohols from benzene: 1, methyl alcohol; 2, ethyl alcohol; 3, *n*-propyl alcohol; 4, n-butyl alcohol; 5, isoamyl alcohol.

Methyl alcohol–benzene–silica

$$H\Delta x/m = 11.429\ (x)^{0.215}\ (1 - x)$$

Ethyl alcohol–benzene–silica

$$H\Delta x/m = 8.840\ (x)^{0.227}\ (1 - x) - 4.664\ (1 - x)^{0.615}\ (x)$$

n-Propyl alcohol–benzene–silica

$$H\Delta x/m = 6.807\ (x)^{0.222}\ (1 - x) - 3.733\ (1 - x)^{0.684}\ (x)$$

n-Butyl alcohol–benzene–silica

$$H\Delta x/m = 7.261\ (x)^{0.222}\ (1 - x) - 4.808\ (1 - x)^{0.643}\ (x)$$

Isoamyl alcohol–benzene–silica

$$H\Delta x/m = 4.529\ (x)^{0.216}\ (1 - x) - 3.491\ (1 - x)^{0.600}\ (x)$$

---

[5] This charcoal was furnished by E. J. Miller of the Michigan Agricultural Experiment Station.

Methyl alcohol–benzene-carbon

$$H\Delta x/m = 5.327\,(x)^{0.222}\,(1 - x) - 12.218\,(1 - x)^{0.465}\,(x)$$

n-Propyl alcohol–benzene–carbon

$$H\Delta x/m = 1.496\,(x)^{0.616}\,(1 - x) - 3.819\,(1 - x)^{0.323}\,(x)$$

n-Butyl alcohol–benzene–carbon

$$H\Delta x/m = 1.738\,(x)^{0.704}\,(1 - x) - 3.475\,(1 - x)^{0.324}\,(x)$$

Isoamyl alcohol–benzene–carbon

$$H\Delta x/m = 2.716\,(1 - x)^{0.270}\,(x)$$

As indicated in Fig. 1, the preferential adsorption of the alcohols by silica from an organic solvent (benzene) having a lower adhesion tension against silica than have the alcohols, decreases as the molecular weight of the alcohols increases. Figure 2 indicates that the preferential adsorption of the series of alcohols from the same solvent by carbon is in the same order, although much less, than with silica. This is because the solvent has a higher adhesion tension against the carbon than have the alcohols. This same solvent has a relatively low adhesion tension against silica and accordingly adsorption by this adsorbent must be high.

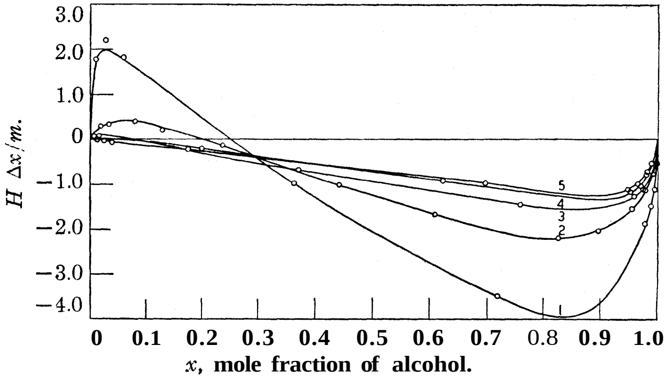

Fig. 2.—Adsorption by carbon, alcohols from benzene: 1, methyl alcohol; 2, ethyl alcohol; 3, n-propyl alcohol; 4, *n*-butyl alcohol; 5, isoamyl alcohol.

The results obtained are consistent and are in general what were to be expected from the energy relationships of the different systems.

Two sets of results only are not as might have been predicted. The results are those obtained with the methyl alcohol–benzene system with silica and the isoamyl alcohol–benzene system with carbon. All other binary organic liquid systems which have been studied have given S-shaped adsorption curves; that is, preferential adsorption of each of the components occurred over some portion of the concentration range. With the methyl alcohol–benzene–silica system no preferential adsorption of benzene could be detected with silica as adsorbent and with the isoamyl alcohol-benzene–carbon system no preferential adsorption of isoamyl alcohol was detected. These systems were checked repeatedly since at least a slight preferential adsorption was expected over the range indicated. Special precautions were taken to insure that perfectly dry (water-free) alcohol was used, but in no case were we able to obtain evidence of negative preferential adsorption over the range indicated.

After the completion of this work and after the paper had been written (June, 1930), a paper by Jones and Outridge[6] appeared on "Adsorption by Silicic Acid Gel in the System n-Butyl Alcohol–Benzene." Adsorption of the liquid components was studied over the entire concentration range. From their results they conclude, "No region occurs, in the high equilibrium concentrations of alcohol, where there is a negative selective adsorption of the alcohol . . . ." The solutions were analyzed by the "critical solution temperature" method of Jones.[7] Their adsorption curve for the n-butyl alcohol–benzene system was not S-shaped. This does not agree with the results presented in this paper for this system. While we shall not at this time attempt to account for the difference in the results obtained in these two researches we have no reasons to believe that our own results covering this system are in appreciable error.

Summary

1. The monobasic alcohols of the saturated hydrocarbon series **are** preferentially adsorbed by silica from benzene over the greater portion of the concentration range and in an order decreasing as the molecular weight increases. The preferential adsorption by carbon from similar systems is in the same order, is of much less magnitude, and occurs over but a limited portion of the concentration range.

2. The modified Freundlich equation which has been used in other investigations recently reported from this Laboratory was found to apply to the preferential adsorption effects for both the silica and the carbon adsorbents.

3. The degree of adsorption of one component, the adsorbate, from a binary organic liquid system is dependent upon the adhesion tension of that component against the adsorbent as compared to the adhesion tension of the solvent against the adsorbent, and also upon the solubility of the adsorbate in the solvent. The effect of solubility is noted when a series of compounds of similar adhesion tensions against an adsorbent are adsorbed from a given solvent, such as benzene. The greater the solubility of the adsorbate, the less will be its tendency to be adsorbed.

EXTRACTION OF KRYPTON AND XENON FROM LIQUID AIR RESIDUES[1,2,3]

BY F. J. ALLEN AND R. B. MOORE

RECEIVED APRIL 15, 1931 PUBLISHED JULY 8, 1931

Introduction

On account of the difficulty and expense of obtaining any considerable quantities of krypton and xenon, there has been little experimental work done with these elements except such as required only small amounts of the gases. Much credit is due to the pioneers in this field, who, in many instances, made up for scarcity of material with what might well be called a microtechnique.

Early in the study of the extraction of krypton and xenon from air it became evident that the evaporation of liquid air brought about an increased concentration of krypton and xenon in the residual liquid and this suggested that liquid air residues might well be the best source of these gases. Experience has confirmed this idea; hence the opportunity to obtain liquid air residues from a plant which carried on fractionation of liquid air on a large scale was welcomed in the hope that sufficient quantities of krypton and xenon might be obtained to permit of a more careful determination of some of their properties.

Source of Raw Material.—The Air Reduction Sales Company of New York kindly supplied cylinders of compressed gas. The bulk of gas in each cylinder was oxygen, but nitrogen, carbon dioxide, argon, krypton and xenon were also present, the latter two in proportions much greater than in ordinary air.

In the fractionation of liquid air the higher vapor pressure of nitrogen allows the liquid air in the still to become mainly oxygen, but with continuous operation there collect in this liquid oxygen the less volatile krypton and xenon.

It has been the custom at certain plants to discard periodically this liquid from the still. Arrangements, however, were made with the company referred to above to transfer liquid so withdrawn to large vacuum-walled vessels and to permit it to reduce its volume by evaporation and thus increase its proportion of krypton and xenon. When the volume had

---

[1] A preliminary note in regard to this work has already been published, THIS JOURNAL, 52,4173 (1930).

[2] This paper represents part of a thesis submitted by F. J. Allen to the Graduate School of Purdue University in partial fulfilment of the requirements for the Degree of Doctor of Philosophy.

[3] Since the completion of this research, Dean R. B. Moore has died. This paper has not, therefore, had the benefit of his criticism. The thesis of which this is a part was, however, carefully gone over by Dr. Moore.

diminished sufficiently, the remaining liquid was poured into a metal cylinder of the type used for marketing compressed oxygen. The cylinder had been previously cooled with liquid oxygen. The valve was screwed in and the pressure checked after the cylinder and contents had come to room temperature. This cylinder was then sent to our laboratory.

Unfortunately, only the briefest sort of record was kept at the plant in regard to this procedure. Knowledge as to the quantity of liquid oxygen from the still, the fraction of this allowed to evaporate and kindred information would have been of much interest.

F. J. Metzger of the Air Reduction Company states that, "Each cylinder of gas represents the rare gases which we have been able to collect from about fifteen million cubic feet of air." It will be seen later that only a small proportion of the krypton and xenon actually in that volume of air got into the cylinders. Rabinowitsch[4] has concluded from a study of all the available data that the most reliable values that can be assigned for the percentages of krypton and xenon in the air are, respectively, 0.0001 and 0.00001. Six cylinders in all were received and the inert gases were extracted in a manner later to be described.

Experimental

Separation of Inert Gases from Liquid Air Residues.—The following workers have reported on the extraction and purification of krypton and xenon: Ramsay and Travers,[5] Ladenburg and Krügel,[6] Moore,[7] Dewar,[8] Valentiner and Schmidt,[9] Aston,[10] Claude[11] and Le Pape.[12]

A number of patents[13] dealing with the extraction of krypton and xenon have been granted.

The extraction of krypton and xenon for the present work had been completed before the papers of Claude and Le Pape were noted, the methods used following in general the principles established by earlier investigators.

The gas from the cylinder was freed from carbon dioxide by bubbling through a concentrated solution of potassium hydroxide and was next dried by calcium chloride and

passed through charcoal at the temperature of liquid air. At first the gas was metered out through a small gas meter, but experience soon showed that the rate could be adjusted suitably by the bubbling in the solution of potassium hydroxide and the total quantity of gas taken out in a given run could be calculated with sufficient accuracy from the initial and final pressures of the gage and the size of the cylinder.

The apparatus was in process of evolution throughout the entire investigation, but a few trials brought it to a fairly satisfactory stage. Figure 1 shows the plan of operation. It represents the set-up as used in the later runs. The various units were joined by means of heavy pressure tubing, but these connections are not shown in the figure.

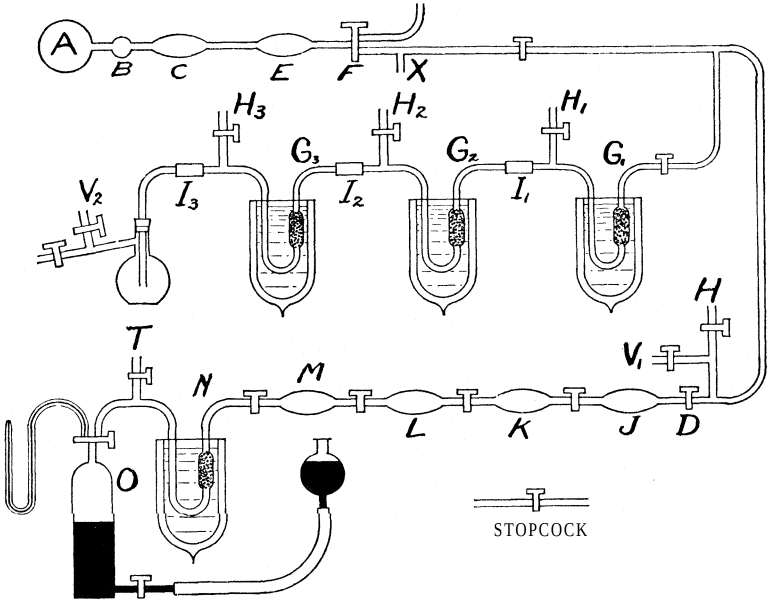

Fig. 1.—Diagram illustrating apparatus used to extract krypton and xenon from liquid air residues.

Gas from the cylinder A was passed through the gage B, the carbon dioxide adsorbers C, the drying agent E and through the two-way stopcock F. The two-way stopcock was put in as a safety unit to permit release of pressure in the event of the line becoming plugged. From F the gas flowed past a connection to a manometer X and on to the charcoal tubes G_1, G_2, G_3, which were cooled in liquid air.

It was not found practicable to prevent the formation of liquid oxygen in the charcoal tubes though reduced pressure was tried in the hope of doing so. The assumption was that krypton and xenon would be taken out by the cooled charcoal while the bulk of the oxygen passed on through. The results partly confirm this idea.

An average run consisted of passing about 300 liters of gas from the cylinder through the liquid-air cooled charcoal. The average rate of flow varied from one-half liter to one liter per minute.

When the gas from the cylinder was shut off, the charcoal tubes were clamped off and kept cooled by liquid air. G_1 was then permitted to deliver its gas through what is called, for want of a better name, the "inerting" line. By a suitable adjustment of stopcocks and of the clamps between the charcoal tubes, the gas could be sent from G_1,

G_2 or G_3 through D and through the soda lime J, the copper K, the drying agent L, the calcium M and could be taken into the charcoal tube N. This process of delivering from G_1 a large volume of gas, which, in the inerting line, is reduced to a small volume of inert gas capable of being collected over mercury in the reservoir O, is believed to be a new procedure. It obviates the use of large reservoirs for the collection and storage of the gases from G_1. Some care was required in the manipulation, such as a slow rate of addition of the oxygen-rich gas from G_1 to prevent over-heating in the copper filled tube.

Previous to use all charcoal tubes were baked out for about two hours under a vacuum of about 0.001 mm. and at a temperature of about 400°. The charcoal used was "Adsorbite," supplied by the Barnebey–Cheney Engineering Company of Columbus, Ohio.

Calcium was obtained in finely divided form by various methods, all of which were tedious. It would be a great advantage if this element were marketed in larger and more coherent lumps. With fair sized pieces good shavings were obtained on the lathe or shaper. Some shavings were drilled out but this is wasteful unless the honeycomb pieces remaining can be utilized. By far the most efficient results were obtained with a milling machine using a slow speed, spiral-grooved, cylindrical cutting tool. With larger lumps of calcium this method would be almost ideal.

The copper was prepared by reducing four mesh copper oxide with hydrogen. Care was taken to bring about the reduction at the lowest possible temperature and thus to obtain the copper in a condition of maximum porosity. The reduction can be carried out in an iron pipe but in the line the copper was contained in a large tube of Pyrex glass. This permits observation but is otherwise subject to criticism. Temperatures higher than the glass can safely stand are easily obtained by the action of the oxygen on the copper.

The "inerting" line, with the exception of the tube N which was baked out separately, was pumped out and the pumping maintained for about four hours while the calcium and copper tubes were strongly heated with bunsen burners. It was usually possible to attend to this part of the work while the run was going on; then as soon as the gas from the cylinder was shut off the gas from a G tube could be admitted through D and the soda lime to the copper by suitable clamp adjustment at I_1, I_2, etc.

The rate of flow of gas from G_1 could be controlled by regulation of the outlet stopcock and the depth of immersion in the liquid air. The line was kept open to the manometer and in all the work a reduced pressure was maintained whenever possible. This meant that in the event of a leak, gas would not be lost but only contaminated by having some air leak into it.

The copper had to be hot to start its action with the oxygen, but once started the burner could be removed, the action being so strongly exothermal as to cause a red glow to travel down inside the tube marking the zone of reaction. It was easy to overheat to the extent of having the glass soft enough to be pressed in against the tube contents. If this occurred only slightly it was usually possible to complete the run, especially if the defective place was kept hot, for on cooling such places often cracked.

As gas collected in the copper tube it was gradually let on through the drying agent to the calcium, which was kept as hot as the Pyrex tube in which it was contained would permit, and thence to the charcoal tube N.

When no more gas came from G_1 by removal of its liquid air bath, its temperature was gradually increased to about 450" with the line open all the way to N, which was cooled in liquid air. The manometer would soon show a fair vacuum. Tube N could then be closed to the line and allowed to deliver its gas to the mercury-filled reservoir O. On heating N to 450° practically all the remaining gas could be pumped off through the T connection to the Topler pump and added to the gas in O.

H could be put in connection with H_2, or H_3 when the gas was to be sent from G_2 or G_3, respectively, to the inerting line. V_1 and V_2 are for connection to the vacuum pump. T could be put in connection with the vacuum pump or the Töpler pump.

At any time during operation the gas from the line could be drawn back into G_1 or N. This was very convenient for example when a copper or a calcium tube needed to be replaced.

The gas from O was subsequently "re-inerted," that is, subjected to the action of fresh calcium. As a rule this "re-inerting" was carried out by passing the gas from O through an appropriate line to another reservoir and thence back to O, this process being repeated until no further diminution in volume was observed. The line contained copper, copper oxide, soda-lime and a drying agent in addition to calcium. This was considered necessary because of the possibility of some moisture getting to the calcium or to the calcium nitride and forming hydrogen or ammonia. Soddy[14] and more recently, Leatherman and Bartlett[15] have shown that under the proper conditions calcium is very efficient in removing all but the inert gases, but in this work a tube was sometimes used overlong with consequent loss of efficiency, hence the "re-inerting."

In the early trials only one 25-g. charcoal tube was used but later a second and third were added. In the last runs three tubes were used, each containing about 50 g. of charcoal. Inert gas was obtained from each one. Whether this gas was carried from one tube to the next by the action of liquid oxygen or whether too large a volume of gas was taken from the cylinder for the total capacity of the charcoal used or whether some other factor was operating remains to be investigated.

The average time for a run was twelve to fifteen hours, and several times as long was usually required between runs in getting the line in shape for use again. Unusual good fortune favored the work in that the accidents which occurred were not at critical times.

About 1100 ml. of inert gas was obtained from the six cylinders. A test run was made on a portion of the gas from the last cylinder received. A volume of 16 liters of gas from this cylinder was freed from all but the inert gases by passing it directly into the inerting line. The 16 liters reduced to 30 ml. of inert gas. This corresponds to about 0.2% inert gas in the gas from the cylinder. Since the cylinder contained 260 liters of gas from which 173 ml: of inert gas was obtained by the charcoal separation it appears that in this case the efficiency of extraction was about 35%.

The inert gas was made up largely of argon, not more than one-third of its volume being krypton and xenon.

Separation of Krypton and Xenon from Mixtures of Inert Gases and Preparation of Samples of Krypton and of Xenon of High Purity

The mixtures dealt with were made up of argon, krypton and xenon. The separation of these was checked by density determinations, the apparatus and method being that of Ramsay and Travers.[5]

The general scheme of purification starting with a sample of the inert gas mixture as it came from the "re-inerting" line will be first considered. The gas was condensed to a liquid or solid by making connection between the reservoir and an evacuated bulb dipping into liquid air. The bulb contents were next allowed to evaporate by reducing the pressure and several fractions thus obtained. The fraction coming off most readily would be mostly argon and that least readily, mostly xenon. The inter-

mediate fractions ranged in composition from krypton in argon to krypton in xenon. This general method is that used by Moore[7] in his work. In any given series the fractions in numerical order are in order of increasing density.

In the preliminary work no attempt was made to check up on the density of the various fractions. When, however, several series of fractions had been obtained in the same way, combinations were made of the corresponding fractions in the several series and density determinations made for these composite samples.

The a, b and d series were thus grouped into the e series for which some data are given in Table I.

TABLE I

DATA FOR SERIES E FRACTIONATIONS

Sample number	Vol. of sample, ml.	Density of sample, g./l.
1	85	2.85
2	52	2.90
3	68	3.04
4	40	3.51
5	50	3.76
6	20	4.13
7	22	5.07
8	22	5.44

Since krypton and xenon have rather slight vapor pressures at the temperature of liquid air, some attempts to separate them were carried out at about −150°.

To obtain and hold this temperature a method was employed which will be referred to again later and which will be called "cold-air-stream cooling." The stream of cold air was obtained by forcing air through a copper coil immersed in liquid air. By careful regulation of the rate of flow of air through the coil and the depth of immersion of the coil in the liquid air a fair regulation of temperature could be obtained in an unsilvered "Dewar" tube into which the cold air was passed. By this method various temperatures from −170 to −100° were obtained. With extreme painstaking a temperature could be maintained within 1° for as long as fifteen to twenty minutes but for the fractionation work it was not felt necessary to maintain such careful control.

The fractionation of the samples richer in krypton and xenon was carried out in a manner somewhat different from that used with the first inert gas samples. Figure 2 will help make this clear.

Sample 1 is divided according to the best judgment of the worker into a a more volatile fraction 7 and a less volatile fraction 8. Sample 8 is added to sample 2 which is the next less volatile than 1 in the starting series used here (numbers 1–6) and fractions 9 and 10 obtained. The less volatile 10 with 3 gives 11 and 12, etc.

Samples 7, 9, 11, 13, 15, 17, 18 thus obtained are used as the starting series for repeating the process and obtaining eight new samples. A large number of fractionations of this sort were carried out and most of the argon was separated from the krypton and xenon.

Reference has been made to studies which showed differences in the adsorptive power of charcoal for argon, krypton and xenon at certain temperatures. These deal in the main with the idea of allowing a mixture of the gases to be adsorbed by charcoal and then obtaining a degree of separation by either slowly raising the temperature of the charcoal and collecting the gas first set free as mainly argon, the next as mainly krypton and that held most firmly and hence last to be given off as mainly xenon; or by a temperature difference between the gas containing charcoal and a fresh tube of charcoal free from any gas. In the latter case, for example, connection might be made between a charcoal tube containing the three gases at say −140° and a gas-free charcoal tube at the temperature of liquid air. With this temperature difference maintained for a period of one, two, or more hours the gas held least firmly would to a large degree migrate to the cooler tube.

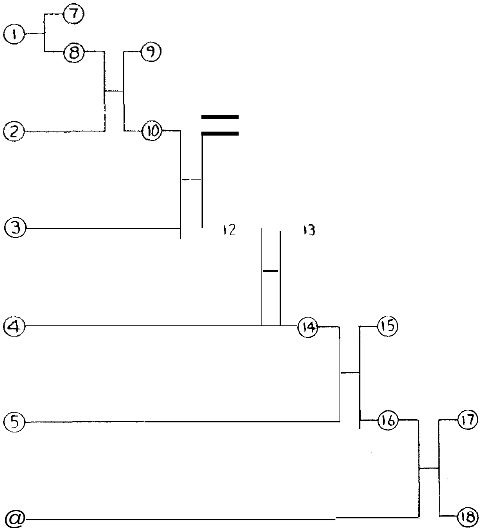

Fig. 2.—Diagram to explain fractionation of inert gas mixture.

A number of experiments were performed making use of the above method but it was soon apparent that a line was required which could be maintained "vacuum-tight" for hours at a time. The use of even the best obtainable vacuum tubing permitted some air to leak in. About fifteen trials were made, however, and the general indications were very favorable. A typical trial is described in the following paragraph.

A sample of gas of density 3.0 g./l. was taken into a five-gram charcoal tube (A) at the temperature of liquid air. Tube A was then allowed to warm up to −120° and was then placed in connection with a similar tube (B) which was at the temperature of liquid air. After three hours the connection between the tubes was closed and B was freed from gas by the usual process of baking and pumping out. The gas from B had a density of 1.7 g./l. Tube A was now brought to −80° and left for one hour in connection with B at liquid-air temperature. This time the gas obtained from B had a density of 3.2 g./l. The operation was repeated with **A** at 20° and B in liquid air again. This time fifteen minutes were allowed for gas to go from A to B and the gas from B had a density of 3.8 g./l. On baking out A a gas of density 4.7 g./l. was obtained. As stated before this method is not new but a density check on the separation as given above has not been previously reported.

The same general results were obtained in the other trials and as a result of these experiments considerable progress was made toward getting pure samples of krypton and xenon.

An inventory of inert gas samples on hand at this time gave results as shown in Table II.

TABLE II

DATA ON FRACTIONS OBTAINED IN PRELIMINARY PURIFICATION

Sample number	Density, g./l.	Approx. vol., ml.
I	1.8 ± 0.1	404
II	2.0 ± 0.1	114
III	2.3 ± 0.1	142
IV	2.7 ± 0.1	95
V	3.4 ± 0.1	63
VI	3.6 ± 0.1	154
VII	4.7 ± 0.1	53
VIII	6.4 * 0.1	29

The accepted densities for argon, krypton and xenon in grams per liter are, respectively, 1.78, 3.708 and 5.851.

Samples V–VIII show by their densities that they consist mainly of krypton and xenon. Accordingly steps were taken toward final purification. The method now employed was that which Ramsay[6] used in his final purifications, namely, the sparking of gas over moist potassium hydroxide after pure oxygen had been added to the inert gas. When further sparking gave no reduction in volume, the excess oxygen was removed by phosphorus, the usual precautions being taken to produce vigorous combustion.

Sample VI so treated increased its density from 3.6 to 3.9 g./l. It should be kept in mind that in all this work the gases were handled over mercury and every precaution was taken to avoid contamination of the samples, but even so traces of air got in, especially when samples had been transferred many times from tube to tube and from tube to reservoir or to pump and thence to other tubes as was necessary in carrying out the various steps in the purification. As higher grade samples were obtained, greater care was used to avoid contamination; in fact, "seasoned" tubes were used; that is to say, a krypton sample if transferred to the pump or fractionating bulb was returned to the tube which had contained it rather than to a tube in which the air had just been displaced by mercury.

Samples V, VII and VIII were also treated in the manner that has just been described for sample VI.

The next step in purification was fractionation and in the case of krypton this was a tedious process, since this gas, having a vapor pressure intermediate between argon and xenon, is hard to separate from them. Enough krypton must be allowed to distil away to carry out all the argon so that the process is far from economical. Better efficiency obtains in getting krypton from xenon but even in such a case some samples must be set aside which, though very largely krypton, contain traces of xenon. Repeated reworking of these "border line" samples permitted getting more and more of the krypton from them. The general scheme involved in fractionation has been explained already.

Sample VI after its purification by sparking yielded on fractionation a sample judged to be mostly krypton, since its density was 3.81 g./l. This fraction, about 90 ml. in volume, was refractionated to give five samples. Of these the first was set aside as possibly containing argon, although in these higher density samples the chance for argon to be present was rather slight. The second and third samples totaling about 60 ml. were fairly pure krypton, but the fourth and fifth were set aside as possibly containing xenon.

The 60 ml. of krypton referred to in the preceding paragraph was divided into three fractions and the middle one of about 30 ml. volume was used. Its density was found to be 3.733 g./l. The temperature of its triple point agreed closely with that of the sample of which it was the middle fraction and with that of another sample of high purity krypton the preparation of which will next be reported.

All second best samples of krypton which had been accumulated in the process of getting out the most nearly pure sample just referred to above were mixed together and repeatedly passed over strongly heated copper, copper oxide and then over calcium and were then dried by standing over phosphoric anhydride. This process was assumed to remove any gases not inert that might have got in as impurities. The treatment with oxygen followed by sparking in contact with potassium hydroxide was omitted. An all-glass apparatus was used which gave no evidence of leakage over a period of twenty-four hours.

The inert gas thus obtained was fractionated from a bulb which was connected to a manometer. There was small evidence of impurities more volatile than krypton; nevertheless, the first 10 or 12 ml. was pumped off and set aside. The next fraction, about 30 ml. in volume, was high grade krypton and its density was found to be 3.728 g./l. It is significant that the vapor pressure remained constant during the entire time that this second fraction was being pumped out. In fact no change was observed in the vapor pressure while the third and most of the fourth fractions were being pumped out. The pumping was stopped from time to time to check up on this by allowing time for equilibrium to be established. Toward the last the vapor pressure diminished, which was taken to indicate the presence of a small trace of xenon.

After the two samples of krypton of respective densities 3.733 and 3.728 g./l. had been used in vapor pressure studies, they were combined into one sample, and this was fractionated into five samples of which the first and last were very small (2–3 ml. each). The density of fraction 2 was found to be 3.737 g./l. and that of fraction 4 was 3.725 g./l., the difference being not greater than the probable experimental error and in the wrong direction to indicate the presence of xenon. The density bulb used held 21.92 ml. and the weight of krypton contained usually varied from 0.0500 to 0.0700 g. depending on the pressure at which the gas was supplied when the bulb was filled. **An** Ainsworth analytical balance was used and the weighings were not in error by more than ±0.0001 g.

The average of all density determinations on the high grade krypton gave a value of 3.733 g./l. and this gives a value for the atomic weight of krypton about 1% higher than that which is now accepted. Aston[16] states that his recent mass spectrograph studies indicate that the present atomic weight assigned to krypton is too low. He also states that there is good reason to believe that much of the information in the literature concerning krypton and xenon is subject to revision.

The atomic weight of krypton calculated from the 3.733 g./l. value and using Watson's[17] value for the compressibility of krypton comes out 83.6.

The xenon was purified by taking the highest density gas into a bulb at the temperature of liquid air and pumping out several fractions through the Tdpler pump. **A** middle fraction of about 50 ml. was fairly pure xenon. From this 50 cc. a middle fraction was taken later which was xenon of high purity. Its vapor pressure checked closely with a sample of xenon which Dr. R. B. Moore kindly loaned and which was known to be of high purity since it had been very carefully purified in order to determine the density of xenon. The present atomic weight of xenon was established from this sample of xenon. Also Aston had tested this sample and found it to show no evidence of krypton.

The density of xenon was found to be 5.887 ± 0.007 g./l. From this value the atomic weight of xenon would be 131.4 using Watson's[17] value for the compressibility of xenon.

Summary

A new method of handling liquid air residues from compressed gas cylinders has been used. This method permits obtaining the bulk of the inert gases present in the liquid air residues without the use of large gasometers and otherwise affords many advantages in manipulation.

---

[16] Aston, Proc. *Roy. Soc.* (London), **A126,** 511 *(1929).*

[17] Watson, *J. Chem. Soc., 97,* **833** (1910).

Krypton and xenon of high purity have been extracted from liquid air residues.

Preliminary density determinations on the most carefully purified krypton and xenon indicate that the atomic weights assigned to these elements are too low.

New quantitative data on the partial separation of argon, krypton and xenon by means of suitably cooled charcoal have been reported.

Fractionations were carried out with a manometer in connection, thus permitting a check on the degree of separation by the change in vapor pressure.

DETERMINATION OF CERTAIN PHYSICAL CONSTANTS OF KRYPTON AND XENON[1]

BY F. J. ALLEN AND R. B. MOORE

RECEIVED APRIL 15, 1931 PUBLISHED JULY 8, 1931

The preparation of samples of krypton and xenon has been reported by the authors in a previous paper.[2] On account of the small amount of experimental work that has been done with these elements it seemed desirable to recheck some of the physical constants. Accordingly plans were made to redetermine the triple point temperatures and pressures as well as the vapor pressures of the krypton and xenon in the range from the temperature of liquid air up to the boiling points of these gases.

The apparatus for the vapor pressure studies was of simple design and in part was patterned after that of Ramsay and Travers.[3] It consists, as shown in Fig. 1, of a siphon pipet (A) through which the gas may be introduced, a trap (B) to stop mercury, the bulb (C) which in operation dipped into an unsilvered Dewar tube into which also extended the copper tube supplying cold air and the platinum resistance thermometer and the open arm manometer (F) which was clamped to a glass scale ruled on a mirror. It should be noted that bulb C is offset, thus permitting more easy adjustment of the cooling assembly. Hair felt was packed snugly about the tubes leading into the Dewar so as to plug the neck and also

[1] This paper represents part of a thesis submitted by F. J. Allen to the Graduate School of Purdue University in partial fulfilment of the requirements for the Degree of Doctor of Philosophy.

Since the completion of this research, Peters and Weil have reported work on purification and properties of krypton and xenon: Z. *physik.* Chem., [A] 148, 1–35 (1930); Z. *angew.* Chem., 43, 608 (1930). The results reported in this paper in general agree very well with those reported by Peters and Weil.

[2] Allen and Moore, THIS JOURNAL, 53,2512 (1931).

[3] Ramsay and Travers, *Trans.* Roy. *Soc.* London, **A197,** 47 (1901).

extend some 5 cm. above the vessel itself. The copper tube supplying the cold air was insulated by a hair felt wrapping throughout the major part of the length from its liquid air bath to the neck of the Dewar tube.

After the work on vapor pressure was once in progress, no gas was admitted to the line except the samples of krypton and xenon and since the less pure samples were used in the first trials it would seem reasonable to think that these served to "wash out" the apparatus. On several occasions the apparatus was left standing under vacuum for more than a week with no perceptible inleak of gas.

The apparatus once exhausted was supplied with the krypton or xenon through A, and C was cooled to the desired temperature. The temperature was then allowed to rise very slowly, thus causing a gradual increase of the vapor pressure. At intervals readings were taken on the manometer, barometer and resistance box. These readings were not quite simultaneous since for the most part they were all made by one observer, but it was possible to adjust the resistance box to the proper reading to get the temperature from the platinum resistance thermometer and then very quickly to read the manometer. The barometer reading could then be obtained with some leisure since its change was not likely to be rapid enough to matter even if the reading were taken several minutes later.

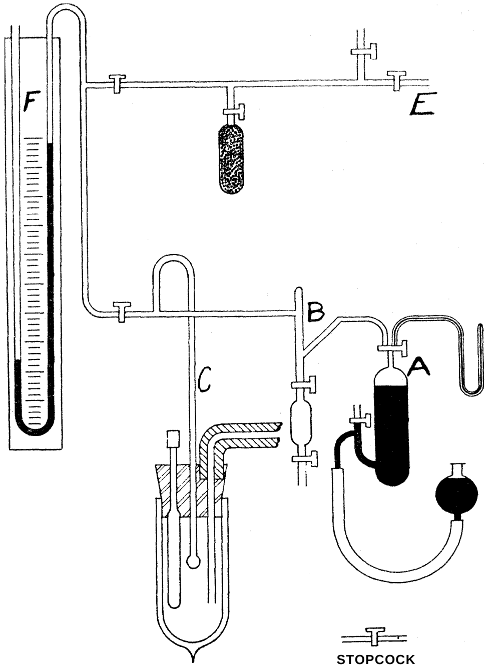

Fig. 1.—Apparatus for finding melting points, boiling points and vapor pressures of krypton and xenon.

Experience showed that on cooling, the vapor pressure was slow to diminish to a minimum value for a given temperature, hence the idea of taking the readings while the temperature was slowly increasing. If, for example, the equilibrium pressure at -150° was desired, the gas would be cooled several degrees below that temperature and allowed to increase slowly to -150°. The temperature change was at the rate of about 0.05" per minute.

Table I shows the vapor pressures found for krypton. Sample A is the one of density 3.728 g./l. and sample B is the one of density **3.733** g./l.

The error in the temperature reading was probably of the order of 0.1" and of the vapor pressure +20 mm., except for the equilibrium pressure at the triple point of krypton, which is not in error by more than ±3 mm. The results indicate that Ramsay and Travers'[3] value on the melting point is far from correct. They give −169.1° for krypton as compared with the −156.6° found in this investigation.

TABLE I

VAPOR PRESSURES OF KRYPTON

−152.0	824	−152.2	803

[a] **Values for the triple point.**

The results also show that the accepted value of −151.8° for the boiling point of krypton is too high, a better value being −153.1°, although the results here reported are not so satisfactory for the boiling point as for the triple point.

The triple point was best observed by getting the solid krypton or xenon in the bulb in as fluffy and snow-like a form as possible and watching for it to melt as the temperature rose. The snow-like form could be produced by cooling the element in the liquid form to the temperature where it was about to solidify and then quickly reducing the pressure for an instant, e. *g.*, by opening momentarily to a low pressure space in A. This usually resulted in a sort of "explosion" of the liquid into solid. The temperature was next kept slightly below the temperature of the triple point found on previous trials until time had been allowed for attainment of equilibrium and then was permitted to rise slowly. With krypton the vapor pressure rose as the temperature rose, up to the triple point, where the pressure held constant until most of the solid had melted. The earlier trials served to develop a technique which permitted more careful work in later ones.

Dr. R. B. Moore and Mr. G. C. Finger assisted in checking the triple point for the krypton from which the sample of density 3.733 grams per liter was later taken as a middle fraction. The average of five trials gave −156.5°, the lowest temperature being −156.8° and the highest −156.3°.

Xenon was less satisfactory to deal with than krypton. The change from solid to liquid was not nearly so sharply defined nor was the corresponding pressure. The quantity of xenon which had been most carefully purified was insufficient to fill the apparatus at the pressure of the triple point and was accordingly supplemented by the high purity xenon loaned by Dr. Moore. Results are shown in Table II.

−107 1	760		
−106.9	771		
−104 3	846		

The erratic behavior of xenon in the vicinity of its triple point suggests the possibility of a transition point of the solid xenon to a different solid form just below the triple point. The results show the triple point of xenon to be between −111.0" and −112.0" and the boiling point to be between −106.9" and −107.4". The only other value that has been reported for the triple point is that of Ramsay and Travers, namely, approximately −140°. The above investigators gave −109.1" for the boiling point of xenon. Patterson, Cripps and Whytlaw-Gray, using some of the xenon purified by Moore,[4] reported a boiling point of −106.9°, but since this was based on extrapolated values they considered it of doubtful accuracy.

In this connection it may be pointed out that the literature shows rather a small range of temperature between the melting and boiling points

---

[4] Moore, *Proc. Roy. Soc.* (London), **A81,** 195 (1908).

of the other rare gases. This work indicates the range for krypton and xenon to be more in keeping with other members of the family.

A summary of the values which this work indicated to be most reliable is found in Table III.

TABLE III

SUMMARY OF RESULTS

	Krypton	**Xenon**
Density in grams per liter	3.733 ± 0.007	5.887 ± 0.009
Atomic weight	83.6 ± 0.2	131.4 ± 0.3
Boiling point, °C.	−152.9 ± 0.3	−107.1 ± 0.3
Triple point temperature, °C.	−156.6 ± 0.1	−111.5 ± 0.5
Triple point pressure, mm.	557 ± 3	600 ± 20

The temperatures were determined by the use of a platinum resistance thermometer, a Wheatstone box bridge set-up being used to measure the resistances.

The galvanometer was of the cylindrical type manufactured by the Leeds and Northrup Company of Philadelphia. It was mounted on a wall shelf and fitted with a telescope and scale. It far exceeded the need as to sensitivity since a difference in resistance corresponding to 0.01° could be detected easily and temperatures are given in this report to 0.1".

The accuracy of the box bridge was checked by connecting a resistance box calibrated by the Bureau of Standards, in place of the platinum resistance thermometer. The bridge was not in error over the range used with krypton and xenon by an amount sufficient to affect the temperature values given as stated above to 0.1".

The platinum resistance thermometer was also a Leeds and Northrup instrument of the type designed especially for low temperature work. Constants for the Van Dusen[5] equation were supplied by a calibration made by the Bureau of Standards and this equation was used to calculate a set of data relating temperature and resistance. From the data so obtained a curve was plotted so that if a value were known for the resistance of the platinum, the corresponding temperature could be read from the curve. The scale used made one mm. equal 0.2° and one mm. equal 0.02 ohm.

Grateful acknowledgment is made to colleagues in the Chemistry Department of Purdue University for helpful suggestions as well as occasional assistance with the experimental work.

Mr. W. E. Fish, department mechanician, often worked after regular hours and on holidays preparing the liquid air which was needed for the work, sometimes in amounts up to fifteen or twenty liters per day. His helpful cooperation has been greatly appreciated.

---

Summary

New values are reported for temperatures and pressures for the triple points of krypton and xenon.

Studies of the vapor pressures of krypton and xenon have been made, principally in the range of temperature just including the triple points and boiling points. The results indicate the accepted values for the boiling points to be in error and new values are reported.

THE PHOTO-POLYMERIZATION OF STYRENE AND VINYL ACETATE

BY HUGH S. TAYLOR AND ARTHUR A. VERNON

RECEIVED APRIL 17, 1931 PUBLISHED JULY 8, 1931

In a number of oxidation processes sensitive to light the chain reaction theory has been shown to account satisfactorily for the phenomenon of inhibition of oxidation in such systems. An examination of the quantum yield of these photo-reactions shows that a large number of molecules react per light quantum absorbed, that the light absorbed, therefore, starts a chain of secondary oxidation processes. It has been known now for some time that many polymerization processes are light sensitive and also show the phenomenon of inhibition by added agents. Thus far, however, quantitative studies similar to those with oxidation reactions have been lacking. An additional interest attaches to such studies with processes of polymerization. It has been shown by Alyea and Bäckström,[1] in certain reactions, that the inhibitor in oxidation processes is oxidized in the process of breaking the reaction chains. Such a fate for the inhibitor molecule is impossible in polymerization processes carried out in the absence of oxygen. The question suggests itself, therefore, as to the nature of the inhibitory act in a polymerization reaction. It was to gain some insight into the quantitative aspects of the photo-polymerization that the following studies were made.

Only recently has any attention been given to the quantitative side of the question although references to qualitative experiments and reaction products are frequent. The theoretical side of the polymerization has drawn attention more recently as is indicated by the work of Carothers,[2] Staudinger[3] and Moureu and Dufraisse.[4]

[4] Moureu and Dufraisse, *Bull. soc. chim. France*, [4] 35, 1564 (1924). Since the completion of this work an article has appeared by Starkweather and G. B. Taylor [THIS JOURNAL, 52, 4708 (1930)] describing experiments made to determine the kinetics of the thermal polymerization of vinyl acetate.

In order to broaden the scope of the investigation, two compounds—styrene and vinyl acetate—were used to study the photochemical polymerization process. Both of these compounds contain an ethylenic bond but oxygen is present in only one,

Experimental Details

Apparatus.—In most of the experimental work, the source of illumination was a vertical mercury arc of the Cooper–Hewitt type operating at about **175** watts. The liquids were illuminated in Pyrex reaction vessels made from tubing **2** cm. in diameter and **15** cm. long. By means of a ground-glass joint at the top, an inlet tube was immersed in the liquid to within **1 cm.** of the bottom. An outlet was provided by a tube in the Pyrex vessel **2** cm. below the ground-glass joint. Both inlet and outlet tubes were provided with stopcocks. The liquid under study could be thoroughly flushed out by allowing a stream of oxygen-free hydrogen to pass in the inlet tube and out at the outlet tube. By closing the stopcocks the liquid could be sealed in an atmosphere of hydrogen and the reaction carried out under these conditions. This procedure was necessary since oxygen was found to influence the reactions and their velocities.

To obtain several checks on each experiment as rapidly as possible, a round copper vessel **10** cm. in diameter and **15** cm. high was used. Through the center of this was fastened by means of a water-tight joint a quartz tube about **2.5** cm. in diameter. The vertical mercury arc was supported in this tube. Water was circulated in and out of the copper vessel and, by means of a heater, any desired temperature up to 100° could be maintained.

Measurement **of** Reaction **Rate.—A** method was used which was suggested by Dr. G. B. Kistiakowsky. One cubic centimeter of the original solution was dissolved in a given amount of benzene and the freezing point of the benzene determined by the usual Beckmann method. After illumination, the same procedure was followed. In this case, the depression was less due to polymerization. Since the molecular weight of the polymer is at least of the order of 3000–4000,[5,6] it can safely be assumed that the effect of the polymeric molecules upon the freezing point of the benzene is negligible as compared with that of the rest of the molecules present. From the differences in the depression of the freezing point of benzene before and after illumination, the amount polymerized could be calculated. These measurements were supplemented by viscosity determinations on the same solutions.

Materials Employed.—In the experiments with styrene, a commercial preparation consisting of a 46% solution of styrene in ethylbenzene, supplied by the U. S. Rubber Company. was employed. To prepare the solution for illumination, the mixture was steam distilled in a partial atmosphere of hydrogen after the system had been freed of oxygen. The distillate was separated from the water, dried over oxygen-free calcium chloride and stored over hydrogen in a ground-glass stoppered bottle. The final styrene content of the purified solutions was determined by polymerizing the styrene with stannic chloride, precipitating the polymer in ethyl alcohol, filtering, drying and weighing.

For the experiments with vinyl acetate, a 30% solution by volume of vinyl acetate in ethyl acetate was employed. The vinyl acetate was kindly supplied by the Union Carbide and Carbon Chemical Corporation and the ethyl acetate was of high grade. In preparing these solutions for illumination, each constituent was distilled in hydrogen separately, the two were mixed in an atmosphere of hydrogen and stored over hydrogen.

[6] Staudinger, **Ber., 59, 3019 (1926).**

Experimental Results

Influence of Oxygen on Polymerization.—This was determined by separating a solution of styrene into two parts. One part was stored over hydrogen and the other part over oxygen. Samples were removed at various intervals and allowed to undergo photo-polymerization at 100° under identical conditions. No correction for thermal polymerization was made in these tests, the results of which are given in Table I.

TABLE I

EFFECT OF OXYGEN ABSORPTION ON PHOTO-POLYMERIZATION OF STYRENE

Time of storage, hours	Contact with H_2 % polymerized per hr	Contact with O_2 % polymerized prr hr
0	**ti 39**	6 39
48	6 50	9.14
96	6.20	9 15
144	5.85	10 25

This summary shows the acceleration due to absorbed oxygen and also the degree of constancy of result obtained when the mixture stands in contact with hydrogen. In all succeeding experiments, values within 10% of those indicated above for contact with hydrogen were recorded.

A further check upon this point was made by testing a solution which had been distilled in vacuum after having been steam-distilled in oxygen-free hydrogen. The results of this experiment indicated a polymerization rate which was within 10% of those given in Table I for contact with hydrogen.

The conclusion from these results is evident. Light alone may cause polymerization of styrene and the true rate of the photo-process is obtained with the hydrogen-distilled samples. That oxidation of styrene, whether thermal or photochemical, is also accompanied by polymerization is evident and, hence, the results of the polymerization of solutions stored over oxygen indicate a sum total of both of these effects. Table I shows that the increase due to complete oxygen saturation is about 50%; but the polymerization due to a very small percentage of oxygen in the hydrogen-prepared solution would be negligible as compared with that due to the ultraviolet light.

TABLE II

EFFECT OF OXYGEN ABSORPTION ON PHOTO-POLYMERIZATION OF VINYL ACETATE

Time of storage, hours	Contact with H_2, % polymerized per hour	Contact with On, % polymerized per hour
0	29.0	29.0
18		20.0
24	29.0	
48		**12.0**
90	29.5	
114		2.0
138	32 0	

The effect of oxygen upon the polymerization of vinyl acetate is different. Here oxygen inhibits the polymerization. The tests upon vinyl acetate solutions were made in the same way as were those with styrene. The results of these tests are embodied in Table II.

Effect of Temperature on Polymerization Velocity.—Using the method as outlined previously, photo-polymerizations were made at temperatures of 30, 70 and 100° in the case of styrene and at 40 and 70" in the case of vinyl acetate solutions. The curves for Fig. 1 and Fig. 2 are plotted from the results of two typical experiments. The straight lines were obtained from freezing point depression measurements while the curves record viscosity changes. The viscosity curve brings out the impossibility of using viscosity measurements to determine the rate of polymerization unless a viscosity–concentration curve has first been made.

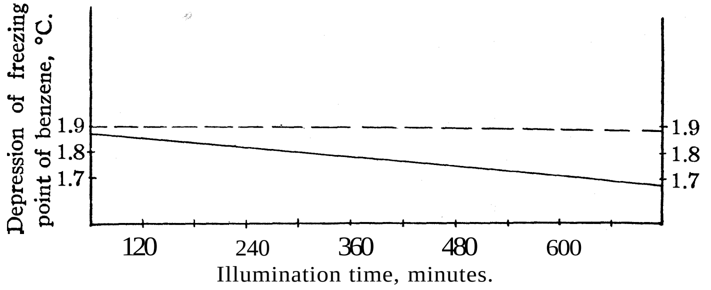

Fig. 1.—Polymerization of styrene–ethylbenzene solution: — — —, thermal, 70°; —, photochemical. 70°.

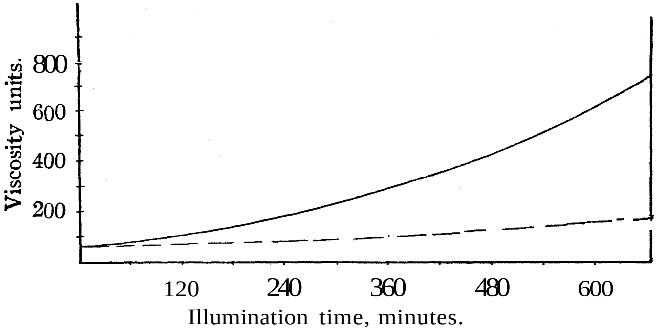

Fig. 2.—Polymerization of styrene-ethylbenzene solution: — — —, thermal, 70°; —, photochemical, 70°.

There is a measurable thermal polymerization of styrene at 70 and 100° which must be taken into consideration when temperature coefficients are determined. At 30° no correction was necessary with styrene and at neither 40 nor 70° was a thermal correction necessary for vinyl acetate. From the freezing point depression curves, rates of reaction can be measured and from these temperature coefficients determined. The results are given in Table III. They have been corrected for thermal effect where necessary.

TABLE III

TEMPERATURE COEFFICIENT OF PHOTOCHEMICAL POLYMERIZATION

Solution	Temperature interval, °C.	Temp coefficient per 10° rise
Styrene	30–100	1 30
Styrene	30–70	1 33
Styrene	70–100	1.27
Vinyl acetate	40–70	1 26

To interpret these results it is necessary to know whether the absorption of the solution changes with temperature, since the wave lengths involved are near the absorption limits of the solutions. To determine this, a monochromator was set up with a mercury arc as the source of light. The emitted light from the monochromator was focused upon a potassium hydride photo-electric cell. The recorder was a sensitive Moll galvanometer connected in series with the cell. No change in light absorption with temperature could be observed within the accuracy of the measurements, which was about 5%.

Effect of Concentration on Polymerization Velocity.—Solutions of several different concentrations were made and these were illuminated for the same length of time. The freezing point depression changes were determined and each polymerized solution was then diluted with ethylbenzene or ethyl acetate to a concentration of 10% by volume. The viscosities of these diluted solutions were thus determined at comparable concentrations. The results of these experiments are incorporated in Tables IV and V.

TABLE IV

CONCENTRATION–VELOCITY DATA FOR STYRENE IN ETHYLBENZENE

Concentration, %	Viscosity change, units	Change in dep. of f. p. of benzene, °C.
10	50	0.03
30	84	.16
65	150	.20
100	149	.305

Concentration, %	Viscosity change, units	Change in dep. of f. p. of benzene, °C.
13	20	0.10
65	44	.14
100	230	.45

To determine whether these results were due to concentration variations, to light absorption variations, or to both, monochromatic light was used with an arrangement as described previously. A quartz vessel was used for the absorption cell and the loss due to reflection was obtained by measurement on the vessel filled with ethyl acetate and ethyl benzene, respectively. Measurements were made with solutions of three different concentrations and from these the absorption coefficients were calculated using the equation

$$I_{\text{abs.}} = I_{\text{ent.}}\ (1 - e^{-\alpha c})$$

where I_{abs} is the intensity of the absorbed light, $I_{\text{ent.}}$ is the intensity of the entering light, α is the absorption coefficient and c is the concentration of the absorbing constituent. The values of the coefficients are necessary to calculate the absorption for the lowest concentration of solution, since the absorption in this case was too low to measure accurately. In the following table these data are incorporated.

TABLE VI

ABSORPTION DATA FOR VINYL ACETATE IN ETHYL ACETATE

		Average	.0125	

The above tables give all the data necessary to interpret the experiments which have been summarized in Tables IV and V.

Effect of Inhibitors.—Hydroquinone was selected as the inhibitor to be studied since it was found to have a large effect and, therefore, could be used in small concentrations. The experiments were made with 40% styrene solution at 100° and 30% vinyl acetate solution at 70°. Table VIII gives a summary of these results.

As shown by Anderson and Taylor,[7] an inhibitor may act in either or both of two ways. In one case it may cause a decrease in reaction rate by

---

[7] Anderson and Taylor, THIS JOURNAL, 45, 650 (1923).

TABLE VIII

INHIBITORY EFFECT OF HYDROQUINONE

Styrene in ethylbenzene		Vinyl acetate in ethyl acetate	
Concentration of hydroquinone	% of normal polymerization rate	Concentration of hydroquinone	% of normal polymerization rate
1 mole in 160	2	1 mole in 150	2
1 mole in 400	24	1 mole in 300	10 8
1 mole in 800	49.1	1 mole in 1500	27 0
1 mole in 4000	86	1 mole in 3000	50.0

absorbing light which would otherwise be used to produce a reaction. In the other case it may cause a decrease in reaction rate by some inhibitor mechanism. Ratios of absorption of styrene or vinyl acetate to that of hydroquinone under the conditions of the experiments were not determined but the fact that hydroquinone does absorb[8] seems to explain the relationship between concentrations of inhibitor and reaction rate. This will be discussed later.

Quantum Yields in the Polymerization.—A series of experiments was made to find the variation of quantum yield with wave length of absorbed light. The first measurements were made with the line of wave length **2300** Å. The source of the energy was a high voltage interrupted spark discharge across cadmium electrodes in air, constructed by Dr. G. B. Kistiakowsky. In order to determine the quanta which fell upon the system, it was desired to use the decomposition of oxalic acid sensitized with uranyl ions. This has been shown by Bowen and Watts[9] to have a quantum yield of one and a temperature coefficient of unity in the near ultraviolet.[10] Experiments made in light of wave length **2300** to 2500 Å. indicated that for our purpose the value of Bowen and Watts could be employed.

Quantum yield measurements were made at $\lambda = 2536$ Å. with both vinyl acetate and styrene. For this a hot mercury arc and chlorine–bromine filter were used. A correction was made for the visible light which passed through the filter and the decomposition of oxalic acid–uranyl acetate solutions was used to determine the number of quanta falling on the system. The absorption of the **2536 Å.** line was measured by means of a thermopile.

Finally the quantum yield was determined when exposed to the mercury arc as in the original experiments. This is designated as the quantum yield at wave lengths between $\lambda = 3000$ Å. and $\lambda = 4000$ Å. Pure styrene and pure vinyl acetate were exposed in a quartz reaction cell. This cell was immersed in a Pyrex water-bath and thus the conditions of the original

---

[8] "International Critical Tables," Vol. V, p. 361.

[9] Bowen and Watts, J. Chem. *Soc.*, 129, 1607 (1926).

[10] Recently Leighton and Forbes [THIS JOURNAL, $2,3139 (1930)] have found that a more careful determination indicates a quantum yield of 0.49 to 0.60 in ultraviolet light. However, since the polymerization quantum yields here presented are only orders of magnitude, the value of Bowen and Watts is sufficiently accurate.

experiments were reproduced. The results of these experiments are summarized in Table **IX.**

Discussion

Effect of Oxygen.—Moureu and Dufraisse[4] pointed out the effect of oxygen upon the photo-polymerization of acrolein and found that small amounts of this gas caused a very great increase in rate of polymerization. Since then there has been a tendency to attribute photo-polymerization to peroxide formation. No objection, theoretically, can be advanced against assuming that polymerization can occur as a consequence of molecules initially activated by light. The experiments described in this paper represent the distinct separation of these two methods of polymerization. **It** seems well established that polymerization may be induced by light which is absorbed by the molecules in question and that all the data of this paper represent the various phases of such a process.

Effect of Temperature.—The curves of Fig. 1 and Fig. 2 are typical of those from which the values of Table II were calculated. Calculations were made from the viscosity curves to find how the viscosity of the solution changed with temperature for the same percentage polymerization as shown by freezing point depression measurements. The results of the calculations are given in Tables X and **XI.** The values for the percentages

TABLE X

CHANGE IN SIZE OF POLYMER WITH TEMPERATURE FOR STYRENE SOLUTION

Total % polymer	Viscosity change at		
	30°, units	70°, units	100°, units
1 35	5	8	20
3 37	15	26	60
6 75	40	72	135
10 6	80	130	200
16 9	245	290	480
21 2	320	450	760

TABLE XI

CHANGE IN SIZE OF POLYMER WITH TEMPERATURE FOR VINYL ACETATE SOLUTION

Total % polymerized	Viscosity change at	
	40°, units	70°, units
14.3	220	220
42.9	2000	1440
57.2	4000	2800

where the viscosity change is less than 50 units are subject to a large error of reading. The other values represent reliable data.

An examination of these tables would seem to indicate that the aggregates of styrene are of a much larger size at high than at low temperatures. This would be different from the thermal polymerization as studied by Staudinger.[6] However, any more definite conclusions from these tables must wait for more experiments to determine completely this viscosity relationship. It would seem that, for styrene, the photochemical effect is stronger than the thermal, while for vinyl acetate the thermal effect somewhat overbalances the photochemical. It is evident, in any case, that the temperature effect is much different in the case of styrene than in the case of vinyl acetate.

Effect of Concentration on Reaction Velocity.—The change in reaction rate with concentration is due entirely to the change in absorption of light with concentration. This is evident by comparing Tables VI and VII with Tables IV and V.

A calculation of per cent. polymerized at the various concentrations shows a practically constant value. This lends further proof to the explanation given previously.

Effect of Inhibitor.—Inhibition which was due to deactivation by collision with the foreign molecules would be inversely proportional to the inhibitor concentration. If the inhibitor also acted in some other way as, for example, by screening, the decrease in reaction rate would be correspondingly greater. Table VIII shows that for styrene solutions a change of inhibitor concentration from 1 molecule in 160 to 1 molecule in 400 produced over a ten-fold change in reaction velocity. A similar effect is evident for vinyl acetate.

Since the only factors present in our case were deactivation by collision and screening by absorption of the active light, it seems clear that the inhibiting effect was due to both of these causes. The belief that hydroquinone could deactivate by collision was further substantiated by the results of some thermal experiments. In these tests it was found that hydroquinone was effective in preventing the thermal polymerization when present in concentrations of the order of magnitude of 1 molecule in 1000.

Quantum Yields.—The quantum yields given in Table IX represent the number of molecules which gather together as a result of the absorption of one quantum of light energy. The values of Table IX are in all cases upper limits of the quantum yields. The low quantum yield of vinyl acetate in light of wave lengths shorter than 3000 Å. was probably due to decomposition.

An example of the quantum yield calculations is given below.

Quantum Yield of Vinyl Acetate Polymerization at λ = 3000–4000 Å.—1. Quanta absorbed by vinyl acetate in one hour as determined from oxalic acid–uranyl acetate experiment and measurements of the relative absorption of vinyl acetate and oxalic acid solution were 1.07×10^{19}.

2. (a) Initial depression of freezing point of benzene due to 1 cc. of vinyl acetate in 25 cc. of benzene = 2.095°.

(b) Change in depression after illumination for one-half hour = 0.11°.

(c) Temperature = 65".

(d) Grams of vinyl acetate exposed = 13.5 *g*.

Therefore the number of molecules of vinyl acetate polymerized in one hour

$$2 \times \frac{0.11}{2.095} \times \frac{13.5}{86.06} \times 6.06 \times 10^{23} = 1.0 \times 10^{22}$$

$$\text{Hence, the quantum yield at } 65° = \frac{1.00 \times 10^{22}}{1.07 \times 10^{19}} = 935 \frac{\text{molecules}}{h\nu}$$

Conclusions

The photochemical polymerization results which have been presented indicate that the polymerization process has many of the characteristics of a chain mechanism. The initially activated molecule initiates the reaction by combining with another molecule. This process is exothermic and as a result these two are energy-rich and can add a third to their aggregate. This addition process continues until the energy of the group is insufficient to cause the addition of another member. This loss of energy may be caused by collision with foreign molecules of the solvent, by collision with the walls or by distribution over the whole aggregate to such an extent that further reaction is impossible.

The authors wish to express their thanks to Dr. G. B Kistiakowsky for his aid in developing the experimental procedure and interpreting the results.

Summary

1. Several phases of the photochemical polymerization of styrene and vinyl acetate have been investigated. A method of studying photochemical polymerizations has been developed which gives reproducible results and avoids all effects due to oxygen absorption.

2. Oxygen aids but is not necessary for the photo-polymerization of styrene.

3. Oxygen inhibits the photo-polymerization of vinyl acetate.

4. Both reactions have temperature coefficients markedly greater than unity.

5. The effect on the reaction velocity of a change in concentration of polymerizing constituent depends upon the change of light absorption with concentration of that constituent.

6. The orders of magnitude of the quantum yields have also been determined for several wave lengths. They indicate clearly that the polymerization process involves a chain mechanism.

THE ENERGY OF ACTIVATION FOR BIMOLECULAR REACTIONS INVOLVING HYDROGEN AND THE HALOGENS, ACCORDING TO THE QUANTUM MECHANICS

BY HENRY EYRING[1]

RECEIVED APRIL 23, 1931 PUBLISHED JULY 8, 1931

Experiment shows that in homogeneous bimolecular reactions the specific reaction rate constant, k, is approximately

$$k = Se^{-A/RT} \tag{1}$$

A is the energy of activation and the proportionality factor, *S*, is equal to the number of collisions at unit concentration of the colliding substances. An *a priori* method of determining *A*, therefore, would make possible the prediction of rates of reactions.

Heitler and London,[2] using the quantum theory, were able to account satisfactorily for the binding of two hydrogen atoms. The so-called zeroth approximation as evaluated by Sugiura[3] gave a binding energy equal to three-fourths of the experimental value. The term "binding energy" will be used to indicate the energy which must be supplied to break the bonds in question. It is, therefore, the negative of the potential energy of the system referred to the dissociated state as the state of zero energy.

The perturbation theory yields expressions for the binding energy of three and four atoms. Agreement between theory and experiment for some typical cases involving three atoms has been reported elsewhere by Polanyi and the author.[4] They made the calculations for the reactions $H_{2para} + H = H_{2ortho} + H$; $Br + H_2 = HBr + H$ and $Br_2 + H = HBr + Br$ and have also considered the dynamics of such reactions. Many details of calculation were also given which it has not been deemed necessary to repeat here. Certain bimolecular reactions involving three and four atoms are considered below.

London[5] gives for the binding energy, E, holding three monovalent atoms together the expression

$$E = Q + \left[\frac{1}{2}\left((\alpha - \beta)^2 + (\alpha - \gamma)^2 + (\beta - \gamma)^2\right)\right]^{1/2} \tag{2}$$

The limitations on this formula will be discussed later. In equation (2) Q is the coulombic binding between three atoms, *i. e.*, the binding energy that one would calculate using classical electrodynamics if one assumed the

---

electrons to be the diffuse clouds of quantum mechanics. The coulombic energy is really the sum of three terms: $Q = A' + B + C$. The A is primed to distinguish it from the activation energy. To define these quantities further, consider the three atoms W, X, Y, which form the triangle of Fig. 1. The energy required to make the distances r_1, r_2, r_3 simultaneously very large is E of Equation 2. The binding between the atoms W and X when Y is far away is $E_1 = A' + a$, and depends only on the distance r_1. Similarly the binding between X and Y with W far away is $E_2 = B + \beta$ and depends only on r_2; and between W and Y with X far away, the energy is $E_3 = C + \gamma$. The energy $E_1 = A' + a$ plotted as a function of r_1 is just the familiar Franck curve for the diatomic molecule, WX. Such curves may be readily constructed using spectroscopic data; it is thus possible to calculate E of Equation 2 if either the coulombic or the interchange binding is known.[6]

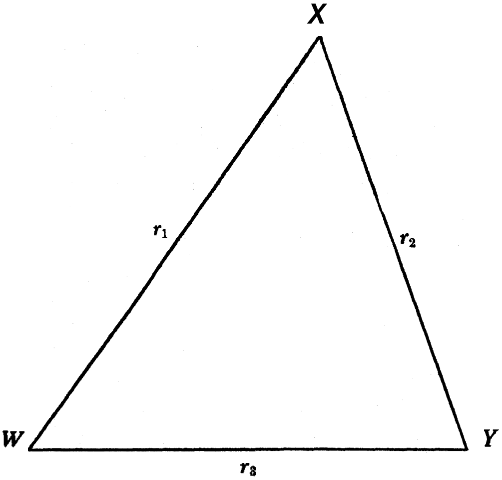

Fig. 1.

Morse[7] has obtained a convenient function which gives the dependence of the binding energy, E, on the distance, r, between the atoms for a diatomic molecule. In this equation

$$E = D'(2e^{-a(r-r_0)} - e^{-2a(r-r_0)}) \qquad (3)$$

a is defined by the equality $a = 0.1227\, \omega_0(M/D')^{1/2}$. D' is the heat of dissociation of the molecule plus the half quantum of vibrational energy it has in the lowest level. ω_0 is the vibration frequency in the lowest level and M, the reduced mass, is defined by the expression

$$M = \frac{M_1 \cdot M_2}{M_1 + M_2}$$

where M_1 and M_2 are the atomic weights of the two elements. D' and ω_0 are to be taken in wave numbers.

E_1 can thus be obtained from optical data and A', the coulombic part of the potential energy, can be calculated from the approximate wave functions of Zener[8] and Slater? The interchange binding a is then given by

---

[6] H. Eyring, *Naturwissen.*, 44, 915 (1930).

[7] Morse, *Phys. Rev.*, 34, 57 (1929).

[8] Clarence Zener, ibid., 36, 51 (1930).

[9] J. C. Slater, *ibid.*, 36, 67 (1930).

the relationship $\alpha = E_1 - A'$ with similar expressions for β and γ. The direct calculation of the interchange binding is not feasible both because of the difficulty of such a calculation and because of the approximate nature of the eigenfunctions.

In what follows, however, the coulombic binding will be taken as 10% of the total binding for all values of r, *i. e.*, the theoretical value for H_2. It was shown in a previous paper[4] that in the case of H_2, for all values of r important in determining the energy of activation, the theoretical coulombic binding energy is about 10% of the total theoretical binding energy and about 8% of the empirically found binding energy. This assumption for other gases, while not strictly correct, will make possible a comparison of the theory with experiment and leads to some striking qualitative predictions which depend only on the coulombic binding being approximately 10% of the total.

Consider the reaction

$$WX + Y = W + XY \tag{3a}$$

To begin with, the distance r_1 may be supposed to have the normal value r_0 for the molecule WX while r_2 and r_3 are very large. The total binding energy is thus equal to $A' + \alpha$. If the atom Y is made to approach the molecule WX in such a way as to keep $\beta = \gamma$, the radical in Equation 2 will decrease continuously, becoming zero when $\alpha = \beta = \gamma$; *i. e.*, three identical monovalent atoms at the corner of an equilateral triangle have no interchange binding.

Examination of Equation 2 shows that Y may approach WX with the smallest increase of potential energy of the system if all the atoms remain on a straight line. In this case two distances, say r_1 and r_2, will fix the third, r_3, and so determine the energy of the configuration. If r_1 and r_2 be plotted at right angles to each other and lines of equal energy be drawn, a contour map results which gives the potential energy of the system. Such a map for three hydrogen atoms is given (Fig. 2).

In Fig. 2 the course of the reaction $H_{2\text{para}} + H = H_{2\text{ortho}} + H$ is indicated by the broken line and the arrows. To begin with, r_2 is very large and $r_1 = 0.76$ Angstrom ($A' + \alpha = 107.6$ Calories, *i. e.*, the heat of dissociation plus a half quantum of vibration), then as the H atom approaches the para hydrogen molecule the potential energy increases adiabatically until the distance $r_1 = r_2 = 0.93$ Ångström when 11.4 Calories of potential energy have been stored up. This is the activation energy for the reaction. The reaction can now go to completion or the system may return to its former configuration. If r_1 increases the reaction goes to completion. The 11.4 Calories is the minimum value of the energy along the line $r_1 = r_2$, *i. e.*, $\alpha = \beta$, but it is the maximum value along the line with arrows which represents the course of the system during the reaction. It is thus a saddle value and may be calculated from Equation 2 by setting

$\alpha = \beta$, finding the minimum, and subtracting this value from the heat of dissociation of the hydrogen molecule. For reactions with unlike atoms the saddle value will not occur along the line $r_1 = r_2$ but will still be along the curve $\alpha = \beta$. Thus the energy of activation, A, for the reaction

$$WX + Y = W + XY \tag{3a}$$

is $A = D - (Q + \alpha - \gamma)_{\text{min.}}$. Here D is the heat of dissociation of the molecule WX and $(Q + \alpha - \gamma)_{\text{min.}}$ is the minimum value for this quantity

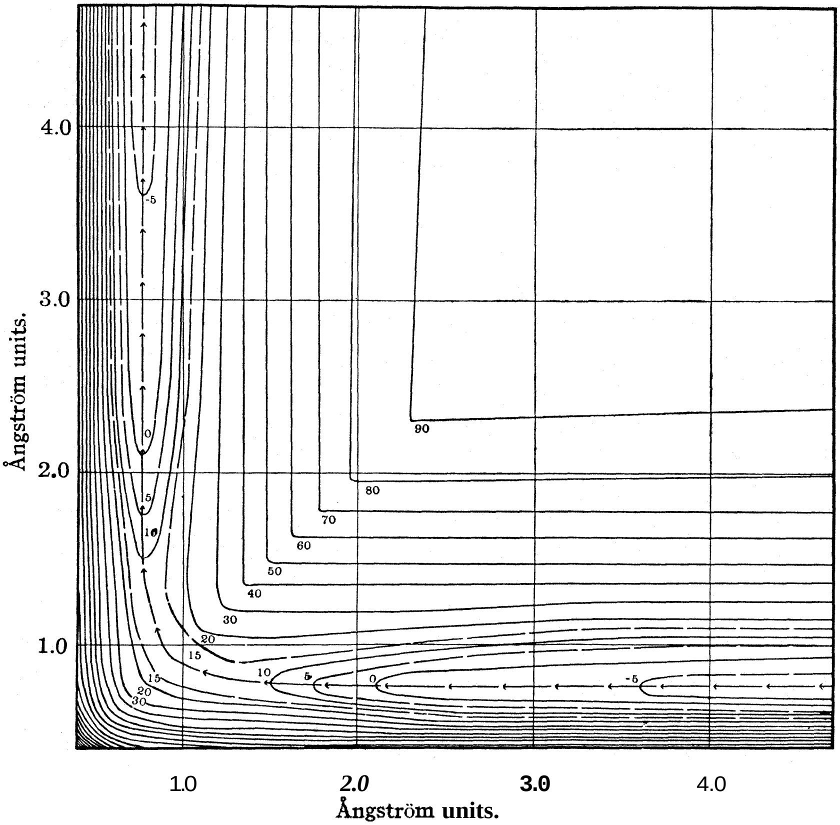

Fig. 2.

along the curve $\alpha = \beta$. It is important to remember that all binding energies are taken, like the heat of dissociation itself, as the negative of the potential energy, referred to complete dissociation as the zero of energy.

This reaction may thus be visualized as the motion of a mass point under the impetus of its kinetic energy moving up a valley until the lowest place in the divide between this valley and a neighboring valley is reached. Here the point may either return or pass over into the adjoining valley. The quantum mechanics provides still another alternative. The point may pass through the energy mountain without bothering to go over the divide. Langer[10] discusses this possibility for chemical reactions. The chance of this happening falls off exponentially with the square root of the area enclosed between the line through the mountain and the one over the divide. This process becomes very improbable for the gentle slopes met in this type of reactions. The probability of going over the top of the mountain falls off exponentially with the height and does not depend on the slope.

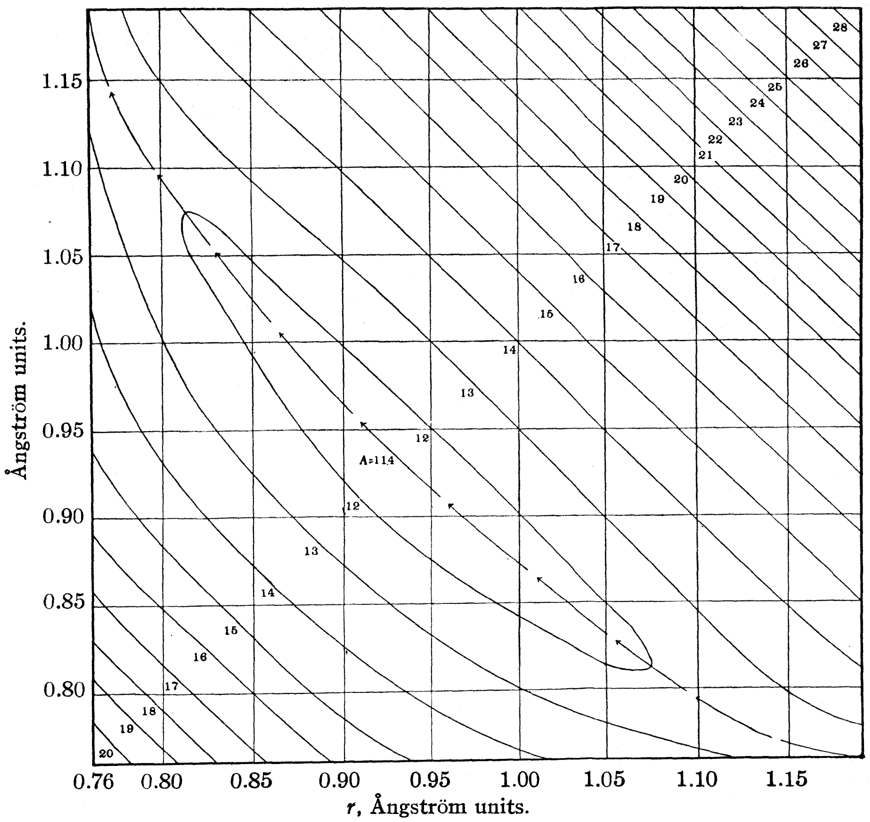

Fig. 3.

It is this exponential dependence on kinetic energy which makes it improbable that the mass point will arrive at the top of the divide with much excess kinetic energy. Thus the height of the divide measured from the bottom of the first valley can be identified with the energy of activation for the forward reaction, whereas for the reverse reaction the height of the divide must be measured from the second valley. The difference in the height of the two valleys is the heat of reaction. Having reached the top

---

[10] R. M. Langer, *Phys. Rev.*, **34**, 92 (1929).

of the divide, if P_1 represents the chance that the mass point will return to the first valley and P_2 the chance that it will continue on into the second, the entropy of the reaction is $\Delta S = R \ln (P_2/P_1)$.

A closer examination of the potential energy surface for three hydrogen atoms as shown in Fig. 3 reveals a slightly more complex surface than Fig. 2 would lead one to suspect. The configuration of lowest potential energy for which both of the outer hydrogen atoms are symmetrically placed with respect to the central atom is 11.4 Calories higher than the configuration in which the hydrogen atom is far away from the hydrogen molecule but this symmetrical configuration, instead of corresponding to a saddle value, is really the floor of a shallow basin with a rim 1.6 Calories higher in the direction of the two valleys. However, since it is rather difficult to calculate the exact position and height of the rim of the basin and since in the reactions with which we are concerned the difference between the height of the rim and the floor of the basin will be about a Calorie and a half the values included in Table II are for the floor of the basin.

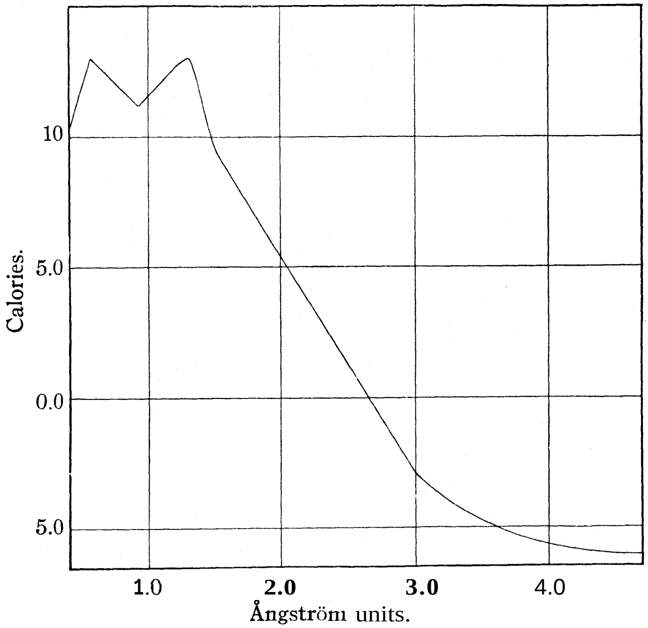

Fig. 4.

In Fig. 4 one simply sees in elevation the section through the contour map 2 traversed by the arrows. Because of the complete symmetry the section is only carried a little way beyond the symmetrical basin.

In Fig. 4 the smallest possible potential energy of the three atoms in a straight line is plotted as ordinate while as abscissa the distance between the nearest atom in the molecule and the approaching free atom is plotted until the symmetrical position is reached at 0.93 Angstrom. From here on the distance between the receding atom and the nearest atom of the new molecule is plotted as abscissa. The profile shows that an H_3 molecule is so unstable (heat of dissociation 1.6 Calories) that even if the heat of formation were carried away it would survive only a very few collisions and consequently has no existence in the ordinary chemical sense.

For reactions involving more atoms the potential energy surface will depend on more than two positional coordinates but with this single exception the discussion just given applies without essential change.

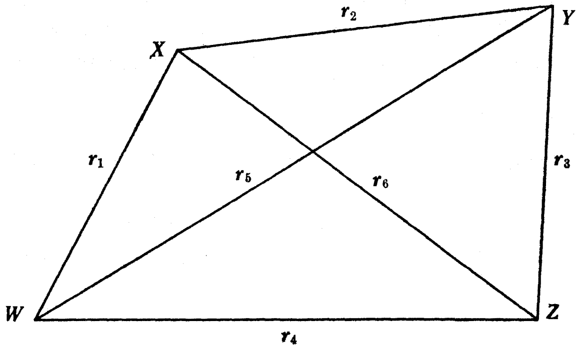

Fig. 5.

For the binding energy, E, of four atoms London[6]'' has given the value

$$E = Q + \sqrt{\frac{1}{2}((\alpha_1 + \alpha_2 - \beta_1 - \beta_2)^2 + (\alpha_1 + \alpha_2 - \gamma_1 - \gamma_2)^2 + (\beta_1 + \beta_2 - \gamma_1 - \gamma_2)^2)} \tag{4}$$

The coulombic energy, Q, has the value Q $= A_1 + A_2 + B_1 + B_2 + C_1 + C_2$. In this equation, α_1 and A_1 depend only on r_1 of Fig. 5; and the dependence of the other quantities may be indicated by writing $\alpha_2(r_3)$, $\beta_1(r_2)$, $B_1(r_2)$, $B_3(r_4)$, $B_2(r_4)$, $\gamma_1(r_5)$, $C_1(r_5)$, $\gamma_2(r_6)$, $C_2(r_6)$. Each of these quantities has the same meaning as in the three atom case and may be determined in the same way from the binding of diatomic molecules.

The reaction may be written

$$WX + YZ = WZ + XY \tag{5}$$

Reaction 5 consists in passing from a configuration in which only r_1 and r_3 are small to a final one in which only r_2 and r_4 are small. The system will necessarily pass through an intermediate configuration for which $\alpha_1 + \alpha_2 = \beta_1 + \beta_2$. A simple argument shows that this is the smallest value E is forced to take in the reaction (*i. e.*, the largest potential energy the system must take) and so is the one to use in calculating the activation energy.

First it may be shown that the reaction will take place with the four atoms in a plane. For suppose any configuration in a plane has been reached, such, for example, as that shown in Fig. 5. Keep all distances except r_5 fixed and make it smaller. Since $(\gamma_1 + \gamma_2) < (\alpha_1 + \alpha_2)$ and also $(\gamma_1 + \gamma_2) < (\beta_1 + \beta_2)$, this change in r_5 which increases γ_5 will decrease the radical in Equation 4. Q will increase but by a smaller amount so that the total binding will be diminished. Since changes occurring in reaction can all take place in a plane and since every departure from a plane decreases the binding energy, it follows that in the activated state all the atoms will lie in a plane. Four identical atoms at the corners of a symmetrical tetrahedron have no interchange binding.

Next consider the change in E for $(\alpha_1 + \alpha_2) = (\beta_1 + \beta_2)$ and $\delta(\alpha_1 + \alpha_2) = -\delta(\beta_1 + \beta_2)$. Then the change in $(\gamma_1 + \gamma_2)$, *i. e.*, $\delta(\gamma_1 + \gamma_2)$ will be negative since this change can be carried out in such a way as to increase the length of r_5 and r_6, and the change in the total binding energy, E, is

$$\delta E = \delta Q + \frac{1}{2}\frac{(\alpha_1+\alpha_2-\gamma_1-\gamma_2)(\delta(\alpha_1+\alpha_2)-\delta(\gamma_1+\gamma_2))+(\beta_1+\beta_2-\gamma_1-\gamma_2)(\delta(\beta_1+\beta_2)-\delta(\gamma_1+\gamma_2))}{\sqrt{\frac{1}{2}((\alpha_1+\alpha_2-\beta_1-\beta_2)^2+(\alpha_1+\alpha_2-\gamma_1-\gamma_2)^2+(\beta_1+\beta_2-\gamma_1-\gamma_2)^2)}}$$

$$= \delta Q - \frac{(\alpha_1+\alpha_2-\gamma_1-\gamma_2)\delta(\gamma_1+\gamma_2)}{\sqrt{\frac{1}{2}((\alpha_1+\alpha_2-\beta_1-\beta_2)^2+(\alpha_1+\alpha_2-\gamma_1-\gamma_2)^2+(\beta_1+\beta_2-\gamma_1-\gamma_2)^2)}}$$

but $(\alpha_1 + \alpha_2 - \gamma_1 - \gamma_2) > 0$ and $\delta(\gamma_1 + \gamma_2) < 0$ so that for δQ small, which is true for reactions with large activation energies, δE is positive, or becomes positive after emerging from the very shallow coulombic basin (depth of the order of a Calorie and a half), which we can ignore as in the case of three atoms. This shows that the reaction WX + YZ = WZ + XY reaches a configuration when $\alpha_1 + \alpha_2 = \beta_1 + \beta_2$ such that the reaction can proceed in either direction with a decrease in the potential energy. Thus to find the activation energy one finds the minimum value of Equation 4 subject to the condition

$$\alpha_1 + \alpha_2 = \beta_1 + \beta_2 \tag{6}$$

which is just the minimum value of $E' = Q + \alpha_1 + \alpha_2 - \gamma_1 - \gamma_2$. This quantity subtracted from the sum of the heats of dissociation of WX and YZ gives the energy of activation.

The following scheme was used in calculating the activation energies given below. First, potential energy curves were constructed for all molecules entering into the reactions. The necessary constants were taken for the most part from the "International Critical Tables" and from Landolt–Bornstein.

r_0 for bromine was calculated from Morse's relation $r_0^3\omega_0 = 3000$. The constants in Table I for hydrogen, bromine and hydrogen bromide are slightly different than those used by Eyring and Polanyi.[4] The difference arises from taking the constants from different sources, and represents a slight uncertainty rather than an improvement. The effects on the calcu-

TABLE I

CONSTANTS USED IN DETERMINING THE MORSE EQUATION

Gas	D	D'	r_0	a	ω_0

Br_2	45.7	46.2	2.09	2.00	326.6
I_2	34 5	34.8	2.66	1.50	213.9
HI	69	72.2	1.62	2.28	2272
HBr	82.1	85.8	1.42	1.83	2603
HCl	101.5	105.7	1.28	1.77	2940.8
HF	146.5	152.2	0.023	2 00	3987
ICl	50.7	51.2	1.99	1.84	382

lated activation energies are very small, as a comparison of the results shows.

D in the table is the heat of dissociation in large calories and D' is the heat of dissociation plus a half quantum of vibrational energy. The other quantities have been defined. Consider for example the reaction

$$I + H_2 = HI + I$$

The maximum value of $(A + B + C + \alpha - y)$ was calculated for the case of the three atoms on a line where in addition $\alpha = \beta$. This maximum value was then subtracted from the heat of dissociation of hydrogen, giving the energy of activation.

Two series of activation energies were calculated: one in which A, B and C were taken as 10% of the corresponding bonds, and the second for which they were taken as 3.5%.

For reactions of the type

$$H_2 + I_2 = 2HI$$

the maximum value of

$$(A_1 + A_2 + B_1 + B_2 + C_1 + C_2 + \alpha_1 + \alpha_2 - \gamma_1 - \gamma_2) \tag{7}$$

was calculated subject to the conditions $(\mathrm{cur} + \alpha_2) = (\beta_1 + \beta_2)$. By considering (4) it can be shown that for the saddle value $r_2 = r_4$ and $r_5 = r_6$. Using these conditions, the maximum value of (7) is soon found. This maximum value is subtracted from the sum of the heats of dissociation of hydrogen and iodine to give the energy of activation. In Table II the results of the calculations are tabulated.

The first column in Table II gives the letter which will be used in referring to the reaction in the second column. The third to sixth columns give the distances between the atoms in the activated state. For three atom reactions the distances to which the r values refer will be clear from considering the general expression (3a) for a reaction in connection with Fig. 1. For four atom reactions the same information is obtained by considering equation (5) in conjunction with Fig. 5. Columns 7 and 8 give the calculated energy of activation when the coulombic binding

q	$H_{2\text{para}} + H = H_{2\text{ortho}} + H$	0.93	0.93		1.86	11	21	4 to 11	19

is taken as 10 and 3.5%, respectively. Column 9 gives the available experimental information on energies of activations. Activation energies are in kilocalories and distances in Ångströms.

To the theoretical activation energy of a reaction of the type $H_2 + I = H + HI$ must be added half the heat of dissociation of I_2 in order to obtain the apparent activation energy for the thermal combination of hydrogen and iodine by way of the atoms. This follows from thermodynamic considerations. Thus the theory shows the combination of hydrogen and iodine will not involve the atoms since this would require an activation energy greater by $41 + 17 - 40 = 18$ Calories than if the reaction involved only molecules. This value is arrived at using the figures in Column 9; exactly the same conclusion is reached using Column 8. Column 8 indicates that bromine will react with hydrogen without dissociating into atoms. Column 9 indicates it will involve atoms. Experimentally it is known to go through the atoms. On the other hand, all the other halogens

will react with hydrogen by way of the atoms. This is in agreement with experiment. The theory also shows that the change of para to ortho hydrogen will proceed by way of the atoms. This too is correct, as Farkas'[19] experiments show.

This evidence is particularly cogent since with the exception of bromine it is independent of the fraction of the binding energy taken to be coulombic and so is direct evidence for the correctness of the adiabatic theory of reactions. Another interesting bit of evidence for the theory may be given.

The energy of activation for a three-atom reaction is $A = D - Q - \alpha + \gamma$. The three atoms in the activated state lie on a line thus: WXY and α is the interchange binding which would exist between W and X and also between X and Y if in each case the third atom were removed. γ is the interchange binding which would exist between W and Y if X were removed without altering the distance between W and Y. Since γ falls off with the distance between W and Y, a lower activation energy is to be expected for reactions in which the central atom is large, *i. e.*, for the halogens the activation energy should decrease progressively as the central atom changes through the series from fluorine to iodine. This fact is suggested and beautifully illustrated by some recent experiments of v. Hartel and Polanyi.[21]

Reactions	Activation energy
$CH_3F + Na = CH_3 + NaF$	25
$CH_3Cl + Na = CH_3 + NaCl$	8.8
$CH_3Br + Na = CH_3 + NaBr$	3.2
$CH_3I + Na = CH_3 + NaI$	0

They suggest that a proportionately greater coulombic binding, Q, for the heavier halogens, together with weaker binding, D, may partly account for this trend. There is, however, no indication in Table II that the coulombic part of the binding is greater for the heavier atoms.

Experimental values are not given in Table II for the reaction of hydrogen atoms with the halogens. However, the experiments of Boehm and Bonhoeffer[13] show that the mean life of hydrogen atoms in the presence of Cl_2 and Br_2 is less than a hundredth of a second and Polanyi shows that the ratio of the rates is as seven to one. These facts are at least consistent with the theoretical activation energy of zero Calories for both reactions.

The heat of dissociation of 63.5 kilocalories for fluorine estimated by Wartenberg and Taylor[1'] is rather uncertain. If, however, even a value as high as 82.6 kilocalories be assumed, the activation energies for (j) are, respectively, 56 and 79 kilocalories; for (k) they are zero and zero and for (l) are 6 and 13 kilocalories for Columns 8 and 9, respectively. These changes would affect none of our conclusions and the intermediate value of

---

[21] H. v. Hartel and Polanyi, *Z. physik. Chem.*, [B] **11**, 97 (1930).

72 kilocalories for D estimated by Mullikan[22] would give intermediate values of the activation energies.

The numerical agreement between the calculated and experimental activation energies in Table II is as good as could be hoped for and indicates the essential correctness of the theory. Better checks must await more accurate experiments as well as the theoretical evaluation of the ratio of coulombic to total binding. The latter, though difficult, is by no means impossible. The above theoretical calculations suffice, however, to decide whether bimolecular reactions will involve single atoms or not and give the actual activation energies as accurately as they are known experimentally in a majority of the cases considered. Taking explicit account of the fact that the valence electron on the halogens is a p-electron would not change the activation energy for three atom reactions but would increase it for four atom reactions. This is in a direction to give better agreement with experiment in every case and to insure that the reaction between bromine and hydrogen will go by way of the atoms. Equations 2 and 4 were first obtained by group theory methods but may be very readily obtained by the method of Slater.[23] The details will not be given here. These equations in the form written are only strictly valid when the atoms are rather far apart. At closer ranges normalizing factors should be introduced. This correction has been approximately achieved in the above calculations by substituting for the quantities $A + a$, etc., the experimental values for diatomic molecules which are automatically normalized.

Certain general remarks can be made regarding the applicability of the method of calculating activation energies that has been used here. It has been assumed that the atoms behave as they would classically in the potential energy fields calculated from quantum mechanics. This is possible because it is permissible to assume eigenfunctions for the atoms which have much greater curvature than the curvature of the potential energy fields in which the atoms move.

Even in reactions where the three and four atoms of the previous calculations are replaced by radicals or even by surfaces, the calculation should give a good approximation for the activation energy provided the bonds made and broken involve only the spins of three or four S electrons. This will include many reactions. The group theory can be used to obtain the potential energy in more complicated cases.

As the fraction of the binding which is coulombic increases, the activation energy decreases, becoming zero, for example, in strong electrolytes.

I have had the advantage of many helpful discussions with Dr. Clarence C. Zener, Professor G. E. Gibson and other members of the Departments of Chemistry and Physics, in the preparation of this paper.

Summary

The adiabatic (London) theory of reaction rates has been applied, for the first time, to reactions involving four atoms. It shows, unambiguously, that the thermal reaction of hydrogen with iodine will involve only iodine molecules, while the other halogens will react with hydrogen by way of the atoms. It shows further that the conversion of para to ortho hydrogen will involve an atom and a molecule rather than two molecules. It explains the well-known greater reactivity of the heavy halogen compounds over the lighter ones. These checks with experiment are independent of the ratio of coulombic to total binding except in the case of bromine. If the known theoretical ratio of coulombic to total binding for hydrogen is assumed to hold for the other atoms, approximate agreement with experiment is obtained. To obtain exact agreement in the reaction $H_2 + I_2 = 2HI$ the coulombic binding must be assumed to be only three and a half per cent. of the total binding. The theoretical evaluation of the coulombic binding is possible, but difficult, using the approximate eigenfunctions of Zener and Slater.

THE VAPOR DENSITY OF SELENIUM TETRABROMIDE AND THE EXISTENCE OF SELENIUM DIBROMIDE

BY DON M. YOST AND JOHN B. HATCHER

RECEIVED APRIL 27, 1931 PUBLISHED JULY 8, 1931

Introduction

The results of the few qualitative observations that have been made on selenium tetrabromide[1] show definitely that it decomposes to some extent at room temperature and much more so at higher temperatures, the products of the decomposition being bromine and a lower bromide or bromides of selenium. Since no information of a quantitative nature seems to exist on the chemistry involved in the decomposition, the experiments described in this paper were undertaken.

Experimental Procedure and Preparation of the Materials.—The experiments consisted essentially in determining by the Dumas method the vapor densities of mixtures of selenium and bromine over the temperature range from 250 to 500°. Carefully weighed portions of bromine and elementary selenium were introduced into a cylindrical Pyrex tube

---

X, p. 899; J. Meyer and V. Wurm, *Z. anorg. Chem.*, **190**, 90 (1930).

of known volume, the bromine being contained in a small glass capsule with an easily breakable tip. The end of the tube was provided with a heavy-walled capillary whose end was drawn down to a thin tip and sealed off. After filling the tube, it was carefully evacuated, and then sealed off. A vigorous shake sufficed to break the tip of the bromine capsule, permitting the bromine to react with the selenium. The tube with the capillary was weighed and then placed in an electric furnace. After temperature equilibrium had been attained, the tip of the capillary was heated until the pressure inside the tube forced an opening through the softened glass and allowed the excess of gas to escape. The tip was not resealed until it was judged that the contents of the tube had again reached the temperature of the furnace, some cooling having resulted from the adiabatic expansion of the gas. The tube was then removed from the furnace, cooled and again weighed. The difference in the weights was the amount of material that had escaped; and this amount, subtracted from the original amount present, yielded the quantity remaining in the tube. The same tube was used for a series of experiments at increasingly higher temperatures.

The method of purifying the selenium was the same as that used in a former investigation.[2] The bromine was prepared by heating C. P. cupric bromide in a vacuum and subsequently drying and redistilling the bromine from pure potassium bromide.

Results of the Experiments

In Table I are presented results of representative vapor density measurements, of which thirty were made in all. It was assumed in making the calculations that the vapor obeyed the perfect gas law, and in the table are given the values of the apparent molecular weight M of the vapors as calculated directly from the equation, $M = 82.07(t + 273.1)m/pv$, p being expressed in atmospheres and v in cubic centimeters. The initial amount of bromine used varied from 0.37 g. to 0.53 g.

In order to determine qualitatively whether or not bromine was present in the hot vapors, their absorption spectra were observed and compared with that of an equal thickness of pure bromine at 200 mm. pressure, a visual spectrometer being used. When the atomic ratio Br:Se was four, the absorption bands of bromine were present with an intensity comparable to that observed in the comparison tube. In experiments where the composition of the mixture corresponded to selenium monobromide, no bromine bands could be seen, indicating that little or none of it was present. With a Br:Se ratio of two the bromine bands were very faint when the tube was hot and increased in intensity when, on cooling, condensation took place. This showed qualitatively that little or no bromine was

[a] Considerable black unvaporized liquid residue was present in these experiments, so that the values for the molecular weight would have no significance.

present until the vapor in the tube began to alter its composition as a result of condensation.

When the atomic ratio was unity, corresponding to Se_2Br_2, complete vaporization of the material was never attained even at 500°. The unvaporized residue was a black liquid, whose appearance was that of molten selenium, but which might have contained some dissolved monobromide. With a Br:Se ratio of two or four the material vaporized completely without difficulty and in the former case gave rise to a molecular weight whose significance will appear later. Clear solutions containing no free bromine always resulted when the tetrabromide tubes were opened under water after the vapor density experiments had been made.

Discussion of Results

Since Table I shows that the molecular weight calculated from the measurements with mixtures having the composition of selenium tetrabromide is almost exactly one-half the formula weight of this substance, it follows that the tetrabromide does not exist as such under the conditions of the experiments, but decomposes completely in such a way that two molecules result from one of the tetrabromide. That this dissociation is complete is shown by the fact that the molal weight remains the same throughout the whole range of temperatures investigated (250–500°).

Such a decomposition might occur in the following ways

$$SeBr_4 = Se(s) \text{ or } (l) + 2Br_2(g) \qquad (1)$$
$$2SeBr_4 = Se_2Br_2(g) + 3Br_2(g) \qquad (2)$$
$$SeBr_4 = SeBr_2(g) + Br_2(g) \qquad (3)$$

The decomposition according to equation (1) is, however, excluded since no solid or liquid selenium (whose vapor pressure[3] is 4 mm. at 400°) was ever present in the tubes having a Br:Se ratio of four.

If the decomposition of the tetrabromide took place according to reaction (2), normal values for the molecular weight of the monobromide[4] would have resulted in the experiments with it alone, and no unvaporizable residue should have remained, providing it were not decomposed. Yet, as may be seen from the last three results in the table, the monobromide experiments do not yield a normal molecular weight and considerable unvaporizable residue remained even at the highest temperature.

The possibility of the monobromide decomposing into the tetrabromide and selenium according to the reaction

$$2Se_2Br_2 = SeBr_4(g) + 3Se(l) \qquad (4)$$

is excluded by the fact that the tetrabromide as such does not exist even in the presence of bromine, as already shown. That decomposition of the monobromide into bromine and selenium did not occur is shown by the fact that no absorption bands of bromine were found when the Br:Se ratio was unity and that the escaping vapor showed itself, on testing, to be rich in selenium. Moreover, no residue of selenium was ever found in the tetrabromide experiments even at 220° where the vapor pressure of liquid selenium is only 0.005 mm.[5] It appears then that the decomposition of the tetrabromide does not take place according to reaction (2).

There remains therefore only the possibility that the decomposition of the tetrabromide takes place in accordance with reaction (3). If this be the case, complete vaporization of the mixtures used should occur when the Br:Se ratio is two, and this was in fact found to be true. Moreover, if the existence of selenium dibromide is assumed, the results of the experiments on the selenium monobromide are easily explained by assuming that the monobromide decomposes according to the reaction

$$Se_2Br_2 = Se(l) + SeBr_2(g) \qquad (5)$$

One must conclude, therefore, that selenium monobromide does not exist to any appreciable extent in the vapor phase at the temperatures of 250–500°; but that the hitherto unknown compound selenium dibromide does so exist. The dibromide vapor, however, seems not to condense as

---

[3] Preuner and Brockmoller, *Z. physik. Chem.*, 81, 129 (1913).

[4] The vapor pressure of the monobromide, if it existed as such, would have exceeded one atmosphere since at the lowest temperatures the total initial pressures in tubes containing the tetrabromide were about four atmospheres, and one-half of this would be due to the monobromide.

[5] L. E. Dodd, THIS JOURNAL, 42, 1579 (1920).

such to a solid or liquid phase, but to break up into the familiar liquid monobromide and solid tetrabromide.

It is of interest to point out that the equilibrium relations of a system composed of selenium and bromine are very similar to those of one composed of selenium and chlorine.[2,6]

Solid Selenium Tetrabromide.—The appearance, on cooling, of the substance in the tubes containing selenium tetrabromide was observed. The vapor itself has a dark red color (as does also selenium dibromide). The first solid material that appears is black in color and forms small hexagonal plates. As the temperature becomes lower still, the crystals that form possess a red color but are not, under a pocket lens, hexagonal in shape. If the temperature is suddenly lowered from about 50° to room temperature by holding the tube under the water tap, the clear portions of the tube are covered with very small lemon-yellow crystals. These differently colored substances may all be different modifications of solid selenium tetrabromide; no attempt was made to study them further.

Summary

The vapor density of mixtures corresponding in composition to selenium tetrabromide has been determined over the temperature range from 250 to 500°. The results show that it is completely decomposed at these temperatures into bromine and the previously unknown selenium dibromide.

Experiments with selenium monobromide showed that it decomposes, to a considerable extent at least, into selenium and selenium dibromide on vaporization. Mixtures of the composition of selenium dibromide vaporize completely, and in the vapor phase consist principally of selenium dibromide itself.

THE FIRST DISSOCIATION OF PHOSPHORIC ACID IN AQUEOUS SALT SOLUTIONS AT 18°

BY JOSEPH W. H. LUGG

RECEIVED APRIL 29, 1931 PUBLISHED JULY 8, 1931

In a previous paper[1] the author has employed conductivity data of pure phosphoric acid solutions in recalculations of the first dissociation constant. The present paper deals with an investigation of this important dissociation in aqueous solutions containing certain inorganic salts.

It is at present impossible to interpret correctly electrical conductivity measurements of solutions of high ionic concentration, and on this account the conductivity method is inapplicable to a study of the first dissociation of phosphoric acid in salt solutions. The method discussed in this paper has been used to determine the stoichiometric dissociation constant in solutions of sodium chloride, potassium chloride, magnesium chloride, and calcium chloride, of varying concentration. From what follows it will be seen that the method presented herein is somewhat similar to that evolved by Harned and Robinson[2] for studying the dissociations of weak electrolytes, but it seems to possess certain advantages over their method. Thus the assumption of complete dissociation of hydrochloric acid (which is later checked and proved experimentally) does not involve a possible error in the e. m. f. of a "chloride" as well as a "hydrogen" electrode, and there is no delay waiting for a "chloride" electrode to reach equilibrium. Furthermore, by replacing the hydrochloric acid with nitric acid the method could be extended to solutions containing nitrates, and corrections might be made if the nitric acid proved to dissociate incompletely.

Outline of the Method and the Principles Involved

Electrometric measurement of hydrogen-ion activity is ordinarily subject to junction potential and standardization errors, and these may influence the second decimal place so seriously that the result can safely be called "PH value" only. A chain consisting of two half-cells in which are solutions of the same concentration with respect to some neutral foreign metal chloride, but of different concentration with respect to very small quantities of hydrochloric acid, has a negligible liquid junction potential, and may be used to find the relative hydrogen-ion activities in the two solutions with great exactitude. If the hydrochloric acid in one half-cell is replaced by a small quantity of phosphoric acid, the junction potential will still be negligibly small and the relative hydrogen-ion activities can

---

[1] Lugg, THIS JOURNAL, 53, 1 (1931).

[2] Harned and Robinson, *ibid.*, 50, 3157 (1928).

again be measured with accuracy. Secondary and tertiary dissociations of phosphoric acid are negligible under these acid conditions, and were the actual concentration of hydrogen ions in the hydrochloric acid solution known, the first stoichiometric dissociation constant, K_1, of phosphoric acid could then be calculated, because the activity coefficients of hydrogen ions are the same in solutions whose thermodynamic environments are kept sensibly constant by a relatively high concentration of foreign salt.

Although it is an experimental fact that the measured hydrogen-ion activity is directly proportional to the small hydrochloric acid concentration when the ionic environment is kept sensibly constant, it cannot be concluded therefrom that the hydrochloric acid is completely dissociated, because it may be shown from the mass law that the same behavior would be observed even if hydrochloric acid were a typically weak acid. But if the provisional assumption of complete dissociation for the hydrochloric acid is made, and the phosphoric acid dissociation constant calculated on it, the validity of this assumption may be tested by repeating the measurement in the presence of a different quantity of phosphoric acid. Theory and experiment show that the activity coefficients of ions and un-ionized solutes in the presence of a preponderating amount of foreign salt are constant. The second determination of K_1 could be the same as the first only if the provisional assumption were valid. Such double determinations of K_1 in sodium, potassium, magnesium and calcium chloride solutions are recorded herein, and from their close agreement provide excellent confirmation for the Complete Dissociation Theory in the case of hydrochloric acid, a typical strong electrolyte.

Instead of employing a chain such as that described above, one might measure the e. m. f. between a calomel electrode and a quinhydrone electrode in the hydrochloric acid solution, and repeat the measurement with phosphoric acid replacing the hydrochloric acid. Provided that precautions are taken to ensure the junction potential being the same in both measurements, the difference in e. m. f. will be the same as that of the chain described earlier, and as the quinhydrone salt error will be the same in both cases, the difference in e. m. f. will be subject to no errors other than experimental ones.

This procedure was actually followed in obtaining the present data, in the hope that the hydrogen-ion activity coefficient could be obtained with fair accuracy in each case, after correcting for the quinhydrone salt error. Junction potentials were of such magnitude, however, and so variable, that this could not be done with any expectation that the results would have physical significance. To ensure that the changes in junction potential would not vitiate the measured difference in e. m. f. between phosphoric acid and hydrochloric acid solutions, the 0.1 N potassium chloride calomel electrode was connected by the same saturated agar bridge successively with the two solutions; the order was then reversed and a mean value of the differences was taken. It was found that the difference could be reproduced by this method to within a few tenths of a millivolt. Stock solutions were standardized to within 0.1%. All measurements were made at 18.0°.

Where ΔE is the e. m. f. difference in volts, (H_3PO_4 solution)-(HCl solution), α_{H^+} represents hydrogen-ion activity, and p signifies negative common logarithm, we have

$$-\frac{\Delta E}{0.05773} = \Delta p\alpha_{H^+} = p\alpha_{H^+(H_3PO_4)} - p\alpha_{H^+(HCl)} \qquad (1)$$

Since γ_{H^+}, the hydrogen-ion activity coefficient, is the same in both solutions

$$\Delta p\alpha_{H^+} = p[H^+]_{(H_3PO_4)} - p[H^+]_{(HCl)} \qquad (2)$$

Assuming $[H^+](HCl) = [HCl]$, $[H^+]$ in the phosphoric acid solution is given by

$$p[H^+] = p[HCl] - \frac{\Delta E}{0.05773} \qquad (3)$$

$[H^+]$ must equal $[H_2PO_4^-]$ for electroneutrality, and where $[H_3PO_4]$ represents the initial phosphoric acid molarity, the mass law gives

$$K_1 = \frac{[H^+]^2}{[H_3PO_4] - [H^+]} \text{ or } pK_1 = 2p[H^+] - p([H_3PO_4] - [H^+]) \qquad (4)$$

Results

The data are given in Table I, which contains in the order of the columns, foreign salt molarity, hydrochloric acid molarity, phosphoric acid molarity, AE, $[H^+]$, pK_1, and $\sqrt{\mu}$. The ionic strength, μ, has been calculated for the phosphoric acid solutions from the definition, $\mu = {}^1/_2\Sigma(Cz^2)$, where C is the concentration of any ion in moles per liter, and z is its valence. In calculating μ, the metal chlorides were assumed to be completely dissociated.

Discussion

By definition the stoichiometric constant, K_1, becomes the activity constant, K_1', at infinite dilution, where the activity coefficients of all ions and molecules concerned are unity. K_1' is a true constant, and its relation to K_1 is given in

$$pK_1 = pK_1' - p\gamma_{H^+} - p\gamma_{H_2PO_4^-} + p\gamma_{H_3PO_4} \tag{5}$$

The Hückel[3] equation connecting the activity coefficient of a univalent ion of the *r*th kind with the ionic strength in aqueous solutions at 18° may be expressed

$$p\gamma_r = \frac{0.5\sqrt{\mu}}{1 + r\sqrt{\mu}} - R\mu \tag{6}$$

where r and R are both positive, and constant for a particular type of ionic environment. *r* is proportional to the mean limit of approach of ions to ions of kind *r*.

The Debye–McAulay[4] equation connects the activity coefficient of an un-ionized molecule of the *s*th kind with the ionic strength

---

[3] Hückel, *Physik. Z.*, **26**, 93 (1925).

[4] Debye and McAulay, *ibid.*, **26**, 22 (1925).

$$p\gamma_s = -\frac{S'}{\rho}\mu = -S\mu \tag{7}$$

where S' is constant for a particular un-ionized solute in a particular solvent and ρ is a mean diameter of the ions present. S is therefore constant for a particular type of ionic environment. The concentration of un-ionized molecules has been found experimentally to influence γ_s relatively little. S', and hence S, may be positive or negative.

Substituting (6) and (7) with appropriate coefficients in (5)

$$pK_1 = pK_1' - \frac{0.5\sqrt{\mu}}{1 + a\sqrt{\mu}} - \frac{0.5\sqrt{\mu}}{1 + b\sqrt{\mu}} - (S - A - B)\mu \tag{8}$$

the r and R of equation (6) being replaced by a and A for H^+ ions, and by b and B for $H_2PO_4^-$ ions. If a and b are equal, or, for practical purposes, when they are not too dissimilar, equation (8) may be simplified to

$$pK_1 = pK_1' - \frac{\sqrt{\mu}}{1 + a\sqrt{\mu}} - C\mu \tag{9}$$

where a now has some mean value, and $(S - A - B)$ is replaced by C.

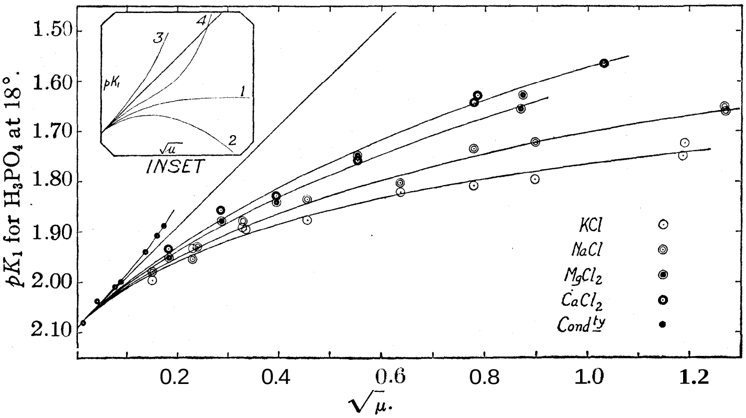

Fig. 1.

Whatever the values of the constants, equations (8) and (9) both reduce in the limit, as $\sqrt{\mu}$ approaches zero, to

$$pK_1 = pK_1' - \sqrt{\mu} \tag{10}$$

An examination of successive differential coefficients reveals that equations (8) and (9) both give similar curve types when plotted with decreasing pK_1 values as ordinates and $\sqrt{\mu}$ values as abscissas. These types are shown in the inset to Fig. 1. If C is zero, both equations give type 1, the curve being asymptotically parallel to the $\sqrt{\mu}$ axis. If C is negative, type 2 (concave downward) results from both equations. If C is positive and greater than $(a + b)/2$ in equation (8) (or greater than a in equation (9)), type **3** (concave upward) results. If C is negative and less than

$(a + b)/2$ in equation (8) (or less than a in equation (9)), type 4 is obtained. This curve is first concave downward to a point of inflection, and then proceeds concave upward. A limiting straight line, representing equation (10), is also shown.

The data in Table I were plotted as shown in Fig. 1, and curves were drawn through the points. As pK_1' has been obtained with sufficient accuracy from conductivity data, the extension of the curves to $\sqrt{\mu} = 0$, $pK_1 = 2.09$, was a matter of interpolation rather than extrapolation. Points from the author's recalculations of conductivity data are reproduced in Fig. 1 and the theoretical limiting straight line, $pK_1 = 2.09 - \sqrt{\mu}$, is also shown. Work done at higher $\sqrt{\mu}$ values might eventually show that the sodium chloride and potassium chloride curves rightly belong together or separately to type 2 or type 4, but at present they seem to satisfy the conditions for type 1 (*i. e.*, C = 0). The first few points on the magnesium chloride and calcium chloride curves suggest curves of type 4, but at higher $\sqrt{\mu}$ values there is no suggestion of this. It is possible that these salts dissociate incompletely, perhaps yielding compound ions, and, if so, the $\sqrt{\mu}$ values would be incorrect and the equation constants upset. Both curves drawn are of type 1. In passing, it should be mentioned that Onsager[6] has shown from conductivity data that salts such as sodium chloride, potassium chloride, magnesium chloride and calcium chloride, behave in dilute solution as if they were completely dissociated. Approximate equations of the form of (9) in which $C = 0$ may be applied to the four salt curves

$$\text{NaCl} \qquad pK_1 = 2.09 - \frac{\sqrt{\mu}}{1 + 1.60\sqrt{\mu}} \tag{11}$$

$$\text{KCl} \qquad pK_1 = 2.09 - \frac{\sqrt{\mu}}{1 + 2.12\sqrt{\mu}} \tag{12}$$

$$\text{MgCl}_2 \qquad pK_1 = 2.09 - \frac{\sqrt{\mu}}{1 + 1.14\sqrt{\mu}} \tag{13}$$

$$\text{CaCl}_2 \qquad pK_1 = 2.09 - \frac{\sqrt{\mu}}{1 + 0.93\sqrt{\mu}} \tag{14}$$

Since C is made zero here, it means that $S = A + B$ and is positive, but it is impossible to evaluate it. The smaller the value of a in equation (9), the smaller p should be in equation (7) and so S should be larger. The curve drawn from conductivity data belongs to type **3**, and the author's equation to it is $pK_1 = 2.09 - \sqrt{\mu}/(1 + 1.0\sqrt{\mu}) - 1.8$, S being positive and so large that A and B were assumed to be negligible in comparison and S was put equal to 1.8. The value 1.0 for a was assumed between discussed limits.

It will be observed in Table I that the higher the initial concentration of phosphoric acid in the presence of a fixed amount of salt, the lower, as a

---

[6] Onsager, *Physik.* Z., 28,277 (1927).

rule, is the value found for pK_1. The reverse would be expected if hydrochloric acid were incompletely dissociated. It has been concluded therefore that small specific ion effects, and possibly those due to the small amounts of undissociated phosphoric acid, alone are responsible for the small decrease in pK_1, that hydrochloric acid is completely dissociated even in presence of very much metal chloride, and that the pK_1 values are quite reliable to within the experimental limits of accuracy. In the absence of detailed knowledge concerning the second dissociation of sulfuric acid, the method cannot be applied to sulfate solutions containing phosphoric acid.

In conclusion the author wishes to thank Professor J. A. Prescott and Mr. R. J. Best of the Waite Institute for provision of a constant temperature laboratory and a suitable potentiometer, the Council for Scientific and Industrial Research for materials used, Professor N. T. M. Wilsmore and Dr. G. A. Elliott of the University of Western Australia for criticism, and Dr. S. W. Pennycuick of the Adelaide University for suggested alterations and assistance in publication.

Summary

A method is discussed for studying weak acid dissociations in salt solutions, particularly the first dissociation of phosphoric acid in chloride solutions. Using a less delicate modification of it, experimental work has been done with phosphoric acid in the presence of sodium, potassium, magnesium and calcium chlorides, and the results are given and discussed.

Evidence is adduced to show that hydrochloric acid must be considered to be completely dissociated in solution, even in presence of much metal chloride.

THE VOLUMETRIC DETERMINATION OF URANIUM. POTENTIOMETRIC TITRATION OF REDUCED URANIUM SOLUTIONS WITH CERIC SULFATE, OR WITH POTASSIUM PERMANGANATE. APPLICATION OF THE DIFFERENTIAL METHOD

BY N. HOWELL FURMAN AND IRL C. SCHOONOVER[1]

RECEIVED APRIL 30, 1931 PUBLISHED JULY 8, 1931

Introduction

This investigation deals with the reduction of hexavalent uranium by amalgamated zinc, and with the potentiometric titration of the reduced solutions with standard permanganate or ceric sulfate solution. This study was found to be a necessary preliminary to the development of volumetric methods which are based upon the reactions of quadri- or hexavalent uranium with other substances as, for example, sodium, fluoride or phosphate ion.

The literature regarding the reduction of hexavalent uranium with zinc, or zinc amalgam, contains many contradictory statements. The chief point upon which disagreement has existed has been the extent to which reduction proceeds. A number of investigators have concluded that reduction proceeds quantitatively to the quadrivalent state.

Belohoubek[2] studied the reduction of uranyl sulfate, chloride, acetate, and nitrate with zinc. An attempt was made to exclude air while the solution cooled after the reduction. The solution was diluted "until the color disappeared," acid was added, and then the titration was made. Good results were reported for the sulfate and chloride solutions, poor ones in the case of the acetate and extremely poor ones for the nitrate solutions. No formation of trivalent uranium was observed.

Follenius[3] reduced uranyl acetate solutions with zinc and sulfuric acid; air was excluded. He found no reduction beyond the quadrivalent state; his results demonstrated clearly that the addition of hydrochloric acid before the titration caused too much permanganate to be consumed.

Zimmermann[4] treated 5 or 10 cc. portions of a uranium nitrate solution with 10 or 20 cc. of sulfuric acid of sp. gr. 1.23. After the mixture had been heated until sulfur trioxide was evolved, the solution was diluted and reduced with zinc in the absence of air. He found no evidence of the formation of trivalent uranium. In hydrochloric acid solutions, on the

[4] Zimmermann, Ann., 213, 300 (1882).

contrary, trivalent uranium was formed. Zimmermann proved that the addition of manganous sulfate prevented the interaction between permanganate and hydrochloric acid, just as is the case with iron solutions.

Kern[5] reported that aluminum, magnesium, zinc, or zinc amalgam, reduce uranium quantitatively to the quadrivalent condition in sulfuric acid solution, whereas stannous chloride in hydrochloric acid solution forms some UCl_3 as well as UCl_4.

Of the more recent investigations in which no over-reduction (*i.* e., formation of U^{III}) was found, especial mention should be made of those of Gustavson and Knudson[6] and of Müller and Flath.[7] Although these investigators excluded air very carefully during the reduction, and performed the titrations potentiometrically, they found no evidence of reduction beyond the quadrivalent state in sulfuric acid solutions.

Failure to find over-reduction may have been due to incomplete exclusion of air in the earlier investigations, or to high acid concentration. The difficulty of reduction of U^{VI} solutions increases with the square of the hydrogen-ion concentration (or rather activity), as is shown by the e. m. f. relation, at 25°

$$E = E_0 + \frac{0.0591}{2} \log \frac{(UO_2^{++})(H^+)^4}{(U^{++++})} = E_0 + \frac{0.0591}{2} \log \frac{(UO_2^{++})}{(U^{++++})} + 0.0591 \log (H^+)^2$$

Luther and Mitchie[8] found that this expression, in terms of concentration, applied accurately over the range 0.1 N to 1 N sulfuric acid concentration.

The following investigators have all found evidence that the reduction proceeds partially to the trivalent stage in sulfuric acid solution with zinc or zinc amalgam as the reducing agent. Guyard[9] reported the formation of a mixture of salts of lower oxides upon reduction of acidified uranium solutions with zinc. He was unable to obtain accurate results with permanganate.

Pulman,[10] using a Jones reductor, found partial reduction of quadri- to trivalent uranium, and called attention to the rapidity with which the latter was reoxidized by air.

McCoy and Bunzel[11] found over-reduction with zinc, and proved that with a uranium solution which was 4 N in sulfuric acid, the trivalent form was rapidly converted to the quadrivalent, and the latter was only slowly oxidized by air at room temperature. The speed of oxidation of U^{IV} to U^{VI} was found to be approximately inversely proportional to the square root of the hydrogen-ion concentration.

Pierle[12] found over-reduction in the Jones reductor with sulfuric acid concentrations approximating one volume of acid in six volumes of solution.

Treadwell[13] and Ewing and Eldridge[14] found over-reduction with zinc or cadmium, or with zinc amalgam, respectively. Air was carefully excluded by a current of carbon dioxide. The potentiometric titrations with potassium permanganate gave a sharp inflection in the e. m. f.–cc. graph at the completion of the oxidation, $U^{III} \longrightarrow U^{IV}$, and a second sharp inflection at the end of the process $U^{IV} \longrightarrow U^{VI}$.

Lundell and Knowles[15] pointed out the advantages of reducing *cold* solutions of iron, uranium and other elements, in the Jones reductor. Over-reduction of uranium occurs in the cold solution to about the same extent as in hot solutions. These investigators[16] demonstrated by quantitative tests that in solutions containing 5% of concentrated sulfuric acid by volume, the trivalent uranium which is formed is oxidized rapidly by the action of a stream of air in one to five minutes; the quadrivalent uranium is relatively stable in air at room temperature (as long as four hours), but is oxidized very rapidly by air at 60–SO°.

The results of this investigation confirm the findings of Lundell and Knowles, Treadwell, Ewing and Eldridge, Pierle, McCoy and Bunzel and Pulman regarding the fact of over-reduction of uranium in solutions containing 2–5% of sulfuric acid of sp. gr. 1.84 by volume. Upon reduction of either hot or cold solutions in the Jones reductor the characteristic brownish color of a mixture of tri- and quadrivalent uranium salts was evident, and the potential (Pt vs. reference electrode) gave evidence of the presence of a more powerful reducing agent than U^{IV}. The amount of standard oxidizing agent which was consumed by the trivalent salt was extremely variable in duplicate determinations made under like conditions. In extreme cases more than 40% of the uranium was reduced to the trivalent state; generally from 25–40% of the uranium was in the trivalent condition.

Our results with regard to the ease of oxidation of U^{III} by air, and the relative stability of U^{IV} in air at room temperature confirm the findings of Lundell and Knowles.

A new method of determination, namely, titration of reduced uranium solutions with standard ceric sulfate, has been compared with the permanganate method; the potentiometric method was employed. The work of Treadwell and of Ewing and Eldridge has been confirmed with reference to the permanganate titration.

[16] Lundell and Knowles, THIS JOURNAL, 47,2637 (1925).

A small quantity of iron (1 mg. per 25 cc.) is present in the 0.1 *N* ceric sulfate solutions which are prepared directly from commercial rare earth oxides.[17] The graph of the potentiometric titration data, therefore, shows three inflections (see Fig. 2), the first at the end of the oxidation of the trivalent uranium

$$U^{+++} + Ce^{++++} = U^{++++} + Ce^{+++}$$

the second at the end of the reaction

$$U^{++++} + 2Ce^{++++} + 2H_2O = UO_2^{++} + 2Ce^{+++} + 4H^+$$

and the third at the end of the reoxidation of the ferrous iron that is produced as the titration progresses. The amount of iron which is introduced up to the end of the oxidation of trivalent uranium is practically negligible. The experimental results show that the amount of ceric sulfate which is added between the first and the third inflections corresponds accurately to two equivalents of ceric ion per mole of U^{IV}. In other words, the ferrous iron is produced at the expense of an equivalent amount of quadrivalent uranium. It is more correct in principle to oxidize the trivalent uranium with air before starting the titration with ceric sulfate. It is at once evident that a crude ceric solution containing ferric iron should not be used in the simultaneous determination of uranium and iron.

It was found difficult or impossible to obtain concordant results when the side-arm of a saturated calomel half-cell dipped directly into the reduced solution. The use of a sulfate half-cell and bridge of saturated potassium sulfate eliminated the error. It was found that the differential titration method of MacInnes and Jones,[18] when used in the modified form which Clarke and Wooten[19] developed for work in an indifferent atmosphere, gave excellent results for all of the three inflections. This is apparently the first time that the possibility of the determination of a succession of oxidation–reduction end-points by the differential method has been demonstrated.

Experimental

Apparatus and Materials.—The titration vessel (a 250-cc. extraction flask) and its accessories are represented in Fig. 1. The simple expedient of inserting electrodes, buret, reductor and thermometer through tightly-fitting rubber tubes (F), mounted on the tops of glass tubes which were permanently mounted in the rubber stopper *(G)*, made it very easy to replace or modify parts of the apparatus.

A Leeds and Northrup students' type potentiometer and portable galvanometer (Type 2320d) and a Weston saturated standard cell were used. Various electrode assemblies were used: (1) Pt *vs.* saturated calomel; (2) Pt *vs.* saturated $K_2SO_4/Hg_2SO_4/$-Hg; (3) Pt *vs.* W; (4) Pt *vs.* sheltered Pt (differential method; see H, Fig. 1).

The calibration of the volumetric glassware used was checked carefully, and the necessary corrections were applied. The tip of the buret was drawn down so that one drop of liquid amounted to 0.025 cc.

[19] Clarke and Wooten, J. Phys. *Chem.*, 33, 1468 (1929).

Carbon dioxide from a cylinder was used.

Zinc of high purity was amalgamated with about 1% of mercury by a solution of mercuric nitrate prepared from the calculated amount of pure redistilled mercury. Frequent blank tests were made by passage of measured amounts of the sulfuric acid wash solution through the reductor. Potentiometric tests of the solutions showed that no blank correction was necessary with 0.1 *N* permanganate or ceric sulfate when the best available materials were selected.

Potassium permanganate and ceric sulfate solutions[20] were standardized potentiometrically against Bureau of Standards sodium oxalate.

Crystallized uranyl acetate, $UO_2(C_2H_3O_2)_2 \cdot 2H_2O$, of reagent grade was used. Careful qualitative tests proved the absence of vanadium, iron and the copper–tin group metals. A stock solution was prepared with 20.000 g. of the salt per liter of dilute sulfuric acid (2% of H_2SO_4 of sp. gr. 1.84 by volume). The uranium content of measured portions of the solution was determined either volumetrically with permanganate by the potentiometric method of Treadwell[13] and Ewing and Eldridge[14] with the $Pt-K_2SO_4/Hg_2SO_4/Hg$ electrode system, or gravimetrically as U_3O_8 after ammonia precipitation.[21]

This extended series of titrations fully confirmed the observations of Treadwell, Ewing and Eldridge and others on the character of this potentiometric titration. The reductions were made in cold solution as described later (under determinations with ceric sulfate). The graphs of the titration data were analogous to that of Fig. 2, except that there was no inflection due to iron. Titrations were made in a carbon dioxide atmos-

[a] The acetate was expelled by repeated evaporations with excess of sulfuric acid before the solution was reduced.

phere, and the temperature was 80–90° at the second end-point (U^{IV} to U^{VI}). The initial volume ranged from 135–230 cc.

Preliminary Experiments.—Measured portions of uranyl solution at room temperature were passed through the reductor. In every case the characteristic color and low potential of a mixed solution of U^{III} and U^{IV} was obtained. It was proved that three to five minutes of stirring of the reduced solution with air reoxidized U^{III} to U^{IV}. The process was followed by potentiometer readings, and a sharp potential break (Pt *vs.* reference electrode) of over 0.1 volt was found at the end of the oxidation, thus confirming the conclusions of Lundell and Knowles.[16]

Several titrations of the U^{IV} solutions were made in air at 80–90°. Too little ceric sulfate was required. For example, portions of solution which required 9.04 cc. of 0.1043 N ceric sulfate under carbon dioxide, required 8.32, 8.77 and 8.90 cc. in the presence of air.

Many preliminary titrations were made potentiometrically with permanganate or ceric sulfate using a Pt–saturated calomel electrode system. Fairly concordant results could be obtained at any given initial volume with a carefully standardized procedure and with a constant amount of uranium. If double the amount of uranium was used, or if the working conditions were varied slightly, the consumption of oxidizing agent was not constant per unit volume of uranium solution, as is illustrated by the following results

Initial volume: 150–170 cc.

U^{VI} solution used, cc.	10	10	20	20	25	25
Ceric solution used, cc.	10.08	10.07	19.75	19.67	24.57	24.48
Ceric solution calcd., cc.	9.58	9.58	19.16	19.16	23.95	23.95

Different uranium and ceric solutions were used from those described under "standardization."

A careful study of the various possible variables: nature of electrodes, presence or absence of acetate, total acidity, etc., established the fact that the variability vanished when the saturated potassium chloride was not used. Too much oxidizing agent is consumed when chloride is present in appreciable amount. This observation confirms Follenius'[3] findings with regard to the error caused by the presence of hydrochloric acid. Others who have used the potentiometric method do not mention the error due to chloride; it is probable that the use of normal or 0.1 N potassium chloride would decrease the error.

The Pt–W electrode system failed to indicate the end of the oxidation of U^{III} to U^{IV}, but gave an excellent indication of the other end-points (U^{IV} to U^{VI} and Fe^{II} to Fe^{III}).

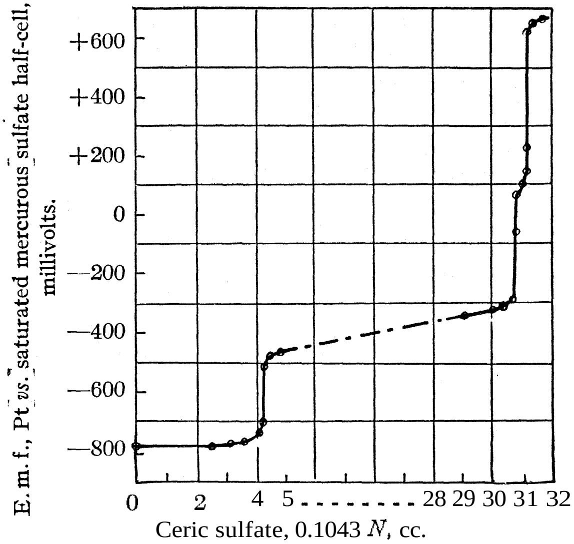

Fig. 2.—Graph representing potentiometric titration of 30 cc. of reduced uranyl solution with ceric sulfate (0.1043 N). The inflection at the left corresponds to the end of the oxidation of U^{III} to U^{IV}; the next to oxidation of U^{IV} to U^{VI} and the last to Fe^{II} to Fe^{III}.

Determinations with Ceric Sulfate Using the Pt vs. **K_2SO_4** (Satd.) **Hg_2SO_4–Hg** Electrode System.—The reductions prior to all determinations to be described subsequently were made by a procedure analogous to that given by Lundell and Knowles.[15,16]

Air was displaced from the receiving flask because it was desired to obtain data upon the extent of over-reduction. Measured portions of uranyl solution containing 2% by volume of concd. sulfuric acid were forced through the reductor by carbon dioxide pressure at room temperature; the reductor was washed with 25–50 cc. portions of 2% (volume) sulfuric acid, and finally with water, until the total volume of the solution was 130–240 cc.

The heating of the reduced solution was commenced, and the titration was started; the first inflection (Fig. 2) was found while the solution was warm, and the final inflections were found in hot solution (80–90°). The graph of the data of a typical titration is shown in Fig. 2. We attribute the third inflection to iron (ferric) that is present in the ceric solution, since the same inflection is found whether acetate is present or absent (see "acetate"). An entirely analogous form of graph was produced in permanganate titrations by adding a little ferric sulfate to the uranium solution after the first inflection had been passed. Quadrivalent uranium reduces ferric iron, and in so far as all of the ferrous iron is produced by oxidation of U^{IV} to U^{VI}, it is obvious that the distance from the first to the third inflection (Fig. 2) should be equivalent to the total uranium (process U^{IV} to U^{VI}). The amount of iron (ferric) that was introduced in the ceric solution up to the first inflection rarely exceeded 0.18 mg. and was generally less than half of this amount.[22] In principle it is preferable to oxidize the trivalent uranium with air before beginning the titration with ceric sulfate. The inflections were determined by the maxima of the Ae. m. f./Δcc. values. The results are summarized in Table I. In this series of determinations the initial volume ranged from 160–240 cc.

TABLE I

POTENTIOMETRIC TITRATION OF REDUCED URANIUM SOLUTIONS WITH CEKIC SULFATE (0.1053 *N*, Nos. 1–10; 0.1043 N, Nos. 11–14)

No.	U^{VI} soln., cc.	$Ce(SO_4)_2$ required for U^{IV}, cc.	U present, g.	U found, g.	Error, mg.	Over-reduction $Ce(SO_4)_2$ used for U^{III}, *cc.*	Over-reduction % of U^{IV} red. to U^{III}
1	10	9.00	0.1123	0.1128	+0.5	1.75	39.1
2	10	9.00	.1123	.1128	+ .5	1.55	34.6
3	10	8.96	.1123	.1123	± .0	1.46	32.6
4	10	8.97	.1123	.1124	+ .1	1.38	30.8
5	10	8.98	.1123	.1126	+ .3	1.47	32.8
6	20	17.97	.2246	.2253	+ .7	3.05	34.0
7	20	17.93	.2246	.2248	+ .2	3.14	35.0
8	20	17.96	.2246	.2252	+ .6	3.22	35.9
9	30	26.93	.3369	.3376	+ .7	4.22	31.4
10	30	26.92	.3369	.3375	+ .6	3.87	28.8
11	25	22.63	.2808	.2810	+ .2	3.15	27.9
12	50	45.16	.5615	.5608	− .7	4.05	17.9
13	50	45.22	.5615	.5616	+ .1	7.60	33.6
14	50	45.17	.5615	.5610	− .5	4.43	19.6

The last column of the table shows clearly the extreme variability in the extent of reduction beyond the quadrivalent stage.

---

[22] The amount of iron was determined by passing measured volumes (50 cc.) of the ceric solution through a Jones reductor, followed by potentiometric titration with standard permanganate. Found 3.20 and 2.9 mg. Average 3.1 mg. per 50 cc. of ceric solution.

Acetate.—Belohoubek[2] stated that acetate caused erratic results if present during the reduction. The results present in Table I show that the error is non-existent, or within the experimental error of the ability of an operator to read an ordinary buret, when uranyl acetate is used. Titrations were also made in absence of acetate.

Portions of the uranyl solution were evaporated to dryness after adding an excess of sulfuric acid. Sulfuric acid was again added, and the acid heated to strong fuming. After cooling and diluting to about 2% sulfuric acid content, the solutions were reduced and titrated in the usual manner. The results are shown in Table II (Nos. 1–4). In other instances weighed portions of the U_3O_8, after the gravimetric determination, were dissolved in sulfuric acid, reduced and titrated (Table II, Nos. 5–6).

TABLE II

TITRATION OF REDUCED SOLUTIONS OF URANIUM IN ABSENCE OF ACETATE, WITH 0.1043 *N* CERIC SULFATE

No	U^{VI} soln., cc.	Ce(SO$_4$)$_2$ requirred for U^{IV}, cc.	U present, g.	U found, g.	Error, mg.	Over-reduction Ce(SO$_4$)$_2$ used for U^{III}, cc.	Over-reduction % of U^{IV} red. to U^{III}
1	10	9.05	0.1123	0.1124	+0.1	1.43	31.6
2	20	18.10	.2246	.2248	+ .2	3.23	35.7
3	10	9.07	.1123	.1126	+ .3	1.08	23.9
4	25	22.61	.2808	.2808	± .0	4.45	39.4
5	20	18.13	.2246[a]	.2252	+ .6	2.74	30.3
6	30	27.10	.3369[b]	.3366	− .3	5.85	43.1

[a] Found gravimetrically, 0.2250; [b] 0.3373 g. of uranium.

Practically the same range of error and percentage of over-reduction is found whether acetate is present or absent. In both series of determinations (Tables I and II) the results with ceric sulfate average slightly higher than those with permanganate, or by the gravimetric method. We believe that this slight discrepancy is in large part accounted for by the reduction of a small amount of iron by the trivalent uranium.

In other determinations 10 cc. of glacial acetic acid was added to the uranium solution before it was reduced. The other conditions were the same as in the previous determinations. The acetic acid (10 cc.) consumed a drop of ceric sulfate (0.05 cc.) in the absence of uranium, and this correction was applied to the volumes of ceric sulfate found. The results were as follows.

U^{VI} soln., cc.	Ce(SO$_4$)$_2$ required, cc.	U present, g.	U found, g.	Error, mg.	Ce(SO$_4$)$_2$ used for , .	Over-reduction, %
10	9.10	0.1123	0.1130	+0.7	0.85	19.8
10	9.08	.1123	.1128	+ .5	.45	9.96
10	9.04	.1123	.1128	+ .5	.65	14.3
20	18.15	.2246	.2254	+ .8	.55	6.1

The results appear to be consistently high in the presence of a large quantity of free acetic acid but, due to the uncertainty introduced by the correction, we are not convinced that pure acetic acid occasions any error. Errors of the same order of magnitude were observed in the absence of acetate (Table II). The percentage of over-reduction is markedly less in the solutions which contain acetic acid.

Application of the Differential Method.—In searching for the cause of the erratic results which were obtained when chloride was present (*cf.* preliminary experiments), the differential method of MacInnes and Jones[23] was applied satisfactorily to the determination of the three inflections of each titration. It was found to be necessary to exclude air from the tube (H, Fig. 1) which contained the sheltered platinum electrode; otherwise very rapid oxidation of the hot solution occurred. It was found to be advisable to attach a small rubber bulb to a T-tube in the carbon dioxide line which was joined to H (Fig. 1), as was suggested by Clarke and Wooten.[19] This bulb acts as a pressure regulator during slight changes in temperature, and serves as a means of expelling the liquid which surrounds the sheltered electrode. If the liquid is not changed after each addition of reagent near the end-point, the electrode, H, acts as a reference electrode, and the graph of the titration data resembles that of Fig. 2. If the liquid in the tube is changed after addition of each small increment of reagent, the succession of maxima is obtained

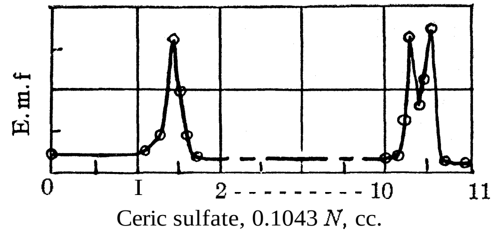

Fig. 3.—Differential titration of 10 cc. of reduced uranyl solution with ceric sulfate (0.1043 *N*). The maxima, left to right, correspond, respectively, to completion of oxidation of (1) U^{III}, (2) U^{IV}, (3) Fe^{III}.

TABLE III

DIFFERENTIAL TITRATION OF REDUCED URANIUM SOLUTIONS WITH CERIC SULFATE (0.1043 N)

No.	U^{VI} soln., cc.	$Ce(SO_4)_2$ required for U^{IV}, cc.	U present, g.	U found, g.	Error, mg.	Over-reduction $Ce(SO_4)_2$ used for U^{III}, cc.	Over-reduction, %
1	10	9.08	0.1123	0.1128	0.5	1.38	30.5

The general conditions of reduction and titration were the same as those which were described for the first series of determinations (Table I).

---

[23] MacInnes and Jones, THIS JOURNAL, 48, 283 (1926).

as shown in Fig. 3, which is typical of a number of titrations. A summary of the results obtained is shown in Table III.

The distance between the second and third inflections was, in general, closely proportional to the amount of ceric solution used, and was close to but slightly greater than the value calculated from the amount of iron known to be present in the ceric solution. For example, with 10 cc. of ceric sulfate used, the value should have been 0.10 cc.; found, 0.11, 0.20, 0.13, 0.20. It is probable that a reliable correction could be made for the iron if the trivalent uranium were oxidized by air before the start of the titration.[24]

This investigation was made possible by the support of a fellowship in analytical chemistry, established by Merck and Company, Inc., of Rahway, N. J., and it is desired to express here our gratitude for this generous support.

Summary

This investigation has confirmed the fact that amalgamated zinc reduces hot or cold acidified uranyl solutions partially beyond the quadrivalent stage. Quantitative data are presented upon the extent of over-reduction. The ease of oxidation of trivalent uranium by air has been observed.

It has shown that a new method of oxidation of reduced uranium solutions, namely, by standard ceric sulfate, gives satisfactory results by the potentiometric method. Chloride interferes, causing erratic high results. The presence of small amounts of acetate causes no measurable interference.

The differential titration method has been applied to the determination of a succession of oxidation–reduction end-points in the titration of reduced uranium solutions with ceric sulfate.

PRINCETON, NEW JERSEY

---

[24] During the correction of the proof of this work a communication along similar lines by D. T. Ewing and Mrs. M. Wilson appeared [THIS JOURNAL, 53, 2105 (1931)]. These investigators report interference of acetate, which we failed to find. We have subsequently applied the uranium titration with excellent results to the indirect determination of sodium in triple sodium magnesium uranyl acetate precipitates. We shall discuss the question of the interference or non-interference of acetate further in our report on the indirect determination of sodium by means of the uranium titration. Ewing and Wilson reduced boiling hot solutions, whereas the reductions reported in our work were made at room temperature; this difference in procedure may be significant.

THE ABSORPTION SPECTRA, STRUCTURE AND DISSOCIATION ENERGIES OF THE GASEOUS HALOGEN CYANIDES

BY RICHARD M. BADGER AND SHO-CHOW WOO

RECEIVED MAY 2, 1931 PUBLISHED JULY 8, 1931

Introduction

Spectroscopic investigations have yielded a great deal of interesting and useful information regarding the nature and strength of binding in diatomic molecules, and it is now desirable to extend studies of this sort to cases of molecules built up of several atoms. Several attempts have been made to do this, but in many instances the results obtained are difficult to interpret in an exact way, since the nature and energy states of the products into which more complicated molecules may dissociate are not known. In order to obtain quantitative information regarding the strength of individual molecular bonds, it seems advantageous to proceed gradually from very simple to more complicated cases, and in particular to choose for study those molecules about whose possible dissociation products we known as much as possible.

For this reason the cyanides seem to be very well suited for study, since the lower energy states of the cyanide radical are well known. Two cyanides have already been investigated: potassium cyanide by Villars,[1] and hydrogen cyanide by Badger and Binder.[2] As the subject of the investigation here described we have chosen the halogen cyanides, because there has been considerable discussion as to the structure of these compounds without any very definite conclusion being arrived at, and because certain inconsistencies in the literature make an independent determination of their heats of formation of interest.

Experimental Procedure

The substances used in the investigation were prepared as described below. In all cases chemically pure reagents were used.

Cyanogen Chloride.—In the preparation of this substance concentrated hydrochloric acid was dropped from a separatory funnel into an all-glass generator containing a solution of potassium chloride, potassium chlorate and potassium cyanide. The gas evolved was condensed in a receiver cooled with ice water. The liquid collected had a slight yellowish green tint which might have been due to the presence of some free chlorine. The liquid was then allowed to evaporate into the absorption cell, which consisted of a Pyrex tube 183 cm. in length, closed at the ends with quartz plates attached by sealing wax. When the absorption spectrum of the gas was photographed immediately after preparation, the chlorine bands as well as bands in the rather far ultraviolet due to cyanogen came out rather strongly. After the gas had stood for some time, these dis-

[2] R. M. Badger and J. L. Binder, *Phys. Rev.*, 37,800 **(1931).**

appeared completely. No polymerization occurred even when the gas was kept in the tube for several days.

Cyanogen Bromide.—The preparation of this substance was similar to that of the chloride. Potassium bromide and bromate were used instead of the corresponding chlorine compounds. The gas was driven from the solution of these substances and potassium cyanide by heating to 70–80°, and was condensed as a solid in the form of white crystals in a receiver cooled in ice water. These crystals were then sublimed into the absorption cell and the pure solid condensed there could be preserved for over a month without any polymerization being evident. The gas used in the absorption experiments was that in equilibrium with the solid at room temperature, and was confined in an absorption cell 91 cm. in length.

Cyanogen Iodide.—In the preparation of this substance pure iodine was resublimed and dissolved in ether to which an excess of mercuric cyanide was then added. After vigorous shaking the solution became colorless, indicating the completion of the reaction. The mercuric iodide which precipitated and the excess mercuric cyanide were removed by filtration. On evaporation of the filtrate cyanogen iodide was obtained, mixed with considerable mercuric iodide. A purification by recrystallization from ether solution, and by sublimation, yielded a product with only a very faint orange tint. The 91-cm. absorption cell was used in this case; but, as the absorption of the gas in equilibrium with solid ICN at room temperature was rather small, it was found necessary to heat the absorption cell, which contained some crystals of the solid, to about 60". In order to eliminate any absorption of free iodine which might be liberated by the dissociation of the compound, some cyanogen was introduced into the absorption cell. This gas gives rise to a set of discrete bands beyond λ2100, which are easily identified and were in no way troublesome.

Optical Apparatus.—As a source of continuous spectrum in the ultraviolet a conventional hydrogen discharge tube was used. The spectra were photographed with a small Hilger quartz spectrograph. Eastman D-C ortho plates were used, and in order to obtain a greater sensitivity in the ultraviolet they were oiled with a light transformer oil which was found to be especially suitable for the purpose.

Experimental Results and Discussion

In the case of each gas only continuous absorption was found, and a careful search failed to detect any discrete bands. The spectra of the three compounds are entirely similar except that in the order ICN, BrCN, ClCN the absorption regions are displaced toward the short wave side, and the absorption becomes weaker in the same order. In the iodine compound two absorption regions were found, in the other cases only one, undoubtedly for the reason that the analogous second regions were further in the ultraviolet than could be reached by the quartz spectrograph. Since the absorption regions shade off rather gradually on the long wave side (and on the other side as well, where it can be observed) and since the apparent long wave limit shifts toward the red when the depth of absorbing gas is increased, it is not possible to give any definite long wave absorption limit. However, it is certain that absorption extends on the long wave side at least as far as the wave lengths given in Table I.

It is reasonable to assume that as a result of light absorption in the continuum of any of the halogen cyanides, a dissociation of the molecule

TABLE I

LONG WAVE LENGTH LIMITS OF THE CONTINUOUS ABSORPTION OF THE HALOGEN CYANIDES

Gas	Region a λ	Region a ν	Region b λ	Region b ν	Upper limit for dissociation energy (volt-electrons) a	Upper limit for dissociation energy (volt-electrons) b
ICN	>2900	<34470	>2100	<47600	4.26	5.88
BrCN	>2450	<40800			5.05	
ClCN	>2270	<44040			5.43	

takes place. This being the case, we may calculate from the long wave limit of the absorption region an upper limit for a dissociation energy of the molecule. Values so obtained are given in the right of Table I. Before discussing the nature of the dissociation products, we must consider the probable structure of the halogen cyanide molecules. As mentioned above there has been considerable discussion in this regard, though particularly relating to the molecules in solution. As regards the gaseous molecules, the similarity of the spectra, and the fact that they fall into a reasonable series, strongly indicates a similarity of structure for the three. In a previous paper[2] it has been shown that the hydrogen cyanide molecule has a linear structure represented by the formula HCN, and that the HNC molecule, if it exists, must be energetically very unstable. Similar but much stronger arguments may be advanced in this case. From a study of the heats of formation of carbon tetrachloride and carbonyl chloride we may estimate the energy of the carbon–chlorine bond to be of the order of 3.5–4.5 volts, while the energy of the nitrogen–chlorine bond is much smaller, say about 2 volts, as may be seen from data on nitrosyl chloride and nitrogen trichloride. Consequently a ClNC molecule which would be formed from an excited CN radical, probably that in the $^2\Pi$ state with 1.78 volts excitation energy, should lie at least 3.3 volts (75,000 cal.) higher in the energy scale than ClCN formed from the normal CN radical. Though ClNC should consequently be very unstable, the argument of course does not exclude the possibility that isocyanide molecules may be produced under certain conditions, and may have a relatively long lifetime. However, in the case of gaseous iodine cyanide it is known that an equilibrium is readily reached between this gas and iodine and cyanogen. It seems unlikely then that this gas can exist for an appreciable length of time in the unstable form. We shall assume for the time being that all three gases exist in the stable cyanide form, and as will be seen later this assumption is justified by the energy relations.

Since the optical dissociation energies are far too small to account for the splitting of the carbon nitrogen bond, we may conclude that the dissociation products are a CN radical and a halogen atom, one or both of which may be in excited states. We may compare the spectroscopic values with the dissociation energies of the molecules calculated from the chemical heats of formation, the known energies of activation of the products, etc. The necessary data are expressed by the equations

E_0 $\mathrm{C(graphite)} + {}^1/_2\mathrm{N_2} = \mathrm{CN\ (normal)} - 3.4$ volts (78,200 cal.)[2]
H_{298} $\mathrm{C(graphite)} + {}^1/_2\mathrm{N_2} + {}^1/_2\mathrm{Cl_2} = \mathrm{ClCN\ (g)} - 1.58$ volts (36,400 cal.)[3]
H_{298} $\mathrm{C(graphite)} + {}^1/_2\mathrm{N_2} + {}^1/_2\mathrm{I_2\ (c)} = \mathrm{ICN\ (c)} - 1.83$ volts (42,000 cal.)[3]
E_0 ${}^1/_2\mathrm{Cl_2} = \mathrm{Cl} - 1.23$ volts (28,400 cal.)[4]
E_0 ${}^1/_2\mathrm{I_2\ (c)} = \mathrm{I\ (g)} - 1.10$ volts (25,000 cal.)[3,4]

Unfortunately heat data on BrCN are lacking. Specific heats are also lacking for correcting the chemical heats of formation at room temperature to the absolute zero, but in any case the correction will be small in comparison with the dissociation energies. The heat of sublimation of ICN is not known but we shall probably not be greatly in error if we estimate it at −0.4 volt.

The dissociation energies of ClCN and BrCN into normal halogen atom and normal cyanide radical, and into normal halogen atom and excited CN radical (${}^2\Pi$ with 1.78 volts excitation energy), as calculated from the above data are tabulated in Columns 2 and 3, respectively, of Table II. In Columns 4 and 5 are given the spectroscopic values for all three substances.

Table II

Dissociation Energies of the Gaseous Halogen Cyanides

	Dissociation energy			
	From chemical data		From spectroscopic data	
Gas	Products: halogen (normal) + CN (normal)	Products: halogen (normal) + CN* (${}^2\Pi$)	(a)	(b)
ClCN	3.04 volts (74,700 cal.)	4.82 volts (112,000 cal.)	$<$5.43 volts	..
BrCN	..	..	$<$5.05 volts	..
ICN	2.27 volts (52,000 cal.)	4.05 volts (93,000 cal.)	$<$4.26 volts	$<$5.88 volts

It is seen that the energy of dissociation into normal products, calculated from the chemical heat of formation, is about what one would expect for the breaking of a carbon–halogen bond, and is much larger than would correspond to breaking a nitrogen–halogen bond. We may conclude that the molecules in their normal state are built from the normal CN radical and normal halogen atom. Since the spectroscopic dissociation energies are much larger than the energy of dissociation into normal products, dissociation by light absorption must result in at least one excited product. Since the lowest excitation energy of the iodine atom is 0.94 volt, it is evident that only one of the dissociation products of ICN can be excited when dissociation takes place as a result of absorption in region **(a).** The rough agreement between the spectroscopic value and the second chemical value in the table indicates that it is the CN which is excited. This is confirmed by the data on ClCN, since the excitation energy of chlorine is only 0.11 volt. The relatively large discrepancy in this case between the spectroscopic value and the second chemical value is to be explained by the

[4] J. Franck, Z. *Electrochem.*, 36, 581 (1930).

weak absorption of this gas, which leads one to estimate the long wave absorption limit relatively farther in the ultraviolet than in the other cases. To make the results strictly comparable it would have been necessary to use a much longer tube of gas than circumstances permitted.

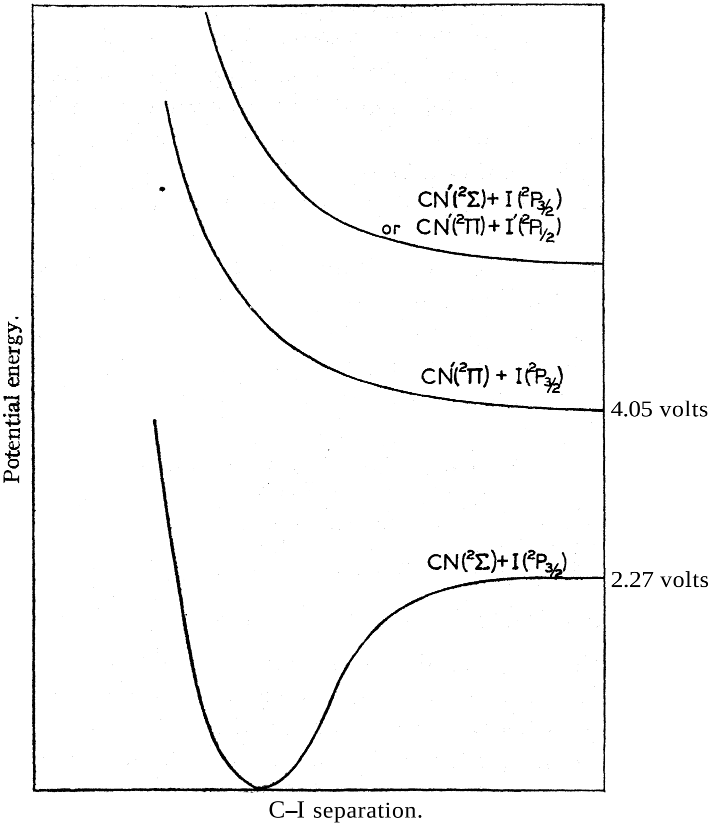

Fig. 1.—Approximate potential energy curves showing the potential energy of the ICN molecule as a function of the carbon–iodine separation, for three electronic states.

It is not possible to decide definitely whether absorption in the region (b) of ICN results in dissociation into an excited iodine atom with 0.94 volt energy and a CN radical ($^2\Pi$) with 1.78 volts energy, or into a normal iodine atom and a CN radical ($^2\Sigma$) with 3.19 volts energy.

Several attempts were made to demonstrate directly the nature of the dissociation products by fluorescence experiments, but unfortunately they were unsuccessful. One might expect that when the gases are illuminated with light of a wave length lying in the region of continuous absorption one should obtain the red cyanogen bands in fluorescence. The conditions are, however, very unfavorable for obtaining such a fluorescence. The absorption, even at the maximum of the continuum, is not very strong and if one uses sufficient gas pressure to obtain appreciable absorption one should expect the fluorescence to be almost completely quenched. Some experiments were made in which ICN gas was illuminated with a mercury arc, and some in which BrCN was illuminated with a cadmium arc. No fluorescence was visible to the eye even under very satisfactory conditions as to a black background, etc. In an investigation using a very fast glass spectrograph and dicyanin plates it was found that any fluorescence present was weaker than stray light which was excluded as far as possible.

As noted above the chemical dissociation energies show that the halogen cyanide molecules in the lowest energy state are formed from normal halogen atom and normal cyanide radical. The nature of the absorption spectra is strong indication that in the two next higher excited electronic states we have a case of repulsion at all distances, or possibly a very small minimum in the potential energy curve at a relatively large distance of separation of halogen atom and cyanide radical. The probable state of affairs is represented in Fig. 1.

This is indeed what one should expect. The normal cyanide radical, since it is formed from a normal nitrogen atom and a carbon atom in the ^5S state (tetravalent),[5] is capable of forming one shared electron pair bond between the carbon atom and some other atom and radical. The $^2\Pi$ cyanide radical, on the other hand, is formed from the ^3P carbon atom (divalent) and one should expect no tendency for molecule formation when an atom is brought up on the carbon side of this radical.

Summary

1. The absorption of the gaseous halogen cyanides has been investigated in the ultraviolet. Regions of continuous absorption only were found, with the following long wave length limits: ClCN, $\lambda > 2270$; BrCN, $\lambda > 2450$; ICN, $\lambda > 2900$ and $\lambda > 2100$.

2. The similarity of the spectra and their relation to each other suggest a similar structure for all three molecules.

3. Consideration of thermochemical and spectroscopic data together shows that in the normal state the halogen cyanide molecules are built from normal halogen atoms and normal cyanide radical, and in the first excited electronic state from normal halogen atom and an excited CN radical in the $^2\Pi$ state. The structures are probably those represented by the formulas: ClCN, BrCN, ICN.

4. The thermochemical heats of formation of the ClCN and ICN seem to be in substantial agreement with the spectroscopic values.

GENERALIZED THERMODYNAMICS INCLUDING THE THEORY OF FLUCTUATIONS

BY GILBERT N. LEWIS

RECEIVED MAY 4, 1931 PUBLISHED JULY 8, 1931

In the present paper I shall assume without discussion the conservation of energy, at least in the sense in which this principle is used in thermodynamics. I shall not discuss the various discoveries of quantum theory which have exerted so great an influence upon present scientific thought. To these subjects I may later revert, but at present I wish to examine only those ideas which have been in the minds, almost since the beginning of thermodynamics, of those who have been troubled by the contradiction between the second law of thermodynamics and the existence of the so-called fluctuations which many systems exhibit, and which it is believed that more and more systems will exhibit as our means of measurement become more refined.

Willard Gibbs, in his early paper, first showed the incompatibility between molecular theory and the statement of classical thermodynamics that every system proceeds steadily toward a unique final state. We now have abundant experimental evidence also that a system left to itself for an indefinite time assumes no single equilibrium state, but passes back and forth through a great number of different states which, however, are not easily distinguishable.

Therefore classical thermodynamics, although aclmittedly invalid, is an extremely good first approximation to the truth. The second approximation, indicated abstractly in Gibbs' "Statistical Mechanics," was given concrete expression by Einstein,[1] who combined the first approximation given by classical thermodynamics with the famous theorem of Boltzmann relating entropy and probability. He thus obtained an equation which is of great value in determining the probability that any one observation will lie within a given range of fluctuation.

Our science is therefore in a position in which it is able to give an answer with almost any desired accuracy to any problem, not only of the older thermodynamics, but also of the theory of fluctuations. But since the science is not quite exact it fails to satisfy our logical desires and also our pedagogic needs, for no valid statement of the second law of thermodynamics has as yet been formulated.

I have long sought the proper way to place thermodynamics upon an exact basis, deriving the laws corresponding to those of classical thermodynamics, as well as the laws of fluctuations, from a single postulate, The task, however, has been a puzzling one and only in recent years have I perceived how

---

[1] **Einstein,** *Ann. Physik*, **22,569** (1907).

simple the solution really is. The problems in which the second law of thermodynamics has been employed are all concerned with the partition of some quantity, such as energy, or some kind of matter, between several systems. We may begin our discussion with the study of such partitions.

Before proceeding with the analysis it may not be superfluous to point out that wen when a mathematical science is made mathematically and logically exact, it is not precisely applicable to any actual physico-chemical system. It corresponds rather to an ideal system which may be regarded as a limit toward which actual systems can be made to approach as near as we please. Such a limit is implied when we define an ***isolated*** system as one which is cut off from all other systems with respect to the passage of matter or energy. In this sense we speak of completely impermeable walls, perfect mirror surfaces and the like.

In a similar way we define ***independent*** systems as those which do not influence the thermodyiiamic properties of one another by their mere propinquity. Thus two bottles of water become more nearly independent as they arc separated spatially, and even the upper and lower halves in the same bottle may be regarded as nearly independent since, owing to the small range of molecular forces, only a very little of one part is much influenced by the other. On the other hand, in dealing with surface phenomena we are often obliged to discuss systems which are far from independent.

A similar idealization is necessary when we discuss equilibrium. If we are studying the relation between the pressure and volume of a mixture of oxygen and hydrogen at 0°, we ignore the fact that the two gases are very slowly combining to form water. If we are measuring the solubility of potassium chloride, we forget that at the end of a trillion years a considerable part of the potassium will have suffered radioactive decay. So in our idealized system we assume that certain specified processes occur at a rate which is infinitely greater than that of all other processes. The former may be spoken of as ***permitted*** and the latter as ***prohibited*** processes. In our present treatment of thermodynamics we may replace the idea of the time required for the attainment of equilibrium by the idea of the time sufficient to give a representative statistical sample of all the permitted states of a system. This length of time, however, does not enter directly into our considerations, and, indeed, time is not one of the variables with which pure thermodynamics is concerned.[2]

Partition Between Two or More Systems

Let us consider the partition of some quantity X between two independent systems. This quantity X may be the energy, of some chemical substance, or, if the two systems are separated by a movable partition, it may be the volume. If such a partition varies from time to time it will not be our present duty to seek the cause; whether the individual parts of the system follow the old mechanics, or the new mechanics, or no mechanics at all, need not concern us now.

If we wish to study some momentary partition we fix or "freeze" that partition by interrupting communication between the two systems.[3]

---

[2] Lewis, "The Symmetry of Time," ***Science,*** 71, 569 ***(1930).***

[3] I have considered it sufficient in the present paper to state what seems **to** me true, without explicitly correcting some false ideas that have crept into thermodynamic literature. However, there is one thing that must be said to avoid serious confusion. If the thermodynamic properties of a system, such as temperature, entropy and pres-

In other words, we isolate them from one another and then we may proceed to determine experimentally what the content of the quantity X is in the system I and in the system II. If such a determination is made from time to time and the results are recorded, they may not permit a satisfactory prediction of what partitions will occur in the future, but if the intervals between the observations, and also their number, are increased without limit, our data may be said to become representative, in the sense that the fraction of all partitions lying within a given range may be equated to the probability that any new observation will lie within that range.

Instead of having our systems I and II isolated from all others, we may have a third system which we may call a reservoir, in communication with these two, and this reservoir may be considered capable of being increased indefinitely in size (without changing its intensive properties, such as density, composition and density of energy). Now when the quantity X is partitioned between these three systems, the probability that the content of X in system I will lie between C_1 and $C_1 + \lambda$ may be designated by $\alpha_1\lambda$, while $\alpha_2\lambda$ will express the probability that the content in system II lies between C_2 and $C_2 + \lambda$. If λ be chosen indefinitely small, there will be the same probability that the content in system II will lie in one or the other of the two equal and adjacent ranges, C_2 to $C_2 + \lambda$ and C_2 to $C_2 - \lambda$. Henceforth we shall choose the latter expression on account of its convenience in the discussion of the distribution between two systems alone.

If the two systems are independent and if the reservoir be made indefinitely large, the probability that the content of system I lies between C_1 and $C_1 + \lambda$, and at the same time that the content of system II lies between C_2 and $C_2 - \lambda$ is given by the expression[4]

$$P = \alpha_1\alpha_2\,\lambda^2 \qquad (1)$$

where α_1 is now independent of the system II, and α_2 of the system I. While the range λ may be made as small as we please, having once chosen this range for a given quantity X, we shall regard it as constant throughout our equations.

---

sure, are to be unambiguously determined by certain independent variables such as the mass, the energy and the volume of a system, it follows that it is meaningless to say, for example, that the temperature of a system is the same or is not the same in all its parts. The temperature of an isolated system must have one and only one value. On the other hand, it is possible, with due caution, to assign a meaning to such a phrase. We may agree to say that the temperature of each part is the temperature it would have if it were suddenly isolated from the rest.

[4] If at the same time we wish to consider the partition of several quantities X, Y, Z, . . ., and choose λ_x as the range of the first quantity, and so on, the equation becomes

$$P = \alpha_1\alpha_2\,\lambda_X^2\,\lambda_Y^2\,\lambda_Z^2\ldots \qquad (1a)$$

where the α's have the same meaning as before, except for a constant factor depending upon the chosen values of λ_Y, λ_Z, etc. Since we gain in simplicity and lose nothing in generality, we shall continue to consider the partition of one quantity at a time.

If C_1' is another content of the first system and C_2' another content of the second system, but such that the total content is the same, namely, $C_1' + C_2' = C_1 + C_2$, the probability P' that the content of the first system will lie between C_1' and $C_1' + \lambda$, and *also* that the content of the second system will lie between C_2' and $C_2' - \lambda$ is given by the corresponding expression

$$P' = \alpha_1'\alpha_2'\lambda^2$$

The ratio of the probabilities of the two partitions is then

$$\frac{P}{P'} = \frac{\alpha_1\alpha_2}{\alpha_1'\alpha_2'} \qquad (2)$$

The product $\alpha_1\alpha_2$ which belongs to a certain pair of systems with contents C_1 and C_2 may be called the *specific probability*, while the a's may be called the probability factors.

We are now in a position to state the cardinal postulate which is designed to validate, and at the same time to generalize, the second law of thermodynamics, and from which the laws of thermodynamics and the laws of fluctuations may both be derived. However, before making this postulate, it may be well to make certain comments which may serve to display its character and contribute to its plausibility.

When we have spoken of two systems as connected we have said nothing concerning the mode of connection. If we were considering a gas distributed between two vessels, they might be joined by a very narrow tube, or a very large one. If we were considering the passage of heat, the systems might be connected by a rod of very low or very high thermal conductivity. In any case, if the connection is a poor one and, having determined some partition, we soon after determine the partition once more, these two partitions will be almost the same. We have tried to eliminate such effects by making infinitely long the interval between two partition measurements, but that we have succeeded in making the relative probability of the various partitions independent of the mode of connection of the systems is, after all, an assumption which must be embodied in our fundamental postulate.

When we consider two systems and a reservoir we might make the connection between the two systems so good, and the connection between each system and the reservoir so poor, that during a time which is long enough to be almost completely representative with respect to all possible partitions between the two systems, there would be almost no exchange with the reservoir. In such case we should expect that the probability of the several partitions of the quantity X in the two systems would depend only upon the total amount of X in the two systems, and not at all upon the nature of the reservoir. Thus if the two systems were in very poor thermal contact with a reservoir and at a certain time the two systems should contain E units of energy, then if the same two systems were in poor contact with another reservoir, for example one of much higher temperature, but if as a result of some rare fluctuation the total content of energy in the two systems were again E, then we should expect the laws of partition of this quantity E between the two systems to be the same in both cases.

The Cardinal Postulate.—Plausible as these ideas may be, they must be embodied in a formal postulate which will serve as a generalization of the second law of thermodynamics. This postulate is as follows: *when a given content is partitioned between two systems, the ratio of the specific probabilities of any two partitions of this content depends solely upon the nature of the two systems and upon the respective contents.* In other words, such a ratio as occurs in Equation 2 depends in no way upon the mode of connection between the systems nor upon the existence, or nature, or mode of connection of other systems.

It is evident from the way in which the probability factors were first introduced that each α depends upon the kind of reservoir chosen, and upon the amount that it contains of the quantity whose partition is being studied, but it now follows from our postulate that the *relative* values of α for a given system are independent of such choices. Aside then from an undetermined, and for the present purposes unimportant, constant multiplier, each α depends solely upon a system and its content. It is therefore a corollary of our postulate that the specific probability for a given partition is (except for the undetermined constant) the product of two factors, one of which depends solely upon the first system and its content, the other solely upon the second system and its content. This corollary might itself have been taken as the generalization of the second law of thermodynamics and then our fundamental postulate would have appeared as a corollary.

In order to apply the methods of the differential calculus it would be convenient if α for any system could be regarded as a continuous function of its content, but in some cases at least we know that the content cannot be varied continuously. Thus we cannot take from the system less than one atom of any element. Nevertheless, we usually approach very close to the limiting case in which the loss of one atom produces the same change in the thermodynamic properties of a system as the loss of a second atom, or a third, thus justifying the use of the differential calculus. In the present paper we shall restrict ourselves to the case in which the calculus is applicable, reserving the more general case for a later occasion.

By the aid of the calculus we may write down immediately the probability that a partition of a certain content will lie within a certain range, divided by the probability that a second partition of the same content will lie within another given range. Let the total content, C, be the same in both cases and let the specification of the first range be that C_1 lies between a and b (and therefore that C_2 lies between C-a and C-b), while the corresponding specification for the second range is that C_1 lies between a' and b'. The ratio of the two probabilities is then given by the formula

$$\frac{P}{P'} = \frac{\int_a^b \alpha_1\alpha_2 \mathrm{d}C_1}{\int_{a'}^{b'} \alpha_1\alpha_2 \mathrm{d}C_1} \tag{3}$$

where $\mathrm{d}C_1 = -\mathrm{d}C_2$. If we wish to make the second range cover all possible values, we obtain as the *absolute* probability that a partition lies within the range $C_1 = a$ to $C_1 = b$

$$P = \frac{\int_a^b \alpha_1\alpha_2 \mathrm{d}C_1}{\int_0^C \alpha_1\alpha_2 \mathrm{d}C_1} \tag{4}$$

These equations will enable us to solve any problem in the theory of fluctuations, as soon as α_1 is known as a function of C_1, and α_2 as a function of C_2, or $C - C_1$.

The Most Probable Partition

In classical thermodynamics some minor assumptions are made in order to eliminate certain cases which, if they ever existed, would have to be treated separately (corresponding to certain zero cases in mathematics). Thus it is assumed, at any finite temperature, that the solubility of one substance in another is always finite, and that the heat capacity of any substance is also finite. Our corresponding assumption is that the most probable partition of any quantity between two systems is not the one in which the whole content is in one system. If such a case did occur it would require a separate treatment.

If then we have a quantity X in total amount C, divided between two systems, there must be some one partition at which the specific probability $\alpha_1\alpha_2$ has at least as high a value as at any other, and since this most probable partition does not lie at $C_1 = 0$ or $C_1 = C$, it has the characteristics of a maximum. If $\alpha_1\alpha_2$ is at a maximum, its logarithm is also, and satisfies the condition

$$\mathrm{d} \ln \alpha_1\alpha_2 = \mathrm{d} \ln \alpha_1 + \mathrm{d} \ln \alpha_2 = 0 \tag{5}$$

If some one quantity whose content is $C = C_1 + C_2$, can vary alone, then

$$\frac{\partial \ln \alpha_1}{\partial C_1} \mathrm{d}C_1 + \frac{\partial \ln \alpha_2}{\partial C_2} \mathrm{d}C_2 = 0 \tag{6}$$

or since $\mathrm{d}C_1 = -\mathrm{d}C_2$

$$\frac{\partial \ln \alpha_1}{\partial C_1} = \frac{\partial \ln \alpha_2}{\partial C_2} \tag{7}$$

This is the simplest expression of the condition that C_1 and C_2 represent the most probable partition of the total content C. This is the partition which is represented by the grossly exaggerated curve shown in Fig. 1.[5]

[5] Aside from the case illustrated in Fig. 1, there is only one other way in which $\alpha_1\alpha_2$ can be at a maximum, that is, when α_1 diminishes with increasing C_1 and α_2 with diminishing C_2. It sometimes happens that this case also has thermodynamic interest, but we need not dwell on this question here, since what we have to say will be true of either case.

Our new thermodynamics makes distinctions which are not made in the older thermodynamics. In the latter there was just one equilibrium partition which was, of course, not only the most probable, but also the average partition. If we now recognize what was formerly called equilibrium, not as a single partition, but as a narrow region into which a vast number of individual partitions are crowded, the most probable partition will not always exactly coincide with the average partition. It is characteristic of our present method of treatment that it is the most probable partition and not the average partition which we must now employ to represent the equilibrium. Henceforth when we say that two systems are in equilibrium we shall mean that for every variable quantity that can be divided between the two systems, the two contents correspond to the most probable partition. We then obtain directly from Equation 7 the important law that *when two systems are in equilibrium with a third system, they are in equilibrium with each other.*

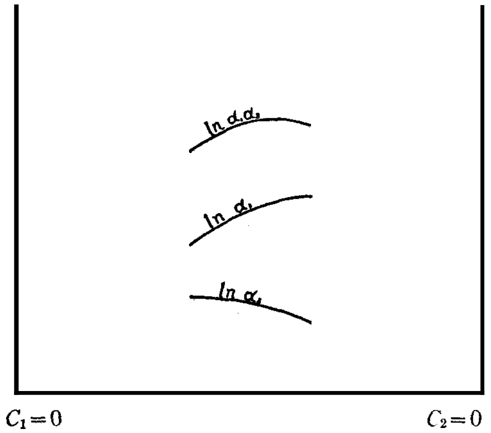

Fig. 1.

The Thermodynaniic Temperature.—If it is the energy whose partition between two systems is being studied, the equation for thermal equilibrium is

$$\frac{\partial \ln \alpha_1}{\partial El} = \frac{\partial \ln \alpha_2}{\partial E_2} \tag{8}$$

Let us define O by the equations

$$\frac{\partial \ln \alpha_1}{\partial E_1} = \frac{1}{\Theta_1}; \qquad \frac{\partial \ln \alpha_2}{\partial E_2} = \frac{1}{\Theta_2} \tag{9}$$

At equilibrium $\Theta_1 = \Theta_2$, but if we depart from equilibrium in such a direction that E_1 is less and E_2 is greater than the values at the most probable partition, then we might show, from a study of the second derivative of $\ln \alpha_1\alpha_2$, that Θ_2 cannot be less than Θ_1. Hence Θ obeys the qualitative laws of temperature, and might be defined as the thermodynamic temperature.

Combination of Abstract Thermodynamics with Experimental Knowledge.—We have now set forth all the essential abstract principles of generalized thermodynamics. In developing them I have endeavored to proceed with the utmost logical rigor. As we now approach the task of applying our abstract science to actual systems, we may afford to be a little more informal, since there are endless ways of making contact between our theoretical principles and experiemnt, and the choice of a particular method of making such contact will be largely a matter of taste.

There is nothing indeed in our preceding development which could possibly enable us to calculate for any physical system how its ln α changes with the several thermodynamic variables. To obtain such information we must either make some experimental study of a system, or some deduction concerning an idealized system based on generalizations of actual experiments. If one is interested in what is called statistical mechanics, it is at this point, and no earlier point, that the special laws of mechanics should be introduced.

At the corresponding stage in classical thermodynamics it is customary to introduce the properties of the actual substance, or rather that idealization of an actual substance, that we call the perfect gas. Thus, for example, the thermodynamic temperature is compared with the temperature recorded by a perfect gas thermometer. There are, however, many equally good ways of introducing the empirical properties of substances. Thus, in place of a gas thermometer we might use as a measure of temperature the potential of the galvanic cell, or the volume of a crystal, or the pressure of a Hohlraum.

We shall choose as our thermometer an idealized system composed of N similar molecules which for simplicity we may assume to be fixed in position, far apart, and subject to no change except that each molecule can exist in either of two states differing in energy by the amount ϵ. Thus the energy of the system over that of the same system with all molecules in the lower state is

$$E = M\epsilon \tag{10}$$

where M is the number of molecules in the higher state. Then $N - M$ are in the lower state, and we may define the temperature T by the equation

$$\frac{M}{N - M} = e^{-\epsilon/kT} \tag{11}$$

The classical work of van't Hoff and Boltzmann showed that this temperature scale may be identified with that of the perfect gas thermometer.

We shall now make the simple assumption that no molecule is more likely to be in the higher state than any other molecule. Let us arbitrarily divide the N molecules into two systems, the first having N_1 and the second N_2 molecules. Suppose that M_1 of the former and M_2 of the latter are in the higher energy state. If now by some method which need not be specified there is a flow of energy from the first system to the second, then M_1 diminishes and M_2 increases so that $M_1' + M_2' = M_1 + M_2$. According to our assumption the relative probabilities of these two partitions is equal to the relative number of ways in which the two partitions can be obtained.

The number of ways in which we may have the M units of energy distributed among N molecules is the number of ways in which M unnumbered objects can be placed in N numbered boxes, no more than one to a box. It is $N!/(M!(N-M)!)$, so that the relative probability of the two partitions is

$$\frac{P}{P'} = \frac{\dfrac{N_1!}{M_1!\,(N_1-M_1)!}\;\dfrac{N_2!}{M_2!\,(N_2-M_2)!}}{\dfrac{N_1!}{M_1'!\,(N_1-M_1')!}\;\dfrac{N_2!}{M_2'!\,(N_2-M_2')!}} \tag{12}$$

Each of the four quotients appearing in the last member depends only upon a single system and its content. These quotients satisfy all the rules that we have laid down for our probability factors and each therefore is to be identified with the corresponding α. Thus we find in general for this type of thermometric system

$$\alpha = \frac{N!}{M!(N-M)!} \tag{13}$$

and

$$\ln \alpha = \ln N! - \ln M! - \ln (N-M)! \tag{14}$$

If again we have the same N molecules, but $M + 1$ in the higher level, we may bear in mind that

$$\ln (M+1)! = \ln M! + \ln (M+1);\quad \ln (N-M-1)! = \ln (N-M)! - \ln (N-M)$$

and say that $\ln \alpha$ has been increased by

$$\Delta \ln \alpha = -\ln (M+1) + \ln (N-M) \tag{15}$$

Let us make the system large enough and M great enough so that M can be used in place of $M + 1$. Using the differential notation we have

$$\frac{\partial \ln \alpha}{\partial M} = \ln \frac{N-M}{M} \tag{16}$$

and now employing Equations 10 and 11 we find

$$\frac{\partial \ln \alpha}{\partial E} = \frac{1}{kT} \tag{17}$$

We see from Equation 17 that kT is equal to our thermodynamic temperature Θ. Having proved this for one system, we have proved it for all, for if we have any other system in thermal equilibrium with our thermometric system so that the Θ and T are the same for both, and if $\Theta = kT$ for one system, this is also true of the other.

If we are dealing with a pure substance under such conditions that the properties of a given mass are completely determined by its energy and volume, all that we need to know further about $\ln \alpha$ is the way it changes with the volume. Here also we must make use of some empirical information. We may take it as experimentally established that any physicochemical equilibrium which is obtained on the first floor of a laboratory will not be changed by taking the whole system to the second floor. This means that if the various α's change with the height, they all change in the same proportion. Since the α's already contain undetermined factors, we may say that the α for each system is independent of its position in a constant gravitational field.

Let us consider a cylinder divided into two parts by a movable piston of unit area and of weight P. The lower part, or system I, contains any substance whose properties are determined solely by the energy and the volume. The upper part, or system II, is exhausted and contains only the piston. As the height of the piston[6] fluctuates there will be one position that is most probable. At this equilibrium position we may say that the pressure in system I is equal to the pressure P exerted by the piston. When this position of equilibrium is reached d ln α, by Equation 5, will be numerically the same for the two systems, but according to our assumption d ln α is zero for the upper system, and therefore is also for the lower system. Hence for the latter

$$\mathrm{d}\ln\alpha = 0 = \frac{\partial \ln\alpha}{\partial V}\,\mathrm{d}\,V + \frac{\partial \ln\alpha}{\partial E}\,\mathrm{d}\,E \qquad (18)$$

By applying the first law of energy to this system

$$\mathrm{d}\,E = -P\,\mathrm{d}\,V$$

Combining the last two equations with Equation 17, we find for any system whose properties are determined by energy and volume

$$\frac{\partial \ln\alpha}{\partial V} = \frac{P}{kT} \qquad (19)$$

Entropy, and its **Use** in Calculating Fluctuations.—If we compare Equations 17 and 19 with those which in classical thermodynamics completely define the entropy, namely

$$\frac{\partial S}{\partial E} = \frac{1}{T} \qquad \frac{\partial S}{\partial V} = \frac{P}{T}$$

we may immediately identify the entropy with k ln α, except for an undetermined additive constant, which need not concern us, since by our definition ln α is determined only to an additive constant, and this is also true for the classical entropy. Hence, in general, we write

$$S = k\ln\alpha \qquad \alpha = e^{S/k} \qquad (20)$$

We have now completely bridged the gap between the new and the old thermodynamics. It is true that we have made use only of a pure substance under such conditions that it is subject only to the variables, volume and energy. However, we may also consider the partition of any quantity between such a substance on the one hand, and on the other hand a substance which is in solution, or which depends upon other variables, such as electric and surface forces. The resulting equations will be the familiar

---

[6] In order to avoid the need of considering the kinetic energy of the piston we may make it as heavy as we please. Indeed, according to the principle of Heisenberg, it is only when the mass of the piston is infinite that we may assign to it zero velocity and also a fixed position.

equations of thermodynamics. To obtain them is a matter of mere routine. From the simple principles with which we started we have therefore obtained the whole of classical thermodynamics.

Moreover, we may now give an equally exact and more useful form of Equation 4. Substituting the values of α from Equation 20, and writing $S = S_1 + S_2$, we have

$$P = \frac{\int_a^b e^S \, \mathrm{d}C_1}{\int_0^C e^S \, \mathrm{d}C_1} \tag{21}$$

This equation enables us to solve any problem regarding fluctuations when the entropies are known as functions of the several contents.

For practical purposes it usually suffices to know the value of S, not over the whole range from zero to C, but over a very small range in the neighborhood of the equilibrium point $C_1 = C_1^\circ$. Indeed by a familiar method we may obtain a very good approximation if we know only the second derivative of S with respect to C_1 at this point. Dividing both numerator and denominator in Equation 21 by e^{S°, where S° is the combined entropy of the two systems at the equilibrium point, the integrals with which we have to deal have the form

$$\int e^{S - S^\circ} \, \mathrm{d}C_1$$

Now if $S - S^\circ$ is developed by Taylor's formula in terms of $C_1 - C_1^\circ$, then, because of the existence of the maximum, the first term in the expansion will be the one containing the second derivative. Neglecting higher terms we have

$$S - S^\circ = \frac{1}{2}\frac{\partial^2 S}{\partial C_1^2}(C_1 - C_1^\circ)^2 \tag{22}$$

The integral with which we are dealing is now in the form of the well-known probability integral, for which there are satisfactory tables.

If we now compare these equations with those given by Einstein, we see a resemblance which becomes an identity if we subject his equations to the interpretation given in the present paper, of which the most important is the interpretation of the classical equilibrium as the partition of highest specific probability.

Summary

By a method which differs radically from the methods used either in classical thermodynamics or in statistical mechanics, it is shown that the laws of thermodynamics and the laws of fluctuations constitute together a generalized thermodynamics which is derivable from a single cardinal postulate. It is claimed, moreover, that this postulate is the first really valid statement of the second law of thermodynamics.

THE CLASSICAL DISSOCIATION CONSTANT OF BENZOIC ACID AND THE ACTIVITY COEFFICIENT OF MOLECULAR BENZOIC ACID IN POTASSIUM CHLORIDE SOLUTIONS[1,2]

BY ELWYN F. CHASE AND MARTIN KILPATRICK, JR.

RECEIVED MAY 6, 1931 PUBLISHED JULY 8, 1931

In a previous paper[3] the authors reported the hydrogen-ion concentration of a series of benzoic acid–benzoate buffers in aqueous potassium chloride solutions. From these values and the composition of the buffer the product of the concentration of hydrogen and benzoate ions was calculated. In all cases the solutions were saturated with benzoic acid so that a determination of the solubility of the acid in these solutions enables one to calculate the classical dissociation constant and the activity coefficient of the molecular benzoic acid. The solubility of the molecular acid is obtained by subtracting the hydrogen-ion concentration from the total concentration of benzoic acid as determined by titration. Column 3 of Table I gives the solubility of benzoic acid in the various solutions and Column 5 gives the amount present as molecular acid.

These results and those in the previous paper can be calculated to mole fractions or molalities with an accuracy within that of the measurements by using the densities for potassium chloride solutions as given in the "International Critical Tables."

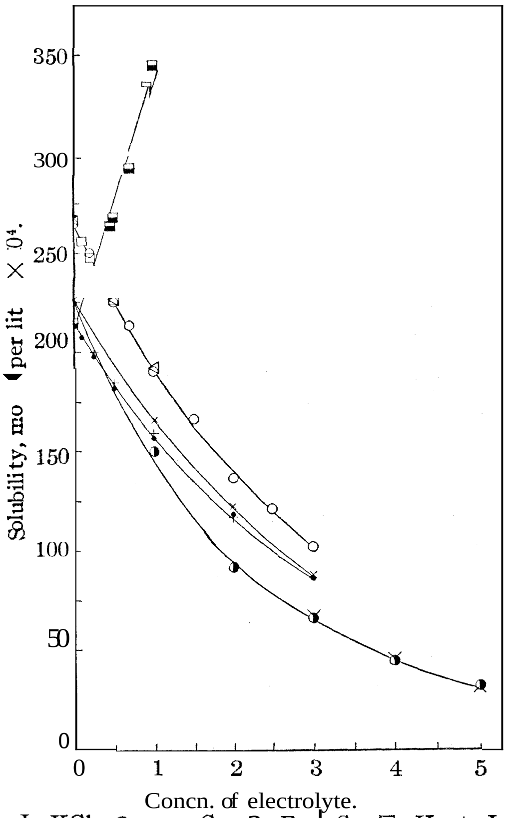
Figure 1 shows graphically the change of the solubility of molecular benzoic acid with the nature and concentration of the solvent electrolyte. With our values at 25.15° are shown those of Hoffmann and Langbeck,[4] and Freundlich and Seal[5] at 25° in potassium chloride solutions. Their solutions were not buffered and their determinations give only the total solubility of the benzoic acid. We have calculated the ionized part from

---

[4] Hoffmann and Langbeck, *Z. physik. Chem.*, 51,385 (1905).

[5] Freundlich and Seal, *Kolloid-Z.*, 11,257 (1912).

our values of the classical dissociation constant and have subtracted that part from their values. As the plot shows, the agreement is good. The values of Berry[6] in potassium chloride and sodium chloride solutions at 20° are shown with those of Güntelberg and Schiodt[7] at the same temperature. Finally the values obtained by Larsson at 18° are shown for potassium chloride and sodium benzoate solutions. Larsson finds a decidedly opposite effect for sodium benzoate, that is to say, the solubility of molecular benzoic acid is increased by the solvent salt, sodium benzoate.[9] The effect of sodium benzoate is noticeable in our buffers but is probably less than 1% for the benzoate ion concentrations used. It does, however, emphasize the dependence of the electrolyte effect upon the individual nature of the solvent salt. For the solvent salts potassium chloride and sodium chloride the solubility of molecular benzoic acid decreases rapidly with increasing salt concentration. The effect is greater for sodium chloride than for potassium chloride.



In KCl: ⊙, K.+ C.; a, F. + S.; ⊡, H. + L. at 25°; X, B. at 20°; +, ●, L. at 18°. In Na Benzoate: ▭, L. at 18°. In NaCl: ◑, B. at 20°; V,Λ, G. + S. at 20°; ● unbuffered + buffered.

Fig. 1.—Solubility of molecular benzoic acid.

In Table II the classical dissociation constant, $K_c = C_{H^+} C_{B^-}/C_{HB}$ has been calculated from our determination of $C_{H^+} C_{B^-}$ by the electrometric and catalytic methods, and

Figure 2 shows the change of the dissociation constant of the acid with increasing electrolyte concentration.

Table III gives the values of the dissociation constant obtained by Berry and by Guntelberg and Schiodt for potassium chloride and sodium chloride solutions.

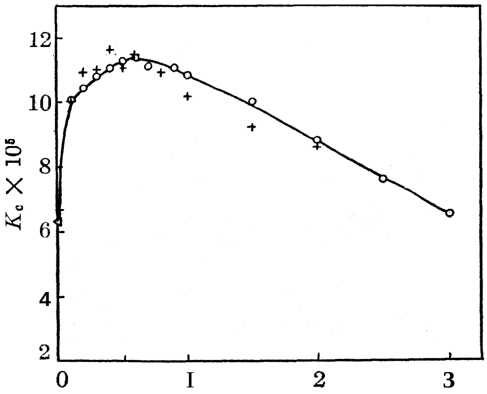

Fig. 2.—Electrolyte effect on the dissociation constant of benzoic acid.

In order to emphasize the fact that the change of dissociation constant with changing electrolyte concentration is different for different acids of the same type in the same solvent salt, we have plotted in Fig. 3 the ratio K_c/K_a for benzoic acid, acetic acid, formic acid and carbonic acid. The values for acetic acid and formic acid are calculated from the papers of Harned and Murphy[10] and Harned and Owen,[11] respectively. The values for the first dissociation constant of carbonic acid are from Guntelberg and Schiödt.[7]

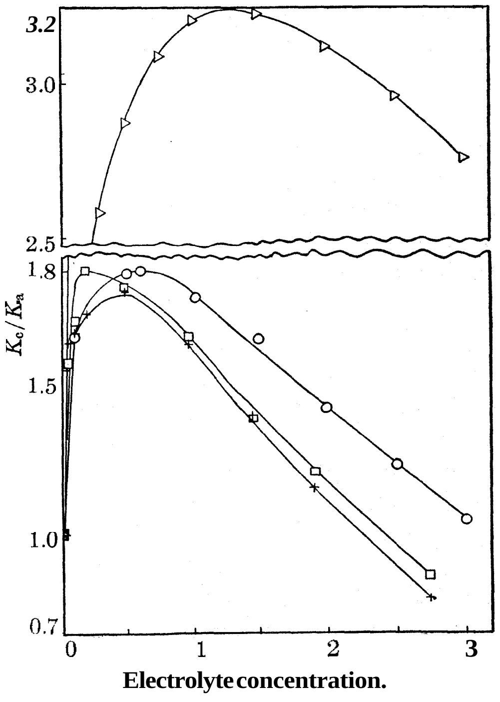
TABLE III

COMPARISON OF K_c FOR BENZOIC ACID IN SODIUM AND POTASSIUM CHLORIDE SOLUTIONS

KCl + NaB, moles per liter	$C_{H^+} C_{B^-}$ × 10^7, Berry, 20°	C_{HB} moles per liter. Berry, 20°	K_c × 10^5, Berry, 20°	K_c × 10^5, G. and S., 20°
1.0	16.9	0.0166	10.18	
2.0	9.81	.0123	7.98	
3.0	5.33	.0880	6.06	5.84
NaCl + NaB				
1.0	16.2	.01500	10.80	
2.0	8.61	.00918	9.38	
3.0	4.20	.00656	6.40	6.25
3.0	1.76	.00442	3.98	4.03
5.0	0.717	.00313	2.29	2.46

The curves for formic and acetic acids are similar, while that for carbonic acid is strikingly different, the maximum value of K_c for carbonic acid being over three times K_a. In general the K_c/K_a curve is different for different monobasic acids. These differences are attributed to two causes, the salting out effect on the ions and molecules and the interaction effect which depends on the deformability. Güntelberg and Schiodt[7] have given an interesting discussion of the effect of these factors upon the dissociation constant of a given acid in different solvent salt solutions.



All in KCl: ▷, carbonic acid, G. + S.; ○, benzoic acid; +, acetic acid, H. + M.; □, formic acid, H. + O.

Fig. 3.—K_c/K_a vs. electrolyte concentration.

The change of the mean activity coefficient of the ions' of benzoic acid with potassium chloride concentration as determined in a previous paper[3] is given by the extended Debye–Hückel equation

$$-\log \sqrt{f_{H^+} f_{B^-}} = \frac{0.5\sqrt{c}}{1 + \kappa b} + \beta c$$

where $\kappa = 0.33 \times 10^8 \sqrt{c}$, b is the apparent average ionic diameter, taken here as 5.15×10^{-8} cm., β is an empirical constant taken equal to -0.139, and c is the electrolyte concentration in moles per liter. Below we show that

$$\log f_{\mathrm{HB}} = 0.138\ c$$

Since

$$K_c = K_a \frac{f_{\mathrm{HB}}}{f_{\mathrm{H^+}} f_{\mathrm{B^-}}}$$

we have

$$\log K_c = \log K_a + \log f_{\mathrm{HB}} - \log f_{\mathrm{H^+}} f_{\mathrm{B^-}}$$

and substituting

$$\log K_c = \log K_a + 0.138\ c + 2\left[\frac{0.5\sqrt{c}}{1 + 1.70\sqrt{c}} + \beta c\right]$$

Taking $K_a = 6.31 \times 10^{-5}$, we have

$$\log K_c = -4.200 + \frac{\sqrt{c}}{1 + 1.70\sqrt{c}} - 0.140\ c$$

an equation which gives our values for K_c for solutions containing from 0.1 mole per liter to 3 moles per liter of potassium chloride within 2%.

Since all the solutions were saturated with benzoic acid, the activity of the molecular benzoic acid remained constant and equal to its solubility in pure water

$$a_{\mathrm{HB}} = f_{\mathrm{HB}}\ c_{\mathrm{HB}}$$

the activity coefficient, f_{HB}, being set equal to one at zero electrolyte concentration. Upon subtracting the ionized part as calculated from conductivity measurements from the solubility of benzoic acid in water, and upon making a small correction for the ion concentration ($\mu = 0.0013$), a value of 0.02650 mole per liter is obtained.[3] Thus

$$f_{\mathrm{HB}} = \frac{0.02650}{c_{\mathrm{HB}}}$$

The values of the activity coefficient calculated in this way are given in Table IV and for comparison we have included a summary of the results of Berry, Hoffmann and Langbeck, Giintelberg and Schiodt and Larsson.

An inspection of the table shows that for low electrolyte concentration the activity coefficient is practically independent of temperature over the range given.

Some of these values are shown graphically in Fig. 4, where the logarithm of the activity coefficient is plotted against the electrolyte concentration.

An equation of the form $\log f = kc$ expresses the results very well. For our results at 25.15° in potassium chloride solution

$$\frac{\log f}{\ } = 0.138$$

For the results of Berry at 20° and of Giintelberg and Schiodt at 25° in sodium chloride solution

$$\frac{\log f}{\ } = 0.176$$

At 18° Larsson gives the values

$$k = 0.137 \text{ for KCl}$$
$$k = 0.177 \text{ for NaCl}$$

When the concentrations are expressed in moles per 1000 g. of water, and log γ is plotted against m, the points do not lie on a straight line as in Fig. 3. The best line which can be drawn, however, is represented by the equation

$$\log \gamma = 0.12\, m$$

Using the data on the solubility of benzoic acid available at that time, Randall and Failey[12] gave $k = 0.13$ for potassium chloride and 0.18 for sodium chloride solution.

The activity coefficient of benzoic acid is larger in sodium chloride solution than in potassium chloride solution, that is to say, the solubility is less in sodium chloride than in potassium chloride solution of the same concentration. Since the salting out effect depends on the change in the

---

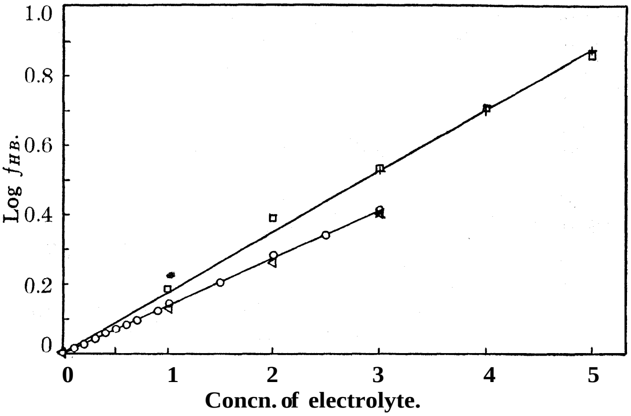
orientation of the water molecules toward the neutral molecule, one would expect the smaller sodium ion to have a greater effect than the larger potassium ion. This is in agreement with the facts and theory as discussed by Debye and McAulay[13] and Scatchard and others.[14] As pointed out by Scatchard, various Hofmeister series have been put forward for the cations and anions. Glasstone and Pound,[15] who studied the electrolyte effect on the solubility of ethyl acetate, give the order $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$ and $Cl^- > Br^- > I^-$ for decreasing solubility of ethyl acetate. Linderström-Lang[16] shows the same order for hydroquinone, quinone and succinic acid (uncorrected for the dissociated part).



○, E. m. f., 25°; ◁, Berry, 20°; ×, G. + S., 20°, in KCl; □, Berry, 20°; +, G. + S., 20°, in NaCl.

Fig. 4.—Activity coefficients of molecular benzoic acid in potassium chloride and sodium chloride solutions.

Haesseler[17] finds the same general order for benzoic acid. Haesseler reports the solubility of total benzoic acid and has not corrected in any way for the part present as ions. Larsson demonstrated that the salting out of benzoic acid is, roughly speaking, an additive property of the ions of the solvent salt, *i. e.*

$$\log f = kc = [k_{C^+} + k_{A^-}]c$$

he arbitrarily set k_{K^+} equal to k_{Cl^-}, and calculated salting out constants for all the ions of the solvent salts studied.

In Table V we give some of Larsson's[18] ionic salting out constants and in

addition the radii of the ions as calculated by Pauling[19] for crystals. While these radii will not necessarily be the same in solution they will probably have the same relative magnitudes.

TABLE V

COMPARISON OF IONIC SIZE WITH SALTING OUT CONSTANT, k

Ion	Radius, Å.	k	Ion	Radius, Å.	k
Li^+	0.60	0.12	Mg^{++}	0.65	0.10
Na^+	0.95	.11	Ca^{++}	0.99	.10
K^+	1.33	.07	Sr^{++}	1.13	.09
Rb^+	1.48	.02	Ba^{++}	1.35	.08
Cs^+	1.69	−.08	Cl^-	1.81	0.07
			Br^-	1.95	0.00
			I^-	2.16	−0.02

From Table V it appears that *k* decreases with increasing ion size. In order to go further with any theoretical discussion, one would have to have information as to the change in dielectric constant and freezing points of these solutions, as pointed out by Debye and McAulay and Scatchard, as well as some knowledge of the deformability of the ions and molecules. Larsson points out that his results are qualitatively in agreement with the available dielectric data. The further study of the solubility of molecular benzoic acid in salt solutions offers a number of interesting possibilities, especially in view of the increase of solubility of benzoic acid in solutions of sodium benzoate (k = −0.21) and a number of other salts such as sodium β-naphthalene sulfonate (k = −0.75).

Summary

1. The solubility at 25.15° of benzoic acid in potassium chloride solutions has been determined and from determinations of the hydrogen-ion concentrations of these solutions the solubility of molecular benzoic acid has been calculated.

2. From these solubility values and the values of the ion product $C_{H^+}\ C_{B^-}$, the classical dissociation constant of benzoic acid has been calculated at the various electrolyte concentrations from 0.1 to 3.0 moles per liter.

3. A comparison of the change of the dissociation constant with electrolyte concentration has been given for different acids in the same solvent salt.

4. The activity coefficient of molecular benzoic acid in potassium chloride solutions has been evaluated. The results are expressed by the equation $\log f = 0.138c$.

5. A discussion of the relation of ion size to salting out has been given.

REACTION OF AMINES WITH SULFUR DIOXIDE. I. ANILINE AND SULFUR DIOXIDE

BY ARTHUR E. HILL

RECEIVED MAY 12, 1931 PUBLISHED JULY 8, 1931

In the year 1909 experiments were conducted in this Laboratory in an effort to study the reactions of acid anhydrides upon basic anhydrides, by Mr. William A. H. Zink and myself. It was found that sulfur dioxide combines readily with aniline, either pure or in solution in anhydrous solvents, giving crystalline yellow compounds with moderately high dissbciation pressures; the same type of reaction occurs with the toluidines, with benzidine, with dimethylaniline and with any amine of a fairly pronounced basic character; the reaction appears to be quite general. Because of the partial decomposition and loss of sulfur dioxide which these compounds underwent during handling, it was not found possible to analyze them by the usual methods, and the work was therefore stopped. During the past year the work was taken up again and the composition of the compounds determined by the phase rule methods made familiar in the early study of the hydrates of copper sulfate and more recently by Bancroft[1] in his studies of salt formation among the proteins; vapor pressure measurements have been made and a study made of the behavior of the compounds upon melting.

Search of the literature has disclosed that previous to our investigation only a single case had been found in which this general reaction figures, namely, that of sulfur dioxide with aniline, and in this instance the facts are given correctly in part and quite incorrectly in other parts. Schiff[2] states, incidentally to his work upon organic amines, that "aniline absorbs sulfur dioxide, as previously noted by Hofmann," that the solid is yellow, appears to contain equivalent amounts of both substances, *i. e.*, has the formula $C_6H_5NH_2 \cdot SO_2$ and can exist only in presence of excess sulfur dioxide; the reference to Hofmann's work has not been located. On exposure to the air, the solid became quickly decolorized with loss of sulfur dioxide, changing to what he believed to be $2C_6H_5NH_2 \cdot SO_2$; his analysis gave 26–28% SO_2, the theory requiring 25.6%; the original yellow solid he did not analyze. Boessneck[3] mentions the original compound and found it to contain 32% SO_2, where the theory requires 40.8% for a 1:1 compound. Michaelis[4] by treating thionyl aniline (C_6H_5NSO) with aniline and water or with moist ether obtained the second of Schiff's compounds, the white solid said to be $2C_6H_5NH_2 \cdot SO_2$, melting at about 60°, and only slowly decom-

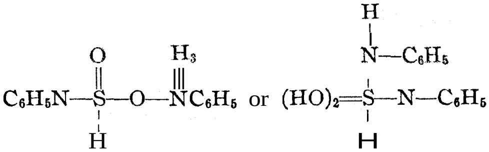
posing into its components; he proposes the structural formula of a phenylamidosulfinic acid for the yellow compound, and



$$C_6H_5N-\underset{\underset{H}{|}}{\overset{\overset{O}{\|}}{S}}-O-\overset{\overset{H_3}{|||}}{N}C_6H_5 \text{ or } (HO)_2=\underset{\underset{H}{|}}{\overset{\overset{\overset{H}{|}}{N}-C_6H_5}{\overset{|}{S}}}-N-C_6H_5$$

for the second. Schiff also records that if sulfur dioxide is passed into a mixture of aniline and water, a heavy precipitate of a ***yellow*** crystalline body is obtained, which will lose sulfur dioxide rapidly until it has reached the composition $4C_6H_5NH_2{\cdot}SO_2 + n$ aq., which compound he regards as belonging to the class of the sulfites of aniline, no analysis being given.

Subsequent to our earlier work, Korezyǹski and Glebocka[5] investigated the action of sulfur dioxide upon a large number of amines and substantiated the formulas of the resulting compounds by the volume of sulfur dioxide absorbed under one atmosphere pressure. In the majority of the cases, although not in all, the ratio of one mole of sulfur dioxide to one amino group was observed. The dissociation pressures of these compounds were not measured.

The results which follow in this paper have established that sulfur dioxide acts upon anhydrous aniline to form only the yellow addition product $C_6H_5NH_2{\cdot}SO_2$, for which neither Schiff nor Boessneck could obtain a satisfactory analysis; that its exposure to the air results not only in the loss eventually of some of the sulfur dioxide, but also in the absorption of water with the formation of a white crystalline mass which is a mixture of the acid sulfite and the normal sulfite, the two true salts formed by aniline and sulfurous acid; the other formulas proposed by Schiff, Boessneck and Michaelis are not substantiated, and the yellow color of Schiff's compound obtained in the presence of water may be taken as evidence that this material held considerable quantities of discolored aniline. It should be remarked that in looking for descriptions of the salts of aniline and other amines with sulfurous acid, it was found that Beilstein's earlier edition, while giving in general the salts with hydrochloric acid, sulfuric acid, nitric acid, etc., gives no evidence that the salts of sulfurous acid have been prepared; the edition now being completed has not yet reached the volume on the aromatic amines. The generalization may be made, on the basis of this work, that amines form yellow addition products usually in the 1:1 ratio with dry sulfur dioxide, and that in the presence of water, as should be expected, normal or acid sulfites are produced, which are, of course, colorless.

For the preparation and study of the addition compound, Kahlbaum's aniline was used, redistilled and stored in a desiccator over sulfuric acid; the sulfur dioxide was

---

[5] Korezyǹski and Glebocka, *Gazz. chim. ital.*, ***50,*** **I,** 378 (1920).

taken from a small commercial cylinder, which was allowed to run for a considerable time to free the gas from possible impurities. For the vapor pressure measurements by which the composition of the compound was determined, the apparatus consisted of a glass-stoppered 50-cc. distilling flask immersed in a water thermostat, connected by its side tube to a 50-cc. gas buret from which it could be shut off by a glass stopcock, and also connected to a mercury manometer and to a Hyvac pump shut off by a mercury-sealed stopcock. The aniline and sulfur dioxide, therefore, were in contact only with glass throughout the entire apparatus. Samples of about one gram of aniline were weighed into the reaction vessel for each run, with the addition of glass beads to increase the surface. After introduction of the aniline the system was connected with the pump, which in less than sixty seconds reduced the pressure to an amount too low to be noted by direct reading on the manometer. For the introduction of known amounts of sulfur dioxide, the gas buret was fitted with a side tube and a three-way stopcock; in filling the buret, the cylinder of sulfur dioxide was connected by rubber tubing to the three-way stopcock and the gas, previously dried by sulfuric acid in a small U-tube, passed through the by-pass to sweep out air for about twenty minutes. It was then turned into the gas-buret and allowed to displace the mercury with which the buret had been filled, care being taken that the gas entered always under a slight excess pressure so that possible leakage of air inward through the rubber tubing was eliminated. By calculation from the volume, pressure and temperature of the gas the weight admitted to the system was known. The initial absorption of the gas by the aniline is very rapid, and equilibrium appears to be reached within a few hours up to the point where the liquid has been largely changed to the solid, at which time entrance of the gas through the crust of solid is slowed up considerably; twenty-four hours were allowed to elapse before final readings of the manometer were made. By making correction for the amount of sulfur dioxide remaining in the apparatus, of known volume, pressure and temperature, the amount absorbed by the aniline could be calculated; these corrections are of relatively small amount only, since the total volume of the apparatus was only 92 cc. and the pressures are low. The probable errors in the reading of the manometer with the correction for variations in barometric pressure are of the order of ±0.5 mm. of mercury. The results of such a run are given in Table I.

TABLE I

VAPOR PRESSURE OF ANILINE + SO_2 AT 25°

Weight of aniline used, 1.311 g.

56.0	885.5	.981
127.5	887.6	.984
475.5	888.2	.985
43.0	(Partial evacuation)	

From the plot of these results in Fig. 1 the interpretation can easily be made. Sulfur dioxide dissolves in liquid aniline at 25° up to a pressure of about 44 mm. and a concentration of about 0.14 mol of the gas per mole of aniline. At this concentration the solid addition product appears and the system, with three phases and a fixed temperature, remains invariant upon further additions of sulfur dioxide until the aniline has been completely converted into the compound, at which point further additions of gas cause an abrupt rise in pressure without further absorption in significant amount. The abrupt rise at an absorption of 0.98 mole is sufficient proof that the components combine in *a* 1:1 ratio to form the compound $C_2H_5NH_2{\cdot}SO_2$, and the absence of any break in the flat portion of the curve rules out the existence of any of the compounds lower in sulfur dioxide content assumed by Schiff and Boessneck. The slight rise which is noted in the nearly flat portion of the curve is due, it is believed, not to impurities in the gas but to incomplete attainment of equilibrium from the higher pressures, impeded by the crust of solid upon the liquid; partial evacuation, as shown in the last line of the table, gave **a** pressure as low as **43** mm., while the same sample, after the higher temperature and higher pressure of Table II, showed a pressure slightly over 44 mm.

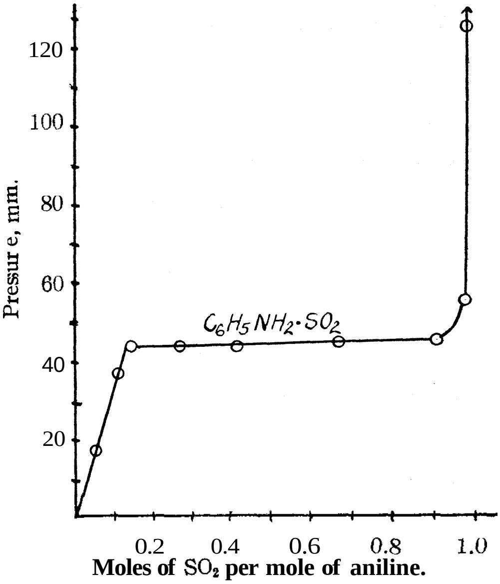

Fig. 1.—Pressure-composition diagram, aniline + SO_2 at 25°.

The color changes in this system are marked, and appear to be alike for all the amines upon treatment with sulfur dioxide. The liquid solution obtained from colorless aniline has *a* deep orange-red color, which appears also upon melting the solid in a sealed vessel; while the solid compound, if freed from all solution, and especially if sublimed, is of a lemon-yellow color.

Vapor pressure measurements were made at several temperatures by first exhausting the system below **43** mm. to insure absence of excess sulfur dioxide and then changing the temperature of the thermostat. **At** the higher temperatures equilibrium appeared to be reached in fifteen to thirty minutes. The results are given in Table II.

The vapor pressure curve, shown in Fig. 2, rises very steeply with the temperature. A plot of the logarithm of the pressure with the inverse of the absolute temperature, shown in Fig. 3, gives a good straight line, in which only the point at 3.5° appears misplaced. From this curve it ap-

TABLE II

VAPOR PRESSURE OF $C_6H_5NH_2 \cdot SO_2$ AT VARYING TEMPERATURES

Temp., °C.	Pressure, mm.	Temp., °C.	Pressure, mm.
3.5	3.7	45	360
25	43	50	630
30	72.5	52	(760) (by extrapolation)
35	125		

pears by extrapolation that the pressure reaches 760 mm. at a temperature of 52°, as given in the last line of Table II. The true melting point of the compound is distinctly higher, so that it would sublime without melting under atmospheric pressure. From the slope of the curve of Fig. **3** the heat of vaporization of the compound, calculated from the formula d In p/d T = X/RT^2, is 19,630 cal.

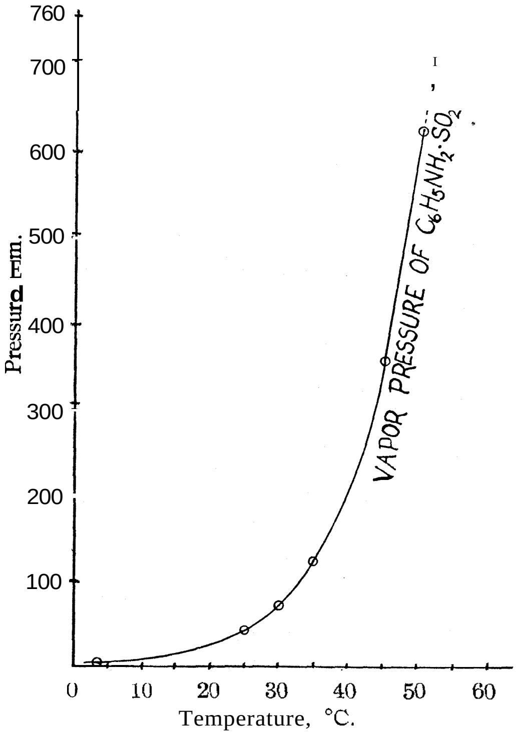

Fig. 2.—Vapor pressure of $C_6H_5NH_2 \cdot SO_2$ at varying temperatures.

Efforts to find the melting point of the compound gave only approximate results. The work, of course, must be conducted in a closed system, to prevent loss of sulfur dioxide. Because of the high pressures developed, only small amounts could be safely handled, and it was not found possible to keep the composition entirely under control. Amounts of 200 to 500 mg. of aniline were weighed into small tubes of total capacity of 2 to **3** cc. and dry sulfur dioxide introduced through a capillary; the tubes were sealed and reweighed to ascertain the amount of sulfur dioxide present, but in no case could the amount be brought up to the requisite one molecule. Samples holding over 90% of this amount came to complete liquefaction at temperatures slightly over 60°; the best sample, containing 0.969 mole of sulfur dioxide per mole of aniline, melted completely at 63.1°. If we assume that the melting point curve of this system forms a blunt angle with the composition axis, as should be true for a compound which dissociates largely into its components, the melting point cannot be greatly higher than the temperature found, and may be set at about 65° and a pressure of about 3.5 atmospheres, from the curve of Fig. 3.

Inspection of Fig. 1, which is a pressure–composition isotherm for 25°, will show that for higher temperatures, since the solubility of the solid in liquid aniline increases, the horizontal section of the curve will become shorter, until it reaches the dimensions of a point and a position at 1:1 composition on the ordinate at the congruent melting point, where the composition of liquid phase and solid phase is the same. A search was made to find some treatment in the literature which should include the effect of the three variables, temperature, pressure and composition, upon a compound having a congruent melting point. Such a treatment is not in Roozeboom's "Die Heterogenen Gleichgewichte," and I have not found it elsewhere. For that reason it seemed worth while to construct a model showing these relationships so that they can be easily visualized; Fig. 4 is a perspective view of such a model, including the three variables and showing the regions of stability for the solid, liquid and gaseous phases. Though drawn to illustrate the system aniline–sulfur dioxide, it may be applied without change to any binary system forming a compound which melts congruently, at temperatures above the melting points of the two components. The curve *bge* will be recognized at once as the solubility curve for the compound, which in the representation of condensed systems is familiarly drawn as a projection upon the composition–temperature surface. What is left out of the familiar projection, however, is that not only is the solubility curve *bg* moving in the direction of higher pressures with increase in temperature, but that *ge* also is moving in the direction of higher pressures with decrease in temperature. To the well-known fact that the solid phase may be in equilibrium at a constant temperature with either of two liquid phases of differing composition (*i. e.*, has two solubilities) is to be added the fact that, of course, the two liquids have different vapor pres-

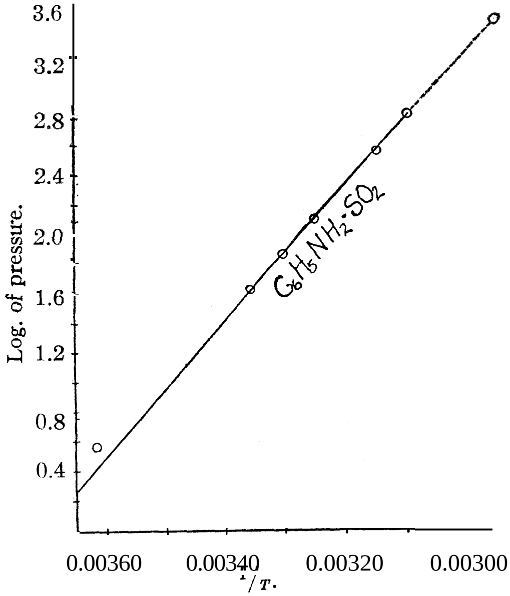

Fig. 3.—Log of pressure *vs.* $1/T$ for $C_6H_5NH_2{\cdot}SO_2$.

sures. The front view of the figure, here given, shows in perspective the regions of stability for the solid, for liquid solution and for vapor alone.

The projection of an isotherm such as t_0 upon the composition–pressure surface is shown in Fig. 5. This is a complete representation of what has been shown in part in Fig. 1 and in the usual representation of vapor pressures in two-component systems. The line ab, shown in both Fig. 5 and Fig. 1, represents the change in solubility of sulfur dioxide in liquid aniline with increase in pressure; at pressures lower than b the system can consist only of a liquid phase conjugate with vapor of the same pressure and a different composition, expressed by a point on the vapor curve *axyf*. At the pressure b solid appears, and addition of sulfur dioxide results only in variation in the amounts of the three invariant phases, b (liquid), *c* (solid compound) and *x* (vapor). Upon addition of sulfur dioxide up to the composition *c* the liquid has all been changed to solid compound; further additions of sulfur dioxide result only in a change in pressure without any change in composition of the compound, *i. e.*, the system is isothermally univariant and consists of solid conjugate with vapor of the compositions shown along the section *xy* of the vapor curve. At *d*, a high pressure not measured in this instance, there is condensation of a new liquid phase *e*, rich in liquid sulfur dioxide, and the system is again isothermally invariant, consisting of compound, liquid phase *e* and gaseous phase y. Additions of sulfur dioxide result now in diminishing the amount of the solid and increasing the amount of the liquid until the solid disappears entirely at e; further addi-

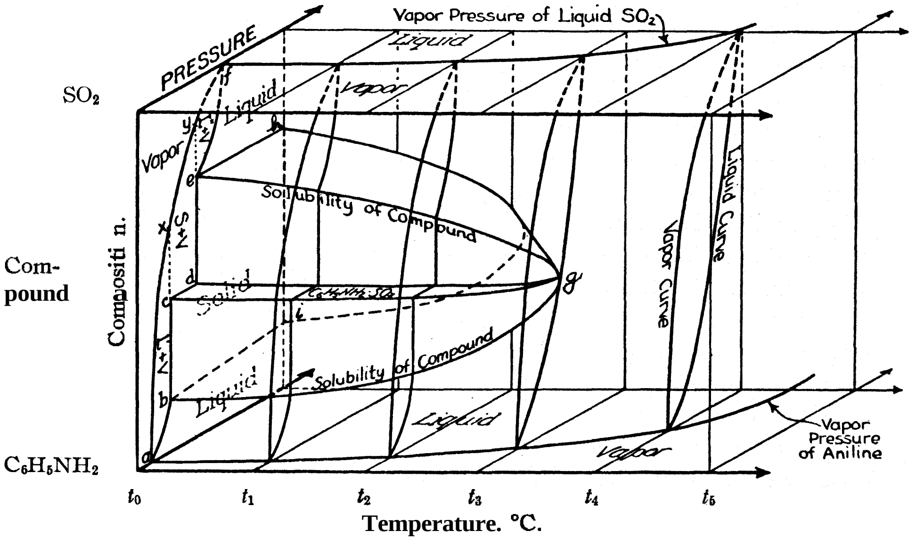

Fig. 4.—Pressure–temperature–composition diagram for a compound with congruent melting point.

tions give the isothermally univariant system consisting of liquid represented on the curve *ef* and vapor represented on the curve *yf*. The pressure at d may be looked upon not only as the second vapor pressure of the system compound–liquid–vapor, but also as the deliquescence pressure of the compound. The curves *bi* and *eh* are boundary curves between the area for the solid and the areas for the two liquid phases; they will tend to meet at high pressures or to separate further according as the volume of the system tends to decrease or increase upon dissolving of solid phases. If isotherms are drawn at successively higher temperatures, the distance cd and the distances bc and de will become shorter; at the congruent melting point the four points will have met at a single point, represented by g in Fig. 4. Above this temperature only liquid and vapor can exist, up to the point where the vapor curve and the liquid curves meet, at the critical temperatures for varying solutions of the two liquids.

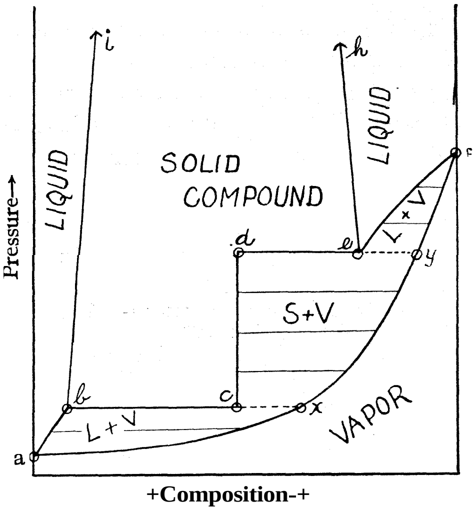

Fig. 5.—Pressure-composition diagram for a compound with congruent melting point.

Experimental work has also been carried out upon the ternary system consisting of aniline, sulfur dioxide and water, in order to determine whether or not normal sulfites and acid sulfites exist, and to explain the observation that the yellow addition product previously discussed turns white on exposure to the air. It is possible to determine the composition of ternary systems such as this by the measurement of vapor pressures as used above, but not with the same simplicity either as to theory or as to practice. Considering that aniline and water have but small mutual solubility, it becomes clear that the addition of sulfur dioxide will, upon the appearance of solid sulfite, give rise to an isothermally invariant system consisting of two liquids, solid and vapor; but in the absence of previous knowledge as to the solubility of the solid in the liquids, it is impossible to predict just what quantities of the two liquids should be taken to insure the appearance of the solid. Again, the absorption of the gas without increase of pressure will not cease abruptly at the point where the composition of the solid is reached, because of the solubility of gas in the liquid phase, but by keeping this liquid at a minimum the amount of this correction can be minimized. Another isothermally invariant system will consist of solution, vapor, solid normal sulfite and solid acid sulfite, if the solubility relations can be properly controlled, with the same error in determining the composition due to absorption of excess gas by the liquid phase. The experiments were therefore begun with aniline and a quantity of water only slightly in excess of the one mole required for the reaction. It was found in this case, and in others in which the water was increased by successive amounts up to eight moles, that the initial absorption of sulfur dioxide was rapid and that an approximately constant pressure was obtained, but that when the absorption had reached from 0.6 to 0.8 mole it ceased quite abruptly and that high pressures allowed to remain in contact with the system for periods up to two weeks caused no further absorption in significant amount. It is believed that this behavior is due solely to mechanical obstruction; that the salt, forming a hard and impenetrable crust in an apparatus in which agitation is almost impossible, acts as a barrier between the water and the gas, and that the reaction with water present only as a vapor is too slow to be followed. This hypothesis was justified by the results of experiments in which larger amounts of water were used, of which the results are given in Table III.

In calculating the moles of sulfur dioxide absorbed, the assumption was made that its partial pressure in the system was the total pressure minus that of pure water, since the aqueous pressure of the solutions was not known. The error introduced by this assumption can affect the position of the points as shown in Fig. 6 only by a fraction of one per cent. The temperature of 20° was used to avoid the distillation of water into the outer parts of the vessel, which occurred at 25°. The two curves, shown in Fig. 6, show that the gas is absorbed with small continuous rise in pressure up to an amount approximating one mole of sulfur dioxide to one of aniline, the approximation being closer where the amount of excess water is smaller (Curve 2) and the error introduced by its presence smaller; above this ratio of sulfur dioxide to aniline, the absorption increases very slowly with large increase in pressure and the upright branches of the curve represent an approximation to Henry's law. In case 1 solid phase appeared at about 0.6 mole of gas present, in case 2 at about 0.3 mole. The curves may be taken as establishing the existence of the 1:1 compound containing water, which would be the acid sulfite, $C_6H_5NH_3HSO_3$, but give no evidence as to the existence of the normal sulfite or other salts.

The effort to prepare the various sulfites in condition for analysis by precipitation from aqueous solution meets with obstacles because of the difficulty in finding such a drying agent for ternary compounds as would absorb the water from the mother liquor upon the crystals without leading to loss of water of composition. The nearest approach to such a desiccant is the anhydrous compound, $C_6H_5NH_2\cdot SO_2$, which has been shown capable of combining with water, but it is not the hydrate immediately below the acid salt, $C_6H_5NH_2\cdot H_2O\cdot SO_2$, and therefore is not the correct drying agent for that compound. It was used, however, with a sample of salt prepared by passing sulfur dioxide to saturation into a 2:3 mixture of aniline and water, from which the white salt crystallized copiously. After rapid centrifuging it was placed in a desiccator over a large amount of the yellow addition product. Loss of weight occurred continuously for thirty-four days, after which the loss dropped to an amount of less than 0.01% per day, which loss doubtless occurred during the transfer of the sample to the balance. At this point an analysis was made for the SO_2 content, by evolving the gas from a sample by addition of acid and passing it into a known solution of iodine in potassium iodide; the sulfur dioxide content found was 23.46%, which is close to that calculated for the normal sulfite, $(C_6H_5NH_3)_2SO_3$ (23.88%). It appears then that aniline forms a crystalline normal sulfite and a crystalline acid sulfite which may be precipitated from aqueous solutions, but

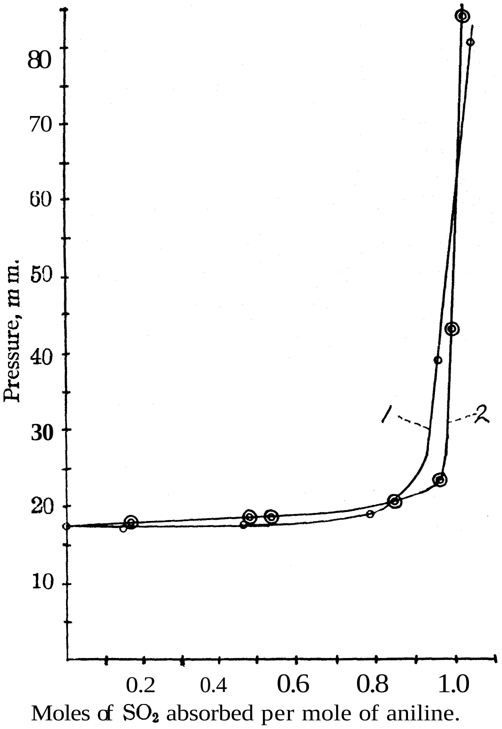

Fig. 6.—Absorption of sulfur dioxide by aniline in the presence of water at 20°.

which have (as shown in Table III and what follows) sufficiently high decomposition pressures to prevent their easy preparation in pure form.

The decomposition pressure of the anhydrous addition compound has been shown, in Table I, to be 44 mm. at 25°. That of the acid salt could not be measured, but is some rather small fraction of the 18–20 mm. of Table III at 20°. That of the normal salt was determined at 20° by direct addition of the dry compound to the apparatus and repeated evacuation with the pump: it is found to be 3.5 mm. ±0.5, of which but half is sulfur dioxide. We may therefore explain the action of the yellow compound on exposure to air as an addition of water and a loss of sulfur dioxide passing through the composition of the acid salt to that of the normal salt.

A sample of the normal sulfite, taken in a closed tube with excess sulfur dioxide, melted incompletely to a red liquid, beginning at 62°, in sufficient proximity to the melting point given by Michaelis[4] to make it probable that his white solid was the normal sulfite.

From the high dissociation pressure which the yellow addition product displays, it seems preferable to consider that the sulfur dioxide is held by secondary valence and that the structural formulas proposed are likely to be misleading. However, it was found that when samples are heated in a closed tube at 100° for about sixteen hours, they change to a nearly colorless solid, not liquefying at 100°, and with no appreciable sulfur dioxide pressure. The nature of these compounds will be the subject of further investigation, as will also vapor pressure measurements of the addition products of sulfur dioxide with other aryl amines and the measurement of the solubility of the two sulfites of aniline in water.

Summary

1. Aniline combines with sulfur dioxide in the 1:1 ratio to form a yellow crystalline solid.

2. The vapor tension of the addition compound was measured between 3.5 and 50°, and the heat of dissociation calculated.

3. A diagram has been constructed and discussed for a binary compound above the melting points of its two components, showing temperature, composition and pressure as variables.

4. In the presence of water aniline combines with sulfur dioxide to form a normal sulfite and an acid sulfite, both of which have dissociation pressures markedly less than that of the anhydrous addition compound.

GRADUAL TRANSITION IN SODIUM NITRATE. I. PHYSICO-CHEMICAL CRITERIA OF THE TRANSITION

BY F. C. KRACEK

RECEIVED MAY 12, 1931 PUBLISHED JULY 8, 1931

Until a few years ago the only transitions recognized in pure crystalline solids were of the polymorphic kind, that is, inversions from one crystalline modification of a substance to another. Inversions of this type are characterized by a more or less great change in the crystal lattice, and each modification has well-defined physical properties which alter by discontinuous steps, theoretically at a point at which two neighboring modifications can be considered to be in equilibrium. From the standpoint of thermodynamics these inversions are analogous to melting in the sense that we can express all the quantities involved by means of a Clapeyron equation and, particularly, there is an equilibrium value of the (latent) heat of transition and of the (latent) volume change at the inversion point which is a function of the temperature and pressure. The salient characteristic of the polymorphic inversions is the phenomenon of hysteresis; the transformations are prompt in some cases, but often they are so sluggish that geologic times have failed to effect the conversion from the unstable to the stable modification in certain minerals. A consequence of this retardation in the inversion is that there is a (hysteresis) band of temperature and pressure values within which two modifications can *co*-exist with little or no tendency to transform.

Some substances exhibit apparent transitions which are abnormal when contrasted with the true polymorphic changes. The specific heat curves, for example, increase gradually over a long interval below the transition point; instead of a discontinuous change at this point, the specific heat merely reaches gradually a high value, and then gradually but more rapidly sinks to a normal value. Other criteria have not yet been sufficiently investigated in most cases, but it is fairly certain from the measurements that have been made that there is very little change in the crystal lattice, and that the volume alters gradually rather than discontinuously on changing the temperature.

The examples hitherto described all occur at temperatures below 0°. The first was ammonium chloride, studied by Simon,[1] who later investigated other ammonium salts. These investigations showed that the heat capacity curves pass through well-defined maxima in the neighborhood of -30 to $-50°$, the different anions in combination with the NH_4^+ altering

---

[1] F. Simon, Ann. *Physik,* 68, 241 (1922); Simon and Simson. *Naturwiss.,* 38, 880 (1926); Simon, Simson and Ruhemann, *Z. physik.* Chem., *129,* 339 (1927); Simon and Bergmann, *ibid.,* 8B, 255 (1930).

the temperature of the peak of the curve only a few degrees. Structurally there is apparently no change, and the expansion curves are gradual, but with abnormal contours in the neighborhood of the transition temperatures (when defined as the temperatures of the peak of the specific heat curves). On the basis of these results it has been suggested that the phenomenon is due to intramolecular rearrangement of the ammonium ions. Other examples are found in the specific heat curves for a number of condensed gases,[2] for which unfortunately other criteria are lacking. Hendricks[3] on the other hand has noted that crystal structure studies on the primary alkyl ammonium halides at room temperature lead to the postulate of a collinear carbon chain, whereas at liquid air temperatures the staggered chain is the more probable. This is in accord with a suggested explanation based on the quantum mechanics, offered by Pauling,[4] who postulates a transition from oscillatory to rotatory motion within the lattice of a crystal. Smits[5] has studied the thermodynamic aspects of the problem, and arrives at a series of pseudo-binary diagrams, without definite suggestions as to the nature of the pseudo-components.

It should be emphasized that the experimental evidence presented in the literature is lacking in one important aspect, namely, that of the reproducibility of the physical properties measured. The specific heat curves give us the best example of this; different investigators agree in general on the form of the curve, but often disagree seriously as to the exact values of the specific heat. The question of reproducibility is of particular importance when any given property is employed to differentiate between a gradual transition and a sluggish polymorphic inversion, for obvious reasons. It must be admitted, however, that this objection is largely of academic interest only, since the very nature of the methods of specific heat measurements at low temperatures is such as to assure the general correctness of the results.

In addition to the two types of transitions mentioned above, it is likely that there exists a third type in which a true polymorphic inversion is preceded by an abnormal change in specific heat and other properties. Quartz appears to belong to this mixed class; it is well known that its properties (specific heat, thermal expansion, optical properties) undergo large changes over a considerable temperature interval below the inversion point at 573° where the crystals suddenly change from trigonal to hexagonal symmetry. No other cases of this type appear to be known.

The investigation reported in this and a following paper is concerned with a gradual transition in sodium nitrate. This substance occupies an apparently anomalous position among the nitrates of univalent metals. With the exception of lithium nitrate, which forms a trihydrate at ordinary temperature, all the other univalent nitrates exhibit one or more normal polymorphic inversions. Bridgman,[6] who studied these inversions under pressure, remarks upon the similarity of the phase diagrams and discusses the crystallographic analogies between the various forms encountered. Sodium nitrate is rhombohedral of the calcite type at ordinary temperature. This crystal type is found in anhydrous lithium nitrate, and as the high temperature modification of potassium nitrate and rubidium nitrate. None of these, however, appears to be completely isomorphic with sodium nitrate.

An unsuccessful search for an inversion in sodium nitrate has been made by Bridgman[6] and by Hissink.[7] Both investigators stopped at temperatures below that at which the gradual transition is completed.

In many respects the thermal behavior of sodium nitrate parallels that of ammonium chloride as already described. The specific heat begins to increase abnormally and reaches a peak value at 275°. Optical examination with a heating microscope fails to show any decided change between room temperature and the melting point, but the thermal expansion curve exhibits an abnormal course between 150 and 275°. The behavior is reproducible, and hysteresis phenomena are completely lacking. Studies have also been made of the solubility in water up to the melting point of the salt, and of the crystal structure at various temperatures.

The results are in good agreement with the postulate of intramolecular rotation[4] of the NO_3 ion at temperatures between 275° and the melting point, the deciding factor being the information gained from the analysis of the structure. This portion of the work, in collaboration with E. Posnjak and S. B. Hendricks, is published separately in a following paper. The results collected in the present article deal with the purely physicochemical determination of the gradual transition, and are independent of any postulate as to the nature of this phenomenon.

Part I. Thermal Capacity

In 1909 a paper was published by Goodwin and Kalmus[8] on the determination of specific heats and latent heats of melting for a number of salts, among which was included sodium nitrate. There is an anomaly in the course of the specific heat curve for the crystals of this substance, which was passed over unnoticed, but which certainly exceeds a reasonable

experimental error,[9] amounting to 5–10 cal./g. in the value of the total heat of the crystals. During the course of another investigation[10] I had occasion to take thermal analysis curves of sodium nitrate, and found an abnormal heat effect in appropimately the same region as that exhibited by the results of Goodwin and Kalmus. The characteristics of this heat effect were different from those usually associated with normal polymorphic inversions, and hence a closer study was made of the phenomenon.

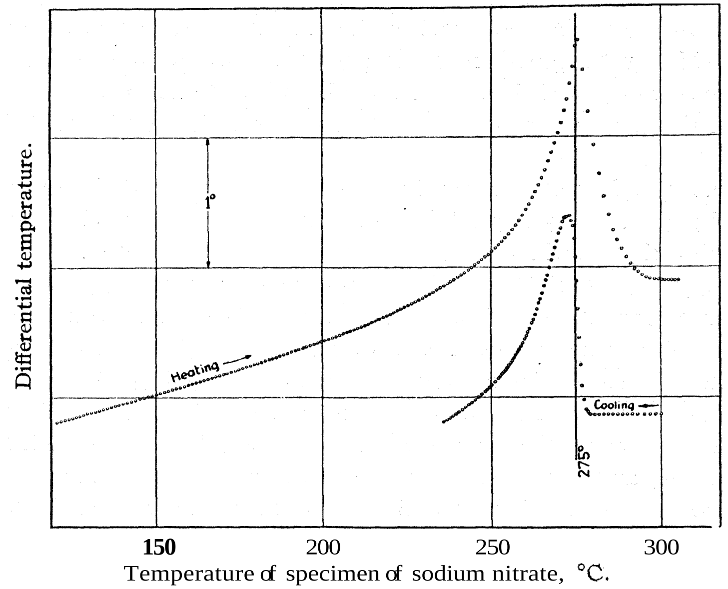

Fig. 1.—Differential heating and cooling curves for sodium nitrate. Note the absence of location of the beginning of the heat effect and its sharp termination on the heating curve.

The accessory apparatus used for thermal analysis was the same as in my earlier work. In order to secure maximum sensitivity and freedom from minor fluctuations of the differential temperature, the furnace was provided with a hollow copper block within which the sample of sodium nitrate contained in a platinum thimble crucible was suspended upon the thermocouple, which was immersed in the salt, but protected from corrosive attack by a capsule made from platinum tubing 1.5 mm. in diameter. The reference thermocouple was located in a well in the copper block. This arrangement has proved to be entirely satisfactory in that the differential temperature readings were perfectly steady. Readings were made to within 0 2 microvolt, using copper–constantan couples, which corresponds to a sensitivity of 0.005°, far in excess of what was actually needed. The thermocouples were calibrated with accepted standards.

The sodium nitrate used for the experiments was recrystallized, starting with the best C. P. material available. About 2.5 g. of the salt was used in each experiment.

---

[9] The melting points quoted in their Table II, p. 12, for sodium nitrate and potassium nitrate are transposed.

[10] F. C. Kracek, *J. Phys. Chem.*, **34,** 225 **(1930).**

Single crystals were produced by melting the samples in place in the furnace and slowly coaling. It may be mentioned, however, that single crystals and crystal aggregates showed no difference in behavior.

Typical results of the thermal analysis experiments are shown in Figs. 1 and 2. The important feature of these curves is that, on heating, the rise in the differential temperature ceases sharply at 275.5°, but on cooling, heat begins to be evolved by the sample at a temperature which is higher, namely, about 279°. This is contrary to all experience with normal polymorphic inversions,[11] in which the heat effect on cooling, in consequence of hysteresis, however slight in amount, always begins at a temperature which is *lower* than that at which the heat effect begins on heating. The second unusual feature of these curves is that *no point of beginning* of the heat effect can be located on the heating curve. The heat capacity increases gradually as temperature rises to 275.5°, and then suddenly decreases sharply to a normal value, within 2 or 3 degrees, as shown by the contour of the recovery curve, and the beginning of the heat effect on cooling. Just below 275.5° the increase in heat capacity is rapid, but it does not have the character of a latent heat, for in the latter case we should expect in a single crystal a fall in the temperature of the sample with a rising

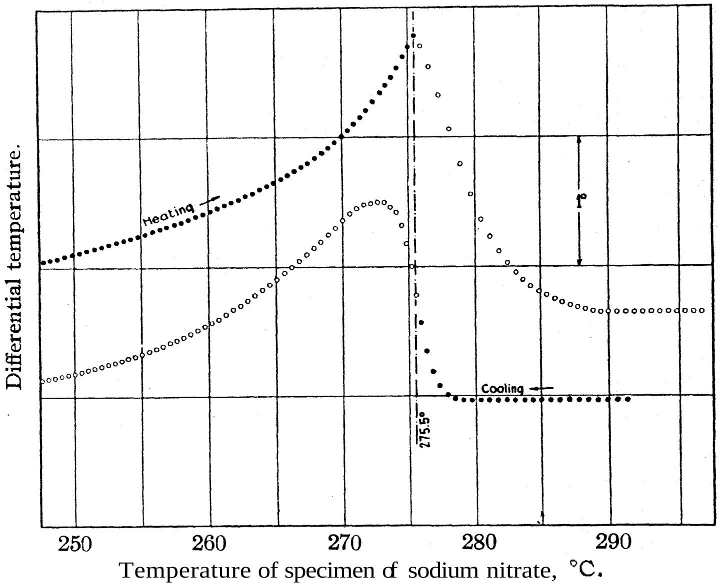

Fig. 2.—Differential heating and cooling curves for sodium nitrate near the peak of the curve. Compare the black circle curves with the curve of the expansion coefficient in Fig. 6.

---

[11] Consult J. *Phys. Chem.*, **34**, 225 (1930), for typical heating and cooling curves obtained with potassium nitrate.

differential temperature, with a heat effect which is so prompt. While these experiments do not yield an absolute value for the heat capacity, they nevertheless furnish relative values, and they describe the character of the behavior as exactly as could be done with a strictly calorimetric procedure.

The results of these experiments on the abnormal increase in the heat capacity, which extends for at least 100° below the temperature at which the peak of the curve is reached, favor the conclusion that the change which takes place in the crystals of sodium nitrate is not that of a typical inversion from one modification to another, but rather a gradual alteration instead of an abrupt one in the properties of the same physical phase.

Part II. Thermal **Expansion** of Sodium Nitrate

The measurements of the volume change which a polymorphic substance undergoes during the transition from one crystal phase into another is important from the standpoint of thermodynamics since the ratio of the heat of inversion to the volume change per unit mass enters into the calculation of the slope of the transition curve in consequence of the Clapeyron equation. In addition to the quantitative consequences of such measurements, there is obtained usually a considerable amount of pertinent information regarding the characteristics of the transition, particularly with respect to the promptness and the rate with which it proceeds. In typical rapid polymorphic transitions the crystals expand uniformly and reproducibly up to the inversion point. At the inversion point the rate of transition is zero, so that it is necessary to raise the temperature some distance beyond that point by an amount dependent upon the characteristics of the substance, for the inversion to proceed. It is well recognized that the growth of nuclei of the new crystal phase is an important factor in determining the rate. Once initiated, the rapid inversions proceed readily to completion, usually within a few degrees above the equilibrium temperature. On cooling, the phenomena are reversed, so that ordinarily there is a hysteresis band extending on both sides of the transition point; within this band the volume measurements are not reproducible. After the volume change of transition is completed, the substance once more exhibits a normal expansion, which is not necessarily the same above and below the transition point.

The expansion of sodium nitrate does not proceed in the manner outlined above through the transition region, and in this respect the salt again differs from typical polymorphic behavior. The measurements were made with a mercury-in-glass dilatometer, and they gave, with suitable auxiliary measurements, values of the specific volume of the salt at various temperatures.

The **apparatus** is shown diagrammatically in Fig. 3. The dilatometer was made of Pyrex glass, in the simple form indicated.[12] The bulb of the dilatometer was in an

---

[12] Compare Kracek and Gibson, *J. Phys. Chem.*, ***34***, 188 **(1930).**

air-bath thermostat heated by electric current, and controlled by a bare five-junction copper–constantan thermocouple which operated a special potentiometer controller. The temperature control was sensitive to ±0.05° at any given setting. The air was kept in motion by a propeller fan rotated at about 800 r. p. m.; this fan maintained the whole enclosure at a uniformly distributed temperature. The reading thermocouple of copper-constantan (calibrated) was fastened to the dilatometer bulb by two clips, and was enclosed in a small porcelain tube, partly for protection, and partly to give it a thermal lag somewhat comparable with that of the contents of the dilatometer.

The exposed portion of the dilatometer was of heavy capillary Pyrex tubing. The reading portion of the capillary was in vertical position, and was placed against a mirror which had a scale engraved upon it. The readings were made with the aid of a cathetometer to avoid parallax, and were recorded to 0.1 mm. Corrections were made for the exposed stem to reduce all the readings to 25°, which was the approximate temperature of the room.

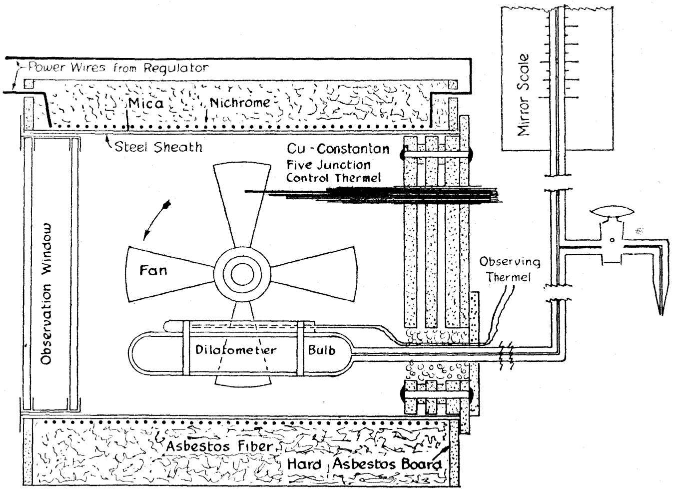

Fig. 3.—The thermostat as used with the dilatometer.

The capillary was calibrated with a weighed thread of mercury in the usual manner, against the same portion of the scale employed in making the observations. The results of the calibration were integrated to give the cubical contents of the capillary from a reference mark to any given reading of the meniscus. The capillary was fairly uniform in cross section.

Filling the Dilatometer.—The bulb of the dilatometer was provided with a side tube through which a known amount of the salt was introduced. This side tube was later sealed off at the entrance to the bulb. Some trouble was experienced at first owing to liberation of occluded moisture by the crystals; this persisted even when the salt was fused before introduction into the bulb. It was found necessary to melt the salt in the bulb under vacuum. The salt used had been recrystallized, and was quite free from all impurities. It was first fused in a platinum dish, then crushed, and screened to remove all dust smaller than 30-mesh. A known amount of this preparation was introduced into the bulb, which was then evacuated and heated to melt the salt. After evolution of bubbles had ceased, the bulb was cooled while still evacuated and mercury was introduced, care being taken to avoid any trapped bubbles of air.

After the conclusion of the measurements the salt was dissolved out, an aliquot portion of the solution evaporated to dryness, carefully fused and weighed. This determination gave 18.824 g. of sodium nitrate, compared with 18.836 g. by direct weighing of the salt introduced into the bulb. The glass showed no evidence of attack by the salt during the fusion, and the salt showed no evidence of decomposition.

The Experimental Procedure.—The thermostat was brought up to the desired temperature and readings were taken of the position of the mercury meniscus in the capillary at five-minute intervals until three successive readings showed no change. The thermostat was then readjusted to another temperature and readings were taken as before. In this fashion a series of determinations was obtained at successively higher temperatures, followed by a series with descending temperatures. At the end of the first cycle another set of observations was begun, allowing thirty to sixty minutes at each constant temperature, to ascertain whether any secular changes were taking place. The readings in all cases remained unchanged during the whole time the temperature was held constant at each point, proving definitely that each final reading represented equilibrium conditions. At a few points in the neighborhood of 275° the temperature was held constant for several hours.

During the first cycle of readings a slight readjustment took place, probably owing to more intimate penetration of the mercury into the cracks in the block of salt in the bulb. In all the succeeding cycles the readings fell reproducibly **3.1** mm. below those for the first cycle. The readings of the first cycle were disregarded. The position of the mercury meniscus at 25° was 8.9 mm. below the zero of the scale at: the end of the first cycle, and remained unchanged thereafter.

The data obtained in these experiments were converted by calculation to give the specific expansion of sodium nitrate from 25°. For this calculation it was necessary to know (a) the total volume of the bulb, the weight of sodium nitrate and the weight of mercury in the bulb at 25°, (b) the specific volume of sodium nitrate at 25°, equal to 0.4426 cc./g. [calculated from Andreae, *Z. physik. Chem.*, **82,** 109 (1913)], (c) the specific volume of mercury at the temperature of the experiment (taken from "International Critical Tables," Vol. II, p. 457), (d) the cubic expansion coefficient of the Pyrex bulb, equal to 9.6×10^{-6}, taken from measurements by the Corning Glass Works, in addition to (e) the effective diameter of the capillary.

The greatest source of uncertainty in ΔV_t lies in the correction for the expansion of the glass bulb, which accounts roughly for 10% of ΔV_t. Some error is also introduced by the assumption that the temperature of the mercury in the capillary at the point of emergence from the thermostat dropped sharply from t to the temperature of the room. These factors introduce systematic errors which may affect the absolute accuracy of the value of ΔV_t by as much as 2%, but which do not affect the relative precision of the calculated values, so that a graph of ΔV_t vs. t°C. has the same relative precision as the original readings of the mercury meniscus.

The results of the dilatometric experiments are collected in Table I, arranged in the order in which the readings were taken. Figures 4 and 5

give a graphical representation of the total expansion per gram of sodium nitrate from 25 to t°C. plotted against the temperature. These figures show the relative precision and the reproducibility of the results. Figure 4 contains data for the third series only; Fig. 5, on the other hand, contains data for series II, III and IV without distinction except for that between ascending or descending order with respect to temperature, the ascending points being marked with open circles, the descending ones with black circles.

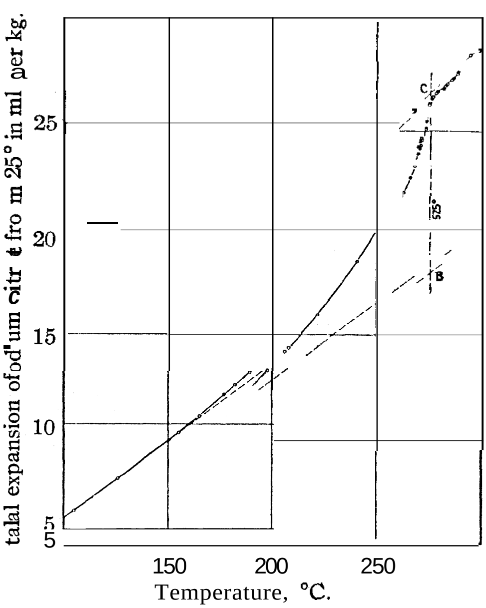

Fig. 4.—The expansion curve of sodium nitrate from 100° upward. The open and the black circles differentiate between ascending and descending sequence of constant temperatures. The distance BC is a measure of the anomalous expansion. Note the gradual character of the curve.

The value of the expansion coefficient $\alpha = 1/v_a \times \Delta v_a/\Delta t$ was obtained at a number of even temperatures from large scale graphs of Figs. 4 and 5. This is represented in Fig. 6. It should be noted that the curve of total expansion does not break sharply, but is rounded in the neighborhood of 275°; the peak of the α-curve of Fig. 6 falls close to 275.5' in agreement with the location of the peak on the differential heating curve of Fig. 2.

The amount of the anomalous expansion was determined from Fig. 4, as the distance BC on the graph, corresponding to 0.00811 cc./g. or 1.73% of the specific volume at 275°. It must be remembered that this does not represent a transition volume change in the usual sense, since the curve represents equilibrium values of expansibility at each temperature.

Extrapolation of the total expansion curve to 309.5°, the melting point of sodium nitrate, yields 0.02963 cc./g. from 25°. The specific volume at 25°, from Andreae's measurements of the density, is 0.44262 cc./g. Jaeger's[13] and Goodwin and Mailey's[14] measurements on the density of fused sodium nitrate yield p = 1.915 ± 0.015, or 0.5223 ± 0.0050 for the specific volume of liquid sodium nitrate at the melting point. We obtain from these, in round numbers, 0.0500 ± 0.005 cc./g. for the change of volume

---

[13] F. M. Jaeger, *Z. anorg. allgem. Chem.*, *101*, *16 (1917)*.

[14] Goodwin and Mailey, *Phys. Rev.*, 25, *469 (1907)*.

during melting, corresponding approximately to 9% of the volume of the liquid.

The most important features of the expansion curve are its complete reproducibility with rising and falling sequence of constant temperatures, the absence of a noticeable break in the curve where the anomalous expansion begins, and the slight round of the curve at 275°. The expansion coefficient rises gradually to a peak value near 275.5°, as has already been pointed out, and then quite rapidly diminishes to a nearly steady value beyond 280°. The character of the expansion curve precludes definitely the possibility of speaking of a finite transition volume change; it adds weight to the results on thermal analysis which indicate that there is no finite latent heat of transition.

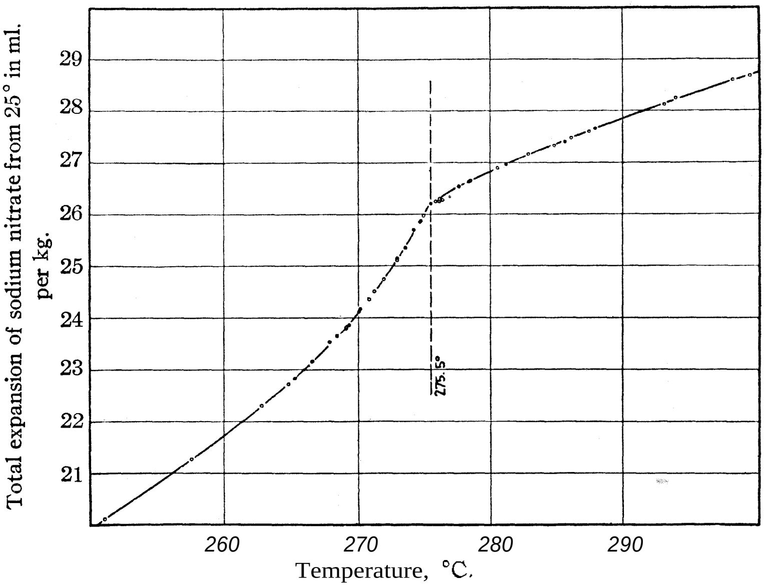

Fig. 5.—The expansion curve of sodium nitrate near 275°. Note the reproducibility of the curve as indicated by the open and black circles which differentiate between rising and falling sequence of constant temperatures, and the absence of a sharp break at 275°.

Part III. Optical Examination

Sodium nitrate at ordinary temperature is optically uniaxial and negative, $\omega = 1.5874$, $\epsilon = 1.3361$. Observation with a microscope equipped with a heating stage[15] shows that the optical character remains unchanged up to the melting point of the salt. The anomalous volume change described in the preceding chapter is clearly observable under the microscope,

---

[15] A very compact heating stage built by Mr. C. J. Ksanda of this Laboratory was used.

particularly during cooling, but it is not accompanied by an alteration in the optical character. No attempt was made to measure the change in the magnitude of the refractive indices with temperature, but it can be stated with confidence that the birefringence does not change suddenly at 275°, the only point at which a sharp change could be expected.

The results of these observations lead to the conclusion that crystalline sodium nitrate does not pass through a change of phase during the gradual transition, the same crystal phase persisting up to the melting point.

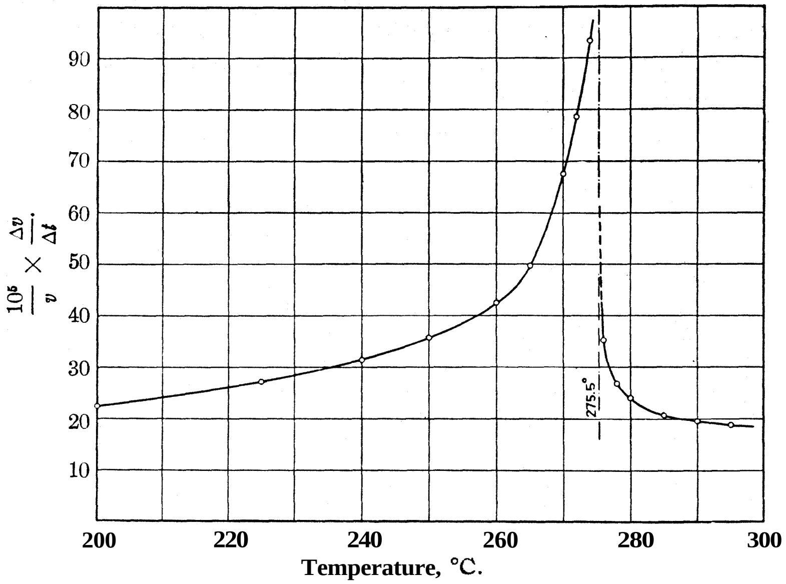

Fig. 6.—Curve of the expansion coefficient of sodium nitrate. Compare with Fig. 2.

Part IV. Solubility in Water up to the Melting Point of Sodium Nitrate

The solubility was determined by the synthetic method in sealed tubes of Pyrex glass, the reliability of the method having already been tested with other systems.[16] The thermostat and accessory apparatus used with the dilatometer (see Fig. 3) were also used in the solubility work, with appropriate modifications. The fan shaft of Fig. 3 is hollow, to allow for the introduction of a smaller shaft which is provided with an arm to carry and rotate the solubility tube. Transparent windows are provided at both ends of the thermostat, for visual observation. The thermocouples are introduced through an opening in one of the windows, the thermocouple for reading the temperature of the thermostat being arranged to hang free in the immediate neighborhood of the rotating solubility tube. The junction

---

[16] F. C. Kracek, J. Phys. Chem., 35, 417, 947 (1931).

of this couple is enclosed in a small mass of alundum to provide an appropriate thermal lag. The fan is rotated at about 800 r. p. m., the solubility tube at about 30 r. p. m., just fast enough to keep the contents of the tube well stirred. Under these conditions the temperature control is sensitive to about ±0.05°.

The results of the individual solubility experiments are given in Table II. The supersolubility limits[17] were also determined in several of the experiments; the temperature of spontaneous crystallization is in general 4° below the solubility curve for this system. Figure 7 represents the data obtained, together with the more significant results from the literature. Below the normal boiling point the solubility curve passes smoothly through the points established by Berkeley,[18] in continuation of the results obtained in this study, and hence no determinations were made below 90°. At higher temperatures we have determinations by Étard,[19] who apparently failed to attain complete saturation in most of his experiments.

TABLE II

DETERMINATIONS OF SOLUBILITY OF SODIUM NITRATE IN WATER

	Grams of				NaNO$_3$, %

..	....	....	....	....	100.0	100.0	309.5

[a] r_w = g. of NaNO$_3$ per g. of H_2O. [b] r_m = moles of NaNO$_3$ per mole of H_2O.

The solubility curve at the higher temperatures is shown in Fig. 8, in a $1/T$ *vs.* log N_2 plot, to bring out the trend of the solubility results as fully as possible. It will be seen that a smooth curve, with a very slight reverse S curvature, fits the results better than one with a sharp break at 275.5°.

[19] **Étard,** *Ann. chim. phys.*, 2, 503 (1894).

No exact conclusions can be drawn from the solubility curve regarding the nature of the gradual transition, other than that the solubility results do not vitiate the conclusions obtained from the other types of evidence, to the effect that the same physical crystalline phase of sodium nitrate persists up to the melting point. These solubility results are hence published more for their intrinsic value rather than as a deciding criterion for the gradual transition. To attempt drawing more definite conclusions from these solubility data would necessitate ascribing much higher accuracy to these results than they warrant.

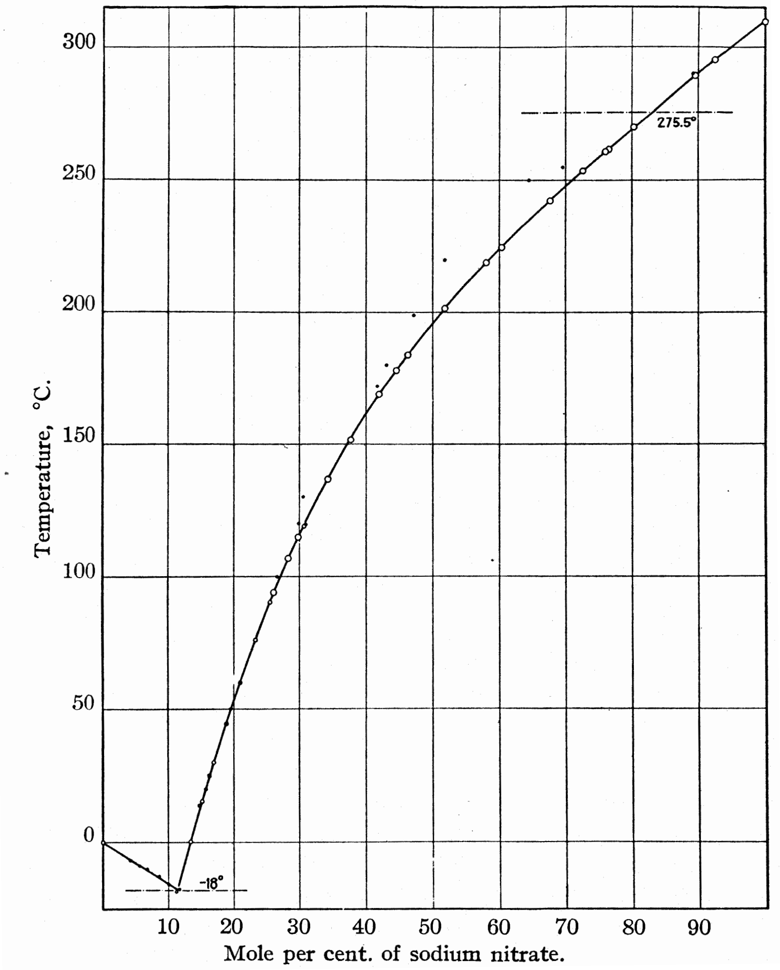

Fig. 7.—The solubility of sodium nitrate in water. The larger, open circles by Kracek. The small black circles above 100° are by Etard. Results below 100° by Berkeley and others.

Part V. Discussion

In transitions of this type the phase change, if we can speak of it as such, must take place gradually, rather than discontinuously, as is the case in normal polymorphic transformations. We cannot write down an expression for the entropy difference between the "phases" when the heat of transition is zero, that is, the Gibbs zeta potential is the same for the two "phases"; even though there may be a considerable difference in properties of the substance at two different temperatures, there can be no finite change at any one given temperature. Strictly speaking, there would be only one phase undergoing abnormal alteration in properties gradually, but the major portion of the transformation may be accomplished over a comparatively narrow range of temperature, as in the case of sodium nitrate near 275°. Similarly, the expression $\Delta H/(T\Delta v)$, which determines the pressure variation of the transition temperature in the Clapeyron equation, is indeterminate, since it has a value of 0/0. The effect of pressure then cannot be calculated, but it should be possible to determine it experimentally; since the anomalous expansion is positive in

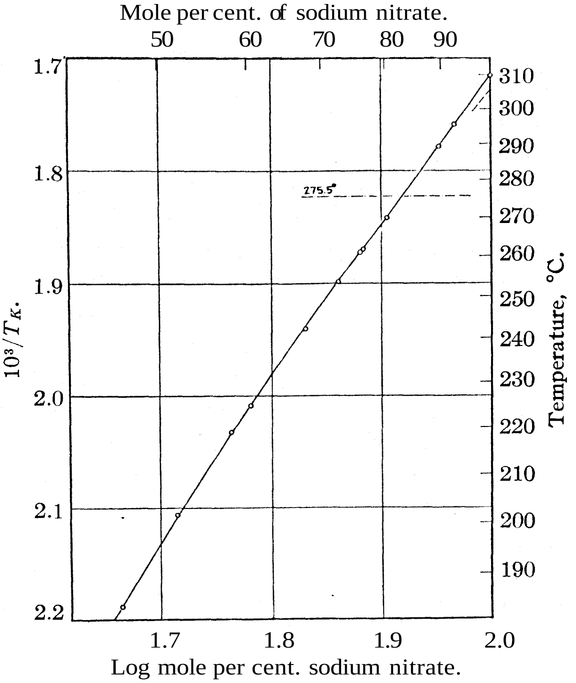

Fig. 8.—$10^3/T$ *vs.* log N_2 graph of solubility of sodium nitrate in water between 180° and the melting point. Note the slight reverse S curvature in the neighborhood of 275°.

sodium nitrate, it is to be expected that the temperature of the completion of the gradual transition should rise with increasing pressure.[20] All the experimental results quoted are in good accord with the view advanced here, to wit, that the gradual transition represents an anomalous change in the properties of a single phase. The rounding of the expansion curve in the neighborhood of 275° (see Fig. 5) appears to be of special significance in this respect. From the standpoint of thermodynamics, it is the Le Chatelier rule, and not the Clapeyron equation, which must be applied.

The most completely investigated other case of the gradual transition is that of the ammonium salts, in which, as already mentioned, the transitions end at temperatures between −50 and −30°. Simon and Bergmann[1] have recently published data on the thermal expansion of the chloride, bromide and phosphate. Their curve for ammonium chloride is very similar to the curve for sodium nitrate, and, although they make no statement with regard to the reproducibility of the curve for a given specimen, it is very probable that it represents equilibrium conditions. The curves for the bromide and phosphate exhibit gradual contractions over a range of temperatures. Simon ascribes the transitions in the ammonium salt to the ammonium ion, but offers no adequate suggestion as to the mechanism. On Pauling's theory the gradual transition in the ammonium salts is due to the initiation of rotation of the ammonium ion in the crystal. There is a possible objection to this in the case of ammonium bromide and the phosphate in view of the contraction encountered with these salts.

The physical conditions in the case of sodium nitrate are such that the above objection to intramolecular rotation of the nitrate ion does not hold. This question will be considered in more detail in the paper which will deal with the structure of sodium nitrate at various temperatures.

The principal conclusion that can be drawn from the physico-chemical study reported in this paper is that sodium nitrate undergoes a gradual transformation accompanied by a change in the specific heat and volume in a manner such that there is at no point a finite discontinuity in the properties of the substance.

Summary

Crystalline sodium nitrate undergoes a gradual transition which ends at 275.5°. The characteristics of the transition differ from those of a normal polymorphic inversion in that there is no finite discontinuity in the properties of the substance during the transition. The results on thermal capacity and expansion, optical properties and solubility in water are presented and discussed in comparison with the behavior of normal inversions.

WASHINGTON, D. C.

THE THERMODYNAMIC CONSTANTS OF IODINE MONOBROMIDE

BY JOHN MCMORRIS AND DON M. YOST

RECEIVED MAY 18, 1931 PUBLISHED JULY 8, 1931

Introduction

The properties of the diatomic interhalogen compounds are, in general, intermediate between those of the elements from which they are formed, and it is therefore of interest to determine whether or not their thermodynamic constants are also intermediate between those of the elementary substances. Moreover, these compounds lend themselves readily to spectroscopic investigations, and it is desirable to have thermodynamic data to confirm the interpretations of such investigations. For these reasons the present research upon one of these conipounds, iodine monobromide, was undertaken.

A determination of the extent to which combination takes place when two diatomic halogen molecules react to form two other diatomic molecules cannot, of course, be made by direct-pressure measurements; but if a substance can be found which is in equilibrium with one of the halogens and does not react with the other, then the extent of combination can be determined either by pressure measurements or by analysis of the vapor phase. In the present case cupric bromide was chosen for this purpose, since the careful work of Jackson[1] has shown that over the temperature range 100–200° convenient partial pressures of bromine vapor were to be expected without any complications arising from indeterminate solid phases. His measurements were made between 281 and 166°; and the log P–$(1/T)$ graph is a straight line. Jackson also found that the solid phases consist of cuprous bromide and cupric bromide. Furthermo , iodine will not replace the more electronegative bromine in either of these bromides.

Experimental Method

A number of experiments were carried out in which a weighed amount of pure iodine and a large excess of cupric bromide were placed in a 200-cc. Pyrex bulb equipped with a click gage. After carefully evacuating and baking out at about 150°, the bulb was sealed off and completely submerged in an oil thermostat. By means of a barometer the pressures were determined at various temperatures. Although this method gave results reproducible in order of magnitude when approaching equilibrium from either direction, the variation of the click constant with temperature

---

[1] **Jackson,** *J. Chem. Soc.,* 99, 1066 (1911).

and the possible presence of adsorbed gases or water rendered the method unreliable. Indeed, the presence of only one milligram of water at 127° gives rise to a pressure of 7 mm., which is unallowably large where the total pressure is less than 100 mm. These experiments did show, however, that the reaction

$$CuBr_2(s) + {}^1/_2I_2(g) = CuBr(s) + IBr(g) \qquad (1)$$

takes place reversibly and at a reasonable rate.

In the experiments whose results are here presented, the composition of the gaseous equilibrium mixture was determined by chemical analysis instead of by pressure measurements. The experiments were carried out in Pyrex bulbs of known volume, each being equipped with a narrow side-arm into which the vapors could be condensed by means of liquid air. Another side-arm was used for the introduction of the cupric bromide and iodine, the latter being contained in an easily breakable evacuated glass capsule. After charging, the bulbs were carefully evacuated and baked out until about one-third of the cupric bromide had been converted to cuprous bromide. The bulbs were sealed off, the tips of the iodine capsules were broken by moderate shaking, and the bulbs then immersed in an electrically heated oil thermostat whose temperature was maintained constant to within 0.1°.

After equilibrium had been reached a bulb was quickly removed from the bath, and the side-arm was plunged into liquid air and then sealed off from the bulb. This whole process required only twenty seconds, of which only a few seconds were necessary for the condensation of the vapor. Blank experiments carried out with cupric bromide alone yielded quantities of bromine which were in very good agreement with those corresponding to the pressures calculated by equation (4) given below. It follows therefore that the evolution of bromine from the cupric bromide is not rapid enough to introduce any serious errors.

That all of the vapors had condensed into the side-arm was shown by the fact that the bulb after again heating contained no iodine.

The side-arm containing the condensed vapor was broken under an acidified solution of potassium iodide, and the liberated iodine was titrated with standard thiosulfate, thus affording a measure of the total number of moles of iodine, bromine and iodine bromide, since they are all diatomic molecules.

The thermometer used was compared with one from the Bureau of Standards.

Preparation of the Materials

Iodine.—A high quality product, purchased on the market, was used. The quality was confirmed by analysis.

Cupric Bromide.—The best quality of material obtainable was dissolved in distilled water, filtered and then recrystallized and dried in a vacuum over phosphorus pentoxide at room temperature.[2] Only cupric bromide which contained initially no acetic acid or acetates was used.

Standard Solutions.—The chemicals used were of the best quality obtainable. The thiosulfate was standardized by the method of Bray and Miller.[3]

Results of the Experiments

The reaction whose equilibrium constant is to be found is

$$\mathrm{IBr(g)} = {}^1/_2\mathrm{I_2(g)} + {}^1/_2\mathrm{Br_2(g)} \tag{2}$$

The corresponding mass action expression is

$$\frac{(\mathrm{I_2})^{1/2}\,(\mathrm{Br_2})^{1/2}}{(\mathrm{IBr})} = K \tag{3}$$

The partial pressure of the bromine at a given temperature is fixed, since it is in equilibrium with the cupric–cuprous bromide mixture. The value of this pressure was calculated from the following formula, which was constructed from Jackson's data

$$\log_{10} p_{\text{mm.}} = -\frac{4921.2}{T} + 11.6682 \tag{4}$$

In an equilibrium mixture the total iodine is known since a weighed amount is introduced initially. The titration of the material condensed out by the liquid air gives the total number of moles of halogen present. If, then, x is the total number of moles of halogen determined by titration, y the moles of iodine weighed out, and z the moles of free bromine calculated from its pressure and the volume of the bulb, then

$$2(x - y - z) = \text{moles of IBr} \tag{5}$$

$$2y - x + z = \text{moles of } \mathrm{I_2} \tag{6}$$

The equilibrium constants were calculated by substituting these derived quantities directly into mass-action equation (3) since the constant K is, in this case, independent of the units in which the quantities on the left-hand side of equation (3) are expressed. In Table I are presented the results of experiments made at three different temperatures.

That equilibrium was attained is shown by the fact that the equilibrium constants are independent of the time, as may be seen from the table and further, that first heating the bulbs to a higher temperature before making the measurements at a lower temperature did not affect their values. Also, in the click-gage experiments, the reaction showed itself to be readily reversible. It is to be noted that the partial pressure of bromine varied fifty-fold over the range of temperatures investigated.

The values for the constants at any given temperature are seen to agree very satisfactorily among themselves. They show a maximum deviation from the mean of 5%, and an average deviation of less than 2%.

Thermodynamical Calculations

The free energy equation which represents the results to within the experimental error was found for the reaction

$$^1/_2I_2(g) + {}^1/_2Br_2(g) = IBr(g) \qquad (7)$$

to be

$$\text{AF}'' = -1270-1.7449\ T \qquad (8)$$

The assumption is made that ΔC_p is negligible, which for a reaction of this type is no doubt justifiable. The error in the heat content term has been estimated to be fifty calories, that is, AH = −1270 ± 50 cal. This value is in good agreement with the recently determined spectroscopic one, −1220 cal.[11]

It is of interest to compare the values of the equilibrium constants found by Müller[4] at 304.8' and by Bodenstein and Schmidt[6] at 1222° with those calculated by Equation 8. Müller's value depends on his interpretation of the rate of the reaction between hydrogen and bromine in the presence of iodine whereas the value at the higher temperature was determined from vapor density measurements, as it is a region in which considerable dissociation of iodine into the monatomic gas occurs. At 304.8°, Equation 8 gives for K the value 0.137, for the reverse of reaction (7), while the average of Müller's results is 0.114, with a variation of ±15% from this value. The agreement is satisfactory and increases our confidence in his interpretation.

For 1222°, Equation 8 gives for K the value 0.271, as compared with Bodenstein and Schmidt's value of 0.305, which was the average from two experiments whose values differ by 8%. Taking into account the long extrapolation and the fact that deviations from the perfect gas laws at the higher temperatures may be considerable, the results are in very good accord.

The thermodynamic constants for iodine monobromide may be calculated from the present results by combining them with the following data. We use for the free energies and entropies of iodine and bromine vapors the values given by Giauque[6a] and by Lewis and Randall.[6b] For the heats of sublimation and of vaporization of one-half mole of solid iodine[6"] and liquid bromine[6b] we take 7438 cal. and 3795 cal., respectively; and we use Berthelot's[7] value of 2470 cal. for the heat of formation of solid iodine monobromide from the elements in their standard states. The heats of dissociation of iodine and bromine[8] into the monatomic gases were taken as

35,400 cal. and 45,200 cal., respectively. The entropy values used for monatomic iodine and bromine were 40.15 and 38.77 entropy units,[6b] respectively.

Table II gives the so-calculated thermodynamic constants (expressed in calories) for one mole of the substance given in the first column. The standard states for the elements are indicated in each case.

TABLE II

THERMODYNAMIC CONSTANTS OF IODINE MONOBROMIDE AT 25°

Substance	Reference substances	Free energy	Heat content	Entropy	Heat of sublimation
IBr(g)	I_2(g), Br_2(g)	−1790	−1270	60.8	
IBr(g)	I_2(s), Br_2(1)	903	9,963		
IBr(s)	I_2(s), Br_2(1)	(−1830)	−2470	(31.8)	12433
I_2(g)	I(g)	−30,030	−35,400	62.29	
IBr(g)	I(g), Br(g)	−36,105	−41,570	60.6	
Br_2(g)	Br(g)	−38,600	−45,200	55.4	

The values in brackets for IBr(s) were calculated on the assumption that the vapor pressure of solid iodine monobromide is 7.6 mm. Its vapor pressure is certainly greater than that of iodine[9] (0.305 mm.), and less than that of iodine monochloride[10] (30 mm.), and doubtless lies closer to the former than to the latter value. If the estimate is in error by two-fold, an error of about 410 cal. will have been made in the free energy, and the value of the entropy will differ by 1.37 entropy units from the one given. The bracketed values are probably not in error by more than these amounts.

Discussion

The entropy of gaseous iodine monobromide (60.6) lies between the value 62.29 for iodine and the value 55.4 for bromine. However, it does not lie midway between them.

The free energy and heat content changes of the monobromide with respect to the monatomic elements in the gaseous form likewise lie between the corresponding values for iodine and bromine. These intermediate characteristics extend to the energy differences between the lowest vibrational levels of the molecules.[11] The entropy of another interhalogen compound, bromine monochloride gas, also lies between those of the gaseous diatomic elements of which it is composed as may be seen from an easy computation of the recent results of Jost.[12] In order to make a similar statement for the case of iodine monochloride it would be necessary to have further experimental data, although the results of Gibson and Ramsperger[13] indicate that such is indeed the case. Whether or not one

---

[13] Gibson and Ramsperger, *Phys. Rev.*, 30, 598 (1927).

would be justified in generalizing the statement to cover all diatomic interhalogen compounds is not certain, but if one may judge by physical properties alone it would seem that even chlorine monofluoride[14] might not prove an exception. The present results show, however, that the entropies of the compounds are not in general the average of those of the elements from which they are formed.[15]

Summary

The equilibrium between solid cupric and cuprous bromides and gaseous iodine and iodine monobromide has been measured. From the results, the free energy equation for the reaction $^1/_2I_2(g) + ^1/_2Br_2(g) = IBr(g)$ has been found to be $\Delta F^\circ = -1270 - 1.7449\ T$. The increases in free energy, heat content and the entropy for this reaction at 25° were found to be (ΔF°_{298}) -1790 cal., (ΔH_{298}) -1270 cal., and (ΔS_{298}) 1.75 cal./degree, respectively. The degree of dissociation of the gaseous monobromide, at this temperature, into gaseous iodine and bromine has the value 8.9%.

With iodine and bromine in their standard states of solid and liquid, respectively, the free energy of formation of IBr(g) is $\Delta F^\circ_{298} = 903$ cal. The heat of sublimation of the solid monobromide has been calculated to be 12,545 cal.

The entropy of iodine monobromide gas is 60.6 and lies between that of gaseous iodine, 62.29, and bromine, 55.4, but is not the average of these. The increase in free energy and heat content at 25° attending the formation of the gaseous monobromide from monatomic iodine and bromine have values which lie between those for the formation of diatomic iodine and bromine from the monatomic elements. From the data for iodine and bromine monochlorides the same was found to be true; and it was suggested that this might be generally the case for diatomic interhalogen compounds in the vapor state.

HEATS OF NEUTRALIZATION AT CONSTANT CONCENTRATION AND THE HEAT OF IONIZATION OF WATER[1]

BY RAYMOND H. LAMBERT AND LOUIS J. GILLESPIE

RECEIVED MAY 20, 1931 PUBLISHED JULY 8, 1931

In an extensive series of investigations Richards and his collaborators have studied the heats of neutralization[2] of a number of pairs of acids and bases, and the heats of dilution[2b,3] of these and of their salts. Unfortunately, from the point of view of those who prefer things simple, the effect of further dilution was in most cases perceptible in the case of each neutralization, the heats of reactions leading to the formation of various salts differed perceptibly even in the most dilute solutions, and the conclusion of a previous generation—that the heats of neutralization of all strong bases and acids are the same, and are equal to the heat of the formation of water from its ions—was shown to be but a rough approximation.

Richards and Rowe[2a] discussed at length the difficulties involved in the extrapolation of the heats of neutralization to infinite dilution in order to find the heat of ionization. As pointed out by Richards and Hall,[2b] their new values for sodium salts improve the extrapolation considerably. Richards and &lair[2'] plot the heats of neutralization for the cases of sodium chloride, sodium nitrate and sodium acetate and estimate the heat of ionization at 20° as 13,650 20"-calories. They also[3'] find the heats of neutralization in the case of the sodium citrates to be much smaller than for the strong inorganic acids, and note that they do not approach the value to which these stronger acids tend at infinite dilution. They note also that citric acid and the acid citrates "are only slightly ionized even in the most dilute solutions investigated, so that it is probable that heat effects due to their ionization continue into solutions infinitely dilute."

Experiments with the continuous-flow calorimeter have confirmed[4] the heats for sodium and potassium chloride in the dilute region at 20°, though measurements at higher temperatures do not appear consistent with the existing temperature coefficients.

Lange and Messner[6] have observed with a 1000-junction thermocouple

significant heats on the further dilution of solutions of univalent salts as weak as 0.01 normal.

Object and Scope of the Work.—At the time of the appearance of the paper of Richards and Rowe we were working with the continuous-flow calorimeter on heats of neutralization. We were much impressed with the difficulties emphasized by them in the extrapolation of the data for various salts to the same point at infinite dilution in order to find the heat of ionization. The suggestion occurred that there is a dilution involved in any experiment on neutralization, a dilution attended by a heat effect which varies from salt to salt. If a systetnatic "correction" were made for this dilution, the results for various products of neutralization reactions ought to be more consistent. Application of the idea to the results of Richards and Rowc bore out the expectation: the picture was very clear, provided we assumed an error of about 25 calories in their result for sodium chloride in the dilute region. This assumption has since been shown true by the data of Richards and Hall[2b] and Gillespie, Lambert and Gibson.[4b] Since our first calculations, the available data have been greatly extended in the publications to which reference has been made above, and we have taken the new data into consideration.

We hoped that the application of our method (1) might give a clearer picture of the relations for various acids and bases, and that better extrapolated results might be obtained for (2) the heat of ionization and **(3)** its temperature coefficient. To anticipate, we think that our hopes have been justified with reference to points (1) and **(3).** As to the heat of ionization, we have not found it expedient to seek to improve by curve-plotting the recent estimation by Richards and Hall[2b] of the limiting value for the heat of neutralization for sodium chloride, based on especially accurate data, but are content to point out that their value gives directly the limiting value of the heat of neutralization at constant concentration and hence the heat of ionization, and to show by a new plot that the data for six inorganic salts appear consistent with their limiting value.

The objects of this paper are (1) to define the heat of neutralization at constant concentration; (2) to give an improved definition of the heat of ionization, in terms of the heat of neutralization at constant concentration; **(3)** to examine by curve plotting the extrapolation to infinite dilution of heats of neutralization at constant concentration for various acids and bases; and (4) to derive a value for the temperature coefficient of the heat of ionization.

The Heat of Neutralization at Constant Concentration and the Neat of Ionization.—When a mole of a (monobasic) acid, dissolved in x moles of water, is neutralized with a mole of a (monoacid) base, dissolved in x moles of water, the change of state may be written

$$[\mathrm{MOH}\cdot x\mathrm{H_2O}] + [\mathrm{HB}\cdot x\mathrm{H_2O}] = [\mathrm{MB}\cdot(2x + 1)\mathrm{H_2O}] \qquad (1)$$

Supposing complete ionization it may also be written in the ionic form

$$[M^+(c_1) + OH^-(c_1)] + [H^+(c_1) + B^-(c_1)] = [M^+(c_2) + B^-(c_2)] \qquad (2)$$

where c_1 in the first solution is the concentration of M^+ and of OH^- in gram ions per liter in the solution of MOH, and there is a similar meaning of c_1 and c_2 for the other two solutions. In all cases the substances whose formulas are represented within brackets are supposed to be mixed, and substances whose formulas, not within the same bracket, are separated by plus or equality signs are supposed to be physically separated.

Since the salt solution contains all the water present in the original solutions (plus one mole), and there is little volume change on mixing the solutions, the concentration c_2 of the ions of the salt is about one-half of c_1. It is therefore clear from equation (2) that in the neutralization experiment there occurs not only a disappearance of OH^- and H^+, but also a dilution of the ions M^+ and B^-. It is generally supposed at present that strong acids, bases and salts are completely ionized at any reasonable dilution. The fact observed and emphasized by Richards and Rowe that the heat attending reaction (I) varies with the nature of the salt formed and with the dilution points therefore to the possible importance of the heat effects attending the dilution of these ions.

Muller[6] obtained nearly the same heats of neutralization at infinite dilution for potassium chloride and sulfate, by subtracting the heat effect for the acid in question on dilution from a molal solution to infinite dilution, from the extrapolated value of the heat of neutralization—a method of finding the heat of ionization not wholly clear, as remarked by Richards and Rowe.

We wish to obtain the heat effect of the reaction

$$H^+\,aq + OH^-\,aq = HOH\,aq \qquad (3)$$

Now it is not clear that equation (3) defines sufficiently a change of state, even if definite values are assigned to the symbol aq (and, of course, the temperature and pressure are fixed) For the equation does not represent the effect of the other ions necessarily present, and we dare not assume that an extrapolation to infinite dilution, when it is conducted without reference to these other ions, will necessarily give a correct or even a definite result.

If we subtract, from the heat effect H_1 of reaction (1), the heat effect H_4 of the reaction

$$MB{\cdot}xH_2O + (x + 1)H_2O = MB{\cdot}(2x + 1)H_2O \qquad (4)$$

we obtain the heat effect H_5 of the reaction

$$MOH{\cdot}xH_2O + HB{\cdot}xH_2O = MB{\cdot}xH_2O + (x + 1)H_2O \qquad (5)$$

Such a reaction will be termed a neutralization at constant concentration. If this is written in the ionic form we have

$$[M^+(c_1) + OH^-(c_1)] + [H^+(c_1) + B^-(c_1)] = [M^+(c_1) + B^-(c_1)] + [H_2O + aq] \quad (6)$$

---

[6] Muller, *Bull. soc. chim.*, [4] **23,** 8 (1918).

This change of state (5) is worth attention. When the ionization is supposed complete, equation (6) shows a disappearance of OH^- and H^+ to form a mole of water, and a bringing together in the same solution of the other ions M^+ and B^-. So far as these ions are concerned, they experience no change of concentration, and are, in fact, associated with the same number of moles of water and the same number of ions of opposite sign after the change of state, as before. At infinite dilution there should be no heat effect involved in replacing an ion A with an ion B of the same sign and charge at the same distance from an ion C of opposite sign. Consequently the limiting value of the heat effect of reaction (5), provided all the electrolytes are strong, may be taken as the heat of formation of water from its ions.

$$\lim_{1/x \to 0} H_5 \text{ (strong electrolytes)} = \text{heat of formation of } H_2O \text{ from its ions} \quad (7)$$

Equations *(5)* and (7) define completely the heat of ionization of water.

The limiting value of H_1 also will be the heat of ionization according to the above definition, provided that the value of H_4 approaches zero at infinite dilution, or provided that the heat effect of the following reaction becomes zero as x becomes infinite

$$MB \cdot xH_2O + xH_2O = MB \cdot 2xH_2O \quad (8)$$

We cannot immediately state that the limiting value of H_8 for this reaction is zero simply because the limiting value is zero for the reaction

$$MB \cdot xH_2O + H_2O = MB \cdot (x + 1)H_2O \quad (9)$$

Nor do the recent data on heats of dilution establish zero as the limit of H_8, though the only cases in which values other than zero are rather definitely suggested by the plots are for lithium nitrate,[3b] citric acid[3'] and sodium acetate.[3c] Yet a *priori* notions suggest the value zero, and in our hands plots of H_1 and of H_5 do not lead to different values for the heat of ionization.

The advantage of the heat of neutralization at constant concentration for finding the heat of ionization by curve-plotting does not depend on a difference in the limits, but lies in the manner in which the limit is approached. The disturbing effect of the dilution, which finally disappears at infinite dilution, is present at the dilutions at which measurements are made.

The method outlined above for finding the heat of ionization of water implies that the electrolytes are strong. In the case of the weak acids, the ionization is but slight at the greatest dilutions in question, and we can hardly expect that the course of the curve in the infinitely dilute region will be definitely established by the available data. Consequently, one may expect to be limited, in any method of extrapolation, to the case of strong electrolytes.

Plots of the Heat of Neutralization

Richards and Hall[2b] combined one value for the heat of neutralization (for sodium chloride) at a finite dilution with three heats of dilution, each extrapolated to infinite dilution, though from rather high dilutions. If the addition of the thermochemical equations is carried out, it is found that their value for the heat of neutralization in the case of sodium chloride at infinite dilution, 13,653 20"-calories at 20°, is for the reaction

$$\mathrm{NaOH}\cdot w\,\mathrm{H_2O} + \mathrm{HCl}\cdot\infty\,\mathrm{H_2O} = \mathrm{NaCl}\cdot\infty\,\mathrm{H_2O} + (\infty + 1)\mathrm{H_2O} \qquad (10)$$

which is strictly of the type of a neutralization at constant concentration. When the measured heats of neutralization, which extend to value of 400 for x of equation (1), are plotted against $1/x$, the course of the curves obtained (reference 2c, Fig. 1) for sodium chloride and nitrate does not suggest so low a value, and Richards and Mair[2c] introduce a bending downward of the curves for these salts, and a bending upward for the curve for sodium acetate, which brings the extrapolated values to 13,650. When the heats at constant concentration are plotted over the same range of values of x, the bending for sodium chloride and nitrate is already in evidence, and the use of a different variable as abscissa is indicated.

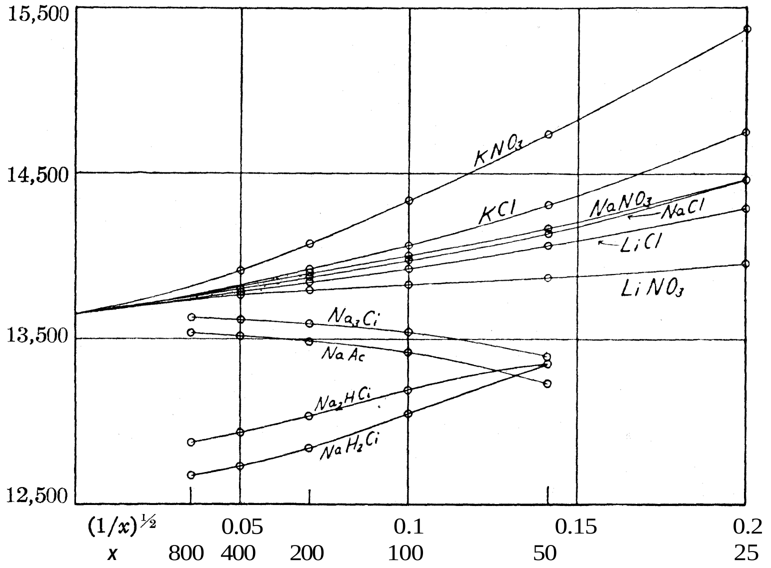

Fig. 1.—Heats of neutralization at constant concentration at 20° in 20°-calories.

The square root of $1/x$ has been used as abscissa for the plots of heat of neutralization at constant concentration shown in Fig. 1, where x and the heat effect are defined by equation (5). Lange[7] has recently published

---

[7] Principally in *Z. Elektrochem.* and *Z. physik. Chem.*

many heats of dilutions of salt solutions, but heats at 20° would have to be determined by interpolation at other temperatures, which interpolation is in some cases uncertain. The results for strong electrolytes at x = 400 were obtained by combining the heat at x = 200 with the heats of dilution of acid and base from 200 to 400 and the estimated heat of dilution of the salt from 400 to 401.

The value 13,650 was found to be an excellent compromise point for the strong electrolytes. No curves intersect below about the concentration $1/x = 0.02$, which is not true of the plots of the ordinary heats of neutralization. At x = 400 four of the six points for inorganic salts lie exactly on the curves; the points for potassium chloride and sodium nitrate are a little lower (10--20 cal.) than indicated by the smooth curves. The plot shows that the value 13,650, given by Richards and Hall for the heat of neutralization at 20° of hydrochloric acid and sodium hydroxide at infinite dilution, is supported by the curves for the six inorganic salts and may be taken therefore as the heat of ionization of water. The curves for the organic salts, with the exception of trisodium citrate, do not point to this value, but this appears to be of little consequence.

The Temperature Coefficient of the Heat of Ionization

The temperature coefficient of the heat of neutralization at constant concentration, $\mathrm{d}H_5/\mathrm{d}t$, is evidently equal to the difference, $\mathrm{d}H_1/\mathrm{d}t - \mathrm{d}H_4/\mathrm{d}t$. The limiting value at zero concentration should be equal to the temperature coefficient of the heat of the formation of water from its ions, and one may expect an easier extrapolation than in the case of the ordinary temperature coefficient, $\mathrm{d}H_1/\mathrm{d}t$.

From the data of Richards and his collaborators both temperature coefficients were computed, using besides the necessary heats of dilution the molal heat capacities given by Richards and Rowe, except when new specific heat values were available, as in the cases of hydrochloric acid[3*] and sodium hydroxide.[3c] In the computations the same atomic weights were used as by Richards, and the new specific heats at 18° in 20"-calories were converted into values at 18° in 18"-calories by multiplication with the factor 0.999737, which was obtained by interpolation from the paper of Osborne, Stimson and Fiock.[8] All the intermediate calculations were referred to 18"-calories at 18°, as consistency is necessary when dealing with the large numbers involved. The results, being small numbers obtained by taking differences, may equally well refer to 20"-calories, and in view of their uncertainty may be taken to refer to the temperature of 20°.

Table I gives the temperature coefficients corresponding to the value of x. A denotes the ordinary coefficient and B the coefficient at constant con-

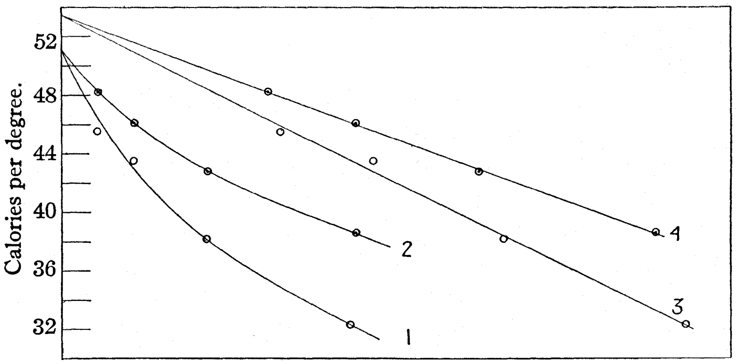
centration. The average values for the six salts are also given for each value of x.

TABLE I

TEMPERATURE COEFFICIENTS OF HEATS OF NEUTRALIZATION

	KCl		NaCl		LiCl		KNO_3		$NaNO_3$		$LiNO_3$		Average	
x	A	B	A	B	A	B	A	B	A	B	A	B	A	B
25	36.2	41.5	33.6	40.6	29.0	31.2	36.0	46.8	33.6	42.0	25.5	29.6	32.3	38.6
50	40.8	44.5	39.3	43.6	34.9	37.7	39.8	47.0	39.9	46.7	34.7	37.4	38.2	42.8
100	45.1	47.0	45.0	47.0	38.7	41.4	45.3	48.0	46.5	49.7	40.4	43.5	43.5	46.1
200	46.1	49.5	46.3	51.4	41.1	42.3	47.2	49.8	60.6	52.8	41.8	43.4	45.5	48.2

When the values for each salt were plotted against the concentration, a confused picture resulted. The extrapolation in any particular case usually appeared uncertain, and it seemed out of the question to find a compromise intercept on the axis of zero concentration, to which a family of curves might be drawn. This was true for the ordinary temperature coefficient, as well as for the one at constant concentration. Such plots are a very severe test of the precision of data on heat capacity.



Concentration (1, 2), square root concentration (3, 4).

Fig. 2.—Temperature coefficients of heats of neutralization.

The data should furnish, however, a means of obtaining a better value for the temperature coefficient of the heat of ionization than has previously been obtained. The average coefficients were therefore plotted, in spite of the large departures from the average shown by the various salts. Figure 2 shows the plot obtained. Curve 1 shows the ordinary temperature coefficient, and curve 2 that at constant concentration, plotted against the final concentration, $1/(2x + 1)$ and $1/x$, respectively. The curves bend sharply upward, curve 2 being the better defined. The straight lines 3 and 4 show the ordinary coefficient and that at constant concentration, respectively, when plotted against the square root of the final concentration. The square root plots help to estimate the degree of bending necessary near the axis of zero concentration in the case of the first two curves. The scales of abscissas are not the same, but are uniform for each curve.

The introduction of a slight curvature in lines **3** and 4 would permit an excellent compromise point for all four lines at 52 calories per degree, which is therefore accepted as the result for $d\Delta H/dt$ for the heat absorption AH for the formation of water from its ions. The indirect computations of Noyes, Kato and Sosman[9] give about 49.4.

Summary

The heat of neutralization at constant concentration is defined to be the heat effect (– AH) of the reaction: $MOH{\cdot}xH_2O + HB{\cdot}xH_2O = MB{\cdot}xH_2O + (x + 1)H_2O$. It was found possible, using the recent precise heats of neutralization and of dilution of Richards and Rowe, Hall, Gucker and Mair, to extrapolate satisfactorily such heats of neutralization to the same point at infinite dilution for six inorganic salts (K, Na, Li; chlorides and nitrates). The square root of $1/x$ was taken as abscissa. The value 13,650 20"-gram calories (or 57.07 kilojoules) found by Richards and Hall for the heat of neutralization at 20° at infinite dilution in the case of *sodium* chloride was found to be an excellent extrapolated value for the family of six curves, and it may be taken as the heat ($-\Delta H$) of the formation of water from its ions at 20°. This is in agreement with the conclusion of Richards and Mair, who introduced, however, bending in the plots in the region of extrapolation and gave considerable weight to the heats for sodium acetate, neither of which has been done in the present case.

For the temperature coefficient of the heats, individual extrapolations for the various salts could not be made. On plotting the average values for the six inorganic salts, the temperature coefficients at constant concentration were distinctly a smoother function of the concentration or of its square root. The temperature coefficient of the heat of formation of water from its ions ($-d\Delta H/dt$) was estimated to be -52 calories, or —217 joules, per degree in the neighborhood of 20°.

THE IDENTIFICATION OF SOLIDS BY MEANS OF THE BOILING POINT ELEVATION IN SATURATED SOLUTIONS

BY J. O. HALFORD[1]

RECEIVED MAY 27, 1931 PUBLISHED JULY 8, 1931

Compounds which decompose before melting, or immediately after melting, are frequently encountered. These compounds cannot be tested and identified, with certainty, by the familiar measurements of melting points and mixed melting points. In such cases a procedure based on solubilities may be substituted. Suppose, for example, that we wish to compare samples of two materials which are suspected of being identical. If we measure first the individual solubilities, then that of a sample made by mixing the two, we have the required information. If the two materials are identical, all three solubilities must be equal, but, if they are different, that of the mixture will be greater than that of either individual. This is a procedure which has not been employed as frequently as its usefulness would warrant. Recent examples are found in the work of Montgomery and Hudson,[2] and that of Austin,[3] who have identified sugar derivatives in this way.

The tests which will be described here may be looked upon as applications of the solubility procedure in which the concentrations of the solutes are evaluated by boiling point measurements, and are based on the fact that the addition of a pure non-volatile solid to a solution can cause an increase of the boiling point only when the solution is not yet saturated with that solid. The substitution of boiling point determinations for analytical measurements, wherever feasible, should effect a saving of time and apparatus. In fact, in some cases, our procedure is as expeditious as the melting point method. Its principal disadvantage is that the best combination of solvent and apparatus for a given measurement is not always evident.

We are not in a position to state exactly which form of ebullioscope will be most useful for our purpose. Probably a small boiling tube of the Beckmann type, fitted with a side-arm condenser, internal heater and a small Beckmann thermometer, will cover the widest range of situations. Our tests have been carried out mainly with the ebullioscope described by Menzies and Wright.[4] This gives satisfactory results, but is perhaps too limited in temperature range to be suitable for general use. However, the high sensitivity of this apparatus is an advantage, for our present purpose, for we have considered it worth while to try out the procedure under

[2] Montgomery and Hudson, THIS JOURNAL, 52,2105 (1930).

[3] Austin, *ibid.*, 52, 2111 (1930).

[4] Menzies and Wright, *ibid.*, 43, 2314 (1921).

conditions near the limit of its applicability, and have found it desirable to be able to measure small temperature differences.

The principal application of our method is in the comparison of materials which may be identical, However, it may also be used to test the purity of individual samples of material.

Comparison Tests

The procedure employed in the test for identity, analogous to the mixed melting point, follows that of the determination of molecular weight, with the simplification that the sample need not be weighed and is preferably added in the form of powder, rather than pellets. After the first addition of solid, the temperature increases slowly and reaches a constant value, indicating saturation, in fifteen to twenty minutes. If the addition of a second portion produces no further temperature increase, the substance may be considered pure and the material to be compared is added. If the two samples are identical, the temperature will not rise, but if they are different, the second substance being soluble, a decided increase of boiling point follows in a few minutes. A second measurement should be made with fresh solvent, reversing the order of addition of the substances. Identical materials, when tested individually, will produce saturated solutions of the same boiling point, and the addition of one to the boiling saturated solution will cause no additional boiling point elevation.

We have tested this procedure with several amino acids, using methyl and ethyl alcohols as solvents. Although the boiling points of individual saturated solutions were somewhat variable, there was no doubt in any case of the identity of two samples of the same material, or the non-identity of samples of different materials.

The first comparison attempted, that of dl-alanine and dl-valine, is typical of the results. The addition of dl-valine to boiling ethyl alcohol produced a temperature elevation of 0.0217°, which was increased to 0.0449° by the addition of dl-alanine. Starting with dl-alanine the initial rise was 0.0211°, increased to 0.0493° by the introduction of dl-valine.

In Table I, the results of similar tests with several amino acids in ethyl alcohol are summarized. Table II is similar for the methyl alcohol solutions. The names above and to the left of any figure show the substances

TABLE I

ELEVATION OF THE BOILING POINT OF ETHYL ALCOHOL IN SATURATED SOLUTIONS OF SEVERAL AMINO ACIDS AND THEIR MIXTURES

	Glycine	dl-Alanine	dl-Valine	*l*-Tryptophane	d-Glutamic Acid
d-Glutamic acid					0.0023
l-Tryptophane	0.0318	0.0392	0.0472	0.0180	
dl-Valine	.0424	.0493	.0292		
dl-Alanine	.0265	.0191			
Glycine	.0143				

TABLE II

ELEVATION OF THE BOILING POINT OF METHYL ALCOHOL IN SATURATED SOLUTIONS OF SEVERAL AMINO ACIDS AND THEIR MIXTURES

	Glycine	*dl*-Alanine	dl-Valine	*l*-Tryptophane	*d*-Glutamic acid
d-Glutamic acid					0.0052
l-Tryptophane	0.0500	0.0626	0.0757	0.0356	
dl-Valine	.0644	.0635	.0392		
dl-Alanine	.0479	.0278			
Glycine	.0244				

compared in the individual test. Where these names are different, the reading recorded was obtained in a single test. The values given for the individual substances are averages of two or three determinations made in starting different comparisons. The values with d-glutamic acid have been included, not because of faith in their accuracy, but to illustrate a case in which comparison by mixing is unnecessary, where the solubilities of the individual substances suffice to distinguish between them.

The results of similar tests with three isomeric leucines are given in Table III.

TABLE III

BOILING POINT ELEVATIONS OF METHYL AND ETHYL ALCOHOLS IN SATURATED SOLUTIONS OF ISOMERIC AMINO ACIDS AND THEIR MIXTURES

Alcohol	I-Leucine	dl-Leucine	*dl*-Isoleucine	1-Leucine + dl-Leucine	dl-Leucine + *dl*-Isoleucine	*dl*-Isoleucine + 1-Leucine
Methyl	0.033	0.031	0.040	0.043	0.050	0.063
Ethyl	.019	.013	.025	.025	.037	.037

The combination of dl-leucine with dl-isoleucine showed a value in methyl alcohol much lower than the sum of the individual elevations. However, the result in ethyl alcohol brings out the difference. The mixture of dl-leucine with I-leucine is interesting, showing a sufficient elevation after the addition of the second substance to indicate that the two are not identical. The fact that 1-leucine alone produces a greater elevation than dl-leucine is sufficient to establish the latter as a racemic compound, for a racemic mixture should produce approximately twice the effect of one of the isomers.

We have also run comparison tests on sulfanilic acid and two isomeric disodium naphthol-di-sulfonates in aqueous solutions. The apparatus consisted of a test-tube with side arm condenser and a mercury thermometer graduated in tenth degrees. The thermometer was first tested in the vapor phase over boiling water, and thereafter the boiling point of water was determined for any one experiment from the barometer, since it is almost impossible to obtain a constant reading with a thermometer immersed in pure water. However, in the presence of excess of the solid materials, readings consistent to 0.1° were obtained. The results are summarized below

Sulfanilic acid	0.25°	
		Mixture 1.9°
Disodium 2-naphthol 6,8-disulfonate	1.7°	
		Mixture > 4°
Disodium 1-naphthol 3,8-disulfonate	..	

As a further example, we have compared triphenylmethyl peroxide and 9-phenylfluorenyl peroxide in benzene, using the Menzies apparatus. The two samples melted with decomposition, respectively, at 179–181° and 193–194". The mixed melting point with the lower melting substance in excess was 178–180°. The results with the ebullioscope were more satisfactory, although not as definite for the individual substances as those with the amino acids. With triphenylmethyl peroxide, the temperature elevation lay between 0.10 and 0.13°, and was a function of the amount of solid added, giving 0.13° as the maximum value for the true elevation. With 9-phenylfluorenyl peroxide a constant value of 0.166° was recorded, and when the former was added to the boiling saturated solution of the latter, the reading increased rapidly to 0.246°, which represents a minimum for the mixture and definitely brings out the difference.

Tests for Purity

The measurement of boiling points of saturated solutions is not sufficiently sensitive to permit the accurate determination of small amounts of impurities. However, when the percentage of impurity is high enough, useful information may be obtained.

In testing for purity, three procedures are available. The first of these we have not tried out, considering it sufficiently evident. It is analogous to the comparison of melting points after successive recrystallizations, and consists of a similar comparison of boiling points. The samples of material added to the apparatus in successive tests should have approximately the same weight, and should be introduced in considerable excess if the procedure is to be sensitive, since a sufficiently high concentration of the impurity must be obtained.

The second test for purity is a variation of the first. A relatively large sample of the substance is boiled with successive portions of the solvent, and the boiling point (or, more frequently, the boiling point elevation relative to the pure solvent) recorded after each change of solvent. In this way the extraction of the impurity by the solvent may be observed. Removal of the hot liquid is effected by a combination of decantation and filtration, and the residue from filtration is returned to the apparatus. A decrease of the boiling point between any two successive measurements indicates the presence of impurity. Erroneous results may be obtained when testing a mixture of two or more similar materials in approximately equal amounts, where it is impossible to extract any one of the substances without dissolving the entire sample.

As an example of this procedure, 0.5 g. of a mixture containing 10% of glycine and 90% of dl-alanine was boiled with three successive 32-cc. portions of ethyl alcohol. The temperature elevations, relative to the boiling point of alcohol, were 0.027, 0.021 and 0.021°, showing that the amount of impurity was sufficient to produce a measurable concentration in 32 cc. of solvent, and that it was extracted almost entirely by the first portion. An estimate from the data indicates 5% of glycine. This could be made more reliable by using a larger sample.

The third test for purity depends upon the difference in concentration of the impurities produced by varying the amount of solid added to a single portion of the solvent. The substance is added to the boiling liquid in small weighed portions, and the boiling point is recorded as a function of the amount of material. This procedure is roughly quantitative, since the change of boiling point between successive additions is determined by the amount of material extracted from a weighed quantity of solid.

Two mixtures of dl-alanine and dl-valine, containing, respectively, 10 and 20% of the latter, were tested by this procedure. Each of the weighed portions contained more dl-alanine than was required to saturate the solution. The volume of boiling alcohol was 32 cc. The results are summarized in Table IV, in which the first row shows the total weight added, and the second and third rows give the temperatures with the 10 and 20% mixtures.

Table IV

Test for Purity Applied to Mixtures of *dl*-Alanine and dl-VALINE

Weight added, g.	0.10	0.15	0.20	0.25	0 30	0.35	0.40	0.50	0.60	0.70
Elevation (10% **valine)**	.019		.027		.032		.035	.038	,042	.045
Elevation (20% **valine)**	.024	.029	.035	.038	.041	.045				

The presence of impurity, greater in quantity in the second sample than in the first, is demonstrated by the fact that a given weight of the 20% mixture produces a larger elevation of the boiling point than the corresponding amount of the 10% mixture. The quantitative interpretation depends principally on an accurate knowledge of the boiling point of a solution saturated with dl-alanine. If the temperature is plotted as a function of the total weight added, and a straight line is drawn through the points to intersect the temperature axis at the value 0.0265, taken from Table I, for dl-alanine, the slope of the line gives a measure of the concentration of impurity built up from unit weight of the solid. If the volume is known, this may be converted to moles per unit weight. Since, in the above tests, the molecular weight of the impurity is known, it may be expressed as weight per cent. The results for the above mixtures were

9.8 and **19.0%.** In the general case, of course, results are expressed as moles per unit weight.

The writer is indebted to Professor James B. Conant, who suggested carrying out the above tests.

Summary

The measurement of the boiling points of saturated solutions is suggested as an aid in identifying and testing the purity of compounds to which the familiar melting point procedure is not applicable because of decomposition. Examples of the method are given.

Negative results in the tests for impurities are not necessarily conclusive. Any of the procedures is subject to essentially the same limitations as the analogous test by the melting point method.

CAMBRIDGE, MASSACHUSETTS

NOTES

A Diaphragm Valve.—In connection with some experiments in which a greaseless device for regulating gas flows was needed, the diaphragm valve described in this note was developed. It consists of an aluminum diaphragm A, about **0.3** mm. in thickness, resting on the flange of a glass cup B, which has an outlet tube C, and a capillary inlet tube D, as shown in Fig. **1.** The upper end of tube D and the flange are ground flat with fine carborundum powder. Around the edge of the diaphragm and the flange of the cup is a rubber gasket, E. These parts are held 'together by a brass frame F. The position of the diaphragm is adjusted by a differential screw G. The lower surface of the diaphragm is roughened with very fine emery paper, so as to have better contact with the ground end of the capillary tube for the regulation of the low flows.

In cases where the gas used is likely to react with or corrode aluminum, a thin piece of mica is cemented with Duco Household Cement across the entire lower surface of the aluminum diaphragm. The mica surfaces should first be roughened with fine emery paper.

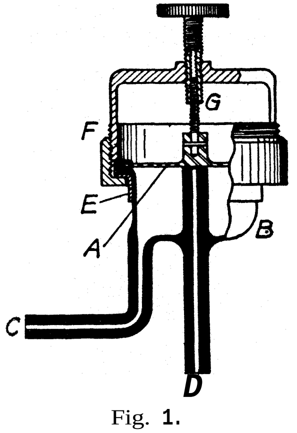

Fig. 1.

By varying the diameter of the inlet and outlet tubes, and the size and thickness of the diaphragm, this type of valve can be adapted to a wide range of gas flows. In connection with some experiments in this Laboratory, this type of valve was used successfully to regulate gas flows ranging from a few tenths of a cubic centimeter to several liters of gas per minute.

This valve is especially useful in controlling very slow flows where an ordinary stopcock is inadequate.

The writers wish to express their thanks to Mr. L. Testa for making the glass cup for the valve.

A Method of Winding Helical Quartz Springs and of Constructing Glass Sorption Buckets.—The construction and characteristics of the quartz helix sorption balance have been described in detail by McBain and Bakr[1] and the technique of its application to sorption studies by McBain and co-workers.[2] The author feels that the method of winding such helices which is presented here is an improvement upon that described by McBain and Bakr as regards ease of manipulation and uniformity of the springs produced.

The fibers are drawn from a quartz rod 3–5 mm. in diameter which is rotated in an oxyhydrogen flame until the quartz is evenly heated. The rod is then removed from the flame and drawn out immediately. The desirable fibers are about 0.2 mm. in diameter and about 100 cm. long. With some practice it is possible to draw fibers, a fair percentage of which will be of a useful diameter.

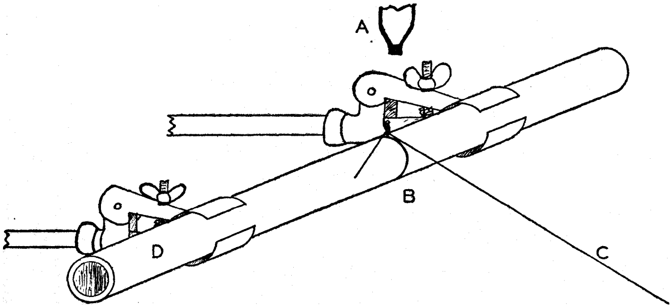

Fig. 1.

The method used in winding the helices is illustrated in Fig. 1. A section of quartz combustion tubing, D, 1.5 cm. in diameter and 30 cm. long is mounted horizontally with two buret clamps holding it loosely so that it can be moved horizontally and rotated freely. A small hand torch, A, is mounted vertically about 2 cm. above the axis of the tube. The author

[1] McBain and Bakr, THIS JOURNAL, 48,690 (1926).

[2] McBain and Britton, *ibid.*, 52,2198 (1930); McBain, Lucas and Chapman, *ibid.*, 52,2668 (1930); McBain, Jackman, Bakr and Smith, *J. Phys. Chem.*, 34, 1439 (1930).

prepared a small glass hand torch for this purpose. A piece of heavy nichrome wire, B, is twisted around the tube to provide a point of attachment for the fiber to be wound. A gas flame about 6 cm. in length is fed an air-oxygen mixture until the inner cone does not impinge upon the tube. The end of the fiber, C, is bent and hooked around the wire post and the tube slid over so that the fiber is in the flame. The tube is then rotated with one hand and the fiber guided with the other.

The amount of oxygen fed to the flame is rather critical. Too hot a flame may melt the fiber or cause it to adhere to the tube. Too cold a flame will result in poor bending and the resulting spring will not be cylindrical. A trial or two will give the proper flame adjustment and the winding may then be quite rapid. If one tires, or if the tube overheats, the spring may be slid out from the flame, and the winding resumed at leisure.

When cold, the hook is broken off and the helix loosened from the tube by gently rotating the ends in opposite directions with the tips of the fingers. It may then be bunched up and slid off the tube. A tube with a slight taper is very advantageous.

Helical springs prepared in this manner are free from corners, and show excellent mechanical strength. The small hand torch with an air-oxygen-gas flame is very conveniently used to bend the ends of the helices to form suspension hooks. McBain and co-workers recommend that the completed helices be annealed at 400° for about forty-eight hours.

McBain and co-workers employed buckets of platinum or gold foil to hold their sorbent. The author has prepared glass buckets for the same purpose. Since these buckets cannot be used to hold weights while the springs are being calibrated, a small pan of mica may be employed. Such a pan need weigh only 0.03 g. The stages in the preparation of the glass buckets are shown in Fig. 2.

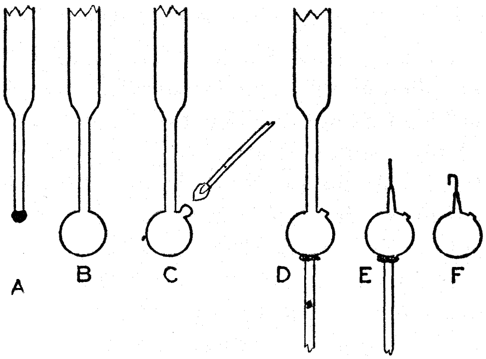

Fig. 2.

A piece of Pyrex tubing, about 1 cm. in diameter, is heated and drawn out to give a capillary about 1.5 mm. in diameter. This capillary is touched to the edge of an air-oxygen-gas flame until a small ball of glass has collected. This ball, A, is then blown out to form a bulb, B, with very thin walls. A tiny gas flame is then touched to the top as shown in C, and a small bulb blown out, broken and the edges melted down. A second capillary is then fastened to the bottom of the bulb with a drop of melted wax as shown in D, and the original capillary drawn off as rapidly as possible in a hot needle flame. The glass stem remaining is then bent into a hook, using the tiny gas flame. The wax is then melted off and the bulb cleaned with an appropriate solvent. A bituminous base wax, such as Piceïn, is recommended over a shellac wax, such as deKhotinsky, because it is readily removed with carbon disulfide or carbon tetrachloride.

Buckets prepared in this manner may be made in any desired size. The author has prepared a number which are more than 1 cm. in diameter and which weigh less than 0.1 g. The weight of such buckets is usually about 0.07 g. These buckets will withstand a baking-out temperature of 450".

ALPHA-NAPHTHOLSULFONIC ACIDS AND DERIVATIVES. II

BY E. GEBAUER-FUELNEGG AND ECKHARD HAEMMERLE

RECEIVED FEBRUARY 12, 1931 PUBLISHED JULY 8, 1931

In a series of articles it has been shown that phenols can be converted in phenolpolysulfonyl chlorides[1] by the action of chlorosulfonic acid. It also was noticed that the reagent caused four distinct types of reaction: namely, sulfonation, sulfochlorination, chlorination and oxidation. In certain cases the hydrovyl group of the phenol was found to be esterified prior to sulfonation, while in other instances condensation products such as the sulfonylides were isolated. 'The predominance of any one of the above-mentioned reaction types will depend on the time, temperature, quantity of reagent and the nature of the phenols.

The most striking aspect of the reaction between unsubstituted phenols and chlorosulfonic acid is the fact that so far it has been impossible to obtain the respective monosulfonyl chlorides.

From these facts a reaction mechanism for the action of chlorosulfonic acid on phenols (and phenolsulfonic acids) was postulated comprising as the first step the primary formation of the phenolsulfonic acid ester, and as the second step its rearrangement to form a phenolsulfonic acid; this is followed by reesterification of the hydroxy group and a second rearrangement to form the phenoldisulfonic acid in presence of sufficient amounts of the reagent.[2] Only when the phenoldisulfonic acid is formed and further

---

[2] E. Gehauer-Fuelnegg and **A.** Schlesinger, Ber., 61, 781 (1928).

sulfonation of the aromatic ring is more difficult, is chlorination of the phenolpolysulfonic acid accomplished with the formation of phenolpolysulfonyl chlorides. Therefore the action of the chlorosulfonic acid on phenols must be regarded as primarily a sulfonation. The chlorination of the sulfonic acid group does not occur until later. It is possible, however, to prepare phenolmonosulfonyl chlorides[2] when the phenolic hydroxy group is carbethoxylated. Other protective groups failed to give the expected results.[3]

The field which thus presented itself seemed interesting from three points of view. (I) Phenolpolysulfonyl chlorides became easily accessible, while their preparation was successful only in special cases before the experiments with chlorosulfonic acid mentioned above. Due to their reactivity they might prove to be interesting intermediates for dyestuff preparation, as well as for certain pharmaceutical purposes.

(II) The isolation and purification of the phenolsulfonyl chlorides as well as the separation of isomers, as compared to the corresponding sulfonic acids, are greatly facilitated on account of their solubility in organic solvents and the ease with which they are crystallized. Their purity can be tested by melting point determination.

(III) The relative ratio of isomeric sulfo derivatives obtained with rhlorosulfonic acid is sometimes altered as compared to sulfonations with sulfuric acid.

While in previous papers a method was developed for the sulfochlorination of various phenols[1] and naphtholmonosulfonic[4] acids, the present report will deal with results obtained with isomeric 1-naphtholdisulfonic acids.

The sulfochlorination of the isomeric a-naphtholmonosulfonic acids had resulted in the isolation of five isomeric I-naphtholtrisulfonyl chlorides, in which the position of only one of the sulfo groups was known. The position of the newly introduced sulfo radicals remained to be determined.

The 1-naphthol-2-sulfonic acid yielded a trisulfonyl chloride with a melting point of 174°. From 1-naphthol-3-sulfonic acid a product was obtained which is not yet identified but which is also believed to be a trisulfonyl chloride. The I-naphthol-4-sulfonic acid was found to form the same trisulfonyl chloride as the isomeric-2-sulfonic acid whose melting point is 174°. Upon treating the 1-naphthol-5-sulfonic acid in a similar manner, a trisulfonyl chloride with a melting point of 140" was obtained. From the 1-naphthol-6-sulfonic acid, a trisulfonyl chloride having a melting point of 203° resulted. The 1-naphthol-7-sulfonic acid yielded again the trisulfonyl chloride with a melting point of 174° and the isomeric

---

[3] E. Gebauer-Fuelnegg and F. v. Meissner, *Monatsh*, **50**, 531 (1928).

[4] E. Gebauer-Fuelnegg and A. Glueckmann, *ibid.*, 53-54, 100 (1929).

8-sulfonic acid was found to give a trisulfonylchloride with a melting point of 217°. From this series of experiments the constitution of only one trisulfonyl chloride could be established: namely, that of melting point 174° which was obtained from the 1-naphthol-2, -4- and -7-acids. It therefore is the 1-naphthol-2,4,7-trisulfonyl chloride.

The present report will deal with attempts to establish the constitution of some of the other trisulfonyl chlorides described above.

Since the isomeric 1-naphtholtrisulfonic acids were not sufficiently reliable for the present study, the isomeric disulfonic acids were used. When two of them upon treatment with chlorosulfonic acid will form only one trisulfonyl chloride, the position of the three sulfonic groups is determined. This scheme was successful with the 1-naphthol-2,4- and -4,7-disulfonic acids, which both yielded the 1-naphthol-2,4,7-trisulfonyl chloride.

The constitution of a second trisulfonyl chloride was established when both the 1-naphthol-4,6- and -6,8-disulfonic acids were found to yield only one trisulfonyl chloride, which therefore has the structure of a 1-naphthol-4,6,8-trisulfonyl chloride. This was identical with the compound obtained from 1-naphthol-8-sulfonic acid.

With the given data the position of the sulfonyl groups in the trisulfonyl chloride with a melting point of 203° can be either that of a 1-naphthol-2,6,8- or 3,6,8-trisulfonyl derivative. From other indications we conclude that the 2,3,6-position probably represents its actual structure. Two other isomers theoretically equally possible are excluded because of the fact that its anilide does condense with diazotized bases (elimination of 2,4,6-position) while the 4,6,8-position was found to belong to the trisulfonyl chloride with a melting point of 217° as stated above.

The constitution of the trisulfonyl chloride of m. p. 140° for which the positions 3,5,7- or 2,5,7- *a priori* are most probable, is not yet definitely settled.

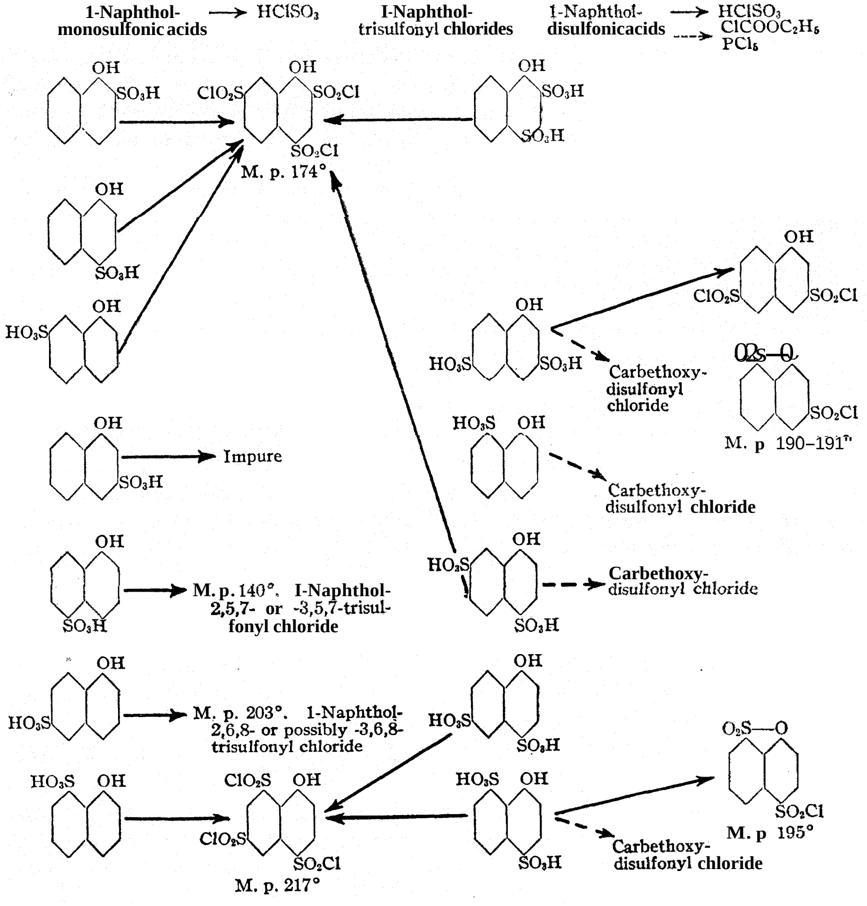
In the course of the present work, a number of new derivatives of 1-naphtholdisulfonic acids were encountered.

Upon treatment of the 1-naphthol-3,8-disulfonic acid with chlorosulfonic acid, the naphthsultone-3-sulfonyl chloride was obtained. From this acid no trisulfonyl chloride was obtained. The isomeric naphthsultone-4-sulfonyl chloride resulted under analogous conditions from the 1-naphthol-4,8-disulfonic acid.

When treated with aniline a reaction takes place, but the products obtained do not seem to be the expected naphthsultone sulfanilides. They will be studied and reported upon later.

The carbethoxy-1-naphtholdisulfonyl chlorides and some of the anilides of 1-naphthol-3,6-, -3,8-, -4,7- and -4,8-disulfonic acid have also been prepared. From the 4,6-disulfonic acid we were unable to isolate the corresponding chloride or anilide. Special care was necessary in the case of the 4,8-disulfonic acid, which was found to be easily converted by the presence of moisture into the corresponding naphthsultonesulfonyl chloride.

The chart shows the relation of the different 1-naphtholsulfonic acids and their derivatives.



Experiments

1-Naphthol **Trisulfonyl** Chlorides.—Ten grams of 1-naphthol-2,4-disulfonic acid was added to 100 g. of chlorosulfonic acid in small portions. After this had stood at room temperature for three days, crystals had formed. The yield did not seem to increase after ten days. They were filtered by suction through a funnel with a porous glass bottom, finally washed with water and dried in a vacuum. The substance was first crystallized from benzene and finally from carbon disulfide and yielded crystals melting at 174°.

The same substance may be obtained after three hours, when the reaction mixture is cautiously poured on crushed ice, carefully dried and crystallized as above. A mixture melting point proved the identity of the two preparations.

Ten grams of sodium salt of 1-naphthol-4,7-disulfonic acid were slowly added to 100 g. of chlorosulfonic acid. After fourteen days the crop of crystals was isolated and purified as above. The melting point of 174° and mixed melting point with the preparations obtained from the 1-naphthol-2,4-disulfonic acid as well as from 1-naphthol-2,4- and -7-monosulfonic acids, proved the identity of the substances. This compound also is formed after a three-hour reaction period from 1-naphthol-4,7-disulfonic acid with chlorosulfonic acid at room temperature.

Ten grams of 1-naphthol-4,8-disulfonic acid is added to 100 g. of chlorosulfonic acid, and the mixture is heated in an oil-bath for one hour at 150°. (The reaction which takes place under milder conditions will be described in a following paragraph.) After repeatedly crystallizing from carbon disulfide, the constant melting point of 217" is reached.

If 1-naphthol-4,6-disulfonic acid is treated analogously at 100 or 150° and the reaction product poured into concd. hydrochloric acid, filtered, completely dried, dissolved in benzene and crystallized from carbon disulfide to a constant melting point, crystals are obtained which melt at 217°, identical with those obtained above as well as with the compound previously obtained from 1-naphthol-8-sulfonic acid.

Anal. Calcd. for $C_{10}H_5O_7S_3Cl_3$: Cl, 24.20. Found: Cl, 24.48.

The corresponding anilide is obtained when an ether solution is refluxed with an excess of aniline on the water-bath.

Naphthsultonesulfonyl Chlorides.—Ten grams of sodium salt of 1-naphthol-3,8-disulfonic acid is added in small portions to 100 g. of chlorosulfonic acid at room temperature. The reaction mixture is cooled in the ice box, poured on crushed ice, filtered and completely dried in *vacuo*. The residue is first dissolved in benzene, crystallized and finally recrystallized from carbon disulfide, whereby crystals with a constant melting point of 190–191° are obtained. The same substance was isolated with better yields, when the reaction was prolonged for thirty days or the mixture heated to 150°.

Anal. Calcd. for $C_{10}H_5O_5S_2Cl$: Cl, 11.64; S, 21.06. Found: Cl, 11.65; S, 20.96.

Ten grams of sodium salt of 1-naphthol-4,8-disulfonic acid is slowly added to 100 g. of chlorosulfonic acid, isolated as before, m. p. 195° (a mixed melting point with the naphthsultone-3-sulfonyl chloride, m. p. 190–191°, gave a depression). The same product is obtained after prolongation of the reaction for thirty days.

Anal. Calcd. for $C_{10}H_5O_5S_2Cl$: C, 39.39; H, 1.65; Cl, 11.64. Found: C, 39.53; H, 2.11; Cl, 11.67.

The two isomeric naphthsultonesulfonyl chlorides do not react with aniline in ether solution to form the corresponding anilides. Only when boiled with aniline does a reaction ensue with the formation of products which are not the expected anilides. They will be discussed elsewhere.

Carbethoxy-1-naphtholdisulfonyl Chlorides.—Twenty grams of sodium salt of 1-naphthol-4,7-disulfonic acid is dissolved in a concd. solution of 15 g. of potassium hydroxide and well cooled, 20 g. of ethyl ester of chlorocarbonic acid is added drop by drop and the reaction mixture mechanically shaken for five to six hours. Alcohol was added to complete the precipitation and to dissolve any excess of reagent and filtered. The well dried substance was finely powdered and mixed with 1.5 molar proportions of phosphorus pentachloride and heated for one hour in an oil-bath at 130–150°. The reaction mixture was cooled to room temperature, poured on crushed ice, filtered and well washed with water. The completely dried residue was crystallized from carbon disulfide, finally giving crystals with a constant melting point of 120°.

Anal, Calcd. for $C_{13}H_{10}O_7Cl_2S_2$: Cl, 17.17. Found: Cl, 17.10.

The preparation of the carbethoxy-1-naphthol-3,8-disulfonyl chloride was analogous with the experiments described above, m. p. 180-181°.

Anal. Calcd for $C_{13}H_{10}O_7S_2Cl_2$: C, 37.76; H, 2.44; Cl, 17.17. Found: C, 38.05; H, 2.81; Cl, 17.46.

Carbethoxy-1-naphthol-4,8-disulfonyl chloride was prepared in the same way. The substance was finally obtained from carbon disulfide and melted from 177-179°. The analysis also indicates that the product is not entirely pure.

Care must be taken to avoid even traces of moisture during the reaction as well as recrystallization since the carbethoxy group is easily split off and as a result the naphthsultone-4-sulfonyl chloride, m. p. 195°, is obtained.

Anal. Calcd. for $C_{13}H_{10}O_7S_2Cl_2$: C, 37.76; H, 2.44; Cl, 17.17. Found: C, 38.52; H, 2.21; Cl, 17.80.

The carbethoxy-1-naphthol-3,6-disulfonyl chloride melted at 95° after crystallization from ether.

Anal. Calcd. for $C_{13}H_{10}O_7S_2Cl_2$: C, 37.76; H, 2.44; S, 15.52; Cl, 17.17. Found: C, 37.44; H, 2.77; S, 15.69; Cl, 17.21.

Some of the anilides of the isomeric carbethoxy-1-naphtholdisulfochlorides were prepared by boiling them with 2.5 molar proportions of aniline in ether solution for three hours. After evaporation the residue is washed with dilute hydrochloric acid and water. The carbethoxydisulfanilides were purified by carefully dissolving in dilute potassium hydroxide and precipitating with dilute hydrochloric acid.

We are indebted to the I. G. Farbenindustrie A.-G. for furnishing us with the 1-naphtholsulfonic acids.

Summary

The value of chlorosulfonic acid as a sulfochlorinating agent for phenols is emphasized.

1-Naphthol-2,4-, -2,7-, -3,6-, -3,8-, -4,6- and -4,8-disulfonic acids were sulfochlorinated with chlorosulfonic acid. 1-Naphthol-2,4- and -2,7-disulfonic acid yielded the same trisulfonyl chloride, the constitution of which therefore is determined as the 1-naphthol-2,4,7-trisulfonyl chloride. 1-Naphthol-4,6- and -6,8- also gave only one trisulfonyl chloride, which therefore must be the 1-naphthol-4,6,8-trisulfonyl chloride. Previously it had been obtained by sulfochlorination of the 1-naphthol-8-sulfonic acid. The constitution of the trisulfonyl chloride previously obtained from the 1-naphthol-6-sulfonic acid is believed to be the 1-naphthol-2,6,8- or possibly -3,6,8- derivative, while the structure of the trisulfonyl chloride derived from I-naphthol-5-sulfonic acid is either that of a 1-naphthol-2,5,7- or -3,5,7- derivative.

From the 1-naphthol-3,8- and -4,8-disulfonic acids the respective naphthsultonemonosulfonyl chlorides were obtained under proper conditions.

The carbethoxynaphtholdisulfonyl chlorides and a number of their anilides also have been prepared from the above acids.

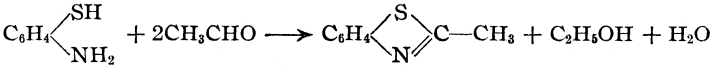
THE CONDENSATION OF ALDEHYDES WITH ORTHO-AMINOTHIOPHENOLS, BENZOTHIAZOLINES AND BENZOTHIAZOLES

BY HERMAN P. LANKELMA AND P. X. SHARNOFF

RECEIVED FEBRUARY 26, 1931 PUBLISHED JULY 8, 1931

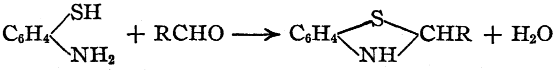
Hofmann[1] obtained benzothiazoles by the action of acids, acid chlorides and acid anhydrides upon o-aminothiophenol. Upon condensing certain aldehydes with o-aminothiophenol, he also obtained benzothiazoles.[2] He formulated the change as involving two molecules of aldehyde, one of which was reduced to the alcohol in the process.



In no case however was he able to show that an alcohol was actually formed.

Green and Perkin[3] also obtained a benzobisthiazole by condensing benzaldehyde with *p*-phenylenediamine-2,5-di-(thiosulfonic acid).

Claasz[4] condensed a number of aldehydes with o-aminothiophenol hydrochloride and obtained products which he described as benzothiazolines.



Since he obtained practically quantitative yields of product upon treating one mole of o-aminothiophenol with one mole of aldehyde, he pointed out that Hofmann's formulation of the reaction could not be correct and concluded that his products were benzothiazolines. In the cases where the corresponding benzothiazoles had previously been prepared, the melting points of Claasz' benzothiazolines were close to them and the melting points which he reported were in most cases not sharp. In no case did he establish his products as benzothiazolines by mixed melting points with the corresponding benzothiazoles.

Bogert and Stull[5] repeated a portion of Claasz' work and, upon purifying the condensation products, obtained benzothiazoles. They therefore characterized Claasz' benzothiazolines as impure benzothiazoles. In order to account for the formation of benzothiazoles from *o*-aminothiophenol and aldehydes they proposed two alternative mechanisms.

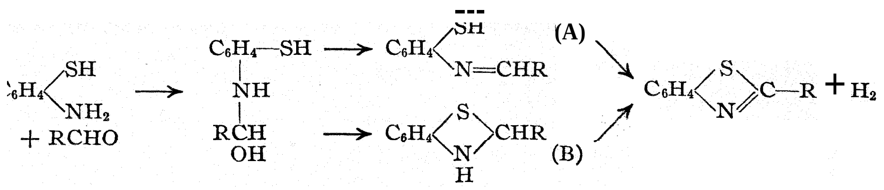
[4] Claasz, *Ber.*, 45, 1031 (1912); 49, 1141 (1916).

[5] Bogert and Stull, THIS JOURNAL, 47,3078 (1925).



As evidence in favor of (A) they point out that o-aminothiophenol will not condense with ketones or their dichlorides.

In the course of an investigation in this Laboratory dealing with the use of substituted o-aminothiophenols as reagents for the identification of aldehydes, we have condensed a number of aldehydes, both aliphatic and aromatic, with 2-amino4-chlorothiophenol hydrochloride and in every case have obtained a product different from the benzothiazole obtained by the action of acid chlorides or acid anhydrides. These products were obtained as crystalline solids of sharp melting point. In some cases the melting points lay within a few degrees of the corresponding benzothiazole. In each such case a mixed melting point with the benzothiazole showed them to be different.

These substances resemble benzothiazolines as described by Claasz with the exception that they are insoluble in mineral acid. Analysis gave values required by the two possible types (A) and (B). Since they are insoluble in aqueous alkali they cannot be thiophenols as represented by (A). They are easily oxidized to benzothiazoles by warming with ferric chloride in alcohol. These facts show that these products are benzothiazolines (B).

Previous work in this field has been practically confined to the use of aromatic aldehydes. In the present work two benzothiazolines were prepared from aryl aldehydes, and both were found to be easily oxidized by the air to the benzothiazole upon crystallizing them from certain organic solvents such as alcohol or carbon tetrachloride. This would indicate that where benzothiazoles are obtained from the action of an aldehyde upon an o-aminothiophenol, a benzothiazoline is first formed and is subsequently oxidized to a benzothiazole, either in the process of preparation or purification. Whether the products which Claasz describes are benzothiazoles or benzothiazolines cannot be stated from the evidence at hand. However, in the light of our results it is quite possible that they are benzothiazolines, which in the process of purification employed by Bogert and Stull, were oxidized to benzothiazoles.

Experimental

Preparation of **Benzothiazoles.**—The action of an acid chloride or acid anhydride upon an o-aminothiophenol has been shown by several investigators to be a general method for the preparation of benzothiazoles.[1,2,6] The method employed in this work

---

[6] Papers of Bogert, THIS JOURNAL (1924–1927).

had previously been used in this Laboratory for the preparation of benzothiazoles,[7] and gave very satisfactory results. A mixture of one mole of 2-amino-4-chlorothiophenol hydrochloride and one mole of the acid chloride or acid anhydride was dissolved in dimethylaniline and the solution boiled for about thirty minutes. The benzothiazole was precipitated by acidifying the cold solution. Yields from 60 to 90% were obtained, depending upon the acid chloride or acid anhydride employed.

Preparation of **Benzothiazolines.**—After trying a number of different condensing agents, the following general method was found to give the best results. One mole of

[7] Lankelma and Knauf, THIS JOURNAL, 53,311 (1931).

[8] The numbering suggested for the benzothiazole nucleus by Bogert and Abrahamson, *ibid.*, 44, 826 (1922), is used here for both the benzothiazole and the benzothiazoline nuclei.

2-amino-4-chlorothiophenol was dissolved in pyridine and one mole of aldehyde added dropwise to the warm solution. The mixture was finally heated from two to thirty minutes on the water-bath, the aromatic and the higher aliphatic aldehydes requiring the longer heating time.[9] The benzothiazoline was precipitated by acidifying the mixture; yields, 70–90%.

Oxidation of Benzothiazolines to **Benzothiazoles.**—The alkyl benzothiazolines could be crystallized unchanged from various solvents. 2-Phenyl-5-chlorobenzothiazoline, however, was couverted to the benzothiazole upon two or three crystallizations from alcohol. Similarly 2-(*o*-chlorophenyl)-5-chlorobenzothiazoline was converted to the benzothiazole upon crystallization from acetone or carbon tetrachloride. Any of the benzothiazolines are oxidized to the benzothiazole in good yield by warming for a few minutes with a slight excess of ferric chloride in alcohol.

Summary

1. Aldehydes condense with 2-amino-4-chlorothiophenol to give benzothiazolines.

2. Benzothiazolines are readily oxidized to benzothiazoles.

THE MOLECULAR WEIGHT OF INSULIN

BY BERTIL SJÖGREN AND THE SVEDBERG

RECEIVED MARCH 10, 1931 PUBLISHED JULY 8, 1931

The eminent physiological importance of the pancreas hormone insulin has in recent years, and especially since the isolation of crystalline insulin by Abel,[1] made it the subject of numerous chemical investigations. The experimental material so far collected decidedly indicates that insulin is of protein nature.[2] It gives several of the characteristic protein reactions,[3] its empirical composition resembles that of the proteins,[3] it is an amphoteric electrolyte possessing an isoelectric point at about PH 5,[3] which is in the same region where the isoelectric points of many proteins are situated and it shows a light absorption in the ultraviolet at exactly the same place as most of the proteins with a maximum at 270 mμ.[4]

At the suggestion of Dr. H. Jensen of The Johns Hopkins University, Baltimore, we have undertaken an ultracentrifugal study of insulin along the same lines as already followed in this Laboratory for the determination

---

[9] The formaldehyde employed was a 30–35% aqueous solution; the other aldehydes used were dried in the process of purification.

of molecular weight and PH-stability region of a considerable number of proteins.[5]

Material Used.—A quantity of 0.25 g. of crystalline insulin was kindly put at our disposal by Dr. Jensen and this small sample proved quite sufficient for a rather complete ultracentrifugal study. According to Dr. Jensen the material was prepared from commercial beef pancreas insulin of Squibb and Sons by the usual method of crystallization. The first crystalline product obtained had been recrystallized twice without the addition of brucine.

Specific Volume.—For the calculation of the molecular weight from ultracentrifugal data it is necessary to know the partial specific volume of the substance in solution. Two determinations were carried out at 20°, as described in previous communications. The data are given in Table I.

TABLE I

PARTIAL SPECIFIC VOLUME OF INSULIN AT 20°

Insulin concn., %	Solvent	PH of soln.	Partial sp. vol.
0.90	0.067 M in Na_2HPO_4	8.1	0.748
.45	.033 M in Na_2HPO_4 .033 M in KH_2PO_4	6.8	.750

The solution of PH 6.8 was prepared from that of PH 8.1 by addition of KH_2PO_4. The two determinations give the same result within the limits of error. As shown by the ultracentrifugal study insulin is (reversibly) dissociated at PH 8.1. This circumstance therefore does not influence the specific volume. A similar behavior has already been observed for several proteins.

The mean value 0.749 of the specific volume of insulin is the same as that of almost all the proteins so far studied in this Laboratory.

Determination of Sedimentation Constant and PH Stability Region.—The high-speed oil turbine ultracentrifuge was used for measuring the sedimentation constant in the PH range 3.5 to 12.3. The temperature of the solution was between 20 and 23° during centrifuging, the time varied from three to four hours and the speed was about 40,000 r. p. m. in all the runs. The insulin solutions were prepared from the dry material immediately before starting a run. In the PH region 6.4 to 7.4 where it is comparatively difficult to bring insulin into solution, the dry material was first dissolved by means of Na_2HPO_4 and then a suitable amount of KH_2PO_4 added. The solution of PH 4.2 was made up by dissolving insulin in acetic acid and adding sodium acetate. The determinations are summarized in Table II.

The sedimentation is independent of PH from about 4.5 to about 7.0 and has a mean value of 3.47×10^{-13}. This PH range therefore represents the stability region of insulin. Special ultracentrifugal tests showed that

the dissociation of the insulin molecule into products of low molecular weight, as demonstrated by the rapid fall in the sedimentation constant outside this range, is reversible both on the acid and the alkaline side, if the PH of the solution is not too far removed from the stability region and provided that the solution is not kept too long outside the stability region. It is of interest to note that similar experiments have been made regarding the physiological activity of insulin. This fact seems to indicate that the activity is destroyed when the dissociation products lose their ability to reconstruct the insulin molecule.

The sedimentation constant is within the limits of experimental error identical with the value previously found for egg albumin[6] and for Bence-Jones protein,[7] *viz.*, 3.54×10^{-13} and 3.55×10^{-13}, respectively. The PH stability range is decidedly narrower for insulin than for egg albumin and for Bence-Jones protein. In the case of insulin it has an extension of only about 2.5 PH units, while egg albumin is stable over 5 *P*H units (PH 4 to 9) and Bence-Jones protein over 4 units (PH3.5 to 7.5). The isoelectric point of insulin is situated at a higher PH than that of egg albumin. The very low solubility of insulin near the isoelectric point has not permitted the determination of this constant accurately enough to allow of a comparison with Bence-Jones protein which, as a matter of fact, has its isoelectric point situated in the same region as insulin (PH5.2).

Determination of Molecular Weight.—When the sedimentation equilibrium method is used, the molecular weight M is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2 (x_2^2 - x_1^2)}$$

where R is the gas constant, T the absolute temperature, V the partial specific volume of the solute, ρ the density of the solvent, ω the angular velocity and c_2 and c_1 are the concentrations at the distances x_2 and x_1 from the center of rotation.

Three equilibrium runs were performed within the stability region of insulin at a temperature of 20.1° and a speed of 10,500–11,000 r. p. m. Table III gives the complete data of a typical run and in Table IV are summarized the results of the three runs.

The mean value for the molecular weight 35,100 is within the limits of error identical with the values previously obtained for egg albumin[6] and Bence-Jones protein,[7] *viz.*, 34,500 and 35,000, respectively. Table III shows that there is no drift in the molecular weight values with distance from the center of rotation and that accordingly insulin is homogeneous with regard to molecular weight.

By means of the values for the molecular weight, M = 35,100, and the sedimentation constant, $s = 3.47 \times 10^{-13}$, we are now able to deduce the value for the molar frictional constant, $f = [M(1 - V\rho)]/s$, and find 2.54×10^{16}. The calculation of the molar frictional constant of a spherical molecule of the same molecular weight and the same specific volume as insulin calculated from the formula $f_s = 6\pi\eta N(3MV/4\pi N)^{1/3}$, where η is the viscosity of the solvent, gives the same value. Accordingly the insulin molecule must be regarded as spherical. The radius, calculated from the formula $r = (3MV/4\pi N)^{1/3}$, is 2.18 mμ. According to previous determinations[6,7] the egg albumin molecules and the Bence-Jones protein molecules are also spherical in shape with values for the radius of 2.17 and 2.18 mμ, respectively.

The fact borne out by the above investigation that the molecules of crystalline insulin are, with regard to mass, shape and size, almost identical with those of egg albumin and Bence-Jones protein and that, within the *P*H region 4.5–7.0, the insulin solutions are built up of molecules of equal mass, strongly support the view that insulin is a well-defined protein. It has a *P*H-stability region which is decidedly narrower than the stability regions for egg albumin and Bence-Jones protein, it has a much lower solubility and also in other respects differs chemically from those two proteins. These circumstances seem to indicate that we are justified in assuming that the physiologically active principle is not a low-molecular substance accidentally adsorbed on some high-molecular material but is the insulin molecule itself or some special group within it.[8]

The expenses connected with these experiments have been defrayed by a grant from the foundation "Therese och Johan Anderssons Minne."

Summary

1. The molecular weight and PH stability region of insulin have been determined by means of ultracentrifugal methods.

2. Insulin is stable from a PH of about 4.5 to about 7.0 with a molecular weight of 35,100. At lower and higher *P*H values the insulin molecule is broken up into smaller units. Near the borders of the stability region this dissociation is reversible.

3. Within the stability region the sedimentation constant of insulin is 3.47×10^{-13} and the molar frictional constant 2.54×10^{16}. The molecules are spherical with a radius of 2.18 mμ.

4. The molecular weight, sedimentation constant, molar frictional constant and molecular radius of insulin are within the limits of error identical with the corresponding constants for egg albumin and Bence-Jones protein. This circumstance makes it extremely probable that insulin is a well-defined protein and that the physiological activity of this hormone is a property of the insulin molecule itself or some special group within it.

THE PREPARATION AND PROPERTIES OF PURE DIVINYL ETHER

BY WILLIAM L. RUIGH AND RANDOLPH T. MAJOR

RECEIVED MARCH 21, 1931 PUBLISHED JULY 8, 1931

The first recorded reference to divinyl ether occurs in a paper by Semmler[1] "On the Ethereal Oil of *Allium Ursinum* L." The divinyl sulfide, which was obtained from the essential oil of this plant, when treated with silver oxide yielded a low-boiling, sulfur-free liquid, the boiling point of which was about 39°. Two determinations of the molecular weight corresponded with the calculated value for divinyl ether. Semmler did not further characterize this liquid.

An attempt to prepare divinyl ether by the exhaustive methylation of morpholine was made by Knorr and Matthes.[2] A few drops of liquid were obtained but the quantity was insufficient for either an analysis or a determination of its boiling point.

Cretcher, Koch and Pittenger[3] attempted to prepare divinyl ether by the action of heated sodium hydroxide on β,β'-dichlorodiethyl ether. The reaction was carried out in an iron pot surmounted by a Crismer column. The distillate came over at 84–85°. From it they were able to isolate β-chloroethyl vinyl ether, 1,4-dioxane, acetaldehyde and a "divinyl ether" which boiled at 39°. The yield of material that boiled at 39° was 4.7% of the amount that would have been expected if the conversion of the β,β'-dichloroethyl ether into divinyl ether had been complete. These authors evidently abandoned the attempt to prepare pure divinyl ether since they gave no properties of their product except its boiling point. The acetaldehyde formed in this reaction amounted to twice the weight of the material that boiled at 39°.

Hibbert, Perry and Taylor[4] modified the method of the previous authors. They replaced the Crismer column with a reflux condenser kept at 40°; they used potassium hydroxide rather than sodium hydroxide, added the β,β'-dichlorodiethyl ether in small portions and lastly increased the time of heating. They obtained a 54.9% yield of a "divinyl ether" which boiled at 34–5°. Presumably, further details are contained in Canadian Patent Application 350,357.[5] On brominating the material that boiled at 34–5° these authors obtained a compound, tetrabromoethyl ether, which melted at 63–64° and was identical with Freundler's "tetrabromobutyraldehyde."[6] This was shown by analysis and by a mixed melting point.

[6] Freundler, *Compt. rend.*, 140, 794, 1693 (1905); Bull. *soc. chim.*, [4] **1**, 71 (1907).

We have continued the study of the reaction between β,β'-dichlorodiethyl ether and the corresponding iodo ether with heated alkalies. In confirmation of the work of Cretcher, Koch and Pittenger we have isolated acetaldehyde, β-chloroethyl vinyl ether and 1,4-dioxane as products of this reaction. We have found, however, that divinyl ether boils at 28.3 ± 0.2° at 760 mm. The small amount of "divinyl ether," b. p. 39°, obtained by these authors was presumably a mixture which they did not further investigate. In addition to these products we have found evidence of the presence of ethylene oxide among the substances formed in the reaction. Also, in our preliminary work the gaseous products of the reaction were investigated and the presence of hydrogen and traces of acetylene were demonstrated.

Although the melting points of both pure sodium and potassium hydroxides are above 300°, ordinary C. P. grades which contain water fuse at a temperature below that at which reaction between the alkali and the chloro ether takes place. The reaction was very slow at temperatures below 170°; the most satisfactory temperatures were between 200–250°.

It was found that during the course of the reaction a crust of sodium or potassium chloride formed over the surface of the fused alkali. When the alkali was well stirred and the crust formation prevented, it was found that only traces of acetaldehyde were formed. Without stirring, the amount of aldehyde was generally two to three times the amount of the divinyl ether formed. There was also considerable gas evolved during the reaction. Analysis showed that the gas consisted mainly of hydrogen with some unsaturated gases including traces of acetylene.

The yield of divinyl ether was very markedly increased by passing a slow stream of ammonia gas through the reaction system. The ammonia may either act as a true catalyst for the reaction or it may increase the yield by inhibiting the decomposition of the divinyl ether formed. A further study is being made of the function of the ammonia in promoting the reaction.

Several other reactions for the preparation of divinyl ether were studied but no other satisfactory process was found.

The important physical and chemical properties of divinyl ether have been determined and apparently for the first time it has been analyzed.

When divinyl ether was catalytically reduced with hydrogen in the presence of a platinum catalyst a 15% yield of diethyl ether was recovered. In addition to this acetaldehyde was found in the reaction mixture. This was evidently formed by hydrolysis of the divinyl ether during the reduction. Although some ethyl alcohol may have been formed by reduction of more of the aldehyde this was not determined. On the other hand, the work of Vavon, Skita and Adams on the selective reduction of olefin and aldehyde groups has shown that a platinum catalyst without a promoter such as iron is not a very effective catalyst for the reduction of aldehydes.[7]

A recent patent by Hibbert[8] has described the polymerization of "divinyl ether" in the presence of benzoyl peroxide. We have found that only 5 to 25% of our divinyl ether was polymerized when it was treated according to the directions given in this patent. Polymerization is practically completely inhibited by minute traces of ammonia.

The reactions of divinyl ether with bromine have been studied. These will be discussed in a forthcoming paper.

Experimental Part

Preliminary Study of the Reaction between β,β′-Dichloroethyl Ether and Heated Caustic Alkalies.—Considerable time was spent in attempts to prepare divinyl ether by the action of potassium hydroxide on β,β′-dichlorodiethyl ether according to the method of Hibbert, Perry and Taylor.[4] The apparatus used by these authors was later modified in most of our preliminary runs by the use of a nickel-lined copper autoclave of about 500-cc. capacity in place of a copper flask. The end of the condenser was connected through the top of the autoclave by means of a tightly fitting stuffing box packed with a mixture of asbestos and graphite. Provision was made for a gas inlet tube and a thermometer well. Ice water was circulated through the second condenser and the liquid products were collected in a flask cooled with either solid carbon dioxide and acetone or ice and hydrochloric acid mixtures.

According to the description given by these authors the copper reaction flask was "strongly heated with a Bunsen burner." In order to control the reaction more carefully, we carried out experiments over the temperature range of 150–300°. They also stated that "finely powdered caustic potash" was employed. The ordinary "C. P." grades of sodium or potassium hydroxide melt at about 140–160° depending upon the amount of water that they contain. Since these authors did not mention any particular drying of the caustic potash we assumed that their reaction mixture actually consisted of fused rather than powdered alkali. However, we varied the water content of the alkali both by the addition of water and by boiling off the excess water at slightly higher temperatures than that at which the reaction was to take place. A mixture of sodium and potassium hydroxides (and water) was also tried.

Throughout these preliminary experiments and also in later work we were never able to obtain any trace of either a compound or a true constant boiling mixture which boiled between thirty and forty degrees.

---

[7] Tuley with Adams, THIS JOURNAL, 47, 3061 (1925); Skita, *Ber.*, 48, 1685 (1915); Vavon, *Compt. rend.*, 154, 359 (1912).

[8] Hibbert, Canadian Patent, 302,437, July 29, 1930.

It was found that a considerable amount of gas was evolved during the reaction. When about eight drops of β,β'-dichlorodiethyl ether was added per minute, the flow of gas varied from 5 cc. per minute at 200° to about 65 cc. at 280'.

A qualitative test with ammoniacal cuprous chloride gave a small quantity of a red precipitate which showed the presence of a small amount of acetylene. The gas also gave a strong positive test for hydrogen with Pereira's test,[9] using sodium tungstate, acetic acid and palladous chloride.

In most of the preliminary runs a small amount of material that boiled between 20 and 30" was obtained. This material contained a large amount of acetaldehyde. We also found 1,4-dioxane and β-chloroethyl vinyl ether in the distillate, in confirmation of the work of Cretcher, Koch and Pittenger.[3] However, we were unable to obtain the "divinyl ether" whose boiling point they gave as 39°.

Since they made no further study of the properties of their "divinyl ether," b. p. 39°, we presume that they abandoned further study of the compound due to the small yield obtained. We were thus forced to the conclusion that if divinyl ether was a product of this reaction it must be contained in the fraction boiling between 20 and 30°.

The low-boiling distillate from five runs using a total of about 400 g. of the chloro ether was collected and amounted to 123.5 g. This material was treated successively with solutions of sodium bisulfite, dilute alkali, sodium carbonate and hydroxylamine hydrochloride, washed several times with water, and finally dried over calcium chloride. The aldehyde-free material from this treatment weighed 37.7 g. After two fractionations, the largest cut weighing 15.9 g. boiled at 27–29' (uncorr.). The method of purification was later improved as follows: the crude low-boiling distillate was shaken with a dilute solution of ammonia, allowed to stand in the ice box for several hours in contact with an excess of the dilute ammonia and finally washed several times with water. After it had been dried over calcium chloride and then sodium, it was distilled through a Clarke column; the fraction which boiled at 28.3 to 28.5' (corr.) at 768 mm. was pure divinyl ether. The corrected boiling point at 760 mm. was 28.3 ± 0.2' (obtained on another 250-g. sample).

Properties of Divinyl Ether.—Divinyl ether rapidly decolorized bromine in carbon tetrachloride; it was also readily oxidized by an aqueous solution of potassium permanganate. The absence of any acetylenic linkage was shown by a negative test with ammoniacal cuprous chloride. Concentrated sulfuric acid reacted violently with it to give a black tarry resin and some free aldehyde. Cold concentrated hydrochloric acid gave a yellow color with divinyl ether and the odor of acetaldehyde was apparent. Dilute hydrochloric acid hydrolyzed divinyl ether rapidly to acetaldehyde (confirmed by the *p*-nitrophenylhydrazone).

A solution of p-nitrophenylhydrazine in 50% acetic acid to which a few drops of

---

[9] Pereira, Chem. *Abstracts*, 7, **3284** (1913).

dilute hydrochloric acid had been added reacted rapidly with divinyl ether and gave the p-nitrophenylhydrazone of acetaldehyde, m. p. 128.5–129°. A mixed melting point with some material prepared directly from acetaldehyde also melted at 128.5–129°.

In the absence of hydrochloric acid, divinyl ether did not react with *p*-nitrophenylhydrazine in 50% acetic acid after standing for thirty minutes at room temperature.

Divinyl ether gave an immediate precipitate of iodoform when the test was applied at 0°, using the procedure of Mulliken.[10]

Tollens' reagent showed no darkening with the ether within half an hour when the mixture was kept cold. Schiff's reagent, however, gradually developed a pink color, due presumably to the acetaldehyde which was liberated by hydrolysis in the presence of the free acid.

Pure divinyl ether boiled at 28.3° = 0.2" (760 mm.); mol. wt. calcd. for C_4H_6O, 70.05; found (Victor Meyer Method): 74.43, 71.15; d_{20}^{20} 0.774; d_4^{20} 0.773; n_D^{20} 1.3989; mol. refraction, calcd. for C_4H_6O (by Lorentz–Lorenz formula),'' 21.38; found, 21.93.

Analysis.—The carbon and hydrogen analyses were performed in a modification of Reid's apparatus (Fig. 2).[12] Owing to the explosive nature of certain mixtures of divinyl ether and air, the inner tube of the apparatus was a 1-mm. Pyrex capillary tube which was loosely plugged at intervals with glass wool. This capillary tube extended to within a half centimeter of the copper oxide. A metallic wool such as silver would have probably been more efficient to prevent "backfires" because of its greater conductivity of heat. A small bulb of about 0.5-cc. capacity was blown in the capillary just below the "sample tube." Before breaking the sample bulb the lower part of the apparatus was chilled with a freezing mixture.

Anal. Calcd. for C_4H_6O: C, 68.52; H, 8.64. Found: C, 67.78, 68.44; H, 8.61, 8.61.

Reduction of Divinyl Ether.—Half a gram of a platinum oxide catalyst[13] in 75 cc. of redistilled n-butyl alcohol was reduced in a Burgess–Parr reduction apparatus.[14] A sealed ampoule containing 12.52 g. of divinyl ether was then placed in the reductor bottle. After the preliminary evacuation of the bottle, the ampoule was broken and hydrogen admitted to the system. Reduction stopped when about half the theoretical amount of hydrogen had been absorbed. The bottle and its contents were cooled in a mixture of solid carbon dioxide and acetone and opened. One tenth of a gram of catalyst and 100 cc. more of n-butyl alcohol were added and the reduction continued. After twenty-four hours 0.3 g. more of the catalyst was added as before. Reduction proceeded rapidly until about the theoretical amount of hydrogen had been absorbed, when absorption abruptly stoppcd. However, since the total reduction required eighty-eight hours, presumably some hydrogen was lost through leakage.

The butyl alcohol solution was filtered and distilled through a Clarke column. The first fraction, which boiled between 30 and 70° (practically all between 30 and 40°), weighed 4.9 g. An odor of acetaldehyde was noticeable. By treatment of 0.11 g. of this fraction with *p*-nitrophenylhydrazine in dilute acetic acid, 0.029 g. of crude acetaldehyde p-nitrophenylhydrazone (m. p. 124–125°) was obtained. The fraction of b. p. 30–70°, therefore, contained about 6.4% of acetaldehyde. This fraction was then treated with dilute hydrochloric acid for half an hour, the acid neutralized with sodium

hydroxide, the ether layer separated, dried first over anhydrous sodium carbonate then over sodium and distilled. All this liquid boiled between 34.6–35.2° at 767 mm. and the distillate weighed 2.02 g. The refractive index was found to be $n_D^{17\ 1}$ 1.3540.[15] The yield of pure ethyl ether was thus 15.2%. Considerable loss of the product occurred during the processes of purification.

Polymerization of Divinyl Ether.—A summary of the results obtained during attempts to polymerize divinyl ether is given in Table I. The general procedure was to add the benzoyl peroxide (recrystallized, m. p. 106–107°) to a cold dry bomb tube, then add the divinyl ether and seal. The tubes were then heated in a Freas electric oven for the period stated, cooled and opened. The polymer together with the unpolymerized divinyl ether was obtained on opening the tubes. The procedure used was that given by Hibbert in a recent patent.[5]

TABLE I

POLYMERIZATION OF DIVINYL ETHER

Run	Diviuyl ether, g.	Benzoyl peroxide, mg.	Temp., °C.	Time of heating, hours	NH_3	Product, g.	Yield of polymer., %
1	5	25	90–96	24	Trace	0.073	0.96
2	5	25	90–96	24	Trace		2
3	5	50[a]	95–100[b]	25	...	1.28	24.6
4	2.5	12.5	92–94	24	...	0.32	12.4
5	2.5	25[a]	92–94	24	...	0.19	6.4
6	2.5	12.5	91–93	24.5	...	0.199	7.5
7	2	12.5	91–93	24.5	Trace	0.012	0
8	2.5	12.5	91–93	24.5	...	0.527	20.6

[a] The ratio of benzoyl peroxide to divinyl ether was twice that given in the patent of Hibbert. [b] The oven overheated for a short time to about 130" at the beginning of this run.

Ethylene Oxide as a Product of the Reaction.—Ethylene oxide was presumed to be a product of the reaction because the low-boiling fraction (15–25°) of these runs was almost completely removed by treatment with ammonia. When efficient stirring of the potassium hydroxide was maintained, very little acetaldehyde was found. Distillation of the product under these conditions showed that 20% of the material came over below 27° during the first fractionation.

To confirm the presence of ethylene oxide the test given by Mulliken was applied in conjunction with several blanks.[16] In each test about 1.5 cc. of a saturated solution of magnesium chloride and 0.1–0.3 cc. of the material to be tested was placed in a tightly stoppered 7.6-cm. test-tube. These were kept at 0° for six hours and then allowed to stand at room temperature.

4.	Pure ethylene oxide	Heavy precipitate after 12–24 hours

Reaction between β,β'-**Diiododiethyl** Ether and Fused Potassium Hydroxide.—To 150 g. of potassium hydroxide in the reaction vessel was added 100 g. of β,β'-diiododiethyl ether[17] during the course of two hours and forty-five minutes. The autoclave was kept at 190–200°. The distillate amounted to 16.7 g. and contained considerable acetaldehyde. After the treatment with ammonia, 6.7 g. of material was left of which **3.3** g. boiled between 23 and 28° (practically all at 27–28" uncorr.). The yield of divinyl ether was thus 15%.

Ammonia as a Catalyst.—The run with the diiodo ether was repeated under practically the same conditions as before except that a slow stream of dry ammonia was ran through the system. A smaller amount (75 g.) of the ether was used. The yield of divinyl ether was 5.6 g. or 34%. The use of ammonia as a catalyst increased the yield slightly more than 120%.

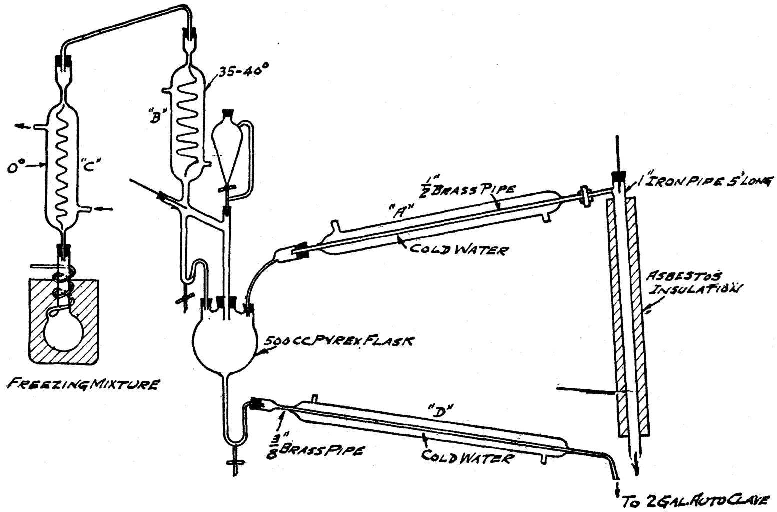

Fig. **1.**

Preparation **of** Divinyl Ether when the Molten **Alkali** was Stirred without the Use of Gaseous Ammonia.—The apparatus was set up as shown in Fig. 1. **A** charge of **7** kg. of technical lump potassium hydroxide was placed in the autoclave. *Efficient stirring of the molten alkali was found desirable.* For this reason the level of the fused alkali was well below the upper arm of the stirrer blades. If this point was disregarded, a crust of potassium chloride, etc., formed over the surface of the fused alkali. This resulted in reduced yields, production of large amounts of acetaldehyde and a very marked slowing down of the speed of reaction. When efficient stirring was maintained, practically no acetaldehyde was formed.

In the preliminary runs in which the original small scale apparatus was used without stirring, the amount of acetaldehyde formed was generally about twice the yield of divinyl ether. **A** run was made in the new apparatus with efficient stirring but without

---

[17] Gibson and Johnson, *J. Chem. Soc.*, 2525 (1930).

the use of ammonia. From 923 g. of dichlorodiethyl ether was obtained 101.5 g. of distillate of which 5 g. was in an aqueous layer. Practically no aldehyde was present as was shown by tests with Tollens' and Schiff's reagents and with *p*-nitrophenylhydrazine. It may be noted here that whereas acetaldehyde formed the *p*-nitrophenylhydrazone with the hydrazine in dilute acetic acid solutions almost immediately, divinyl ether gave the hydrazone only very slowly after long standing.

Ethylene oxide was, however, a by-product of this run as shown by the previously described test.

From this reaction, 59.8 g. of material was obtained, b. p. 20–33°. This corresponds to a yield of 13.3% if this were all divinyl ether, Due to accidental loss of one of the fractions, the product was not purified by treatment with ammonia.

The reaction took place best when the temperature of the fused alkali was kept at about 200–240°; lower temperatures result in slowing up the reaction. The effect of temperatures above 250° was not determined in this apparatus.

Samples of the gas from this reaction were collected over water and then analyzed. The flow of gas varied from 400 to 500 cc. per minute and a total of four liters of gas was taken at intervals during the reaction. The analyses were made over water with a Hempel apparatus. The following results were obtained

Unsaturated	15.7%	(absorption in bromine water)
Oxygen	1.0%	(absorption in alkaline pyrogallol)
Hydrogen	78.5%	(combustion over copper oxide at 270°)
Residue	4.7%	
Total	99.9%	

The residual gas after the removal of the unsaturated gases, oxygen and hydrogen was analyzed for methane and ethane in a mercury-filled combustion pipet. Less than 0.5% of saturated hydrocarbons was found in the total sample. The 4.7% residue was thus principally nitrogen.

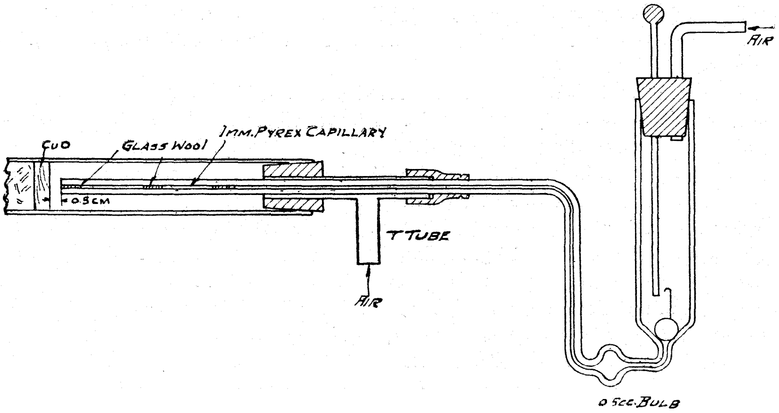

Fig. 2.

The unsaturated gas probably contained some divinyl ether since the condenser for the liquid products of the reaction was cooled only to about −15° during this run. A trace of acetylene in the gas was shown to be present by the small amount of red precipitate which was formed when the gas was passed through an ammoniacal solution of cuprous chloride.

Reaction in the Presence of Gaseous Ammonia.—When a slow stream of gaseous ammonia was passed through the system, the yield of divinyl ether was considerably increased. Using the new apparatus, the autoclave was first heated to about 230° and ammonia gas passed in through the gas inlet tube at about 1 to 3 bubbles per second. The addition of the β,β'-dichlorodiethyl ether was so regulated that condenser "B" did not become choked with the refluxing liquid. From time to time it was necessary to withdraw from the trap the excess of water, dioxane and β-chloroethyl vinyl ether which otherwise would have choked the condenser "B." The apparatus had a capacity of 1.5–2 kg. of the dichloro ether in eight hours. The capacity could have been increased by the employment of more efficient condensers. Condenser "B" in particular, being of spiral form, was rather readily choked with the refluxing liquid.

From 1850 g. of the dichloro ether in ten hours was obtained 272.8 g. of organic distillate. On fractionation, 192.5 g. of crude divinyl ether, b. p. 26.3–30° (uncorr.), was collected. The yield was thus 21%. From four runs using a total of 4750 g. of the chloro ether was obtained 478 g. of crude divinyl ether (b. p. 25–30°), or a yield of 20.3%. When the yield was corrected for losses due to a breakdown and for withdrawals of β-chloroethyl vinyl ether, the yield was about 25%.[18]

In comparing these results with the yield obtained without the use of ammonia (13.3%) it must be remembered that this yield was of relatively impure divinyl ether since it had not been purified by treatment with aqueous ammonia. In the runs using gaseous ammonia the purification consisted in washing the crude distillate several times with water, drying over calcium chloride and distilling through a Clarke column.

In order to remove all traces of ammonia, the fraction of b. p. 27–29" was washed once or twice with ice water (testing the wash water with methyl orange), dried over calcium chloride, then over sodium and redistilled.

Reaction between β,β'-Dihalogen Diethyl Ether and Sodamide.—The copper autoclave of the apparatus used in the preliminary runs was replaced by a 1-liter 3-necked distilling flask equipped with a mercury-sealed stirrer. In the flask were placed 300 cc. of dry xylene and 70 g. of very finely powdered sieved sodamide. The mixture was heated to the boiling point of the xylene and 100 g. of dichlorodiethyl ether run in during the course of four hours. Toward the end of the reaction, an additional 20 g. of fresh sodamide was added.

The product, collected in a receiver cooled with a solid carbon dioxide–acetone mixture, consisted mostly of liquid ammonia. About 1.5 g. of crude divinyl ether was obtained on fractionating this distillate; yield, 3%.

A run was made in which 50 g. of β,β'-diiododiethyl ether was used. The yield from this reaction was likewise very poor.

Action of Tertiary Amines on β,β'-Dihalogen Diethyl Ethers.—β,β'-Dichloro diethyl ether (5 g.) was refluxed with 15 g. of dimethylaniline for two hours. No reaction took place as was shown by the absence of any precipitate on the addition of dry ether.

The β,β'-diiododiethyl ether when refluxed for five minutes with dimethylaniline gave a voluminous precipitate. When recrystallized from alcohol it formed shimmering white leaflets of m. p. 220–230° (decomp.).

Anal. Calcd. for $C_{20}H_{30}I_2N_2O_2$: C, 41.28; H, 5.33; N, 4.93. Found: C, 41.47, 31.43; H, 5.53, 5.60; N, 5.12.

The material was thus the diiodide of bis-β,β'-phenyldimethylaminoethyl ether.

A mixture of 25 g. of the chloro ether and 100 g. of pure synthetic quinoline was gradually heated up to the boiling point and then refluxed for several hours. No trace

---

[18] The best yield obtained, using a solid carbon dioxide–acetone mixture to cool the receiving flask, was 38%.

of divinyl ether was obtained. The reaction mixture solidified to a tarry mass when it was cooled.

Attempts to Dehydrate β,β'-Dihydroxydiethyl Ether.—Activated alumina was heated in the autoclave at 200° and β,β'-dihydroxydiethyl ether slowly added. No divinyl ether was obtained, the products being mainly aldehydes.

Phosphorus pentoxide reacted violently with the β,β'-dihydroxydiethyl ether and gave a tarry gum. The reaction was tried with xylene as a diluent but no divinyl ether was obtained.

Soda Lime and β,β'-Dichlorodiethyl Ether.—Several runs were made in an attempt to prepare divinyl ether by passing the vapor of the chloro ether over soda lime at 250–300°. Aldehydes were obtained but no divinyl ether.

We take pleasure in acknowledging the assistance of Doctor William Engels in the design of the apparatus for the preparation of divinyl ether, and of Mr. Douglass Hayman for the analysis of the diiodide of bis-β,β'-phenyldimethylaminoethyl ether.

Summary

1. Several methods for the preparation of divinyl ether have been studied, the most successful being the reaction of β,β'-dichlorodiethyl ether and caustic alkali in the presence of ammonia.

2. Divinyl ether has been prepared, analyzed and a number of its physical and chemical properties determined.

3. Pure divinyl ether was partially polymerized by the method described in a recent patent.[5] Traces of ammonia inhibited this polymerization.

4. Diethyl ether has been formed by the catalytic reduction of divinyl ether.

5. In addition to divinyl ether, the following substances were formed during the reaction between β,β'-dichloroethyl ether and caustic alkali: hydrogen, acetylene, ethylene oxide, β-chloroethyl vinyl ether, 1,4-dioxane and acetaldehyde.

RAHWAY, NEW JERSEY

[Contribution from the Chemistry Laboratory of the University of Michigan]

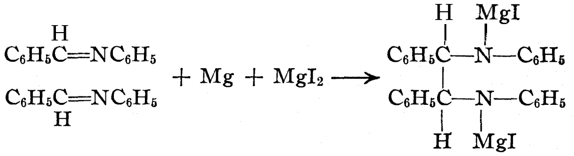
THE REDUCTION OF BENZALANILINE, BENZOPHENONE-ANIL AND BENZIL-ANIL BY THE SYSTEM MAGNESIUM + MAGNESIUM IODIDE

By W. E. Bachmann

Received April 9, 1931 Published July 8, 1931

The successful addition of the MgI group to the N=N group[1] as well as to the C=O group[2] encouraged the belief that the C=N group would take up MgI in a similar fashion. Experiment showed that benzalaniline, benzophenone-anil and benzil-anil react readily with a mixture of magnesium and magnesium iodide and in each case addition of MgI to the C=N group takes place.

Benzalaniline is reduced by the binary system in the manner of benzaldehyde; unlike the reduction of the aldehyde, however, the reaction stops when the iodomagnesium derivative of dianilino-dibenzyl is formed.



$$\begin{matrix} C_6H_5\overset{H}{C}{=}NC_6H_5 \\ C_6H_5\underset{H}{C}{=}NC_6H_5 \end{matrix} + Mg + MgI_2 \longrightarrow \begin{matrix} C_6H_5\overset{H}{C}-\overset{MgI}{N}-C_6H_5 \\ | \\ C_6H_5\underset{H}{C}-\underset{MgI}{N}-C_6H_5 \end{matrix} \qquad (1)$$

Exactly one gram atom of metallic magnesium reacts for two gram molecules of benzalaniline. This addition of the MgI group is analogous to the addition of sodium to benzalaniline,[3] which results in the disodium derivative of dianilino-dibenzyl. Hydrolysis of the reduction product gives dianilino-dibenzyl.

Benzophenone-anil, unlike benzophenone[4] which gives a pinacol derivative, takes up two MgI groups and is reduced to the iodomagnesium derivative of N-benzohydryl-aniline.

$$(C_6H_5)_2C{=}NC_6H_5 + Mg + MgI_2 \longrightarrow (C_6H_5)_2\underset{MgI}{C}-\underset{MgI}{N}-C_6H_5 \qquad (2)$$

The amount of metallic magnesium that reacts corresponds exactly to that required by the equation. Hydrolysis of the reduction product gives N-benzohydryl-aniline. Fluorenone-anil is reduced by the binary system in the same manner. These reactions are similar to the action of sodium on benzophenone-anil[3] and on fluorenone-anil, in which cases the disodium derivatives are formed.

Benzil-anil reacts with the binary system in the manner of benzil.[5]

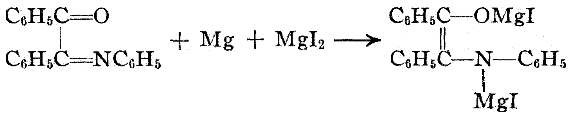
[4] Gomberg and Rachmann, This Journal, 49, 236 (1927).

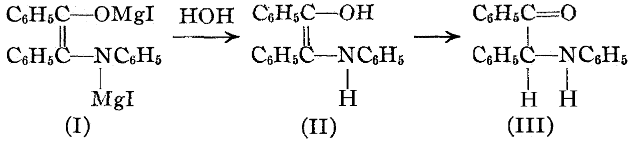
[5] Gomberg and Bachmann, *ibid.*, 49, 2584 (1927); Gomberg and Van Natta, *ibid.*, 51, 2238 (1929).

One gram atom of metallic magnesium reacts for each gram molecule of benzil-anil. It is considered that the following reaction most probably takes place



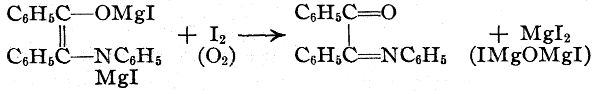
$$\begin{array}{l}C_6H_5C{=}O\\ \quad|\\ C_6H_5C{=}NC_6H_5\end{array} + Mg + MgI_2 \longrightarrow \begin{array}{l}C_6H_5C{-}OMgI\\ \quad\|\\ C_6H_5C{-}N{-}C_6H_5\\ \qquad\;\;|\\ \qquad\; MgI\end{array} \tag{3}$$

In the process of reduction the solution displays a series of intense colors which parallel those given by benzil on reduction. Hydrolysis of the reduction product (I) gives the unsaturated alcohol (II) which rapidly tautomerizes to the stable form, anilbenzoin (III).



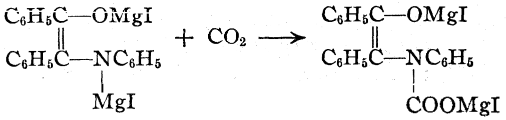
$$\underset{(I)}{\begin{array}{l}C_6H_5C{-}OMgI\\ \quad\|\\ C_6H_5C{-}NC_6H_5\\ \quad|\\ \quad MgI\end{array}} \xrightarrow{HOH} \underset{(II)}{\begin{array}{l}C_6H_5C{-}OH\\ \quad\|\\ C_6H_5C{-}NC_6H_5\\ \qquad\quad|\\ \qquad\quad H\end{array}} \longrightarrow \underset{(III)}{\begin{array}{l}C_6H_5C{=}O\\ \quad|\\ C_6H_5C{-}NC_6H_5\\ \quad|\quad\;|\\ \quad H\quad H\end{array}} \tag{4}$$

The reduction product (I) reacts rapidly with iodine and with oxygen and is converted by them to benzil-anil.



$$\begin{array}{l}C_6H_5C{-}OMgI\\ \quad\|\\ C_6H_5C{-}NC_6H_5\\ \quad\; MgI\end{array} \begin{array}{c}+ I_2\\ (O_2)\end{array} \longrightarrow \begin{array}{l}C_6H_5C{=}O\\ \quad|\\ C_6H_5C{=}NC_6H_5\end{array} \begin{array}{c}+ MgI_2\\ (IMgOMgI)\end{array} \tag{5}$$

Carbon dioxide is absorbed by the reaction mixture with the formation of the salt of an N-carboxylic acid.



$$\begin{array}{l}C_6H_5C{-}OMgI\\ \quad\|\\ C_6H_5C{-}NC_6H_5\\ \quad|\\ \quad MgI\end{array} + CO_2 \longrightarrow \begin{array}{l}C_6H_5C{-}OMgI\\ \quad\|\\ C_6H_5C{-}NC_6H_5\\ \qquad\quad|\\ \qquad\quad COOMgI\end{array} \tag{6}$$

Experimental

Reduction of **Benzalaniline.**—To a filtered solution of magnesium iodide, prepared from 8 g. of iodine in 30 cc. of anhydrous ether and 60 cc of dry benzene, were added 9.05 g. of benzalaniline and a weighed rod of magnesium. The flask was stoppered and shaken mechanically at room temperature for two days. After one day the solution contained a large amount of a light yellow solid. The rod was withdrawn from the mixture, washed with alcohol, dried and weighed: loss in weight, 0.608 g.; calcd., 0.608 g

The mixture was hydrolyzed by means of ice; dilute acetic acid was added in order to dissolve the magnesium hydroxide which was formed. The ether–benzene solution was separated and the solvents were allowed to evaporate. The residual oil crystallized completely when it was stirred with methyl alcohol. The crude product (9 g.) melted at 137–139° and was found to be identical with the dianilinodibenzyl obtained by reduction of benzalaniline by aluminum amalgam[6] as well as with the product resulting from the hydrolysis of the disodium compound prepared from benzalaniline and metallic sodium according to the directions of Schlenk and Appenrodt. Anselmino considers the product to be a mixture of stereoisomeric dianilino-dibenzyls of m. p. 139 and 164°.

---

[6] Anselmino, *Ber.*, 41, **623** (1908).

By repeated recrystallizations colorless needles of m. p. 165–166° were obtained which were identical with those isolated from the amalgam reduction product.

Reduction of **Benzophenone-anil.**—Benzophenone-anil was prepared according to the directions of Reddelien[7] from benzophenone and aniline with aniline hydrochloride as a catalyst. In agreement with Reddelien we obtained 80% yields of benzophenone-anil although Gilman and Dickey[8] reported recently that they obtained yields of only 20% by this method.

A mixture of 12.85 g. of benzophenone-anil, 15 g. of magnesium iodide and a rod of magnesium in 105 cc. of ether–benzene (1:2) was shaken for several days. The reaction began immediately as was evidenced by the violet-colored streamers which came off from the surface of the rod. The solution became opaque red and finally dark reddish-brown in color: loss in magnesium, 1.21 g.; calcd., 1.21 g. The same loss of magnesium occurred when only one-quarter of the above amount of magnesium iodide was employed, indicating that the iodomagnesium derivative is able to split off magnesium iodide and thus make the latter available for further reaction as in other similar reductions.[9]

Hydrolysis of the reduction product gave a solid melting at 54–58'. When this solid was recrystallized from alcohol, a small amount of the addition complex[10] composed of a molecule each of benzophenone-anil and of benzohydryl-aniline crystallized out; from the filtrate there was obtained pure benzohydryl-aniline. Repeated crystallizations raised the melting point of the complex to 84"; the compound so obtained was found to be identical with the complex obtained by recrystallizing a mixture of equal parts of benzophenone-anil and benzohydryl-aniline from alcohol. The crude reduction product as obtained by hydrolysis was shown in the following manner to contain 90% of benzohydryl-aniline. The product was heated with concentrated hydrochloric acid until the mixture became colorless; this treatment hydrolyzed the benzophenone-anil to benzophenone and aniline and at the same time formed the hydrochloride of benzohydryl-aniline. This hydrochloride was filtered off, dried and extracted with warm petroleum ether in order to remove the benzophenone. The hydrochloride was converted to the free base by treatment with ammonium hydroxide and extracting with ether in a separatory funnel. After recrystallization from alcohol the benzohydryl-aniline melted at 57–58'; its identity was established by comparison with authentic benzohydryl-aniline.

It was found that benzohydryl-aniline can be prepared in practically quantitative yields by reduction of benzophenone-anil by means of magnesium and methyl alcohol, a method employed successfully by Zechmeister and Rom[11] for reducing nitro compounds. A mixture of 5 g. of benzophenone-anil and 1.8 g. of magnesium ribbon in 80 cc. of methyl alcohol was warmed until all of the metal had dissolved and the solution was colorless. Addition of dilute acetic acid caused precipitation of the benzohydryl-aniline.

The benzohydryl-aniline was further identified by rearranging it to *p*-aminotriphenylmethane.[12] We found that a few minutes of heating with aniline hydrochloride sufficed for complete rearrangement. One gram of benzohydryl-aniline was heated with a gram of aniline hydrochloride in 2 cc. of aniline at 180° for five minutes. The cooled mixture was shaken with 30% acetic acid in order to remove aniline and its salt, and the *p*-aminotriphenylmethane was filtered off; yield 72%, m. p. 84°. The product was

---

identical with *p*-aminotriphenylmethane prepared by reduction of *p*-nitrotriphenylmethane.[12]

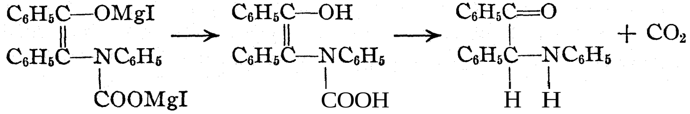
Reduction of Fluorenone-anit.—A mixture of 5.10 g. of fluorenone-anil, 6.6 g. of magnesium iodide and a magnesium rod in GO cc. of ether–benzene (1:2) was shaken for several days. As the reaction proceeded, the orange-red solution became dark green in color and a precipitate appeared. This green product is probably a complex formed from unchanged fluorenone-anil and the fully reduced product. Further shaking changed the mixture color to a bright scarlet; loss in magnesium, 0.485 g., or 100% of the theoretical value. Hydrolysis gave 9-fluorenyl-aniline. By recrystallization from a mixture of acetone and methyl alcohol, it was obtained in the form of needle-like prisms melting at 121–123°; yield, 83%. Staudinger and Gaule[13] report the value 121° and Schlenk[14] gives 124° for the melting point of 9-fluorenyl-aniline.

Reduction of Benzil-anil.—Addition of 10 g. of benzil-anil to a solution of magnesium iodide gave a dark red solution which quickly deposited a large amount of a complex in the form of orange-red crystals. After one and one-half hours of shaking with a rod of magnesium, the crystalline complex had completely disappeared and the solution was opaque reddish-brown in color. After six hours of shaking the solution was transparent yellow in color: loss in magnesium, 0.86 g.; calcd., 0.85 g. Hydrolysis was carried out in an atmosphere of carbon dioxide in order to avoid oxidation of the reduction product, and there was obtained 8.0 g. (80% yield) of anilbenzoin[15] (desylaniline), $C_6H_5CH(NHC_6H_5)CO(C_6H_5)$; after recrystallization from alcohol, the anilbenzoin melted at 97–98" and was identical with the product prepared from benzoin and aniline. Prior to hydrolysis, the reduction product did not react with phenylmagnesium bromide, indicating the absence of a free C=O group (see I, equation 4); after hydrolysis the anilbenzoin reacted readily with the Grignard reagent.

Reaction of the Reduction Product with Iodine and with Oxygen (Equation 5).—The calculated amount of iodine (2.54 g.) was added to the reduction mixture which had been prepared from 2 85 g. of benzil-anil. A considerable amount of heat was developed in the reaction that took place, and the solution became opaque reddish-brown in color. A large amount of the complex of benzil-anil and magnesium iodide precipitated. Hydrolysis gave 2.50 g. (88%) of benzil-anil.

In another experiment, dry air was passed into the transparent yellow reduction mixture obtained from 2.85 g. of benzil-anil. The solution became opaque reddish-brown and finally transparent red in color. Hydrolysis, after passing in air for four hours, gave 2.45 g. (86%) of benzil-anil.

Reaction with Carbon Dioxide.—Carbon dioxide was passed into the reduction mixture which had been prepared from 5.0 g. of benzil-anil. Within ten minutes glistening, granular crystals of the salt of the N-carboxylic acid (equation 6) appeared. After three hours the crystals were filtered off, washed with ether and dried. When this salt was treated with dilute acetic acid, carbon dioxide was evolved (collected in barium hydroxide solution) and the solid that remained was found to be pure anilbenzoin; weight, 3.6 g. (71%). The reactions that take place are undoubtedly the following



$$\begin{array}{l} C_6H_5C{-}OMgI \\ \quad\| \\ C_6H_5C{-}NC_6H_5 \\ \quad | \\ \quad COOMgI \end{array} \longrightarrow \begin{array}{l} C_6H_5C{-}OH \\ \quad\| \\ C_6H_5C{-}NC_6H_5 \\ \quad | \\ \quad COOH \end{array} \longrightarrow \begin{array}{l} C_6H_5C{=}O \\ \quad | \\ C_6H_5C{-}NC_6H_5 \\ \quad |\quad | \\ \quad H\quad H \end{array} + CO_2 \qquad (7)$$

Summary

Benzalaniline is reduced by a mixture of magnesium and magnesium iodide to the iodomagnesium derivative of dianilino-dibenzyl.

Benzophenone-anil is reduced by the binary system to the iodomagnesium derivative of N-benzohydrylaniline.

Benzil-anil takes up two MgI groups to give a stilbene derivative which is very reactive to iodine, oxygen and carbon dioxide. Hydrolysis of the reduction product yields anilbenzoin.

The results of this investigation substantiate the hypothesis that the active reducing agent is MgI.[16]

THE ACTIVATION OF ERGOSTEROL WITH RADIUM EMANATION

BY RICHARD B. MOORE[1] AND THOS. DEVRIES

RECEIVED APRIL 13, 1931 PUBLISHED JULY 8, 1931

Introduction

The existence of an antirachitic vitamin (D) has been recognized for some time. Recently, however, it has become possible to prepare an antirachitic substance by "irradiative" or "activating" ergosterol with ultraviolet radiation. Such a product is called viosterol and is considered by some to be vitamin D.

To Huldschinsky[2] perhaps should go the credit for first using ultraviolet light on children afflicted with rickets. Two years later in 1924, Steenbock reported on his work[3] with rats cured by the use of activated cholesterol. He took out patents that same year. The high-speed electrons from a Coolidge tube have been used by Knudsen.[4] He and C. N. Moore activated cholesterol in a few minutes with 200,000 volt electrons, such that 0.0050 g. per day was the minimum dosage required to cure rachitic rats, whereas 0.00002 was the minimum dosage using ultraviolet activated cholesterol.

The activation of cholesterol or ergosterol with radium has not been

---

[16] In a recent article [*Z. physik. Chem.*, *153*, 83 (1931)], Sven Bodforss reports results obtained from a study of magnesium potentials in aqueous salt solutions, which are best explained by considering that magnesium metal can send into solution univalent ions, Mg^+.

reported. Chick and Tazellar[5] used radium emanation in a study of vitamin A deficiency in rats. Their results were negative. Kofman and Chizet[6] demonstrated that radium emanation through x-rays made sterols photoactive even as ultraviolet had done.

In this investigation ergosterol was activated with radium emanation and the results as given below show that a reasonably active viosterol can so be produced.

Experimental Methods and Results

Reasonably pure ergosterol was activated with radium emanation on four different occasions under different experimental conditions and with two varieties of ergosterol. The one sample, prepared at the Eli Lilly Laboratories, had *a* melting point of 148°, and a specific rotation of −100° in chloroform solution. The other sample, sent from Germany by C. H. Boehringer Sohn, had a more crystalline appearance, a melting point of 157" and a specific rotation of −121° in chloroform.

The activated samples were tested on white rachitic rats by C. R. Eckler of the Eli Lilly Laboratories under the direction of Mr. H. W. Rhodehamel. A modification of the line test[7] was employed for the determination of the antirachitic potency. The extent of healing is designated in the tables by the following notation:

– – – – no healing
+ – – – very slight healing
+ – – slight healing
+ – healing (calcification line not continuous)
\+ healing (calcification line continuous)
++ moderate healing
+++ marked healing
++++ complete healing

There is also included in the tabulation of results a quantity called "millicurie hours per cubic centimeter" (mch/V) which is a measure of the concentration of radium emanation multiplied by the time of its action on the ergosterol and is therefore a measure of the amount of radiation to which different samples were exposed and so can be used in the comparison of samples. The quantity millicurie hours is given by the definite integral

$$mch = \int_{t_1}^{t_2} Q\,dt \qquad (1)$$

where

$$Q = Q_0 e^{-kt} \qquad (2)$$

which is the radioactivity decay formula. If the units of time are in hours or days, the relations become

$$\log Q = \log Q_0 - 0.00326\, t \text{ (hours)} \qquad (3)$$

$$\log Q = \log Q_0 - 0.0782\, t \text{ (days)} \qquad (4)$$

$$mch = 133.2\,(Q - Q_0) \qquad (5)$$

[7] Bills, J. *Biol. Chem.*, **51,** 41 (1922).

In each of the four series, the radium emanation was mixed with air in a Ramsay style gas buret over mercury and admitted to the evacuated tube containing a known amount of ergosterol. In Series I, approximately one gram of the Eli Lilly sample was placed in each of three tubes, with stopcocks attached. Each tube had a volume of about 15 cc. About 0.2, 0.3 and 0.5 of 60 millicuries of radium emanation was admitted to each tube, and left in contact for three and one-half, eighteen and seventy-two hours and labeled as R-1, R-2 and R-3, respectively. At the end of seventy-two hours there was no visible sign of decomposition except a pale yellow color. The results given in Table I show that for a 0.0001 g. dosage, 20 millicurie hours per cc. is sufficient to activate ergosterol. For a 0.00001 g. dosage it is necessary to submit it to about 100 mch per cc.

Sample R-3 was retested after three months and also after five months, at which time the results were practically identical. This would indicate that the activated samples were permanent.

TABLE I

AMOUNT OF IRRADIATION AND EXTENT OF HEALING FOR SAMPLES OF SERIES I

$Q_0 = 12$, 18 or 30 millicuries, respectively. Vol. of containers, 15 cc.

Sample no.	Withdrawn after	*mch/V*	*Dosage* in grams *per* day				
			0.0002	0 0001	0.00001	0.000001	0.0000001
R-1	3.5 hours	2.7	(2) ++ (3) +− (1) −	lost weight	died	−	
R-2	18 hours	20.2	(6) ++	++	−	−	
R-3	72 hours	110.1	(8) +++ (2) ++	++	++	+−−	
Ultraviolet treated					(6) +++	(2) +++ (1) ++	+−−

The numbers in parentheses indicate number of rats giving the indicated results. No figure means only one rat used.

Series 11.—The second set of samples was prepared with the purpose of determining whether prolonged radiation would modify the antirachitic properties of the ergosterol. For this experiment, 114 millicuries of emanation was available and after mixing with air in the usual way, it was placed with 7 g. of ergosterol in a 30-cc. tube, fitted at one end with a rubber tube (one end closed) and a pinch clamp, so that samples could be withdrawn without loss of emanation or admitting any undue amount of air. Five samples were withdrawn, the first after seventeen hours, the last after having been in contact with the emanation for two hundred eleven hours. The results (see Table II) substantiated those of the first series. The lowest radiation this time was 50 mch per cc., and was more than sufficient to activate lor dosages of 0.0001 g. For dosages of 0.00001 g. per day, more than 100 units of radiation were required. The results also indicated that there was no noticeable deleterious effect due to the prolonged irradiation; in fact, such samples were more efficient, as shown by the results when dosages of 0.000001 g. were used.

The result for X-5 with the 0.000001 g. dose was perhaps not as conclusive as might be desired. The rat which gave this negative result seemed to be a poorer specimen than usual.

Series III.—The third series of samples was prepared using the ergosterol prepared by Boehringer Sohn in Germany. It was also our belief that the active rays from the emanation did not penetrate very deeply into the ergosterol, so that by crushing the material, fresh surfaces would be exposed to the rays and so increase the potency of the product. For the latter a specially designed Pyrex tube, filled half full with glass rods, was constantly rotated at the rate of twelve revolutions per minute. The effective volume of this apparatus was 56 cc. About 4 g. of ergosterol was put in with 31 millicuries of emanation. As a comparison experiment with Series I and II, about 2 g. of the German ergosterol was placed in the 30-cc. tube used for Series II with 16 millicuries of emanation. (The emanation was first mixed with air and this mixture subdivided itself between the two containers in the ratio of their volumes.)

It should be mentioned that Sample R-19 was the ergosterol which had caked on the inside of the rod mill and was dissolved out with alcohol. Upon evaporation of the solvent, there was evidence that organic decomposition products were present. There was only a small amount of yellow product at the crystallizing edge, however.

In Table **3A** are listed the results for the control samples and in 3B the results for the stirred samples.

Series IV.—The fourth series of samples was prepared to obtain a check on the previous results and to compare the efficiency of stirring with Eli Lilly product in place of the German material.

The samples were activated in substantially the same way as in Series III. A smaller rod mill was made, with 23-cc. capacity. The A-1 to A-7 samples were prepared in it. The B-1 to B-7 samples were activated in the 30-cc. tube used previously. At the start 120 millicuries of emanation

TABLE IV (Concluded)

B—Lilly ergosterol, stirred

Q_0 = 50 millicuries. Vol. of apparatus, 23 cc.

Sample no.	Withdrawn after	mch/V	Dosage in grams per day 0 0001	0 00001	0 000001	0 0000001
A-1	23 minutes	1.0	(2) –			
A-2	65 minutes	3 0	(2) –			
A-3	160 minutes	7 5	(1) –			
A-4	330 minutes	15	(2) +–		(1) –	
A-5	15.7 hours	42	(2) ++		(2) –	
A-6	39.5 hours	96		(2) ++	(2) –	
A-7	184.0 hours	280		(2) ++	(2) +–––	(2) –

The results of previous series were well confirmed (see Tables IVA and IVB) although the results with 0.0001 g. doses seem to indicate that the German product activates slightly faster, being capable of producing moderate healing after 10 mch per cc. of radiation, while the Eli Lilly ergosterol required 40 units of radiation. At TO, both gave results of "marked healing." The 0.00001 dosage also indicated that the German product had only a slightly higher degree of potency.

Acknowledgment.—The authors wish to express their gratitude to Dr. S. C. Lind and to Dr. C. F. Burnam who were so generous in donating the radium emanation, and to Mr. H. W. Rhodehamel of the Eli Lilly Laboratories for his generous advice, cooperation and experimental aid with the rat-feeding experiments.

Summary

1. Ergosterol can be activated with radium emanation to a degree of potency perhaps 0.01 of that of a good grade of ultraviolet irradiated ergosterol.

2. Stirring the sample while under the influence of the emanation increases the speed of activation but does not increase the potency appreciably.

3. There is no appreciable loss in potency if the activation is carried on to even as much as a twenty-fold excess. There are some decomposition products formed in all cases.

THE SULFUR DERIVATIVES OF THE SIMPLE AMINES. I. AMINE HYDROSULFIDES[1]

BY MARVIN ACHTERHOF,[2] ROLLIN F. CONAWAY[2] AND CECIL E. BOORD

RECEIVED APRIL 15, 1931 PUBLISHED JULY 8, 1931

During the preparation of the polysulfides of certain organic bases it was noted that a white crystalline deposit was formed in the upper part of the reaction chamber and in the inner tube of the condenser. Since, under the conditions of the experiment, the principal constituents of the vapor phase were free amine and hydrogen sulfide, it seemed probable this deposit was the amine hydrosulfide. An examination of the literature revealed the fact that the hydrosulfides of the simple amines have not been definitely described.

As some of our more prominent theories on the mechanism of the activation of sulfur[3] assume the formation of amine hydrosulfides and polysulfides, it has seemed altogether worth while to examine more carefully into the nature of these products.

Very early in the history of amines Wurtz[4] observed a reaction between ethylamine and hydrogen sulfide when the two gases were brought together in a reaction chamber immersed in an ice-bath. The product was a white crystalline compound which soon turned yellow but no analysis or other descriptive details were given. Isambert[5] in his vapor pressure studies measured the vapor pressure of ethylamine and diethylamine sulfhydrates but did not separate the free compounds. Kindler[6] has assumed the formation of dimethylamine hydrosulfide and attributed to it the function of a catalyst in the addition of hydrogen sulfide to benzonitrile. Peters,[7] on the other hand, has studied the action of hydrogen sulfide upon several simple amines at the temperature of the carbon dioxide-ether bath. He concluded that under these conditions the normal sulfides were formed. The products were obtained as white crystalline powders all decomposing below 0°.

Bineau[8] more than ninety years ago studied the interaction of ammonia and hydrogen sulfide by volume. He came to the conclusion that the

normal sulfide is stable only at very low temperatures, the usual form of the salt being the hydrosulfide. The work of Bloxam[9] on ammonium hydrosulfides, sulfides and polysulfides is almost the only detailed study in the field. Although Bloxam obtained many of the sulfides of ammonium in the solid state, his reactions and analyses were almost wholly made on aqueous solutions. Ammonium hydrosulfide was obtained in colorless needles and scales but chiefly as a porcelain-like deposit by leading ammonia and hydrogen sulfide simultaneously into a bottle cooled with ice. The preparation of the pure hydrosulfide was found to depend upon having the hydrogen sulfide always in excess.

Using a procedure somewhat analogous to that of Wurtz, Peters and Bloxam, the hydrosulfides of twelve of the simple amines have been prepared. The successful preparation of these products may be accomplished by bringing together the dry, free amine and an excess of dry hydrogen sulfide at a temperature below 0°, and in the complete absence of air. The formation, filtering, washing and drying must be done in an atmosphere of hydrogen sulfide.

The solid amine hydrosulfides are rapidly decomposed on exposure to air. Those of low molecular weight show an appreciable vapor pressure of free amine and hydrogen sulfide, but the chief cause of their instability arises from a rapid decomposition by oxidation. The hydrosulfides of the more volatile amines are spontaneously oxidized with an almost quantitative deposition of free sulfur. Those of the less volatile amines are oxidized under the same conditions to give large yields of the corresponding thiosulfate. All of these changes occur without the product taking on a color deeper than the tinge of yellow characteristic of free sulfur.

In the light of the above facts it would seem necessary to adopt a mechanism for the oxidation of these solid hydrosulfides different from that used by Bloxam in explaining the transformations characteristic of ammonium hydrosulfide in aqueous solution. He says: "These changes may be explained as follows. In the first stage, polysulfide alone is formed. . . . At the surface of the liquid some of the aqueous solution of ammonium hydrosulfide is resolved into ammonia, water and hydrogen sulfide, the latter undergoing oxidation and yielding water and sulfur. This sulfur then acts on ammonium hydrosulfide forming polysulfide. . . . There is not the slightest ground for supposing ammonium disulfide to be formed.

"In the second stage, the polysulfides are acted on by oxygen, sulfur being liberated.

$$(NH_4)SS_x + O = 2NH_3 + H_2O + S,S_x$$

"In the third stage, the sulfur acts upon ammonia as follows

$$4NH_3 + 4H_2O + S_3 = (NH_4)_2SO_3 + 2NH_4SH + H_2O$$

resulting in the production of ammonium sulfite and hydrosulfide.

---

[9] Bloxam, *J. Chem. Soc.*, 67, 277 (1895); 77, 753 (1900).

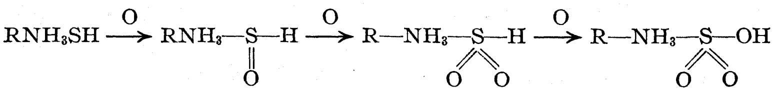
"In the fourth stage it will be observed that there are now two modes in which sulfur may combine, namely, by union with ammonium sulfite, thereby transforming it into thiosulfate or by acting on ammonium hydrosulfide whereby more polysulfide is formed."

It is true that stages (I) and (II) would account for the quantitative deposition of sulfur by the oxidation of the lower amine hydrosulfides except for the fact that the mechanism requires the intermediate formation of the polysulfide. This seems a doubtful explanation in view of the fact that the product during these changes never takes on a color deeper than a faint yellow.

The mechanism indicated is objectional also from another point of view. Bloxam assumes a dissociation of the hydrosulfide previous to any oxidation. In solution this assumption offers no difficulty. But for the solid hydrosulfide such an assumption would mean a dissociation into gaseous amine and hydrogen sulfide. It seems scarcely logical to believe gaseous hydrogen sulfide will oxidize leaving approximately a quantitative deposition of sulfur at the point of generation. Experiment has shown that dimethylamine hydrosulfide is spontaneously oxidized in air with a deposition of more than 97% of its total sulfur.

By the same reasoning the mechanism as given seems inadequate to explain the formation of thiosulfates. It is true the amine hydrosulfides when confined in a closed space, as in the bottom of a test-tube or in a loosely stoppered bottle, decompose slowly with partial liquefaction of the product. Under these conditions the mass takes on the blood-red color indicative of polysulfide formation. But if the solid hydrosulfide is exposed as a mass of loose crystals or spread out in a thin layer, thus insuring a free circulation of air, the oxidation proceeds to the formation of thiosulfate with no evidence of polysulfide formation.

Since the amine hydrosulfides pass through the initial stage of the oxidation previous to dissociation, and since the oxidation can continue to the formation of thiosulfate without the polysulfide stage as an essential step in the process, a mechanism quite analogous to that commonly used to explain the oxidation of mercaptans to sulfonic acids or of thio ethers to sulfones would seem to be applicable to the present case.



$$RNH_3SH \xrightarrow{O} RNH_3{-}\underset{\overset{\|}{O}}{S}{-}H \xrightarrow{O} R{-}NH_3{-}\underset{O\;\;O}{S}{-}H \xrightarrow{O} R{-}NH_3{-}\underset{O\;\;O}{S}{-}OH$$

I II III

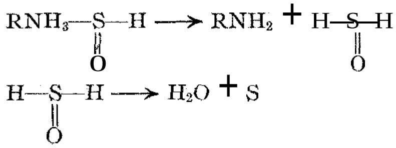
T. M. Lowry[10] has shown that the oxygen acids of sulfur corresponding to I and II must be expected to show marked instability when considered from the standpoint of their electronic structure.

The quantitative deposition of sulfur by the spontaneous oxidation of

---

[10] Lowry, *Trans. Faraday Soc.*, 18,289 (1923).

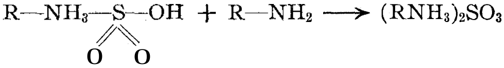
the lower amine hydrosulfides will be sufficiently accounted for by the dissociation of I according to the scheme



$$\text{(a)}\quad RNH_3\text{—}\underset{\underset{O}{\|}}{S}\text{—}H \longrightarrow RNH_2 + H\text{—}\underset{\underset{O}{\|}}{S}\text{—}H$$

$$\text{(b)}\quad H\text{—}\underset{\underset{O}{\|}}{S}\text{—}H \longrightarrow H_2O + S$$

In the case of the hydrosulfides of the less volatile amines the dissociation of I will not be so rapid or if dissociation does take place the dissociation products may remain in juxtaposition for a sufficient length of time for the oxidation to proceed through stage II to III. The bisulfite, III, being more acid in character than I or II, will take up an additional molecule of amine to form the normal sulfite.



$$R\text{—}NH_3\text{—}\underset{O\;\;O}{\underset{/\,\backslash}{S}}\text{—}OH + R\text{—}NH_2 \longrightarrow (RNH_3)_2SO_3$$

The formation of thiosulfate may then be accounted for by the well-known fact that sulfites readily take up free sulfur to form thiosulfates.

$$(RNH_3)_2SO_3 + S \longrightarrow (RNH_3)_2S_2O_3$$

The formation of polysulfides, when the hydrosulfide is permitted to decompose in the presence of a limited quantity of oxygen as in a closed tube or in solution, may be equally well explained if, after the initial stage in the oxidation, "active" (monatomic) sulfur is assumed to play the role of oxygen in the above transformations. From this point of view it would seem the formation of polysulfide and thiosulfate may be regarded as concurrent as well as consecutive phenomena. That the polysulfides of organic bases are spontaneously oxidized by air to thiosulfates is an easily demonstrated fact. The mechanism of this transformation will be discussed in a later communication.

Experimental Part

The successful preparation of the amine hydrosulfides depends upon the entire series of operations being carried out in the absence of oxygen or air. The apparatus shown in Fig. 1 was devised for this purpose. For those amines which are liquid at ordinary temperatures two grams of the anhydrous amine was dissolved in 50 to 60 cc. of anhydrous ether and placed in the separatory funnel, **A.** Hydrogen sulfide, dried over calcium chloride, was passed through the large test-tube, T, until the air had been expelled. The amine solution was then allowed to flow into the reaction chamber, which was immersed in a bath of ice and salt. The passage of the hydrogen sulfide was continued until the deposition of the crystalline hydrosulfide was complete. The wide delivery tube, D, which fitted loosely in the stopper, was then thrust downward into the reaction mixture and the crystalline suspension of the amine hydrosulfide filtered by suction into the Gooch crucible, C. After washing with an additional portion of anhydrous ether, the crystalline product was dried in a current of dry hydrogen sulfide.

For those amines which are gaseous at room temperatures, the amine and hydrogen sulfide gases were admitted simultaneously into the reaction chamber, care being taken to keep the latter always in excess of an equimolecular amount. The hydrosulfide was deposited as an encrusted mass upon the walls of the reaction tube and suspended as feathery crystals. After a suitable deposit had been formed, the passage of the amine vapor was discontinued and 50–60 cc. of anhydrous ether admitted from the funnel A. The feathery crystals were loosened by shaking the tube and the suspension filtered into the crucible and dried as described above. The encrusted mass adhering to the walls of the reaction chamber was dried *in situ*.

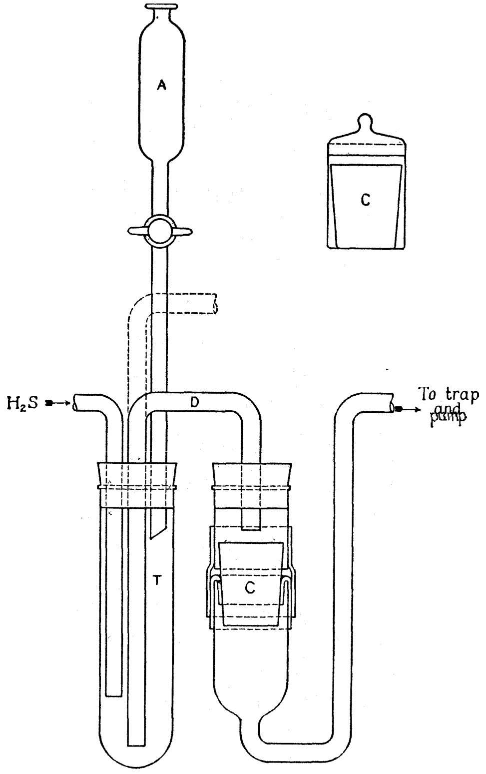


Fig. I.—Apparatus for the preparation of amine hydrosulfides.

The amine hydrosulfides were usually obtained as white needle-shaped crystals, less frequently as clear colorless plates. Melting points taken in an open tube were quite indefinite since the products melted with decomposition over wide ranges of temperature. The molten hydrosulfides decomposed rapidly, with marked ebullition, as the hydrogen sulfide was expelled. Melting points taken in a sealed tube were higher and more clearly defined, but still were not sharp. The crystalline products in sealed tubes frequently sublimed below their melting points. Methylamine hydrosulfide melts at 90–92° in a sealed tube. The melting points of the higher members decrease with increasing carbon content. The hydrosulfide of *n*-butylamine was obtained as a colorless, viscous liquid, which only partially solidified on cooling in a bath of ice and salt. Tri-n-butylamine hydrosulfide could not be induced to crystallize but on the other hand the isoamyl derivative melted at 62–67°.

The rapid decomposition of the amine hydrosulfides upon exposure to air necessitated that for analysis the samples be freshly prepared for each determination. The experimental conditions were set so as to provide a sample of from 0.2–0.5 g. in the crucible C. When the sample was thoroughly dried it was quickly transferred to the weighing bottle, W, and rapidly weighed.

The sulfur determinations were made by oxidizing the hydrosulfides in sodium peroxide solution, acidifying and precipitating as barium sulfate. The nitrogen determinations were for the most part made by the Kjeldahl method but in a few cases it was determined as the amine hydrochloride by adding an excess of hydrochloric acid and evaporating to dryness.

The physical characteristics and analyses of twelve amine hydrosulfides, prepared as described above, are shown in Table I.

TABLE I

THE AMINE HYDROSULFIDES

		Melting point, °C.		Analysis, S, %			Analysis, N, %		
Formula	Crystal form	Open tube	Closed tube	Calcd.	Found		Calcd.	Found

The amine hydrosulfides are readily soluble in water and alcohol but only slightly soluble in ether and benzene. The solubility in water decreases and the stability increases with increasing molecular weight. The freshly prepared water solutions precipitate yellow cadmium sulfide and black lead sulfide from solutions of the respective acetates. The aqueous solutions soon become yellow on standing and will dissolve free sulfur, taking on a blood-red color indicative of the formation of polysulfides.

Oxidation of Dimethylamine Hydrosulfide.—A sample of **0.3418** g. of dimethylamine hydrosulfide was placed on a watch glass and exposed to the air for two days. The residue was dried and weighed. The weight of the residual deposit was **0.1344** g. and an examination showed it to be entirely free sulfur. This yield corresponds to 97.1% of the total sulfur content of the original sample.

Oxidation of Isoamylamine Hydrosulfide. Preparation of Isoamylamine Thiosulfate.—A quantity of the isoamylamine hydrosulfide was exposed to the air for several days. The product took on a slightly yellowish tinge. At no time did the product assume the blood-red color indicative of polysulfide formation. The major product was purified from the small quantity of free sulfur by recrystallization from water. The purified product was crystalline, stable and free from water of crystallization.

Analysis for nitrogen by the Kjeldahl method and titration by standard iodine solution gave the following results. Subs., **0.3000, 0.3000: 10.06, 10.03** cc. of **0.20845** N HCl. Found: N, 9.79, 9.76. Calcd. for $(C_5H_{11}NH_3)_2S_2O_3$: **N, 9.78.** Subs., 0.1000, 0.1000, **0.1000: 34.80, 34.60, 34.62** cc. of $N/100$ iodine. Calcd. for $(C_5H_{11}NH_3)_2S_2O_3$: **34.73 cc.**

Isoamylamine thiosulfate partially sublimes when heated to 176° and melts with decomposition at 192–196°. Its aqueous solution decolorizes permanganate, precipitates sulfur when acidified with hydrochloric acid and gives a white precipitate, which slowly changes through brown to black, when treated with silver nitrate solution. These reactions are characteristic of the thiosulfate ion.

Several residues, formed by the spontaneous oxidation of a number of amine hydrosulfides, had been standing in open tubes for eight months. The residue from *n*-butylamine hydrosulfide was large in comparison with the others at hand. Recrystallization of this product from water yielded a white crystalline compound which began to sublime at 175" and melted with decomposition and charring at 180–193°.

Analysis for nitrogen and titration with standard iodine gave the following results. Subs., 0.3000, 0.3000: 11.23, 11.20 cc. of 0.2485 N HCl. Found: N, 10.93, 10.90. Calcd. for $(C_4H_9NH_3)_2S_2O_3$: N, 10.85. Subs., 0.1000: 38.86 cc. of *N*/100 iodine. Calcd. for $(C_4N_9NH_3)_2S_2O_3$: 38.90 cc.

The residues from n-propyl and methylamine hydrosulfides were extracted with water and the solutions evaporated to dryness. The amount of product in each case was too small to be analyzed quantitatively, but qualitative tests were positive for the thiosulfate ion. The residues from trimethyl and trimethylamine hydrosulfides proved to be entirely free sulfur.

Summary

The hydrosulfides of twelve of the simple amines have been described. These include the hydrosulfides of methyl-, ethyl-, n-propyl-, n-butyl-, *i*-amyl-, dimethyl-, diethyl-, di-*n*-propyl-, di-n-butyl-, dibenzyl-, trimethyl- and triethylamines.

The amine hydrosulfides undergo rapid oxidation upon exposure to air. Those derived from the more volatile amines leave an almost quantitative deposition of sulfur. Those derived from the less volatile amines are oxidized to the corresponding thiosulfates. These oxidation reactions take place without evidence of polysulfide formation. A mechanism is suggested for the oxidation reactions which fully accounts for all the facts observed.

RHODANINES. I. DERIVATIVES OF β-PHENYLETHYLAMINES

BY JOHANNES S. BUCK AND CLIFFORD S. LEONARD

RECEIVED APRIL 15, 1931 PUBLISHED JULY 8, 1931

Apparently no rhodanine derivatives of β-phenylethylamines have been described previously in the literature. The pharmacological properties of such compounds may prove interesting on account of their relation to compounds such as adrenaline, epinine, etc. On the other hand, they also contain the rhodanine (keto-thioketo-thiazolidine) ring, which, when alkylated in the methylene carbon, has been shown by Leonard[1] to possess pharmacological properties of the same type as the barbituric acid derivatives. The compounds described in the present paper contain an unsubstituted or an ether-substituted benzene ring and a non-alkylated

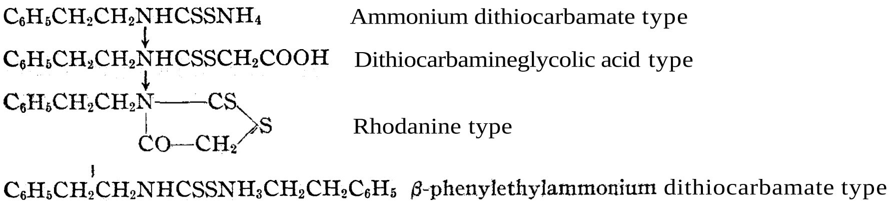
---

[1] Leonard, Medd. Vetenskapsakad. *Nobelinst.*, Bd. 4, No. 14 (1921).

rhodanine ring. On account of their low solubility in water, they would probably not be of practical use in pharmacology. The authors are endeavoring to remedy this defect in solubility by (a) introducing hydroxyl groups in place of the ether groups, and (b) by modifying the rhodanine ring. The introduction of hydroxyl groups into the benzene ring would bring the compounds very close to the chemical type of epinine.

The preparation of the compounds here described is a relatively simple matter. The β-phenylethylamine is condensed with ammonia and carbon bisulfide to the ammonium dithiocarbamate[2] and this is then condensed, by means of potassium chloroacetate, to the dithiocarbamineglycolic acid.[3] This, on warming with dilute acetic acid, gives the rhodanine. The isolation of the dithiocarbamineglycolic acid may be omitted, and the rhodanine obtained directly by heating the dithiocarbamate with potassium chloroacetate, acidified with acetic acid.

Another method is to form the phenylethylammonium dithiocarbamate by treating the amine with carbon bisulfide. On heating this with potassium chloroacetate acidified with acetic acid, the rhodanine is produced. The steps may be shown as follows



$C_6H_5CH_2CH_2NHCSSNH_4$ Ammonium dithiocarbamate type

$\downarrow$

$C_6H_5CH_2CH_2NHCSSCH_2COOH$ Dithiocarbamineglycolic acid type

$\downarrow$

$C_6H_5CH_2CH_2N \begin{matrix} —CS \\ | \\ CO—CH_2 \end{matrix} > S$ Rhodanine type

$\uparrow$

$C_6H_5CH_2CH_2NHCSSNH_3CH_2CH_2C_6H_5$ β-phenylethylammonium dithiocarbamate type

Four series of compounds, derived from β-phenylethylamine, homoanisylamine, homopiperonylamine and homoveratrylamine are described. One compound, the dithiocarbamineglycolic acid from homoveratrylamine, could not be obtained in the pure state, as it spontaneously passes into the rhodanine.

Experimental

Ammonium Dithiocarbamates.—One mole of the amine, dissolved in twice its volume of absolute alcohol, is treated with one mole of ammonia (satd. aqueous soln.). Slightly more than one mole of carbon bisulfide is then slowly added, the mixture being cooled in ice throughout the above operations. After standing for a few hours the solid is filtered off and washed on the filter with alcohol and ether, and is then sufficiently pure. Recrystallization may be carried out by adding ether to a cold alcoholic solution, when the compound is obtained in the form of shiny leaves. Recrystallization, however, is not advisable on account of the instability of the compounds in solution. The yields are good. The ammonium dithiocarbamates are well-crystallized compounds, soluble in the cold in water, alcohol, acetic acid and ammonium hydroxide. They give colorless solutions in cold sulfuric acid, with the exception of the homopiperonyl derivative, which

---

[2] Hann, THIS JOURNAL, 47, 1998 (1925).

[3] Holmberg, *J. prakt. Chem.*, [2] 79, 253 (1909).

gives a deep claret color. The compounds are sparingly soluble in warm chloroform and moderately soluble in warm acetone. On melting, they froth violently.

β-Phenylethylammonium Dithiocarbamates.—The amine, dissolved in twice its volume of absolute alcohol, is cooled in ice, and one-half its volume of carbon bisulfide added slowly, with stirring. After standing for a few hours, the product is filtered off and washed with alcohol and ether and recrystallized by adding ether to the cold alcoholic solution. The compounds form well-defined crystals, soluble in warm water, alcohol, chloroform and acetone and soluble in the cold in acetic acid and in sulfuric acid. Only the homopiperonylamine derivative gives a color with the latter (deep red). The yields are excellent. On melting, pronounced frothing takes place.

Dithiocarbamineglycolic Acids.—The preparation of these compounds is simple. The ammonium dithiocarbamate is dissolved in a little warm water, and treated with a solution of an equal weight of chloroacetic acid which has been accurately neutralized with potassium bicarbonate. A white magma rapidly forms. After one hour the mixture is diluted with water and made slightly acid with acetic acid. The white, crystalline precipitate which forms is filtered off and washed on the filter with water. Although stable when dry, it is not possible to recrystallize the compounds. The dithiocarbamineglycolic acids are fairly soluble in water, the solution decomposing when heated. They are soluble in cold alcohol, acetic acid, ammonium hydroxide and ether and moderately soluble in cold chloroform. With cold concd. sulfuric acid, only the homopiperonyl compound gives a color (deep crimson). All attempts to prepare a homoveratryl derivative resulted in the isolation of products containing the corresponding rhodanine, formed by loss of water and cyclization. On melting, the acids froth violently.

Rhodanines.—The rhodanines are readily obtained by heating an aqueous solution of the ammonium or phenylethylammonium dithiocarbamate with an aqueous solution of potassium chloroacetate, made acid with acetic acid, on the water-bath for thirty minutes. They are also formed by warming the dithiocarbamineglycolic acid with dilute acetic acid. The rhodanines are best recrystallized from alcohol, in which they are moderately or readily soluble when heated. They are practically insoluble in water, very soluble in cold chloroform and acetone, soluble in warm acetic acid and insoluble in ammonium hydroxide. The rhodanines, when pure, are quite stable, but liquors and impure solutions soon develop red colors. For brevity, the individual compounds are tabulated.

Summary

The ammonium dithiocarbamates, phenylethylammonium dithiocarbamates, dithiocarbamineglycolic acids and rhodanines derived from β-phenylethylamine, homoanisylamine, homopiperonylamine and homoveratrylamine are described, together with their preparations.

TUCKAHOE, NEW YORK

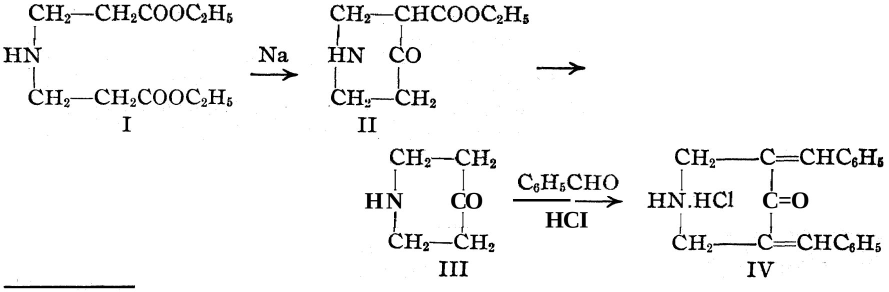
PIPERIDINE DERIVATIVES. XI. 3-CARBETHOXY-4-PIPERIDONE AND 4-PIPERIDONE HYDROCHLORIDE

BY GLEN M. KUETTEL AND S. M. MCELVAIN

RECEIVED APRIL 18, 1931 PUBLISHED JULY 8, 1931

In an effort to prepare 4-piperidone, Ruzicka and Fornasir[1] carried out an internal acetoacetic ester condensation of β,β[1]-dicarbethoxydiethylamine. No attempt was made to isolate the intermediate 3-carbethoxy-4-piperidone. The reaction mixture containing this latter compound was subjected directly to reaction conditions which would bring about its hydrolysis and decarboxylation. The resulting 4-piperidone was not obtained in the form of a crystalline salt and since the free base appeared to be quite unstable it was isolated in the form of the hydrochloride of the dibenzal derivative. These transformations may be illustrated as follows



---

[1] Ruzicka and Fornasir, *Helv. Chim. Acta*, **3,806** (1920).

A considerable number of the 1-alkyl-4-piperidones have been prepared in excellent yields and isolated as crystalline hydrochlorides[2] in this Laboratory from the corresponding 1-alkyl-3-carbethoxy-4-piperidones. These latter compounds were obtained by a condensation similar to that shown above from the β,β'-dicarbethoxy diethyl alkyl amines and were isolated and purified in the form of the hydrochlorides.[3] It seemed quite probable from this work that if the intermediate 3-carbethoxy-4-piperidone (II) could be isolated and purified, the 4-piperidone (III) resulting from its hydrolysis and decarboxylation might be obtained in a useful form as a crystalline salt, since its purification would not be complicated by the association of side-reaction products resulting from the condensation of the β,β'-di-carbethoxydiethylamine (I). The carbethoxy compound (II) would appear to offer better opportunities for purification on account of its amino-β-ketonic ester structure which causes it to be soluble in acids and alkali hydroxides, but not in alkali carbonates. The present paper reports the results of this effort.

The β,β'-dicarbethoxydiethylamine which was used in the condensation was obtained from the hydrochloride which had been carefully purified by recrystallization. Whereas the di-esters of type (I) containing the various alkyl groups attached to the nitrogen instead of hydrogen are condensed by sodium to give 55–75% yields of the corresponding 1-alkyl-3-carbethoxy-4-piperidone, only a 11% yield of (II) was obtained by the condensation of β,β'-dicarbethoxydiethylamine (I). The major portion of the reaction product is a yellow gum which appears to be derived from a further condensation of (II) with itself. The 3-carbethoxy-4-piperidone was easily isolated and purified as the hydrochloride.

The hydrolysis and decarboxylation of (II) in the form of the hydrochloride took place quite readily and a crystalline hydrochloride of the piperidone (III) was obtained. Recrystallization of the latter compound from an alcohol–ether mixture gave an apparently pure product which melted at 138–140°, but gave chlorine analyses which were considerably lower than that calculated for the piperidone hydrochloride (calcd. 26.15% Cl; found, 17.41, 17.45%). All attempts to alter these values by drying the product under diminished pressure were unsuccessful. If this 138–140" melting material were dissolved in water and the solvent then evaporated off under diminished pressure, a product melting at 92–94' and containing 23.00% Cl was obtained. The analyses in the case of the product from the alcohol crystallization correspond to the piperidone hydrochloride with 1.5 C_2H_5OH of crystallization and in the case of the

---

[2] (a) Bolyard and McElvain, THIS JOURNAL, 51, 922 (1929); (b) Bolyard, *ibid.*, 52, 1030 (1930).

[3] McElvain, *ibid.*, 46, 1721 (1924); 48, 2179 (1926); Thayer and McElvain, ibid., 49, 2862 (1927).

water crystallization the analysis corresponds to the piperidone hydrochloride with $1H_2O$ of crystallization.

Similar abnormal analyses were obtained with certain of the 1-alkyl-4-piperidone hydrochlorides.[2] In these cases it was shown that these analyses were of no fundamental significance, since by reduction and benzoylation these 1-alkyl-4-piperidones were converted into the corresponding 1-alkyl-4-benzoyloxypiperidines. In the case of the 4-piperidone hydrochloride obtained in the present work a similar conclusion may be drawn from the fact that it was readily converted into the hydrochloride of the dibenzal-4-piperidone (IV), the structure of which has been established by Ruzicka and Fornasir.[1]

Experimental

All melting points and boiling points herein given are corrected.

β,β'-Dicarbethoxydiethylamine (I).—This compound was prepared by Ruzicka and Fornasir by the action of ethyl β-iodopropionate on ethyl β-aminopropionate and was purified by fractional distillation. The following procedure seems to be simpler and in general much more satisfactory. To a mixture of 308 g. of β-bromopropionic acid ("Organic Syntheses," Vol. III, p. *25)* in 300 cc. of water, was added a suspension of 168 g. of sodium bicarbonate in 500 cc. of water. After complete neutralization and solution, 1100 cc. of ammonium hydroxide (sp. gr. 0.90) was added and the solution allowed to stand in a stoppered bottle at room temperature for four days with occasional stirring. The solution was then evaporated on a steam-bath to a volume of about 600 cc., and made acid to Congo red with dilute hydrochloric acid, using a small excess of the acid. The acidified solution was then evaporated to dryness under diminished pressure. The amino acid hydrochlorides were extracted from the gummy residue by thorough shaking with two 400-cc. portions of alcohol. After the inorganic salt was filtered off, this alcoholic solution was evaporated to dryness under reduced pressure over a steam-bath. The residue obtained after the removal of the alcohol was then esterified by refluxing with 1500 cc. of a 4% solution of dry hydrogen chloride in absolute alcohol for twelve hours. The alcohol was then completely removed under reduced pressure from a steam-bath. The thick residue was poured into a one-liter beaker and allowed to cool to room temperature. The distillation flask was rinsed with 50 cc. of water and the rinsings added, together with 70 g. of ice, to the mixture of the amino acid ester hydrochlorides. The beaker was placed in an ice–salt mixture, 200 cc. of ether was added and the contents stirred until the temperature of the liquid was below 10°. Then 100 cc. of cold concentrated potassium hydroxide solution (45% by weight) was added slowly and with rapid stirring. The temperature of the mixture was kept below 10° during the addition of the alkali. The ether layer, which now had assumed a brownish coloration, was removed and 200 cc. more of ether was added. A 50-cc. portion of the potassium hydroxide solution was then added. The ether layer was separated and the aqueous layer extracted with another 100 cc. of ether. The combined ether extracts were evaporated on a steam-bath and the residue immediately distilled under diminished pressure from an oil-bath.

The distillate was collected in two fractions. The first fraction, consisting of primary and secondary amino esters, distilled from 70–130° (10 mm.) and the second fraction, consisting of comparatively pure β,β'-dicarbethoxydiethylamine, distilled at 130–140" (10 mm.). The first fraction, upon refractionation, yielded a portion of ethyl β-aminopropionate which distilled at 70–80° (10 mm.), and a portion of the secondary amino-ester. The total yield was 15–20 g. (6–8%) of the primary amino ester and 51–57 g. (23–26%) of the β,β'-dicarbethoxydiethylamine fraction.

The secondary amino ester so obtained is best purified by recrystallization of the hydrochloride to constant melting point as described below. The pure β,β'-dicarbethoxydiethylamine is then obtained by the decomposition of the hydrochloride with potassium hydroxide in the manner described above for the liberation of the crude primary and secondary amino esters from their hydrochlorides. The pure β,β'-dicarbethoxydiethylamine boils at 137–138° (12 mm.); n^{25}_{D} 1.43802, d^{20}_{20} 1.0462. A recovery of 88–93% of the free secondary amino ester is possible from its hydrochloride. On account of the fact that the free secondary amino ester slowly undergoes self-condensation it is advisable to keep it as the hydrochloride.

β,β'-Dicarbethoxydiethylamine Hydrochloride.—The secondary amino ester fraction which boiled at 130–140° (10 mm.) was dissolved in 150 cc. of dry ether and any insoluble material filtered off. Dry hydrogen chloride was slowly passed into this ethereal solution. The hydrochloride, which formed readily in white flaky crystals, was filtered and washed several times with small portions of dry ether. These ether washings were similarly treated with hydrogen chloride and a second crop of crystals was obtained. In a like manner a third crop of crystals was obtained but succeeding ether washings and hydrogen chloride treatments yielded only a small amount of an oil that failed to crystallize. The secondary amine hydrochloride, upon first precipitation from the ether solution, must be thoroughly washed with ether, or be immediately recrystallized because the impure ester hydrochloride, upon standing a short time, assumes a reddish coloration that is difficult to remove. The hydrochloride after several recrystallizations from an alcohol–ether mixture melted at 79.5–80.5°.

Anal. Calcd. for $C_{10}H_{20}O_4Cl$: Cl, 14.02. Found: Cl, 13.98, 13.90.

3-Carbethoxy-4-piperidone Hydrochloride (II).—The pure β,β'-dicarbethoxydiethylamine (b. p. 137–138°, 12 mm.) as obtained from the decomposition of its hydrochloride in the manner described above was used in the preparation of the carbethoxypiperidone. To a mixture of 40 cc. of xylene and 3.9 g. of powdered sodium was added 37 g. of the secondary amino ester and the mixture warmed to 85° in an oil-bath until the reaction started. The condensation started in gradually but soon became sufficiently vigorous to cause the xylene to boil. After this initial reaction subsided, the mixture was cooled and treated with 200 cc. of ice water and the xylene extracted with ether. The water layer was made acid with hydrochloric acid and the free carbethoxy-piperidone base liberated with excess potassium carbonate. The free base was immediately extracted with ether and precipitated as its hydrochloride with dry hydrogen chloride. A yield of 4.0 g. (11%) was obtained.

The hydrochloride crystallized in the form of fine white needles and after recrystallization from alcohol-ether mixture melted at 168–169° with decomposition. It produced the characteristic deep red coloration with ferric chloride.

Anal. Calcd. for $C_8H_{14}O_3NCl$: Cl, 17.28. Found: Cl, 17.10, 17.10

The greater portion of the reaction product consisted of a yellow gum insoluble in ether. This was dissolved in alcohol, the alcohol evaporated and the gum dried in a vacuum desiccator over sulfuric acid. It was then dissolved in 20% hydrochloric acid. A drop of the solution produced a distinct coloration with ferric chloride. Evolution of carbon dioxide resulted when this solution was refluxed and after thirty minutes' boiling no coloration was shown by ferric chloride. After removal of the water and excess hydrochloric acid under diminished pressure, an uncrystallizable gum was obtained. The original gummy reaction product appears to be a further condensation product of 3-carbethoxy-4-piperidone.

4-Piperidone Hydrochloride (III).—To 2.33 g. of 3-carbethoxy-4-piperidone was added 80 cc. of 20% hydrochloric acid and the solution refluxed until it showed no coloration with ferric chloride (about thirty minutes). The carbon dioxide which was evolved was carried by a current of carbon dioxide-free air from the reaction flask through a series of drying tubes and absorbed in a weighed ascarite bulb. A yield of 0.4451 g. (90%) of carbon dioxide was obtained. The acid solution was then evaporated to dryness under diminished pressure The resulting solid after recrystallization from an alcohol–ether mixture weighed 1.1 g. and melted at 139–141° with decomposition. After drying at 100° and 10 mm. it was analyzed.

Anal. Calcd. for $C_5H_{10}ONCl$ (4-piperidone hydrochloride): Cl, 26.15; calcd. for $C_5H_{10}ONCl \cdot 1.5C_2H_5OH$: Cl, 17.34. Found: Cl, 17.41, 17.45.

An attempt was made to free the hydrochloride from the associated solvent by recrystallization from other solvents, such as acetone, which have been found (*cf.* Ref. 2b) to give analytically pure piperidone hydrochlorides. These efforts were unsuccessful on account of the insolubility of the hydrochloride in these solvents. However, a solution of the 139–141° melting piperidone hydrochloride in water yielded a product after evaporation to dryness that melted at 92–94°. This product was found to contain 23.00% of chlorine; calcd. for $C_5H_{10}NCl \cdot H_2O$, 23.10.

3,5-Dibenzal-4-piperidone Hydrochloride (IV).—The identity of the 4-piperidone hydrochloride, melting at 138–140°, was established by converting it into the dibenzal-4-piperidone hydrochloride which has been characterized by Ruzicka and Fornasir.[1] A solution of 0.08 g. of the piperidone hydrochloride in 3 cc. of glacial acetic acid saturated with dry hydrogen chloride was treated with 0.15 cc. of benzaldehyde. After standing for twenty-four hours, a mass of yellow needle-like crystals had separated which after decantation of the acetic acid and recrystallization from alcohol weighed 0.069 g. (58%) and melted at 276–277° with decomposition. Ruzicka and Fornasir reported this compound as melting at 275–277°.

Summary

1. The preparation of 3-carbethoxy-4-piperidone hydrochloride and its hydrolysis and decarboxylation to 4-piperidone hydrochloride are described. The latter compound could not be obtained free from solvent used in its recrystallization but was characterized by its conversion into the known dibenzal-4-piperidone hydrochloride.

2. An improved method for the preparation of β,β'-dicarbethoxydiethylamine is given.

MERCURY DERIVATIVES OF CYCLOHEXYL- AND BENZYLPHENOLS[1]

BY JOHN W. HAUGHT,[2] C. E. GARLAND AND H. A. H. PRAY

RECEIVED APRIL 22, 1931 PUBLISHED JULY 8, 1931

Only a few references to the mercuration of compounds similar to the cyclohexyl- and benzylphenols have been found.

Dimroth[3] prepared mercury derivatives of *p*-cresol by heating with alcoholic mercuric acetate at 90° for half an hour. About equal quantities of the mono- and di-mercurated products were formed but the latter, being less soluble, separated out almost pure. The mono-acetoxymercuri-*p*-cresol was rather difficult to crystallize on account of its solubility, so it was precipitated from solution in the form of chloromercuri-p-cresol by the addition of sodium chloride solution. He dissolved chloromercuri-p-cresol in sodium hydroxide and precipitated the anhydride by passing carbon dioxide into the solution. The di-acetoxymercuri-*p*-cresol as crystallized from the reaction mixture contained one molecule of water of crystallization. When the compound was heated to drive off this water it was converted into hydroxymercuriacetoxymercuri-*p*-cresol.

Henry and Sharp[4] have mercurated several alkyl phenols and alkylphenol aldehydes and studied their bactericidal properties. They found that the bactericidal action of organo-mercury compounds was not entirely dependent on the number of mercury groups present, but was largely influenced by the configuration of the organic part of the molecule. They prepared both mono- and di-mercurated derivatives of *p*-tertiary butyl phenol by refluxing the alcoholic solution of the phenol with mercuric acetate dissolved in alcohol containing a small quantity of acetic acid. When this solution was diluted with water the acetoxymercuri compounds were precipitated. The mono- and di-acetoxymercuri compounds were also prepared from *p*-isoamylphenol, carvacrol and thymol. The acetoxymercury groups assumed the ortho position to the hydroxyl group in the mono derivatives and the ortho, ortho prime positions in the di-substituted compounds. These positions were determined by converting the mercury groups to nitro groups by treatment with cold nitric acid.

Mameli[5] found that o-cresol could be mercurated in either hot or cold

[4] Henry and Sharp, J. *Chem. Soc.*, 2432 (1926).

[5] Mameli, Gazz. *chim. ital.*, 56, 948 (1926); *Chem. Abstracts*, 21, 1252 (1927).

alcohol or acetic acid solution. The best results were obtained for mono-acetoxymercuri-o-cresol in cold dilute acetic acid and for di-acetoxymercuri-*o*-cresol in hot dilute acetic acid. Both the mono- and di-acetoxymercuri-o-cresols dissolved in sodium hydroxide, from which mono- and di-chloromercuri-o-cresols were precipitated by the addition of sodium chloride solution.

Either 95% alcohol slightly acidified with acetic acid or glacial acetic acid may be used as a solvent for the mercuration of ortho and para cyclohexyl and benzyl phenols. The acidified alcohol was found to be more satisfactory because there was less coloration of the product in this solvent. If the mercuration was carried out in dilute acetic acid, the product separated on cooling as a sticky mass which could not be crystallized.

The di-acetoxymercuri compounds of both ortho and para cyclohexyl phenol and ortho and para benzylphenol were so soluble in the acidified alcohol that they could not be crystallized from solution even by evaporation to a small volume. They were precipitated by slowly diluting the alcoholic solution with water.

Much difficulty was encountered in freeing these compounds of water. They slowly decomposed at 100° so they were heated for twenty-four hours in an oven at 50° but without effect. They were further heated in a vacuum oven at 60° for twenty-four hours. This treatment removed the water from the mercurated para cyclohexyl and benzyl phenols but not entirely from the similar ortho compounds. This was especially true of the chloromercuri and hydroxymercuri derivatives of ortho benzylphenol.

An effort was made to prepare the anhydromercuri or hydroxymercuri derivatives by treatment of the chloromercuri compounds with hot concentrated sodium carbonate solution but the conversion was not complete. Sodium hydroxide solution was substituted for the sodium carbonate solution and complete conversion resulted.

The hydrogen in the hydroxyl group of the phenols used seems to have only very slight acid properties, because the mercury derivatives of the para cyclohexyl and benzyl phenols were not soluble in sodium hydroxide and the similar derivatives of ortho cyclohexyl and benzyl phenols only slightly soluble. This is in marked contrast to the action of the mercury derivatives of phenol and the cresols.

The acetic acid in the acetoxymercuri derivatives was determined by the method of Brieger and Schulemann, as described by White,[6] which is based on the decomposition of the compound with phosphoric acid in water solution, followed by distillation and titration of the acetic acid. The acetoxy compounds analyzed in this work were so insoluble that it was found necessary to use a larger quantity of phosphoric acid and to collect more of the distillate than indicated by White.

---

[6] White, THIS JOURNAL, **42**, 2355 (1920).

All of the preparations were dissolved for mercury determination by the method described by Hart and Hirschfelder.[7] The mercury was then determined by the method of Jamieson.[8]

The ortho cyclohexylphenol and para cyclohexylphenol used in preparing these mercuration products were supplied through the courtesy of Dr. R. **R.** Read, of Sharp and Dohme, Baltimore, to whom the thanks of the authors are due.

Experimental Part

Di-acetoxymercuri derivatives of cyclohexyl and benzyl phenols were prepared by reacting 0.025 mole of the phenol dissolved in 15 cc. of ethyl alcohol with 0.05 mole of mercuric acetate dissolved in 100 cc. of ethyl alcohol acidified with 5 cc. of glacial acetic acid. The two solutions were mixed and heated on a steam-bath for two hours, after which time the reaction mixture did not give a test for inorganic mercury with sodium hydroxide. The resulting solution was evaporated to a volume of 50 cc. and the mercury derivative either crystallized from this solution or precipitated by dilution with a large volume of water. The precipitate was filtered, washed, dried at 50° and then in a vacuum oven at 60°. The numerical data appear in Table I.

TABLE I

PREPARATION, DATA AND ANALYSES

Compound, -phenol	Yield, %	Dec. at	Formula	Analyses Mercury, % Calcd.	Analyses Mercury, % Found		Analyses OAc, % Calcd.	Analyses OAc, % Found

-*o*-Cyclohexyl-	85	230–235	$C_{12}H_{16}O_3Hg_2 \cdot H_2O$	63.16	62.94	63.16			

Di-chloromercuri derivatives were prepared from the corresponding acetoxymercuri compounds by dissolving them in glacial acetic acid and adding the solution so obtained to a saturated sodium chloride solution. The insoluble di-chloromercuri compounds were precipitated as white powders. These were washed free of sodium chloride and dried in the same way as the acetoxymercuri derivatives. It was not found possible to free the di-chloromercuri-o-benzylphenol of water without decomposi-

[8] Jamieson, *J. Ind. Eng. Chem.*, 11,296 (1919).

tion, so a satisfactory analysis of this material was not obtained and therefore it does not appear in the above table.

Anhydromercuri-hydroxymercuri and di-hydroxymercuri derivatives were obtained by moistening the di-chloromercuri compounds with ethyl alcohol and treating with hot (10%) sodium hydroxide solution. The mixture was filtered and the sodium hydroxide washed from the residue which was dried in a vacuum oven. In the case of the di-hydroxymercuri-o-benzylphenol and the di-hydroxymercuri-o-cyclohexylphenol, it was found necessary to neutralize with dilute hydrochloric acid in order to cause precipitation. Due to the difficulty of drying the former, a satisfactory analysis of this material was not obtained.

Summary

The following ten mercury derivatives of ortho and para cyclohexylphenol and ortho and para benzylphenol have been prepared and analyzed: di-acetoxymercuri-*p*-benzylphenol, di-acetoxymercuri-o-benzylphenol, di-acetoxymercuri-p-cyclohexylphenol, di-acetoxymercuri-o-cyclohexylphenol, di-chloromercuri-*p*-benzylphenol, di-chloromercuri-*p*-cyclohexylphenol, di-chloromercuri-o-cyclohexylphenol, anhydromercuri-hydroxymercuri-p-benzylphenol, di-hydroxymercuri-*p*-cyclohexylphenol, and di-hydroxymercuri-o-cyclohexylphenol.

FORMIC ACID FROM HYDROLYSIS OF CELLULOSE OXALATE[1]

BY JACK P. MONTGOMERY

RECEIVED APRIL 30, 1931 PUBLISHED JULY 8, 1931

One of the usual laboratory methods for making formic acid is to prepare glyceryl mono oxalate, convert it to glyceryl mono formate by heating, and hydrolyze by adding more crystallized oxalic acid, the water of the crystallized acid serving as that required for the hydrolysis. Finally, steam distillation completes the hydrolysis and delivers all the formic acid produced.[2]

It has been found that cellulose in the form of absorbent cotton can be substituted for glycerine with some changes in the technique of the process.

Procedure.—Eighty grams of crystallized oxalic acid, 100 g. of absorbent cotton and 100 cc. of concentrated hydrochloric acid are required. The oxalic acid is melted in its water of crystallization in a 1000-cc. round-bottomed flask over the water-bath and the cotton, torn into small bits, thoroughly shaken with it. The hydrochloric acid is added and the flask

---

[1] Presented before the Division of Cellulose Chemistry of the American Chemical Society at the Indianapolis Meeting, March 30–April 3, 1931.

[2] Cohen, "Practical Organic Chemistry," 3rd ed , The Macmillan Co., Preparation 47, p. 130.

connected for steam distillation in the usual manner, the flask being supported on gauze and tripod and not on the water-bath. Before the admission of steam, the flask is heated by the burner flame and kept boiling until about 50 cc. of distillate is obtained. The distillate is returned to the flask, 100 cc. of water added and the mixture steam distilled until about 150 cc. of distillate is collected.

Lead oxide is added to the distillate in slight excess and the liquid filtered. The filtered liquid is evaporated to small bulk and allowed to crystallize. The yield is 65 g. of lead formate, equivalent to 20 g. of formic acid. If it is assumed that one mole of oxalic acid gives one mole of cellulose mono formate and that the cellulose mono formate is completely converted to formic acid, it follows that one mole of oxalic acid in this procedure should yield, theoretically, a maximum of one mole of formic acid. On this basis 126 g. of crystallized oxalic acid will give 46 g. of formic acid.

$$126 : 46 : : 80 : X$$
$$X = 27.2$$

The theoretical yield of formic acid is therefore 27.2 g. If desired, the formic acid is recovered by dissolving the lead formate, precipitating the lead with hydrogen sulfide and distilling off the formic acid.

THE CHEMISTRY OF ORGANIC GOLD COMPOUNDS. II. THE PREPARATION AND PROPERTIES OF GOLD–CARBON COMPOUNDS OF THE TYPE R_2AuX AND $RAuX_2$[1]

BY M. S. KHARASCH AND H. S. ISBELL[2]

RECEIVED APRIL 30, 1931 PUBLISHED JULY 8, 1931

Introduction

In 1902 Pope and Gibson[3] published a paper on the preparation of diethyl auric bromide and ethyl auric dibromide. Diethyl auric bromide was prepared by the action of ethylmagnesium bromide upon an ethereal solution of auric bromide. Ethyl auric dibromide was prepared by subjecting diethyl auric bromide, dissolved in chloroform, to the action of bromine.

---

[1] Published by permission of the Surgeon-General.

[2] This work, as well as the other papers on organo–gold compounds in this series, was submitted by H. S. Isbell in 1926 to the Graduate School of the University of Maryland in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[3] Pope and Gibson, J. Chem. *Soc.*, 91, 2061 (1902). This early work was recently repeated and confirmed by Gibson and Simonsen (*ibid.*, 2531 (1930)), who prepared, in addition, diethyl gold iodide and diethyl gold acetylacetone.

These ethyl gold compounds are the only ones whose preparation is described in the literature. This fact appears remarkable if one examines the numerous compounds of arsenic, antimony, mercury, lead, tin and the organo-metallic derivatives of other metals which have since been described. The lack of organo-gold compounds is certainly not due to unfamiliarity of the organic chemist with the element, for gold salts have found considerable application in the identification of many organic substances, particularly amines.

In 1926 Feldt reviewed the subject of organic gold compounds. This investigator, whose research in the field of gold chemotherapy covered a period of fifteen years, had evidently overlooked the paper of Pope and Gibson and wrote as follows in the "Klinische Wochenschrift," summarizing his experience in the synthetic preparation of gold carbon compounds. "Organische Goldverbindungen waren nicht bekannt. Gold besitzt keine Verwandschaft zum Kohlenstoff. Komplexe organische Goldverbindungen in denen das Gold unmittelbar am C sitzt, sind nicht existenzfahig, zum mindesten nicht isolierbar. Monatelange dahingehende versuche schlugen daher fehl."[4] (("Organic compounds of gold are unknown. Gold has no affinity for carbon. Complex organic compounds of gold in which the gold is directly attached to carbon are incapable of existence, or at least cannot be isolated. This has been shown by prolonged experimentation.")

The Significance of the Properties of Auric Salts in the Synthesis of Organic Gold Compounds.—The failure to synthesize organic compounds may have been due to a lack of consideration of the following salient facts regarding auric salts: first, the tendency of auric salts to form compounds of the aurate type (i.e., $HAuX_4$); second, the insolubility of auric salts in most organic solvents; third, the interaction of auric salts with solvents that are commonly employed in the Grignard syntheses.

The tendency of auric salts in solution toward compound formation has been known for a long time. Thus it is postulated that if a water solution of gold chloride is acidified with hydrochloric acid, the solution contains hydrochloroauric acid, $HAuCl_4$. Again, when auric chloride is added to a water solution of sodium chloride, the sodium chloroaurate is supposed to be formed. Furthermore, a water solution of sodium chloroaurate contains fewer auric ions than a water solution of auric chloride which presumably exists in the form $H^+(AuCl_3OH)^-$. Whether this difference is merely a common ion effect or the formation of a more stable chloroaurate complex is impossible to determine from the available data, but it can be brought out in a very striking manner by the following experiment. If a water solution of auric chloride is treated with sulfanilic acid, an instant precipitation of gold results. On the other hand, if to

---

[4] *Feldt, Klinische Wochenschrift,* Feb. 19, *1926.*

another sample of the same solution of gold chloride one or two moles of sodium chloride are added, followed by sulfanilic acid, it takes fifteen or more minutes (depending upon the concentration of the solution) before any precipitation of gold becomes noticeable. This experiment indicates that the concentration of auric ion, or the active oxidizing ion, has been suppressed. The change in the intensity of color of a water solution of auric chloride upon addition of sodium chloride is also quite significant.

Naturally it is to be expected that anhydrous gold chloride would also combine readily with many organic substances. The proof of the validity of this statement will be taken up in other papers.[5] For the present, suffice it to say that except for nitrobenzene and aliphatic hydrocarbons, most substances either react or form double compounds with anhydrous auric chloride or bromide. In the case of ether this combination can be illustrated by the following experiment. It was found by us that anhydrous auric chloride, under well controlled conditions, reacts with anhydrous benzene to form phenyl auric dichloride.[5] However, if we suspend the anhydrous auric chloride in anhydrous ether, or some other oxygen-containing substance, or add any of these substances to anhydrous benzene, no phenyl auric dichloride is formed.

With the above facts in mind it is not at all surprising to find that auric chloride does not react smoothly with a Grignard reagent, and that the yields of the gold carbon–compounds are very small.

Criteria Regarding Types of Gold-Carbon Compounds That May Be Prepared by the Grignard Reagent.—The facts cited above are of fundamental importance in interpreting the low yields of gold–carbon compounds by the Grignard reagent. However, in addition to the limiting factors mentioned previously, there are still others of equally vital importance. Our experience regarding these additional limitations of the use of the Grignard reagent in the preparation of organ—gold compounds may be summarized as follows.

(1) Gold–carbon compounds in which the gold is directly attached to three carbon radicals, *i. e.*, AuR_3, cannot be prepared by the Grignard reagent; at least our numerous efforts, under a variety of conditions, with a variety of radicals have been totally unsuccessful. Other indirect methods were also of no avail. We have prepared numerous compounds of the type $R_2Au(CN)$, but do not consider them, in the absence of definite proof, as compounds in which the three valences of the gold are attached directly to the carbon atoms.

(2) There appears to be a definite limitation to the use of the Grignard reagent in that it is impossible (at least we were unable to accomplish the synthesis) to prepare by that method gold-carbon compounds of the

---

[5] Kharasch and Isbell, unpublished work: IV, Direct Auration; III, Gold–Nitrogen Compounds

type R_2AuX, if the radical R is a strongly electronegative radical. This limitation is forced upon us by our laboratory experiences: first, our inability, after many trials and under a variety of experimental conditions, to prepare by the use of the Grignard reagent any gold–carbon compounds of the phenyl radical and those radicals which are above the phenyl radical in the table of electronegativity of radicals[6] (the tolyl, naphthyl, *p*-methoxyphenyl, etc.); second, the successful isolation of the gold-carbon compounds of the ethyl radical and radicals below the ethyl radical in the above-mentioned table.[7] Thus, the gold-carbon compounds of the type R_2AuX of the following radicals were readily prepared: ethyl, n-propyl, isopropyl, n-butyl, isobutyl, isoamyl, cyclohexyl, benzyl and phenylethyl.

That the electronegativity of the radical as a whole is of prime importance in determining whether a stable gold–carbon compound will be formed becomes apparent from the fact that such radicals as benzyl and phenylethyl, although they contain phenyl nuclei, yielded extremely stable gold-carbon compounds. The explanation is that both of these radicals are extremely weak electronegative radicals compared with the phenyl radical and are to be found at the bottom of the table of electronegativity of radicals. The gold compounds of the benzyl and phenylethyl radicals were sufficiently stable to enable us to sulfonate the benzene ring with the aid of fuming sulfuric acid. The table of radicals thus served as an excellent guide in the preparation of gold-carbon compounds, for it enabled us to pick out successfully the range of radicals which yielded stable gold-carbon compounds.

General Properties and Stabilization of Gold–Carbon Compounds.—It has been found feasible to synthesize the compounds of the type R_2AuCl and R_2AuBr by starting with the organomagnesium halide and treating that with the corresponding gold halide. It is to be noted that irrespective of whether one starts with gold chloride and an organomagnesium bromide or gold bromide and an organomagnesium chloride, the bromides of the gold-carbon compounds were formed in each case.

The gold-carbon compounds R_2AuCl or R_2AuBr have characteristic odors, suggestive of pine needles or of bromocamphor. The odors are decidedly nauseating. The gold-carbon compounds are soluble in pyridine, benzene and chloroform, less readily soluble in ether and petroleum ether, difficultly soluble or insoluble in acetone and alcohol and practically insoluble in water. Most of them are somewhat soluble in olive oil. They are all light sensitive and are readily decomposed by heat.

---

[6] Kharasch and Marker, This Journal, 48, 3130 (1926); Kharasch and Flenner (unpublished work); Kharasch and Legault (unpublished work); Kharasch and Pines (unpublished work).

[7] The gap between the phenyl and ethyl radicals still remains to be filled.

The diethyl gold chloride and bromide are well-defined crystalline solids, but as the length of the chain is increased the melting point first decreases to a minimum, while subsequent lengthening of the chain increases the melting points again. In addition to the difficulties involved in the isolation of many of the gold–carbon compounds because of their low melting points, their instability in general was a quite troublesome feature. Thus, most of the compounds R_2AuCl could be kept without decomposition for but a few days—the only compounds which may be kept for some time without appreciable decomposition are those of extremely weakly electronegative radicals, such as the benzyl and cyclohexyl radicals.

Organo–Gold Cyanides.—We were extremely fortunate in that both of the above difficulties, *i. e.*, low melting point and instability, were overcome by the replacement of the halogen by the (CN) radical.[8] This was accomplished by shaking an ether or benzene solution of the compound $R_2AuCl(Br)$ with silver cyanide. An examination of the table reveals the fact that the cyanides have the highest melting points, followed by bromides, and that the chlorides have the lowest melting points. The advantages that accrue from the fact that the decomposition points of the cyanides are so much higher than the chlorides are quite obvious.

TABLE I

STABILITY OF COMPOUNDS OF THE TYPE R_2AuX

	Chloride		Bromide		Cyanide	
Compound	Melts, °C.	Dec., °C.	Melts, °C.	Dec., °C.	Melts, °C.	Dec., °C.
Diethyl	48	48	58	58	92 Slight dec.	92–160 Shows dec.
Di-*n*-propyl	Liq.	107 Gas 120	Liq.	95	84	128–147
Di-isopropyl	Dec.	95 Gas 120	Dec.	100-130	88–90	121–133
Di-n-butyl		.....	Liq.	65	Dec.	125–130
Di-isobutyl		.....	Liq.	.....	112–113	160
Di-isoamyl		.....	Liq.	.....	70	135–140
Dicyclohexyl		180–190 Dec.	148	Dec. 140–148	152, s.d.	155
Dibenzyl	Dec.	70–110	Dec.	77 Detonates 85	Dec.	122
Diphenylethyl		.....	112–115	105–115	.....	.....

Furthermore, the cyanides of most of the compounds can be kept in brown bottles without darkening. The compounds $R_2Au(CN)$ when freshly prepared are soluble in benzene. Many of these compounds, particularly the compounds from the benzyl radical, upon standing for a period of time become insoluble in benzene, although the empirical formula of the compound remains the same.

---

[8] The halogen can evidently be replaced by any negative radical. Thus, shaking the organo–gold bromides with silver sulfate gave the corresponding organo–gold sulfates.

The above-mentioned behavior of the organo–gold halides toward silver cyanide is of considerable interest if one bears in mind that auric chloride reacts with silver salts to give compounds of the chloroaurate type. The tendency toward formation of chloroaurate complexes is entirely absent under anhydrous conditions in the organic gold compounds of the type R_2AuX. However, they still form complexes with various nitrogenous substances such as pyridine, hexamethylenetetramine, etc.

Organo–Gold Sulfur Compounds.—Very striking also is the behavior of gold-carbon compounds of the type R_2AuX toward thio compounds. Thus it is well known that when an auric salt is treated with a mercaptan, the auric ion is reduced to the aurous state and the mercaptan salt of the aurous compound is formed.

$$AuCl_3 + 3HS{-}R \longrightarrow AuSR + 2RSSR + 3HCl$$

However, when gold is firmly attached to two organic radicals, it is possible to prepare the corresponding sulfur compounds

$$R_2AuX + HSC_6H_4COOH \longrightarrow R_2AuSC_6H_4COOH + HX$$

The mercaptides of these compounds while readily soluble and stable in alcohol are easily hydrolyzed in water containing less than 33% of alcohol.

Behavior of Organo-Gold Compounds toward Reducing Agents.—Gold–carbon compounds of the type R_2AuX are much more stable toward reducing agents than auric salts. Thus, while stannous chloride, sodium hydrosulfide and hydroquinone instantly reduce auric chloride, the organic gold compounds react with these reagents much more slowly. Of interest is the observation that while mercury diphenyl and diethyl when treated with dibenzyl auric bromide precipitate metallic gold, mercury dibenzyl is without any effect on that substance.

Sulfonation of Organo–Gold Compounds.—As previously indicated, the stability of organo–gold compounds toward various chemical agents increased as the electronegativity of the radical attached to the gold decreased. Notable among these properties of gold-carbon compounds of the weakly electronegative radicals is their stability toward acids. Thus, the dibenzyl and diphenylethyl auric salts were readily sulfonated under properly controlled conditions. The type of the inorganic radical X, attached to the molecule R_2AuX, made little difference in the ease of sulfonation, for the chlorides, bromides and cyanides as well as the sulfates were sulfonated by the use of fuming sulfuric acid (25% excess SO_3). It was noticed, however, that in the case of the bromides some free bromine was formed, which caused the decomposition of some of the gold compound. The sulfonated organoauric salts were usually isolated first in the form of their calcium salts. The latter by double decomposition with sodium sulfate were converted into the sodium salts.

The calcium salts of the sulfonated gold compounds are fairly soluble in water and very stable toward reducing agents. Hydroquinone, sodium formate or sodium stannite have no immediate effect, and it is only by prolonged boiling that gold can be detected in the compounds by the above reagents.

Gold–Carbon Compounds of **the Type $RAuBr_2$.**—A number of organo-gold dibromides were prepared by treatment of the compounds R_2AuBr with bromine in chloroform. The benzyl, phenylethyl and cyclohexyl gold dibromides were thus prepared. All of these substances as well as the ethyl compound described by Pope and Gibson[3] were obtained as ruby-red needles.

The organo–gold dibromides are in general much less stable than the di-organo–gold bromides. Thus, while the latter substances are quite stable toward reducing agents, the treatment of the organo-gold dibromides with stannous chloride or hydroquinone leads to the formation of metallic gold in a few minutes, while with sodium hydrosulfite an immediate separation of gold takes place.

Solutions of the organo–gold dibromides in organic solvents such as benzene, chloroform and carbon tetrachloride are intensely colored. Strikingly, however, in solvents which contain unsaturated groups, such as olive oil, oleic acid, methyl cyclohexene, etc., these ruby-red compounds yield colorless solutions. This change in color of the solution is suggestive not of a true solution of the compounds $RAuBr_2$ but rather of an addition to the double bond, yielding substances of the type R_2AuBr.

Experimental Part

The Preparation of Organo–Gold Compounds of the **Type R_2AuX.**—The general method employed for the preparation of organic gold compounds of the type R_2AuX, which gave the most satisfactory results, is given below in detail for the preparation of di-phenylethyl auric bromide. Modifications of this method whenever desirable are indicated under the respective compounds in the main table.

The Preparation **of** Di-phenylethyl Auric Bromide.—An ether solution of phenylethylmagnesium bromide was prepared from 42.8 g. of phenylethyl bromide, 6.6 g. of magnesium turnings and 500 cc. of anhydrous ether. Thirty grams of auric chloride was added to 500 cc. of anhydrous ether which previously had been cooled to −15°. To this latter solution, vigorously stirred with a mechanical stirrer, a filtered solution of the phenylethylmagnesium bromide was added dropwise.

The addition of the Grignard reagent required about fifty minutes. Although the reaction appears to be almost instantaneous, a period of ten minutes was allowed before the addition of about 50 g. of finely crushed ice. The precipitated magnesium hydroxide was dissolved in 500 cc. of 2% acetic acid and after the addition of about 200 cc. of benzene the ether–benzene solution was separated and successively washed with portions of a 5% aqueous sodium bromide solution until all gold was removed from the ether–benzene layer. The use of a dilute sodium bromide solution instead of pure water facilitated the removal of auric bromide from the ether layer. Finally, the ether–benzene solution was washed with distilled water, separated and evaporated to a small volume at room temperature in *vacuo*. Di-phenylethyl auric bromide crystallized on evaporation. The filtrate was diluted with ten volumes of 95% ethyl alcohol, which

precipitated an additional quantity of di-phenylethyl auric bromide. The combined precipitates were crystallized from a chloroform–ligroin mixture.

Di-phenylethyl auric bromide is easily soluble in chloroform and benzene, less soluble in ether, ligroin, and almost insoluble in alcohol. It crystallizes from benzene or chloroform in long, branching needles. In a melting point tube it begins to darken at 105° and melts with decomposition at 112–115°.

Preparatian of Di-phenylethyl Auric Sulfate.—A benzene solution of di-phenylethyl auric bromide was mixed with a large excess of silver sulfate and shaken until a test portion of the filtrate gave a negative test for halogen. The filtrate was evaporated in *vacua.* A white crystalline residue remained which was dried to constant weight in vacuo at 40°.

Anal. Subs., 0.0766: Au, 0.0331. Calcd. for $C_{32}H_{36}Au_2SO_4$: Au, 43.30. Found: Au, 43.21.

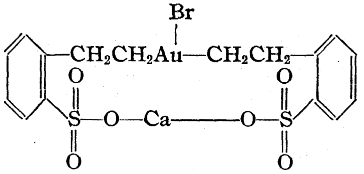
Di-phenylethyl auric sulfate is easily soluble in chloroform, less soluble in benzene, ether and low boiling ligroin and very slightly soluble in ethyl alcohol. It is insoluble in water. In a melting point tube it begins to darken at about 105" and decomposes violently at about 108°.

Sulfonation of Di-phenylethyl Auric Bromide.—To 1.25 g. of di-phenylethyl auric bromide dissolved in 10 cc. of chloroform and cooled to −15°, 6.25 cc. of cold fuming sulfuric acid (25% excess SO_3) was slowly added while the mixture was kept in an ice-salt bath at −15°. After the solutions were thoroughly mixed the temperature was allowed to rise by removing the flask from the ice-bath. The temperature was allowed to rise to about 10°. That the reaction had proceeded to completion was ascertained by the facts that evaporation of a few drops of the chloroform layer did not give a residue of unchanged di-phenylethyl auric bromide and that the acid layer when poured into water gave a clear solution. The mixture was then cooled again to about −10° and slowly poured with stirring into a mixture of 50 g. of crushed ice containing 1.25 g. of calcium bromide. The resulting solution was kept cold and, as soon as possible, neutralized with 25 g. of calcium carbonate. The solid that separated was collected on a small Büchner funnel and washed with a small amount of water. The residue showed only a faint test for gold while the filtrate gave a very strong test.

The filtrate was then mixed with about five volumes of absolute alcohol. A precipitate of calcium sulfate formed which was collected on a filter. The filtrate was then evaporated in vacuo at 20° to a volume of about 10 cc. It was then diluted again with three volumes of absolute alcohol and the small amount of calcium sulfate which formed was collected on a filter. The resulting filtrate was practically free from calcium sulfate and upon the addition of 500 cc. of absolute alcohol a very fine white precipitate separated. After standing overnight in the ice box the precipitate was collected on a filter, washed with alcohol and dried *in vacuo*. The weight of the dry material was 0.84 g.

The compound was further purified by dissolving it in the smallest possible quantity of water and precipitating it by the addition of absolute alcohol. The resulting precipitate was very fine and the solution filtered slowly. It was dried in *vacuo* over phosphorus pentoxide to constant weight.

Anal. Subs., 0.2064: Au, 0.0596; subs., 0.1088: 2.9 cc. of 1.098 *N*/20 KSCN; 0.1511: 4.0 cc. of 1.116 *N*/10 $KMnO_4$. Calcd. for $C_{16}H_{16}O_6S_2CaAuBr$: Au, 28.77: Br, 11.66; Ca, 5.85. Found: Au, 28.88; Br, 11.69; Ca, 5.92. This corresponds to the formula[9]



The calcium salt when heated turns dark and begins to decompose at about 130". It is insoluble in alcohol and organic solvents. It is fairly soluble in water. Strikingly, it is much more soluble in solutions of calcium chloride, bromide or sodium bromide than in pure water, thus recalling to mind the characteristics noted for ammonium succinimide aurate.

A water solution of the calcium salt is not reduced by hydroquinone, stannous chloride or sodium formate, thus indicating an extremely low ionization of the gold from the carbon atoms.

The following points are of importance in the sulfonation of the gold compounds. (1) There was some decomposition of the organo–gold bromide by the fuming sulfuric acid, which resulted in the formation of some free bromine. This bromine decomposed some of the organic gold–carbon compound and led to the formation of some auric bromide. Thus, it would appear that the use of the organ—gold chlorides might be more advantageous than the use of bromides.

(2) Calcium bromide was added to the ice prior to pouring in the sulfonated mixture because it was found that the addition of calcium bromide or chloride at this point prevented the formation of much metallic gold.

(3) The success of the sulfonation depends to a large extent upon the technique. The following additional points are of importance. The period during which the fuming sulfuric acid is allowed to react must be regulated. A few drops of solution may be

---

[9] It is understood, of course, that a molecular weight determination is essential before one could state with certainty that the simple formula given for the calcium salt of the sulfonated di-phenylethyl auric bromide is correct or whether a number of the sulfonated molecules are linked together through the calcium atom.

tested in water or the chloroform layer may be sampled and its residue on evaporation noted.

The concentration of the solution? in vacuo is usually attended with some decomposition unless a low temperature is maintained.

The precipitated calcium salt of the gold compound is very fine and may be best separated by the use of a centrifuge.

Sulfonation of Di-phenylethyl Auric Sulfate.—One gram of di-phenylethyl auric sulfate was gradually stirred into 4 cc. of fuming sulfuric acid (25% excess SO_3) kept at −15". After thorough mixing, the temperature was allowed to rise to about 15°, when the di-phenylethyl auric sulfate seemed to be completely in solution. The mixture was then cooled to −10° and poured on 50 g, of finely crushed ice. A nearly clear solution resulted. The acid was neutralized by adding calcium carbonate. The calcium sulfate and excess calcium carbonate was collected on a filter and the filtrate poured into 15 volumes of absolute alcohol. A flocculent precipitate resulted which consisted of the calcium salt of the sulfonated organic gold compound and a small amount of calcium sulfate. The precipitate was collected upon a filter. As the filtrate contained only a trace of gold, it was discarded. The precipitate was extracted with a few cc. of water. The gold compound went into solution leaving an insoluble residue of calcium sulfate. The water solution of the calcium salt of the sulfonated di-phenylethyl auric sulfate was poured into ten volumes of absolute alcohol. A very fine white precipitate resulted which was collected on a filter.

The compound corresponded in properties to that obtained by the sulfonation of the di-phenylethyl auric bromide. Thus it did not give the usual gold test with stannous chloride or hydroquinone but after decomposition by either heat or bromine a strong test for gold was obtained. Qualitative tests for calcium and sulfate ion were also obtained. The compound was water soluble.

Dibenzyl auric chloride and dibenzyl auric cyanide were also sulfonated in a manner similar to the di-phenylethyl auric bromide. The reaction proceeded smoothly and a solution was obtained which was not reduced by hydroquinone and exhibited similar properties to the corresponding di-phenylethyl gold compounds.

Organo–Gold Sulfides

The Preparation of **Dicyclohexyl** Auric **Thiosalicylate.**—A quantity of dicyclohexyl auric chloride (1.9935 g.) was dissolved in 20 cc. of benzene, mixed with 0.7520 g. of thiosalicylic acid dissolved in 30 cc. of ethyl alcohol and the calculated equivalent of an alcoholic solution of potassium hydroxide ($N/2$) necessary to react with the hydrochloric acid formed was added. The mixture was evaporated to dryness and the residue was washed free from chlorides with cold water followed by several washings with cold alcohol. The product was easily and completely soluble in one equivalent of sodium hydroxide dissolved in 50% alcohol, from which it was precipitated by the addition of acid. The product thus obtained was dried to constant weight over phosphorus pentoxide.

Anal. Subs.: 0.1170: Au, 0.0446. Calcd. for $(C_6H_{11})_2AuSC_6H_4COOH$: **Au,** 38.18. Found: Au, 38.12.

The compound decomposed at 173–180°. It is quite stable when kept in brown bottles, as indicated by the fact that even after several months the salt of the compound was still completely soluble in dilute alcohol.

The Preparation of Phenylethyl Auric **Dibromide.**—A chloroform solution of diphenylethyl auric bromide was mixed with a chloroform solution of bromine which contained approximately two equivalents of bromine. Upon spontaneous evaporation of the solvent ruby-red needles which formed in fan-like clusters were obtained. These were washed first with a small quantity of chloroform, then ether, and dried in *vacuo* at 40° to constant weight over phosphorus pentoxide.

Anal. Subs., 0.0542: Au, 0.0231. Calcd. for $C_8H_9AuBr_2$: Au, 42.67. Found: Au, 42.62.

The compound is difficultly soluble in chloroform, almost insoluble in ether, benzene, petroleum ether and water. Phenylethyl auric dibromide decomposes at 150–160°.

Preparation of Ethyl Auric **Dibromide.**—This compound was prepared by the method used by Pope and Gibson. Three grams of di-ethyl auric bromide was dissolved in 25 cc. of chloroform and 1.5 g. of bromine dissolved in 30 cc. of chloroform was added. The mixture was allowed to stand overnight in an open beaker. All of the chloroform had evaporated and a reddish black residue remained. This was extracted successively with 15 cc. of cold chloroform and with five portions of petroleum ether. A quantity of unchanged diethyl auric bromide was thus recovered. The residue was washed with water and finally crystallized from chloroform; 0.95 g. of ethyl auric dibromide was thus obtained. The compound forms red needles difficultly soluble in chloroform and easily soluble in alcohol.

Reactions of Ethyl Auric Dibromide: Behavior with Unsaturated Derivatives.—Solutions of ethyl auric dibromide in all saturated organic solvents are intensely colored. However, solutions of this substance in unsaturated solvents are practically devoid of any color. Thus, the ethyl auric dibromide dissolves to a colorless solution in olive oil, methylcyclohexene, cyclohexene, etc. This phenomenon is probably due to the addition of ethyl auric dibromide to the double bond, giving rise to compounds of the type R_2AuBr which have very little color.

Preparation of Benzyl Auric **Dibromide.**—To 0.202 g. of di-benzyl auric bromide dissolved in 10 cc. of chloroform, 12 cc. of 0.0962 N bromine dissolved in carbon tetrachloride was added. After standing for two days the solvent was evaporated and the residue was washed with water and finally crystallized from chloroform.

Anal. Subs., 0.0745: Au, 0.0327. Calcd. for $C_6H_5CH_2AuBr_2$: Au, 44.01. Found: Au, 43.89.

The compound separates from chloroform in the form of dark needles. It is soluble in acetone and alcohol, imparting to these solvents a yellow color, while red solutions are obtained in chloroform and benzene. The compound is rather insoluble in carbon tetrachloride, petroleum ether and ether. Benzyl auric dibromide decomposes at about 140°. The change in appearance was slight and gradual over a considerable temperature range.

The Preparation **of Cyclohexyl** Auric **Dibromide.**—To 0.9 g. of di-cyclohexyl auric bromide dissolved in 20 cc. of chloroform, 48 cc. of 0.09 N bromine solution in chloroform was added. The mixture was allowed to stand overnight. The residue upon evaporation of the chloroform was washed with water and crystallized from chloroform.

Anal. Subs., 0.1025: Au, 0.0456. Calcd. for $C_6H_{11}AuBr_2$: Au, 44.81. Found: Au, 44.53.

The compound is obtained from chloroform in the form of dark red needles which decompose without melting at 150°. It is soluble in benzene, chloroform and carbon tetrachloride with a red coloration. However, yellow solutions are obtained in alcohol and ethyl acetate. Similar to the ethyl compound, cyclohexyl gold dibromide gives colorless solutions when dissolved in unsaturated solvents, like olive oil or methylcyclohexene.

Summary

1. The limitations of the Grignard reagent in the preparation of gold-carbon compounds, of the type R_2AuX, are discussed.

2. It is pointed out that the table of electronegativity of radicals serves as an excellent guide in the preparation of gold compounds R_2AuX. Thus it has been found that gold compounds of the ethyl radical and all the radicals below the ethyl radical in that table can be readily prepared from the appropriate Grignard reagents and auric chloride. However, no stable gold–carbon compounds R_2AuX of the phenyl radical, or radicals more strongly electronegative than the phenyl radical, can be prepared by that method.

3. The stabilization of gold–carbon compounds R_2AuX through the preparation of the corresponding cyanides is described.

4. It is shown that although no inorganic sulfides of trivalent gold are known, when two of the valences of the gold are attached to organic radicals as in R_2AuX, it is possible to prepare compounds of the type $R_2Au—S—R$. It is further shown that these substances are hydrolyzed in water solution, a behavior characteristic of the amphoteric elements of the third group.

5. The stability toward acids of gold compounds R_2AuX of weakly electronegative radicals is discussed, and the sulfonation of di-phenylethyl auric bromide and di-benzyl auric chloride is described.

6. The gold compounds R_2AuX have been found to be extremely stable toward powerful reducing agents.

7. The preparation of a number of gold compounds $RAuX_2$ is described.

8. It is shown that compounds of the type $RAuX_2$ are extremely unstable toward reducing agents.

9. The fact is emphasized that compounds $RAuX_2$, while insoluble in water, dissolve readily in sodium chloride solution. This fact is explained upon the assumption that complexes of the chloroaurate type are thus formed.

10. It is shown that gold compounds $RAuX_2$ are intensely colored in chloroform solution, but that their colors disappear instantly when substances containing ethylene bonds are added to them. Direct addition of the gold complex to the double bond is postulated.

11. The preparation of a large number of organo-gold compounds is described and their behavior toward many reagents is given.

CHICAGO, ILLINOIS

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE REACTIONS OF ACETALDEHYDE OVER ZINC CHROMITE UNDER A PRESSURE OF 210 ATMOSPHERES

BY HOMER ADKINS, KARL FOLKERS AND MAURICE KINSEY

RECEIVED MAY 1, 1931 PUBLISHED JULY 8, 1931

The formation of esters and the higher alcohols by the hydrogenation of carbon monoxide or from the lower alcohols under similar conditions may well depend upon the behavior of aldehydes which are first formed. It was thus of interest to ascertain the nature and ratio of products formed from acetaldehyde under the experimental conditions used for the reactions referred to above. A rather extensive study of the condensation of acetaldehyde over a zinc chromite catalyst at 360° under a pressure of 200 atmospheres of hydrogen has therefore been made.[1]

The zinc chromite catalyst used in this work was prepared in the same way as has been previously described for copper chromite,[2] except that a mole of zinc nitrate was substituted for a mole of copper nitrate. The general process used in preparing the zinc chromite catalyst was first described by Lazier.[3]

The liquid product from the reactions of acetaldehyde over the zinc chromite catalyst is a mixture of water and saturated and unsaturated alcohols, esters, aldehydes, lactones, hydrocarbons and acids. All attempts to separate this mixture into its components by fractionation were unsuccessful. On this account and because of the tendency for the unsaturated compounds to condense it was necessary to reduce the carbonyl and alkene linkages and to saponify the esters prior to further attempts for the isolation of pure compounds.

All of the significant findings in connection with these attempts to isolate, identify and estimate the products from the condensation of acetaldehyde over a zinc chromite catalyst may be illustrated by describing the results of a single experiment in which the methods used were the resultant of the experience in many similar experiments carried out on a smaller scale. In this experiment a mixture of two parts of acetaldehyde and one part of ethanol was pumped at the rate of 270 cc. per hour over 30 cc. (30 g.) of

---

[1] A paper having to do in part with material herewith presented was published in *Industrial and Engineering Chemistry*, 22, 1046 (1930). The previous paper was prepared as an outline of an oral report given before a symposium at the Cincinnati (1930) meeting of the Society, and was not intended for publication. It was in proof before the authors were aware that it had been submitted to the Editor by the Secretary of the Symposium.

[2] Adkins and Connor, THIS JOURNAL, 53, 1091 (1931).

pellets of zinc chromite in a steel bomb held at 360±5°, under a pressure of 210±10 atmospheres of hydrogen. The apparatus and procedure used for this purpose have been previously described.'

The general scheme followed in working up the reaction product was as follows. The reaction product weighing 4732 g. was fractionated giving fraction A (2941 g.), b. p. from 21 to 85°; fraction B (762 g.), b. p. from 85 to 170°; fraction C (519 g.), b. p. 50–160° (2 mm.); and fraction D (419 g.), which was not distilled. Widmer fractionating columns with glass spirals were used for all fractionations except that a Claisen flask was used in obtaining fraction C. One of the Widmer columns had a spiral 50 cm. in length while the other contained a spiral 15 cm. in length. When necessary the columns were heated externally in a shield containing spirals of nichrome wire.

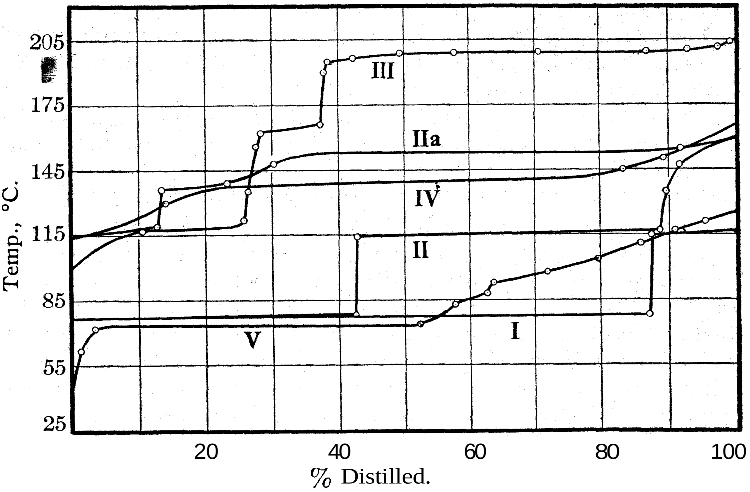

Fig. 1.—Distillation curves obtained in the fractionation of products from the condensation of acetaldehyde.

Fraction A contained 6 millimoles of aldehyde per gram according to the sodium sulfite method of analysis. An aliquot of 260 g. was hydrogenated at 150–175° under a pressure of 150 atmospheres over a nickel catalyst by the method previously described.[4] Six millimoles of hydrogen per gram of fraction A was absorbed and the hydrogenated product contained 1.34 millimoles of ester per gram. The hydrogenated aliquot was saponified and the alcohols dried. These alcohols (203.7 g.) were fractionated with the result shown in Curve I of Fig. 1.

Fraction B was washed with a 5% sodium hydroxide solution in order to remove acids. The neutral compounds were recovered from the wash water by distillation and salting them out from the distillate. The neutral compounds so obtained were returned to fraction B which was hydrogenated after being partially dried over magnesium sulfate. The hydrogen absorption was 6.7 millimoles per gram and the ester content was

---

[4] Adkins and Cramer, This Journal, 52, 4349 (1930).

2.23 millimoles per gram. The fraction was then saponified and 246.7 g. of neutral compounds obtained. The fractionation of 211 g. of this material is shown in Curve II, there being a residue of 35.7 g. The portion boiling at 117–160° was refractionated as shown in Curve IIa. The acids originally washed out of fraction B were added to the acids obtained from the saponification and after drying over magnesium sulfate 117.6 g. of acids was obtained. The fractionation of 104.8 g. of acids is shown in Curve III, there being 12.8 g. of residue.

Fraction C upon hydrogenation absorbed 7.6 millimoles of hydrogen per gram. It had an average molecular weight of 195 as determined by the depression of the freezing point of benzene and contained 0.5 millimole of acids, 2.9 millimoles of esters and 1.3 millimoles of alcohols per gram. This latter value was calculated from the saponification value of the fraction as compared with the value after it had been acetylated through the use of acetic anhydride. Fraction C after hydrogenation was saponified and there was obtained after drying 237.7 g. of neutral compounds, and 112 g. of acids. The fractionation of 24 2 g. of the neutral compounds is shown in Curve IV of Fig. 1. The residue weighed 213.4 g. Ninety per cent. of the acids was taken for fractionation at 3 mm. Forty-six grams distilled as shown in Curve V, leaving a residue of 54.7 g.

The Identification of Products.—Curve I. This fraction was made up exclusively of ethanol and n-butanol, which were identified by the boiling points and by the preparation of the 3,5-dinitrobenzoates.

Curve *II*. The fractions boiling 77–78° and 115–116° were identified as ethanol and butanol as above. The fraction 117–160" was a mixture of butanol and hexanol which were refractionated as indicated below.

Curve *IIa*. The fraction 115–119° was butanol and that from 136–148° contained p-xylene and is referred to again under Curve IV. The main portion of this fraction (b. p. 148–154°) was identified as n-hexanol by comparing the melting point of its 3,5-dinitrobenzoate with that from an authentic sample of n-hexanol.

Curve *III*. The lower fraction was acetic acid, the middle one was butyric acid and the highest and chief fraction was caproic acid. These were identified by their boiling points and also by the preparation of the *p*-toluidide of acetic acid and *p*-bromoanilides of butyric and caproic acids, and the determination of mixed melting points with authentic specimens. However, the caproic acid was not pure, since a 1.000-g. sample at 25° required 8.26 ml. of 1 N alkali for its neutralization but when refluxed with an excess of alcoholic alkali 8.63 ml. of alkali reacted. From these data it may be calculated that the sample was 95.8% caproic acid and 4.2% *a* lactone having a saponification equivalent of 113.3. This value is almost identical (114) with that for caprolactone. The caproic acid fraction was shown to contain none of the isomeric diethylacetic acid by the following experiment. The p-bromoanilide of caproic acid, m. p. 103–104°, was obtained in a 60% yield from a sample of caproic acid of known purity, while a 61% yield of the derivative of m. p. 104–105° was obtained from the sample of acid referred to above. Recrystallization of these two preparations of the p-bromoanilide of caproic acid raised the melting points to 105–105.5° and reduced the yields to 55 and 58%, respectively.

Curve *IV*. The lower-boiling portions of this material was n-butanol while the highest was n-hexanol with perhaps some octyl alcohol. The chief fraction of 136–145° was identical with that indicated on Curve IIa and was shown to be p-xylene. This fraction after treatment with sodium and distillation had the following physical characteristics: b. p. 137–138°, n_{25} 1.4910, d_{25}^{25} 0.8595, mol. wt. by lowering of freezing point of benzene, 105.9, 100.5. The trinitro derivative after two recrystallizations melted at 138–140°, which was not changed when the unknown substance was mixed with the trinitro derivative of an authentic sample of p-xylene supplied by Dr. Carl S. Marvel.

p-Xylene has a molecular weight of 106 and has been described[6] as boiling at 137.5° and as having d_{25}^{25} 0.8593. The trinitro-*p*-xylene is reported to melt at 138.5–139°.[6] The identification of *p*-xylene in the reaction mixture was so unexpected that the whole experiment on the condensation of acetaldehyde was repeated on the same scale as before. *p*-Xylene was again obtained in a similar quantity, so that there can be no doubt as to its formation in these experiments. The fact that *p*-xylene did not undergo hydrogenation when fraction C was subjected to the action of nickel and hydrogen is due no doubt to the effect of water in the reaction mixture inhibiting the hydrogenation of the benzenoid ring.[7]

***Curve** V.* About 79% of the material boiling 72–74° (3 mm.) was caproic acid as identified by its *p*-bromoanilide, mixed melting points being taken.

There remained to be identified the neutral compound boiling above 160" and the acids boiling above 205°. No specific compound except perhaps octyl alcohol has been identified among these mixtures so it is possible only to describe their general character. The neutral compounds boiling above 160° are mixtures of alcohols and hydrocarbons. This is indicated by the fact that the acetylation values are always greater than the average molecular weight as determined cryoscopically. Further, by the treatment of the mixtures with phthalic anhydride a residue was obtained which apparently contained no more than 4% of any alcohol, yet which had a boiling point of 55–75° (8 mm.), approximately the same as the alcohol mixture from which it was separated and an average molecular weight of 144. This residue was not entirely soluble in cold concentrated sulfuric acid. Attempts to separate these inert compounds completely from the alcohols by means of metallic sodium were uniformly unsuccessful. However, an alcohol boiling in the temperature range (190–191.5°) for n-octyl alcohol was obtained by the hydrolysis of the sodium alkoxides so obtained. The 3,5-dinitrobenzoate ester of this alcohol melted 4–7° lower than the ester of an authentic sample of n-octyl alcohol. The saponification equivalent of the acetate of this alcohol indicated a molecular weight of 184 as compared with a value of 172 for octyl acetate. Glycols were apparently absent from the neutral compounds for the saponification equivalent from the acetylated neutral compounds was always considerably more than the average molecular weight as determined by the cryoscopic method. A comparison of acetylation values obtained before and after hydrogenation indicated no increase in hydroxyl groups, so that aldehydes and ketones must have been absent from fraction C.

The acids of fraction C from the saponification of the esters always contained lactones or acyloxy acids after they had been subjected to distillation. This is evidenced by the fact that 25 to 50% more alkali was required for the neutralization of a sample of these fractions at 100" than was required at 25°. Further, .it was found that after acetylation twice as much alkali was required to saponify a fraction at 100° as was required to titrate the sample at 25°.

There are given in Table I the weights of products calculated to be present in the reaction mixture after hydrogenation. For convenience in calculation and tabulation the assumption is made that acetic, butyric and caproic acids were in the form of ethyl esters, while the butyl, hexyl and higher alcohols were present as such. This assumption ignores the fact that in a mixture of acids, esters and alcohols, alcoholysis will occur so

that all possible esters will be formed. The figures in Table I are calculated for the data given in Fig. 1, and elsewhere in this paper.

TABLE I

THE WEIGHT OF THE PRODUCTS (G.) AFTER HYDROGENATION

Ethyl alcohol	1800	Higher alcohols	180
Ethyl alcohol (from acetaldehyde)	593	Inerts (hydrocarbons)	77
Ethyl acetate	420	Ethyl butyrate	17
n-Butyl alcohol	456	Ethyl caproate	143
n-Hexyl alcohol	14	Higher acids and lactones	127
p-Xylene	19	Residue	419

Hypothesis Concerning the Formation of Alcohols and Esters from Acetaldehyde.—We are now in a position to consider the reactions by which alcohols and esters of higher molecular weight may be synthesized from acetaldehyde. The formation of ethyl acetate can hardly be explained except as a result of an autoxidation–reduction reaction (equation I) in which the zinc chromite plays the Same role as the metallic alkoxide in the well-known Tischtschenko reaction.

$$2CH_3CHO = CH_3COOC_2H_5 \qquad (I)$$

The similar autoxidation–reduction of alcohols over oxide catalysts has recently been observed.[8] The formation of butanol and its possible precursors crotonyl alcohol, crotonic aldehyde and butyraldehyde, would result from a combination of the reactions shown in equations II to VIII, inclusive.

$$2CH_3CHO = CH_3CHOHCH_2CHO \qquad (II)$$
$$CH_3CHOHCH_2CHO = CH_3CH{=}CHCHO + H_2O \qquad (III)$$
$$CH_3CH{=}CHCHO + C_2H_5OH = CH_3CH_2CH_2CHO + CH_3CHO \qquad (IV)$$
$$CH_3CH{=}CHCHO + H_2 = CH_3CH{=}CHCH_2OH \qquad (V)$$
$$CH_3CH{=}CHCH_2OH = CH_3CH_2CH_2CHO \qquad (VI)$$
$$CH_3CH_2CH_2CHO + H_2 = CH_3CH_2CH_2CH_2OH \qquad (VII)$$
$$CH_3CH_2CH_2CHO + C_2H_5OH = CH_3CH_2CH_2CH_2OH + CH_3CHO \qquad (VIII)$$

There is no direct evidence that reaction II occurs over oxide catalysts, but the aldol reaction is known to occur under such a wide variety of conditions that its tentative assumption seems justifiable. G. T. Morgan[9] has formulated the formation of the higher alcohols from carbon monoxide as depending upon the aldol reaction. The dehydration of an alcohol (equation III) has long been known to occur over a variety of oxide catalysts. Reaction IV was recently shown to take place over oxide catalysts[10] while reactions V and VII are hydrogenations of a type for which zinc

---

[8] Adkins and Folkers, THIS JOURNAL, 53, 1420 (1931).

[9] Morgan, *Proc. Roy. Soc.* (London), 127A, 247 (1930).

[10] Adkins and Wcston, THIS JOURNAL, 51, 2430 (1929).

chromite is quite active.[11] The occurrence of reaction VI in the case of allyl alcohol was also recently observed.[12]

The formation of small amounts of butyrates (or crotonates) would be expected as the result of a reaction similar to equation I except that butyraldehyde or crotonic aldehyde played the role of acetaldehyde

$$2CH_3CH{=}CHCHO = CH_3CH{=}CHCOOCH_2CH{=}CHCH_3 \qquad (IX)$$

The formation of caproates (or their unsaturated precursors) can hardly occur exclusively as a result of a similar reaction, for the amount of hexyl alcohol in the reaction mixture is very much less than molecularly equivalent to the acid. This is not surprising in view of the great excess of acetaldehyde which would be present at any reaction surface and thus favor a reaction of the type indicated in equation X.

$$CH_3CH{=}CHCH{=}CHCHO + CH_3CHO = CH_3CH{=}CHCH{=}CHCOOC_2H_5 \qquad (X)$$

The formation of the hexadienal represented in equation X would result from a repetition of the aldol reaction followed by dehydration in which crotonaldehyde reacted with acetaldehyde as in equation XI.

$$CH_3CH{=}CHCHO + CH_3CHO = CH_3CH{=}CHCH{=}CHCHO + H_2O \qquad (XI)$$

Hydroxy acids as esters would result if a partly undehydrated aldol would react as in equation XII in a fashion similar to that indicated in equation X.

$$CH_3CHOHCH_2CH{=}CHCHO + CH_3CHO = CH_3CHOHCH_2CH{=}CHCO_2C_2H_5 \qquad (XII)$$

Esters of such hydroxy acids would readily give lactones as indicated in equation XIII.

$$CH_3CHOHCH_2CH{=}CHCO_2C_2H_5 = CH_3\underbrace{CHCH_2CH{=}CHCO}_{O} + C_2H_5OH \qquad (XIII)$$

Morgan in a discussion of the formation of higher alcohols and aldehydes from carbon monoxide and hydrogen states that "the aldolization hypothesis accounts for the products hitherto isolated, but it also postulates the transitory existence of intermediate hydroxyaldehydes and glycols which have not so far been detected." The detection in the present investigation of esters of hydroxy acids which would be derived from such hydroxy aldehydes thus lends strong support to the aldolization hypothesis.

The xylene was chiefly obtained from fraction C of the hydrogenated and saponified reaction mixture which boiled above 170". It could not have been there as such because its boiling range (136–139°) is too low and *n*-hexanol, which boils higher (151–154°), was readily obtained from the fraction B boiling below 170". That it was chiefly formed during the distillation of fraction C is further evidenced by the fact that water, which was not originally present in the mixture undergoing distillation, appeared

in the distillate. It is probable then that xylene resulted from the dehydration accompanied by cyclization of an unsaturated octyl alcohol or aldehyde.

Summary

The reactions of acetaldehyde over a zinc chromite catalyst at 360° under a pressure of 210 atmospheres of hydrogen resulted in the formation of a complex mixture of saturated and unsaturated alcohols, aldehydes and esters. After hydrogenation of this product over nickel the following products were identified and estimated: *n*-butanol, *p*-xylene, n-hexanol and the esters of acetic, butyric and caproic acids. The chief components of the mixture were ethyl acetate, butyl acetate and ethyl caproate. There were also produced in considerable amounts higher alcohols, lactones, hydrocarbons and acids. The synthesis of these products may be accounted for as the result of aldol and Tischtschenko-like reactions accompanied by such dehydrations, hydrogenations, autoxidation–reductions and intramolecular rearrangements as have been demonstrated previously to occur over oxide catalysts.

THE PREPARATION OF FLUORENONE FROM FLUORENE AND FROM DIPHENIC ACID

BY E. H. HUNTRESS, E. B. HERSHBERG AND I. S. CLIFF

RECEIVED MAY 1, 1931 PUBLISHED JULY 8, 1931

In the extension of various studies in progress in this Laboratory[1] it became necessary to secure an adequate supply of fluorenone. Of the numerous reactions in which the formation of fluorenone has been noted, the most promising seemed to be the oxidation of fluorene. Since the published methods do not indicate the best results, we have studied the process in detail. Our results are expressed in the specific directions and accompanying notes in the Experimental Part.

During the course of the work, however, it was observed that fluorenone could be obtained in substantially quantitative yield merely by the action of heat upon diphenic acid. Since the latter is readily preparable from commercial anthranilic acid, this mode of formation of fluorenone has the advantage of starting with conventional intermediates. Careful search of the literature yielded no reference to the action of heat alone upon diphenic acid save the statement[2] that when heated 10° above its melting point, (*i.e.*, at 238°) for half an hour, no diphenic anhydride was isolated. The

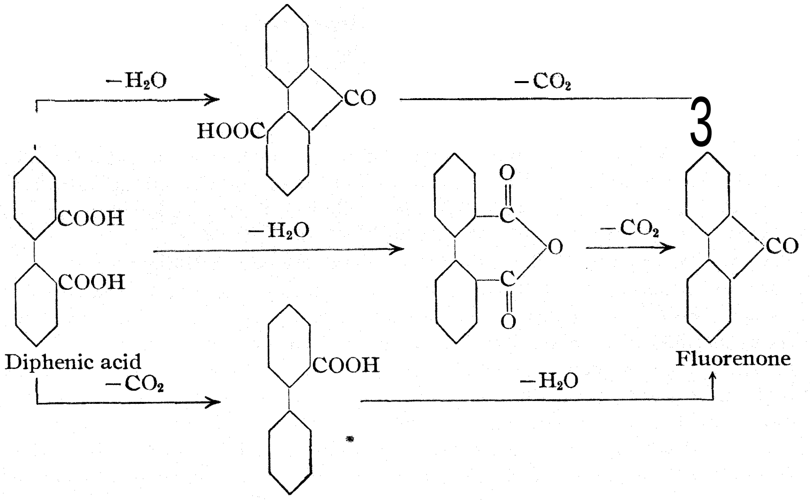
[2] Underwood and Kochmann, *ibid.*, 45, 3071–7 (1923).

formation of fluorenone and carbon dioxide at higher temperature might be accounted for by several possible mechanisms, as follows:



Although our purpose was not to study the mechanism of the reaction, we have observed that the same result is obtained whether the starting material be diphenic acid, fluorenone-4-carboxylic acid or diphenic anhydride. Since a trace of diphenyl was found in the product, decarboxylation of diphenic acid evidently occurs very slowly as compared with ring closure. It seems probable, since the keto acid and diphenic anhydride can be interconverted under certain conditions, that both types of ring closure are involved.

By means of following the yields of carbon dioxide obtained upon heating fluorenone-4-carboxylic acid, it was found that a temperature of 360" sufficed for quantitative splitting out of carbon dioxide. Application of similar conditions to diphenic acid gave similar results. Acting on this preliminary study, runs were carried out on a larger scale, measuring the resultant fluorenone directly. It was found also that good results were obtained using a crude diphenic acid not subjected to the usual zinc dust-acetic acid purification.

Experimental Part

Fluorenone by Oxidation of **Fluorene.**—Equip a 3-liter ring-necked flask with an addition tube carrying a 500-ml. dropping funnel and a water condenser. Place in the flask 200 g. (1.2 moles)[2a] of technical fluorene (Note 1), add 400 ml. of technical glacial

---

[2a] Since acceptance of this paper for publication, Mr. W. W. Hartmann, Department of Synthetic Chemistry, Eastman Kodak Company, has found that these directions may be applied to ten times the quantities here given, the oxidation being carried out in a 22-liter flask, and the final yield of pure recrystallized fluorenone amounting to 1450 g., or 66.8% of the calculated yield.

acetic acid and heat to gentle boiling. In another flask dissolve 600 g. of technical crystals of sodium bichromate (Note 2) in a warm mixture of 800 ml. of glacial acetic acid and 200 ml. of water. By means of the dropping funnel (Note 3) add this warm oxidizing solution in a slow steady stream to the boiling fluorene solution, so that boiling is never interrupted (Note 4) and no precipitation of lumps occurs. This will require about half an hour, as at first the reaction is quite vigorous. The mixed solutions are then refluxed for two and one-half hours more. The deep green liquid is then poured into 4 liters of ice water, allowed to stand for at least two hours and finally filtered through cloth on a 120-mm. Büchner funnel. The first wash water should contain a little sulfuric acid to avoid possible hydrolysis of the chromium salts, but the residue on the filter is presently washed free from all trace of chromic ion with pure water. If air dried at this point the bright yellow residue weighs 190–200 g.

Place the air-dried crude fluorenone in a 500-ml. Claisen distilling flask arranged to distil into an ordinary 300-ml. distilling flask, the Claisen side-arm serving as the only condenser. The Claisen flask is provided with the usual tube for the admission of air in vacuum distillations. The upper part of the Claisen may advantageously be wound with asbestos paper or twine. The flask is preferably heated with an electric cone heater as this facilitates smooth distillation. The receiver is connected to a vacuum pump (suitably protected from vapors and preferably arranged with pressure regulator) and the fluorenone distilled under reduced pressure. Toward the end of the distillation the clear bright yellow liquid will commence to acquire an orange tinge, the appearance of which serves as a convenient signal to stop distillation. The temperature range of distillation is not particularly important because its purpose is merely to remove rubicene and other highly colored impurities which cannot be separated by crystallization. Fluorene, if still present, is removed during the subsequent recrystallization.

The clear bright yellow distillate is dissolved in that number of ml. of benzene numerically equal to its weight in grams, this solution is warmed and to it is slowly added twice the benzene volume of petroleum ether, b. p. 30–60°, in such a way that no permanent separation of precipitate occurs. On allowing this solution to stand, extraordinarily beautiful crystals of fluorenone separate. These are filtered off, washed with petroleum ether and dried in the air. The yield based on the original crude fluorenone is 60–70% of crystals melting at 83.0–83.5°, uncorr.

Notes on the Preparation of Fluorenone

1. The purification of the technical fluorene prior to oxidation has no advantage. When fluorene which had been four times recrystallized from alcohol to a freezing point of 113° was used in this process, 70% of pure fluorenone was ultimately obtained. Precisely similar treatment of unrecrystallized hydrocarbon gave repeatedly 60–65% of final pure product. This slight difference in yield does not warrant the time and trouble required for preliminary purification. In this connection the recommendation of Thiele and Henle[3] that fluorene is best purified by recrystallization from alcohol containing sodium ethylate was tested, but the color and freezing points of the product from alcohol with or without sodium ethylate were substantially the same.

2. The use of a higher proportion of sodium dichromate is without advantage, since it does not affect either the yield or purity of the final product. The proportion here recommended is that originally proposed by Graebe and Rateanu and appears to represent about the minimum. Substitution of the equivalent quantity of potassium dichromate makes no difference in the yield or purity of the product, and because of the much smaller solubility in the aqueous acetic acid it does not completely dissolve and is therefore inconvenient to handle. Fanto's recommendation that 10% of sulfuric acid

---

[3] Thiele and Henle, *Ann.*, 347, 296 (1906).

be added to the oxidizing mixture was tested but since tar formation resulted its use was abandoned.

3. Since the solution of sodium dichromate in acetic acid and water crystallizes at room temperature, it is recommended that the stock oxidizing solution be kept warm in the second flask and added to the dropping funnel in small increments.

4. During the first part of the oxidation external heating may not be required. Care should be taken, however, to see that constant vigorous ebullition of the liquid is not interrupted, as otherwise an impenetrable lump of hydrocarbon precipitates which redissolves only with difficulty, and generally leads to much unchanged fluorene. With vigorous boiling, however, the use of a motor stirrer is unnecessary.

5. In the literature the recrystallization of fluorenone from alcohol is usually recommended for purification. This has the disadvantages, however, that the ketone separates first as liquid phase, and that any unchanged hydrocarbon is not completely removed. The precipitation of fluorenone from benzene by means of petroleum ether not only serves to remove every trace of hydrocarbon but also yields magnificent crystals. From the mother liquor additional fluorenone can be precipitated by more petroleum ether. An extensive crystallographic examination of fluorenone from alcohol has been made by Fittig and Schmitz.[4]

6. Distillation of the crude oxidation product prior to recrystallization is imperative. The process removes highly colored substances such as rubicene which otherwise follow the ketone through the purification process. Under atmospheric pressure fluorenone boils at **341.5°**.

Fluorenone from Heating Diphenic Acid

Action of Heat upon Fluorenone-4-carboxylic Acid.—A 100-ml. distilling flask was arranged to be heated by fused potassium nitrate–sodium nitrate mixture contained in a hemispherical iron pan, and provided with a suitable thermometer. By means of an inlet tube reaching nearly to its bottom, a stream of air could be aspirated through the flask. This air was admitted through a Kunz spiral absorption bulb containing 50% potassium hydroxide solution. As the air left the reaction flask it passed through a U-tube containing glass beads and concd. sulfuric acid and thence through a glass wool plug into a second Kunz bulb with 50% potassium hydroxide solution. This bulb was protected from possible adventitious atmospheric carbon dioxide with a soda-lime tube. By heating a weighed quantity of substance in the reaction flask the carbon dioxide evolved was carried along by the air stream to the second Kunz bulb and absorbed. Results on fluorenone-4-carboxylic acid are as follows.

Expt	Acid, g.	Time, min	Temp, °C.	CO_2, g.	% of calcd.
2	2.0246	20	320	0.0130	3.3
3	2.1225	135	330	.0962	23.2
4	1.8855	135	340	.3255	88.2
5	1.5210	120	360	.2625	88.5

The fluorenone-4-carboxylic acid used was prepared by the action[5] of sulfuric acid on diphenic acid.

Action of Heat upon Diphenic Acid.—For Expt. 7 the apparatus described above was employed. For the other runs, in which the fluorenone obtained was measured rather than the accompanying carbon dioxide, a distilling flask of suitable size was heated in the same heating bath and the distillate condensed in a test-tube cooled by ice water. After heating as indicated, the temperature was raised until distillation occurred at

---

[4] Fittig and Schmitz, **Ann,** 193, **117–119 (1878).**

[5] Moore and Huntress, THIS JOURNAL, 49, **1329 (1927).**

atmospheric pressure; the use of diminished pressure is possible but unnecessary. The diphenic acid employed was all prepared by the method of Huntress.[6]

Expt.	Add, g.	M. p., acid, °C.	Time, min.	Temp., °C.	CO_2, g.	% CO_2	Fluorenone Wt.	Fluorenone % yield	M. p., u. c. dist. fomd.
7	2.0607	226–228	105	360	0.3728	99.5	...	..	....
9A	2.005	213–215	90	360	....	..	1.22	82	83.5–84.5
9B	10.10	213–215	90	360	....	..	7.52	89	83.5–84.5
12	50.0	213–223	90	360	....	..	29.8	80	70–80
13	50.0	226–228	90	360	....	..	33.7	91	75–82
14	100.0	220–225	30	360	....	..	63.0	85	....

Notes.—1. Run 7 was made to verify for diphenic acid itself the optimum temperature which had been found for fluorenone-4-carboxylic acid.

2. Examination of the product from Expt. 13 showed that the principal impurity was diphenyl. This hydrocarbon is readily removed by the benzene–petroleum ether recrystallization.

3. Various grades of diphenic acid were purposely employed. In Expts. 9A, 9B, 12 and 14 diphenic acid was used which had not been subjected to the usual zinc dust–acetic acid purification. The use of copper diphenate instead of diphenic acid[7] gave only a low yield (36%).

Action of Heat upon Diphenic Anhydride.—During the course of the work one experiment was carried out on diphenic anhydride. When 2.152 g. of this substance was heated for one hundred and twenty minutes at 360° in the apparatus of Expt. 7, there was obtained 0.4061 g. of carbon dioxide corresponding to a 96% yield of fluorenone.

Solubility of Fluorenone and of Diphenyl.—A few solubilities were determined at 23° with results as follows, expressed as grams of substance per gram of solvent.

Solvent	Fluorenone	Diphenyl
Alcohol (95%)	0.075	0.054
Carbon tetrachloride	.19	.43
Ether	.31	.75
Benzene	.68	1.00

Summary

1. Heating diphenic acid at 360° causes rapid and nearly quantitative conversion to fluorenone and carbon dioxide. No previous observation of this fact could be found in the literature. The method is well suited for the preparation of either small or large quantities of fluorenone.

2. Under the same conditions both diphenic and fluorenone-4-carboxylic acids give similar results. Because of this fact no conclusion can at present be drawn regarding the mechanism of the reaction.

3. The preparation of fluorenone by oxidation of fluorene has been critically examined, and an improved procedure worked out which gives 60–70% yields of pure fluorenone, using ordinary apparatus.

[COMMUNICATION NO. 467 FROM THE KODAK RESEARCH LABORATORIES]

TREATMENT OF CELLULOSE AND OXIDIZED CELLULOSE WITH ACETIC–SULFURIC ACID MIXTURES

BY R. H. VANDYKE, C. J. STAUD AND H. LEB. GRAY

RECEIVED MAY 1, 1931 PUBLISHED JULY 8, 1931

Introduction

It has previously been recorded in the literature that cellulose could be partially converted to the formic acid ester by the action of anhydrous formic acid.[1] Some years later it was shown by Malm and Clarke[2] that by heating cellulose with glacial acetic acid an acetylcellulose containing approximately one acetyl group for four $C_6H_{10}O_5$ groups could be obtained. This product contained from 6 to 7% of CH_3CO. A recent patent[3] has claimed the preparation of a stable tri-formate of cellulose by the action of anhydrous formic acid and zinc chloride on cellulose.

It has been known since 1879[4] that sulfuric acid is a powerful catalyst in the acetylation of cellulose. Therefore it appeared of interest to investigate the effect of acetic–sulfuric acid mixtures on cellulose. Since none of the previous workers; as far as could be ascertained, had used oxidized cellulose, it seemed that the extension of the investigation to include such products might also be of interest. The oxidation procedures employed were similar to those given in a paper by Murray, Staud and Gray[6] in which definite oxygen equivalents per $C_6H_{10}O_5$ group were used.

As the method of acetyl determination usually employed appeared open to question for the analysis of the acetyl derivatives of oxidized celluloses, several of the preparations were also analyzed by another method in which the oxidation products were less likely to invalidate the results. The comparison of the data obtained by the two methods appears to be of possible interest.

Experimental

The cellulose employed in this investigation was high grade commercial processed cotton linters prepared by treatment of crude linters with alkali under pressure, followed by mild bleaching. The material had the following constants

Cuprammonium viscosity.......................... 9600 centipoises[6]

Alpha cellulose content	99 1%[7]
Copper number	0.042[8]
Ash	0.168%
Moisture	3.37%[9]

Oxidations.—(I) One hundred and sixty-two grams of cellulose (1 mole of $C_6H_{10}O_5$), which had been dried at 105° for sixteen hours, was placed in a solution consisting of 31.6 g. of potassium permanganate (Baker's Analyzed C. P.) ($^1/_2$ available oxygen atom per $C_6H_{10}O_5$) in six liters of normal phosphoric acid for six hours at 20–25°. After filtration on a Büchner funnel, the oxidized material was treated with a dilute solution of sodium bisulfite, approximately 1%, and washed with water until the filtrate after standing in contact with the oxidized cellulose for approximately sixteen hours was neutral to brom thymol blue.

(II) The same procedure was repeated using 63.2 g. of potassium permanganate (one available oxygen atom per $C_6H_{10}O_5$).

(III) One hundred and sixty-two grams of cellulose, dried at 105°, was placed in a solution consisting of 39.2 g. of 85% chromic oxide in six liters of water (CrO_3 content, 33.3 g., $^1/_2$ available oxygen atom per $C_6H_{10}O_5$) for twenty-four hours at 20–25°. The oxidized cellulose was then washed with water until the filtrate was neutral to brom thymol blue.

(IV) The same procedure was repeated using 156.8 g. of 85% chromic oxide (CrO_3 content 133.3 g, 2 available oxygen atoms per $C_6H_{10}O_5$).

All of the above oxidations were made in duplicate with an interval of several months between the first and second series.

TABLE I

WEIGHTS OF THE OXIDIZED CELLULOSE RECOVERED BY THE VARIOUS OXIDATIONS

Oxidation procedure		Weight in grams of starting material	Weight in grams of oxidized cellulose recovered	% loss
$KMnO_4$				
$^1/_2$ available oxygen atom per $C_6H_{10}O_5$	I	162	150	7.4
(6 hours, 20-25°)	II	162	147	9.3
1 available oxygen atom per $C_6H_{10}O_5$	I	162	138	14.8
(6 hours, 20-25°)	II	162	137	15.4

(24 hours, 20-25°)	II	162	...	..
2 available oxygen atoms per $C_6H_{10}O_5$	I	162	160	1.2
(24 hours, 20-25°)	II	162	...	..

Treatment with Acetic–Sulfuric Acid Mixtures.—Fifty grams of oxidized cellulose from each of the treatments described above and 50 g. of unoxidized cellulose were dried at 55–60° for twenty-four hours and placed in 3-liter balloon flasks, each containing 1500 cc. of glacial acetic acid (99.6–99.8% CH_3COOH) and 15 cc. of concentrated sulfuric acid (specific gravity 1.84). After stoppering, the flasks were maintained at 20–25°

[9] Determined by drying for twelve hours at 105°.

with occasional shaking. Approximately seven gram samples were removed after various intervals of time. The maximum time of treatment was 335 hours.

The samples were washed with water until the wash water in contact with the products remained neutral to brom thymol blue for sixteen hours. In some cases the products were treated with dilute sodium bicarbonate solutions for a few minutes, in the early stages of washing, followed by washing to neutrality with distilled water.

After washing, the samples were dried at 55–60° for twenty-four to forty-eight hours. The products from the first series of oxidations were analyzed for acetyl content by the modified Knoevenagel method given below. Those from the second series were subjected to acetyl determination by two methods: (A) the modified Knoevenagel procedure and (B) a method for determining acetic acid in the presence of other acidic groups. These methods are given in detail below.

Acetyl Content of Cellulose and Oxidized Cellulose Treated with Acetic-Sulfuric Acid Mixtures

(A) Modified Knoevenagel Method.[10]—Approximately one-half gram samples weighed to the nearest centigram are placed in a weighing bottle and dried at 105° for at least four hours. They are then cooled in a desiccator and the bottle and contents weighed to one-tenth milligram. The dried material is transferred to a 250-cc. Erlenmeyer flask and the weight of the sample taken for analysis determined by difference.

Twenty cubic centimeters of 75% by weight aqueous ethanol is added and the flask placed in a $56 \pm 1°$ bath for thirty minutes. Twenty cubic centimeters of $N/2$ sodium hydroxide is added and the flask again placed in the 56° bath for fifteen minutes, after which it is allowed to stand at 20–25° for twenty-four to forty-eight hours. The flasks are kept tightly stoppered during this period and the contents stirred occasionally by gentle shaking. The sides of the flasks are finally washed down with distilled water and the excess alkali is titrated with standard $N/2$ hydrochloric acid. The acetyl percentage is calculated by the formula.

$$\text{Percentage acetyl} = \frac{\text{cc. of } N/2 \text{ NaOH used} \times 0.0215 \times 100}{\text{Weight of sample}}$$

(B) Method for Determining Acetic Acid in the Presence of Other Acidic Groups.[11]—The neutral solutions obtained at the conclusion of analysis by the modified Knoevenagel method are transferred to a one-liter distilling flask and acidified with 25 cc. of 20% tartaric acid. Tartaric acid is used because it is strong enough to free acetic and formic acids from their salts, but not of sufficient strength to liberate hydrochloric and sulfuric acids. The volatile acids, which are freed from their salts in this way, are then steam distilled from the solutions. They are for the most part acetic and formic acids. One liter of distillate is usually required for their complete removal, which is determined by testing the distillate with litmus paper as it drops from the condenser and then distilling 200 to 300 cc. additional.

This distillate is then made alkaline with sodium carbonate and evaporated to dryness on a steam-bath. The alkaline residue is taken up with approximately 25 cc. of distilled water and to it are added 10 cc. of approximately $N/10$ potassium permanganate. The solution is heated on a steam-bath for a few minutes to assure complete oxidation of the formic acid. This solution is next acidified with dilute sulfuric acid

---

[10] Knoevenagel, *Cellulosechemie*, 3, 119 (1922).

[11] "The Acid Value of Cellulose Fatty Acid Esters and a Rapid Method for the Analysis of Certain Cellulose Acetates," by T. F. Murray, Jr., C. J. Staud and H. LeB. Gray, to be published presently as Communication No. 461 from the Research Laboratories of the Eastman Kodak Company.

(15% by volume) and the excess potassium permanganate destroyed with *a* slight excess of *N*/10 oxalic acid. This excess of oxalic acid is in turn removed by *N*/10 potassium permanganate until a very faint pink color remains. The solution is then made faintly alkaline with 5% sodium hydroxide for the purpose of converting all acids into the sodium salts. Finally this solution is again acidified with 25 cc. of 20% tartaric acid, when again only those acids weaker than tartaric are freed from their salts. The acids volatile with steam are distilled as before. The distillate should contain only acetic and carbonic acids at this point. This distillate is refluxed for ten to fifteen minutes to remove the dissolved carbon dioxide, cooled to room temperature and the solution titrated with standard *N*/10 alkali using phenolphthalein as indicator. From the amount of alkali used, the amount of acetyl in the sample is calculated.

It is necessary to make a correction for acids in the reagents. This is done by carrying out the determination using water and the reagents only. This correction factor is expressed in centimeters of *N*/10 alkali and is applied before final calculation is made.

Acetyl Content of Products.—The values obtained by analysis of the various oxidized celluloses using the modified Knoevenagel method described above are given for the first series of oxidations in Table II.

TABLE II

RESULTS OR ANALYSES

Treatment, hours	Unoxidized cellulose, % acetyl		Cellulose oxidized with CrO_3 Available oxygen atoms per $C_6H_{10}O_5$				Cellulose oxidized with $KMnO_4$ Available oxygen atoms per $C_6H_{10}O_5$			
			1/2		2		1/2		I

The relationship of the severity of oxidation and the acetyl content of the products as determined by the distillation method is shown in Fig. 4.

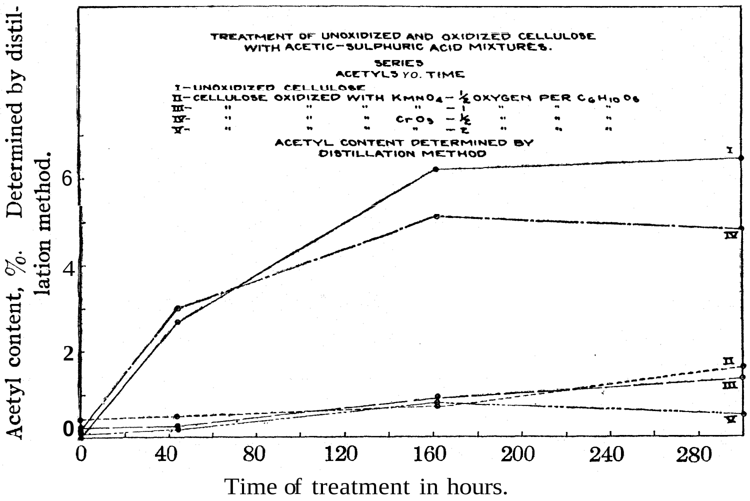

Fig. 3.

Discussion

From an examination of Table I it is seen that the yield of oxidized cellulose is an inverse function of the severity of the oxidizing solutions employed. This confirms the results of Hibbert and Parsons[12] and also that of Murray, Staud and Gray.[5]

When the results of acetyl determinations of the first and second series of unoxidized cellulose and oxidized celluloses, after treatment with acetic-sulfuric acid mixtures, are considered, as given in Tables II and III and in Figs. 1 and 2, at least three points are evident. First, when unoxidized cellulose is used, the acetyl content after **330** and **335** hours approximates that obtained by Malm and Clarke[2] by the action of boiling acetic acid on cellulose. This appears to be another indication that in the reaction between unoxidized cellulose and acetic acid, there is one hydroxyl group

[12] Hibbert and Parsons, *J. Soc. Chem. Ind.*, 44,4731' (1925).

per $C_{24}H_{40}O_{20}$ which behaves in a different manner from the other eleven as indicated by the cellulose formula put forward by Gray.[13]

The second point is that in both series of experiments the acetyl content, as determined by the modified Knoevenagel method, of the materials which had been oxidized using chromium oxide, for 330 and 335 hours, approximates more closely that of the unoxidized cellulose. The third point is that the most vigorously oxidized celluloses show the least acetyl content.

The fact that in many cases the apparent acetyl contents of the starting materials were higher than values subsequently obtained and that these appeared to show correlation with the vigor of the oxidizing solution, led to the trial of the distillation method of determination of acetyl content. It seemed fairly obvious that during the oxidation groups showing acidic reaction had been produced in the cellulose which were of course titrated as acetyl content in the modified Knoevenagel method.

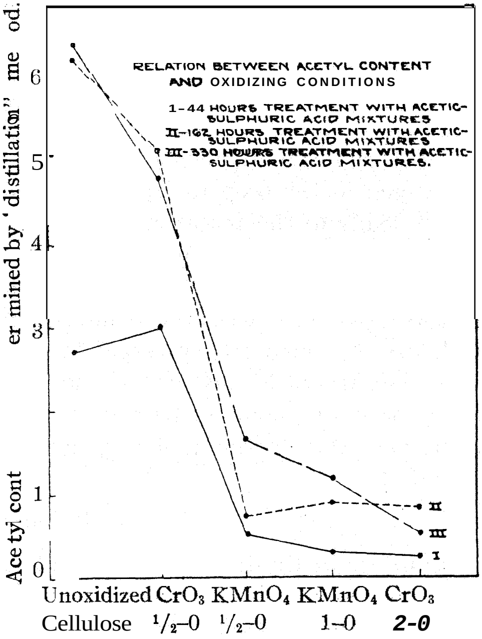

Fig. 4.

It was believed that the presence of combined sulfuric acid might be a factor in the results, but the results given in Table V do not indicate this.

TABLE V

PERCENTAGE OF COMBINED SULFURIC ACID

	Treatment with $CH_3COOH-H_2SO_4$		
	Before	After 44 hours	After 330 hours
Unoxidized cellulose	0.0	0 03	0 33
Cellulose oxidized, 1/2 available oxygen atom per $C_6H_{10}O_5$ using CrO_3	.0	.08	.30
Cellulose oxidized, 2 available oxygen atoms per $C_6H_{10}O_5$ using CrO_3	.0	.07	.50
Cellulose oxidized, 1/2 available oxygen atom per $C_6H_{10}O_5$ using $KMnO_4$	.0	.08	.30
Cellulose oxidized, 1 available oxygen atom per $C_6H_{10}O_5$ using $KMnO_4$	.0	.0	.24

When the distillation method was used in the analysis of the products,

---

[13] Gray, *Ind. Eng. Chem.*, 18,811 (1926).

the results given in Table IV and in Fig. **3** illustrate a striking difference from those obtained when the modified Knoevenagel method was used. Although the untreated materials did not give zero results, indicating the probable presence of other volatile materials of acid character not oxidized by potassium permanganate, the values are very much nearer zero and there is a much greater divergence between the acetyl content of the unoxidized and oxidized celluloses.

It is observed in this instance that the values for the acetyl content of the unoxidized cellulose after treatment with acetic–sulfuric acid mixture again approximate that of $C_{24}H_{39}O_{19}(O{-}CO{-}CH_3)$. It is also seen that the esterification is in an inverse ratio to the severity of the oxidizing conditions employed in the preparation of the oxidized cellulose, as shown in Fig. 4, which leads to the tentative conclusion that the hydroxyl group which is most readily acetylated is also probably the most easily oxidized.

Finally, the data obtained by the modified Knoevenagel method offer possible evidence that the acidic groups produced by the oxidation of cellulose are partially converted to non-acidic form by the action of the acetic–sulfuric acid mixture as indicated by the decreased values obtained after forty-four hours of treatment as compared with the apparent acetyl content of the starting materials as shown in Tables II and III and Figs. 1 and 2.

Summary

Cellulose in the form of cotton linters has been oxidized using chromic oxide in amounts of one-half and two available oxygen atoms per $C_6H_{10}O_5$ group and by potassium permanganate at concentrations of one-half and one available oxygen atom per $C_6H_{10}O_5$ group in N phosphoric acid.

The unoxidized and oxidized celluloses have been treated with acetic–sulfuric acid mixtures with the removal of samples at intervals during approximately **330** hours.

The products from the treatment of unoxidized and oxidized celluloses after treatment with acetic–sulfuric acid mixtures have been analyzed by two methods.

The results are given.

NATURAL AND SYNTHETIC RUBBER. VII. FRACTIONAL PRECIPITATION OF NATURAL RUBBER

BY THOMAS MIDGLEY, JR., ALBERT L. HENNE AND MARY W. RENOLL

RECEIVED MAY 2, 1931 PUBLISHED JULY 8, 1931

Crude rubber is an indeterminate mixture of several substances. The constituents of the mixture can be classified as "resins," soluble in acetone, rubber hydrocarbon $(C_5H_8)n$, soluble in benzene and insoluble "proteins."

The so-called "resins" are conveniently removed by a Soxhlet extraction with acetone. This treatment leaves behind a mixture of the rubber hydrocarbons and the "proteins." The latter can be separated by a variety of methods, which are well summarized by Fisher.[1] However, none is entirely satisfactory, because the methods based on a physical property effect only an imperfect separation, while chemical methods injure one or both constituents.

This paper presents a method of separation based on the progressive precipitation of natural rubber from a mixture of alcohol and benzene by slow cooling. Within certain limits, a system containing definite amounts of natural rubber, benzene and alcohol is homogeneous above a definite temperature, its critical temperature of solution. This critical point is best determined by allowing a hot mixture of rubber, alcohol and benzene to cool and reading the temperature at which a sudden increase of turbidity occurs. The determination can be duplicated within 0.3°.

When a mixture of rubber, alcohol and benzene is heated to a temperature higher than its critical point, until it has become completely clear, and is then allowed to cool to a temperature about 1° below its critical point, a certain amount of gel collects at the bottom of the container, while the supernatant liquid becomes transparent. The gel is a mixture of rubber and nearly all of the "protein." The supernatant liquid contains rubber practically free of "protein"; it can be decanted and yields its rubber content upon cooling or by alcohol addition. If a very pure hydrocarbon is desired, the procedure is repeated.

To systematize the preparation of nitrogen-free rubber, the diagrams given in Figs. 1, 2 and 3 have been experimentally determined. The procedure used was the customary one for the determination of critical temperatures of solution. Figure 1 refers to crude crepe rubber, alcohol and benzene; Fig. 2 refers to pure rubber hydrocarbon, alcohol and benzene; and Fig. 3 refers to synthetic rubber (sodium rubber), alcohol and benzene. The diagrams show that the isotherms have generally the same trend; they are located farther to the right in Fig. 3 than in Fig. 2, and in Fig. 2 than in Fig. 1.

---

[1] H. L. Fisher, *Chem. Reviews,* **7,** 51 (1930); *J. Chem. Education,* **8**, 7 (1931).

The use of the diagrams is almost self-evident. A system containing 2.0% of natural rubber, 23.1% of alcohol and 74.9% of benzene is found to have a critical temperature of 43.0". Such a system is represented by the circle *A* on Fig. 1. When this system is kept at 43.0°, it separates into two phases. The gel phase precipitates; it is a mixture of rubber hydrocarbon, "protein" and solvent, with a ratio benzene–alcohol larger than that of the system taken as a whole. The supernatant liquid contains rubber practically free of nitrogenous matter, dissolved in benzene–alcohol, and in this liquid the ratio benzene–alcohol is smaller than in the system taken as a whole. The composition of the supernatant liquid is represented by the circle B, on Fig. 2; it corresponds to 0.55% of nitrogen-free rubber, 30.7% of alcohol and 68.75% of benzene. When such a system is cooled to 41°, it becomes heterogeneous and when it is cooled to 35°, it retains less than 0.1% of dissolved rubber.

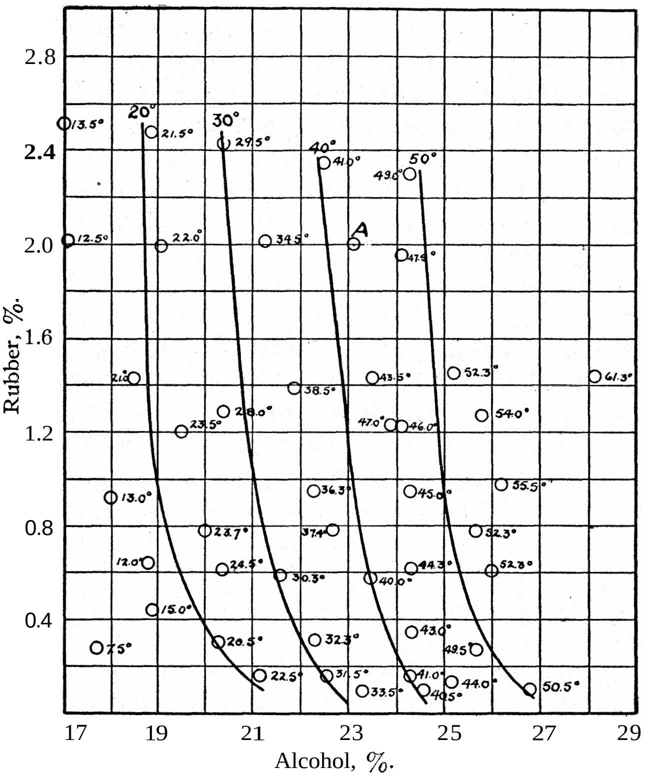

Fig. 1.

Experimental Procedure

Two hundred and fifty grams of crepe rubber with a nitrogen content of 0.25% was dissolved in 8083 g of benzene, heated to about 50". A hot mixture of 4500 cc. of absolute alcohol and 1400 cc. of benzene was added slowly, with constant stirring, until complete solution was obtained. The critical temperature, determined on a 50-cc. sample, was 43.0°. The mixture was then held at 42.0" in a thermostat, for one hour. At the end of this period, the mixture was no longer homogeneous, but consisted of a completely settled gel phase and a clear supernatant liquid. This liquid was decanted, then cooled in an ice-bath, and yielded 52.9 g. of rubber hydrocarbon, hereafter designated as A_1. After removal of the A_1 rubber, the liquid was warmed and poured back on the gel phase. By warming and stirring, the gel phase was caused to dissolve, and a clear solution was then obtained. A sample of this solution exhibited a critical point of **43.5".** Consequently, the solution was placed in a thermostat regulated at 42.5° for one hour, and the above procedure was repeated. This time 30.5 g. of rubber hydrocarbon was obtained, called A_2 hereafter. Two repetitions of these operations yielded fractions A_3 and A_4.

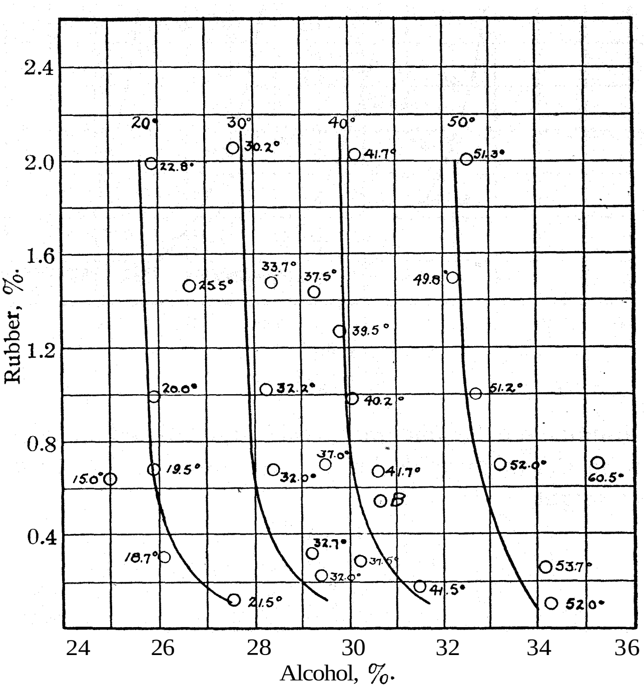

Fig. 2.

After the fraction A_4 had been collected, it was found that the gel phase would no longer dissolve completely in the alcohol–benzene mixture, even when the solvent was brought to its boiling point. Consequently, the insoluble matter was separated from the solvent; the solvent, upon cooling, yielded a fraction called A_5. Finally, the insoluble matter was extracted in a Soxhlet extractor with benzene. The material obtained from the benzene was called A_6, while the insoluble matter was called B. The various fractions were then analyzed for nitrogen. They were decomposed according to the usual Kjeldahl procedure.2 After the addition of alkali, three 50 cc. portions were

---

[2] Scott, "Standard Methods of Chemical Analysis," D. Van Nostrand Co., New York, 1927, Vol. II, p. 1593.

distilled, nesslerized, and compared with a set of standard tubes. Blanks were run on all reagents; ammonia-free water was used throughout. Fraction B was decomposed by the usual Kjeldahl method, but the distillate was received in standardized hydrochloric acid, whose excess was titrated with standard sodium hydroxide.

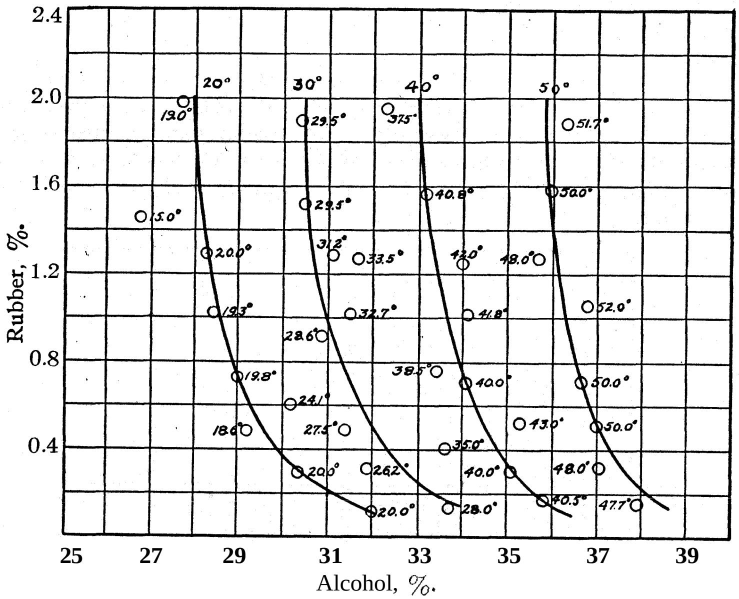

Fig. 3.

Table I summarizes the amounts of each fraction obtained, their critical temperature in the mixture alcohol–benzene described, and their nitrogen contents, by weight.

TABLE I

FIRST FRACTIONATION

	A_1	A_2	A_3	A_4	A_5	A_6	B
Grams	52.9	30.5	26.6	23.6	24.8	38.9	11.6
Crit. temp.	43.0	43.5	44.0	44.7	45.5	....	...
Nitrogen, %	0.026	0.033	0.044	0.125	0.142	0.160	4.21

After the first fractionation was completed, fractions A_1, A_2 and A_3 were combined, dissolved in *a* mixture of alcohol–benzene, and the whole procedure was repeated. Five successive fractions were thus obtained, as during the first fractionation, and they were analyzed for nitrogen. The results are reported in Table II.

TABLE II

SECOND FRACTIONATION

	A_2–1	A_2–2	A_2–3	A_2–4	A_2–5
Grams	28.1	17.1	13.8	16.0	6.4
Nitrogen, %	0.000	0.021	0.028	0.048	0.100

Fractions A_2–2, A_2–3 and A_2–4 were combined, dissolved in alcohol–benzene, and refractioned as previously. The results were as shown in Table III.

TABLE III

THIRD FRACTIONATION[3]

	A_3–1[a]	A_3–2	A_3–3
Grams	20 8	6 1	7.8
Nitrogen, %	0 000	0 011	0.015

[a] The carbon and hydrogen contents of Fraction A_3–1 were determined by micro-combustion. Calcd.: C, 88.17; H, 11.83. Found: C, 88 28, 88.32; H, 11.74, 11.74. This indicates the complete absence of oxygen.

The rubber hydrocarbon obtained by cooling the supernatant liquid has, so far, been referred to as "nitrogen-free rubber." When freshly prepared, this material bears a strong resemblance to the so-called "α-rubber" of Pummerer[4] and it probably contains little if any "β-rubber." During the course of the fractionation, the "0-rubber" seems to concentrate in the fractions rich in protein.

Summary

Temperature–concentration diagrams are given of the systems natural rubber–alcohol–benzene, pure rubber–alcohol–benzene and synthetic rubber–alcohol–benzene A method based on these diagrams is given for the separation of nitrogen-free rubber hydrocarbon by fractional precipitation of natural rubber from a mixture of alcohol and benzene.

COLUMBUS, OHIO

---

[3] A point of interest in the behavior of the rubber hydrocarbon was discovered in the course of this fractionation. For example when As–2 was dissolved in benzene and precipitated with acetone, only 14.1 g. was recovered. The other 3 g. remained in the turbid solution, irrespective of the amount of acetone added. The addition of water, however, caused precipitation. Likewise, the addition of a small amount of acetic acid would cause precipitation, seemingly at a different P_H. The residual three grams recovered by the addition of water was nitrogen-free.

CRYSTALLINE SOLVATES OF ROTENONE

BY HOWARD A. JONES

RECEIVED MAY 2, 1931 PUBLISHED JULY 8, 1931

Rotenone ($C_{23}H_{22}O_6$, m. p. 163°) as ordinarily crystallized from alcohol or ether separates as well-formed, thin plates of rather characteristic hexagonal outline. These crystals may be heated at 105° under atmospheric, or even under reduced, pressure for an extended period of time without loss in weight, indicating that they contain no solvent of crystallization.

Tattersfield and Roach[1] have reported that rotenone separates from certain solvents with solvent of crystallization. Thus they obtained from benzene needle-like crystals which contained 23 and 16% of benzene in two determinations. These investigators also obtained from alcohol needle-like crystals which contained about **3%** of alcohol of crystallization. In a previous paper[2] the present author reported that rotenone separates from some other solutions as crystalline solvates.[3] Thus it was found that the long, needle-like crystals obtained from carbon tetrachloride lost weight on heating, evidently owing to the expulsion of solvent of crystallization.

In order to determine the composition of the compounds formed, two rather simple methods were adopted. In the first of these the crystals were obtained by cooling warm solutions containing rotenone in excess of that soluble at room temperature. The separated crystalline material was filtered and placed in a desiccator containing a 50–50 mixture of the solvent and petroleum oil[4] until the material came to constant weight. A definite amount of this was then weighed and allowed to stand in air for some time to determine its stability, after which it was heated in an electric oven at 105° to constant weight. The total loss in weight was considered to be the amount of solvent of crystallization.

In the other method a weighed quantity of rotenone was dissolved in the solvent, the excess solvent evaporated by placing the dish in a draft of air at room temperature, and the solid material allowed to stand in the solvent–petroleum oil desiccator until it had come to constant weight. The increase in weight was considered to be the solvent added to the rotenone in the solvate compound. Blanks were run on the solvents alone to determine the residue on evaporation, and a suitable correction was made. The material was then allowed to stand in the air to determine roughly its

---

[1] Tattersfield and Roach, *Ann. Appl.* **Biol.,** *10,* 1 (1923).

[2] Jones and Smith, THIS JOURNAL, 52,2554 (1930).

[3] The term "solvate" as used in this paper is intended to apply only to solid materials containing solvent of crystallization.

[4] Such mixtures were used arbitrarily in an effort to insure the evaporation of the mother liquor without decomposition of the compound. In the case of the acetic acid compound, 50-50 glycerin and acetic acid was used.

rate of loss of solvent, and finally heated to constant weight at 105°. In the case of solvates this loss in weight should equal the gain in weight on evaporation and should again be the amount of solvent of crystallization.

In the paper[2] previously referred to it was reported that rotenone crystallized from acetic acid, benzene, carbon tetrachloride, chlorobenzene, chloroform, *sym.*-β-dichloroethyl ether, ethylene dichloricle and sometimes from toluene and trichloroethylene in the form of needles, and it was thought that all these might be solvates. In the present determinations *sym.*-β-dichloroethyl ether, toluene and trichloroethylene were not tested because they will be little used as solvents for rotenone. On the other hand, acetone, ethyl acetate and ethyl alcohol were used to prove that these solvents do not form crystalline solvates of rotenone.

The high solvent power of chloroform for rotenone made it impossible to use the procedures outlined, because concentrated, sirupy solutions were formed from which it was difficult to obtain crystalline material. Accordingly a modification of the first method was adopted. A solution of rotenone in chloroform was prepared at a concentration considerably below the saturation value, this solution was warmed, and four to five times its volume of warm petroleum ether added slowly. On cooling, long, needle-like crystals separated. This crystalline material was then filtered and treated as outlined in the first procedure. It was established that this solvate did not contain petroleum ether.

The results obtained are given in Table I. As will be noted acetone, chlorobenzene, ethyl acetate, ethyl alcohol and ethylene dichloride, under the conditions of the experiment, did not form solid solvates. Since Tattersfield's results with alcohol would require a compound with the unusually high proportion of about four molecules of rotenone to one of alcohol, it is probable that his result was incorrect and was due to retained mother liquor. Acetic acid forms a crystalline compound containing two molecules of rotenone to one of acetic acid. These crystals lost only 0.2% of their weight on standing in the air for forty-eight hours, showing efflorescence to be extremely slow. Benzene, carbon tetrachloride and chloroform form crystalline compounds containing one molecule of rotenone to one of solvent. The benzene result agrees with one of the analyses by Tattersfield. These benzene crystals effloresced appreciably in air, losing 1.2% of their original weight on standing for forty-eight hours in the air at room temperature. The chloroform crystals lost about 1.5% in the same time. The crystals containing carbon tetrachloride, however, were fairly stable in air, losing only 0.5% in the same time. On warming these crystalline solvates the odor of the solvent was readily detected.

Attempts were made to determine the melting points of these materials. All lose their solvent of crystallization gradually at a rate dependent on the rate of heating, and then melt at temperatures ranging between 171 and

[a] The rotenone underwent some oxidation in this case.

179°, which is above the melting point of ordinary rotenone. On cooling and remelting all give about the same melting points. These temperatures are in the region of the melting point given by Butenandt[6] for a polymorphic form of rotenone (m. p. 176°) which he obtained by grinding ordinary rotenone in a mortar.

All of these solvates separate in the form of rod-like crystals except the acetic acid compound, which is lath-like in appearance. The crystals all have high birefringence, parallel extinction and negative elongation. Crystals of rotenone obtained from ethyl acetate, although not a solvate, are lozenge-shaped instead of hexagonal in outline. We have found this of value as a diagnostic feature in the microscopic examination of crystalline material for rotenone.

---

[6] Butenandt and Hildebrandt, Ann., 477, 245 (1930).

The formation of the solvates may also be of value as diagnostic features of rotenone and may be of some application in analytical procedures. Thus in the extraction of derris root with carbon tetrachloride, the rotenone–solvent compound crystallizes from the evaporated extract and may be separated, dried and weighed in the air without heating in the oven, the weight being calculated to that of rotenone.

Summary

Under ordinary conditions rotenone forms with benzene, carbon tetrachloride and chloroform crystalline solvates containing one molecule of rotenone to one of solvent, and with acetic acid a solvate containing two molecules of rotenone to one of solvent.

No crystalline solvates were formed with acetone, chlorobenzene, ethyl acetate, ethyl alcohol and ethylene dichloride.

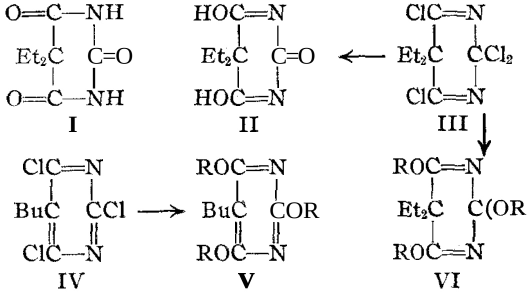
OXYGEN ETHERS OF BARBITAL

BY ARTHUR W. DOX

RECEIVED MAY 4, 1931 PUBLISHED JULY 8, 1931

The formula commonly assigned to barbital (5,5-diethylbarbituric acid) represents the keto–lactam structure (I). On theoretical grounds this structure should be more stable than the isomeric enol–lactim (II). At least one of the lactam groupings has the properties of an imide, since a monosodium salt can be prepared which reacts with alkyl halides to form N-alkylated barbitals. If the sodium salt exists as the tautomeric enol, it should yield an oxygen ether, but no such oxygen ethers have thus been obtained. After alkylation of one lactam the resulting 1,5,5-trialkylbarbituric acid again behaves as an imide, the remaining lactam forming a sodium salt which reacts as before. It is thus possible to prepare a 1,3,5,5-tetraalkylbarbituric acid.[1]



---

[1] Dox and Jones, THIS JOURNAL, 51, 316 (1929).

From analogy to similar structures, *e. g.*, isatin, carbostyril, etc., the tautomeric enol–lactim (II) should be the less stable form. Nevertheless, its oxygen ethers, once formed, should be relatively stable, though possibly subject to molecular rearrangement under drastic treatment.

In a previous paper[2] the hydrolysis of 2,2,4,6-tetrachloro-5,5-diethyldihydropyrimidine (III) was discussed. Replacement of the four chlorines by hydroxyl, followed by loss of water at C-2, should yield the tautomeric barbital (II). Aside from a quantitative liberation of hydrochloric acid, the only product obtained was diethylmalononitrile, the logical decomposition product of the unstable tautomer. Whether this tautomer exists momentarily as an intermediate product cannot as yet be stated with certainty. In view of the results obtained in the analogous alcoholysis of this tetrachloro derivative, the tentative explanation which assumes the momentary existence of an unstable tautomer acquires greater validity.

The substitution of alkoxyl for chlorine in a chlorinated derivative of an alkylbarbituric acid is recorded in one instance. V. Merkatz[3] treated 2,4,6-trichloro-5-ethylpyrimidine with sodium methoxide and obtained 2,4,6-trimethoxy-5-ethylpyrimidine. No evidence, beyond the method of preparation, was offered in support of the oxygen ether structure of the product. The possibility of rearrangement to an isomeric N-alkyl structure was not mentioned. In the case of tautomeric barbital, which represents a dihydropyrimidine and has two double bonds instead of three, the possibility of rearrangement is a more serious consideration.

Experimental

The reaction described by v. Merkatz, in which the three chlorines of 2,4,6-trichloro-5-ethylpyrimidine were replaced by methoxyl, was first tried with the homologous 2,4,6-trichloro-5-*sec.*-butylpyrimidine (IV),[2] using several alkoxides. The chlorinated pyrimidine was treated with the equivalent of sodium dissolved in the appropriate absolute alcohol. The reaction began almost immediately, as shown by the evolution of heat and the precipitation of sodium chloride. The mixture was heated in a steam-bath for two to four hours, then treated with water and the separated oily product distilled at atmosphere pressure.

2,4,6-TRIALKOXY-5-*sec.*-BUTYLPYRIMIDINES (V)

			Nitrogen, %	
Alkoxyl	B. p., °C.	Formula	Calcd.	Found

Ethoxyl	260-264	$C_{14}H_{24}O_3N_2$	10.44	10.29 10.28
Propoxyl	285-290	$C_{17}H_{30}O_3N_2$	9.03	9.27 9.22
Butoxyl	310-315	$C_{20}H_{36}O_3N_2$	7.95	8.09

---

[2] Dox, This Journal, 53, 1559 (1931).

[3] V. Merkatz, *Ber.*, 52, 876 (1919).

Proof of structure was not attempted, since the proof given for the tetraalkoxy derivative below should be equally applicable here.

The 2,2,4,6-tetrachloro-5,5-diethyldihydropyrimidine (III), obtained by treatment of barbital with phosphorus pentachloride, reacted in the same manner with sodium ethoxide and sodium butoxide. The oily products were separated as above, but distilled at 3 mm. instead of atmospheric pressure.

2,2,4,6-TETRAALKOXY-5,5-DIETHYLDIHYDROPYRIMIDINES (VI)

Alkoxyl	B. p., °C. (3 mm.)	Formula	Calcd., % C	H	N	Found, % C	H	N
Ethoxyl	122–123	$C_{16}H_{30}O_4N_2$	61.15	9.55	*8.92*	60.12	9.49	8.88
Butoxyl	180–183	$C_{24}H_{46}O_4N_2$	67.60	10.80	*6.57*	67.36	10.56	6.71

Both are high-boiling liquids, the tetrabutoxy derivative being considerably more viscous than its lower homolog.

Proof of structure was obtained by examining the products of hydrolysis. A homogeneous solution of 1.3885 g. of the tetraethoxy derivative in 10 cc. of concentrated hydrochloric acid was heated in a sealed tube for five hours at 140–150". Considerable pressure was released on opening the tube and the contents, consisting of an aqueous solution and a supernatant oil, were separated in a small funnel. The oil was washed with water and dried with calcium chloride. It was acid to litmus, boiled at 192–193°, and its titration value represented a molecular weight of 114. These properties identify the substance as diethylacetic acid, boiling point 195°, molecular weight 116. It is obviously a secondary product resulting from loss of carbon dioxide from diethylmalonic acid, the direct product of hydrolysis.

Evaporation of the aqueous layer of the reaction mixture left a white crystalline residue. After washing this with absolute alcohol, the yield was 0.4472 g. A portion was analyzed and found to contain 66.22% Cl; calculated for NH_4Cl, 66.36% Cl. The ammonium chloride actually recovered and analyzed accounts for 94.5% of the nitrogen present in the original material. If, however, the substance had been the isomeric N-alkyl derivative, hydrolysis by hydrochloric acid would have yielded ethylamine hydrochloride instead of ammonium chloride. The alcoholic washings from the ammonium chloride gave no picrolonic acid reaction for ethylamine. From another preparation which had been distilled at 260–265° under atmospheric pressure, a very small amount of ethylamine was obtained on hydrolysis, barely enough for analysis of the chloroplatinate and melting point of the picrolonate. The amount was estimated at less than 2% of the total nitrogen. The recovery of ammonium chloride, as before, was almost quantitative.

It is thus apparent that the substance is actually an oxygen ether with alkyl linked to oxygen and not to nitrogen. The isomeric N-alkyl derivative if present occurs in mere traces. The tetraethoxy and tetrabutoxy derivatives obtained as above are of especial interest as representing the first known derivatives of the hypothetical tautomeric barbital. They possess in addition to ether linkages in positions 4 and 6, an acetal structure in the 2-position. Hence they may be regarded as acetals of the ethers of enolic barbital. The isomeric 1,3,5,5-tetraethylbarbituric acid, but without the acetal grouping in position 2, has been prepared by Fischer and Dilthey[4] from ethyl diethylmalonate and *sym.*-diethylurea. This also was a high-boiling liquid.

Summary

2,2,4,6-Tetrachloro-5,5-diethyldihydropyrimidine, a product obtained by chlorination of barbital with phosphorus pentachloride, reacts with sodium alkoxides to form the corresponding 2,2,4,6-tetraalkoxy-5,5-diethyldihydropyrimidines. Hydrolysis by concentrated hydrochloric acid converts the tetraalkoxy derivative into diethylacetic acid and ammonium chloride, the latter in almost quantitative yield, showing that the alkyl is actually linked to oxygen. These tetraalkoxy derivatives represent acetals of the ethers of a hypothetical enolic barbital.

A series of 2,4,6-trialkoxy derivatives was also prepared from 2,4,6-trichloro-5-*sec.*-butylpyrimidine.

STUDIES ON POLLEN AND POLLEN EXTRACTS. VII. A GLUCOSIDE FROM CERTAIN GRASS POLLENS

BY MARJORIE B. MOORE AND EDMOND E. MOORE

RECEIVED MAY 4, 1931 PUBLISHED JULY 8, 1931

The existence of glucosides in pollen has been previously recognized. Heyl[1] found the coloring substances of ragweed pollen to be entirely glucosidic, and was able to isolate and identify glucosides of quercitin and isorhamnetin in the alcoholic extract. More recently, Fukuda[2] has isolated a glucoside of isorhamnetin from an alcoholic extract of the pollen of *Typha angustata Bory et Chaub.*

A new glucoside has been isolated in this Laboratory from two grass pollens. The first preparation of this compound was made from the pollen of orchard grass (*Dactylis glomerata L.*) and for this reason we are proposing the name "dactylin." An identical compound was found to separate from an extract of timothy pollen (*Phleum pratense* L.).

---

[2] Masao Fukuda, *Chem. Abstracts,* 22, 1993 (1928), from Bull. Soc. *Chem. Japan,* 3, 53–56 (1928).

Experimental

Isolation and Purification.—A distilled water extract of either grass pollen (previously ether extracted) was found to deposit a pale yellow crystalline substance after standing for a few hours. After twenty-four hours at 2–5° a good yield of the crystals was obtained. A second smaller crop was recovered after longer standing.

The crystals were separated from the water extract by centrifugation. They were then purified by two recrystallizations from boiling water, washed with alcohol and ether and dried. The melting point, never sharp, is not appreciably changed by the second recrystallization. As the yield of crude crystals is less than 0.5% of the weight of pollen used, the quantity of purified material available for a study of the properties of dactylin was quite small.

Properties.—Dactylin separates as pale yellow tasteless needles, which may be dried at 100°. Decomposition begins slightly below the melting point and the material fuses to a darkened mass before it becomes truly liquid. This behavior is shared by many of its derivatives. The "melting points" as recorded represent the temperatures at which the crystals fuse to form a viscid mass. On this basis the melting point of dactylin from either source or mixed is 183–185° (corr.).

This glucoside is very sparingly soluble in alcohol, glycerol, or cold water, readily soluble in boiling water and practically insoluble in ether, chloroform, acetone, carbon disulfide, benzene, or glacial acetic acid. It is freely soluble in pyridine, with which it forms a compound, m. p. 261–263° dec. (corr.). In cold water which contains sufficient alkali to raise the P_H to about 3.4 or greater, dactylin dissolves, giving an intense yellow solution.

A water solution of the glucoside gives a strongly positive Molisch test, and does not reduce Fehling's solution. With Millon's reagent it gives a red solution, soon changing to brown. If a trace of ferric chloride is added to the dactylin solution, a permanent dull purplish-green color is produced. No precipitate or characteristic color appears in the solution upon addition of barium chloride, silver nitrate, mercuric chloride, calcium chloride, or lead acetate. In cold concentrated sulfuric acid, the glucoside gives a yellow solution, which develops a greenish fluorescence upon standing.

A suspension of dactylin in water is not hydrolyzed by an active emulsin preparation within a week at 37°.

Hydrolysis readily occurs when the glucoside is heated with 5% sulfuric acid in a boiling water-bath. At first a clear solution is formed, but after a few minutes a yellow crystalline precipitate separates. There remains a colorless solution which reduces Fehling's reagent.

The yellow precipitate formed by acid hydrolysis, when washed with water until free from sulfates, then with alcohol and ether and dried at 100°, melts with decomposition at 298–300° (corr.). This melting point was checked with the preparation from each pollen and with a mixture. The crystals appear microscopically as small feathery collections of fine needles. The saturated solution of this material in alcohol, in which it is slightly soluble, gives no characteristic reaction with water solutions of calcium chloride, barium chloride, silver nitrate or mercuric chloride. Lead acetate increases the yellow color of the solution. With ferric chloride it gives a permanent brownish-purple color. When the compound is added to magnesium and glacial acetic acid, a brick-red color appears after the mixture is allowed to stand for a minute. Addition of hydrochloric acid changes the color to a cherry-red.

The soluble hydrolysis product gives no test for pentoses with phloroglucinol. It forms an osazone having the microscopic appearance of dextrosazone, and melting at 204–205° (corr.). This was checked by preparations from both sources.

In two hydrolyses, using crystals from the separate sources, the insoluble material was found to amount to 40.16 and 40.25% of the original glucoside.

Dactylin was found to contain only carbon, hydrogen and oxygen. Samples for analysis were dried at 100°.

Anal. Calcd. for $C_{23}H_{28}O_{15}$: C, 50.74; H, 5.15; for $C_{26}H_{32}O_{17}$: C, 50.65; H, 5.19; for $C_{29}H_{36}O_{19}$: C, 50.58; H, 5.23. Found: (source–orchard grass pollen) C, 50.59; H, 5.25. (Source—timothy pollen) C, 50.56, 50.64; H, 5.19, 5.06.

Which of the above formulas is preferable may be inferred from a consideration of the percentage of insoluble hydrolysis product formed. Assuming the reaction: $C_{23}H_{28}O_{15} + 2H_2O \longrightarrow 2C_6H_{12}O_6 + C_{11}H_8O_5$, the theoretical percentage of this product would be 40.4% (found, 40.2%). If this percentage is calculated, using either of the other above formulas, the values do not agree with the experimental within the limits of probable error. For this reason we believe the formula $C_{23}H_{28}O_{15}$ is justified.

Discussion

The method of isolation of dactylin raises the question as to whether it is originally present as such in the pollen or is formed in its water extract by the action of enzymes upon some parent substance. The latter theory is supported by the fact that the crystals will spontaneously precipitate from a water extract of pollen at the same temperature as that used for extraction. Moreover, in the presence of 50% glycerol (by volume), the precipitation of dactylin does not occur, although the compound after isolation is very difficultly soluble in glycerol.

The reaction with magnesium and acids makes it appear that this glucoside is closely related to those of the hydroxy flavones.[3]

The fact that it is not hydrolyzed by emulsin indicates that dactylin is not a β-glucoside. The sugar present is probably a hexose, two molecules of monosaccharide being present for each molecule of the insoluble hydrolysis product.

Further work is planned to determine the molecular formula and structure of this compound, when a sufficient supply of grass pollen becomes available.

Summary

A glucoside "dactylin" has been isolated from water extracts of orchard grass and timothy pollens, and its properties studied. Analytical results indicate $C_{23}H_{28}O_{15}$ as the empirical formula.

RESEARCHES ON ALDEHYDES. IV. THE CATALYTIC REDUCTION OF SIMPLE AND OF SUBSTITUTED CINNAMIC ALDEHYDES

BY MARSTON TAYLOR BOGERT AND GARFIELD POWELL[1]

RECEIVED MAY 5, 1931 PUBLISHED JULY 8, 1931

Introduction

In previous papers we have reported on the synthesis of simple and of substituted 2-alkylcinnamic aldehydes,[2] and on the reduction of some of these to the corresponding unsaturated alcohols by the use of aluminum ethylate or of magnesium chloroethylate.[3]

The present contribution records the catalytic reduction of these cinnamic aldehydes to the corresponding saturated aldehydes, saturated alcohols and aryl paraffins.

Depending upon the amount of hydrogen taken up per mole of initial material, and excluding bimolecular reactions, the various products theoretically obtainable by reduction of a 2-alkylcinnamic aldehyde may be represented thus

$$\mathrm{ArCH{=}CRCHO} + \mathrm{H_2} \longrightarrow \left\{\begin{matrix}\mathrm{ArCH{=}CRCH_2OH}\\ \mathrm{ArCH_2CRHCHO}\end{matrix}\right\} + \mathrm{H_2} \longrightarrow$$

$$\left\{\begin{matrix}\mathrm{ArCH{=}CRCH_3}\\ \mathrm{ArCH_2CRHCH_2OH}\end{matrix}\right\} + \mathrm{H_2} \longrightarrow \mathrm{ArCH_2CRHCH_3}$$

In our experiments we followed the process of Skita,[4] using colloidal palladium as the catalyst in most cases, since he found that with cinnamic aldehyde itself this process caused neither hydrogenation of the benzene nucleus nor formation of bimolecular compounds, under conditions similar to ours. With one mole of hydrogen per mole of cinnamic aldehyde, he reported that his product was nearly pure hydrocinnamic aldehyde.

Straus and Grindel[5] repeated the experiment and stated that their products were the saturated alcohol, the propane and a little unsaturated alcohol, but no saturated aldehyde (except in one case), although pressure and proportion of hydrogen and of catalyst were varied considerably. Since they found that neither the saturated aldehyde nor the saturated alcohol separately could be reduced under these conditions, they suggested that the cinnamyl alcohol and phenylpropene were formed first and were

[2] Bogert and Powell, *Am. Perfumer Ess. Oil Rev.*, 25, 617 (1930).

[3] Bogert and Powell, THIS JOURNAL, 53, 1605 (1931).

[4] Skita, Ber., 48, 1685 (1915).

[5] Straus and Grindel, *Ann.*, 439, 276 (1924).

then reduced to the saturated alcohol and phenylpropane, respectively, the velocity of these latter changes being greater than that of the reduction of the initial unsaturated aldehyde. This was their explanation of why little or none of these hypothetical intermediate products was detected.

Such a postulation, however, does not explain the formation of saturated aldehyde noted by Skita and by ourselves. It is true that the unsaturated alcohols are easily reduced under the conditions of the Skita process, while the saturated aldehydes are not, but the saturated aldehyde itself must be formed from its unsaturated progenitor either by direct saturation of the olefin bond, or by a 1,4-addition with subsequent rearrangement

$$\text{ArCH}{=}\text{CRCHO} + \text{H}_2 = \text{ArCH}_2\text{CR}{=}\text{CHOH} \longrightarrow \text{ArCH}_2\text{CRHCHO}$$

It is suggested, therefore, that we may be dealing with several types of reactions taking place concurrently, the saturated aldehyde being formed as just indicated and the saturated alcohol and phenylpropane as postulated by Straus and Grindel, although it should be pointed out that because the saturated aldehyde and saturated alcohol cannot be readily reduced separately and individually by the Skita method, it does not follow necessarily that they may not undergo such a direct reduction under the catalytic effect of the other substances present in the mixture while the unsaturated aldehyde is being reduced.

Adams and Tuley[6] have described a selective reduction of cinnamic aldehyde either to the unsaturated or the saturated alcohol, by suitable additions of small amounts of iron or zinc salts to their platinum-oxide platinum black catalyst, these additions promoting reduction of the aldehyde group and inhibiting the saturation of the olefin bond. The conditions for such selective reduction seem to be highly specific and likely to require prolonged experimentation in each case to learn the correct mixture for the purpose.

With the unsaturated aldehydes we were studying, the Skita process of reduction gave more satisfactory results than we were able to secure with the Adams methods.

Our first run was always made on a 1.5 mole reduction basis, *i. e.*, until 1.5 moles of hydrogen per mole of initial unsaturated aldehyde had been absorbed. The results obtained in that run determined what changes, if any, were desirable in subsequent runs. The saturated aldehydes and saturated alcohols were the principal products with a one or two mole hydrogenation, the propanes being formed in small amounts only. The limit of hydrogenation, with repeated use of catalyst, was not far from two moles of hydrogen, and the amount of hydrogen absorbed in proportion to catalyst varied according to the unsaturated aldehyde used. The yield of saturated aldehyde was favored by restricting the quantity of hydrogen absorbed, while that of the propane was improved by increasing

---

[6] Adams and Tuley, THIS JOURNAL, 47, 3061 (1925).

the gas pressure. In one experiment, only the saturated alcohol and aryl paraffin were found. In all other cases, both these and the saturated aldehyde were produced. No unsaturated alcohols or aryl olefins were detected in any of the runs.

The palladous chloride used for the preparation of the catalyst contained traces of platinum, rhodium and hydrochloric acid. The catalyst was not poisoned by the addition of traces of iron, cobalt or nickel salts.

Skita reported that the reduction of cinnamic aldehyde by colloidal palladium yielded mainly hydrocinnamic aldehyde and that the further reduction of the latter was accomplished better with platinum than with palladium. We have found the same to be true in the case of the substituted hydrocinnamic aldehydes prepared by us, namely, that they are either not at all, or certainly not easily, reduced by the usual Skita process with colloidal palladium.

In addition to the products already mentioned, the catalytic reduction of these unsaturated aldehydes always gave higher boiling products, which remained in the distilling flasks after the removal of propanes, saturated aldehydes and saturated alcohols, in the order named, but which have not yet been identified.

Commercial hydrogen from cylinders was used in all of the reductions. The unsaturated aldehyde was subjected to the action of the gas in an Adams hydrogenator. Practically all of the distillations were conducted under diminished pressure and in an atmosphere of nitrogen, to guard against oxidation.

While this investigation was in progress, a French patent[7] appeared, claiming improvement in color and in odor of perfumes by subjection to reduction by hydrogen in the presence of a nickel catalyst, by aluminum amalgam, zinc dust, etc., and citing ionones, geraniol and others as examples of perfumes improved by such reduction, but it does not specifically cover any of the field reported in the following pages.

The saturated aldehydes were colorless, mobile liquids which boiled lower than the corresponding saturated alcohols or unsaturated aldehydes. They all possessed agreeable odors, which varied with the nature of the side chains.

In general, their reactions were normal. The ability of the 2-amyl derivatives to form bisulfite compounds seems doubtful. The other saturated aldehydes prepared all gave bisulfite compounds, although in some instances they formed very slowly.

When this research was begun, the only aldehyde of this type in the literature was the 2-methyldihydrocinnamic aldehyde of Miller and Rohde.[8]

---

[7] I. G. Farbenind. A.-G., French Patent 643,352 (Nov. 4, 1927); *Chem. Abstracts*, **23**, 1475 (1929).

[8] Miller and Rohde, *Ber.*, 23, 1080 (1890).

The saturated alcohols were colorless, more or less viscous liquids and, with the exception of the hpdrocinnamic series, practically odorless. They were recovered from the middle fractions of the reduced unsaturated aldehydes, after oximation to remove all aldehydes. In the case of some of the higher homologs, their isolation as acetate or as dinitrobenzoate proved more satisfactory than as the free alcohol.

The aryl paraffins were found in the first runnings of the distillate from the mixture obtained by reduction of the unsaturated aldehyde. Aldehydic impurities were removed by oximation when necessary. The purified propanes were all colorless, mobile liquids. They were all fragrant, the aroma of some of them being quite potent. The scent of 2-benzyl-*n*-butane may be likened to that of safrole containing a little citral. Dihydrosafrole has been described as having only a weak safrole odor, whereas in our judgment it possesses fully as strong if not a stronger odor than safrole itself. The 2-substituted dihydrosafroles all exhaled a strong safrole aroma but rather sweeter than safrole, and the scent of the substituted dihydroanetholes was strongly reminiscent of anethole. The odor of 2-ethyl-3-p-anisylpropane was of anethole type, but also somewhat stronger and sweeter.

Experimental Part

Reduction of Piperonylidene Acetaldehyde, $(CH_2O_2)[3,4]C_6H_3CH{=}CHCHO$

Dihydrosafrole, $(CH_2O_2)[3,4]C_6H_3CH_2CH_2CH_3$.—Piperonylideneacetaldehyde (3,4-methylenedioxycinnamic aldehyde) was reduced by the method of Skita.[4]

To a solution of 12 g. of the unsaturated aldehyde in 125 cc. of 95% alcohol and 40 cc. of water, there were added 20 cc. of a 2% aqueous solution of gum arabic and 10 cc. of a 1% aqueous palladous chloride solution, and the mixture was immediately treated with hydrogen at 3 atmospheres' pressure in the Adams hydrogenator. After forty-five minutes, the absorption of hydrogen ceased abruptly. It was found that two moles of hydrogen had been absorbed and the pressure had fallen to two atmospheres.

The solution was filtered from the catalyst, the filtrate diluted largely with water, extracted with ether and the ether extract treated with 4–6 volumes of saturated sodium bisulfite solution for a day with frequent shaking, to remove aldehydes. This ether solution usually contained 15–25% of the reduction products, and these were the conditions employed in the case of other reductions as well for the separation of the aldehyde bisulfites, the only important variation being in the length of time required for such compounds to separate.

The bisulfite compound precipitated was removed, washed thoroughly with ether and the washings added to the filtrate. The ether layer in this filtrate was separated, washed with a sodium carbonate solution, then with water, dried, the ether distilled off and the residue fractionated under diminished pressure in an atmosphere of nitrogen. The first fraction was dihydrosafrole, without admixture with any safrole or isosafrole, which on rectification boiled at 226–228° (uncorr.). The odor of this dihydro derivative, as mentioned in the introductory portion of this paper, was fully as powerful as that of safrole itself. It was unchanged by digestion with strong potassium hydroxide solution; yield, about 10%.

---

[9] Ciamician and Silber, *Ber.*, 23, 1162 (1890).

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.13; H, 7.37; for $C_{10}H_{10}O_2$ (safrole or isosafrole); C, 74.04; H, 6.22. Found: C, 73.41; H, 7.55.

The higher boiling fraction, after removal of the dihydrosafrole, contained the saturated alcohol.

Attempts to carry out this same reduction with the Adams and Tuley[6] platinum-oxide platinum black catalyst were less satisfactory, for it was found necessary to re-activate the catalyst thrice before the two mole hydrogenation could be completed. As far as our examination went, the reduction products seemed to be the same as with palladium.

In the palladium reductions, variations in the pressure (1.3, 2, 2.5 or 3 atmospheres) of the hydrogen, did not alter the fact that exactly two moles of hydrogen was absorbed in every case. It affected only the rate of this absorption, which naturally increased with the pressure.

2-Piperonylethanol, $(CH_2O_2)[3,4]C_6H_3CH_2CH_2CH_2OH$, as mentioned above, was found in the second fraction from the distillation of the reduction products of the 3,4-methylenedioxycinnamic aldehyde. It was a colorless, odorless, viscous liquid, b. p. 149–150° (uncorr.) at 6 mm.; n_D^{21} 1.54427; yield, about 70%.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.64; H, 6.72. Found: C, 66.63; H, 6.69.

Acetate.—From the alcohol digested two hours with fused sodium acetate and excess of acetic anhydride; colorless liquid, of faint but agreeable odor, b. p. 145° (uncorr.) at 4 mm.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.83; H, 6.35. Found: C, 64.92; H, 6.58.

Reduction of 2-Piperonylidene-propionaldehyde, $(CH_2O_2)[3,4]C_6H_3CH{=}C(CH_3)CHO$

2-Piperonylpropane, $(CH_2O_2)[3,4]C_6H_3CH_2CH(CH_3)_2$.—A mixture of 10 g. of the unsaturated aldehyde, 150 cc. of 95% alcohol, 5 cc. of the catalyst solution, 20 cc. of gum arabic solution and 30 cc. of water, was treated with hydrogen at atmospheric pressure until 1.25 moles of hydrogen had been absorbed per mole of aldehyde. Several runs were made with these proportions and the accumulated reduction mixtures then worked up as described for the reduction of the piperonylidene acetaldehyde. The bisulfite compound separated was decomposed by agitation with sodium carbonate solution and ether, until the solid had all disappeared. The ether layer was removed, washed with water, dried and the solvent evaporated. The residue was almost pure initial unsaturated aldehyde (oxime, m. p., 124–126°, uncorr.).

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.44; H, 5.30. Found: C, 69.38; H, 5.44.

After the removal of the aldehyde bisulfite from the original reduction mixture, the ether extracts, as before, were washed with sodium carbonate solution, then with water, dried and distilled. After removal of the ether, two fractions were collected, one of boiling point around 120" at 4 mm., and the other at about 150° at 4 mm.

The first fraction on redistillation yielded a colorless mobile oil, b. p. 238–240° (uncorr.) at 760 mm., n_D^{23} 1.51841, of safrole odor, and proved to be the expected arylpropane.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.85. Found: C, 73.99; H, 7.82.

From a similar reduction, with acetic acid as solvent in place of alcohol, the bisulfite separation yielded a mixture of aldehydes, b. p. 140–158° (uncorr.) at 4.5 mm., of an odor quite different from that of the initial unsaturated aldehyde, and which presumably contained some of the saturated aldehyde. The amount of material available, however, was insufficient to enable us to isolate the latter pure.

A preliminary experiment, using 5 g. of the unsaturated aldehyde in place of 10, and the other ingredients of the mixture as already stated, with hydrogen at ordinary pressure, showed that after two moles of hydrogen had been absorbed, the absorption ceased abruptly. As it was believed that this might be carrying the reduction too far, in view of the results obtained by a two-mole reduction of piperonylidene-acetaldehyde, we investigated the piperonylidene-propionaldehyde chiefly from the standpoint of a 1.25-mole reduction as outlined above.

2-Piperonylpropanol, $(CH_2O_2)[3,4]C_6H_3CH_2CH(CH_3)CH_2OH$.—The higher boiling fraction (b. p. around 150" at 4 mm.) referred to above, after taking off the arylpropane in the first runnings, was dissolved in aqueous alcohol and refluxed for one and one-half hours with hydroxylamine, to remove any aldehydes present. The product of this oximation was diluted with water, extracted with ether, the ether extracts washed with dilute hydrochloric acid, to remove any excess of hydroxylamine, then repeatedly with water, with sodium carbonate solution and finally with water again. The ether was removed and the residue, as usual, distilled under diminished pressure in an atmosphere of nitrogen, collecting the fraction of b. p. 147–148° (uncorr.) at 4 mm. The alcohol thus purified formed an odorless, colorless, viscous liquid, $n_D^{22.5}$ 1.54054, which did not absorb bromine in carbon tetrachloride solution.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.0; H, 7.27. Found: C, 68.08, 67.97; H, 7.41, 7.40.

Reduction of 2-Piperonylidene-butyraldehyde, $(CH_2O_2)[3,4]C_6H_3CH{=}C(C_2H_5)CHO$

2-Piperonyl-butyraldehyde, $(CH_2O_2)[3,4]C_6H_3CH_2CH(C_2H_5)CHO$.—A mixture of 10.2 g. of the unsaturated aldehyde, 65 cc. of glacial acetic acid, 30 cc. of water, 7 cc. of gum arabic solution and 5 cc. of the catalyst solution absorbed 1.6 moles of hydrogen in two hours at ordinary pressure. A mixture of 10.2 g. of the unsaturated aldehyde, 100 cc. of 95% alcohol, 20 cc. of water, 10 cc. of gum arabic solution and 5 cc. of the catalyst solution, absorbed 1.8 moles of hydrogen in one and one-half hours at ordinary pressure. This latter reduction mixture was worked up in the manner already described.

Decomposition of the bisulfite precipitate yielded the pure saturated aldehyde as a colorless liquid, b. p. 136° (uncorr.) at 3 mm., of weak but agreeable odor.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.86; H, 6.85. Found: C, 70.21; H, 6.82.

2-Piperonylbutane, $(CH_2O_2)[3,4]C_6H_3CH_2CH(C_2H_5)CH_3$.—After removal of the aldehyde bisulfite, the ether extracts were distilled and, following the evaporation of the ether, a fraction of b. p. up to 130" at 3 mm. was collected and then a second one, b. p. about 150° at 2 mm. The lower fraction carried the arylbutane, the upper one the saturated alcohol.

The piperonylbutane on rectification boiled at 255–260° (uncorr.) at 760 mm., mainly at 257°, and its odor was very faint. It was a colorless mobile oil.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.95; H, 8.39. Found: C, 74.73; H, 8.28.

2-Piperonylbutanol, $(CH_2O_2)[3,4]C_6H_3CH_2CH(C_2H_5)CH_2OH$.—From the fraction above the piperonylbutane, the butanol was isolated in the same way as noted for the analogous piperonylpropanol, removing aldehydic contaminants by oximation. After repeated distillation, it was obtained as a colorless, odorless, viscous liquid, b. p. 148–150° (uncorr.) at 2 mm., n_D^{22} 1.53853.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.19; H, 7.75. Found: C, 68.89; H, 7.57.

Reduction of 2-Ethylcinnamic Aldehyde, $C_6H_5CH{=}C(C_2H_5)CHO$

2-Ethylhydrocinnamic Aldehyde (β-Benzyl-*n*-butyraldehyde), $C_6H_5CH_2CH(C_2H_5)CHO$.—The mixture used for reduction was composed of 23 g. of the unsaturated aldehyde, 110 cc. of 95% alcohol, 30 cc. of water, 10 cc. of gum arabic solution and 10 cc. of the palladous chloride solution. At ordinary temperature and pressure, this absorbed less than one mole of hydrogen per mole of aldehyde in forty-five minutes. After the addition of 10 cc. more of the catalyst solution, the absorption rose to 1.25 moles of hydrogen and was increasing so slowly that it was interrupted and the reduction products examined as described under the reduction of piperonylidene-acetaldehyde.

Hydrolysis of the bisulfite compound yielded the pure saturated aldehyde as a colorless liquid, b. p. 115–116" (uncorr.) at 12.5 mm., $n_D^{22.5}$ 1.50839, which formed a mirror with ammoniacal silver solutions. Its odor was agreeable, but not very strong.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.42; H, 8.70. Found: C, 81.32; H, 8.67.

It was not reduced by the Skita process under the condition., which caused reduction of the unsaturated aldehyde, but was reduced by hydrogen under pressure in the presence of the platinum-oxideplatinum black catalyst.

2-Benzyl-n-butane, $C_6H_5CH_2CH(C_2H_5)CH_3$.—After the separation of the above saturated aldehyde, the solvent was removed from the ether extracts and the residue fractionated under diminished pressure in an atmosphere of nitrogen. The first fraction contained the hydrocarbon, the second the saturated alcohol. Both were freed from aldehyde impurities by oximation.

The benzylbutane present in the first fraction (b. p. 98–100° at 30 mm.), was isolated as a liquid, b. p. 190° (uncorr.) at 710 mm., of a weak safrole-type of odor. It has been reported before by Dumesnil,[10] who gave its b. p. as 102° at 15 mm., and by Glattfeld and Cameron,[11] who prepared it by five different methods and found an approximate boiling point of 192° at 710- 720 mm.

2-Benzyl-n-butanol, $C_6H_5CH_2CH(C_2H_5)CH_2OH$.—This saturated alcohol, as separated from the higher boiling fraction of the above reduction mixture, was a colorless, viscous liquid, with a faint sweetish odor, b. p. 105–107° (uncorr.) at 4 mm., or about 256–257° (corr.) at 755 mm.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.43; H, 9.83. Found: C, 80.19; H, 9.63.

It has been prepared previously by other methods, by Guerbet,[12] who recorded its b. p. as 258–261° (corr.) and its odor as lilac-like, and by Von Braun, Rohmer and co-workers,[13] who found a boiling point of 134–135° at 13 mm., and described its fragrance as rose-like.

Reduction of 2-n-Amylcinnamic Aldehyde, $C_6H_5CH{=}C(C_5H_{11})CHO$

2-Amyl-γ-phenylpropane, $C_6H_5CH_2CH(C_5H_{11})CH_3$, was isolated by fractional distillation of accumulated reduction products of the amylcinnamic aldehyde, being found in the first runnings. It was a colorless mobile oil, b. p. 128–130° (uncorr.) at 16 mm., of not very pleasant odor.

Anal. Calcd. for $C_{14}H_{22}$: C, 88.34; H, 11.66. Found: C, 86.95; H, 11.92.

The low figure for carbon suggests that the product was not quite pure.

2-Amyl-3-phenylpropanol (2-Amyl-dihydrocinnamic Alcohol), $C_6H_5CH_2CH(C_5H_{11})$-CH_2OH.—Using the same proportions of ingredients as noted above for the reduction of 2-ethylcinnamic aldehyde, a 1.6 mole reduction product (34 g.) was refluxed for forty-five minutes with 100 g. of acetic anhydride and 3 g. of fused sodium acetate. Distillation of the product gave a principal fraction, b. p. 134–135° (uncorr.) at 3.5 mm., which proved to be the acetate of the saturated alcohol.

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.36; H, 9.74. Found: C, 77.85; H, 9.82.

---

[10] Dumesnil, Ann. *chim.*, [9] 8, 91 (1916).

[13] Von Braun, Rohmer and co-workers, Ann., **451**, 50 (1926).

This *acetate* was hydrolyzed by refluxing it for an hour with a 5% alcoholic potassium hydroxide solution. The alcohol was a colorless, viscous liquid, b. p. 119–120. (uncorr.) at 2.5 mm., of weak but rather pleasing odor.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.48; H, 10.76. Found: C, 81.68; H, 10.54.

3,5-Dinitrobenzoate.—The saturated alcohol present in a one-mole reduction product of the amylcinnamic aldehyde was converted to its 3,5-dinitrobenzoate, a reddish, viscous liquid, hydrolysis of which yielded the saturated alcohol, in an impure form (C, 82.15; H, 10.56), but which contained no unsaturated alcohol (no bromine absorption).

Reduction of 2-Methyl-o-methoxycinnamic Aldehyde, $o\text{-}CH_3OC_6H_4CH{=}C(CH_3)CHO$

2-Methyl-3-o-anisyl-propionaldehyde, $CH_3OC_6H_4CH_2CH(CH_3)CHO$.—A mixture of 21 g. of the unsaturated alcohol, 150 cc. of 95% alcohol, 30 cc. of water, 10 cc. of gum solution and 12 cc. of catalyst, when subjected to the action of hydrogen at an average pressure of 2.5 atmospheres, absorbed 1.9 moles of hydrogen exothermally in an hour.

The bisulfite compound separated from the reduction mixture gave the pure saturated aldehyde when hydrolyzed, as a colorless liquid, of a weak sweet odor, b. p. 113–114" (uncorr.) at 5.25 mm., which formed a mirror with ammoniacal silver solutions.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.11; H, 7.93. Found: C, 74.11; H, 8.16.

2-Methyl-3-o-anisylpropane, $CH_3OC_6H_4CH_2CH(CH_3)_2$.—Fractionation of the residual ether solution after removal of the above bisulfite compound gave a fraction, b. p. near 90° at 9 mm., which contained the propane. This hydrocarbon was isolated in the pure state by rectification, without requiring oximation, and was a colorless liquid, b. p. 111–112° (corr.) at 31.25 mm., of agreeable aromatic odor.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.44; H, 9.81. Found: C, 80.34; H, 9.77.

2-Methyl-3-o-anisylpropanol, $CH_3OC_6H_4CH_2CH(CH_3)CH_2OH$.—The fraction boiling just above that containing the anisylpropane carried the saturated alcohol. Its boiling point was around 130° at 6 mm. It was oximated, to remove a small amount of aldehyde present, and was then purified by distillation. It was a colorless, odorless oil, h. p. 131.5–132.5° (corr.) at 8.75 mm.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.29; H, 8.94. Found: C, 72.95; H, 8.82.

Reduction of 2-Ethyl-o-methoxycinnamic Aldehyde, $o\text{-}CH_3OC_6H_4CH{=}C(C_2H_5)CHO$

2-Ethyl-3-o-anisylpropionaldehyde, $CH_3OC_6H_4CH_2CH(C_2H_5)CHO$.—A mixture of 20 g. of the unsaturated aldehyde, 150 cc. of 95% alcohol, 30 cc. of water, 10 cc. of gum solution and 10 cc. of the catalyst, was reduced with hydrogen at an average pressure of 2.5 atmospheres, and approximately one mole of hydrogen was absorbed.

On working up the reduced mixture, the aldehyde bisulfite separated very slowly. Its hydrolysis yielded the pure saturated aldehyde as a colorless liquid, b. p. 144–145° (uncorr.) at 16 mm., of faint but not unpleasant odor.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.95; H, 8.39. Found: C, 74.70; H, 8.64.

2-Ethyl-3-o-anisylpropane, $CH_3OC_6H_4CH_2CH(C_2H_5)CH_3$.—The ether filtrate from the aldehyde bisulfite separation was distilled and the following fractions collected: (1) near 100° at 9 mm., and (2) near 135° at 6 mm.

Redistillation of Fraction (1) gave the propane as a colorless, mobile oil, b. p. 100.5–102.5" (corr.) at 9 mm., with an odor like that of the lower homolog described above.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.83; H, 10.19. Found: C, 80.27; H, 10.37.

2-Ethyl-3-o-anisylpropanol, $CH_3OC_6H_4CH_2CH(C_2H_5)CH_2OH$.—Fraction (2) noted in the last preparation and boiling at about 135" at 6 mm. consisted mainly of unchanged initial unsaturated aldehyde but, after its removal as oxime, a small amount of the saturated alcohol was isolated, as a colorless, odorless liquid, b. p. 132–134" (corr.) at 55 mm.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.17; H, 9.35. Found: C, 74.17; H, 9.43.

Reduction of 2-Ethyl-p-methoxycinnamic Aldehyde, *p*-$CH_3OC_6H_4CH{=}C(C_2H_5)CHO$

2-Ethyl-3-p-anisyl-propionaldehyde, $CH_3OC_6H_4CH_2CH(C_2H_5)CHO$.—The mixture used was 14 g. of the unsaturated aldehyde, 100 cc. of 95% alcohol, 30 cc. of water, 10 cc. of the gum solution and 10 cc. of the catalyst. The hydrogen was applied at an average pressure of two atmospheres. The absorption ensued exothermally and in thirty minutes about two moles of hydrogen was taken up. With a larger proportion of catalyst, somewhat more hydrogen was absorbed. The reduction product was worked up as in the other cases.

Hydrolysis of the bisulfite precipitate gave the saturated aldehyde practically pure, as a colorless liquid, b. p. 116–117" (uncorr.) at 3 mm., $n_{\mathrm{D}}^{23\ 5}$ 1.51673, which formed a mirror with ammoniacal silver solutions. Its odor resembled that of the 2-ethylhydrocinnamic aldehyde.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.95; H, 8.39. Found: C, 74.61; H, 8.55.

2-Ethyl-3-*p*-anisylpropane (**β-Ethyldihydroanethole**), $CH_3OC_6H_4CH_2CH(C_2H_5)$-$CH_3$.—As usual, after separation of the above aldehyde bisulfite, the ether extracts were distilled and after removal of the ether two fractions were collected, the first one containing the hydrocarbon and the second the saturated alcohol. Both fractions were oximated, to remove any aldehyde still present.

The first fraction was collected at 105–110° at 10 mm., and yielded the pure hydrocarbon as a colorless mobile liquid, b. p. 135–136° (uncorr.) at 29 mm., of anethole odor.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.83; H, 10.19. Found: C, 80.15; H, 9.92.

2-Ethyl-3-p-anisylpropanol, $CH_3OC_6H_4CH_2CH(C_2H_5)CH_2OH$.—The higher boiling fraction referred to above was collected at about 140° at 3 mm., and from it was recovered the saturated alcohol, as a colorless, odorless oil, b. p. 129–130" (uncorr.) at 2.5 mm., n_{D}^{22} 1.52398.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.17; H, 9.35. Found: C, 74.42; H, 9.64.

In the above reduction, 36 g. of crude reduction product (from several runs) yielded 4 g. of the saturated aldehyde, 4 g. of the hydrocarbon and 10 g. of the saturated alcohol.

Summary

1. The following have been reduced catalytically: piperonylideneacetaldehyde, its 2-methyl- and 2-ethyl-derivatives; 2-ethyl- and 2-amylcinnamic aldehydes; 2-methyl- and 2-ethyl-o-methoxycinnamic aldehydes and 2-ethyl-*p*-methoxycinnamic aldehyde.

2. The reduction products isolated were the corresponding saturated aldehyde, saturated alcohol and arylparaffin. No unsaturated alcohols or arylolefins were detected.

3. Most of the products described are new. Their physical and chemical properties are recorded, as well as their odors.

EXPRESSED BRAZIL NUT OIL

BY H. A. SCHUETTE AND W. W. F. ENZ

RECEIVED MAY 6, 1931 PUBLISHED JULY 8, 1931

The seeds of the Brazil nut tree, Bertholletea *excelsa,* yield an oil whose individuality depends upon the mode of recovery. For example, a "virgin" oil of a color lying between water-white and pale yellow is obtainable by expression, whereas an inferior and materially darker product results when the residual pulp is exhausted with a suitable solvent. Qualitatively there appear to be few, if any, significant differences in the chemical composition of the constituent glycerides of these oils. That they are quantitative was, in a sense, indicated in an earlier communication[1] by the statement that the virgin oil readily solidifies (5–lo°) whereas the residual oil does not show a similar behavior.

The evident desirability of verifying this statement has prompted us to repeat quantitatively an analysis once reported qualitatively.[1] Pertinent data are recorded in this communication.

I. Preparation of Materials and Methods of Analysis

The nuts from which this oil was expressed[2] were purchased in the open market during the Christmas holiday season, when the stocks were fresh, confirmatory evidence for which was found in the very low acidity (0.006% as oleic) of the oil. A division of the fatty acids into two groups was effected by application of the lead salt-ether method[3'] with the necessary correction for the small amount of unsaturated acids contaminating the saturated when this procedure is used.[3b] The former (71.74%) were separated and identified by means of their bromine addition products,[4] while the latter (20.28%) were isolated as methyl esters.[5]

II. Analysis of Oil

(a) Titer Test.—The solidifying point of the insoluble fatty acids (titer test) is one of the few remaining constants of virgin Brazil nut oil which have not been heretofore reported. It was determined by the usual procedure[6]—the fatty acids were prepared by the glycerol–potassium hydroxide method of saponification—and found to be 33.3". This value agrees with that reported' for the residual oil.

(b) Unsaturated Acids.—That linolenic acid is not a constituent of this group was apparent from the fact that no hexabromide separated from the ether solution of the

brominated product at −10°. Linoleic and oleic acids, however, are present in appreciable amounts. The presence of the former was shown in the formation of its tetrabromide (m. p. 114°), whereas the latter was indicated by its dibromo derivative (Br, 39.85%). Using this value and the theoretical iodine numbers of oleic and linoleic acids, the percentage composition of the whole was then calculated[5] with the results shown in Table I.

TABLE I

COMPOSITION OF THE UNSATURATED ACID FRACTION

Acid	In oil, %	Glycerides in oil, %	Total,[a] %
Oleic	36 67	41 61	42.79
Linoleic	22.72	25.80	26.54

[a] This column includes the unsaturated acids present with the saturated.

(c) Saturated Acids.—The methyl esters of the saturated acids were separated into five fractions (Table II) whose boiling range lay between 147 and 163° (3 mm.). The mean molecular weights of the respective fractions as calculated from saponification and iodine numbers—the latter serving as a basis for correcting each for the presence of unsaturated acids—indicated the presence of acids in the C_{14} to C_{18} group. These data lead to the following statement of the percentage composition of the saturated acid fraction.

TABLE II

RESULTS OF ANALYSIS OF METHYL ESTERS OF THE SATURATED ACIDS

Undetermined	1.61	..

Summary

The approximate percentage composition of a sample of virgin Brazil nut oil has been found to be myristin, 0.48; palmitin, 13.74; stearin, 5.45; olein, 42.79; linolein, 26.54. Its solidifying point is higher than that of the oil recoverable from the residual pulp, a difference which is apparently largely due to a lower olein content. The linolein and palmitin contents of both grades of oil are of the same order of magnitude. Myristin, on the other hand, is present in the virgin oil to the extent of one-fourth as much

as in the product of lower quality. The former contains approximately twice as much stearin as the latter.

THE REDUCTION OF AROMATIC KETONES AND BENZILS BY TRIPHENYLMETHYLMAGNESIUM BROMIDE

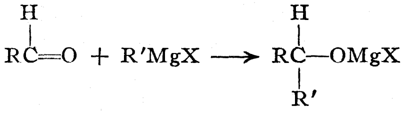
BY W. E. BACHMANN

RECEIVED MAY 11, 1931 PUBLISHED JULY 8, 1931

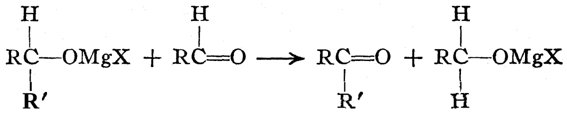
It is clear that the reduction which so frequently occurs in the Grignard reaction may be occasioned in several ways.[1] It has long been known that aliphatic Grignard reagents can exercise a reducing action toward certain compounds; as a rule an unsaturated hydrocarbon is formed in addition to the reduction product.

The work of Gomberg and Bachmann[2] on the reducing action of a mixture of magnesium and magnesium iodide has made it obvious that the Grignard reagent must be filtered from unused magnesium if reduction by this system is to be avoided. A number of instances have been reported in which reduction occurred when unused magnesium was allowed to remain in the Grignard reagent.[3]

Marshall[4] discovered that a mutual oxidation and reduction reaction may occur between excess of an aldehyde and the normal addition compound which is formed by the action of a Grignard reagent on the aldehyde. The reaction which occurs may be formulated as follows



$$\mathrm{R\overset{H}{C}{=}O + R'MgX \longrightarrow R\overset{H}{\underset{R'}{C}}{-}OMgX} \qquad (1)$$



$$\mathrm{R\overset{H}{\underset{R'}{C}}{-}OMgX + R\overset{H}{C}{=}O \longrightarrow R\underset{R'}{C}{=}O + R\overset{H}{\underset{H}{C}}{-}OMgX} \qquad (2)$$

The reaction involves a transfer of H and MgX from a molecule of the secondary alcohol to a molecule of aldehyde; the products are a ketone and a primary alcohol. The importance of this mode of reduction has been overlooked to a great extent; its applicability has been indicated by

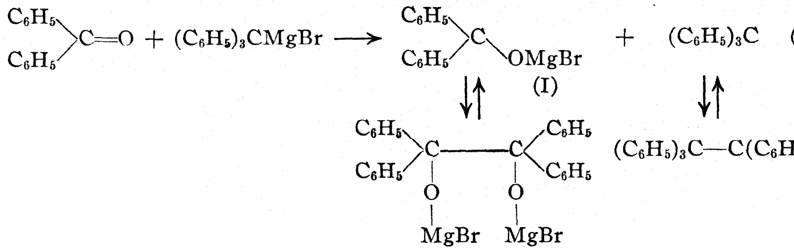
Meisenheimer[5] and more recently by the work of Gomberg and Bachmann[6] and of Shankland and Gomberg.[7] It should be pointed out that this reaction may take place even when the aldehyde is not used in excess; in fact, it may occur when the Grignard reagent preponderates. Thus, if the Grignard reagent is added slowly to the aldehyde, there may be time enough for the oxidation–reduction reaction[8] to take place before all of the aldehyde has reacted with the Grignard reagent. The latter, then, reacts not only with the aldehyde but also with the ketone that is formed in the secondary reaction. We have carried out such a reaction between one mole of benzaldehyde and two moles of phenylmagnesium iodide and obtained 25% of benzyl alcohol and 16% of triphenylcarbinol in addition to benzhydrol.

A singular type of reduction has been found to take place between triphenylmethylmagnesium bromide and certain aromatic ketones. Instead of a normal addition reaction taking place, this Grignard reagent reduces the ketones to pinacols. The reaction proceeds through the intermediate formation of free radicals. The reactions which take place with benzophenone[9] may be formulated as follows



$$(C_6H_5)_2C{=}O + (C_6H_5)_3CMgBr \longrightarrow (C_6H_5)_2C{-}OMgBr\ (I) + (C_6H_5)_3C \qquad (3)$$

Two free radicals, bromomagnesium ketyl[10] (I) and triphenylmethyl, are formed primarily; their presence is indicated by the color of the solution, the triphenylmethyl contributing an orange-yellow and the ketyl a red color (with phenylbenzophenone and especially with diphenylbenzophenone this latter color is an intense blue). These radicals associate to their corresponding dimolecular forms rather than unite with one another to form pentaphenylethanol. On hydrolysis a 93% yield of benzopinacol[11]

---

[6] Gomberg and Bachmann, THIS JOURNAL, 52, 4967 (1930).

[7] Shankland and Gomberg, *ibid.*, 52, 4973 (1930).

[8] See Ref. 7 for the speed of this type of reaction.

[9] This reaction was first carried out with Professor M. Gomberg in connection with our study of the action of Mg + $MgBr_2$ on triphenylmethyl.

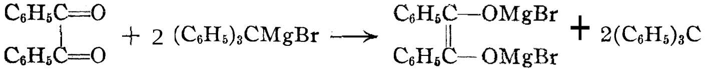
[10] This ketyl radical is identical with that formed by the action of MgBr on benzophenone [Gomberg and Bachmann, THIS JOURNAL, 49, 236 (1927)].

[11] Schmidlin, *Ber.*, 39, 4198 (1906), was the first to obtain benzopinacol from the interaction of triphenylmethylmagnesium chloride and benzophenone; however, he attributed the reduction to the magnesium which was present in the mixture. Gilman

and a practically quantitative yield of triphenylmethyl are obtained. Not only benzophenone but also *p*-chloro-, *p*-phenyl- and *p,p'*-diphenylbenzophenone in addition to fluorenone and xanthone have been found to be reduced to pinacols by triphenylmethylmagnesium bromide.

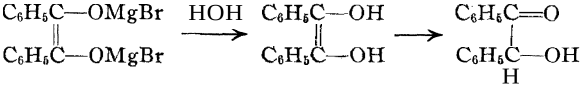
This type of reduction takes place to a slight extent in the reaction between phenylmagnesium bromide and benzophenone. If a filtered solution of the Grignard reagent is added to a solution of benzophenone in a nitrogen atmosphere, the red color of the bromomagnesium ketyl becomes visible. If diphenylbenzophenone is employed, the characteristic deep blue color of the corresponding ketyl appears. Indeed, the colors which have been observed by others[12] in the course of the Grignard reaction are attributed to the formation of ketyl radicals, albeit in minute amounts. Whether other types of reduction or whether even the normal addition reaction of the Grignard reagent takes place through the intermediate formation of radicals[13] is left undecided.

It has further been found that benzil is reduced by triphenylmethylmagnesium bromide. Two molecules of the Grignard reagent react with one molecule of the benzil and there is formed the bromomagnesium salt of stilbene-diol[14] (II) and triphenylmethyl.



$$\begin{array}{l} C_6H_5C{=}O \\ \quad | \\ C_6H_5C{=}O \end{array} + 2\,(C_6H_5)_3CMgBr \longrightarrow \begin{array}{l} C_6H_5C{-}OMgBr \\ \quad \| \\ C_6H_5C{-}OMgBr \end{array} + 2(C_6H_5)_3C \qquad (4)$$

Hydrolysis of the reaction mixture gives benzoin in addition to triphenylmethyl



$$\begin{array}{l} C_6H_5C{-}OMgBr \\ \quad \| \\ C_6H_5C{-}OMgBr \end{array} \xrightarrow{HOH} \begin{array}{l} C_6H_5C{-}OH \\ \quad \| \\ C_6H_5C{-}OH \end{array} \longrightarrow \begin{array}{l} C_6H_5C{=}O \\ \quad | \\ C_6H_5C{-}OH \\ \quad H \end{array} \qquad (5)$$

The presence of the bromomagnesium salt of stilbene-diol prior to hydrolysis was indicated by the color of the mixture during the reaction and was proved by the formation of stilbene-diol dibenzoate,[14] $C_6H_5C(OOCC_6H_5){=}(C_6H_5COO)CC_6H_5$, when the reaction mixture before hydrolysis was

---

and Fothergill, THIS JOURNAL, 51, 3149 (1929), likewise, reported the formation of some pinacol (22–31% yields). Compare also the reaction of thio-ketones with the Grignard reagent [Schonberg and Schütz, *Ber.*, 60, 2351 (1927)].

[12] Of these, Davies, Dixon and Jones, *J. Chem. Soc.*, 1916 (1930), report not only that the red color of the ketyl is produced on the addition of benzophenone to amyl Grignard reagents but also that small yields (4–9%) of benzopinacol were isolated. As Noller, Ref. 1, points out, however, these investigators siphoned or decanted but did not filter their solutions from excess of magnesium. Noller subsequently was unable to find any benzopinacol among the products of the action of isobutylmagnesium bromide on benzophenone.

treated with benzoyl chloride. Dimethylbenzil and dichlorobenzil react with triphenylmethylmagnesium bromide in the same manner as benzil. The reaction of this Grignard reagent with benzil is analogous to the reaction that occurs between iodomagnesium hydrazobenzene, $C_6H_5N(MgI)—(IMg)NC_6H_5$, and benzil in which azobenzene[15] and the iodomagnesium salt of stilbene-diol are produced.

Experimental

All operations, including the preparation of the Grignard reagent and its reactions with ketones and benzils, were carried out in an atmosphere of nitrogen.

Triphenylmethylmagnesium Bromide + Benzophenone.—The Grignard reagent was prepared from 16.2 g. of triphenylmethyl bromide in a mixture of 30 cc. of ether and 60 cc. of benzene according to the directions of Gomberg and Bachmann.[16] The filtered solution of triphenylmethylmagnesium bromide was treated with 9.1 g. of benzophenone. The solution immediately became deep red in color. After three hours of refluxing, the solution was hydrolyzed with ice and dilute acetic acid. Air was passed into the orange-yellow solution until oxidation of triphenylmethyl was complete; by using a sintered-glass distributor, this result was attained in less than an hour. The triphenylmethyl peroxide which had precipitated was filtered off and washed with benzene and with acetone: wt., 10.3 g.; m. p. 186°.

The ether–benzene filtrate was allowed to evaporate to dryness. The solid residue was digested with warm petroleum ether (40–60°) in order to remove unreacted benzophenone; only traces of this compound were found in the filtrate. The crude pinacol was then dissolved in 140 cc. of cold acetone; this treatment left 0.5 g. of peroxide undissolved. Evaporation of the acetone solution gave a solid which after treatment with alcohol consisted of practically pure benzopinacol: wt., 8.5 g.; m. p. 186–188°.

In another experiment, the crude pinacol which was obtained on evaporation of the acetone solution was rearranged to β-benzopinacolin by heating it for a few minutes with 40 cc. of glacial acetic acid which contained a few crystals of iodine.[17] In this manner 7.5 g. of pinacolin was obtained. The yield of peroxide was again 10.8 g.

The results obtained from the interaction of triphenylmethylmagnesium bromide and a number of ketones are given in Table I. In each case one mole of Grignard reagent was employed for one mole of ketone.

Triphenylmethylmagnesium Bromide + Benzil.—A solution of 5.2 g. of benzil in 30 cc. of benzene was added to a solution of triphenylmethylmagnesium bromide prepared from 16.2 g. of triphenylmethyl bromide. An opaque dark brown color was formed but this disappeared as the reaction proceeded; at the end of the reaction the solution was transparent orapge in color. These color phenomena are entirely analogous to those observed in the reduction of benzil by the binary system $Mg + MgI_2$. After the solution had been refluxed for two and one-half hours, it was hydrolyzed. Air was passed into the solution in order to oxidize the triphenylrnethyl. The peroxide was filtered off and the filtrate was evaporated to dryness. The solid residue was extracted with ether in a Soxhlet extractor in order to dissolve the benzoin and leave peroxide undissolved. In this manner there was obtained 11.5 g. of triphenylmethyl peroxide and 4.2 g. of benzoin.

Reaction with Benzoyl Chloride.—After refluxing a mixture of 5.2 g. of benzil and the Grignard reagent from 16.2 g. of triphenylmethyl bromide for two hours, the solution

TABLE I

REDUCTION OF KETONES BY TRIPHENYLMETHYLMAGNESIUM BROMIDE

Ketone	Ketone, g.	Yields of products			
		Pinacol		Peroxide	
		G.	%	G.	%
Benzophenone	9.1	8.5	93	10.8	83[a]
4-Chlorobenzophenone	5.41	4.2	78	5.2	80
4-Phenylbenzophenone[b]	6.5	5.6	86	4.5	70
4,4'-Diphenylbenzophenone[c]	8.35	8.0	98	5.0	77
Fluorenone[d]	4.5	3.6	80	4.8	74
Xanthone[e]	4.9	4.1	84	5.0	77

[a] Since solutions of pure triphenylmethyl give only 80–85% yields of triphenylmethyl peroxide, this yield represents practically a quantitative formation of triphenylmethyl.

[b] The color of the reaction mixture was green (from the blue of the ketyl and the orange-yellow of triphenylmethyl). Since the pinacol is little soluble, hydrolysis was carried out in a nitrogen atmosphere and the pinacol which precipitated was filtered off; the triphenylmethyl in the filtrate was then oxidized to peroxide. A portion of the pinacol was rearranged to pinacolin by heating it with acetic acid and iodine; there was obtained the pinacolin, benzoyl-4,4'-diphenyl-triphenylmethane, of m. p. 198°. For descriptions of these and related compounds see Gomberg and Bachmann, THIS JOURNAL, 49, 236 (1927).

[c] The mixture was refluxed for one hour. The solution was intense greenish-blue and then intense green in color. The same procedure was employed here as is given under phenylbenzophenone.

[d] Part of the pinacol (1.7 g.) precipitated on hydrolysis of the reaction mixture. For purposes of identification a portion of the pinacol was warmed with 70% sulfuric acid; it gave the expected 9-diphenylenephenanthrone of m. p. 255°.

[e] Most of the xanthopinacol (3.2 g.) precipitated on hydrolysis. A sample when warmed with 70% sulfuric acid gave dixanthylene; m. p. 312°.

was cooled and treated with a solution of 7 cc. of benzoyl chloride in 30 cc. of benzene. After being kept warm for two hours, the mixture was allowed to stand at room temperature for twelve hours. Hydrolysis of the mixture, followed by oxidation of the triphenylmethyl, gave 6.0 g. of stilbenediol dibenzoate of m. p. 158° and 10.5 g. of triphenylmethyl peroxide.

In Table II are listed the results obtained from the interaction of two moles of triphenylmethylmagnesium bromide and one mole of the benzil.

Phenylmagnesium Iodide (2 Moles) + Benzaldehyde (1 Mole).—A filtered solution of phenylmagnesium iodide which had been prepared from 42 g. of iodobenzene in 75 cc. of ether was added drop by drop in the course of an hour to a warm solution of 10.6 g. of freshly distilled benzaldehyde in 30 cc. of benzene. After the addition, the mixture was warmed for one hour and was then allowed to stand overnight. The mixture was hydrolyzed, washed and dried. The solvents were removed by distillation and the mixture was then distilled on a steam-bath under a pressure of 1 mm. The benzyl alcohol which distilled was freed from biphenyl by extraction with water. From the aqueous extract was obtained 2.7 g. (25%) of benzyl alcohol (identified as the phenyl urethan, m. p. 76°, and as the *p*-nitrobenzoic acid ester, m. p. 84-85°).

The residue in the distilling flask was warmed with 40 cc. of ligroin (60-80°); this dissolved the benzohydrol and left 3.5 g. of triphenylcarbinol in the form of large crystals. From the ligroin filtrate there were obtained 8 g. of benzhydrol and an additional 1.0 g. of triphenylcarbinol.

TABLE II

REDUCTION OF BENZILS BY TRIPHENYLMETHYLMAGNESIUM BROMIDE

Benzil	Benzil g.	Yields of products Benzoin G.	 %	 Peroxide G.	 %
Benzil	5.2	4.2	80	11.5	88
Benzil	5.2	6.0[a]		10.5	80
4,4′-Dichlorobenzil	3.5	3.4	95	5.3	81
4,4′-Dichlorobenzil	3.5	4.0[b]		3.6	56
4,4′-Dimethylbenzil	3.0	2.3[c]		2.9	44

[a] Stilbene-diol dibenzoate.

[b] Dichloro-stilbene-diol dibenzoate [Gomberg and Van Natta, THIS JOURNAL, 51, 2238 (1929)] produced by treating the reaction mixture with 4 cc. of benzoyl chloride.

[c] Dimethyl-stilbene-diol dibenzoate. After recrystallization from alcohol it melted at 137–138° and was identical with the dibenzoate prepared from the benzil through the MgI reaction.

Summary

A number of aromatic ketones have been reduced to pinacols by means of the Grignard reagent, triphenylmethylmagnesium bromide. The reduction proceeds through the intermediate formation of radicals according to the following formulation: $RRC{=}O + (C_6H_5)_3CMgBr \longrightarrow RRC{-}OMgBr + (C_6H_5)_3C$. The ketyl radicals then associate to the pinacolate: $2RRC{-}OMgBr \longrightarrow RRC(OMgBr)(OMgBr)CRR$.

Benzils are reduced by triphenylmethylmagnesium bromide to the bromomagnesium salt of stilbene-diols: $RCOCOR + 2(C_6H_5)_3CMgBr \longrightarrow RC(OMgBr){=}(OMgBr)CR + 2(C_6H_5)_3C$.

SOME NEW LOCAL ANESTHETICS CONTAINING THE MORPHOLINE RING[1]

BY JOHN H. GARDNER[2] AND EDWARD O. HAENNI

RECEIVED MAY 11, 1931 PUBLISHED JULY 8, 1931

In view of the very pronounced local anesthetic activity of the aromatic esters of the dialkylamino alcohols, such as procaine and butyn, it has seemed of interest to study the preparation and physiological properties of an analogous series in which the dialkylamino group is replaced by a morpholine ring. It is not to be expected that the morpholine ring as such should have any particular effect but it is possible that the ether linkage in the ring might serve to increase the solubility of the morpholine derivatives in lipoids and so increase the anesthetic powers.

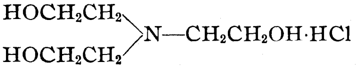
---

[1] Presented before the Organic Division of the American Chemical Society at Indianapolis, Indiana, April, 1931.

[2] This research has been assisted by a grant to the senior author from the Science Research Fund of Washington University.

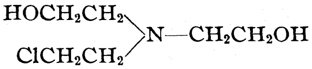
The starting point in this investigation was the preparation of β-4-morpholine-ethanol from triethanolamine. This had been accomplished by Knorr,[3] who dehydrated triethanolamine by heating with sulfuric acid, but did not give a full description of the product. A repetition of Knorr's method led to unsatisfactory results. It was found much more satisfactory to start with triethanolamine hydrochloride. This was obtained from the commercial product by saturating an alcoholic solution with hydrogen chloride gas, the hydrochlorides of the mono- and diethanolamines being soluble in alcohol.[4]

Boehmer and Hancock[6] dehydrated di-β-hydroxyethylaniline to 4-phenylmorpholine by heating under reduced pressure. Triethanolamine was not dehydrated under these conditions, but the hydrochloride (I) gave a product which, after heating with alcoholic potassium hydroxide, yielded the morpholine-ethanol. It seems probable that an intermediate chlorohydrin (II) is first formed and that this, on treatment with potassium hydroxide, is converted into morpholine-ethanol (III). This mechanism is supported by the fact that the crude dehydration product forms morpholine-ethanol only slowly on treatment with cold alkali. A similar mechanism was suggested by Knorr for the preparation of morpholine by heating diethanolamine with hydrochloric acid and subsequent treatment with alkali. He also isolated in an impure condition such an intermediate product obtained by heating di-β-hydroxyethylaniline with hydrochloric acid.[6]



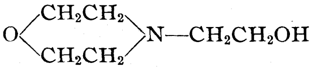
$$\begin{matrix} HOCH_2CH_2 \\ HOCH_2CH_2 \end{matrix} > N-CH_2CH_2OH \cdot HCl$$

I



$$\begin{matrix} HOCH_2CH_2 \\ ClCH_2CH_2 \end{matrix} > N-CH_2CH_2OH$$

II



$$O < \begin{matrix} CH_2CH_2 \\ CH_2CH_2 \end{matrix} > N-CH_2CH_2OH$$

III

From β-4-morpholine-ethanol, the hydrochlorides of the benzoate and p-aminobenzoate were prepared. Morpholine-ethanol, on treatment with benzoyl chloride and sodium hydroxide, yielded the benzoate from which β-4-morpholine-ethyl benzoate hydrochloride was obtained by precipitation with hydrogen chloride gas in benzene solution. β-4-Morpholine-ethyl p-nitrobenzoate hydrochloride was prepared by the interaction of morpholine-ethanol and *p*-nitrobenzoyl chloride in benzene solution. On reduction with hydrogen using Adams' platinum–platinum oxide catalyst, this yielded β-4-morpholine-ethyl p-aminobenzoate hydrochloride.

For the preparation of y-4-morpholinepropanol, trimethylene chloro-

hydrin was condensed with potassium phthalimide and the product hydrolyzed to y-aminopropanol. The general procedure is that described by Putochin[7] with the substitution of trimethylene chlorohydrin for the trimethylene bromide which he used, avoiding complications due to the formation of the diphthalirnido compound. y-Hydroxypropyl phthalimide has been previously prepared by Gabriel.[8]

y-Aminopropanol was converted into y-4-morpholinepropanol by condensation with β,β'-dichloroethyl ether in the presence of anhydrous potassium carbonate. Some other morpholine derivatives have been prepared in a similar manner by Cretcher and his associates,[9] using an excess of the amine in place of the potassium carbonate, but the method has never been described for the preparation of morpholine alcohols. A similar procedure was used in a preliminary experiment for the preparation of morpholine-ethanol from ethanolamine.

γ-4-Morpholinepropanol was converted into the benzoate and *p*-aminobenzoate hydrochlorides in the same manner as the corresponding compounds were prepared from morpholine-ethanol.

Experimental

Triethanolamine Hydrochloride.—Four hundred grams of commercial triethanolamine[10] was dissolved in an equal volume of alcohol, the solution cooled in an ice-bath, and dry hydrogen chloride passed in until precipitation was complete. The precipitate was filtered off, washed with cold alcohol and recrystallized from 70% alcohol; yield, 338 g. of colorless rhombohedra1 crystals, m. p. 176.5–177°.[11] Knorr gives 177°.[4b]

β-4-Morpholine-ethanol.—Five hundred sixty-one grams of triethanolarnine hydrochloride in a 3-liter flask provided with a reflux condenser was heated in an oil-bath at 200–205° under a pressure of 40 mm. for fourteen hours, keeping the water in the condenser jacket at 50–60° to facilitate the removal of water. The resulting brown mass was repeatedly extracted with hot alcohol until only a slight residue of tarry matter remained. The alcoholic extract was cooled and filtered from 65 g. of triethanolamine hydrochloride which crystallized out. The filtrate, about 1500 cc., was boiled under reflux with 175 g. of potassium hydroxide, the resulting solution being strongly alkaline. The morpholine-ethanol solution was filtered from the precipitated potassium chloride and the alcohol removed by distillation. The residue was distilled under 25 mm. pressure, yielding 158 g. (46%) of crude morpholine-ethanol, b. p. 116–123°. Upon redistillation, β-4-morpholine-ethanol was obtained as a colorless oil with a piperidine-like odor, b. p. 118–120° under 24 mm.; d_{25}^{25} 1.0712; d_4^{25} 1.0681; n_D^{25} 1.4770; M_D calcd.: 34.71. Found: 35.46. ***Anal.*** Subs., 0.3776, 0.4023: 31.14, 31.26 cc. of 0.1116 N HCl; 5.49, 3.95 cc. of 0.1235 N NaOH. Calcd. for $C_6H_{13}O_2N$: N, 10.68. Found: N, 10.37, 10.44. Neutral equivalent. β-4-Morpholine-ethyl Benzoate Hydrochloride.—To a mixture of 8 g. of benzoyl chloride and 7.2 g. of morpholine-ethanol, there was added a 10% solution of sodium hydroxide until the mixture was alkaline. A vigorous reaction occurred and a heavy brown oil separated. The mixture was warmed until the odor of benzoyl chloride was no longer noticeable. The oil was dissolved in benzene and the solution dried over anhydrous sodium sulfate. The benzene solution was saturated with dry hydrogen chloride with the formation of a voluminous white precipitate which was filtered off, washed several times with benzene and dried in the air; yield, 10.7 g. (72%); m. p. 204.6–205.8°.

β-4-Morpholine-ethyl *p*-Nitrobenzoate Hydrochloride.—To a solution of 32 g. of *p*-nitrobenzoyl chloride in 250 cc. of benzene there was slowly added a solution of 22 g. of morpholine-ethanol in 50 cc. of the same solvent. The mixture was warmed on the steam-bath for an hour, forming a yellow pasty mass. The solid product was filtered off and washed with benzene. After recrystallization from alcohol, the yield was 26 g. (49%) of short yellow needles, m. p. 214.6–215.4'.

Anal. Subs., 0.5560, 0.6024: 39.91, 39.84 cc. of 0.1070 N HCl; 8.68, 5.19 cc. of 0.0956 N NaOH. Subs., 0.6010, 0.6195: 30.30, 30.39 cc. of 0.1026 N $AgNO_3$; 10.42, 9.94 cc. of 0.1159 N KSCN. Calcd. for $C_{13}H_{17}O_5N_2Cl$: N, 8.85; Cl, 11.20. Found: N, 8.66. 8.75; Cl, 11.21, 11.25. Neutral equivalent. Subs., 0.5122, 0.5256: 16.87, 17.30 cc. of 0.0956 *N* NaOH. Calcd. for $C_{13}H_{17}O_5N_2Cl$: neut. equiv., 316.6. Found: 317.5, 317.7.

P-4-Morpholine-ethyl *p*-Aminobenzoate Hydrochloride.—A solution of 5 g. of the nitrobenzoic ester hydrochloride in 200 cc. of boiling alcohol was shaken for twenty minutes with hydrogen under two to three atmospheres' pressure in the presence of 0.20 g. of Adams' platinum–platinum oxide catalyst.[12] The theoretical amount of hydrogen was absorbed in about seven minutes. The solution was filtered from the catalyst and evaporated under reduced pressure to 40 cc. Upon cooling light yellow crystals deposited. A further quantity was obtained on concentrating the solution to 10 cc. and cooling; yield, 3.3 g. (73%), m. p. 225.8–226.2°.

Anal. Subs., 0.4016, 0.3724: 31.12, 31.19 cc. of 0.1116 N HCl; 6.17, 7.85 cc. of 0.1235 N NaOH. Subs., 0.4604, 0.4885: 30.28, 30.31 cc. of 0.0986 *N* $AgNO_3$; 14.43, 13.44 cc. of 0.0977 N NH_4SCN. Calcd. for $C_{13}H_{19}O_3N_2Cl$: N, 9.77; Cl, 12.37. Found: N, 9.45, 9.44; Cl 12.14, 12.17. Neutral equivalent. Subs., 0.4604, 0.4885: 12.74, 13.49 cc. of 0.1235 N NaOH. Calcd. for $C_{13}H_{19}O_3N_2Cl$: neut. equiv., 286.6. Found: 292.6, 293.2.

γ-Aminopropanol.—A mixture of 50 g. of trimethylene chlorohydrin and 88 g. of potassium phthalimide in a three-necked 500-cc. flask provided with a reflux condenser and an efficient mechanical stirrer was heated, with stirring, in an oil-bath to 155°. At this temperature a vigorous reaction took place and the bath was removed until the reaction subsided. The bath was again placed under the flask and the mixture was heated

---

[12] Adams, Voorhees and Shriner, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 92.

to 180–190° for two and one-half hours. The resulting pasty mass was extracted several times with hot water. The extract was filtered and cooled. The heavy brown oil which precipitated was separated. After standing for two days it solidified to a yellowish sticky mass. A portion dried on a porous plate softened at 68° and melted at 74°. Gabriel[ab] gives m. p. 75° for γ-hydroxypropyl phthalimide.

The crude product was boiled for a half hour under reflux with a solution of 100 *g.* of potassium hydroxide in 450 cc. of water. The resulting solution was distilled using a short Hempel tube until 200 cc. of distillate had been collected. This fraction was practically free of γ-aminopropanol and was discarded. The Hempel tube was then removed and the remaining liquid distilled without a column. In order to drive over the last of the aminopropanol, two portions of 50 cc. of water were added to the residue and distilled. The combined distillates were freed from water by redistillation using the Hempel tube and the residue was finally purified by distillation from a Claisen flask; yield 15 g. (42%), b. p. 185–190°. Putochin gives 185–186°.[7]

γ-4-Morpholinepropanol.—A mixture of 22.5 g. of γ-aminopropanol, 45 g. of β,β'-dichlorodiethyl ether and 45 g. of powdered anhydrous potassium carbonate in a two-necked 200-cc. flask provided with a reflux condenser and an efficient mechanical stirrer was heated with vigorous stirring in an oil-bath. When the temperature reached 120" a vigorous reaction set in with a rapid evolution of carbon dioxide. The oil-bath was removed until the reaction moderated. After about half an hour, the bath was replaced and the mixture was heated for two and one-half hours at 170°. After cooling, the mixture was extracted four times with 50-cc. portions of hot benzene, the combined extracts dehydrated over anhydrous potassium carbonate and the benzene distilled off. The residue was distilled under 24-mm. pressure, the γ-4-morpholinepropanol being collected at 134–136°. The yield was slightly increased by redistilling the lower and higher fractions; yield, 29 g. (67%); d^{25}_{25} 1.0452; d^{25}_{4} 1.0422; n^{25}_{D} 1.4752; M_D calcd.: 39.33. Found: 39.21.

Anal. Subs., 0.3618, 0.3922: 30.18, 29.81 *cc.* of 0 1116 N HCl; 8.18, 5.52 cc. of 0.1235 N NaOH. Calcd. for $C_7H_{15}O_2N$: N, 9.65. Found: 9.55, 9.45. Neutral equivalent. Subs., 0.5309, 0.5178: 32.21, 31.48 cc. of 0.1116 N HCl. Calcd. for $C_7H_{15}O_2N$: neut. equiv., 145.1. Found: 147.7, 147.4.

γ-4-Morpholinepropyl Benzoate Hydrochloride.—The procedure was the same as that used in the preparation of p-4-morpholine-ethyl benzoate hydrochloride: yield from S *g.* of γ-4-morpholinepropanol and 9 *g.* of benzoyl chloride, 8 *g.* (51%), m. p. 190.1–190.5".

Anal. Subs., 0.5220, 0.4937: 29.98, 30.10 cc. of 0.1116 N HCl; 12.53, 13.39 cc. of 0.1235 *N* NaOH. Subs., 0.4229, 0.5186: 30.06, 30.48 cc. of 0.0986 *N* $AgNO_3$; 12.63, 12.37 cc. of 0.0977 *N* NH_4SCN. Calcd. for $C_{14}H_{20}O_3NCl$: N, 4.90; Cl, 12.42. Found: N, 4.83, 4.84; Cl, 12.29, 12.28. Neutral equivalent. Subs., 0.5207, 0.5314: 14.80, 15.10 cc. of 0.1235 N NaOH. Calcd. for $C_{14}H_{20}O_3NCl$: neut. equiv.. 285.6. Found: 284.9, 285.0.

γ-4-Morpholinepropyl p-Nitrobenzoate Hydrochloride.—The procedure was the same as that used in the preparation of the lower homolog except that a mechanical stirrer was used and the time of heating was increased to two hours; yield from 10 g. of γ-4-morpholinepropanol and 17 g. of *p*-nitrobenzoyl chloride, 20 g. (89%), after recrystallization from alcohol, m. p. 232.8–233.2°.

Anal. Subs., 0.6190, 0.5307: 38.01, 30.15 cc. of 0.1116 N HCl; 5.45, 2.13 cc. of 0.1235 *N* NaOH. Subs., 0.5046, 0.5006: 30.11, 30.03 cc. of 0.0986 *N* $AgNO_3$; 14.98, 15.03 cc. of 0.0977 *N* NH_4SCN. Calcd. for $C_{14}H_{19}O_5N_2Cl$: N, 8.47; Cl, 10.72. Found: N, 8.08, 8.18; Cl, 10.58, 10.58. Neutral equivalent. Subs., 0.5006, 0.5355: 12.25, 13.08 cc. of 0.1235 N NaOH. Calcd. for $C_{14}H_{19}O_5N_2Cl$: neut. equiv., 330 6. Found: 330.9, 331.2.

γ-4-Morpholinepropyl *p*-Aminobenzoate Hydrochloride.—The reduction was carried out in the same manner as was described for the lower homolog. From 7.5 g. of the p-nitrobenzoate hydrochloride there was obtained 4.8 g. (70%) of γ-4-morpholinepropyl p-aminobenzoate hydrochloride, m. p. 193.3–193.7'.

Anal. Subs., 0.3303, 0.3342: 29.92, 30.43 cc. of 0.1116 N HCl; 10.04, 9.88 cc. of 0.1235 *N* NaOH. Subs., 0.3727, 0.5436: 25.21, 30.30 cc. of 0.0986 *N* $AgNO_3$; 12.91, 12.38 cc. of 0.0977 N NH_4SCN. Calcd. for $C_{14}H_{21}O_3N_2Cl$: N, 9.31; Cl, 11.79. Found: N, 8.90, 9.12; Cl, 11.66, 11.60. Neutral equivalent. Subs., 0.4977, 0.5436: 13.05, 14.25 cc. of 0.1235 N NaOH. Calcd. for $C_{14}H_{21}O_3N_2Cl$: neut. equiv., 300.6. Found: 308.8, 308.9.

Pharmacological Report.—Some preliminary pharmacological tests on these compounds were made by Dr. H. S. Gasser of the Washington University School of Medicine. While the data available will not justify any quantitative summary, some qualitative conclusions can be drawn. Studying the effect in nerve block, all compounds showed at most slight action when made up to one per cent. in Ringer's solution. When adjusted to *P*H 7.4, however, all were effective. In each case it was found that the p-aminobenzoate was more effective than the corresponding benzoate, and each of the propanol derivatives more effective than the corresponding ethanol derivative. γ-4-Morpholinepropyl p-aminobenzoate hydrochloride was more effective than cocaine.

On the rabbit's cornea, none of the compounds was effective when applied in one per cent. solution, but when adjusted to *P*H 8, the propanol derivatives produced almost immediate anesthesia. In 0.2% solution at PH 8, γ-4-morpholinepropyl p-aminobenzoate hydrochloride produced anesthesia in almost as short a time as cocaine, but in 0.05% solution, PH 8, while cocaine produced anesthesia in two minutes, the new compound was without effect.

The toxicity of only two of the new compounds has been tested. β-4-Morpholine-ethyl benzoate hydrochloride gave a minimum lethal dose in rabbits of approximately 120 mg. per kg. body weight, and γ-4-morpholinepropyl p-aminobenzoate hydrochloride, 60 mg., as compared to 15 mg. for cocaine.

Relative Acidities.—Since it is well known that the effectiveness of a local anesthetic varies with the hydrogen-ion concentration of the solution in which it is applied,[13] determinations were made of the hydrogen-ion concentrations of 0.5% solutions of each of these compounds. Since precipitates were formed on adding alkali to solutions of the *p*-aminobenzoate hydrochlorides, the PH values at precipitation were determined in these cases. For comparison, similar determinations were made on solutions of procaine and diethylaminoethyl benzoate hydrochloride.

---

The latter compound was prepared for us by Mr. L. A. Burrows of this Laboratory. The results are shown in Table I.

TABLE I

RELATIVE ACIDITIES

Morpholine-( )-hydrochloride	PH	0.5% solution PH at precipitation
Ethyl benzoate	4.0	8.0 no precipitation
Ethyl *p*-aminobenzoate	4.2	6.7
Propyl benzoate	4.3	8.0 no precipitation
Propyl *p*-aminobenzoate	4.4	6.9
Procaine	5.2	8.0 no precipitation
Diethylaminoethyl benzoate hydrochloride	4.8	7.9

Summary

1. A series of local anesthetics of the alkamine ester type in which the dialkylamino group has been replaced by a morpholine ring has been prepared and described.

2. Some preliminary pharmacological tests on these compounds have been made.

3. These compounds have been found to possess considerable local anesthetic activity and low toxicity.

This investigation is to be continued.

CONDENSATIONS BY SODIUM INSTEAD OF BY THE GRIGNARD REACTION. II.[1] REACTION WITH BENZONITRILE. PREPARATION OF DIPHENYLKETAZINE

BY AVERY A. MORTON AND JOSEPH R. STEVENS

RECEIVED MAY 15, 1931 PUBLISHED JULY 8, 1931

When benzonitrile is added to a mixture of chlorobenzene and sodium in ether the solution becomes intensely red. We ascribe the occurrence of this color to the presence of sodium diphenyl methylene imine, which is formed according to equation (1) below. This appears reasonable since the reactions of the solution with water, oxygen and iodine lead to the formation of benzophenone, benzophenone oxime and diphenylketazine, respectively (equation 2), in all of which the red color is destroyed.

$$C_6H_5CN + C_6H_5X + 2Na \longrightarrow (C_6H_5)_2C{=}NNa + NaX \qquad (1)$$

$$2(C_6H_5)_2C{=}NNa + \left\{\begin{array}{l} 4H_2O \longrightarrow 2(C_6H_5)_2C{=}O + 2NH_3 + 2NaOH \\ O_2 \longrightarrow 2(C_6H_5)_2C{=}NONa \\ I_2 \longrightarrow [(C_6H_5)_2C{=}N]_2 + 2NaI \end{array}\right. \qquad (2)$$

The action of iodine on the corresponding magnesium compound, diphenyl methylene imino magnesium bromide, obtained by the addition

---

[1] First paper of this series, THIS JOURNAL, 53, 2244 (1931).

of benzonitrile to phenylmagnesium bromide has never been observed. It therefore followed naturally to try such a reaction, equation (3), with

$$2(C_6H_5)_2C{=}N{-}MgBr + I_2 \longrightarrow (C_6H_5)_2C{=}N{-}N{=}C(C_6H_5)_2 + 2MgIBr \quad (3)$$

the result that the diphenylketazine was prepared in good yield. This is a decided improvement over the older method of Curtius and Rauterberg.[2] The corresponding reaction of the magnesium compound with oxygen did not cause the formation of any oxime.

We are unable to say that sodium is better than magnesium with benzonitrile probably because of the strong tendency of the latter to polymerize under the influence of sodium.[3] We overcame this in part by the use of a stirrer and the gradual addition of the benzonitrile to the reaction mixture. However, the work has led to a better method of preparing diphenylketazine and to the preparation of the oxime by the reaction of oxygen with a nitrogen–sodium linkage.

Further studies are being made on the decomposition of the sodium imine compound and the corresponding magnesium compound as well as other condensations by sodium instead of by the Grignard reaction.[4]

Experiments

Benzonitrile and Chlorobenzene.—The experiment was performed in an atmosphere of dry nitrogen: 4.6 g. of sodium sand was put into a three-necked flask with 200 cc. of anhydrous ether; 11.2 g. of chlorobenzene was added and the flask heated on a hot-plate while the mixture was stirred. As soon as the reaction began, 10.3 g. of benzonitrile in 30 cc. of ether was added slowly through a dropping funnel over a period of one and a half hours. The solution became of a very deep red color, probably owing to the formation of the sodium imine compound. At the first part of the reaction enough heat was evolved to maintain refluxing, but after all of the nitrile had been added the mixture was again heated on the hot-plate for two hours. The sodium imine compound was not isolated from this mixture but was treated directly with other substances.[5]

Reaction with Air.—When air was blown through the cold imine solution, with stirring, the red color disappeared. The mixture was then treated with water, the ether evaporated and the water solution filtered. When neutralized with dilute hydrochloric acid, 6 g. of benzophenone oxime, as shown by a mixed melting point, was precipitated; yield, 30.5%.

Reaction with Iodine.—Iodine added to the solution of the sodium imine prepared as described above decolorized the solution, the completion of the reaction being almost

[3] Hofmann, *Ber.*, 1, 194 (1868); Lottermoser. *J. prakt. Chem.*, [2] 54,132 (1896).

[4] In our study of the reaction of carbon dioxide with organic chlorides, chlorobenzene was heated under 30 pounds' pressure of carbon dioxide in the presence of sodium. The exothermic nature of the reaction once started was so great that it became uncontrollable and blew the container with explosive violence. This word of caution is given in advance of the article describing all of these experiments in order to emphasize again the care that must be exercised when working with sodium.

[5] Preliminary experiments on the decomposition of the sodium imine compound with water showed a mixture of benzophenone and the corresponding orime, the latter being due to the presence of air.

equivalent to an end-point in a titration. Much heat was evolved and a yellow solid was precipitated. The mixture was decomposed with water in the cold and filtered without evaporating the ether. The solid residue was extracted with carbon bisulfide and the latter was evaporated to dryness, yielding a yellow solid. Upon washing with hot acetone, 3 g. of a bright yellow crystalline solid (m. p. 160–162°) was obtained; yield, 16.7%. Diphenylketazine is recorded as melting at 162 and 164°.[2,6]

Anal. Calcd. for $C_{26}H_{20}N_2$: C, 86.67; H, 5.60. Found: C, 86.68, 86.47; H, 5.78, 6.81.

Preparation of the Sodium Imine Compound from Sodium and Diphenyl Methylene Imine.—Diphenyl methylene imine[7] (approximately 0.05 g.) dissolved in anhydrous ether was sealed up in a small tube with a sliver of sodium. A deep red color, similar to that obtained in the reactions given above, developed. When iodine was added, a yellow precipitate formed but the material could not be purified sufficiently in the micro tube to determine whether it was the ketazine. However, when the sodium imine compound so prepared was kept in an open tube in a desiccator for two days so that air could come in contact with it (ether added to compensate for evaporation loss) benzophenone oxime was formed in quantities sufficiently large for easy identification, m. p. 141°.

Preparation of the Ketazine from the Magnesium Compound.—To a warm ether solution of phenylmagnesium bromide, made from 20 g. of bromobenzene and 3.1 g. of magnesium in 200 cc. of ether, was added 10 g. of benzonitrile. After five minutes the stirring was stopped and the ether solution was allowed to cool. The magnesium compound crystallized out in needles from a common center. The crystals were then broken up and 16 g. of iodine added to the mixture with heating and stirring. The stirring was continued for two hours and the mass allowed to stand for a day. It was again stirred for ten hours, the ether evaporated, the mass heated to 100° and stirred for two hours. It was then decomposed with dilute acid, the precipitate filtered, dried and extracted with hot benzene. The benzene was evaporated to 100 cc., an equal volume of petroleum ether added and the resulting precipitate washed with more petroleum ether. The solid had a melting point of 164° and showed no depression when mixed with the product obtained from the reaction of iodine with the sodium imine compound; yield, 10 g. (57.4%). Instead of using iodine the decomposition of the magnesium compound was carried out by the addition of bromine to the solution under a gentle refluxing. A large amount of heat was evolved but no hydrobromic acid was observed. When decomposed with cold dilute hydrochloric acid and purified as described above, 2 g. (7.6%) of ketazine, m. p. 162°, identical with that formed by the addition of iodine was obtained.

Attempted Reaction of the Magnesium Compound with Oxygen.—Oxygen was blown through a solution of the magnesium compound, prepared as above described, for ten hours, benzene being added to compensate for the loss of ether. No benzophenone oxime could be isolated. The experiment was repeated using dry lead dioxide instead of oxygen but again no oxime was found.

Conclusion

Benzonitrile reacts with phenyl halides in the presence of sodium forming, probably, sodium diphenyl methylene imine.

The mixture so obtained reacts with water, air and iodine forming benzophenone, benzophenone oxime and diphenyl ketazine.

[6] Purgotti and Viganò, *Gazz. chim. ital.*, **31**, II, 550 (1901).

[7] Prepared according to the directions of Lachman, "Organic Syntheses," 10, 28 (1930).

The ketazine may also be prepared by means of the reaction of the corresponding magnesium compound with iodine.

The formation of the ketazine is a new and better method of preparing these compounds.

THE REACTIVITY OF THE METHYLATED SUGARS. IV. THE ACTION OF DILUTE ALKALI ON TRIMETHYLXYLOSE[1]

BY CHARLES EZRA GROSS WITH W. LEE LEWIS

RECEIVED MAY 18, 1931 PUBLISHED JULY 8, 1931

The theory of intermediate enol formation[2] which has proved so valuable in elucidating sugar reactions has nevertheless rested more upon plausibility than proof. The methylated sugars lend themselves to testing more directly the mechanism of these reactions by limiting in a predictable manner enol formation.[3] This follows from the lesser lability of the methyl group as compared with the replaced hydrogen of the sugar hydroxyl. Thus the theory of selective hydration and dehydration in enol formation

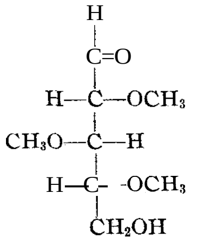
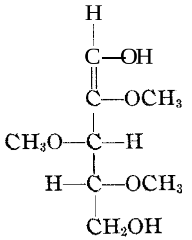
has been shown untenable, and the elimination of ketose formation in the Lobry de Bruyn reaction controlled at will.[3b,c]

The present paper deals with an extension of this method of study to a pentose, 2,3,4-trimethylxylose. For purposes of comparison, xylose was first treated with dilute alkali using the conditions of time, temperature and concentration previously found to give a minimum of saccharinic acid formation.[3b] Under these conditions, the system shown in the formulas just given would be expected. The major products were found to be d-lyxose and d-xylose and a condensation product of four moles of the expected 2-keto-xylose.

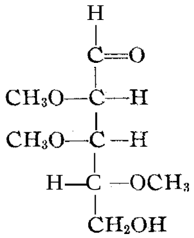
In the case of the trimethylxylose, no ketose formation would be expected due to the blocking effect of the methoxyl group on the second carbon atom. The following system should result from the treatment of 2,3,4-*d*-xylose with dilute alkali



Trimethylxylose

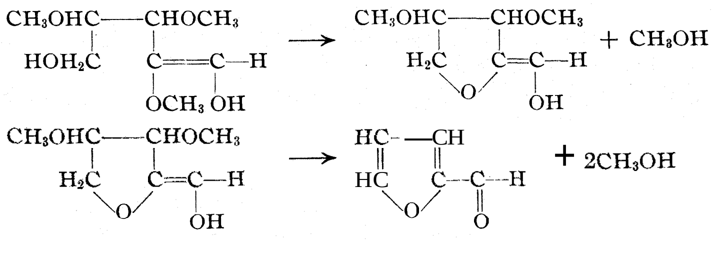


Common monomethyl enol



Trimethyllyxose

When trimethylxylose was treated with dilute alkali under the conditions applied to d-xylose, evidence was obtained of a stable enol. Trimethylxylose and trimethyllyxose were proved to be present. When, however, dilute acid was added to the reaction mixture in order to de-enolize it, the total aldose fell below 100% and furfural appeared. It is suggested that the furfural results from the action of acid upon the monomethyl enediol according to the equations



This conclusion is based upon the fact that a direct relation was established experimentally between the amount of presumptive enol present and of furfural formed. Furthermore, the amount of alcohol found after de-enolization with dilute acid was roughly twice the amount found in the alkaline reaction mixture. This removal of alcohol in two portions of roughly one-third and two-thirds supports the preceding equation. Since no ketose was found present, the methyl alcohol could not have had its source in demethylation incident to ketose formation. It is believed that no furfural results from xylose under these conditions because the intermediate enol is transient. In none of the studies of the action of dilute alkalies upon unmethylated sugars have we ever found evidence of a substance of high iodine absorbing power.[4]

The gum isolated from the de-enolized reaction mixture was shown to consist of about 70% of trimethyllyxose and 26% of trimethylxylose with about 4% of partially demethylated material. The sugars were separated by fractional crystallization of the brucine salts of their acids. These were further converted into the crystalline phenylhydrazides for identification.

Experimental Part

Preparation of **Trimethylxylose.**—Normal 2,3,4-trimethylxylose was prepared by the methylation of four moles (600 g.) of commercial xylose with dimethyl sulfate according to the method of Carruthers and Hirst.[5] The yield of β-methyltrimethylxyloside was 528 g. or 69% of the theoretical collected at 80° and 3 mm. pressure. Four hundred and twenty grams of purified β-methyltrimethylxyloside was hydrolyzed by heating a 7% solution containing 7% of hydrogen chloride at 80° for three hours. The solution was then neutralized, evaporated and the trimethylxylose extracted from the salty residue with chloroform. After the chloroform was removed. the residue was crystallized from ethyl ether. In the above manner, 230 g. of crystalline material was obtained, a yield of 60% of the theoretical. Upon recrystallization from absolute ether and careful drying, there was obtained 190 g. of pure material giving a final $[\alpha]^{20}_{D}$ of +17.8° (a = +1.0° in a 2-dm. tube when c is 2.8116 in water). Carruthers and Hirst[5] record a final [a], of +20° in water and +21° in methyl alcohol. Phelps and Purves[6] found $[\alpha]^{20}_{D}$ +17.7° in aqueous solution, for the final specific rotation of pure trirnethylxylose. Hirst and Carruthers record a melting point of 87–90"; Phelps and Purves record 91–92". In order to check the purity of the product, it was redistilled and collected at 111° and 3 mm. and at 121° and 5 mm. The liquid gave a refractive index of 1.4603 when supercooled to 20". The entire product solidified upon cooling and was again crystallized from absolute ether. After careful drying the substance was analyzed for methoxyl.

Anal. Subs., 0.0335, 0.0911; AgI, 0.3410, 0.3353. Calcd. for $C_5H_7O_2(OCH_3)_3$: OCH_3, 48.4. Found: OCH_3, 48.2, 48.6.

The substance was optically homogeneous in polarized light. It gave a final specific rotation of +17.8° (a = +1.32° in a 2-dm. tube when c is 3.70 in water). In methyl alcohol the final specific rotation was +21.3° (a = +1.11 in a 1-dm. tube when c is 5.214").

The Action of Dilute Alkali on *d*-**Xylose.**—One-half mole (75 g.) of pure d-xylose [specific rotation +19.2° (a = +0.94" in a 1-dm. tube when *c* = 4.895 in water)] was made to 500 cc. with 0.04 N calcium hydroxide solution saturated at 35°. The final concentration of the sugar was molar in 0.035 N calcium hydroxide solution at 32°.

[6] Phelps and Purves, THIS JOURNAL, 51, 2443–9 (1929).

The iodine oxidation method of Cajori[7] as modified by Wolfrom and Lewis[3b] was found to apply to the determination of xylose if the time of oxidation was thirty-five to forty-five minutes. The change in aldose content is shown in Table I and graphically in Fig. 2. The change in rotation appears in Table I and graphically in Fig. 1. The final rotation was +11.2° at 30° when *c* was molar and the aldose content 77.4%. The hydrogen-ion concentration corresponds to a P_H of 5.85 as determined by the quinhydrone electrode. The initial P_H of the lime water was 12.6, and dropped to 10.6 upon addition of the sugar.

[a] C = molar. [b] By iodine titration. [c] The sample is treated with 3 *N* hydrochloric acid for three hours at 20°. It is then neutralized and oxidized in the usual manner, and the excess of iodine titrated with thiosulfate.

The saccharinic acid content was calculated as 3.4% by direct titration after removal of calcium ions. No furfural was present according to the aniline acetate test.

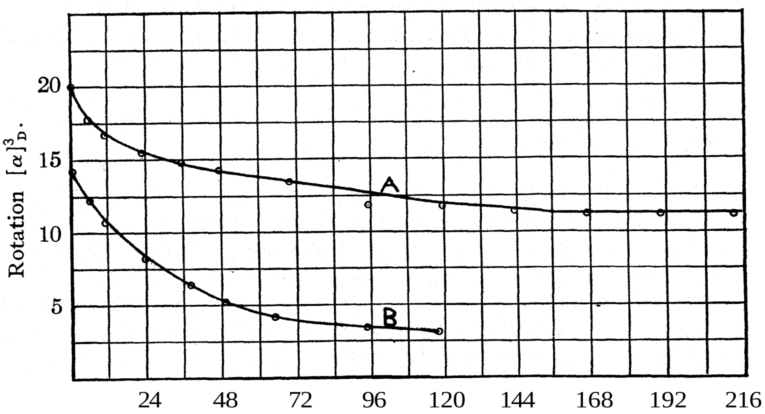

Fig. 1.—Change in rotation of d-xylose and trimethyxlylose in dilute alkali: A, xylose; B, trimethylxylose.

Separation of Aldoses and Ketoses.—By the oxidation of 350 cc. (corresponding to 50.03 g. of xylose) of the final equilibrated solution using Hudson and Isbell's[8] neutral bromine method, the aldoses were converted to aldonic acids and the ketoses presumably unattacked. The final solution (corresponding to 49.0 g. of xylose due to

---

[7] Cajori, *J. Biol. Chem.*, 54, 617 (1928).

[8] Hudson and Isbell, THIS JOURNAL, 51, 2225 (1929).

sampling) freed of benzoate, bromide and silver ions, after concentration to 150 cc. was treated with an excess of cadmium carbonate. The excess cadmium carbonate was removed by filtration and the cadmium salts precipitated by the addition of 500 cc. of ethyl and 500 cc. of methyl alcohols with rapid stirring. The cadmium salt dried over sulfuric acid *in vacuo* weighed 58.0 g.

The filtrate from the precipitation of cadmium salt was evaporated to dryness and then taken up in absolute methyl alcohol and added with vigorous stirring to absolute ether. A very fine white precipitate formed which on standing became distinctly granular. The total yield of this ketosic material was 4.82 g.

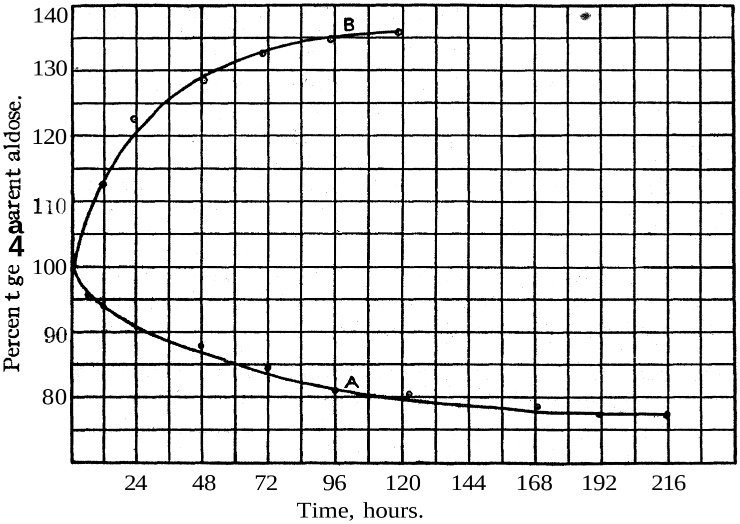

Fig. 2.—Change in apparent aldose content calculated from the iodine titration: A, xylose; B, trimethylxylose.

Separation of the Cadmium Salts.—Fifty-seven grams of cadmium salt was dissolved in water and the amount of cadmium bromide sufficient to convert all cadmium salts to cadmium bromide, cadmium xylonate double salt was added. Sixty-six and one-tenth grams of the double salt was obtained after concentrating and allowing the solution to stand. It gave a specific rotation of +8.4° (α = 0.20° in a 2-dm. tube when *c* is 1.182 in water). It contained 21.23% of bromine. Nef[9] recorded a specific rotation of +7.4°, while Hudson and Isbell[8] found a rotation of +8.8°.

Anal. Subs., 0.0912: AgBr, 0.0455. Calcd. for $CdBr_2 \cdot Cd(C_5H_9O_6)_2 \cdot 2H_2O$: Br, 21.31. Found: Br, 21.23.

To identify the xylonic acid further, 6.0 g. of the double salt was converted to the brucine salt after removal of the cadmium and bromine ions. There was obtained 3.5 g. of once recrystallized brucine xylonate which melted at 172–173° and gave a specific rotation of −19.1° (α = −0.544° in a 1-dm. tube when *c* is 2.842 in water). Nef[10] records a melting point of 172–174° and a specific rotation of −18.7°.

The residual liquor from the precipitation of cadmium bromide cadmium xylonate double salt was freed of cadmium and bromide ions and then converted to the brucine

[9] Nef, *Ann.*, 403, 263 (1914).

[10] Nef, Ref. 9, p. 234.

salt. This yielded 16.9 g. which was very sparingly soluble in alcohol. From the alcohol-soluble portion **0.5 g.** of brucine xylonate and **0.8** g. of brucine lyxonate were separated by fractional crystallization. The total of **17.7** g. of brucine lyxonate had a specific rotation of −26.4° ($\alpha = -0.92°$ in 1-dm. tube when c is **3.483** in water). Ten grams was then converted to the phenylhydrazide, which gave **4.0** g. of anhydrous phenylhydrazide. This melted at 162–164° and gave **a** specific rotation of **−11.0°** ($\alpha = -0.18°$ in a 2-dm. tube when c is **0.818** in water). Wohl and List[11] recorded a melting point of **162–164°** and a specific rotation of **−11.2°** for the anhydrous phenylhydrazide. The brucine xylonate was identified by melting unchanged with known brucine xylonate.

Nature and Constants of the **Ketose.**—The ketose isolated reduced Fehling's solution only upon heating and did not reduce neutral permanganate solution. The ketose expected would be a "gamma" sugar and yet the material isolated exhibited none of the properties of a "gamma" sugar. The isolated solid material would not condense with methyl alcoholic hydrogen chloride even after three hours' refluxing. The final rotation in water was +3.0° ($\alpha = +0.09$ in a 2-dm. tube when c is **1.474** in water). In methyl alcohol the final rotation was +6.4° ($\alpha = +0.133°$ in a 1-dm. tube when c is 2.068 in methyl alcohol). **A** determination of the molecular weight by rise in boiling point of methyl alcohol gave **524** and **540.** If four moles of keto-xylose condensed with the elimination of three moles of water, the resulting compound would have a molecular weight of **546.**

Summary of Products Isolated from Equilibrated Solution of **Xylose.**—From 100 g. of xylose equilibrated there were isolated the following products calculated to equivalent xylose: first, **52.9** g. of xylose as xylonic acid derivatives (this represents the amount of xylose unchanged after equilibration); second, 8.3 g. of xylose as lyxonic acid derivatives; third, 9.8 g. of xylose as the crystalline condensed ketose; fourth, **3.4** g. of xylose as the presumptive saccharinic acid.

Action of Dilute Alkali on **Trimethylxylose.**—It was determined in preliminary experiments that the iodine oxidation method for aldose, as used on xylose, was applicable to trimethylxylose if the time of oxidation was at least ten minutes. The changes in rotation and in aldose content when trimethylxylose was treated with saturated lime water at 35° are recorded in Table II and graphically in Figs. 1 and 2. The solutions gave a final specific rotation of +3.0° and were but very slightly alkaline. No furfural was present in the alkaline equilibrated solution. Calculations based on the known rotations of the two epimers, trimethyllyxose and

[11] Wohl and List, **Ber.,** 30, **3105** (1897).

trimethylxylose, and the final rotation indicated the presence of 37.2% of trimethyllyxose. Direct titration after removal of the calcium ion indicates 2.5% of acidic substances calculated as saccharinic acid.

The high apparent aldose indicates the presence of an "enolic" substance encountered by Wolfrom and Lewis[3b] and Greene and Lewis[3c] in treating methylated sugars with dilute alkali. The latter authors showed that, in the case of tetramethylglucose and tetramethylmannose, no ketose or methyl alcohol was present in the reaction mixture. In the present work no direct evidence has been obtained for the absence of ketose, but the materials isolated were entirely aldonic in character since no reducing sugar was left after neutral bromine oxidation.

When the equilibrated solutions (200 cc.) were distilled at low pressure and in a 35°-bath using all precautions to prevent the loss of vapor from multiple receivers at −20°, a distillate one-third the volume of the equilibrated solution distilled was collected. Upon repeated refractionation at atmospheric pressure, a final distillate was obtained upon which methyl alcohol was determined by means of the specific gravity and refractive index. Two separate equilibrations gave, respectively, 0.359 and 0.342 mole of methyl alcohol per mole of trimethylxylose equilibrated. A trace of furfural was also found in the distillate amounting to 0.0006 and 0.0005 mole per mole of trimethylxylose, respectively.

The Action of Dilute Acid upon the Equilibrated Solutions.—It was found that very low concentrations of acid produced furfural from the equilibrated solutions of trimethylxylose. This is in decided contrast to the behavior of dilute acid upon either equilibrated solutions of xylose or tetramethylglucose. In the case of tetramethylglucose, the effect of acid is primarily that of de-enolization. In the case of trimethylxylose, the action is primarily that of furfural production and, perhaps, of de-enolization as well. The rate of de-enolization is shown in Table III and graphically in Fig. 3.

TABLE III

DE-ENOLIZATION OF EQUILIBRATED TRIMETHYLXYLOSE SOLUTION (0.0667 M) BY DILUTE ACID (0.667 N)

1.33	104.9	28.0	90.7
3.67	101.9	44.0	90.0

[a] By iodine titration.

It was found that the action of the same concentration of acid upon untreated trimethylxylose, the condensed keto-xylose isolated and equilibrated solutions of xylose, produced no furfural. The production of furfural by the action of acid upon equilibrated solutions of trimethylxylose was attributed to the decomposition of the 1,2-monomethylene-diol.[12]

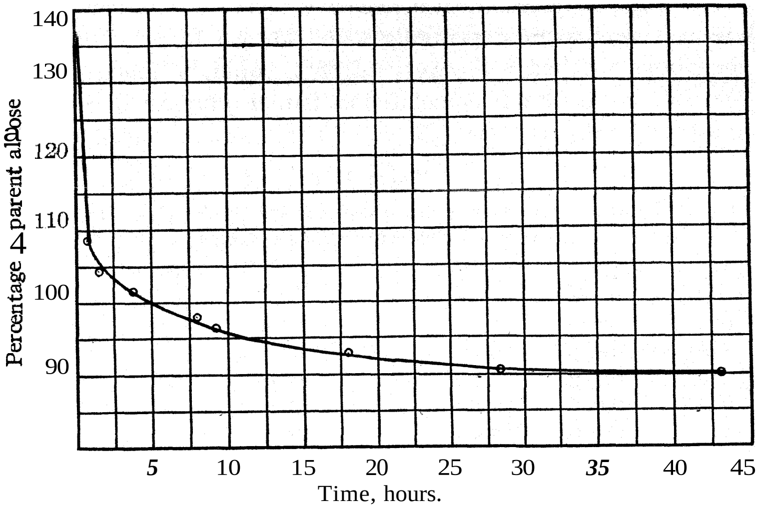

Fig. 3.—Rate of de-enolization of trimethylxylose solutions in dilute acid.

In Table IV and Fig. 4 are shown the relative amounts of furfural produced by the action of the same acid concentrations for the same time upon equilibrated solutions having various apparent aldose values (enol content).

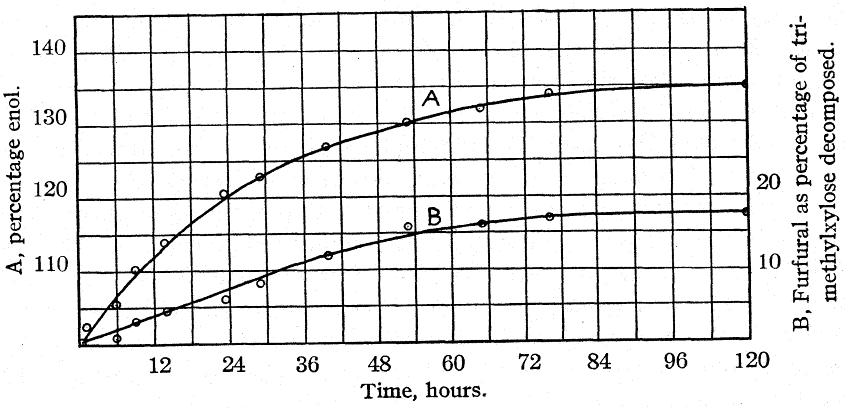

Fig. 4.—Relationship of presumptive enol to furfural formation.

Molar solutions of trimethylxylose made as usual with saturated lime water were heated at 35° until the aldose values were as indicated. They were made 0.0667 M in sugar and 0.667 *N* in hydrochloric acid and heated

---

[12] *Cf.*, however, Carruthers and Hirst, Ref. 5, who report furfural formation during the acid hydrolysis of trimethyl-β-methylxyloside.

for twelve hours at 35°. The furfural was then determined colorimetrically[13] on the distillate from the acid solution after neutralization. The distillation was continued until a negative test was obtained on 1 cc. of distillate. It was found repeatedly using known furfural mixtures that with the above method a recovery of 88% could be made consistently. In Table IV the furfural is calculated as trimethylxylose decomposed and corrected for an 88% recovery.

TABLE IV

RELATION OF IODINE TITRATION EXPRESSED AS APPARENT PER CENT. ALDOSE TO FURFURAL PRODUCTION BY ACID

0	100.0	..	29.0	123.0	8.17
1.0	102.5	0.25	40.0	127.0	11.82
6.0	105.2	.80	53.0	130.0	15.90
9.5	110.0	3.22	65.0	132.0	15.80
14.0	114.0	4.70	76.5	134.0	16.60
23.5	120.5	6.36	120.0	135.0	17.75

Amount of Methyl Alcohol after De-enolization.—In a manner similar to the determination of methyl alcohol present in the equilibrated solution, the amount of methyl alcohol formed during de-enolization was determined. This amounted to 0.790 mole per mole of trimethylxylose equilibrated. Thus, the total methyl alcohol found after de-enolization was 0.350 and 0.790 or 1.140 moles, an amount corresponding to 38.1% of trimethylxylose decomposed to furfural, assuming that all methyl groups are lost from each molecule of trimethylxylose decomposing. It was shown in preliminary experiments that furfural itself is decomposed by the mild acid used; so the difference of 17.75% of furfural found and the 38.1% indicated by methyl alcohol found may be explained on the basis that some furfural was decomposed by the acid before it was determined.

A significant fact appears to be the relationship of the amounts of methyl alcohol in the alkaline equilibrated solution and that formed by the action of acids upon the equilibrated solution after removal of the free methyl alcohol. The relationship is roughly 1 to 2, suggesting that one mole of methyl alcohol is split off in alkaline solution and two additional moles in the acid solution from each mole of trimethylxylose decomposing. This would be in conformity with the equations given on page 2773.

Preliminary Separation of the Equilibrated Solution.—The presence of trimethyllyxose was indicated by the levo rotation of the sirup isolated after acid treatment of the equilibrated solution. An impure *d*-trimethoxyglutaric dimethyl ester was formed by the method of Hirst and Purves[14]

---

[13] Leach, "Food Inspection and Analysis," 3d ed., **1913**, p. 746.

[14] Hirst and Purves, *J. Chem. Soc.*, **123**, 1352 (1923).

from the trimethylpentose gum isolated. A pure *l*-trimethoxyglutaramide was separated after conversion to the amides. A pure *i*-trimethoxyglutaramide could not be obtained.

A bromine oxidation and subsequent formation of brucine salts gave derivatives which could be separated due to differences in their solubilities in acetone.

Quantitative Study of the Equilibration of Trimethylxylose.—Two-tenths of a mole (38.4 g.) of trimethylxylose was made up to a volume of 200 cc. with lime water saturated at 35". The initial aldose content by the iodine oxidation method was 100.5% and after heating at 35° for one hundred and twenty hours, it was 138%. The final specific rotation was +3.0° and the solution was alkaline to phenol red indicator. No furfural was present according to the aniline acetate test.

The above equilibrated solution was de-enolized by heating a solution 0.1 M in trimethylxylose and 1 M in respect to hydrochloric acid for one hour at 35°. The solution was then neutralized with sodium carbonate.

The solution was then concentrated under diminished prescure, precautions being taken as usual to prevent loss of methyl alcohol from the distillate. Upon continued refractionation of the neutral distillate after polymerizing the furfural by the use of sodium hydroxide and determining the content of methyl alcohol by means of the specific gravity and refractive index of the final distillate, it was found that 7.74 g. of methyl alcohol boiling at 65° was recovered from 37.4 g. of trimethylxylose. The methyl 3,5-dinitrobenzoate formed from it melted at 107°[15] and melted unchanged on mixing with the known compound. The total amount of methyl alcohol found (7.74 g. from 37.4 g. of trimethylxylose) corresponds to 1.24 moles per mole of trimethylxylose equilibrated. Calculated *as* trimethylxylose decomposed, it represents a complete decomposition of 41.3%.

After concentration of the de-enolized solution to 100 cc., this volume was extracted with five 200 cc. portions of chloroform. The aqueous portion was then evaporated to dryness and the salt residue crushed and extracted with two 500 cc. portions of boiling chloroform. The combined chloroform extracts were dried and evaporated. The gum was then dried by heating at 80° and 10 mm. for several hours. The gum weighed 20.8 g., which is a recovery of 55.7% of the theoretical of trimethylpentose. This gum gave 100.3% presumptive trimethylpentose by the iodine oxidation method. It gave a specific rotation of −13.2" (c = 5 in water) and contained 44.6% of methoxyl (calcd. 48.4%). The above constants indicate a mixture largely of trimethyllyxose with some trimethylxylose and probably some partially demethylated pentose.

After the above determination had been made, 20.0 g. of gum remained which was oxidized with bromine according to the method of Hudson.[8] After fifty-six hours the

TABLE V

PARTIAL SEPARATION OF BRUCINE SALTS

Fraction	Weight, g.	Rotation, degrees
I	42.0	−18.9
II	5.5	−23.1
III	2.7	−22.7
IV	5.2	−33.0
Total	55.4

[15] Kamm, "Qualitative Organic Analysis," John Wiley and Sons, Inc., New York, 1923, p. 151.

solution no longer reduced boiling Fehling's solution. It was then treated in the usual manner for the removal of the objectionable ions and the free acids converted to brucine salts. After removal of the water, the brucine salts were dissolved in a minimum of hot water and fractionated as shown in Table V.

The theoretical yield of brucine salt of trimethylpentonic acid would be **60.6** g. The yield was then **91.4%** of the theoretical. By a tedious process of fractional crystallization from acetone, the above fractions were resolved into the least soluble brucine trimethylxylonate and the more soluble brucine trimethyllyxonate, with a small residue of extremely soluble partially de-methylated pentonic acids.

Table VI

Separation of Brucine Salts

Compound	Weight, g.	Specific rotation, degrees	M. p., °C.	Methoxyl, %
Trimethylxylonate	12.63	-6.6	114–115	26.45
Trimethyllyxonate	33.59	-23.0	99–100	26.68
Partially methylated pentonates	2.0	-30.2	145–150	19.0
	48.22	Calcd. methoxyl,		25.8

The brucine salts separated **(45.22 g.)** amounted to a recovery of **89.0%** of the theoretical **(55.4 g.)**. The amount separated **(48.22** g.) corresponds to a yield of **79 6%** from the **trimethylpentose gum** oxidized **(20.0** g.).

Known brucine trimethylxylonate gave a specific rotation of $-6.2°$ ($\alpha = -0.221$ in **a** 1-dm. tube when c is **3.57** in water) and melted at **114.5–115°**. The methoxyl content was **26.42%.**

Anal. Subs., **0.1107: AgI, 0.2215.** Calcd. for $C_{26}H_{27}N_2O_5(OCH_3)_5$: OCH_3, 25 8. Found: OCH_3, 26.42.

The presumptive brucine trimethylxylonate **(12.63** g.) gave a specific rotation of -6.6" ($\alpha = -0.187$ in a 2-dm. tube when c is **1.42** in water) and melted at 114–115°. It contained **26.45%** methoxyl.

Anal. Subs., **0.1013: AgI, 0.2032.** Calcd. for $C_{26}H_{27}N_2O_5(OCH_3)_5$: OCH_3, 25.8. Found: OCH_3, 26.45.

To identify still further the presumptive brucine trimethylxylonate, **9.0** g. was converted to the phenylhydrazide according to the method of Hirst.[16] The hydrazide once recrystallized from benzene weighed 3.18 **g.,** which is **68.8%** of the calcd. It melted at 134–135° and when again recrystallized melted at 136–137°. The rotation is +31.1° ($\alpha = +0.335$ in a 1-dm. tube when c is **1.079** in methyl alcohol). It contains **30.8%** of methoxyl. **Hirst[16] records** a melting point of **137–138.5".**

Anal. Subs., **0.0908: AgI, 0.2120.** Calcd. for $C_{11}H_{13}N_2O_2(OCH_3)_3$: OCH_3, 31.2. Found: OCH_3, 30.8.

The presumptive brucine trimethyllyxonate **(33.59** g.) melted at 99–100° and gave a specific rotation of $-23.0°$ ($\alpha = -0.554$ in a I-dm. tube when c is **2.41** in water). The methoxyl content was **26.68%.**

Anal. Subs., **0.1066: AgI, 0.2155.** Calcd. for $C_{26}H_{27}N_2O_5(OCH_3)_5$: OCH_3, 25.8. Found: OCH_3, 26.68.

Ten grams of the presumptive brucine trimethyllyxonate was converted to the phenylhydrazide according to the method of Hirst[16] after removal of the brucine. There was obtained 3.82 g. once recrystallized from benzene, which amounts to a yield of 74.6%.

---

[16] Hirst. J. *Chem. Soc.*, **3147 (1928).**

It melted at 179–180° and after a second recrystallization melted at 179.5–180°. The specific rotation was −30.1" (α = −0.465" in a 1-dm. tube when c is 1.548 in methyl alcohol). It had a methoxyl content of 30.78%.

Anal. Subs., 0.1144: AgI, 0.2663. Calcd. for $C_{11}H_{13}N_2O_2(OCH_3)_3$: OCH_3, 31.2. Found: OCH_3, 30.78.

The presumptive brucine partially demethylated pentonates (2.0 g.) melted at 145–150° and when mixed with either brucine trimethyllyxonate or xylonate melted over a range 20° lower. The specific rotation was −30.2" (α = −0.37° in a 1-dm. tube when c is 1.231 in water). It contained 19.2 and 18.8% of methoxyl.

Anal. Subs., 0.1047, 0.1295: AgI, 0.1521, 0.1842. Calcd. for $C_{26}H_{28}N_2O_6(OCH_3)_4$: OCH_3, 21.1; for $C_{26}H_{29}N_2O_7(OCH_3)_3$: OCH_3, 16.2. Found: OCH,, 19.2, 18.8.

Therefore the gum consisted of about 70% trimethyllyxose, 26% trimethylxylose and 4% of partially methylated materials. Considering the methyl alcohol isolated as indicating the complete decomposition of trimethylxylose to furfural and methyl alcohol, then 41.3% was decomposed. The gum isolated accounts for 55.7% and therefore a calculated total of 97% of the equilibrated xylose is accounted for as isolated. The furfural found is only a portion of that formed since acid causes its decomposition. The gum isolated was separated into its components in 79.6% yield after conversion to aldonic acid and separation of the brucine salts from acetone. Trimethylxylonic and trimethyllyxonic acids were identified as the known crystalline phenylhydrazides.

Conclusion

From the equilibration of 38.4 g. of trimethylxylose (less 1 g. for samples) there was isolated 20.8 g. of trimethylpentose gum or 55.7%. There was also isolated 7.74 g. of methyl alcohol, which indicates the decomposition of 41.3% of the trimethylxylose used, assuming loss of three moles of methyl alcohol from each mole of trimethylxylose decomposed. The total trimethylxylose accounted for in this manner is, therefore, 97.0%.

The remainder of the trimethylpentose gum (20.0 *g.)* was oxidized to trimethylpentonic acids and converted to brucine salts. A total of 55.4 g. of brucine salt was isolated or a yield of 91.4%. The 55.4 g. of brucine salt was separated by fractional crystallization from acetone into brucine trimethyllyxonate 33.59 g., brucine trimethylxylonate 12.63 g. and brucine mono- and di-methoxypentonic acids 2.00 g. The separation was effected with a recovery of 89.0%. The brucine salts separated amounted to 79.6%.

If the amount of trimethylxylose and trimethyllyxose were relatively the same in the original equilibrated solution as in the gum isolated, then the equilibrated solution would have had 38.8% of trimethyllyxose and data for rotations indicated 37.0%. The composition of the isolated gum was trimethyllyxose, 69.6%, trimethylxylose, 26.2% and partially demethylated pentose, 4.2%.

Summary

1. When xylose was treated with lime water at 35°, there were identified 52.9% of xylose, 8.3% of lyxose, 9.8% of a crystalline condensed ketose and 3.4% of presumptive saccharinic acid, expressed as percentage of pentose.

2. The equilibrated solution gave no evidence of a stable enol and treatment with acid did not produce furfural.

3. When trimethylxylose was treated with dilute alkali under the same conditions, it was transformed in part into the epimeric trimethyllyxose, a high iodine absorbing compound believed to be the monomethylenediol and saccharinic acid, the latter in small amount.

4. Methyl alcohol was found in the alkaline solution of trimethylxylose approximately in the proportion of one mole to each mole of methylated sugar decomposed. On treatment with dilute acids, two further moles of methyl alcohol was liberated per mole of sugar decomposed and furfural was formed. A mechanism is proposed for this reaction.

5. The gum formed consisted of trimethylxylose, trimethyllyxose and partially demethylated products in the proportion of 26 to 70 to 4 parts, respectively. Indirect evidence is advanced for the absence of ketose.

6. The conversion of normal trimethylxylose into normal trimethyllyxose confirms the identity of their ring structures.

MIXED BENZOINS. VI. FURTHER EXAMPLES OF REVERSIBILITY. THE FORMATION OF ADDITION COMPOUNDS

BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED MAY 21, 1931 PUBLISHED JULY 8, 1931

In Part V[1] the reversibility of the benzoin condensatio[redacted]as demonstrated by means of the reaction $\mathrm{RCHOHCOR} + \mathrm{R'CHO} \quad \mathrm{RCHOHCOR'}$. This change took place under conditions comparable to those of the usual benzoin reaction. A scheme was formulated for the equilibrium conditions of a benzoin reaction mixture of any type. As noted in part V the scheme implied that a number of other transformations were possible, and most of these implications have now been investigated. Positive results were obtained in two of the possible reactions, namely

$$\mathrm{RCHOHCOR'} + \mathrm{R''CHO} \longrightarrow \mathrm{RCHOHCOR''} \qquad \text{(I)}$$
$$\mathrm{RCHOHCOR} + \mathrm{R'CHOHCOR'} \longrightarrow \mathrm{RCHOHCOR'} \qquad \text{(II)}$$

The results are tabulated. The remaining possibilities

$$\mathrm{RCHOHCOR'} \longrightarrow \mathrm{RCHOHCOR} + \mathrm{R'CHOHCOR'} \qquad \text{(III)}$$
$$\mathrm{RCHOHCOR'} + \mathrm{R''CHOHCOR'''} \longrightarrow \mathrm{R'CHOHCOR''} + \mathrm{RCHOHCOR}^{W} \qquad \text{(IV)}$$

were examined, but only negative results were obtained. The inability to isolate the expected product means either that it was formed in amounts

---

[1] Buck and Ide, THIS JOURNAL, 53, 2350 (1931).

too small to isolate by the methods available or that it was less stable under the conditions of the reaction than was the starting material. It must be borne in mind that continual destruction of material takes place in the reaction mixture, and that the reaction therefore cannot be forced beyond a certain point. Also, the fact that many aldehydes do not form simple benzoins greatly limits the choice of starting materials.

The transformation RCHOHCOR' → R'CHOHCOR was not investigated in the present work.

Experimental

The experimental work was carried out in a manner similar to that described in part V,[1] the starting materials being refluxed in aqueous-alcoholic potassium cyanide solution for a given time, determined by trial. The positive results are recorded in Tables I and II. Negative or indecisive results were obtained in all of the following cases.

Reaction (I).—Benzanisoin and o-chlorobenzaldehyde, benzpiperoin and furfural, benzanisoin and furfural, o-chlorobenzveratroin and benzaldehyde, *o*-chlorobenzveratroin and *p*-dimethylaminobenzaldehyde, o-chlorobenzveratroin and anisaldehyde, *o*-chloro-*p'*-dimethylaminobenzoin and piperonal.

Reaction **(II)**.—**Benzoin** and anisoin, piperoin and anisoin, furoin and anisoin, piperoin and furoin.

Reaction **(III)**.—**Benzanisoin,** benzpiperoin, benzfuroin.

Reaction **(IV)**.—**Benzpiperoin** and *o*-chloro-*p'*-dimethylaminobenzoin, benzanisoin and o-chlorobenzpiperoin, o-chlorobenzpiperoin and p-dimethylaminobenzoin.

Reaction **(V)**.—**Benzpiperoin and** o-chlorobenzpiperoin, *p*-**dimethylaminobenz**anisoin and o-chlorobenzanisoin, *p*-dimethylaminobenzanisoin and benzanisoin.

Reaction (VI).—*p*-Dimethylaminobenzanisoin and anisaldehyde.

The above-cited examples do not, of course, exhaust all the possibilities,

Table I

Reaction (I)

Benzoin	Taken, g.	Aldehyde	Taken, g.	Product	Yield, g.	KCN, g.	Alcohol, cc.	Heating, hours

but they represent what, in the authors' opinion, are the ones offering the best prospects of success.

Note on the Formation of Addition Compounds.—There is a remarkable tendency among mixed and simple benzoins to form crystals containing equimolecular amounts of two different benzoins. The following pairs show this property clearly: (a) benzoin and benzpiperoin, (b) benzoin and anisoin, (c) benzoin and piperoin, (d) anisoin and piperoin, (e) piperoin and p-dimethylaminobenzoin. If equimolecular amounts of these are dissolved together in alcohol and allowed to crystallize, well-formed crystals are obtained in almost the theoretical yield. The crystal form differs from that of either of the components, and the solubility is generally somewhat less. The melting points are lower (about what would be expected for a mechanical mixture of the components) and are raised by the addition of either component. Repeated crystallization from alcohol fails to separate the constituent benzoins. It is evident that an additive compound is formed. If this were not so, oils or gums, or at any rate a mixture of crystals, would be obtained. Oils and gums are in fact painfully frequent outside of the above and perhaps a few other cases.

Molecular weight determinations in acetic acid and in benzene (both cryoscopic) gave values approximately the mean of the molecular weights of the component benzoins, indicating that the addition compounds do not persist in solution. No optical phenomena appear to be involved as solutions and liquors, even after several fractionations, show no rotation.

The bearing of the above observations on mixed benzoin work is important. Apart from complicating fractional crystallizations, these additive compounds interfere with certain preparations. Thus, in the preparation of benzpiperoin, if the reaction mixture (containing very little water) is refluxed for twenty to thirty minutes only, the addition compound of benzoin and piperoin is produced. It is evident that, on further heating, the reaction (II) [Table 11] must take place, resulting finally in a mediocre yield of benzpiperoin. It is precisely in cases where such addition compounds have not been observed or cannot have been formed that the best yields of mixed benzoins are obtained, e. g., with p-dimethylaminobenzoin.

The formation of addition compounds between certain benzoins is doubtless analogous to the formation of dimerides in the acyloin series. Dirscherl and Braun,[2] in discussing the dimerides of acetoin, attribute their existence to partial valency linkages. In the benzoin series such partial valency linkages must be very feeble, as no dimerides are known and the addition compounds do not persist in solution.

Summary

The reversibility of the benzoin condensation has been further demonstrated by means of two of the reactions previously mentioned.' The

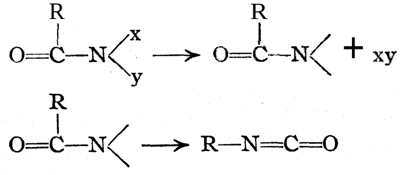
MOLECULAR REARRANGEMENTS INVOLVING OPTICALLY ACTIVE RADICALS. II. THE HOFMANN REARRANGEMENT OF OPTICALLY ACTIVE ACID AMIDES

BY EVERETT S. WALLIS AND S. C. NAGEL

RECEIVED MAY 23, 1931 PUBLISHED JULY 8, 1931

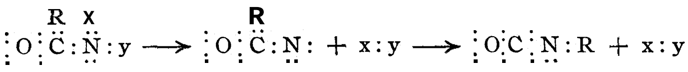
It has long been known that aliphatic and aromatic acid amides are converted into amines by treatment with chlorine or bromine and an alkali. Hofmann discovered this reaction[1] and detected among the products an isocyanate. It has since been shown, however, that the first product formed is a halogen amide. Of the several theories which have been advanced to explain this rearrangement, perhaps the most fruitful has been the interpretation of Stieglitz and his students[2] developed from the suggestion of Tiemann[3] that an acid amide is converted into an amine through the formation of an unstable intermediate univalent nitrogen compound. Their investigations have made it evident that the Lossen, Curtius and Hofmann rearrangements are fundamentally alike and they have proposed that all rearrangements of this character take place as follows



$$O{=}\overset{R}{\overset{|}{C}}{-}N\begin{matrix}x\\y\end{matrix} \longrightarrow O{=}\overset{R}{\overset{|}{C}}{-}N\langle + xy$$

$$O{=}\overset{R}{\overset{|}{C}}{-}N\langle \longrightarrow R{-}N{=}C{=}O$$

In terms of modern valence relationships Jones and Hurd[4] suggested an interpretation of this mechanism based on the Lewis conception of chemical bonds and electrons:



$$\vdots O \vdots \overset{R}{\ddot{C}} : \overset{X}{\ddot{N}} : y \longrightarrow \vdots O \vdots \overset{R}{\ddot{C}} : \ddot{N} : + x : y \longrightarrow \vdots O \dot{:} C \dot{:} \ddot{N} : R + x : y$$

From this interpretation it was assumed that the radical, R, in its wandering from the carbon atom to the nitrogen atom existed momentarily as a free radical, and that the ease of the rearrangement of such types of compounds depended upon the tendency of the radical, R, in the univalent

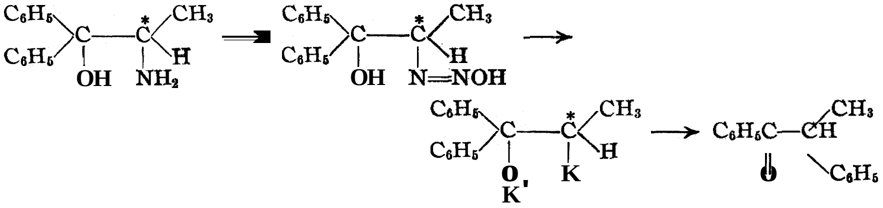
nitrogen derivative to exist as a free radical. This hypothesis has since been tested in this Laboratory by Jones and his co-workers[4,5] and many facts have been found which are wholly in agreement.

In carrying out certain of these investigations Jones and Wallis[6] studied the nature of the products formed by the rearrangement of certain optically active acid azides and optically active hydroxamic acids in which the radical, R, is an optically active radical. From the viewpoint of the above hypothesis three possibilities suggested themselves: (1) the radical might racemize during rearrangement and yield inactive products; *(2)* it might retain its activity and its configuration; (3) it might retain its activity but change its configuration, that is, undergo Walden inversion. The first possibility was excluded by their experiments with *d*-benzylmethylacetazide, $(C_7H_7)(CH_3)CHCON_3$. This compound was found to give on rearrangement an optically active isocyanate, which could be converted by aniline into an optically active monosubstituted urea, and by hydrolysis into an optically active amine hydrochloride. These facts suggested two possible interpretations, one based on the theory of partial valence, the other based on the assumption of carbonium ions. A survey of the properties of optically active compounds described in the literature led them to suggest that the second interpretation was perhaps the more probable; that in such rearrangements the radical, R, if existing momentarily as a free radical must do so in such a way as to maintain a configuration required to produce an optically active rearrangement product, that is, it is a positive radical which is of the nature of a carbonium ion, and that in its migration from the carbon atom to the nitrogen atom it leaves behind the electron it shared with the carbon atom.

Since the publication of these experiments McKenzie and his co-workers[7] have carried out investigations on molecular rearrangements of optically active compounds involving migration of groups from one carbon atom to another adjacent carbon atom. It has been shown by them that under certain conditions optically active tertiary amino alcohols and pinacols can undergo rearrangement to give optically active ketones. They have suggested the following mechanism for the change which takes place in the tertiary amino alcohols



---

[5] Jones and Root, THIS JOURNAL, 48, 181 (1926).

[6] Jones and Wallis, *ibid.*, 48, 169 (1926).

[7] McKenzie, Rogers and Mills, *J.* Chem. *Soc.*, 129, 779 (1926); Ber., 62B, 272 (1929).

where K and K' are electric charges. It is evident from this that their interpretation involves the same assumption as previously expressed by Jones and Wallis[6] for the rearrangement of optically active acid azides, that is, that in the rearrangement it is possible that the optically active radical may exist for a certain length of time as a carbonium ion, and that the asymmetry is retained due to the fact that an electric charge plays the part of the fourth grouping.

We have continued these investigations on carbon to nitrogen rearrangements involving optically active radicals in order to seek an answer to the second and third possibilities suggested by the above interpretation for the rearrangement of acid azides, hydroxamic acids and halogen amides. Does the radical retain its configuration during the rearrangement, or does it change its configuration and undergo Walden inversion? For this purpose d-benzylmethylacetamide $(C_7H_7)(CH_3)CHCONH_2$, $[\alpha]_D^{20}$ +38.94°, was prepared, and its rearrangement by bromine and an alkali studied. It was thought that some information could be obtained from a comparison of the specific rotation of the amine hydrochloride produced in the Curtius rearrangement of an optically active acid azide with the same amine hydrochloride produced by the Hofmann rearrangement of an optically active acid amide. The conditions of the rearrangement are very different and if partial inversion (racemization) takes place it can be detected, as it is improbable that in two rearrangements carried out under such different conditions the amount of inversion would be the same in the two instances. McKenzie[7] has found that in the rearrangement of optically active tertiary amino alcohols and pinacols the molecule undergoes partial racemization. In the case of the tertiary amino alcohols there is a change in the sign of the rotatory power. Our experiments with d-benzylmethylacetamide show that in the rearrangement and subsequent hydrolysis of the isocyanate the amine hydrochloride which is produced is optically active, $[\alpha]_D^{20}$ +16.8°. It has the same sign for the rotatory power as the acid amide from which it is obtained, and its specific rotation is the same as the specific rotation of the amine hydrochloride produced in the rearrangement of the *d*-benzylmethylacetazide.[6] It seems, therefore, that we can now state with some degree of certainty that in these two rearrangements the amine hydrochloride has either the same configuration as the original acid amide and acid azide, or that during the rearrangement the radical undergoes complete Walden inversion. Partial inversion seems unlikely.

Experimental Results

Preparation of ***d*-Benzylmethylacetamide**, $(C_7H_7)(CH_3)CHCONH_2$.—This compound was prepared from d-benzylmethylacetic acid. The acid used in these experiments was prepared from ethyl acetoacetate according to the method of Conrad[8] with a

---

[8] Conrad, *Ann.*, 204, 177 (1880).

few modifications as described by Jones and Wallis.[9] It was resolved into its optically active isomers by the method of Kipping and Hunter.[10] Its rotation, **a,,** at 20° without solvent in a 50-mm. tube was +10.08'. The acid was converted into its chloride by means of thionyl chloride according to the method of Pickard and Yates.[11] The chloride boiled at 120° (15 mm.) and gave a rotation of +12.60° in a 50-mm. tube at 20" without solvent; 15 g. of the chloride was dissolved in 200 cc. of dry ether, and the solution saturated at 0° with dry ammonia gas. A heavy white precipitate of ammonium chloride formed. The mixture was allowed to stand at room temperature for fifteen minutes and then filtered. The ether solution was concentrated to about one-half its volume, and then placed in the ice box overnight. A white crystalline material separated out. This was filtered, washed with petrol ether (30–60°) and dried in a vacuum desiccator. *d*-Benzylmethylacetamide crystallizes from ether in long, beautiful needles. It melts at 104.5°; 0.3916 g. dissolved in ether, and made up to a volume of 50 cc. gave α_D $0.61 ° at 20° in a 2-dm. tube; $[\alpha]^{20}_D$ +38.94°.

Anal. Subs , 0 4270: N, 33.05 cc. (23°, 758 mm.). Calcd.: N, 8.59. Found: N, 8.66.

The filtrates from the fractional crystallization of the quinine salt of benzylmethylacetic acid were worked up and a mixed levo acid was obtained. This acid was converted into the corresponding mixed levo amide by the method described above for the pure dextro modification: 0.3269 g. of this material in 25 cc. of benzene solution gave **a,** −0.83" at 20° in a 2-dm. tube; $[\alpha]^{20}_D$ −31.7".

Rearrangement of ***d*-Benzylmethylacetamide** to d-Benzylmethylmethylamine Hydrochloride, $(C_7H_7)(CH_3)CHNH_3Cl$.—Several experiments were carried out in order to determine the best conditions for the rearrangement. It was found that an excess of bromine greatly diminished the yield of the amine hydrochloride. The following procedure gave the best results: 1.5 g. of sodium hydroxide was dissolved in 12 cc. of water and cooled to 0°; 0.5 cc. of liquid bromine was then added in small portions and the contents stirred until homogeneous. To this solution was added 1.0 g. of *d*-benzylmethylacetamide. After it had dissolved the solution was slowly warmed. When the temperature reached about 70–80° rearrangement took place, the solution became suddenly cloudy, and an oil separated out on top of the liquid. The mixture was heated to the boiling point and distilled. Water was added frequently. The oily distillate was strongly alkaline in its reaction toward litmus and had an amine odor. When acidified with dilute hydrochloric acid a clear water-white solution was obtained. This was evaporated to dryness on the water-bath. The white crystalline salt was extracted twice with ether to remove any unchanged amide that might have passed over, and then thoroughly dried in a vacuum desiccator; 1.0 g. was obtained. A portion of it melted at 145°; 0.7810 g. dissolved in water and made up to 25 cc. gave a, +1.33° at 20°; $[\alpha]^{20}_D$ +21.3°. Experiments showed that the specific rotation of this substance changed with concentration. Therefore for a comparison of the rotatory power with the same amine hydrochloride prepared from the d-acid azide the following solution was prepared, and its rotatory power determined: 0.9584 g. was dissolved in water, and made up to 20 cc. This solution gave **a,** at 20° in a 2-dm. tube +1.61°; $[\alpha]^{20}_D$ +16.8°. This is the same concentration that was used by Jones and Wallis6 in their experiments on *d*-benzylmethylmethylamine hydrochloride prepared from d-benzylmethylacetazide. The value of the specific rotation reported by them was $[\alpha]^{20}_D$ +16.6°. The mixed levo amide on rearrangement gave the corresponding levo amine hydrochloride; 0.3500 g. in 25 cc. of aqueous solution gave **a,** at 20° in a 2-dm. tube −0.28"; $[\alpha]^{20}_D$ −10.0°

Summary

Benzylmethylacetamide has been prepared in a pure dextro and a mixed levo modification.

Evidence is submitted to show that when this compound undergoes the Hofmann rearrangement the amine hydrochloride so obtained is optically active. It is further shown that the rotatory power has the same sign as the amide from which it is produced, and that the value of the specific rotation of the *d*-amine hydrochloride produced from the d-acid amide is the same as the value of the amine hydrochloride obtained by Jones and Wallis from d-benzylmethylacetazide.

A discussion of these results is given with special reference to the Walden inversion.

THE PREPARATION OF CYCLOPROPYL CYANIDE AND TRIMETHYLENE CHLOROBROMIDE[1]

BY J. B. CLOKE, R. J. ANDERSON, J. LACHMANN AND G. E. SMITH

RECEIVED JUNE 2, 1931 PUBLISHED JULY 8, 1931

Cyclopropyl Cyanide.—During the last few years workers in this Laboratory have found it necessary to prepare quantities of cyclopropyl cyanide as the starting material in a series of investigations on the stability of certain cyclopropane derivatives. Since the ordinary procedures for the preparation of this rather costly reagent have given unsatisfactory yields, a number of attempts have been made to devise a better process.

Cyclopropyl cyanide was first made by Henry in 1898 by the distillation of y-chlorobutyronitrile with dry potassium hydroxide,

$$ClCH_2CH_2CH_2CN + KOH = \underline{CH_2—CH_2—CH}—CN + KCl + H_2O$$

but its true nature was not recognized until a year later.[2] Although certain workers have claimed that this process gives "satisfactory" results, this has not been the general experience, since losses arise as the result of hydrolysis end polymerization. More recent descriptions of the method have been given by Haller and Benoist, Nicolet and Sattler and by one of us.[3] It is

---

[1] The experimental data reported herein have been abstracted from theses on cyclopropane derivatives which have been presented to the Rensselaer Polytechnic Institute by Raymond J. Anderson, John Lachmann and Gustavus E. Smith in partial fulfilment of the requirements for the degree of Chemical Engineer.

[2] M. L. Henry, Bull. *sci. acad. roy. belg.*, [3] **36**, 34 (1898); *ibid.*, [3] 37, 17–22 (1899).

[3] Haller and Benoist, *Ann. chim.*, [9] 17, 28 (1922); Nicolet and Sattler, THIS JOURNAL, 49, 2068 (1927); Cloke, *ibid.*, 51, 1180–1181 (1929).

our opinion that the 40–55% yields of Nicolet and Sattler were unusually good for the potassium hydroxide method.

Other attempts to devise better methods for the preparation of cyclopropyl cyanide have been recorded. Bruylants and Stassens[4] carried out the reaction with potassium hydroxide in alcohol, but only γ-ethoxybutyronitrile was obtained and not a trace of cyclopropyl cyanide. In another investigation in which sodium alcoholate was allowed to react with y-chlorobutyronitrile Bruylants[5] obtained a mixture of the cyclopropyl cyanide and γ-ethoxybutyronitrile. By the action of pyridine and quinoline at water-bath temperature on y-chlorobutyronitrile, this investigator obtained only vinylacetonitrile and none of the cyclic compound. The present paper describes the preparation of the cyclopropyl cyanide by the action of sodamide on γ-chlorobutyronitrile in both liquid ammonia and ether solutions.

The formation of cyclopropyl cyanide by the action of sodamide on γ-chlorobutyronitrile may be explained in the same way as the alkylations of such substances as ethyl acetoacetate, diethyl malonate, phenylacetonitrile, etc. Thus, the y-chlorobutyronitrile may be assumed to exist in two tautomeric forms, *viz.*, the nitrile, $ClCH_2CH_2CH_2CN$, and the imide, $ClCH_2CH_2CH{=}C{=}NH$, structures. In the light of the carbide ion theory of Stieglitz, which has been extended by Rising[6] to salts of phenylacetonitrile, the action of sodamide on the y-chlorobutyronitrile may first be assumed to give both the "nitride" ion, $ClCH_2CH_2CH{=}C{=}N^-Na^+$, and the "carbide" ion, $(ClCH_2CH_2CHCN)^-\ Na^+$, which also are tautomeric, as follows

$$\left.\begin{array}{l} Cl{-}CH_2CH_2CH{=}C{=}NH \\ \qquad\downarrow\uparrow \\ Cl{-}CH_2CH_2CH_2{-}CN \end{array}\right\} + Na^+NH_2^- = \left.\begin{array}{l} Cl{-}CH_2CH_2CH{=}C{=}N^- \\ \qquad\downarrow\uparrow \qquad - \\ Cl{-}CH_2CH_2{-}\overset{-}{C}H{-}CN \end{array}\right\} Na^+ + NH_3$$

Finally the latter carbide salt may be supposed to undergo almost instantaneous internal condensation to give the cyclopropyl cyanide and sodium chloride

$$ClCH_2CH_2CH^-(Na^+)CN = \underbrace{CH_2CH_2CH}{-}CN + Na^+Cl^-$$

Dry sodamide was first employed in place of the potassium hydroxide of Henry in order to eliminate the hydrolysis of the nitriles, since it was first supposed that the hydrolyses were chiefly responsible for the losses in the Henry reaction. Next, after the foregoing work had demonstrated that a large amount of polymerization also occurred, the reaction was carried out in liquid ammonia with the expectation that the low temperature would minimize the polymerization. The first results, however, were disappoint-

---

[4] Bruylants and Stassens, Bull. *sci. acad. roy.* belg., [5] 7, 702–719 (1921).

[5] Bruylants, *ibid.*, [5] **6**, 479–486 (1920).

[6] Rising and Zee, THIS JOURNAL, 49, 541–545 (1927); 50, 1699–1707 (1928); Rising, Muskat and Lowe, *ibid.*, 51, 262–265 (1929).

ing, since only 40–50% yields of the monomeric cyclic nitrile were obtained, polymerization accounting for most of the loss. Finally, these polymerization losses were largely eliminated: first, by the neutralization of the excess sodamide in the liquid ammonia-ether solution by the use of ammonium chloride; and, second, and more important, by the carrying out of all distillation work under diminished pressure with the aid of a very efficient condensing system. In this way, the later runs, starting with 21 g. of the γ-chlorobutyronitrile and **10** g. of sodamide, have consistently given from 75–90% of the cyclopropyl cyanide. With ether as the solvent and a comparatively long period of stirring and gentle simmering, the same quantities of reagents have given yields which have been about 10–20% lower, due to larger polymerization losses. Similar results have been obtained by E. C. Knowles[7] in the preparation of 1-phenyl-1-cyanocyclopropane from α-phenyl-γ-chlorobutyronitrile.

Trimethylene Chlorobromide.—Trimethylene chlorobromide was required for the preparation of the γ-chlorobutyronitrile, $ClCH_2CH_2CH_2Br + KCN = ClCH_2CH_2CH_2CN + KBr$,[8] which was employed in the synthesis of the cyclopropyl cyanide. The trimethylene chlorobromide has been prepared by the addition of hydrogen bromide to allyl chloride,[9] by the action of mercuric chloride on trimethylene dibromide,[10] and by the addition of sulfuric acid to a mixture of trimethylene chlorohydrin and hydrobromic acid solution.[11] Although the last process is definitely superior to those which precede, it has never given entirely satisfactory results in this Laboratory, since the product contains considerable quantities of trimethylene dibromide. The formation of the latter compound, which has always occurred with us, not only leads to diminished yields of the trimethylene chlorobromide, but it also entails a time-consuming fractionation. This difficulty is eliminated by the method which is described in this paper by means of which 90–94% yields of practically pure chlorobromide have been obtained by the addition of trimethylene chlorohydrin to phosphorus tribromide. The addition of the tribromide to the chlorohydrin has been found by Van Wyck[12] to be much less advantageous. Furthermore, the interaction of phosphorus trichloride and trimethylene bromohydrin gave poor yields, as would be expected.

Experimental Part

Trimethylene Chlorohydrin, $ClCH_2CH_2CH_2OH$.—The trimethylene chlorohydrin which was used for the preparation of the trimethylene chlorobromide was prepared

according to the directions of Marvel and Calvery.[13] The process of Hultman, Davis and Clarke[14] gives less trouble.

Anal. Calcd. for C_3H_7OCl: Cl, 37.51. Found: Cl, 37.40.

Trimethylene Chlorobromide, $ClCH_2CH_2CH_2Br$.—Two methods were studied for the preparation of the trimethylene chlorobromide. In the first process one mole of trimethylene chlorohydrin was distilled with two moles of 48% hydrobromic acid in a continuous separation apparatus similar to that of Hultman, Davis and Clarke. Three variations of the method gave only 40% yields of the pure chlorobromide.

In the optimum variation of the second process, the phosphorus tribromide method, a two-liter, three-necked, round-bottomed flask was provided with a dropping funnel, a motor stirrer and a small reflux condenser to which was attached a calcium chloride tube. One mole (271 g.) of phosphorus tribromide was then run into the flask, which was immersed to the neck in an ice-bath; the stirrer was started and, as soon as the tribromide was cold, a two-mole quantity (189 g.) of trimethylene chlorohydrin was allowed to drop slowly into the cold tribromide over a period of two hours. The solution was then heated with stirring on a water-bath for about ten hours. At this point the mixture was allowed to cool, when it was poured into a liter of cold water and then washed with several portions of 10% sodium carbonate solution until all acid had been removed. Finally the chlorobromide was dried over calcium chloride and distilled, which gave 296 g. of chlorobromide, b. p. 140–143°. This corresponds to a 94% yield.

In several earlier runs in which 1.75 moles of chlorohydrin and 1 mole of phosphorus tribromide were used, but without the stirring during the heating on the boiling water-bath, 90% yields of the trimethylene chlorobromide were obtained.

γ-**Chlorobutyronitrile.**—The γ-chlorobutyronitrile was made by the action of potassium cyanide on the trimethylene chlorobromide.[8]

Cyclopropyl Cyanide, $\overline{CH_2CH_2C}HCN$.—Three different procedures were employed for the preparation of the cyclopropyl cyanide. Although the first method has been found to be inferior to the other two, it has been included for the sake of completeness.

Procedure 1. The Preparation of Cyclopropyl Cyanide in Liquid Ammonia.—About 250 cc. of liquid ammonia was run out of a cylinder into a 500-cc. Dewar flask. A quantity of sodamide (Kahlbaum's) was then ground up in a mortar under ether in order to exclude direct contact with moist air. At this point the γ-chlorobutyronitrile was added to the ammonia, and this was followed by the moist sodamide, which was added in small portions with a spoon. After standing for five hours, during which the flask was connected with a calcium oxide tower, about 200-300 cc. of anhydrous ether was added to the ammonia solution; next the etherammonia solution was separated from the solid by filtration through a Buchner funnel under a hood and the residue was washed with a little ether. The solution was then distilled on the water-bath with the aid of a Vigreux column until most of the ether had been removed; finally, the residue was transferred to a 50-cc. round-bottomed flask and distilled through a 1 X 60 cm. Vigreux column. The results of the first four of several such runs are given in Table I.

In another run in which the liquid ammonia was allowed to evaporate completely before the ether was added, only polymers of the cyclopropyl cyanide were obtained, several of these were formed.

Procedure 2. Optimum Procedure for the Preparation of the Cyclopropyl Cyanide.—As before, the sodamide (Kahlbaum's) was ground up in a mortar under about 150 cc. of dry ether, but to a greater degree of subdivision. About half of the ether was

TABLE I

RESULTS OF RUNS

Run	γ-Nitrile, g.	$NaNH_2$, g.	Time in hrs of standing	Yield, %
1	50	25	5	44.7
2	50	30	5	51.5
3	25	16	5	43
4	50	30	5	35.4

then carefully decanted from the sodamide into a dry flask, when the sodamide was transferred a little at a time to a solution of 21 g. of γ-chlorobutyronitrile in 250 cc. of liquid ammonia in a Dewar flask, which was well shaken after each addition of the sodamide. Except when it was necessary to add or remove material, the flask was connected to a 152-cm. lime tower. The addition of the sodamide was made by means of a medicine dropper, which readily sucked up the fine sodamide together with the ether. From time to time some of the previously decanted ether was returned to the mortar in order to keep the sodamide completely covered by a layer of ether. After all of the sodamide had been transferred to the ammonia–ether solution, the mixture was shaken more or less steadily during the periods recorded in Table II.

At the cessation of the shaking the excess sodamide was neutralized by the addition of ammonium chloride (usually 2 g.), using solid phenolphthalein as indicator, when the solution was filtered through a Buchner funnel into a suction flask with the usual precautions. The suction flask was then provided with a stopper carrying a bubbling tube, which was connected through a stopcock to a source of dry air, and an exit tube, which was connected to the receiver. The latter was made by the sealing of a 76-cm. length of 8-mm. tubing 7.6 cm. from the bottom of a 2.5 × 25 cm. Pyrex test-tube, followed by the winding of the long tube around the test-tube and the sealing of an adapter to the end. This condenser was cooled in an ice–ammonium chloride mixture, which was contained in a liter vacuum flask. Suction was then carefully applied to the receiver, but with the stopcock practically closed, until the ammonia and some of the ether had been removed. At this point the receiver was connected with a 50-cc. modified Claisen–Vigreux distilling flask, wherein the ether solution of the nitrile was fractionally distilled under diminished pressure. Care was taken to recover any nitrile which was carried over into the receiver with the ether. The yields of cyclopropyl cyanide from the γ-chlorobutyronitrile with the other pertinent facts follow in Table II.

TABLE II

YIELDS OF CYCLOPROPYL CYANIDE

Run	γ-Nitrile, g.	$NaNH_2$, g.	Time of addn., minutes	Reaction time, minutes	Yield, %	Yield (corr.), %
1	21	9	30	30	78.5	
2	21	10	40	20	74.7	81.3
3	21	10	30	60	89.7	
4	45	21.5	55	90	77.5	

The corrected yield in Run 2 takes into account the amount of γ-chlorobutyronitrile which was recovered. The combined runs, which boiled from about 35–38° at 16–19 mm., distilled completely from 133–135° at ordinary pressures.

Procedure 3. The Preparation of Cyclopropyl Cyanide in Ether.—A weight of 10 g. of finely ground sodamide, about 200 cc. of ether and 21 g. of γ-chlorobutyronitrile were transferred to a 500-cc. flask which was provided with a reflux condenser and a stirrer. The temperatures and the durations of the reaction for three experiments will be found in Table III. The distillation process was the same as that described for Procedure 2. For the first two runs, in which chloronitrile was recovered, corrected yields have been given. In this procedure, however, more polymerization occurred than in Procedure 2, but less than in Procedure 1.

TABLE III

DATA FOR EXPERIMENTS

Run	Approx. temp., °C.	Reaction time. hrs.	Yield, %	Yield (corr.), %
1	30	7–8	41	64.7
2	Refluxing	16	69.4	80.2
3	Refluxing	25	74.7	..

Summary

1. Cyclopropyl cyanide may be obtained in 75–90% yields by the action of sodamide on γ-chlorobutyronitrile in a liquid ammonia–ether solution. The reaction in ether solution appears to be less efficient.

2. Trimethylene chlorobromide may be prepared in 90–94% yields by the action of phosphorus tribromide on trimethylene chlorohydrin.

TROY, NEW YORK

NOTES

The Cholesterol Content of Shrimp Waste.—The ethyl ether extraction of the dried shrimp and shrimp waste prepared by Vibrandt and Abernethy[1] produced a viscous oil, dark red by transmitted light and soluble in the common organic solvents. According to elemental analysis the oil contains no sulfur, halogens, nitrogen or heavy metals.

Treatment of the oil with alcohol at 60° precipitated an insoluble brown resinous material and subsequent cooling of the alcoholic solution to 0° effected a fairly rapid separation of monoclinic crystals from the viscous, red oily residue.

Purification of Crystals.—Decolorization of the hot alcoholic solution of the crystals thus obtained with animal charcoal and subsequent crystallizations from hot alcohol produced a material which melted at 146.5°. Measurements under the microscope showed monoclinic plates with angles of 79.5 and 100.5". The average yield of these crystals from three separate crystallizations and purifications is 19.08% on the basis of the original oil. The total quantity of sterols in the shrimp waste was not determined.

Identification.—The purified crystals were then treated with digitonin by the method of Windaus[2] and further identified by the Liebermann[3]

and the Hagarsalkowski[4] tests for cholesterol, obtaining positive tests. Further identification of the crystals as cholesterol was accomplished by the preparation of the benzoate[5] and acetate[6] derivatives.

The high cholesterol content of the shrimp oil led to feeding tests for antirachitic potency of the oil by the authors and F. P. Brooks,[7] giving encouraging results. Since the extract of shrimp waste amounts to 2.25% of the waste, a production of 80,000 pounds of cholesterol could have been accomplished by the extraction of the waste of the 1927 crop of shrimp.

A Simple Method for the Preparation of Glycine.—The preparation of glycine by the classical method,[1] employing the reaction between monochloroacetic acid and ammonia, has proved generally unsatisfactory because of the lengthy procedures involved in the isolation of a product free from ammonia and chloride and because of the low yield of pure glycine resulting. Robertson[2] found after a careful study of the course of the reaction between monochloroacetic acid and ammonia, that the yield of glycine could be greatly increased by the use of a large excess of ammonia and that there occurred a corresponding decrease in the amount of imino-diacetic acid and trimethylene-amine-tricarboxylic acid, the principal impurities resulting from side reactions. Based upon this observation, he proposed a method in which a 60 to 1 molecular ratio of ammonia to monochloroacetic acid was employed. This increased the actual concentration of glycine formed in solution to 86% of the theoretical. While a 50% final yield of pure glycine was obtained, the isolation of the product was accomplished after the laborious and expensive procedure of removing the ammonium chloride by the use of silver oxide.

Since, when a large excess of ammonia was used, the concentration of glycine formed was large in comparison with the amount of side reaction products, the possibility of *direct* precipitation of glycine seemed worthy of investigation. As was suggested by Robertson, 60 moles of

ammonia and 1 mole of monochloroacetic acid were allowed to react. The excess ammonia was distilled off and the resulting aqueous solution was concentrated to a small volume. When 95% methyl alcohol was added to this solution, glycine promptly crystallized out and a 72–74% yield of an impure product resulted. By careful recrystallization a 60–64% yield of ammonia and chloride-free glycine was obtained. Our work does not indicate that the use of pyridine with methyl alcohol in the precipitation of glycine is necessary as was reported by Boutwell and Kuick.[3] As a result of our experiments, a simple, rapid and inexpensive method for the preparation of pure glycine is offered.

Experimental

Method of Preparation.—One mole (94.5 g.) of monochloroacetic acid is added gradually with shaking to 4 liters of ammonium hydroxide (sp. gr. 0.90) in a 5-liter round-bottomed flask. When all of the monochloroacetic acid is dissolved and the solution is thoroughly mixed, the flask is stoppered and set aside undisturbed for forty-eight hours at room temperature. The solution, which is colorless or faintly yellow, is then concentrated on a water-bath under reduced pressure to a volume of about 200 cc. The concentrated aqueous solution is then made up to 250 cc. with water and transferred to a 2-liter beaker, and the glycine is crystallized out by gradually adding, with stirring, 1500 cc. (six volumes) of 95% methyl alcohol (the use of absolute methyl alcohol offers no advantage). The mixture is placed in an ice box for four to six hours to allow complete crystallization. The supernatant liquid is then decanted from the crystals onto a Biichner funnel, the remaining crystals are suspended in approximately 500 cc. of 95% methyl alcohol, and are transferred to the filter. The beaker is rinsed twice with 100–120 cc. portions of 95% methyl alcohol, and the rinsings are poured over the crystals in the funnel. Finally, as much of the liquid as possible is pressed out, the crystals are washed with a small amount of ethyl ether, and dried in air. A yield of 54–55 g. of glycine, 72–74% of the theoretical, is obtained.

Since the product contains a trace of ammonia (by Nessler's reagent) and chloride (by silver nitrate), a second crystallization is carefully made by dissolving the crystals in 210–215 cc. of water, with warming, and precipitating with 5 volumes (1250 cc.) of 95% methyl alcohol. After crystallization in an ice box, the glycine is filtered, washed and dried, as previously outlined. A yield of 48–49 g., 64–65% of the theoretical, results. If the product still shows a faint trace of ammonia, a second recrystallization may be made, which will yield 45–48 g. The final product is white and finely crystalline. The recovery of further amounts of glycine from filtrates is not practicable because only a small amount

---

[3] P. W. Boutwell and L. F. **Kuick,** THIS JOURNAL, ***52*,4166** (1930).

of the product, heavily contaminated with ammonium chloride, is obtained. The recovery of the excess ammonia and of the methyl alcohol greatly reduces the cost of preparation by this method. The use of permutit in removing the last traces of ammonia was not found to be superior to precipitation with methyl alcohol alone.

Analysis of Product.—Molar solutions of five samples of glycine prepared by the above method showed no trace of ammonia with Nessler's reagent, nor of chloride with silver nitrate. Melting points and mixed melting points (with Eastman's ammonia-free glycine, No. 445) were determined by the capillary tube method. Both gave values of 236–239° (uncorrected), with decomposition and effervescence, after browning at 228°. Analyses for the nitrogen content, determined by the Kjeldahl method, gave values ranging from 18.44 to 18.76% (theoretical 18.67%).

Summary.—1. A simple, inexpensive method for the preparation of glycine from monochloroacetic acid and ammonia is outlined.

2. A 60–64% yield of glycine free from ammonia and chloride is obtained.

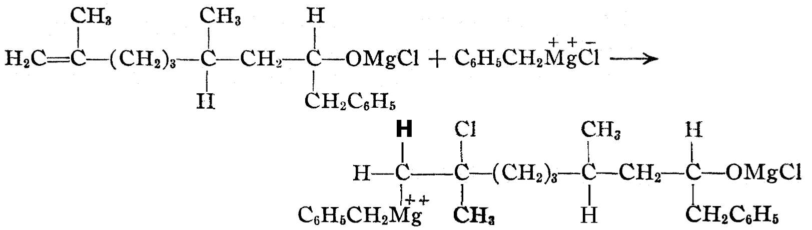
The Purported Addition of Benzylmagnesium Chloride to the Ethylenic **Linkage** in **Citronellal.**—It has been suggested[1] that the recent[2] indirect proof offered for the non-addition of benzylmagnesium chloride to the ethylenic linkage in citronellal is not decisive, and that a new possible mechanism is



$$\mathrm{H_2C{=}\overset{\overset{CH_3}{|}}{C}{-}(CH_2)_3{-}\underset{\underset{H}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH_2{-}\underset{\underset{CH_2C_6H_5}{|}}{\overset{\overset{H}{|}}{C}}{-}OMgCl + C_6H_5CH_2\overset{++}{Mg}\overset{-}{Cl} \longrightarrow}$$

$$\mathrm{H{-}\underset{\underset{C_6H_5CH_2\overset{++}{Mg}}{|}}{\overset{\overset{H}{|}}{C}}{-}\underset{\underset{CH_3}{|}}{\overset{\overset{Cl}{|}}{C}}{-}(CH_2)_3{-}\underset{\underset{H}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH_2{-}\underset{\underset{CH_2C_6H_5}{|}}{\overset{\overset{H}{|}}{C}}{-}OMgCl} \qquad \text{(I)}$$

(A)

In this manner, "a complex molecule is obtained which is similar to that suggested by Rupe,[3] except that the second molecule of the Grignard reagent is attached in a slightly different manner."

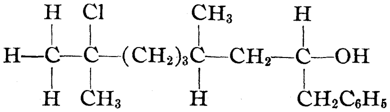
[2] Gilman and Schulz, This Journal, 52, 3588 (1930).

[3] Rupe, Ann., 402, 161 (1914).

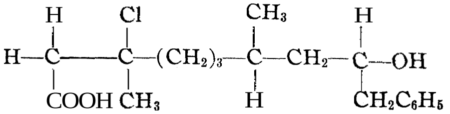
Actually, this mode of addition is quite unlike that proposed by Rupe. On hydrolysis, one would expect Compound (A) to give



$$\mathrm{H{-}\underset{H}{\overset{H}{C}}{-}\underset{CH_3}{\overset{Cl}{C}}{-}(CH_2)_3\underset{H}{\overset{CH_3}{C}}{-}CH_2{-}\underset{CH_2C_6H_5}{\overset{H}{C}}{-}OH}$$

and toluene. However, Rupe's analysis shows his product to contain no chlorine, and to have in place of the chlorine the equivalent of a benzyl group. Furthermore, the same product is obtained with benzylmagnesium bromide. Accordingly, Compound (A) is without any experimental support.

Granting that Compound (A) is correct, it represents an unsymmetrical organomagnesium compound of the general formula R—Mg—R'. Although such compounds have not yet been prepared, it is known that the symmetrical R—Mg—R compounds on carbonation (followed by hydrolysis) yield the corresponding carboxylic acids, RCOOH. We do not know how R—Mg—R' compounds would behave on carbonation, but it appears altogether reasonable to expect them to give the two carboxylic acids, RCOOH and R'COOH, in varying quantities depending on the nature of the R— groups. If this be true then Compound (A) on carbonation should give $C_6H_5CH_2COOH$ and



$$\mathrm{H{-}\underset{COOH}{\overset{H}{C}}{-}\underset{CH_3}{\overset{Cl}{C}}{-}(CH_2)_3{-}\underset{H}{\overset{CH_3}{C}}{-}CH_2{-}\underset{CH_2C_6H_5}{\overset{H}{C}}{-}OH}$$

Actually, the latter acid is not obtained, because when the reaction mixture of citronellal and an excess of benzylmagnesium chloride is carbonated, only phenylacetic acid is obtained, as evidenced by melting point, mixed melting point and neutralization equivalent.

The possibility that RMgX adds to an ethylenic linkage to give an R—Mg—R' compound which might undergo but partial carbonation to give RCOOH to the exclusion of R'COOH is rendered remote by other reported experimental evidence. First, a different RMgX compound (phenylmagnesium bromide) after reaction with citronellal and then carbonation gave presumably pure benzoic acid.[2] Second, if addition of RMgX to an ethylenic linkage did occur with olefins of a type to give rise to R—Mg—R' compounds in which the R— and the R'— groups were closely related but not identical, then carbonation should give a mixture of acids, but no such mixtures have been obtained.[4]

[4] Giman and McGlumphy, *Rec. trav. chim.*, **47**, 418 (1928). Earlier pertinent references are contained in this article.

Our unavoidable conclusion is that benzylmagnesium chloride does not add to the ethylenic linkage in citronellal.[5]

THE STABILITY OF NITROGEN PENTOXIDE AT 1000 ATMOSPHERES OF OXYGEN IN THE PRESENCE OF NITROGEN TETROXIDE

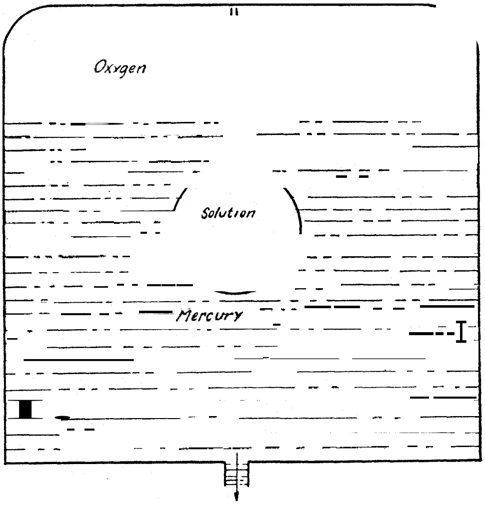
Sir:

The equilibrium

$$N_2O_5 = N_2O_4 + {}^1/{}_2O_2$$

has been investigated at 1000 atmospheres' pressure of oxygen by dissolving nitrogen tetroxide and nitrogen pentoxide in carbon tetrachloride in an apparatus shown schematically in Fig. 1.

It was found that at this pressure of oxygen the reaction goes completely to the right. With the gas evolution apparatus used for analysis it was possible to detect as little as 0.5 cc. of oxygen, which, with the volumes of nitrogen pentoxide solution used, is equivalent to a partial pressure of **0.00155** atmosphere of nitrogen pentoxide at 25°. The partial pressure of nitrogen tetroxide in one of the runs was 0.710 atmosphere, so that the equilibrium constant in atmospheres is greater than 1.48×10^4. The values given for the partial pressures depend on the assumption of a perfect solution of nitrogen tetroxide, nitrogen pentoxide and carbon tetrachloride and upon a solubility determination of nitrogen pentoxide in a solution of nitrogen tetroxide in carbon tetrachloride. This equilibrium constant gives a free energy change less



To pressure pump and gage

Fig. 1.

Professor Rupe is in agreement with this conclusion, and he is now engaged in a further study of the constitution of the product obtained from citronellal and benzylmagnesium chloride.

than —5600 cal. Now, assuming that the entropy of nitrogen tetroxide is equal to or less than that of nitrogen pentoxide, then the total increase in entropy is equal to or less than 24 units, the entropy of $^1/_2O_2$. Using these values in the equation

$$AF^o = \Delta H - T\Delta S^\circ$$

we obtain for ΔH a value equal to or less than 1600 calories.

The value given for ΔH in the "International Critical Tables" is 2690 cal. Either this value is too high or the entropy of nitrogen tetroxide is greater than that of nitrogen pentoxide, which would be surprising.

It was not feasible, with the apparatus used, to go higher than 1000 atmospheres' pressure.

THE PHOTO-REACTION OF HYDROGEN AND IODINE MONOCHLORIDE

Sir:

In a recent communication [THIS JOURNAL, 52, 2793 (1930)] Rollefson and Lindquist criticize our conclusions [Nature, **127,** 93 (1931)] regarding the photo-reaction of hydrogen and iodine monochloride, namely, that excited chlorine atoms may not be necessary for it to take place. They maintain that, as our hydrogen pressure was large compared with the pressure of iodine monochloride, the chlorine atoms (excited *to* the $^2P_1$ state by collisions) would have more chance of reacting with the hydrogen than with the iodine monochloride. Nevertheless, we have been able to bring about the reaction with hydrogen pressures (circa 70 mm.) comparable with the pressure of iodine monochloride.

We used Merck's crystalline iodine monochloride contained in a small glass tube which was subsequently broken in the reaction vessel. Hydrogen passing through a palladium tube was brought to the required pressure in the reaction vessel, which was then sealed up. The pressure was recorded on a glass spiral gage, and no contact with impurities, tap-grease, etc., was permitted [Ashley and West, Nature, **127,** 308 (1931)]. The vessel was then irradiated with a mercury vapor lamp through a filter of quinine sulfate solution, and also through a filter of picric acid and cupric sulfate, transmitting only the 5461, 5764 and 5791 A. lines. The reaction is slow but measurable, and the rate of iodine formation increases when the initial hydrogen pressure is increased. If the chain mechanism suggested is correct, the reaction, even under the most favorable conditions, could only have roughly 1/500,000 the speed of the hydrogen-chlorine reaction. Doubtless the reaction $ICl + Cl = Cl_2 + I$ takes place as Rollefson and Lindquist suggest, but it would be unwise to infer from any of these experiments that the chlorine atom is unexcited.

Rollefson and Lindquist give only a few details of their experimental conditions, gas pressures, etc., but they mention one significant fact, namely, that their chlorine pressure was always large compared with the pressures of hydrogen and iodine monochloride. In these circumstances the iodine compound in the vapor phase may have been mainly iodine trichloride. This substance is of a lighter color than iodine monochloride, and must have an altogether different absorption spectrum. We have found that the vapors of iodine monochloride and chlorine react very readily, and, indeed, Rollefson and Lindquist themselves admit that they froze out iodine trichloride in the solid phase.

We do not wish to make any further statement until we have completed the study of the reaction kinetics.

CATALYTIC REDUCTION OF MIXTURES OF PARA-NITRO- AND NITROSO-PHENOLS WITH KETONES

Sir:

It has recently been shown by the writer that *p-sec.*-alkylaminophenols are formed by the catalytic reduction of mixtures of p-nitro- or nitrosophenol and ketones at room temperatures [Major, THIS JOURNAL, 53, 1901 (1931)]. The suggestion was made that the reaction probably involved formation of *p*-hydroxy-phenylhydroxylamine as an active intermediate product of the reduction and that this compound condensed with the ketone and finally that the condensation product was reduced to the alkylaminophenol. Vavon and Krajčinović have reported that they have been able to make the condensation product between benzaldehyde and phenylhydroxylamine, $C_6H_5CH{=}N(O)C_6H_5$, by the catalytic reduction of a mixture of nitrobenzene and benzaldehyde [Vavon and Krajčinović, Compt. rend., 187, 420 (1928)].

However, it was noted that heat was formed during the catalytic reduction of mixtures of p-nitro- and nitrosophenol and acetone. There remained, then, the possibility that the heat of the reaction between p-nitro- or nitrosophenol and hydrogen was sufficient to cause the *p*-aminophenol which formed to condense with the ketone. This condensation product would then be readily reduced to *p-sec.*-alkylaminophenol.

Evidence which apparently favored this point of view was obtained when a solution of 0.1 mole of *p*-aminophenol in acetone was heated to the boiling point and then shaken with hydrogen in the usual way in the presence of a platinum oxide catalyst. Hydrogen was absorbed and 50% of the theoretical yield of p-isopropylaminophenol was recovered from the reaction mixture.

On the other hand, it was found that a mixture of 0.05 mole of p-aminophenol, 3.5 moles of acetone and 0.1 g. of Adams' platinum oxide catalyst did not absorb any more hydrogen than was necessary to reduce the platinum oxide when the temperature of the reaction mixture was kept at 4–5° or at 26–32.5°. The mixture was shaken at 4–5° for one hour and at 26–32.5° for two and three-quarter hours.

It was also found that in one and one-half hours very little *p*-isopropylaminophenol was formed during the reduction of a solution of 0.05 mole of *p*-nitrosophenol in 3.5 moles of acetone in the presence of the platinum oxide catalyst at 4–5°. On the other hand, in one hour at 16–32.5° the catalytic reduction of 0.05 mole of p-nitrosophenol in 3.5 moles of acetone gave a 60% yield of p-isopropylaminophenol.

It seems fairly evident, then, that while catalytic reduction of a mixture of *p*-aminophenol and acetone at elevated temperatures will produce *p*-isopropylaminophenol, this reduction does not occur to any appreciable extent during a few hours at room temperature. However, catalytic reduction of a mixture of p-nitrosophenol and acetone at room temperature does give p-isopropylaminophenol. Accordingly, it seems most likely that *p*-hydroxyphenylhydroxylamine is formed as an intermediate during the reduction and that due to its somewhat greater activity than p-aminophenol it condenses with the ketone and the condensation product is in turn reduced to *p-sec.*-alkylaminophenol.

AN ADSORPTION METHOD FOR THE DETERMINATION OF THE AREA OF A POWDER

Sir:

The writers have devised a simple procedure which seems to give information that is more definite with respect to the area of a fine powder than that given by any earlier method.

The powder, titanic oxide or silicon dioxide, for example, is dried in a high vacuum at as high a temperature as can be used without affecting the area of the crystals. The cool, dry powder is immersed in a solution of oleic acid, butyric acid or some other suitable acid, in very dry benzene, and the suspension is shaken until equilibrium is attained. After the powder has settled, a sample of the supernatant liquid is drawn off. The benzene of this sample and of a sample of the initial solution is evaporated off, if oleic acid is the solute chosen, and the oleic acid left from each solution is dissolved in 95% ethyl alcohol. The alcohol solutions are then titrated with carbonate-free sodium hydroxide dissolved in water. The difference in concentration is considered to give the amount of acid adsorbed by the surface of the powder. Only air that is thoroughly dried by phosphorus pentoxide is allowed to enter the vessel in which the solution is prepared and the flasks in which the adsorption experiments are carried out.

Figure 1 shows how the amount of oleic acid adsorbed by the surface of one gram of powder varies with the concentration of the final or equilibrium solution of oleic acid in benzene. At concentrations above 0.01 to 0.02 mole per kilogram of benzene, the adsorption becomes practically constant, and the oleic acid on the surface of the grains of powder may be said to form a condensed film. There is some evidence which seems to indicate that this film is monomolecular.

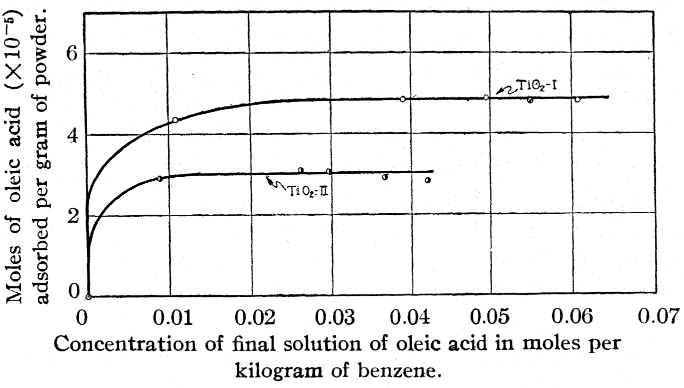

Fig. 1.

It may be assumed that the area occupied per molecule of oleic acid at the interface is 20.0 sq. Å., which is about the mean value for condensed films of the acid on water at a zero film pressure. On this basis, the area for TiO$_2$-I was calculated as 22.9 sq. m. per cc. of titanic oxide (3.89 grams), and for TiO$_2$-II as 14.4 sq. m. per cc. The ratio of these values is 1.59, while the ratio for the energy of immersion [Harkins and Dahlstrom, to be published] in ethyl acetate for the same two powders is 1.53, and the ratio of the weights of propyl alcohol adsorbed [Gans and Brooks, to be published] from the vapor per unit weight of these powders at a constant vapor pressure equal to one-half the saturation pressure at room temperature is 1.53.

The area of the powder TiO$_2$-II as determined for us by a microscopic method [Dunn, *Ind. Eng. Chem., Anal. Ed.*, *2*, 59 *(1930)*], applicable to crystalline powders, is 13.8 sq. m. per cc. of powder, on the assumption of a spherical shape for each particle. This is in good agreement with the value 14.4 obtained by the adsorption method. However, the closeness of the agreement is to some extent accidental, since the adsorption method includes the area of the colloidal part of the powder, which is not included by the microscopic method. Further comparisons with various other methods will be made later.

CRYSTALLIZATION OF ANHYDROUS SODIUM ACETATE FROM AQUEOUS SOLUTION AT ROOM TEMPERATURE

Sir:

If the trihydrate of sodium acetate, $CH_3COONa\cdot 3H_2O$, is placed in a sealed tube and heated to 58°, it loses its water of crystallization and partially dissolves in this water. At 80° all the salt is dissolved. On cooling in the sealed tube, the writer, experimenting under the supervision of Professor Stuart Woodford Young, made the interesting and unexpected observation that the form crystallizing from this aqueous solution is anhydrous. This anhydrous form appears whether the solution be cooled rapidly or slowly, the only difference being in the appearance of the crystal. The slowly cooled solution will start crystallizing at only a few nuclei, from which there is a radial growth of thin needles. The rapidly cooled solution is immediately filled with small nuclei. Both of these are flattened and elongated orthorhombic crystals with the three indices of refraction lower than 1.45. This anhydrous form is shown by crystallographic observation, for which we are indebted to Professor A. F. Rogers, to be the same as the anhydride formed by direct dehydration, and the normal solubility curve is exhibited.

The crystals remain unaltered as long as the tube is kept sealed. Here, then, is a solution that is 2400% supersaturated and yet can be kept indefinitely in contact with the anhydrous form. Cooling below 0° has no effect, but cooling in liquid ammonia or liquid air brings about conversion to the stable trihydrate.

In 1904 and 1905 Dr. Young and W. E. Burke were able to form and identify ten new hydrates of sodium thiosulfate. At the beginning of the work on sodium acetate it was thought that some new hydrates might be produced, but so far none has been found.

This recent work of Dr. Young, who had been on the faculty of Stanford

University since 1892, was halted by his unexpected death on April 9, 1931, and is discontinued for the present.

DISCONTINUITIES IN ADSORPTION ISOTHERMS

Sir:

In previous communications[1] we have shown that the adsorption of hydrogen by nickel and copper at low temperatures increases with pressure in a markedly discontinuous manner. Recently Allmand and Burrage[2] have reported a large number of isotherms for charcoal and silica gel which show discontinuities, and have suggested that the failure on the part of other investigators to detect this phenomenon is to be ascribed to an insufficient number of experimental points. In the course of an extended study, during the past four years, of the adsorption isotherms of hydrogen, nitrogen and carbon monoxide by nickel, copper and iron, at pressures up to one atmosphere and at temperatures which cover the range, —200 to +200°, we have found a considerable number of discontinuous isotherms, and have studied them in some detail, particularly from the standpoint of the effects produced by temperature and the presence of poisons.

The evidence now available points clearly to the conclusion that a step-wise increase of adsorption with pressure is a general characteristic of the physical, or "secondary," type of adsorption. There is no evidence that discontinuities ever occur in "chemical" adsorption. The steps have been found under conditions which preclude the existence of liquid films or of multimolecular layers of gas; further, the phenomenon appears to have no direct relation to the "active spots" of catalytic theory.

We have been led to advance a new hypothesis of physical adsorption, according to which the observed steps represent the formation of concentric rows of adsorbed molecules, first at the edges of each crystal face, and building up successively toward the center. The evidence in support of this hypothesis rests primarily on the uniformity in the volumes corresponding to successive steps, and on the actual magnitude of the individual step. The mechanism by which adsorption can occur in successive rows may readily be derived on the assumptions that neighboring adsorbed molecules evaporate from the surface less readily than isolated molecules,

HAZARDS IN CATALYTIC HYDROGENATION AT ELEVATED TEMPERATURES AND PRESSURES

Sir:

T. S. Carswell [THIS JOURNAL, **53**,**2417** (1931)] has reported an explosion which occurred while he was attempting to hydrogenate o-nitroanisole in the liquid phase with a nickel catalyst. He states that the purpose of his communication "is to call the attention of other investigators to the dangers of this type of reduction when carried out on other than a very small scale." There is no doubt that a warning is needed but in my opinion it should be against-the procedure used by him and not against catalytic hydrogenation at elevated temperatures and pressures. This general method has been in successful use in this Laboratory for the past three years [THIS JOURNAL, **52**, 4349, 5192 (1930); 53, 1091, 1095, 1402, 1425, 1868, 2012 (1931); **J.** Yhys. Chem., **35,** 1684 (1931)] using a wide variety of compounds and dealing with quantities similar to those used by Dr. Carswell. The procedure used by him is, in my opinion, ill-advised in several respects. The bomb was inadequate and sufficient information was not available to him before the attempt was made to hydrogenate 400 g. of nitroanisole. A bomb for experimental purposes 15 cm. in diameter should have a wall thickness several times as great as that (5 mm.) used by Carswell. Our own bombs have a wall thickness of 2 to 2.5 cm. and are only 6 cm. in internal diameter. They were bored out of properly annealed rolls of nickel–chromium steel [cf. Ernst, *Ind. Eng.* Chem., 18, 664 (1926)]. In order to control the rate of hydrogenation it is important that the bomb be provided with a thermometer or thermocouple well, so designed that there is little lag between the actual temperature of the liquid contents of the bomb and the reading of the temperature measuring device.

The temperature and amount of catalyst used by Carswell were excessively high for the compound to be hydrogenated, and apparently he made no attempt to control the rate of hydrogenation by control of the rate of shaking of the bomb. The reactions are quite exothermic and would result in local superheating if heat **was** being liberated more rapidly than it could be dissipated. In the hydrogenation of 100 *g.* of toluene with less than 0.5 *g.* of nickel, for example, we have observed a temperature rise of as much as 150° within two or three minutes. In the hydrogenation of only 20 g. of nitrophenol at 100° with **0.3** g. of nickel a temperature rise of 100° was observed. It is not surprising that in the hydrogenation at 250° of 400 g. of nitroanisole in the presence of perhaps 50 g. of nickel, the temperature of the contents of the bomb rose so high that there resulted an explosive decomposition.

There is little doubt that after suitable investigation the catalytic hydrogenation of such compounds as nitroanisole can be carried out on a commercial scale in relatively light equipment. However, one is not justified, as Carswell has demonstrated, in attempting to hydrogenate even so small a quantity as a few hundred grams of material without preliminary study and without having available a properly designed bomb.

POSITIVE ION CATALYSIS IN THE KNOEVENAGEL REACTION

Sir:

Dakin [*J. Biol.* ***Chem.***, 7, 49 (1909)] found that amino acids might be employed in place of the amines usually used to effect condensations of the Knoevenagel type. In the presence of amino acids, the velocity of the condensation of cinnamic aldehyde with malonic acid in 50% alcohol was found to increase with increase in the hydrogen-ion concentration of the solution [D. L. Klein, Master's Thesis, New York University, 1930]. This result suggested the amino acid cation to be a more active catalyst than the other ions derivable from the ampholyte. As is well known, secondary aliphatic amines are preferable to primary amines for the catalysis of reactions of this type. Since, as a rule, such secondary amines are stronger bases than the corresponding primary amines, it appeared that with such substances the amine ion is the active catalyst. In agreement with this concept various amines have been found to be more active catalysts in acid solutions.

Extremely weak bases such as urea do not ordinarily appear to catalyze condensations of the Knoevenagel type in aqueous or alcoholic solution. When, however, the solutions are made strongly acid, such weak bases display some catalytic activity. By taking advantage of the fact that weak bases dissolved in acetic acid appear to be highly dissociated, it was found that in this solvent urea and similar substances are extremely efficacious catalysts for the condensation of aldehydes with substances containing an "active" methylene group.

On the basis of these results, it is concluded that condensations of the

Knoevenagel type are instances of positive ion catalysis. The details of this investigation will shortly be submitted to THIS JOURNAL.

THE SEPARATION OF COLUMBIUM AND TANTALUM

Sir:

When columbium is reduced in acid solution from a valence of five to a valence of three the solution becomes blue. In the course of a study of the electrolytic reduction of columbium, with a view to the separation of this element from tantalum, reduction in alkaline solution was attempted. Although no color change was obtained, the formation of an amalgam at the mercury cathode was noted. This suggested the possibility of obtaining metallic columbium in the form of an amalgam by reduction in alkaline solution, Shortly thereafter the writer's attention was called to the article of Fink and Jones,[1] where they show that tungsten can be plated from a saturated solution of sodium carbonate at elevated temperature and high current density. Since that time, the writer has found that, at a current density of approximately 3 amp./sq. dm. and a temperature of 103°, columbium may be plated from a saturated solution of sodium carbonate containing ignited columbium oxide (Cb_2O_5). A copper cathode was used. Tantalum will not plate out from a similar bath under identical conditions of temperature and current density. Further, it has been found that a metallic plate is obtained from a carbonate bath containing a mixture of the ignited oxides of columbium and tantalum using the same temperature and current density as that indicated above. It seems to be a fairly safe conclusion that only columbium may be plated from a saturated solution of sodium carbonate containing a mixture of the ignited oxides of tantalum and columbium.

At present further studies are being made concerning the nature of the plates obtained by this method.

NEW BOOKS

Das Buch der grossen Chemiker. (The Book of the Great Chemists.) **Vol. II. From Liebig to Arrhenius.** Edited by Dr. Günther Bugge. Verlag Chemie, G. m. h. H., Berlin W 10, Germany, 1930. x + 559 pages. 16 X 23.5 cm. Illustrated. Price, bound, M. 32.

This fine book is in every way a proper sequel to the first volume. The twenty-seven chapters, written by twenty different scholars, cover the history of chemistry from the beginning of organic synthesis to the triumphs of Fischer and Ehrlich, from the discovery of colloids and of the spectroscope to the periodic table and the theory of electrolytic dissociation, The two volumes complete the story to the point where the accomplishments of chemists now living must be discussed.

The work comes much nearer to being a history of chemistry than its title indicates, not because "history is a series of biographies" but, rather, because the authors of the various chapters have not confined themselves to biography but have placed each chemist in a setting of the chemistry of his time and have discussed his work in relation to the work of other chemists. The work is scholarly, attractive, readable and authoritative.

In addition to its own indexes, the second volume contains lists of the Nobel Prize winners in physics and chemistry, 1901–1930, and an extensive bibliography supporting the material of both volumes.

TENNEY L. DAVIS

A Short History of Atomism. **By** JOSHUA C. GREGORY, Lecturer in Chemistry in the University of Leeds. A. & C. Black, Ltd., London; New York Agents, The Macmillan Co., 60 Fifth Avenue, New York, 1931. 258 pp. 14 × 22 cm. Price, $3.50.

Due to the enormous flux of recent theory and experiment in the field of atomic structure, there exists a definite need for an historical survey of the entire subject. Unfortunately Professor Gregory's offering cannot be said to satisfy this need.

The subject matter of the present volume is delimited by the sub-title "From Democritus to Bohr," but the last chapter, entitled "Recent Atomism," is concerned with the developments of the last five years. An attempt has apparently been made to present an up-to-the-minute account in that the author mentions a number of researches that have been reported during the past year.

The description of Greek thought on atomism, its introduction into European philosophy, and finally its incorporation into chemistry to explain the laws of stoichiometry, have all been treated admirably. The author has taken pains to stress both the philosophical difficulties of the atomic concept and the large amount of cooperative research that was required to establish a detailed atomic theory, These chapters are clearly the product of a broad and well applied knowledge of the subject.

As the narrative proceeds to the closing decades of the nineteenth century, however, one feels that the author is about to commit two rather serious faults. The concluding chapters amply confirm these premonitions. In the first place, it seems that the author has shown greater partiality to the discoveries of British scientists than to those of other nations. For example, the names of Clausius, von Laue and Kossel do not appear in the book and, in general, non-British work is treated from the comments of English contemporaries rather than from the workers' own writings.

Rather more serious than this criticism, however, is the fact that Professor Gregory has neglected the more physical evidence in support of the atomic theory. The determinations of the Avogadro number are omitted and the results of the kinetic theory and of crystal structure are dismissed in a few paragraphs. These omissions assume even more startling proportions in the last chapter, which is composed for the most part of not too well selected excerpts from the recent popular books of Jeans and Eddington. Most surprising of all, the author barely mentions the corpuscular theories of light and confines the wave properties of matter to a single paragraph. Indeed, the problem of the dual aspects of both light and matter receives but casual mention. The discussion of recent work is confused and cannot but leave a blurred and uncertain picture in the mind of the reader.

Professor Gregory has written an excellent and scholarly account of the chemical aspects of nineteenth century atomism. The deficiencies of the remainder of the book lead one to suspect that the subject is now too extensive to allow comprehensive treatment by a single author. Perhaps it is too early to expect a balanced history of this field of thought, including the recent developments, but it is to be hoped that a complete account will be available in the near future.

HUGH M. SMALLWOOD

Inorganic Qualitative Chemical Analysis. By ALLAN R. DAY, Ph.D., Assistant Professor of Chemistry, University of Pennsylvania. The Chemical Publishing Company, Easton, Pennsylvania, 1930. ix + 197 pp. 15.5 X 23.5 cm.

This textbook can perhaps be best characterized as corresponding to an abbreviated compromise between the well-known textbooks of Stieglitz and of Treadwell Hall.

The reviewer fails to see that the author has achieved what he intended to do as expressed in the Preface, namely, "to realize a closer relationship between fact and theory." Though he treats, very briefly to be sure, oxidation–reduction from the ionic standpoint, the reactions in the laboratory section are written in the molecular form, just as they were written thirty years ago. This is not correlation of theory but, rather, neglect of it. This textbook also does not consider the modern aspects of the theory of electrolytic dissociation. Indeed, the author contends that "the student is unable to cope with the advancements which have been made in recent times in the theories of solutions." This has not been the reviewer's experience nor, judging from the numerous thoroughly modern texts that have appeared in the last few years, that of other teachers in Qualitative Analysis.

This book has no distinctive features to differentiate it from many similar manuals in existence. It will doubtless be useful in connection with a set of explanatory lectures and close laboratory supervision such as is evidently contemplated by the author, but can hardly be recommended to those who are looking for guidance in the newer paths.

The book is well printed and bound and free from typographical errors.

J. Enrique Zanetti

The Conductivity of Solutions and the Modern Dissociation Theory. By Cecil W. Davies, M.Sc. (Wales), A.I.C., Senior Lecturer in Physical Chemistry, Battersea Polytechnic. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1931. viii + 204 pp. 22 figs. 14.5 × 22.5 cm. Price, $4.00.

This is the first textbook on a branch of Electrochemistry in which the interpretation of the experimental facts is based mainly on the Debye–Hückel theory instead of on the older theory of Arrhenius, van't Hoff and Ostwald and should therefore be a distinct advance. The author apparently assumes that his readers are unacquainted with the calculus—at any rate no differential equations or integral signs appear in the entire book. To attempt an advance into the new realms of thought opened up by the Debye–Hückel theory with a mathematical equipment limited to algebra and analytical geometry can only result in a superficial and inadequate view. This method of treatment is defended by the author on the ground that "the chemist will judge the Debye–Hückel–Onsager equations not by the manner of their derivation, but by the degree of success with which they interpret and predict the results of experiment." Although, of course, the theory must meet this test if it is to survive, nevertheless the reviewer believes that the student should not be encouraged to ignore the derivations of the formulas merely because they are difficult, involve calculus and vector analysis and some principles of physics not familiar to most students of chemistry but should be aided in understanding the derivations.

The discussion of interionic attraction is by no means comprehensive. The Onsager modification of the conductance equation is discussed at considerable length; the variation of conductance at very high frequencies and the failure of Ohm's law at very high field strengths are also discussed. But very little is said about the application of the theory to solubility, or to the colligative properties of solutions, or to the viscosity of solutions. The early form of the equation for the activity coefficient of an ion which is applicable only to extremely dilute solutions is given but the modified form later derived by Hückel, which is apparently valid up to three normal solutions, is not mentioned.

The discussion of experimental methods is brief and lacks detail as to design of apparatus. The differences in technique required for direct current and alternating current bridges are treated in a most sketchy manner. The author apparently assumes that his readers are ignorant of alternating current theory and makes very little attempt to supply the deficiency. The figures given are purely diagrammatic. They show no arrangement for grounding the bridge, which is a matter of considerable importance for precise work. Nearly a page is devoted to a description of induction coils as a source of current while audion tube oscillators receive only a bare mention with a few references, although anyone who had ever used an audion tube oscillator would regard an induction coil as junk.

The discussion of polarization is especially weak. Kohlrausch developed a mathematical theory of polarization based on the idea that the electrode effects of alternating current electrolysis were electrically equivalent to a perfect condenser in series with the electrolytic resistance being measured. If this were the whole truth the effects of polarization could be compensated wholly by introducing a condenser into another arm of the bridge. Kohlrausch found experimentally that this device, although extremely helpful, is not a sufficient means of avoiding error due to polarization and suggested and used other experimental devices to minimize this error, but without revising his mathematical theory of polarization. Other investigators, some of them contemporaneous with Kohlrausch, including Wien, Warburg, Neumann, Reichinstein, Miller, and Haworth, have added much to our knowledge of the phenomena and have developed a theory which goes far beyond Kohlrausch. In this book the discussion of polarization is based on the ideas of Kohlrausch, although his mathematical theory is omitted, and contains no hint of the advances made by other authors.

In spite of its defects this book has points of merit. There is a good discussion of the correction for the conductance of the solvent, of the problem of the extrapolation of the conductance to infinite dilution, and of the application of conductance measurements to the solution of many chemical problems. The style is clear. It may be recommended to students ignorant of the calculus as interesting, instructive and easy reading.

GRINNELL JONES

Electrolytic Conduction. BY F. H. NEWMAN, D.Sc., A.R.C.S., F.Inst.P., Professor of Physics, University College of the South-West of England, Exeter. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1931. xii + 441 pp. 70 figs. 14.5 X 22.5 cm. Price, $6.50.

The title of this book is similar to Davies' "The Conductivity of Solutions" reviewed above, but the books are very different. Newman has chosen his title poorly because his work covers a far wider field than is indicated by the title. This book includes, in addition to subjects clearly covered by the title, a discussion of the first, second and third laws of thermodynamics, Clapeyron's equation, the phase rule, the colligative properties of solutions, the law of mass action, Gibbs' adsorption equation, the factors influencing the potential of voltaic cells, hydrogen electrodes, quinhydrone electrodes, the determination of the transference numbers by electromotive force measurements, oxidation–reduction potentials, dropping electrodes, electrocapillarity, overvoltage, passivity and some technical applications of electrolysis. Considered as a textbook on Electrochemistry the most serious omission is the absence of an explanation of the PH scale and a discussion of its significance in many diverse fields of science.

The book also differs radically from that of Davies in that the treatment is much more mathematical. Newman clearly prefers to state relationships and laws in mathematical form whenever feasible and the book gains in precision, clarity and brevity thereby. Of course he uses the calculus freely.

To write a textbook on Electrochemistry, which this book really is in spite of its title, or to teach the subject is especially difficult at the present time because the science is in a transition period. The older books and nearly all of the original literature are based on the classical theory. Now, thanks to the genius of Debye, we have a radically new point of view and method of attack which gives great promise of transforming the science. But the new theory is complicated and difficult mathematically—so much so that Debye and his school have been forced, or at least tempted, to introduce inexact mathematical procedures and approximate or incomplete premises for the frankly avowed purpose of simplifying the mathematics, with the result that the equations derived are in most cases only valid as limiting laws for extreme dilution or for "slightly polluted water." But the theory is yet in its infancy and it is to be hoped and expected that later developments will give equations which are valid in much more concentrated solutions and that the theory will be extended to problems, such as the electromotive force at liquid junctions, which have not yet been treated by the new method. In the meantime students must be taught the old theory in order that they may be able to understand the great bulk of the chemical literature and because of the considerable remnant of truth in the older although imperfect views. They must be taught the new point of view in order to move with the procession. This book by Newman gives a clearer and more nearly complete presentation of the newer theory than is available in any other book; nevertheless, large portions of the book are written from the old point of view, Thus, for example, there is a table occupying almost a full page comparing percentage ionization as computed from the freezing point and from the conductance for a large number of salts over a considerable range of concentration. This table is discussed at considerable length in a manner which might have been written twenty years ago. However this is not intended as a serious criticism because it is probably at least a decade too early to present the entire subject of electrochemistry in a logical and consistent manner in accordance with the theory of interionic attraction.

To an unusual degree this book by Newman gives the impression that it was written from the original literature rather than from older books. It has a wealth of tables of numerical data and of well-selected reading references. It may be recommended to students familiar with the calculus as interesting and instructive but not easy reading.

GRINNELL JONES

Theoretical Mechanics. The Theory of the Potential. By WILLIAM DUNCAN MACMILLAN, A.M., Ph.D., Sc.D., Professor of Astronomy, The University of Chicago. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1930. xiii + 469 pp. 112 figs. 15.5 × 23.5 cm. Price, $5.00.

This is an extensive and thorough treatment of one of the older and well-known branches of theoretical physics. The earlier chapters are elementary in their form of presentation and should provide a good introduction for the student, and the later chapters provide an enormous amount of useful material. The volume will be of use for chemists only in so far as they are working on the border line of physics. The book is well printed and arranged, and is provided with a bibliography and index.

RICHARD C. TOLMAN

An Outline of Wave Mechanics. By N. F. MOTT, Lecturer in Theoretical Physics, The University, Manchester. Cambridge, at the University Press; The Macmillan Company, 60 Fifth Ave., New York, 1930. 155 pp. 21 figs. 14 × 21.5 cm. Price, $2.80.

It has apparently been the author's aim in this outline to stress the physical aspects of the new quantum theory rather than the mathematical technique involved in its applications. Following a general discussion of waves and particles, the Schrodinger equation is introduced and used as a basis for a brief treatment of the scattering and reflection of electrons. Succeeding chapters deal with the uncertainty principle, radioactivity, absorption of radiation, the helium atom, the hydrogen molecule and a number of collision problems. The discussion of electron spin is postponed to the last chapter. No mention is made of topics chiefly of interest to the spectroscopist, that is, energy levels of atoms and molecules and intensities of spectral lines.

The developments of those subjects that are included are brief in the extreme, as may be judged from the size of the book. More disappointing, however, is the fact that the author has nowhere given a correlation between the theory and experiment. Some of the outstanding experimental work is mentioned but one is left with the feeling that the author has followed in the footsteps of the legendary mathematician who concluded a series of lectures with the remark: "And now gentlemen, since we see that the problem has a solution, we lose all further interest in it."

Dr. Mott has addressed his book primarily to physicists familiar with the older quantum theory and the classical theory of wave motion. To those who have this background, this outline will afford an excellent means of acquiring a general acquaintance with some of the methods and results of the new theory.

HUGH M. SMALLWOOD

Naphthenverbindungen, Terpene und **Campherarten inkl. Pinusharzsäuren** sowie **Körper** der Kautschukgruppe. (Naphthene Compounds, Terpenes and Camphors, Including the Rosin **Acids** and Substances in the Caoutchouc Group.) By OSSIAN ASCHAN. Walter de Gruyter und *Co.*, Genthinerstrasse **38,** Berlin W 10, Germany, 1929. xv + 378 **pp.** 17.5 × 25.5 cm. Price, unbound, RM. 30, bound, RM. **32.**

The contents of this book are adequately summarized in the sub-title which is "Original contributions to the chemistry of alicyclic compounds dealing in part with industrial applications and supplemented with suggestions concerning further research problems." The four main divisions of the work are: (1) alicyclic compounds with a simple carbon ring; (2) saturated bicyclic compounds; (3) alicyclic compounds with a tricyclic nucleus; (4) studies of caoutchouc and other condensation products of isoprene of high molecular weight (including a consideration of the possibility of large-scale manufacture). Among the many topics considered under these main divisions may be mentioned: naphthenic acids and their isolation from petroleum, naphthenes, camphoric acid and its relatives, dipentene, sylvestrene, camphor (including its synthetic production), the composition of crude wood spirits, the rosin acids, the artificial production of rubber. None of the topics mentioned are treated in a systematic or complete fashion and the volume will therefore be of little use to one who wishes to familiarize himself with any particular branch of alicyclic chemistry. It will be of interest, however, to investigators who themselves are working in any of the many fields of alicyclic chemistry which the author's manifold interest has embraced. The treatment consists of a discussion of each problem from the point of view of the author's own work, which in part has been published and which in part is given for the first time. The discussion is full and many of the suggestions concerning further work very interesting, but the lack of experimental detail would force many readers back to the author's original papers. This relatively small volume is not a collection of papers but rather a discussion of the results of the author's long years of research in alicyclic chemistry.

HYSTERESIS IN THE WESTON STANDARD CELL[1]

BY WARREN C. VOSBURGH AND KELLY L. ELMORE

RECEIVED DECEMBER 6, 1930 PUBLISHED AUGUST 5, 1931

A theory of hysteresis in the Weston standard cell has been proposed by Niederhauser and Hulett[2] based on the formation of a supersaturated solution of mercurous sulfate at the cathode as a result of a decrease in temperature. This involves the assumption that the solubility of mercurous sulfate increases with temperature and that the rate of crystallization from a supersaturated solution is slow while the rate of dissolving in an unsaturated solution is rapid.[3]

Barre[4] found that the solubility of mercurous sulfate increases with the temperature, and it is probable that the solubility in a saturated cadmium sulfate solution would do the same. Calculation on the basis of the Nernst theory indicates that a concentration of mercurous ion 1% in excess of that of a saturated solution would account for an electromotive force about 1 mv. higher than the normal. The increase in solubility observed by Barre for a ten-degree increase in temperature was several times 1%, and so is sufficient to account for many, at least, of the hysteresis data.

Marc[5] showed that the velocities of crystallization of ammonium alum, potassium sulfate and potassium dichromate from their water solutions were slower than the velocities of dissolving under comparable conditions. Furthermore, Marc and Wenk[6] found that the presence of certain salts decreased the velocity of crystallization of potassium sulfate somewhat, and that certain dyes which were strongly adsorbed by the crystals of potassium sulfate greatly retarded the crystallization. In some cases no crystallization at all was observed during a period of six hours after seeding the super-

saturated solution. On the other hand, the dyes had little or no effect on the rate of dissolving of the crystals.

The results of Marc and Wenk support the supersaturation theory of hysteresis, which now seems preferable to that proposed by Vosburgh[7] based on a lag in the attainment of equilibrium between mercuric and mercurous ions and mercury.

A somewhat different mechanism than the one proposed by Niederhauser and Hulett is suggested by Marc's work. The rate of crystallization of the various salts from their supersaturated solutions as observed by Marc was rapid as compared with the change in electromotive force of many Weston cells after a decrease in temperature. However, in the light of the results of Marc and Wenk, adsorbed impurities on the surface of the mercurous sulfate might well account for the hysteresis phenomena, their effect being to retard crystallization.

The experiments described below were suggested by the theory of Niederhauser and Hulett and were undertaken with the object of obtaining more data on hysteresis.

Materials

Water.—For the preparation of other materials, water redistilled from alkaline permanganate was used. For the solutions used in the cells this water was again redistilled in a silica still,

Mercury.—Commercial redistilled mercury was passed several times through a column of mercurous nitrate solution and redistilled in a current of air.

Cadmium Amalgam.—By electrolysis with a cadmium sulfate electrolyte cadmium was transferred from c. p. sticks to mercury which had been washed with mercurous nitrate solution. It was again transferred to purified mercury by electrolysis, using the same electrolyte, forming a 12% amalgam to which was added enough mercury to give a 10% amalgam.

Cadmium. Sulfate.—Material of c. p. grade was dissolved and the solution treated with basic cadmium sulfate to precipitate impurities. The cadmium sulfate was then recrystallized twice by slow evaporation at room temperature,

Basic cadmium sulfate[8] was prepared from the normal salt by precipitation with ammonium hydroxide. It was washed free from ammonium salts by decantation, with the help of a small centrifuge.

Nitrogen and Oxygen.—Nitrogen from a tank of the compressed gas was passed through acidified potassium permanganate solution, alkaline pyrogallate solution. alkaline sodium thiosulfate solution, potassium hydroxide solution and then distilled water and a plug of cotton. Oxygen was passed through acidified potassium permanganate solution, potassium hydroxide solution, distilled water and a plug of cotton.

Mercurous Sulfate.—For the two similar preparations A and B, 400 g. of thrice recrystallized mercurous nitrate was dissolved in three liters of 0.1 M nitric acid solution, and this solution was added drop by drop to four liters of hot 2 M sulfuric acid solution. Preparation A was digested for twelve hours with the mother liquor on a hot-plate, and

---

[7] Vosburgh, This Journal, **49**, 87 (1927).

[8] It is immaterial for present purposes whether this is a basic salt or a mixture of oxide and normal salt.

Preparation B was digested for one hour. Both were washed with 2 *M* sulfuric acid solution and Preparation *A* was not further treated. Preparation B was digested for another hour with *2* M sulfuric acid solution.

The crystals of Preparation A ranged in size from **30** to 2300μ, most of them being between **300** and 500μ. The crystals of Preparation B ranged from **15** to 1000μ, most of them being between 30 and 50μ.

Preparation C was made like Preparation B except that the mercurous nitrate solution was added rapidly to the sulfuric acid solution, and it was digested for a total of eight hours, three hours under the mother liquor and five hours under a fresh *2 M* sulfuric acid solution. The crystal size ranged from **15** to 40μ.

Preparation D was like Preparation C except that it was prepared from C. P. mercurous nitrate and ordinary distilled water.

Preparation E was made by the electrolytic method.[9] It was digested for three hours with *2* M sulfuric acid solution on a hot-plate. The crystals were about 9μ in length.

Preparation F was one made for an earlier investigation by reduction of mercuric sulfate by mercury. The crystals ranged from 20 to 40μ in length and the material contained much finely divided mercury.

Cell Vessels.—The vessels used were of soft glass with sealed-in platinum wires for connection to the electrodes. They were of the usual H form, the length of the vertical tubes being **11** cm. and that of the cross-arm **3.5** cm. Both had a diameter of **1.5** cm.. and the cross-arm was **3.5** cm. from the bottom.

Preparation of the Cells

The cells were prepared essentially as described previously.[10] For the protection from air the pipet described by Randall and Stone[11] was used.

When it was desired to prepare comparable groups of cells which differed more or less in materials or method of construction, care was taken to use as nearly the same procedure as possible. The method of washing the mercurous sulfate received special attention. In setting up a group of cells protected from air and a comparable group exposed to oxygen, all the cells were constructed from the same materials. Two portions of mercurous sulfate were filtered and washed in the same way, one in an atmosphere of oxygen with an electrolyte saturated with oxygen and the other in an atmosphere of nitrogen with an oxygen-free electrolyte.

In sealing the cells the tops of the tubes were flushed out with nitrogen (or in special cases oxygen) and the nitrogen was kept running into them as long as possible during the sealing process. It is not claimed that all oxygen was kept out by this process, but that its concentration was materially reduced.

In some of the earlier cells a little trouble was experienced with gas collecting above the amalgam. This trouble, at first thought to be caused by reaction of acid with the cadmium, was not confined to acid cells. It was probably caused by air trapped in and around the amalgam. Evacuation

of the vessel with the amalgam in place and a little electrolyte above it overcame the trouble.[12]

Electromotive Force Measurements

The electromotive forces were measured by means of a Leeds and Northrup Type K potentiometer, the measuring system being properly shielded. The standards were the previously described Cells 353–6 and 496[10,13] to which an electromotive force of 1.01805 v. was assigned. The five cells agreed within 0.01 mv. A cell of larger capacity than the standards was used as the working standard, and a value was assigned it that would lead to the assumed value for the standards when they were measured. The absolute values of the standards were checked by means of two portable cells certified by the Bureau of Standards. The value found for the portable cells on the basis of the assumed values for the standards agreed with the certified value within 0.01 to 0.02 mv. There was evidence of a slight change in the portable cells, perhaps as a result of shipment.

Since the unknown electromotive forces were measured in the same manner as the standards and since the electromotive forces differed little from those of the standards, the errors of measurement must have been less than 0.01 mv. in most cases. Although in many standard cell investigations the precision attained is better than 0.01 mv., this was considered sufficient because the objective was to investigate relatively large deviations from constancy rather than to establish conditions for the preparation of cells of the highest quality.

Experimental Results

The cells were kept in an oil thermostat at $25 \pm 0.02°$ (fluctuations of temperature were usually not more than $\pm 0.005°$) for some" time after their preparation. Subsequently they were kept at room temperature, but put into the thermostat for measurements. In such a case their constancy was tested by at least three measurements made a day or more apart before final results were recorded. Care was taken that a change from room temperature to the thermostat was an increase in temperature rather than a decrease.

The electromotive forces were measured at intervals and the change of electromotive force with time is shown in the tables below. An hysteresis test was made from one to three and a half months after the cells were set up. A second hysteresis test was made later, all the cells being tested at one time. The ages of the cells at the time of the second test varied from three to eight months and are given in the tables. A third test was made four months after the second and a fourth three months after the third.

---

[12] It was learned later that Dr. Marion Eppley (private communication) had previously discovered the same remedy.

[13] Vosburgh, THIS JOURNAL, 49, **85 (1927).**

Hysteresis tests were made by transferring the cells to a thermostat at 35°, leaving them there for at least three days, then transferring back to the thermostat at 25° and measuring after one hour and six hours. The hysteresis was measured by the difference between the electromotive force at the time in question and that at 25° previous to the test.

Acid **Cells.—A** number of cells with slightly acid electrolytes were prepared to test the materials and technique and to act as controls for the other cells. The concentration of acid was 0.01 mole per liter. The electromotive forces of these cells over a period of twelve to sixteen months are shown in Table I and the results of four hysteresis tests carried out at different times are given in Table II.

TABLE I

CELLS WITH ACID ELECTROLYTES

Cells	Hg_2SO_4	E − 1018.00 mv., 25°

[a] The hysteresis of Cell 533 (see note *a*, Table I) was omitted from the average. It was much larger than that of the others. [b] Cell 626 showed larger hysteresis and a more rapid increase than the other two.

The effect of impurities on the hysteresis of acid cells was investigated by making cells comparable with certain of those described above except that impurities were introduced. The impurities tried were formaldehyde, urea, material extracted from cork and gelatin. The formaldehyde was suggested by the fact that the coarse mercurous sulfate preparation found by Vosburgh and Eppley[14] to lead to more hysteresis than various finer

---

[14] Vosburgh and Eppley, THIS JOURNAL, 46, 109 (1924).

preparations was made by reduction of mercuric sulfate by formaldehyde.[15] Urea was tried because it affects the growth of sodium chloride crystals.[16] That material extracted from cork had the effect of increasing hysteresis was shown by Vosburgh and Eppley.[17] The present experiment was a repetition of theirs, except that the cork material was introduced in a different manner.

The methods of introducing the impurities were the following. For Cells 620 and 622 mercurous sulfate was allowed to stand overnight under an acid solution containing 2 g. of formaldehyde per liter. For Cells 636–638 the mercurous sulfate was untreated, but 0.04 g. of formaldehyde was added to 100 *g.* of the electrolyte. For Cells 623–625 and 644–646 the electrolyte was shaken with finely divided cork which had been digested previously with two portions of boiling water. In the former group some of the cork was included in the cells also. Cells 639–641 contained 0.1 g. of urea per 100 g. of electrolyte. For Cells 642–643 the electrolyte was heated with gelatin, 0.05 g. of the latter to 100 g. of electrolyte, and approximately half dissolved. The results are shown in Tables III and IV.

[a] The age at the time of the first hysteresis test was one or two months and at the time of the second test was four or five months.

As far as hysteresis is concerned, formaldehyde seems to have a favorable effect, if any. Cells 620 and 622 differed little from Cells 626–628 (Table II)

---

[15] Since formaldehyde did not increase hysteresis, the conclusions of Vosburgh and Eppley are not affected by the present work.

[16] Neuhaus, *Z. Krist.*, 68, 15 (1928), cited in *Chemical Abstracts*, 24, *9* (1930).

[17] Vosburgh and Eppley, *J.* Optical *Soc. Am.*, *9*, 70 (1924).

in this respect, while 636–638 showed less hysteresis than Cells 632 and 634 (Table II). With respect to electromotive force, Cells 636–638 were abnormal, though constant, as far as observed.

The material extracted from cork by the solution undoubtedly caused some hysteresis. This is unmistakable in the case of Cells 623–625. The hysteresis of Cells 644–646, however, is not large as compared with many of the other groups, but it is the largest of any of the cells made with Mercurous Sulfate E.

Urea had little or no effect, but there can be no doubt that gelatin had a very pronounced effect.

The behavior of gelatin toward mercurous sulfate was tested qualitatively in another way. If gelatin prevents crystallization from a supersaturated solution, it should interfere with the growth of crystals in the precipitation of mercurous sulfate. Accordingly, mercurous sulfate was precipitated by the addition of mercurous nitrate solution drop by drop to a portion of dilute cadmium sulfate solution containing 0.01 mole of sulfuric acid per liter. Gelatin was dissolved in a second portion of the cadmium sulfate solution (0.025 g. per 100 cc.) and the mercurous nitrate solution added as before. Much more of the mercurous nitrate solution was added before precipitation started in the second case than in the first. Examination of the first mercurous sulfate under the microscope showed that it consisted of clusters of thick needle-like transparent crystals, while the second consisted of much smaller particles of roughly circular cross section.

Neutral **and Basic** Cells.—Hysteresis in acid cells has been found to increase with decreasing acid concentration.[17,18] If the supersaturation theory of hysteresis is to be applied to this case, a mechanism must be assumed to account for the effect of decreasing acidity on the velocity of crystallization. Such a mechanism might be based on the observation of Gardiner and Hulett[19] that mercurous sulfate becomes covered with a surface layer of basic mercurous sulfate when in contact with a cadmium sulfate solution. How large a concentration of sulfuric acid must be present to prevent such an action is uncertain.

It was thought that some data on the effect of a surface layer of basic mercurous sulfate might be obtained by comparing the hysteresis of groups of cells made with different opportunities for hydrolysis. **A** number of cells without added acid were made, and some others were made at the same time and of the same materials, but with the inclusion of some basic cadmium sulfate.8 The basic cadmium sulfate was placed either above the mercurous sulfate, separated from it by a layer of fine crystals of the normal sulfate, or in a similar position on the amalgam side of the cell.

---

[18] Ref. 10, p. 1265.

[19] Gardiner and Hulett, *Trans. Am Electrochem. Soc.*, 56, 121 (1929).

The results are given in Tables V and VI. For convenience, the cells containing no added acid are called neutral cells and those containing basic cadmium sulfate are called basic cells.

TABLE V

VARIATION OF ELECTROMOTIVE FORCE OF NEUTRAL AND BASIC CELLS

Cells	Hg_2SO_4	Basic salt	E − 1018.00 mv., 25° 1 mo.	3	5	8–10	12	16
546–50	A	None	0.06	0.04	0.03	−0.01	−0.03	−0.07
556–60	A	Hg leg	.03	−.01	.00	+.01	.00	.00
561–4	A	Cd leg	.03	.00	.00	.00	−.01	−.01
584–6	B	None	.06	+.05	−.31	−.57	−.81	....
590–4	B	Cd leg	.02	.04	+.03	+.03	+.04	....

The cells containing basic cadmium sulfate were less variable in electromotive force than the neutral cells, and the various groups agreed fairly well with each other. The average variation from the group mean of the individual cells within the groups was about ±0.01 mv. It is quite evident that the inclusion of basic cadmium sulfate has in these cases led to better cells than its omission. This recalls the precaution taken by Shaw and Reilley[20] to make the electrolyte in standard cells slightly basic.

It was observed at the end of the twelfth month (the eighth month for Cells 590–4) that the cells containing the basic salt all had a thin layer of gray material above the layer of fine cadmium sulfate crystals which covered the mercurous sulfate. A few contained spots of yellow basic mercurous sulfate in the paste, but no other changes were noticed. In order to learn to what extent basic cadmium sulfate can hydrolyze mercurous sulfate, a nearly saturated cadmium sulfate solution was shaken with a mixture of mercurous sulfate and basic cadmium sulfate. The first result was hydrolysis of the mercurous sulfate to yellow basic mercurous sulfate. On standing in the dark, the mixture turned gray in color, indicating further hydrolysis to oxide. If basic cadmium sulfate can hydrolyze mer-

TABLE VI

HYSTERESIS OF NEUTRAL AND BASIC CELLS

	Hysteresis I[b]		Hysteresis II[b]		Hysteresis III		Hysteresis IV

[a] In the first two hysteresis tests Cells 547 and 563 and the others indicated were omitted. At the time of the third test these cells agreed with the others as well as could be expected. [b] The age at the time of the first hysteresis test was one and a half to three months, and at the time of the second test five and a half to eight months.

---

[20] Shaw and Reilley, *Trans.* Roy. *Soc. Canada* [III], 13, 174 (1919).

curous sulfate to this extent, equilibrium was not attained in the basic cells. The constancy of electromotive force must have been the result of a local equilibrium or a steady state of change.

Cells made with Mercurous Sulfate B had more hysteresis than similar cells made with Mercurous Sulfate A, regardless of whether the electrolyte was acid, neutral or basic. It is uncertain what the difference between these two preparations was.[21] It is believed that in the preparation of the neutral and basic cells made with Mercurous Sulfate B, the mercurous sulfate was washed more thoroughly with the neutral electrolyte than in the case of Mercurous Sulfate A. This would lead to a thicker layer of basic salt on the surface.

The basic cells showed less hysteresis than the cells containing no added acid or base. In the basic cells the hysteresis decreased with the age of the cells. Hysteresis in the first group of neutral cells increased with age at first but after a year it was practically constant. In the second group a maximum seems to have been attained, after which there was a decrease to a more or less variable value.

Basic cadmium sulfate was also added to some cells made with an electrolyte containing 0.004 mole of acid per liter. Their behavior and that of some control cells made at the same time are shown in Tables VII and VIII.

TABLE VII

ELECTROMOTIVE FORCES OR SLIGHTLY ACID AND BASIC CELLS

Cells	Hg_2SO_4	Basic salt	E − 1018.00 mv., 25°					
			1 mo.	3	5	7	12	16
543–5	A	None	0.08	0.07	0.07	0.07	0.07[a]	[b]
537–9	A	Hg leg	.05	.00	.00	.02	.01	0.00
540–2	A	Cd leg	.03	.03	.03	.02	.00	.00

[a] The agreement of the three cells was not good at this time. [b] Hysteresis interfered with the measurement.

In this case slightly acid cells are compared with basic cells. In electromotive force the basic cells agreed better with the other basic cells shown in Table V than with the acid cells. Any important differences between the acid and basic cells must have been caused by changes which took place after the cells were set up, because acid cells are easy to reproduce. Such changes were doubtless accompanied by a decrease in the acid concentration in the vicinity of the mercurous sulfate—or were the result of it. The hysteresis results for these cells are given in Table VIII. The results for the separate cells are given rather than the average for the groups because of the lack of agreement.

---

[21] All the digestion of Mercurous Sulfate A was carried out in a solution containing nitric acid, while the last part of the digestion of Mercurous Sulfate B was carried out in sulfuric acid solution. A portion of the latter preparation was given an additional digestion in a sulfuric acid solution containing nitric acid, and two acid cells were made. The hysteresis was very small. Whether or not this was fortuitous was not determined.

[a] The age of the cells at the time of the first hysteresis test was one and a half months and at the time of the second test eight months.

At the beginning, the acid cells were definitely superior with respect to hysteresis. Their hysteresis increased with age, and by the time of the third hysteresis test, ten months after the first, the basic cells were definitely superior. During the early life, the acid cells agreed among themselves in electromotive force better than the basic cells. At the end of a year, however, the basic cells were superior in this respect. After a year, some of the basic cadmium sulfate was still present, though less than in the basic cells made with a neutral electrolyte.

It is of interest to consider the behavior of some neutral cells made with mercurous sulfate that had been washed with water (Cells **598–600)** or a very dilute sodium carbonate solution (Cells 572–4) before the cells were set up, and so presumably hydrolyzed on the surface. In the latter case there was a slight change of color.

598–600	.52	.32	0.74	0.55	0.86	0.65	0.89	0.67

[a] The cells were one month old. [b] The cells were seven months old.

Cells **572–4** made with hydrolyzed mercurous sulfate A showed considerably more hysteresis than Cells **546–50** (Table V) made in the usual way. The hysteresis increased with age in both groups made with the hydrolyzed mercurous sulfate.

It seems to be pretty well established[18] that in slightly acid cells the hysteresis increases with decreasing acid concentration. The increase of hysteresis as the quantity of added acid approaches zero must either parallel or be caused by hydrolysis of the mercurous sulfate. The same might be said of the decrease of electromotive force with time. Tables IX and X show that hydrolysis of the mercurous sulfate previous to setting up the cells leads to a still more rapid decrease in electromotive force, or to an initially high and decreasing electromotive force, and to increased hysteresis. However, as shown above, the introduction of basic cadmium sulfate leads to smaller hysteresis than in neutral cells, and the hysteresis in this case decreases with the age of the cells. The difference must have been in the extent of the hydrolysis. As shown above equilibrium could not have been attained in the basic cells and hydrolysis of the mercurous sulfate must have gone on continuously from the time the cells were set up. It is hoped that research now in progress will throw light on why basic cells have so little hysteresis.

The Effect of Oxygen.—Conflicting opinions have been expressed as to the effect of the exclusion of oxygen in the preparation of cells. Vosburgh[22] and Eppley[23] considered this precaution necessary, while Gardiner and Hulett[24] considered that it did not help any. Hydrolysis of the mercurous sulfate by washing seems to have been a very important factor in the results of the latter investigators, and its effect may have masked a smaller effect of the oxygen.

If oxygen has any chemical effect, the ultimate result must be to make the cell contents more basic. This could result either from direct union with cadmium or mercury, or the oxidation of mercurous ion to mercuric ion with subsequent reduction by mercury. If this is true, the reported good effect of exclusion of oxygen may have resulted from preventing the neutralization of a small quantity of acid present in the cell. It might be predicted, however, on the basis of the above results and discussion, that in a cell with an electrolyte containing very little free acid, oxygen might have a beneficial effect, making the electrolyte more basic.

Two groups of cells were made with Mercurous Sulfate A, two with Mercurous Sulfate B and two with Mercurous Sulfate F. In each case the two groups were made by as nearly the same procedure as possible except that air was excluded by means of nitrogen in one group and oxygen was used in place of nitrogen in the other. The results are shown in Tables XI and XII.

In the first two groups little effect of oxygen on the constancy is apparent. The oxygen-containing cells were more nearly constant over a period of

three or four months, but later decreased to a slightly lower value. On the other hand, the decrease in electromotive force of the nitrogen-containing cells was slower during the first three or four months, and the electromotive force was nearer the normal. In the other four groups there is no question as to the oxygen-containing cells being less variable in the long run, though none of the cells can be called good. Cells 584–6 had an electromotive force nearer the normal for the first three months than the comparable oxygen-containing cells.

TABLE XII

HYSTERESIS OF CELLS CONTAINING OXYGEN

Cells	Hysteresis I[c] 1 hr., mv.	6 hr., mv.	Hysteresis II[d] 1 hr., mv.	6 hr., mv.	Hysteresis III 1 hr., mv.	6 hr., mv.	Hysteresis IV 1 hr. mv.	6 hr.. mv.
546–9[a]	0.34	0.23	0.52	0.36	0.69	0.39	..	..
551–4[b]	.43	.31	.89	.69	.31	.17	0.33	0.18
584–6	1.43	.83	3.48	2.32	2.70	2.17	..	..
587–9	1.38	.76	1.56	0.87	1.86	1.10	2.14	1.31
579–80	3.26	2 66	3.47	2.93	3.03	2.33	3.10	2.40
581–3	3.23	2 86	2.31	1.91	1.72	1.24	1.84	1.26

[a] See note *a*, Table VI. [b] Cell 553 was omitted; it agreed with the others in the third and fourth hysteresis tests, as did Cell 555 also. [c] The age of the cells was one to three and a half months. [d] The age of the first two groups was eight months and that of the last four groups was six months.

In the first hysteresis test the presence or absence of oxygen seemed to make no appreciable difference; the groups that were comparable agreed as well as could be expected. In the other hysteresis tests the oxygen-containing cells showed less hysteresis than the others, except in the cells made with Mercurous Sulfate A in the second test. The presence of oxygen, if enough time is allowed, seems to bring about a reduction of hysteresis. The effect of oxygen is in the same direction as the effect of the addition of basic cadmium sulfate, though not as pronounced.

Discussion

Hysteresis does not in all cases increase with the age of a cell, In some of the acid cells the increase was small, while in some of the basic cells the hysteresis decreased rather than increased. The mechanism of the change is probably more complicated than that proposed by Niederhauser and Hulett. Instead of an approach toward perfection of the crystal surfaces it seems that adsorption of impurities, or of basic mercurous sulfate, on the surface may be at least a partial explanation.

If the surface is covered with basic mercurous sulfate as a result of hydrolysis, the case is more complicated than when gelatin or a similar material is adsorbed. A layer of basic mercurous sulfate would not necessarily prevent the deposition of mercurous ions from a supersaturated solution, but might make it necessary for these to be deposited as the basic salt rather than the normal salt.

Whether or not protection from oxygen can be considered beneficial depends on the point of view. Slightly acid or neutral cells made with care to avoid appreciable hydrolysis are more likely to give an electromotive force near the normal at the beginning if oxygen is absent. Oxygen in neutral cells seems to cause a more rapid decrease at first, but less variation later. However, the addition of basic cadmium sulfate (or cadmium hydroxide) to the electrolyte helps more in this respect than the addition of oxygen. In a basic cell oxygen should do no harm.

If the action of oxygen in a cell results in the addition of basic material, it follows that its presence in a slightly acid cell is undesirable. Hysteresis increases with a decrease of acidity, and if the added acid should be used up, the electromotive force would be likely to vary. If acid cells are made without protection from the air, enough acid should be added so that after the clean-up of the oxygen present a sufficient excess of acid will still remain. Other sources of basic material, such as cadmium oxide introduced with the amalgam, should be eliminated or taken into account.

Summary

Gelatin and material extracted from cork increased the hysteresis in acid Weston cells considerably. An explanation based on adsorption is suggested.

Cells with no added acid or basic material (neutral cells) had more hysteresis than cells containing basic cadmium sulfate.

The electromotive forces of cells to which basic cadmium sulfate was added were less variable over a period of several months and more reproducible than those of similar cells with no added basic material (or acid). The electromotive forces of the basic cells were lower than what is considered normal, however, after the first month.

The presence of oxygen caused a decrease of hysteresis in two groups of neutral cells and an increase at first in a third group, with a subsequent decrease. The electromotive forces of most of the cells containing oxygen decreased less than corresponding nitrogen-containing cells.

CHEMICAL KINETICS. II. THE INFLUENCE OF RELATIVE POSITION OF ELECTRIC CHARGE AND REACTING GROUP ON THE VELOCITY OF THE BROMOPROPIONATE-THIOSULFATE REACTION

BY VICTOR K. LAMER AND MILDRED E. KAMNER

RECEIVED MARCH 24, 1931 PUBLISHED AUGUST 5, 1931

I. Introduction

It is well known that the velocities of bimolecular ionic reactions are markedly influenced by the number of ions present as well as by the sign and magnitude of the excess charge upon them. These kinetic effects designated by Bronsted as primary salt effects are the result of the relatively greater opportunity for collision between ions of opposite sign than between ions of the same sign. They have been accounted for successfully in dilute solutions by the theory of inter-ionic attraction.

Except for two papers[1] (which will be considered later), giving relevant but not complete data, no measurements exist for a consideration of the more detailed problem of the possible kinetic effect arising from the structural position of the charge of the ion in relation to the structural position, within the ion, of the specific group which reacts chemically with the second ion. Except for a remark by Bjerrum[2] that the problem is not without interest and a brief discussion by Christiansen, no one appears to have even considered this possibility. The reactions between thiosulfate ion and the various brominated fatty acids furnish a type of reactions capable of answering this question. Thus, if we consider the reaction

$$CH_2BrCOO^- + S_2O_3^{--} \longrightarrow CH_2(S_2O_3)COO^{--} + Br^- \qquad (1)$$

which has been studied, previously, in this Laboratory,[3] and elsewhere,[4] and the analogous reactions

$$CH_3CHBrCOO^- + S_2O_3^{--} \longrightarrow CH_3CH(S_2O_3)COO^{--} + Br^- \qquad (2)$$

$$CH_2BrCH_2COO^- + S_2O_3^{--} \longrightarrow CH_2(S_2O_3)CH_2COO^{--} + Br^- \qquad (3)$$

it is evident that the chemical reaction involves the exchange of bromine for thiosulfate in each case. From electrostatic considerations, (3) should be more rapid than (2) because the electrical field of force repelling the entering negative thiosulfate ion is less intense in the beta position than in the alpha position. Chemical theory, alone, without electrostatic considerations would predict the opposite effect.

[3] Victor K. La Mer, THIS JOURNAL, 51, 3341 (1929); Paper No. 1 of this series.

[4] (a) A. Slator, *J. Chem. Soc.*, 87, 481 (1905); (b) S. Krapiwin, *Z. physik. Chem.*, 82, 439 (1913); (c) A. N. Kappana, *J. Indian Chem. Soc.*, 6, 45 (1929); 6, 419 (1929).

In order to determine quantitatively the role which relative position of charge and reacting group plays, it is necessary to eliminate the various influences upon the reactivity of the bromine atom which are dependent upon its structural position but independent of the presence of a neighboring charge. This can be accomplished by determining the rates of reaction of thiosulfate with the corresponding esters of the brominated fatty acids.

$$CH_2BrCOOCH_3^\circ + S_2O_3^{--} \longrightarrow CH_2(S_2O_3)COOCH_3^- + Br^- \qquad (4)$$
$$CH_3CHBrCOOCH_3^\circ + S_2O_3^{--} \longrightarrow CH_3CH(S_2O_3)COOCH_3^- + Br^- \qquad (5)$$
$$CH_2BrCH_2COOCH_3^\circ + S_2O_3^{--} \longrightarrow CH_2(S_2O_3)CH_2COOCH_3^- + Br^- \qquad (6)$$

Then, by comparing the ratios of ion rate/ester rate in each case, we measure the influence which the electric charge exercises in determining the rate of reaction.[5]

As the investigation proceeded, it became apparent that reactions (2) and (3) are not as simple as represented. Although the rate of the simultaneous water reaction

$$CH_2BrCOO^- + HOH \longrightarrow CH_2OHCOO^- + Br^- + H^+ \qquad (7)$$

is quite negligible as compared with the thiosulfate reaction (1), when bromoacetate ion is employed, this simplicity does not obtain in the spontaneous water reactions of the homologous acids—the water reactions being sufficiently rapid, in the case of the propionates, to be appreciable. These two reactions to be discussed later are[6]

$$CH_3CHBrCOO^- + HOH \longrightarrow CH_3CH(OH)COO^- + Br^- + H^+ \qquad (8)$$
$$CH_3BrCH_2COO^- + HOH \longrightarrow CH_2(OH)CH_2COO^- + Br^- + H^+ \qquad (9)$$

II. Preparation and Purification of Reagents

For an investigation of this kind purity of reagents is important. A redistilled sample of Kahlbaum's bromoacetic acid, m. p. 50.6–50.9° (Beilstein 50–51°), yielded kinetic results almost identical with those obtained with the bromoacetic acid used in the previous investigation. The propionic acids were Eastman's products and were redistilled at 10 mm. pressure before use. The esters were prepared according to the directions of Lepercq,[7] Lederer,[8] and Drushel and Hill,[9] by heating on a sandbath a mixture of the brominated acid with an excess of methyl alcohol and refluxing for two hours. The product was neutralized with sodium carbonate, poured into a large volume of water and after washing was

---

[5] Except for one value of Slator's, *J. Chem. Soc.*, 87, 481 (1905), for the rate of reaction between methyl bromoacetate and thiosulfate, there are no data in the literature for these last three reactions.

[6] Reactions (8) and (9) have been studied by Senter [*ibid.*, 91, 460 (1907)], but only at 52.4 and 79°, and the results of Simpson [THIS JOURNAL, 40, 674 (1918)] were obtained at 70°.

dried over calcium chloride and fractionated. The esters of bromoacetic and bromopropionic acids were distilled at reduced pressure to prevent decomposition. Table I gives a summary of the properties indicating the purity of the compounds used. The figures for bromine content were determined by the micro Carius method.[10]

TABLE I

PURITY OF COMPOUNDS

Compound	Final purification	Bromine content, % Calcd.	Bromine content, % Found
Bromoacetic acid	Distn., 79° 10 mm.	57.52	56.58 ± 0.02
α-Bromopropionic acid	Distn., 73–75" 10 mm.	52.24	53.12 ± 0.03
β-Bromopropionic acid	Distn., 94–95° 10 mm.	52.24	52.26 ± 0.01
Me ester bromoacetic acid	Distn., reduced pressure	52.24	53.09 ± 0.08
Me ester α-bromopropionic acid	Distn., 147–150°	47.86	48.94 ± 0.06
Me ester β-bromopropionic acid	Distn., reduced pressure	47.86	48.10 ± 0.10
Sodium hydroxide	Concentrated solution of Kahlbaum product was filtered according to directions of Clark[11]		
Sodium thiosulfate	C. P. salt was recrystallized and air dried		

It has been found by Slator and Twiss[12] and by La Mer[13] that one equivalent of sodium bromoacetate reacts with one equivalent of sodium thiosulfate, and in the present investigation that one equivalent of sodium β-bromopropionate reacts with 0.98 equivalent of sodium thiosulfate when the latter is in excess. Under the same conditions one equivalent of sodium α-bromopropionate was found to react with not more than 0.935 equivalent of sodium thiosulfate before the solution showed signs of decomposition, due to the exceedingly long time (more than thirty days) required for the completion of the reaction. There is no valid reason to doubt that the results would have been similar to those for the salt of the @-acid had it not been for this interference.

In the case of the esters it was observed by Slator that one equivalent of methyl bromoacetate reacts with one equivalent of sodium thiosulfate[4]" and that the ethyl ester of α bromopropionate reacts with only 0.93 equivalent of sodium thiosulfate.[12]

III. Experimental

All experiments were made at 25 ± 0.01". Volumetric apparatus was calibrated. Distilled water, freed from carbon dioxide by boiling, was used in the reaction mixtures.

For thiosulfate reactions (1), (2) and (3) the required amount of bromi-

---

[10] These bromine determinations were made in duplicate by the Research Service Laboratories. 37 East 28th Street, New York City.

nated acid was weighed out, neutralized with sodium hydroxide solution, using phenolphthalein, and, in some cases, brom thymol blue as an indicator, and made up to volume. The desired amount of sodium thiosulfate solution was pipetted into each reaction flask (200-cc. capacity, fitted with ground-glass stopper and trough for potassium iodide solution when needed to prevent loss of vapor if the flask contained iodine solution). With both salt and thiosulfate solutions at 25° the former was added to the latter in the reaction flask, taking into account the time of delivery of the pipets. The stopwatch was frequently checked against Naval Observatory Time. The reaction was stopped by adding an excess of iodine solution. The excess (approximately 0.01 N) was back titrated at once with dilute sodium thiosulfate solution.

For reactions (4), (5) and *(6)* the procedure was the same, the ester solution replacing the salt solution.

To study reactions (7), (8) and (9) solutions of the sodium salts of the brominated acids were kept in the thermostat and portions removed for titration with standard sodium hydroxide solution.

In a second series of experiments, to avoid the catalytic effect of the hydrogen ion liberated, the standard base was added at frequent intervals to a large volume of the solution to keep the solution neutral to brom thymol blue as an internal indicator—that is, the hydrogen ion was titrated as soon as it was liberated.

IV. Analytical

The iodine solutions containing 4% of potassium iodide were kept in dark bottles. They were standardized against Kahlbaum's arsenious oxide according to the directions of Washburn.[14]

Sodium thiosulfate was made up in 0.1 M solutions from which more dilute solutions were prepared and standardized against iodine. The use of stock bottles which had been dried at a high temperature, boiled water, and a minimum time of contact of solutions with air made possible quite stable solutions of thiosulfate, although frequent restandardizations were performed as a check. We have many data to show that 0.01 N thiosulfate solutions when so prepared retain their titer to within one part per thousand for at least a week. With weight burets a precision of one part per thousand is easily obtained.

The 0.5% starch solutions were prepared from potato starch by boiling for two hours, filtering through cotton and sterilizing at eighteen pounds' pressure in cotton stoppered tubes. Under the conditions of our experiments we find that $6 \cdot 10^{-7}$ equivalent of iodine is sufficient to produce a detectable color. This correction is negligible except for the most dilute solutions; the blank correction was applied whenever it was significant.

---

[14] E. W. **Washburn,** THIS JOURNAL, **30,** 31 (1908).

The stability of the very dilute thiosulfate solutions under the exact conditions of the experiments was controlled by blank experiments. After four thousand minutes we recovered 99.99% at *P*H 6.5 and 99.96% at PH 4.5. In the more acid solutions necessary for studying the rate of reaction of the undissociated brominated fatty acid, the instability of thiosulfate becomes important. and the necessary corrections for blanks were made in these cases. These data for very acid solutions, however, are used only in a qualitative sense.

Although the *P*H of the brominated ion plus thiosulfate ion reactions was initially 7, owing to access of carbon dioxide from the air and the liberation of traces of hydrogen bromide, the PH at the time of titration was more often 6 than 7. Moreover, even at *P*H 7 recovery of thiosulfate from 0.002 N thiosulfate solutions (by adding excess iodine and back titrating with thiosulfate) was 100.9%, the initial amount present having been determined by a 0.01 *N* thiosulfate, 0.03 N iodine standardizaiton.

We have been unable to detect any perceptible difference in the velocity constants when the reaction is stopped by titrating the residual thiosulfate with standard iodine as against the method of adding excess iodine and back titrating with thiosulfate. It is important to note that any minute error due to the course of the iodine–thiosulfate reaction in 0.01 N solution is canceled out since the thiosulfate was always standardized by the same iodine solution at the time of making the experiment.

It has been shown that the constants for the β-bromopropionate–thiosulfate reaction, in the most dilute region, obtained when the reaction was carried on under nitrogen and with the reaction mixture brought to a *P*H of approximately 5, immediately before the addition of iodine (run number 83), show no significant difference from those obtained in the other runs.

For the second order reactions (1), (2), (3), (4), (5), (6)

$$k = \frac{1}{(a-b)} \cdot \frac{1}{t} \cdot \ln \frac{b}{a} \frac{(\text{"}a\text{"} - x)}{(\text{"}b\text{"} - x)} \qquad \text{when } a > b$$

$$k = \frac{1}{t} \frac{1}{a} \frac{x}{(a-x)} \qquad \text{when } a = b$$

where k is velocity constant: a is initial concentration in moles per liter of thiosulfate; b is initial concentration in moles per liter of salt, or ester; x is equivalents of b converted = equivalents of thiosulfate used; "a" and "*b*" are equivalents present, at beginning of reaction; *t* is time in minutes. For the first order reactions (7), (8) and (9), $k = (1/t) \ln [a/(a - x)]$, where a is equivalents of salt present, at beginning of reaction; x is equivalents of H^+ titrated with alkali = equivalents of salt converted by water reaction.

Since so far as we are aware no one has worked out the kinetics of first and second order reactions proceeding independently and simultaneously in a solution, we give the following development by R. W. Fessenden of this Laboratory.[15] Let k_1 be velocity constant for first order reaction; k_2, velocity constant for second order reaction; a, substance disappearing by two reactions; b, substance disappearing by second order reaction only; dx/dt be rate of first order reaction; dy/dt be rate of second order reaction; then

$$\frac{dx}{dt} = k_1(a - x - y) \tag{10}$$

$$\frac{dy}{dt} = k_2(a - x - y)(b - y) \tag{11}$$

where a is concentration of salt in moles per liter; b is concentration of thiosulfate in moles per liter; x is moles per liter of salt transformed by water reaction; and y is moles per liter of salt transformed by thiosulfate reaction. Dividing *(10)* by *(11)* we obtain

$$\frac{dx}{dy} = \frac{k_1}{k_2(b - y)} \tag{12}$$

which gives

$$-x = \frac{k_1}{k_2} \ln (b - y) + C \tag{13}$$

When $x = 0$ and $y = 0$, then $C = -(k_1/k_2) \ln b$, or

$$x = \frac{k_1}{k_2} \ln \frac{b}{(b - y)} \tag{14}$$

Substituting this value of x in *(11)* we obtain

$$\frac{dy}{dt} = k_2 \left[a - y - \left(\frac{k_1}{k_2} \ln \frac{b}{(b - y)}\right)\right] (b - y) \tag{15}$$

By use of the calculus of finite differences, dy/dt can be evaluated for any given time, t. All other quantities except k_2 are known, and the equation is solved for k_2. This formula applied to the β-bromopropionate–thiosulfate runs in the dilute region gives a corrected bimolecular constant greater than the uncorrected constant. The correction is negligible in concentrated solutions. Evidence will be given later to show that the assumption that the two simultaneous reactions are proceeding independently is not warranted and that the k_1 values obtained in the absence of thiosulfate are much larger than those obtained in its presence. The correction consequently becomes negligible even in dilute solution. It is important, however, to note that this water reaction correction is of the wrong sign to account for the anomalous results for the β-ion to be discussed later.

---

[15] The formula of Bronsted, Kilpatrick and Kilpatrick, [THIS JOURNAL, 51, 428 (1929)], for the disappearance of epichlorohydrin in a buffer solution, by two paths—that is, by reaction with water and with an anion—was developed for a case in which the concentration of anion remains constant. This cannot be applied to reactions in which brominated fatty acid ion reacts with water and with thiosulfate, since the concentration of the thiosulfate ion does not remain constant throughout the reaction.

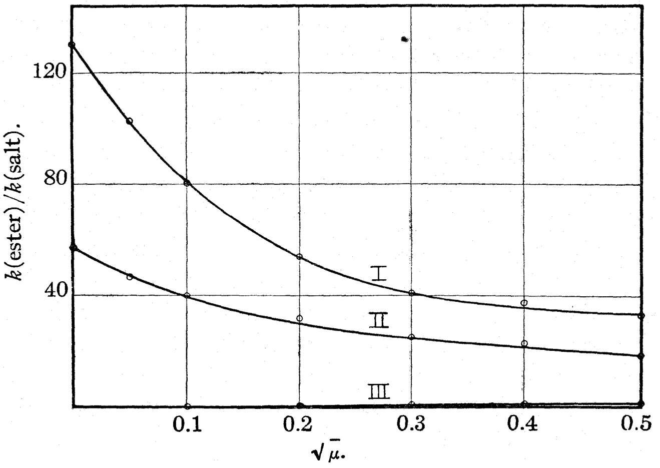
VI. Discussion

Position of Charge in Relation to Velocity.—From Table XVI and Fig. 6, where the value of k for the methyl ester is compared with that for the salt, we find in the case of bromoacetate and a-bromopropionate that the rate of reaction of the negative thiosulfate ion is twenty to a hundred and thirty-fold faster with the ester than with the ion, depending upon the concentration of the reactants. When the bromine is in the @-position, thiosulfate ion reacts about as rapidly with the ester as with the salt, since in this case the number of impacts of the thiosulfate upon the bromine is less influenced by the presence or absence of a charge on the carboxyl group.



Pig. 6.—I, α-Bromopropionic acid; II, bromoacetic acid; III, β-bromopropionic acid.

Although the *a-ester* reacts five to seven times faster than the *β-ester* in harmony with the rule that the a-position is more reactive than the @-position,the velocity of reaction of the β-bromopropionate ion greatly exceeds that for the a-bromopropionate ion. The recent data of Backer and Van Mels[1b] on the rate of reaction of the negative sulfite ion with the β-bromopropionate ion show it to be double that for the corresponding a-ion at the 0.1 M concentration used. These data, consequently, support our view that the electrostatic interaction is the dominant factor in regulating the rates of ionic reactions.

With reactions between ions of opposite sign, a reverse result should be obtained. Euler,[1a] studying the reaction $ClCH_2COO^- + H_2O + Ag^C \longrightarrow AgCl + (OH)CH_2COOH$, actually found that the rate of reaction of the corresponding ester of chloroacetic acid is only about one-eighth that for the sodium salt. Here the presence of the negative charge increases the probability that a positive silver ion will collide with the chlorine atom and react. Euler's data show also that sodium thiosulfate reacts fourteen times as rapidly with the ester as with the sodium salt of chloroacetic acid.

Concentration Dependence of the Ratios in Table XVI.—We had hoped to determine the values of k_0 for each reaction, *i. e.*, k, freed from interionic effects, by extrapolating the values of log k plotted against $\sqrt{\mu}$ to infinite dilution in accordance with the limiting slope predicted by the Debye–Hückel limiting theory; namely, $\log k_{\text{obs}} = \log k_0 + Z_AZ_B \sqrt{\mu}$. This limiting slope of $Z_AZ_B = 2$ is approached in the case of bromoacetate and also by the α-bromopropionate reaction as shown in Figs. 1 and 2. Much to our surprise, however, we found that the observed values for k for the β-bromopropionate salt, instead of decreasing with concentration, actually increased! The β-bromopropionate–thiosulfate reaction is the only one in dilute solution which, to our knowledge, is in direct contradiction to this prediction of the Bronsted theory. The cause of the discrepancy is, consequently, a matter of considerable theoretical interest.

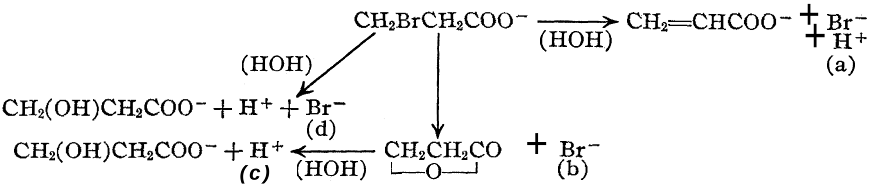
Several factors which might be relevant have been investigated. Experiments to detect errors in procedure were first carried out. The data have been confirmed in a second series of experiments performed nine months after the first. Reaction flasks, scrupulously cleaned with soap and chromic acid, before rinsing with distilled water and finally steamed, showed no difference in reaction rate for their contents as compared with the rate in cases where flasks had been merely cleaned with cleaning mixture and rinsed with distilled water. The possibility of traces of catalyst from the glass affecting the dilute solutions is not likely. Results no different from the others were obtained when the reactants were protected from the action of light.

In those experiments extending over several days where perceptible drifts in k occurred with time, the possibility was considered that the liberation of hydrogen bromide from concurrent water reaction might produce an analytical error in the iodine–thiosulfate titration. Some experiments were therefore made in which the reaction mixture was brought to a P_H of 7 using brom thymol blue as indicator, immediately before the iodine was added to stop the progress of the reaction. This did not eliminate the drifts in the case of a-salts (which will be discussed later) but gave for the β-bromopropionate–thiosulfate reaction values which showed no drift with time and were not appreciably different (Nos. 32, 74 and 37, 77) from the extrapolated values of the earlier runs in which neutralization of the hydrogen bromide before addition of iodine was omitted. This precaution is unnecessary for the runs at higher $\sqrt{\mu}$ values, since in the more concentrated solutions the iodine–thiosulfate reaction is less sensitive to acidity, and the reaction time being less there is a quite negligible accumulation of hydrogen ion. Moreover, the rate of development of acidity in the concentrated β-bromopropionate–thiosulfate reaction mixtures is enough less than the rate in the dilute mixtures that the actual titratable hydrogen ion formed is less in the former solutions, for a given period of time.

It has been found that the rate of formation of hydrogen ion in water solution by sodium β-bromopropionate in the absence of thiosulfate is considerably greater than the rate for the same concentration of salt in the presence of sodium thiosulfate. For instance, Run 72 shows that after 1523 minutes in the presence of thiosulfate of about twice its concentration, titratable hydrogen ion equivalent to only 0.2% of the original salt present (0.0375 M) has been formed, while in the absence of thiosulfate about one hundred times this amount would be formed. This can hardly be considered a salt effect in the ordinary sense. It would appear that the bromine atoms in the activated state react preferentially with thiosulfate rather than with water. Another fact pointing to this conclusion is that we found that 98% of the sodium β-bromopropionate present in a 0.0333 M solution reacted with thiosulfate as calculated from the disappearance of the latter. Reaction 9 therefore proceeds more slowly in the presence of Reaction **3** than in its absence. *These observations cast considerable doubt upon the validity of corrections for side reactions based upon the rate of the side reaction in the absence of the main reaction.* Therefore, the previously mentioned correction of the bimolecular reaction due to the monomolecular side reaction (water reaction) has not been used.

Since owing to its monomolecular character the rate of the water reaction is relatively greater then the bimolecular thiosulfate reaction in the dilute solutions of sodium β-bromopropionate, and it is these same solutions which show the unusually large value of k for the thiosulfate reaction, the question arises as to whether the accumulation of the hydrolysis products, either by catalytic action or by reaction with the thiosulfate, can cause this increase in velocity. Run 74, with concentration of thiosulfate 0.002512 M and sodium β-bromopropionate 0.00125 M ($\sqrt{\mu} = 0.0937$), performed by adding thiosulfate to salt immediately after its preparation and making up to volume, gave a velocity constant of $8.40 \pm 0.27 \times 10^{-2}$. A portion of the same salt solution was kept in the thermostat until the water reaction had converted 74.6% of the original salt (as determined by titration of hydrogen ion formed). To this neutralized solution, thiosulfate to give the same final concentration as above was added, and the mixture made up to the same volume. The velocity constant of this run was $6.61 \pm 0.39 \times 10^{-2}$ (calculated on the basis of concentration of salt remaining unchanged by water reaction). A similar experiment using more concentrated solutions also showed that the presence of the water reaction products *decreases* the rate of the reaction of sodium β-bromopropionate with thiosulfate and, therefore, their presence (which even in the runs of greatest dilution and longest time never approaches the large concentration, here) can be eliminated as the cause of the increase in velocity constants in the dilute region.

Possible courses of the water reaction of sodium β-bromopropionate are



The velocity of the water reaction as determined by the titration of hydrogen ion indicates how much salt has been converted to (a), (c) or (d) but if (b ⟶ *c)* is slower than (salt ⟶ b), this fact is not detected by acid titration, alone. Difference in concentration of bromide ion and hydrogen ion would be an index of whether more of (b) than (c) exists, but since silver nitrate reacts to some extent with the salt itself this does not promise to be a very satisfactory procedure. It has been found,[16] however, that at 70° solutions of a-bromopropionate and of β-bromopropionate show a negligible excess of bromide ion over hydrogen ion. We found in Run 11 that 0.98 equivalent of thiosulfate disappeared per equivalent of sodium p-bromopropionate present originally. It appears, then, that whatever water reaction products had accumulated, reacted (within two parts per hundred) with thiosulfate in the same ratio as postulated for the original salt. Whether the reaction took place through the intermediate step of lactone, hydroxy compound or even unsaturated compound should not influence the interpretation of the results since one equivalent of each is formed from one equivalent of salt. If the (b ⟶ c) conversion is slower than the formation of (b), then lactone accumulates and the water reaction products mixture should contain enough to make the velocity constant exceed that of the usual runs if the lactone reacted very rapidly with thiosulfate. That no appreciable thiosulfate was used up as soon (after *a* few minutes) as the reactants were mixed is evidence that the water reaction mixture contains no very reactive substance which could account for the increase in velocity of the dilute β-bromopropionate–thiosulfate runs.

In order to isolate the reaction product, equivalent amounts of sodium β-bromopropionate and thiosulfate were allowed to react for a sufficient time to approach completion of the reaction (adding sodium hydroxide occasionally to neutralize acidity). After proceeding according to the directions of Purgotti[17] for preparation of the barium salt of the thio deriva-

---

[16] G. S. Simpson, THIS JOURNAL, 40,674 (1918).

[17] A. Purgotti, *Gazz. chim. ital.*, 22,416 (1892).

tive of chloroacetic acid, a fine, white crystalline substance was obtained. After recrystallization, analysis[18] showed 19.60% sulfur. The theoretical sulfur content of $CH_2(S_2O_3)\overline{CH_2COOBa}$ is 19.94%. The corresponding sodium salt has been postulated as the reaction product in the thiosulfate reactions studied in this paper. **A** solution of the barium salt prepared had no perceptible action on an iodine solution.

The dissociation constant of a-bromopropionic acid is 108 X 10^{-5}, that of β-bromopropionic acid is 9.8 × 10^{-5}. Can the acidity resulting from hydrogen ion liberated by the reaction of the salt with water, by repressing the ionization of these rather weak acids, particularly the latter, cause thiosulfate to react with undissociated acid molecules as well as with the ion? By the use of citric acid–phosphate buffer solutions, the reacting mixtures for salts of the above acids were maintained at various ***PH*** values and the rate of thiosulfate reaction determined. In the more acid solutions the stability of the thiosulfate was determined by "recovering" it by iodine titration in control experiments from buffer mixtures of the same ***PH*** value and these values were used as the initial concentration of thiosulfate in calculating the velocity constant. With sodium β-bromopropionate 0.00125 M and thiosulfate 0.0027 M, the velocity constant decreased rapidly as the solutions became more acid than ***PH*** 4.5 and at **3.5** had fallen to a value but slightly more than half that at ***PH*** 6.5. The plot of these results has the form of a titration curve and shows that the undissociated molecule of β-bromopropionic acid reacts more slowly than does the ion with thiosulfate. This possibility of explaining the anomalous rise in velocity constant with decreasing $\sqrt{\mu}$ value is thus eliminated.

In the case of a-bromopropionate in buffered solutions (salt 0.0125 *M*, thio controls, varying slightly about the value 0.0266 M), the velocity constant is increased markedly with increasing acidity and at ***PH*** 4.0 has more than doubled its value at PH 6.5. The plot of these results also takes the form of a titration curve. The upward drift of the constants in runs of low concentrations of the a-salt can be accounted for by the increasing acidity which occurs during the many days required for a run. On this basis, then, it seems justifiable to extrapolate the results to determine the a-bromopropionate–thiosulfate velocity constant at zero time, for any run which shows a drift with time.

The fact that repression of the ionization of the acid increases more markedly the velocity of the reaction of the a-acid with thiosulfate than it decreases the velocity of the β-acid is in harmony with what we have found in comparing the effect of removal of charge in forming a methyl ester.

[18] Analysis by Research Service Laboratories, **37** East **28th** Street, New York, N. Y.

An Orientation Theory of Reaction Velocity.[19]—Having exhausted the possible chemical explanations, we present a physical explanation which is in harmony with the known facts and at the same time does not entail rejection of the Brönsted–Debye theory. In order to test Bronsted's theory it is necessary to introduce the Debye–Hückel limiting law. This law is derived on the simplifying assumption that the charges on the ions may be considered as symmetrically distributed upon a sphere of radius "b" so that the distance of closest approach of their centers equals the parameter "a." This assumption appears to be sufficiently valid to account for the bromoacetate–thiosulfate data and for the α-bromopropionate–thiosulfate data but can hardly be considered valid for β-bromopropionate if we are to consider the formulas of structural organic chemistry as representing even the approximate positions of the bromine atom and the charge on the carboxyl group. Since a reaction occurs only when a thiosulfate ion collides with the bromine in the β-position, our molecular model should be revised to take the form of one spherical ion (thiosulfate) and a long chain ion with a negative charge at one end and reacting bromine atom at the opposite end. From this model of structural organic chemistry, we contend that an orientation effect should be superimposed upon the effect predicted for spherical ions on the basis of the Brönsted–Debye equation.

Although the influence upon the activity coefficient produced by superimposing a dipole upon an excess charge has never been worked out quantitatively, it is generally recognized that the contribution of the dipole to the free energy should be small and vanish more rapidly with dilution than the contribution of the excess charge.[20] The influence of the dipole upon the reaction velocity, however, is not exactly comparable, for in reaction velocity we measure only the frequency of those collisions which occur between a thiosulfate ion and a β-bromopropionate chain when the chain is oriented within a given critical solid angle such that a chemical reaction will occur. Thus, the comparatively minute contribution to

---

[19] In his important paper on reaction kinetics, Christiansen [Z. *physik. Chem.*, **113**, **35** (1924)], in a carefully worded sentence, considers the possibility of orientation but expresses the opinion that it is of less importance than that of deactivating collisions. Christiansen, however, was, apparently, drawing primarily on his experience with gaseous reactions where the possibility of the orienting effect of the net charge of one ion upon another ion is remote as contrasted with the case of aqueous ionic solutions. We do not believe his analogy applicable in the present case. He does mention, however, the importance of attention to electrical forces in calculating concentration dependence of the velocity constant especially in treating a reaction in which large organic molecules are concerned, representing the organic molecule as being a chain and burdened with a charge at one place and at a proportionally great distance from the center of reaction. His reference to Holmberg's acetylglycolic acid experiments does not make clear, however, his point as we would interpret it.

[20] Discussion of one of us with Professor Debye in 1926.

the activity coefficient arising from the orientation due to dissymmetry of the charge in the β-bromopropionate ion may become the predominant factor in such a specific process as the oriented collision necessary for a chemical reaction.

That the molecular model, spherical ion and non-spherical ion with the point of attack at a great distance from the excess charge, should lead to a decreased velocity on increasing ionic concentration, may be shown as follows. Consider the extreme case of a volume of solution containing only one thiosulfate ion and one β-bromopropionate ion. Collisions will be very infrequent but, when they do occur, the bromine end will collide with the thiosulfate owing to the repulsive effect of the negative charges on the two ions. Every collision having a velocity sufficient to exceed the critical increment should, therefore, be fruitful. As we pass to slightly more concentrated solutions, the rapidly fluctuating fields produced by the thermal movement of the neighboring ions, will disturb the ideal orientation of the collisions that prevails at extreme dilution. Many of the collisions predicted by the term $C_A \cdot C_B$ in the rate equation $dx/dt = k \cdot C_A \cdot C_B$ will no longer occur with an orientation represented as lying within the critical solid angle necessary for chemical reaction. The result will be a decrease in the value of the velocity constant with increasing concentration which will be most pronounced in the highly dilute region. Since this effect will be superimposed upon the Debye–Hückel effect arising from the net charges on the ions, it is clear that we have a plausible explanation of the anomaly which does not conflict with the Bronsted theory.

It is hoped that theoretical physicists will essay a solution of this problem suitable for numerical evaluation. In the meantime, we are testing the idea by studying the rates of reaction in a homologous series of brominated compounds. Our theory requires a greater change in the temperature coefficient for the β-reaction as compared with the a-reaction, with variation in concentration, since an orientation effect should be more sensitive to temperature changes than is the Brönsted–Debye effect.

VII. Summary

1. Data are given for the rates of reaction of bromoacetate, α-bromopropionate and β-bromopropionate ions, and of their methyl esters, with sodium thiosulfate over a wide range of concentrations. The rates of the corresponding spontaneous water reactions have been investigated.

2. At all concentrations the velocity constant for the reaction of negatively charged thiosulfate ion with bromine in the β-position to a negatively charged carboxyl group greatly exceeds that for the reaction with bromine in the a-position to the carboxyl group. The converse is true when the esters are used in place of the salts.

3. Removal of the negative charge on the brominated ion either by

ester formation or by repression of ionization increases the velocity constant over a hundred fold when the bromine is in the a-position to the group bearing the charge, but has little effect when the bromine is in the β-position. All of these facts are in accord with the predictions of the electrostatic theory of reaction velocity.

4. For the α-bromopropionate–thiosulfate reaction, the limiting slope predicted by the Brönsted–Debye theory is approached for concentrations less than $\sqrt{\mu} = 0.06$. For the β-bromopropionate–thiosulfate reaction the velocity constant contrary to this theory **increases** with decreasing $\sqrt{\mu}$ values, the effect being most marked in the very dilute region.

5. As an explanation of this anomalous result for the β-bromopropionate, a theory based on the assumption of oriented collision is submitted.

THE CRYSTALLINE FORM OF SOME NEW COBALTAMMINES[1]

BY LESTER W. STROCK[2] AND THOMAS P. McCUTCHEON

RECEIVED APRIL 24, 1931 PUBLISHED AUGUST 5, 1931

Introduction

The recent work of V. M. Goldschmidt on crystal chemistry has shown that crystal structure is determined by the relative numbers, size and deformability of the constituent particles[3] These results are based largely on x-ray investigation, but deal primarily with relatively simple compounds. The structure of a compound consists of an interpenetration of a definite anion and cation arrangement, whose mutual influence on each other determines the final structure of the compound. A given cation structure is expanded by the introduction of various anions, but this expansion has a limit, at which the fundamental cation arrangement alters. The substitution of various cations similarly influences the structure of the anion.

The cation of a complex cobaltammine must represent the largest and most determining part of the final structure of compounds containing this cation in combination with a simple anion. The structure of compounds of

[1] This paper is a thesis submitted to the Faculty of the Graduate School of the University of Pennsylvania in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Acknowledgment is made to the George Leib Harrison Foundation of the University of Pennsylvania for fellowships granted for 1929–1930 and 1930–1931.

[3] V. M. Goldschmidt, *Skrifter Norske Videnskap. Akad. Oslo*, **1926**, No. 2; *ibid.*, **1926**, No. 8; *Naturwissenschaften*, 14, 477 (1926); *Trans. Faraday Soc.*, 25, 253–83 (1929).

this type is determined to a large extent by the cation, whose fundamental arrangement can be altered only with great difficulty. The axial ratio of suitable cobaltammines containing various simple anions should offer a means of determining the effect which an anion produces on a given cation structure. It must be remembered that when the structure of the cation does not represent a large portion of the final structure, and when the cation is not complex and heterogeneous, the axial ratio will be inadequate to measure the effect which the anion produces, as is seen from Fig. 1.

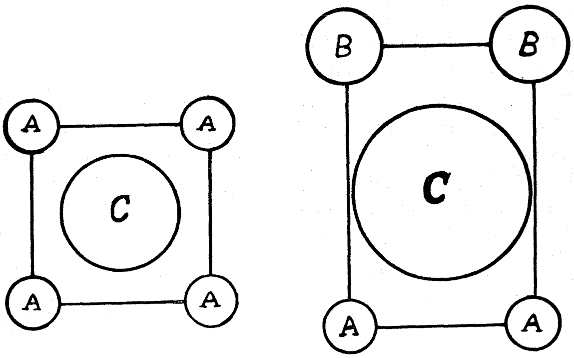

Fig. 1.—If the substitution of (C) increases the absolute dimension of the cell from 5×5 to 10×10, the axial ratio is not changed.

Fig. 1a.—If the substitution of (C) increases the absolute dimension of the cell from 4×10 to 8×12, the axial ratio changes from 1:2.5 to 1:1.5.

Fig. 1.—Illustrating the type of atomic arrangement, whose expansion may be detected by axial ratio determinations.

The figures show that the effect of the anion can be measured by a determination of the axial ratios only in the second case, where various anions (C) expand the cation structure (AABB) to different extents in different directions depending upon the atoms involved in the expansion. Only x-ray measurements will ascertain the absolute expansion in either of the above cases, but any irregular expansion in different directions may be detected in the axial ratios as determined by geometrical crystallography. The acido cobaltammines are compounds of the type shown in Fig. 1a, and should be well suited for testing this view. The introduction of various anions will not produce any regular differences on the crystalline form of the compound if the new anion causes a change in structural type to occur. However, the structural type of the compounds reported in this paper appears to be the same, and regular differences in the crystalline form should be and are observed.

Experimental

Preliminary work showed that compounds in the oxalato series were very stable and could be obtained in measurable crystals; therefore, several oxalato tetrammines were prepared, analyzed and their crystalline form determined. None of the compounds studied, except the perchlorate, has been previously described; therefore their methods of preparation and properties are included in this paper.

Preparation of Compounds.—Oxalato tetrammine cobalti sulfate was first prepared by the method of Schramm, and this was used to prepare the other compounds in the oxalato series.[4]

1. Oxalato Tetrammine **Cobalti Dichromate.**—A saturated solution of potassium dichromate at 30 to 40° is added slowly and with stirring to a saturated solution of the oxalato sulfate. A few drops of acetic acid or a little ammonium acetate is added to the oxalato sulfate solution to prevent decomposition. A bright orange-red precipitate is formed, which is filtered off at once, washed with cold water and alcohol, then dried in the air. The precipitate is a mass of minute but perfect crystals.

Composition 
$$\left[\overset{C_2O_4}{Co(NH_3)_4}\right]_2Cr_2O_7\cdot H_2O$$

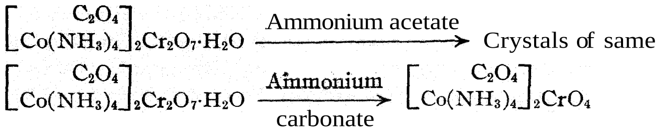
Constituent	Calcd., %	Found, %
Cr	15 66	15.69
Co	17.76	18.21
NH_3	20.513	20 55
H_2O	2.712	2.71
C_2O_4	Not determined	

The salt was found to be more soluble in a solution of ammonium acetate than in water. Since a more concentrated solution of the salt could be obtained in ammonium acetate than in water, this was used as a means of obtaining crystals suitable for measuring. The following procedure was followed. A 5 to 30% solution of ammonium acetate was carefully saturated with the salt at 40°. The excess salt was removed, and the saturated solution was allowed to cool very slowly (fifteen hours) down to room temperature while immersed in a large thermostat. This produced many small, but extremely perfect, deep ruby-red crystals. The crystals were always distorted when the concentration of the ammonium acetate was above 30 to 40%. The composition of the recrystallized and precipitated salt was found to be the same on analysis, showing that the treatment with ammonium acetate did not alter the composition of the salt.

2. Oxalato **Tetrammine** Cobalti Chromate.—All attempts to prepare this salt by the direct action of potassium chromate upon oxalato sulfate failed, but a small amount of acetic acid present caused the slow formation of the dichromate. When a small amount of ammonium carbonate was present no reaction occurred, and on evaporation the reactants were deposited unchanged. It was found that when the orange-red oxalato dichromate was boiled with ammonium carbonate it was transformed to a salt of a more nearly pure red color. An excess of the oxalato dichromate was then boiled with ammonium carbonate, and the salt, after boiling, was filtered off and used to saturate a 5 to 10% solution of ammonium carbonate at 40°. By slowly cooling this solution as described above, perfect deep red crystals were obtained which proved to be the oxalato chromate. Therefore even though the chromate cannot be made directly, it can be obtained by crystallizing the dichromate from ammonium carbonate.

---

[4] Schramm, *Z. anorg. Chem.*, 180,179 (1929).



$$\left[\begin{matrix} C_2O_4 \\ Co(NH_3)_4 \end{matrix}\right]_2 Cr_2O_7\cdot H_2O \xrightarrow{\text{Ammonium acetate}} \text{Crystals of same}$$

$$\left[\begin{matrix} C_2O_4 \\ Co(NH_3)_4 \end{matrix}\right]_2 Cr_2O_7\cdot H_2O \xrightarrow[\text{carbonate}]{\text{Ammonium}} \left[\begin{matrix} C_2O_4 \\ Co(NH_3)_4 \end{matrix}\right]_2 CrO_4$$

From several ammonia determinations the composition of the chromate was found to correspond to the formula written above. The ammonia required by the formula is 24.92% and the average found from four determinations was 24.94%.

3. **Carbonato Tetrammine** Cobalti **Dichromate.**—A saturated solution of potassium dichromate at 30 to 40° is added to a solution of carbonato sulfate at 60° in the presence of a little ammonium acetate. The mixture is stirred vigorously under running water, cooled quickly and filtered at once. The filtrate after removing the precipitate, and frequently even before, turns very dark brown in color, and on standing deposits crystals of similar color. These crystals could not be obtained pure for analysis. If the carbonato sulfate solution is not completely saturated, and if the potassium dichromate solution is much above 40° and also unsaturated, no precipitate will form, but the solution turns at once dark brown in color. The bright red salt changes to this dark brown substance on standing in water solution, acetic acid, ammonium acetate, potassium and ammonium dichromate, and most attempts to recrystallize it formed this brown solution.

Composition 
$$\left[\begin{matrix} CO_3 \\ Co(NH_3)_4 \end{matrix}\right]_2 Cr_2O_7$$

Constituent	Calcd., %	Found, %
Cr	17.62	17.63
NH3	23.08	23.00
Co	19.98	20.79
CO_3	Not determined	

The carbonato dichromate could not be crystallized, since all solutions of the salt change in composition before crystals form.

4. Carbonato **Tetrammine** Cobalti Chromate.—A solution of ammonium carbonate of almost any strength is saturated with the carbonato dichromate at 30 to 40° and allowed to stand. Large individual crystals deposit on cooling which are deep red in color.

Composition 
$$\left[\begin{matrix} CO_3 \\ Co(NH_3)_4 \end{matrix}\right]_2 CrO_4\cdot H_2O$$

Constituent	Calcd., %	Found, %
Cr	10.23	10.17
NH_3	26.81	26.76
Co	23.21	23.98
H_2O	3.54	3.45
CO_3	Not determined	

As in the oxalato series the chromate could not be prepared directly, but was obtained by crystallizing the dichromate from ammonium carbonate.

5. Oxalato **Tetrammine** Cobalti **Chlorate.**—This salt, not previously described, was prepared in order to study the crystalline form of a compound containing the oxalato cation combined with a univalent anion. Oxalato sulfate was treated with the calculated quantity of barium chlorate, the barium sulfate was filtered out, and the oxalato chlorate crystallized from the filtrate in measurable crystals after several days. The cobalt found in these crystals was 19.92%, and the cobalt required by the formula is 19.83% 
$$\left[\begin{matrix} C_2O_4 \\ Co(NH_3)_4 \end{matrix}\right] ClO_3.$$

6. Oxalato **Tetrammine** Cobalti Perchlorate.—This salt was prepared by Bronsted, and used by him in his studies on solubility. It forms readily on mixing saturated solutions of ammonium perchlorate and oxalato sulfate. Measurable crystals were obtained by slowly cooling an aqueous solution of the salt:  $\left[\begin{matrix}C_2O_4\\Co(NH_3)_4\end{matrix}\right]ClO_4\cdot H_2O$. Cobalt found, 17.78%; calcd., 17.74%.

7. **Carbonato** Tetrammine Cobalti Perchlorate.—This salt was prepared by mixing solutions of ammonium perchlorate and oxalato sulfate. The crystals were more difficult to obtain in measurable form, but were not investigated since other salts in this series could not be crystallized.  $\left[\begin{matrix}CO_3\\Co(NH_3)_4\end{matrix}\right]ClO_4$: Cobalt found, 20.69%; calcd., 20.59%.

Remarks on the Oxalato Tetrammine Ion

Solutions of salts containing a complexly bound acido group usually undergo hydrolysis, whereby a water molecule is exchanged for the acido group. The oxalato and the carbonato tetrammine ions show a marked difference in this respect. The carbonato dichromate changes to the diaquo compound rapidly, but the chromate ions which are produced in the hydrolysis of the dichromate group immediately replace the water molecules from the complex, so that the result of the hydrolysis of the unstable carbonato group is the formation of a chromato complex compound, which is the cause of the dark brown solutions previously mentioned. Briggs[6] has prepared compounds of this series by reactions involving the replacement of water by the CrO_4^{--} group.

Oxalato dichromate is very different from the carbonato dichromate, and hydrolyzes, producing the brown chromato compound only to a small extent after several days. Lamb has shown that the carbonato tetrammine base is as highly ionized as the alkali bases.[6] The presence of the carbonato ion in solution appears to favor the formation of hydroxyl ions, which in turn produces a high concentration of chromate ions when the carbonato dichromate is dissolved in water. These chromate ions either replace the CO_3 directly or replace the water molecule which had previously replaced the CO_3 group. Lamb did not determine the strength of the oxalato tetrammine base, so that we can make no prediction as to whether the oxalato tetrammine ion will favor hydroxyl-ion formation. From the behavior of oxalato dichromate solutions, it appears that very few chromate ions are formed. This would indicate that the oxalato ion favors hydrogen-ion formation. Solutions of oxalato dichromate do not change to the chromato compound, either because of the failure of the oxalato group to be replaced by water, or because the oxalato complex prevents the formation of chromate ions from the dichromate group. In the event that the aquo compound is formed there is no evidence that the dichromate group becomes com-

plexly bound as does the chromate group. Rây and Sarkar have described a compound which contains a complexly bound Cr_2O_7 group, but this has a very complex structure and is not comparable to the type of compounds considered here,[7]

Solubility of the Salts in Water

The solubility was determined by the same method used by Bronsted.8

Cobalt tetrammines	Solubility at 25° G. of salt per 100 cc. of satd. soln.	Specific gravity at 25°
Oxalato sulfate	0.7712	....
Oxalato dichromate	.0734	2.0995
Oxalato chromate	.3156	1.9790
Oxalato perchlorate	.4403 (At 20°, Bronsted)	....
Carbonato sulfate	6.061	....
Carbonato dichromate	Decompose rapidly in water and could not be determined	2.0300
Carbonato chromate		2.0135

The composition of the salts was ascertained by determining the constituents in the following way. Chromium was determined by the lead chromate method, ammonia by the method of Bronsted, and cobalt by the nitroso beta naphthol method, not igniting the precipitate in hydrogen.

Crystallography

Crystals of the compounds studied were obtained suitable for measuring by methods already mentioned. They were, as desired, very small and did not exceed 0.1 to 0.2 mm. in their greatest dimension. A crystal which was typical of the compound was selected and accurately sketched. This sketch was used to make the final drawing from the measured angles, so that each drawing would be a faithful portrait of the compound and not a drawing of the ideal form. A small piece of wax, fastened on a spindle, was drawn out to a thin thread, which was then attached to a suitable point on the crystal. The crystal when mounted on the wax was placed on a Goldschmidt two-circle goniometer and measured with a prominent zone vertical.

The average values from the measurement of a number of crystals were used to calculate the crystallographic elements. These elements and symbols were calculated by the method of Victor Goldschmidt from a gnomonic projection.[9] Care was taken to select the unit face so that

[9] A series of papers edited by Edgar T. Wherry and Charles Palache describes these calculations and covers the important bibliography of the subject [*Am. Mineral.*, 5, Nos. 2–12 (1920)].

similar faces on different compounds would have similar indices, and so that the orientation of the various crystals would be comparable. The same plan was followed in assigning letters to the faces.

The crystal tables which follow contain the measurements, calculations and results of the compounds studied. The figures are reproductions of drawings made from the gnomonic projections of the average values obtained, and are in all cases real portraits and not drawings of the ideal crystal, as Victor Goldschmidt insists is the best procedure.

No actual values for V_0 were obtained, but the (V) values were orientated by getting the best average angle between like faces from twelve different crystals. Face *(5)* was then set at 90° and from the angles obtained all other faces were orientated with respect to this one. The plot of these values (V') showed that it was necessary to move all these values clockwise 0.15' in order that zone (0–01) be parallel to the horizontal meridian. This gave at once the necessary known terms to calculate the polar elements. This procedure was necessary because no (010) face was present on any of the crystals examined. Even though these crystals appeared to be very brilliant, they gave many blurred and ghost signals. For this reason the calculations were made entirely from averaged values. The compound was at first thought to be monoclinic, and faces 5, 1, **3,** 20 and 9 to be in the plane of symmetry. Because of the blurred signals the variation of the measurements from monoclinic values were within the limit of reading error. That the crystal was triclinic was demonstrated by examining it with polarized light. With crossed nicols an extinction angle of 8° was obtained for all faces whose face poles were parallel with the supposed symmetry plane. Hence the measurements were averaged and calculated as triclinic. The symmetry of the crystal is very close to monoclinic since angles alpha and gamma are near 90°.

A special form table for the oxalato chromate is not included, since almost each face is a separate form. The last two columns of Table III give the average angles from the measurement of twelve different crystals instead of the angles from one typical crystal for, as mentioned above, the signals from many of the faces were so poor that the calculations had to be made solely from average values. Reference to Fig. 4 will show the prominence of the forms. The results are listed below.

The ordinary methods for determining (V_0) could not be employed here. After plotting, faces (7) and (10) were found to be (010) and when correctly rotated should have a (φ) angle of zero and be at zero on the projection. The angles between all forms measured were determined and the values in each case averaged. By this means the best average angle between that form and (010) was found. This gave a set of vertical readings which are recorded in column (V^-) of Table VII. By examining the plot it was found that the negative end of the crystal had been measured and sketched. The (V^-) values, therefore, were adjusted to their complementary position.

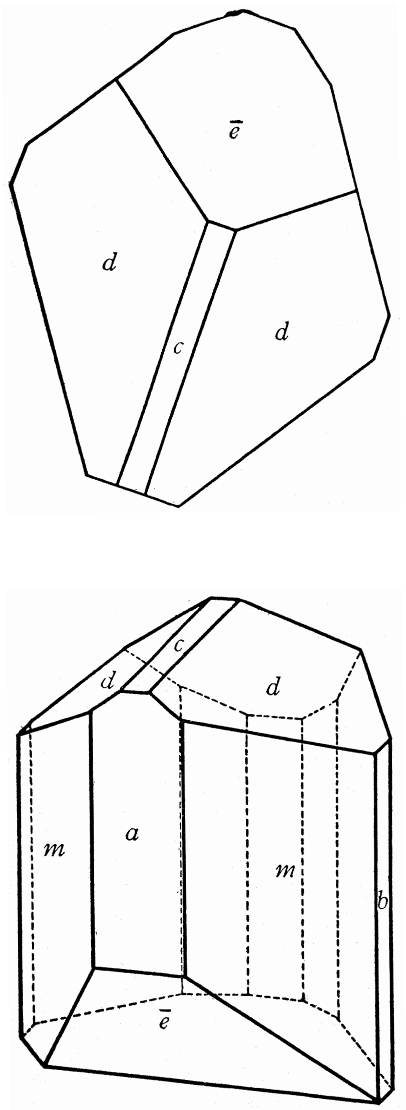

Fig. 6.—Oxalato tetrammine cobalti perchlorate, monoclinic.

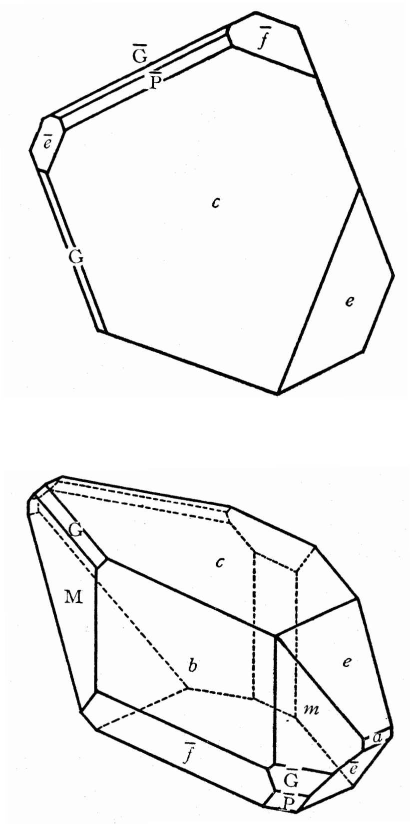

Fig. 7.—Carbonato tetramtnine cobalti chromate, triclinic (drawn with *b* front).

The values in column ($V+$) are the results of this readjustment, and from them the (φ) values were calculated.

Conclusions

As anticipated, the crystalline form and habit of a compound was affected as one of the groups was substituted. It appears that the structural type of all the oxalato tetramine compounds studied is the same, because the symmetry of their crystalline forms bear simple relations to one another. If this is correct, then the deforming influence of the substituted anions upon the structure of the oxalato group may be stated as having the following increasing order: Cr_2O_7, ClO_4, ClO_3 and CrO_4.

From infra-red absorption data, Rawlins[10] has suggested that in compounds of the type ABX, the AB portion of the compound may preserve a well-defined skeleton structure in various compounds as various atoms or groups are substituted for the X portion. Similarly, the oxalato tetrammines described in this paper may be given a type formula as follows—AXY. In the compounds described by Rawlins the two cations preserve a definite structure in various combinations. In the oxalato complexes, or in any acido ammonia complex, it is entirely possible that the AX portion of the molecule preserves a definite skeleton structure which is merely altered or deformed as various substitutions of (Y) are performed. This is merely another definition of a complex ion, and states that two atoms or groups which under some conditions exist as a single anion and cation are now combined in some way so that the combination acts as a definite new ion.

[10] **Rawlins, *Trans. Faraday Soc., 25* 283 (1929).**

Complex ions are usually considered in the same way as more simple ions, *i. e.*, to be more or less spherical. Pauling[11] has discussed the ionic radii of a few complex ions and their radius ratios. There is no literature which is opposed to assigning a definite skeleton structure to a complex ion of the type $AX^{\pm}$, and indeed such a structure appears to exist. Quantitative verification of the exact effect of the substituted anion in these oxalato complexes will be possible only after an x-ray determination of their structural types and cell dimensions. If the structural type is not altered by the substitution of the anion, then, as stated in the introduction, the axial ratios of a series of compounds which contain a complex ion will be adequate to measure the effect produced by the substituted anion.

Summary

1. The following new compounds have been prepared and analyzed: the chromate, dichromate and chlorate of the oxalato tetrammine series of cobalt, also the chromate and dichromate of the carbonato series.

2. Crystals of all the above compounds, except the carbonato dichromate have been prepared. These crystals, in addition to the oxalato perchlorate, were measured and the crystalline forms determined.

3. The difficulty encountered in preparing the oxalato chromate suggests an interesting example of the manner in which affinity of ions for each other may limit their deforming influence.

4. It is suggested that the complex oxalato cobalti tetrammine ion, and other acido complexes, may have a definite skeleton structure in crystals containing this complex ion, and that the substitution of various anions merely alters the shape and dimensions of this structure.

A PERIODIC ARRANGEMENT OF THE ATOMIC NUCLEI. THE PREDICTION OF ISOTOPES

BY HERRICK L. JOHNSTON

RECEIVED APRIL 29, 1931 PUBLISHED AUGUST 5, 1931

Interesting and suggestive regularities in the existence and abundance of mass numbers have been called to attention by various authors in recent years.[1] The most thorough tabulations of such empirical regularities are those of Harkins. The discovery of such relationships is useful not only in

---

[11] L. Pauling, THIS JOURNAL, 49, 765 (1927).

[1] (a) Harkins, *ibid.*, 39, 859 (1917); 42, 1976 (1920); 43, 1050 (1921); 45, 1426 (1923); *Phil. Mag.*, 42, 331 (1921); *Phys. Rev.*, 15, 85 (1920); *J. Franklin Institute*, 195, 554 (1923). *Chem. Reviews*. 5, 371 (1928); (b) Beck, *Z. Physik*, 47, 407 (1928); (c) Barton, *Phys. Rev.*, 35, 408 (1930); (d) Latimer, THIS JOURNAL, 53, 981 (1931).

offering a basis for the prediction of new isotopes but also in providing a key to the as yet obscure nature of nuclear structure. In these two respects such empirical tabulations play a role entirely analogous to that of the Periodic Table in the search for new elements and in the explanation of the structure lying outside the nucleus.

A new arrangement of the atoms in order of isotopic mass numbers is presented in Table I, which may be referred to as a Periodic Table of the nucleus. We believe that this arrangement possesses the advantage of easy comprehension and is, at the same time, suggestive both of unambiguous predictions of many undiscovered isotopes and of significant relationships with respect to nuclear structure.

In this table the atoms are first classified into four main types, differing in respect to the numbers of "free" protons in the respective nuclei. These four types are: the 4 N type, with atomic weight evenly divisible by four, which may be arbitrarily regarded as composed of exactly *N* alpha particles; the 4 N + 1 type, made up of N alpha particles plus one "free" proton; the 4 N + 2 type, consisting of N alpha particles with two additional protons; and the 4 *N* + **3** type, with three extra protons. This classification is made arbitrarily from consideration of mass number alone and is not regarded as precluding the possibility that in some nuclei four or more "free" protons may exist without combination into an alpha particle. N, of course, differs for various atoms and, in general, may assume any value from 0 to about 60, the latter corresponding to the mean value of N for isotopes of uranium. Successive rows in the table are characterized by successive values of N, given for convenience at the extreme left of the columns for each main type. A further classification is carried out, based on the numbers of "free" electrons in respective nuclei. The numbers which stand at the heads of columns represent the numbers of *nuclear* electrons in *excess* of 2 *N*. These may be arbitrarily taken as nuclear electrons outside of alpha particles.

Atoms experimentally observed and reported in the literature[2] are shown in bold-faced type. O^{17} and O^{18},[3] C^{13},[4] N^{15},[5] Be^8,[6] and Cl^{39},[7] were observed

---

[2] It is perhaps worthy of comment that about twenty-five isotopes have been reported since this table was prepared in its present outline several months ago. That these have fitted into the table without exception, as the reader may observe, inspires confidence in the use of the table for further predictions.

THE ATOMIC NUCLEI

Isotopes as yet undiscovered but whose existence is predicted unambiguously by the regularities in the table, are marked lightly in squares bordered with hachuring. In three instances which occur in the 4 N + 1 column it is safe to predict only that either one, or perhaps both, of a pair of atoms must exist. These qualified predictions are indicated by means of hachuring at diagonally opposite corners. We do not feel that there is, in general,' sufficient basis to predict either upward or downward extrapolations of members of columns. In a few instances observed regularities increase the probability of such extrapolations, indicated by question marks. However, the question marks which represent extrapolation to mass numbers 2 and **3** in positions which correspond to isotopes of hydrogen are intended literally as question marks.

The table is carried only to mass numbers of about 140 since the group of elements with mass numbers ranging from about 140 to 200 has received very little investigation. Lead, mercury, tungsten and bismuth fall regularly in order in the positions surrounding mass number 200, indicating that the regularities observed in the table persist to the heavier atoms. La^{139}, Nd^{144}, Nd^{145} and Nd^{146} are also known, and fit regularly into the table, but were omitted through an oversight.

Aston[9] has recently called attention to the existence of an isobaric triplet of mass 96. This table predicts the existence, as well, of isobaric triplets of masses 77 and 124. It is probable that several others exist in the latter half of Table I, although the uncertainty as to the upper and lower limits of the members of the columns does not permit definite predictions in other cases. It is not improbable that isobaric quadruplets may make their appearance among the heavy atoms.

We wish to point out certain very obvious regularities characteristic of the respective four chief nuclear types. The 4 N group is made up of a staggered progression occupying all *even-numbered* columns. The 4 N + 1 group, on the other hand, occupies *all* columns. The 4 N + 2 group makes its first progression in the manner of the preceding group *and then continues in the fashion of the 4 N group.* The *4 N +* **3** group makes its first progression like the 4 N group, *and then continues like the 4 N + 1 group.* These regularities must possess some significance with respect to structural relationships within the nuclei.

We were at first inclined to doubt the authenticity of Ge^{77} until we observed at approximately the same position in column 7 of the 4 N + **3** group a sequence of at least seven atoms. We do not know what significance can be attached to these rather long sequences in the midst of groups consisting ordinarily of much shorter sequences.

In the light of the table we believe that we can make some modification of Harkins' abundance rules[10] in a way which improves the usefulness of the latter. Thus Harkins' statement that atomic species which contain even numbers of nuclear electrons are much more plentiful than those which contain odd numbers can be better expressed as follows: Atoms made up of even numbers of protons as a rule do not contain odd numbers of nuclear electrons, while atoms of odd mass are distributed between even and odd nuclear electron types without essential distinction as to abundance. Likewise the distinction between species abundance (not gross abundance) of even and **add** mass numbers seems to be overemphasized. Eighty-six known isotopes of even mass are listed in the table and nineteen more predicted with certainty. Sixty-four known isotopes of odd mass number are listed and twenty-three more are predicted. Nor is there any essential difference between the numbers of atomic species in the 4 N and the 4 N + 2 groups. In terms of gross abundance, of course, O^{16} and Si^{28} alone furnish approximately three-fourths of matter as has been pointed out by Harkins[1a] and, in general, the prevalence of even mass types is well established. Even here there are frequent instances, particularly in higher atomic weights, in which the percentage of a particular species of odd mass among isotopes of a given element is considerably higher than one would be led to predict from a statement of the more general abundance ratios.

Since preparing the present table we have observed that the tabulation of Beck[1"] is capable of leading to the same predictions of isotopes as is the present arrangement, since it contains the same sequences of atoms which appear in the columns of Table I although the general plan of arrangement is quite different and, we believe, more difficult to comprehend. For atoms of mass 4 N, Latimer's[1d] tabulation is closely analagous to the present one. Professor Urey[10] has recently arrived at a, formally, quite different graphical plot of mass numbers which he informs us leads to predictions of isotopes nearly identical with those in this table.

We are at present engaged in the program of searching for predicted isotopes by means of spectroscopic analysis.

We do not attempt to offer, at present, any theoretical explanation of the observed arrangement.

Summary

A tabular arrangement of known isotopic species of atoms is presented, being essentially a Periodic Table of the Atomic Nuclei.

On the basis of the table, many undiscovered isotopes are predicted. The probable existence of certain isobaric triplets is pointed out.

Attention is called to significant relationships between the numbers of "free" protons and "free" electrons in atomic nuclei.

Certain of Harkins' abundance rules are restated in an amended form.

No theoretical explanation is offered for the observed regularities.

THE NATURAL SYSTEM OF ATOMIC NUCLEI

BY HAROLD C. UREY

RECEIVED MAY 7, 1931 PUBLISHED AUGUST 5, 1931

Recently Barton[1] has shown several interesting regularities in the known atomic nuclei when these are plotted with the numbers of nuclear protons and electrons as coordinates. The known nuclei lie on this diagram between two lines whose slopes are 2 and 1.61,[2] the points for nuclei of low mass lie on or near the first line while, with increasing mass, the points approach the second line so that the occupied region of the diagram is a band, narrow near the origin and wider for nuclei of higher masses. Barton pointed out that several well-defined groups of nuclei, which he called "clusters," appear in this diagram such that each cluster possesses an approximate center of symmetry. These centers of symmetry he places at P = 24, E = 12; P = 80, E = 45; and P = 124, E = 72, while Urey and Miss Johnston[3] showed that there are indications of another cluster of radioactive nuclei with a center at P = 222, E = 136. In this paper it will be shown that there are indications of another cluster with center at P = **38,** E = 20, that there is probably no cluster in the region of the diagram below A^{36}, and a correlation of these clusters with the stability of the nuclei as indicated by radioactivity and relative abundances of nuclei may exist. Further, a suggestion is made in regard to nuclei, as yet unknown, to be expected in the region from A to Cu.

Figure 1 is the proton–electron plot of the known nuclei from hydrogen to neodymium. The numbers of protons and electrons are plotted as abscissa and ordinate, respectively, with the scale drawn near the nuclei to facilitate comparison. Figure 2 is a similar plot of the radioactive nuclei in which it has been assumed that the nuclei of the actinium series have odd mass numbers.[4]

It is evident that the number of kinds of nuclei per unit length of the occupied band varies greatly with especially large numbers between P = 65 and P = 100 and between P = 110 and P = 150. There is another dense region near the radioactive elements shown in Fig, 2. The pattern of the nuclei from Li^6 to A^{36} is very regular and leads one to postulate that all possible nuclei of this region are known or that any unknown ones are very rare. Between A^{36} and Cu^{63} is a region having a very low density of points scattered in what appears to be a very irregular way on the diagram.

[4] Aston reports that Pb^{207} is present in sufficient amounts in Norwegian broeggerite to indicate that this lead is the end-product of the actinium series.

It is almost a certainty that all possible types of nuclei in this region have not yet been detected. The removal of Be^S, C^{13}, N^{15}, O^{17}, O^{18} and Ne^{21}[5] from the diagram would cause the plot in the region of these atoms to

Fig. 2.—The proton--electron plot of the radioactive nuclei and of Hg, Pb and Bi. Io and UY both occupy the point of P = 230, *E* = 140 and UX_2 and UZ probably the point P = 234, E = 143.

assume an irregular appearance similar to that of the region from A^{36} to Cu^{63} and we are led to expect that more refined methods will add many more points to the latter region.[6]

In searching for a possible regularity of nuclei in the region above A^{36}, we have well-known rules in regard to the relative abundance of nuclei of different types, due mainly to Harkins.[2] The most abundant nuclei of the earth's crust are those with proton numbers divisible by 4. The solid circles of Figs. 1 and 2 are such nuclei. From helium to Ca^{40} there are ten nuclei which are multiples of the helium nucleus in so far as the numbers of protons and electrons are concerned. From A^{40} to Zn^{64} there are seven nuclei which contain two electrons in addition to an integral number of helium nuclei. This region appears fairly complete in so far as this type of nucleus is concerned. Above Zn^{64} more of these "binding" electrons are required in these nuclei with mass numbers divisible by four. These nuclei are labeled as Series 0, 2, 4, ... in the diagram; the figures represent the numbers of binding electrons present in addition to those present in the α-particles or helium nuclei present.

From O^{16} to A^{36}, three nuclei in a vertical or diagonal row is a prominent feature of the diagram. If we draw lines through all such rows of three nuclei, we secure parallelogram figures as shown by the solid lines of Fig. 1. This feature is so prominent that the completion of the figures as indicated by broken lines is the next obvious step. In completing them, the rule that no element of odd atomic number has more than two isotopes has not been violated for no exceptions to this rule are known outside the radioactive elements.[7] The diagram as so drawn predicts the existence of many more nuclei than are now known, but methods used up to the present would probably not detect isotopes whose abundance is one-thousandth of the abundance of that of the most abundant one. The recent discovery of such rare isotopes by the molecular spectra method shows that the existence of more isotopes in this region is not only possible but very probable.

This pattern for existing nuclei in the proton–electron plot was derived as indicated above, but it is really only an expression of well-known rules due to Harkins[2] in regard to the abundance of nuclei in point of numbers in the earth's crust and in meteorites and the varieties of nuclei classified according to atomic number and nuclear electrons. These can be stated as follows.

(1) The most abundant nuclei, in point of numbers, have mass numbers divisible by 4 and are at the acute angles of the parallelograms. (2)

---

[6] The points Cr^{50}, Cr^{53} and Cr^{54} have recently been added by Aston, *Nature*, 126, 200 (1930).

[7] An isotope of chlorine of mass 39 has been reported by Becker [*Z. Physik*, 59, 601 (1930)], but not confirmed by Ashley and Jenkins (Washington meeting of the American Physical Society, April 30 to May 2, 1931).

Nuclei of even atomic number and even proton number are very abundant. In addition to the nuclei given under (1), this class includes the nuclei at the obtuse corners of the parallelograms. **(3)** Nuclei of even atomic number and odd numbers of nuclear electrons are less abundant. These occupy the midpoints on the diagonal sides. (4) Nuclei of odd atomic number and even number of nuclear electrons are less abundant and only two for each element are known. These occupy the midpoints of the vertical sides. (5) Finally, nuclei of odd atomic number and odd number of nuclear electrons are very rare, Li^6, B^{10} and N^{14} being the only known examples among non-radioactive nuclei. Such nuclei would occupy the centers of the parallelograms. In drawing in these parallelogram figures, then, we have only indicated the regions of the proton-electron diagram where it is most probable on the basis of the relative abundance of known nuclear types that other nuclei exist, with the additional assumption that these additional nuclear types will fall near the known nuclei having mass numbers divisible by 4.

The Structure **of** Nuclei.—This proton–electron plot with its parallelogram patterns suggests certain points in regard to nuclear structure. **A** nucleus may be considered as composed of (1) helium nuclei, (2) internal binding electrons, **(3)** additional protons and electrons. A chemical formula for a nucleus might be written $\alpha_n E_m p_k e_l$, where n gives the number of a-particles, m (always even) the number of binding electrons, k and l the numbers of additional nuclear protons and electrons, respectively. There is considerable evidence that the maximum possible number of helium nuclei is not present in all nuclei. Assuming that the protons alone contribute to the nuclear spin, it would be impossible to have nuclear spins greater than $^3/_2$, if the maximum possible number of protons and electrons were combined into helium nuclei having no spins. On the other hand, in the case of nuclei of low atomic number, either the maximum possible numbers of helium nuclei or other combinations of four protons and two electrons having about the same stability as helium nuclei are present. This is shown by the packing fraction curve, which shows a marked periodicity with atoms with mass numbers divisible by four having minimum packing fractions.[8]

Nuclei with mass numbers divisible by four may have additional binding electrons, 0, 2, 4, . . . , as indicated by the numbers of the series defined above. Latimer[9] has constructed a model of this type of nucleus in which extra pairs of electrons are bound in the interior of the nucleus in a regular way. Finally, the additional protons and electrons give the approximate parallelogram pattern of Fig. 1. Having a nucleus containing an integral number of helium nuclei, additional probable nuclei can be secured by

---

[8] H. Olson, *Phys. Rev.*, 35,213 (1930).

[9] **W. M.** Latimer, THIS JOURNAL, 53,981 (1931).

adding a proton + a proton + a neutron + a neutron or a neutron + a neutron + a proton + a proton. (A "neutron" is used here as a convenient way of referring to a proton + an electron.) In the region where the series overlap, it is possible to have nuclei occupying the common obtuse corners of the overlapping series. There is the possibility that these two nuclei are not identical, for their formulas as written above differ in the number of internal binding electrons, E, and the number of external electrons, e. The internal electrons occupy some deep-lying position of the nucleus such as suggested by Latimer, while the outer electrons with the addition of two protons may form another a-particle within the nucleus. These formulas would be $\alpha_n E_m p_k e_l$ and $\alpha_n E_{m+2} p_k e_{l-2}$. Such a case is known, for Io^{230} and UY occupy the same position in the plot, which is one of these obtuse corners as can be seen in Fig. 2. UX_2 and UZ also occupy the same position but not such an obtuse corner position.

The nuclei of elements with odd atomic numbers lie toward the middle of the occupied band of this plot. In most cases no attempt is made to predict additional nuclei of odd atomic number and what predictions are attempted are based on this regularity only.

Barton's clusters seem to be due to the overlapping of these series of approximate parallelograms in certain regions. Wherever this occurs it will be possible to select some point in such a region that the rotation of half the figure through 180° will result in the many coincidences of points just as observed by Barton. The best illustration of this is given by his cluster whose center was located by him at $P = 80$, $E = 45$. Because of the discovery of additional germanium isotopes, this is no longer a very good center but the point $P = 78$, $E = 44$ is. This is due to the overlapping of Series 4 and Series 6 and the diagram as sketched in (without any thought of the cluster by the way) is completely symmetrical from $P = 68$, $E = 38$ to $P = 88$, $E = 50$. The isotopes of Mo and Ru recently reported by Aston[10] do not destroy this symmetry within these limits. It may be that nuclei will be found which will fill in the diagram and so destroy the symmetry. Another cluster may be postulated with center at $P = 38$, $E = 20$ (A^{38}) due to the overlapping of Series 0 and Series 2. The cluster with center at $P = 124$, $E = 72$, may be regarded as due to the overlapping of Series 8, 10 and 12.[11]

The cluster with center at $P = 38$, $E = 20$ is imperfect partly because there are fewer known nuclei above this point than postulated by the

---

[10] Aston, *Nature*, 126,348 (1930); *Proc. Roy. Soc.*, (London), **A130**, 302 *(1931)*.

[11] It may be said that the cluster at $P = 124$, $E = 72$ is only a symmetry of the isotopes of xenon and tin. In point of numbers this is true but from Cd^{110} to Ce^{140} it is possible to assume isotopes of elements of odd atomic number so that the symmetry in these nuclei is perfect and yet so that there are only two isotopes of odd atomic number differing in mass numbers by two. It would be necessary to add I^{125} to secure complete symmetry in the odd-numbered elements in this region.

parallelogram pattern of Series 2, and partly because the pattern below this point obviously consists of only half parallelograms. If these parallelograms were completed, the additional nuclei required would violate the rule that the number of nuclear electrons can never be less than half the number of protons except in the case of the proton itself. The pattern as drawn for Series 2 does not violate this rule.

The Relation of the Clusters to Nuclear Stability.—It is well known that the elements which occur with greatest abundance in nature have comparatively few isotopes. Thus the most abundant elements, oxygen, silicon and iron, have 3, 3 and 2 known isotopes, respectively, while the rarer elements may have many more. Moreover, the minimum of Aston's packing fraction curve comes near iron and, as mentioned above, the region from Ca^{40} to Cu^{63} evidently has comparatively few nuclear species. Moreover, radioactivity outside the characteristically radioactive group of elements appears to be confined to K, Rb and Cs and though these elements have only 2, 2 and 1 known isotopes, respectively, the elements of even atomic number near the latter two have many isotopes. Thus krypton and xenon have 6, and 9 known isotopes, respectively. Even if the positions outlined in Fig. 1 were completely filled in, there would still be a relatively large number of nuclear varieties in the neighborhood of K, Rb and Cs.

It seems possible to relate the clusters of nuclei to the regions of nuclear instability. This relationship can be illustrated most readily by means of the imperfect cluster at argon. Series 0 breaks off at Ca^{40} and if we assume that higher members of the series are too unstable to exist in detectable amounts, it may be expected that the last members of the series are relatively unstable as compared to the preceding members. On the other hand, Series 2 begins only with Cl^{37}, Cl^{39}(?) and A^{40}, which may mean that the series below this point is unstable and that the first members of the series are relatively so compared to members of the series with larger numbers of protons and electrons. Thus the overlapping parts of the two series will be relatively unstable, but nuclei of both series may occur. Many varieties of nuclei will be found, though due to the instability of these they will be comparatively few in actual numbers as compared to nuclei of elements outside these regions. In the region where the series do not overlap, the one series appears to be very much more stable than the two neighboring series, so that nuclei of only one series are present (referring now to the region of Series 0 and 2) and due to high stability these are present in large numbers. Thus the clusters in agreement with general and well-known facts should lie in regions of comparatively low nuclear stability.

By making the assumption that the relative abundance of nuclei is a measure of their relative stability, we can secure a partial confirmation of the suggestion made in this paper that the clusters should occur in regions of comparatively low stability. The relative abundance of different atomic nuclei should be a test for relative stability if a sample of matter could be studied which conformed to the following conditions: (1) the nuclei of the sample were synthesized from protons and electrons under such conditions that a close approach to thermodynamic equilibrium was attained; (2) since that synthesis, no changes in relative abundance occurred due to the synthesis or disintegration of some nuclei and not of others so as to cause deviations from the equilibrium mixture; (3) no fractionation of the elements has occurred. All available samples do not conform to the third condition certainly regardless of the first two conditions. Thus meteorites consist of three "phases," the stone, iron and troilite phases, of which the first approximates to the crust of the earth.[12] We may be very cautious in accepting the reality of any regularities in abundances which follow the periodic system of the elements, for this may be due only to the well-known chemical similarities. An excellent example is the extreme rarity of the inert gases in the earth's crust, due possibly to their inability to form high-boiling compounds with the other elements.

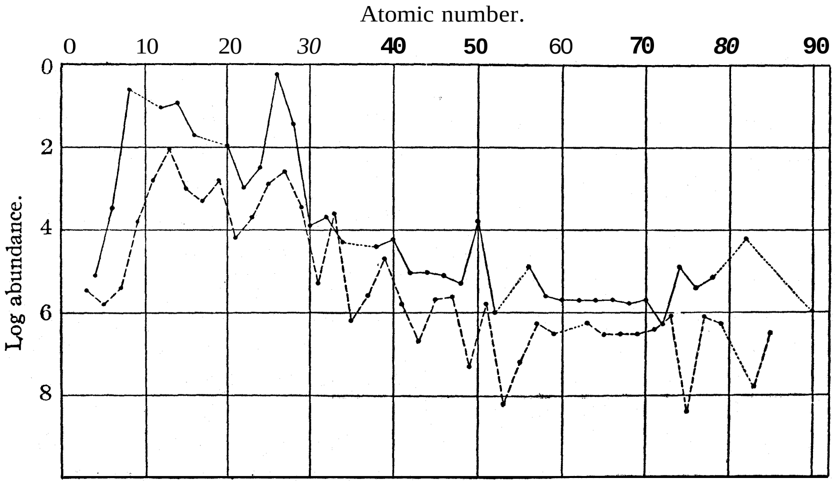

Fig. 3.—The logarithm of the atomic abundances in meteorites plotted against the atomic number. The abundances are expressed as fractions by mass taken from the data by Noddack and Noddack.

Figure 3 is a plot of the logarithm of the fraction of the meteorites by mass contributed by an element against its atomic number as given by the Noddacks. The solid line connects the points of the even-numbered elements and a broken line (long dashes) those of the odd-numbered ones. The short dark lines indicate that an intermediate element has not been

---

[12] See Noddack and Noddack, *Naturwissenschaften*, 18, 757 (1930).

detected in meteorites. The method of estimating the amounts of elements not directly determined is described in the legend of the figure.

The well-known Harkins rule that elements of even atomic number are more abundant than those of odd number is evident from the figure and there are at least two well-defined maxima in the even-numbered curve at oxygen and at iron and two in the odd-numbered curve at aluminum and cobalt. The minima between these come at titanium and at scandium. These minima do not coincide exactly with the suggested region of instability at chlorine, argon, potassium and calcium. The abundances of elements in the sun as given by Russell[13] follow a very similar curve. Titanium is relatively more abundant in the sun than in the meteorites, but potassium and calcium have rather high abundances. It seems impossible to decide definitely whether this disagreement in detail is real, especially since we have no assurance that the abundance curve is exactly related to stability anyway. Roughly, however, the abundance curve indicates that the elements of both Series 0 and Series 2 first increase in abundance, reach a maximum and then decrease again, and that there is a minimum near the region where the two series overlap.

Beyond copper the abundance curve is so irregular and the overlapping of the series so continuous that all correlation of the two is uncertain. The present data would indicate a complete contradiction to the assumption of a maximum of stability in each series, for the addition of Mo^{92} and Ru^{g6} would indicate that Series 4 does not follow a regular course.

Whether a minimum occurs at neon is an interesting point. The curves as drawn from the data on meteorites certainly do not suggest the presence of such a minimum. Similar curves for the crust of the earth do, but the crust of the earth approximates the stone phase of meteorites as mentioned so that meteorites probably are the better "sample." An interpolation from the even-numbered curve would indicate that neon should be a very abundant element (between oxygen and magnesium), and the same conclusion is reached on the basis of Russell's curve for the elements in the sun. Yet the spectrum of neon has not been detected in the sun or stars.[14] Since Na^{23} has a nuclear spin greater than $^5/_2$, it may be that Ne^{20} does not consist of five helium nuclei and the rarity of neon may be due to a less stable arrangement of protons and electrons, an instability, however, which must be compensated in Na^{23}.

The system of nuclei suggested by Johnston[15] is very nearly identical

---

[13] H. N. Russell, "Contributions from the Mt. Wilson Observatory," No. 383,1929.

[14] Latimer [THIS JOURNAL, **53**, 981 (1931)] has suggested a very interesting model for nuclei which would indicate that Ne^{20} should be less abundant than 0^{16} and Si^{28}. However, the model is not able to satisfy the writer in regard to the striking rarity of Ne^{m}, Ne^{21} and Ne^{22} with respect to F^{19} and Na^{23}, both of which are known to occur in the sun's atmosphere.

[15] Johnston, *ibid.*, **53**, 2866 (1931).

with that suggested here and all conclusions in regard to the relative abundances of the nuclei apply equally well to his system. He does not postulate the existence of so many additional nuclear species, but all those postulated here can be fitted into his scheme. In fact, his classification of nuclei and that of this paper appear to be only different presentations of the same scheme. Beck's[16] classification of nuclei is formally more like that presented by Johnston.

Harkins[2] has given a number of classifications of nuclei emphasizing particularly the use of his isotopic number. The writer believes that the simple proton–electron plot is simpler and more direct than these methods of classification, since it emphasizes the number of ultimate particles in nuclei of different types.[17] In view of the many systems of classification proposed, it would be difficult to originate another system which did not overlap previous ones in many points. This paper is written to emphasize the prominent parallelogram feature of these diagrams and the indication that additional stable nuclei are secured from those having most numbers divisible by four by adding protons and neutrons as indicated by these figures. In this way, it fits in very well with the recent interesting suggestions of Latimer.[9]

Summary

1. By using the proton–electron plot for atomic nuclei, predictions are made in regard to unknown nuclei between A^{36} and Cu^{63}.

2. The formula of a nucleus as consisting of helium nuclei, internal binding electrons, external protons and external electrons is proposed. It is shown that the isotopic isobars Io^{230} and UY may be expected.

3. It is suggested that Barton's clusters may be related to nuclear stability.

4. The system of nuclei proposed is compared to those proposed by other authors.

NEW YORK, N. Y.

ACTIVITY COEFFICIENTS OF SULFURIC ACID IN **ANHYDROUS** ACETIC ACID

BY A. WITT HUTCHISON AND G. C. CHANDLEE

RECEIVED MAY 8, 1931 PUBLISHED AUGUST 5, 1931

In a recent series of papers entitled "Superacid Solutions"[1] acid–base relationships in glacial acetic acid solutions have been studied. These authors reached the conclusion that acids dissolved in this solvent possess a high acidity when compared with similar aqueous solutions. The explanation of this relationship is based on the modern conception of acids and bases expressed by Brönsted.[2]

The conclusions of Hall and co-workers[1] are based in part on the nature of titration curves for anhydro bases with acids in glacial acetic acid solution. The potential difference between a saturated chloranil electrode in the solution of the base and an aqueous saturated potassium chloride calomel half-cell joined to the acetic acid solution by means of a stoppered salt bridge containing a saturated solution of lithium chloride in acetic acid was measured. This potential changed with the addition of acid solutions to the base and a plot of the potentials measured against the quantity of acid added showed clearly the course of the neutralization and its end-point.

Since the reference potential of the saturated chloranil electrode is independent of the solvent, a knowledge of the liquid junction potentials involved would allow such a cell to be used as a measure of the familiar P_H of the solution. The authors have considered the sum of these potentials to be constant in the various solutions measured and have estimated it. From these values they have calculated values of the acidities of the various solutions in terms of a quantity $P_H^{(HAc)}$ comparable to the usual P_H. These values for acid solutions were generally negative, indicating a greater acidity than is possessed for aqueous solutions of the same acids.

This work suggested the desirability of obtaining further information regarding the activity of acids in a solvent of the high acid character possessed by acetic acid.

The measurement of cells without transference furnishes at once a method of obtaining values for the activity or the mean ionic activity coefficients for a solute with no uncertainty beyond the accuracy with which the measurements are made. The activities so obtained are expressed in terms of a standard reference state for the solvent concerned and are not directly comparable to activities in water solution.

[1] Hall and Conant, THIS JOURNAL, **49**, 3047 (1927); Conant and Hall, *ibid.*, **49**, 3062 (1927); Hall and Werner, ibid., 50, 2367 (1928); Conant and Werner, *ibid.*, 52, **4436** (1930).

[2] Bronsted, *Rec. trav. chim.*, **42**, 718 (1923).

In the present work the potential differences between a hydrogen electrode and a mercury–mercurous sulfate electrode in solutions of sulfuric acid in anhydrous acetic acid from 0.0025 to 0.9 molal in strength have been measured. The reference potential for this cell in acetic acid has been obtained by an extrapolation method based on the Debye–Hückel theory of strong electrolytes and the applicability of this theory to a solvent of a very low dielectric constant has been demonstrated.

Experimental

Preparation of Materials.--Glacial acetic acid of U. S. P. grade was purified by refluxing for ten hours with an excess of chromium trioxide to remove any easily oxidizable material. The acid was distilled from the solid residue and then carefully fractionated in a packed column rectifying still similar to that described by Marshall.[3] A reflux ratio of one to ten was used. The packing of the column was of glass tubing of small diameter cut in such lengths as to give cylinders of equal height and diameter. The packing in the column extended five feet. All of the operations were conducted in all-glass apparatus and at all times the acid was protected from atmospheric moisture by calcium chloride tubes. The main fraction melted at 16.55°, corresponding to an acid of 99.975% purity on the reasonable assumption that the freezing point lowering was due to water.[4]

Anhydrous sulfuric acid was made by mixing concentrated acid with fuming acid, both of Baker's analyzed grade, as described by Kendall and Carpenter.[5] It froze at 10.3°.

The mercurous sulfate was of the best grade obtainable. Mercury of a C. P. grade was further purified by washing in dilute nitric acid and distilling in a current of air as recommended by Hulett and Minchin.[6] Electrolytic hydrogen, dried with phosphorus pentoxide, was used for the hydrogen electrodes.

The solutions were made by adding to a weighed amount of the pure acetic acid the desired amount of sulfuric acid from a weight buret. In the calculations of the molalities of the solutions the necessary corrections for vacuum weights were made. The densities of five of these solutions were determined and the equation $d_4^{25} = 1.043 + 0.062m$ was found to express the relationship between density and molality up to 0.87 molal. This equation was used in calculating the concentrations from the molalities.

The potentials listed are the average of readings taken on two cells prepared at different times, Three pairs of platinum electrodes were used in each cell, thus giving a total of twelve readings at each concentration. When the cell solution was saturated with hydrogen equilibrium was reached almost immediately. The reproducibility of these measurements was about 2 millivolts. In the case of solutions 1 and 9 hydrogen was allowed to bubble slowly for five hours through the cell with no change in potential greater than 4 millivolts. In the case of other cells the constancy of potential for one hour was assumed sufficient test that equilibrium had been reached. The potentials were independent of the rate of hydrogen flow after the solution had been thoroughly saturated with hydrogen

All electromotive force measurements were made with a Leeds and Northrup type K potentiometer by the null method. The potentiometer calibrations were checked in this Laboratory and were found to be as indicated within the limits demanded by the experiments. A saturated Weston standard cell was used as a reference e. m. f. It was

checked from time to time during the course of the experiments against two other cells of the same type recently calibrated at the Bureau of Standards. In place of the usual galvanometer a Compton quadrant electrometer was used as an indicating instrument. The instrument was used with negative electrostatic control as described by Compton and Compton.[7] Its sensitivity was 3000 mm. per volt. All of the apparatus was completely shielded, the lead wires by lead pipe, and the potentiometer, standard cells, and working battery in specially constructed metal boxes. The electrometer was suspended in a Julius suspension so as to free it from possible mechanical disturbances and the shielding completely eliminated accidental electrical effects. Switches were placed near the potentiometer so that the electrical stirring device as well as the heating system of the thermostat could be disconnected at the time readings were being taken. The lead wires were of No. 18 copper wire. Platinum wires were fused to the ends of the wires used to make connections by means of dipping into mercury. This prevented the possible contamination of the mercury.

The thermostat was maintained at a temperature of 25 ± 0.01°. The cells were placed in a copper tank, filled with oil, suspended in the thermostat water.

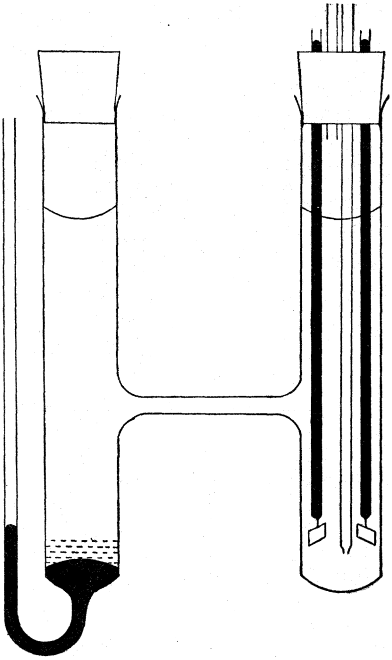

Fig. 1.—The cell.

The cells were of the H type, Fig. 1, similar to that described by Noyes and Ellis[8] and were made by connecting two Pyrex test-tubes by means of a short, about 8-cm., piece of tubing of 7-mm. diameter. A piece of the same tubing was sealed to the bottom of one of the tubes and bent so that it became parallel to the tube. This tube then became the mercury–mercurous sulfate half-cell, and connection was made to it by means of a platinum wire dipping into the mercury. In the second tube was placed a stopper through which were inserted two hydrogen electrodes with mercury contacts and tubes for the inlet and outlet of hydrogen. In some of the preliminary experiments cells of different types were used, some with a stopcock on the cross arm. No difference in potential was noted, so that the simple type described was used in all of the final work. Hydrogen was saturated with acetic acid before entering the cell by bubbling it through a wash bottle, immersed in the thermostat, containing the solution being measured. The outlet tube was protected from the atmosphere by an acetic acid seal.

Data and Calculations

In order to evaluate the activity of the mean ionic activity coefficient of sulfuric acid in the solutions, we may use the equations of Lewis and Randall[9]

---

[7] Compton and Compton. Phys. *Rev.*, **14**, 85 (1919).

[8] Noyes and Ellis, THIS JOURNAL, **39**, 2532 (1917).

[9] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, **1923**, p. *355*.

$$E = E^\circ - \frac{RT}{2F} \ln a_2 \tag{1}$$

$$E = E^\circ - \frac{3RT}{2F} \ln (\gamma m 4^{1/3}) \tag{2}$$

Before a_2 or γ can be evaluated, a value for E° must be determined. Transforming (2) and introducing common logarithms

$$2.303 \times \frac{3RT}{2F} \log \gamma = E^\circ - \left(E + 2.303 \times \frac{3RT}{2F} \log m4^{1/3}\right) \tag{3}$$

If the quantity in the parentheses, $E^{\circ\prime}$, is plotted against some function of m, extrapolation of the curve to $m = 0$ gives at once the value of E°. The data are given in Table 1 and in Fig. 2 values of $E^{\circ\prime}$ have been plotted against $(m)^{1/3}$. Inspection of the graph shows that the curve is approaching a straight line with, however, such a steep slope that a slight error in the choice of its slope would make a large one in the value of E° obtained by simple extrapolation. Solutions less concentrated than 0.0025 molal gave erratic potentials, so that no significance could be attached to them.

TABLE I

EXPERIMENTAL DATA

Solution	m	$(m)^{1/3}$	E	$E^{\circ\prime}$
1	0 002461	0.1350	0 537	0 323

9	.8715	.9552	.452	.465

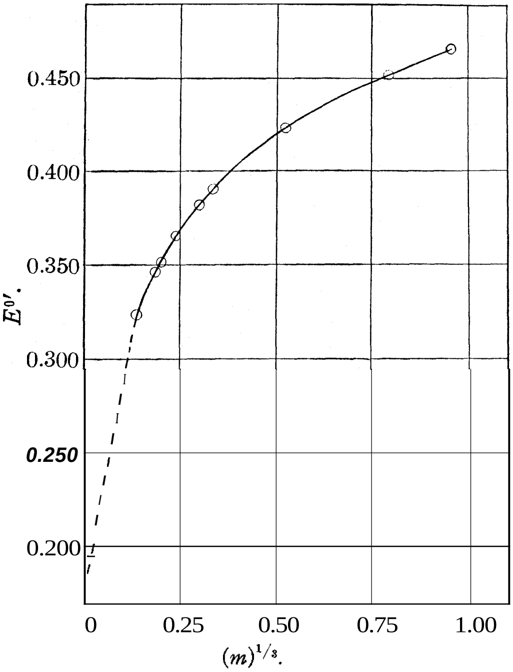

Fig. 2.

The Debye–Hückel[10] theory, however, allows an evaluation with reasonable security of activity coefficients in very dilute solutions. The fundamental equation may be written

---

[10] Debye and Hückel, *Physik. Z.*, 24, 185 (1923).

$$-\ln f = \frac{A\epsilon^2 z_1 z_2 K}{2DRT(1 + Kb)} \quad (4)$$

$$K^2 = \frac{8\pi\epsilon^2 A^2 \mu}{1000\ DRT} \quad (5)$$

The values for the universal constants were taken from the "International Critical Tables," that of the dielectric constant. $D = 6.165$, from the recent work of Smyth.[11] Substituting the numerical values for the constants

$$K = 1.1734 \times 10^8 \sqrt{\mu} \quad (6)$$

Transforming to common logarithms and noting that in the very dilute solutions $f = \gamma$ where γ is the mean ionic activity coefficient based on molality

$$-\log\gamma = \frac{23.033\ z_1 z_2 \sqrt{\mu}}{1 + 1.1734 \times 10^8 b \sqrt{\mu}} \quad (7)$$

which for an electrolyte of the 2–1 type in acetic acid can be written

$$-\log\gamma = \frac{79.79\sqrt{c}}{1 + 2.0325 \times 10^8 b \sqrt{c}} \quad (8)$$

This equation has been modified by Hückel[12] for use in more concentrated solutions by the introduction of a third term to allow for consideration of the changing dielectric constant of the pure solvent brought about by the introduction of solute. For sulfuric acid solutions in acetic acid the equation may be written

$$-\log\gamma = \frac{79.79\sqrt{c}}{1 + 2.0325 \times 10^8 b \sqrt{c}} - \beta c + \log(1 + 0.18m) \quad (9)$$

The last term is necessary in concentrated solutions because of the transformation from an activity coefficient based on mole fraction to one based on molality.

Equation (2) may be written

$$E = E^\circ - 0.08872 \log(\gamma m 4^{1/3}) \quad (10)$$

$$\log\gamma = -\frac{E}{0.08872} - \log m + \left(\frac{E^\circ}{0.08872} - \log 4^{1/3}\right) \quad (11)$$

and denoting the quantity in parentheses by K

$$-\log\gamma + K = \frac{E}{0.08872} + \log m \quad (12)$$

The constants b and β of equation (9) were evaluated by the method proposed by Hückel[12] on page 123 of his article. Such modification of the equations given as was necessary for a 2–1 type electrolyte was made. The values found were $b = 1.5 \times 10^{-7}$ and $\beta = -0.35$.

If the data of Table II are substituted in equation (12) and values of $-\log\gamma + K$ are plotted against the half-power of the concentration, the

curve should be of the same nature as that of equation (9). In Fig. **3** the full curve is that of equation (9). The circles represent values of (– log y + K) – K, taking K as 1.84.

It is of interest to see just how much influence the various terms of equation (9) have on values of $-\log\gamma$. In the extremely dilute solutions the slope of the curve should be 79.79, represented by the straight line of Fig. **3.** It is not surprising that even at the very low concentrations measured this slope is not reached since the dielectric constant of acetic acid has such a small value. Introduction of the ion diameter term, however, gives a coincidence of the four experimental points with the curve up to 0.014 molal. The addition of the second term includes three additional points up to 0.15 molal. The more concentrated solutions depart from the theoretical curve. In Table III are listed the values for the terms of the Huckel equation, – log γ calculated from this equation and – log γ experimentally determined from the value of (– log γ + K) – K taking K as 1.84.

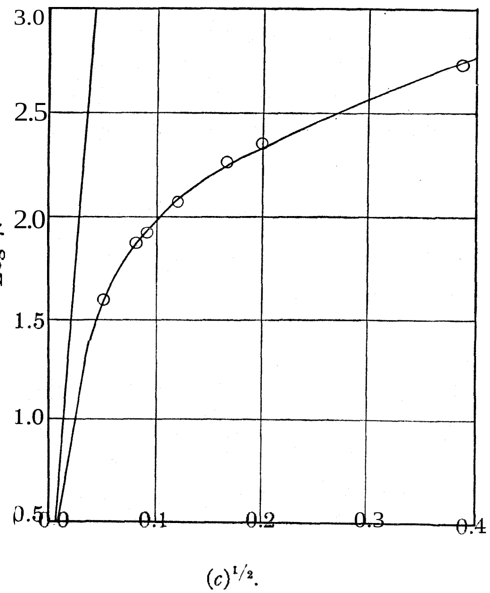

Fig. 3.

A comparison of the values used for the arbitrary constants with those chosen by other workers may be of interest. The value chosen for b, the average ion diameter in the solution, is somewhat larger than is generally used in aqueous solutions but is of the same order as values used by other

TABLE III

workers in acetic acid solutions. Conant and Werner,' in applying the Debye–Hückel equation to data for sulfuric acid–anhydro base buffer solutions in acetic acid used values of 1.3×10^{-7} and 1.24×10^{-7} for b, with, however, a slightly different limiting slope because of a different value for the dielectric constant. Webb[13] in studying the freezing points of acetic acid solutions of salts used for b, in the case of lithium bromide, 7.1×10^{-8}, for sodium bromide, 6.8×10^{-8}, and for sodium acetate, 6.2×10^{-8}. He apparently used a still different value for the dielectric constant.

The large values for b in acetic acid solutions might be accounted for by considering the ions solvated in all solvents, and since the acetic acid molecules are probably larger than water molecules, an increased diameter would be expected. In general the ion diameter b is larger than the diameter of ions in the crystal lattice.

The value of B in aqueous solutions is ordinarily a small positive number. However, Webb[13] found that his data were in accord with an equation of the type of (9) only when B was a negative number. Thus for lithium iodide b is taken as 6.75×10^{-8} and B as -1.38. The sign of the constant could be explained on the assumption that the dielectric constants of the solutions are greater than that of the pure solvent. Walden and Ulich[14] and Walden, Ulich and Werner[15] have found that with many organic solvents the dielectric constant is increased on the addition of electrolytes.

From the value of 1.84 assigned to K a value for E^0 of 0.181 volt can be calculated. Then for solutions of sulfuric acid in acetic acid at 25.0° may be written the equation

$$E = 0.181 - 0.08872 \log (\gamma m 4^{1/3}) \qquad (13)$$

from which activity coefficients can be calculated at any molality measured.

Summary

A convenient method for the preparation of large quantities of anhydrous acetic acid of a high grade has been found.

---

[13] Webb, THIS JOURNAL, 48, 2266 (1926).

[14] Walden and Ulich, Z. *physik. Chem.*, 110, 43 (1924).

[15] Walden, Ulich and Werner, *ibid.*, 116, 261 (1925).

A general equation for the calculation of activity coefficients of sulfuric acid in glacial acetic acid solutions has been developed.

It has been shown that an equation of the type proposed by Huckel as a modification of the Debye–Hückel theory of strong electrolytes is applicable in a solvent of very low dielectric constant.

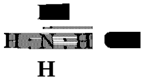
THE DIPOLE MOMENT OF SEMI-POLAR BONDS

BY JOHN DEVRIES AND WORTH H. RODEBUSH

RECEIVED MAY 8, 1931 PUBLISHED AUGUST 5, 1931

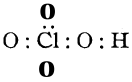
The term semi-polar bond has been used to designate a shared electron bond in which both electrons are contributed by one atom. This term has been used in the absence of a more suitable designation without much idea as to its fitness since it has not been known with certainty whether any considerable degree of polarity is characteristic of this bond. Two common examples of this bond are ammonium chloride and perchloric acid.



[redacted]

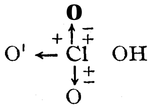
$$\underset{H}{H:N:H}$$

[redacted]



$$\begin{matrix} & & O & & \\ O & : & \ddot{Cl} & : & O:H \\ & & O & & \end{matrix}$$

In the case of the ammonium chloride the identity of the semi-polar bond is completely lost. In the perchloric acid the strength of the acid may be explained by assuming a considerable degree of polarity in the semi-polar bonds thus



Any other explanation of the strength of perchloric acid seems to be barred, since double bonds are out of the question.

It is impossible to determine the dipole moment of the semi-polar bonds in the above-mentioned molecules for obvious reasons. Recently, however, Professor Shriner[1] of this Laboratory has synthesized some organic sulfur compounds which contain semi-polar bonds. Professor Shriner has kindly furnished us with samples of these compounds for measurement of the electrostatic moment. The compounds were diphenyl sulfoxide, diphenyl sulfones and homologs. The electronic structures of the sulfoxide and sulfone arc

$$\underset{O}{:S:}$$

$$\overset{O}{\underset{O}{:\ddot{S}:}}$$

---

[1] Shriner, Struck and Jorison, THIS JOURNAL, 52,2060 (1930).

It is impossible to assign any other electronic structure which seems at all probable. In both compounds the electrons linking the oxygen to the sulfur are both furnished by the oxygen. These compounds are stable and sufficiently soluble in benzene for satisfactory determinations. For purposes of comparison measurements were made upon diphenyl sulfide.[2]

Experimental

The method used to measure the dielectric constants of the liquids under consideration was essentially the same as that developed by Nernst[3] and his students The apparatus consisted of a Type 216 capacity bridge manufactured by the General Radio Company in which capacities as well as resistance are balanced. The bridge consists of two resistance arms, R_1 and R_2, of 5000 ohms each and two capacity arms In one arm of the bridge was placed a balancing condenser, and in the other arm two standard variable air condensers made by the General Radio Company and having capacities of 1500$\mu\mu$ farads. Only one of these was accurately calibrated, the other being used so that there would be a larger capacitance in each arm of the bridge, this giving a sharper minimum point in the phones. Connected in parallel with these two condensers was the comparison condenser (modeled after that of Hartshorn and Oliver)' built of brass plates and mounted in a shielded Pyrex tube with a ground glass top. The capacity of this condenser was 403.1$\mu\mu$ farads. This was measured by submerging the plates in purified benzene, the dielectric constant of which has been accurately determined by Hartshorn and Oliver[4] as 2.282 ± 0.002 at 20". The capacity of this cell was frequently checked throughout the course of the work. All of the work was carried out at 25°.

The entire apparatus was placed on a metal topped table and carefully grounded. All possible precautions were taken to prevent stray capacities The frequency used in measuring the dielectric constant was 1000 cycles, which was produced by a General Radio Audio oscillator Power was brought from the oscillator to the bridge by a pair of twisted wires, heaviiy insulated.

Experimental Procedure

The method of operation was to vary the capacity of the standard condenser and the balancing resistance of the bridge until a sharp minimum was received on the phones. This reading was noted and then the comparison cell containing the binary mixtures under investigation was connected in parallel and readings again were taken. The difference between the two readings represents the capacity of the cell plus the liquid. In filling the comparison condenser, care was taken to prevent the formation of bubbles between the plates by tilting the cell and allowing the liquid to flow slowly down the side of the tube.

It must be noted that the capacity of this cell is made up of two parts, the capacity due to the leads and insulation and the capacity between the plates. In the neighborhood of dilute solutions, when the dielectric con-

---

[2] Since this research was started, Bergmann, Engel and Sandor [Z. *physik. Chem.*, [B] 10, 397 (1930)] have published results for diphenyl sulfide and diphenyl sulfoxide. The agreement between their values and ours is satisfactory.

[3] Nernst, *ibid.*, 14, 622 (1894).

[4] Hartshorn and Oliver, *Proc.* Royal *Soc.* (London), April, 1929

stant is nearly the same as that of benzene, the error due to the leads capacity cancels out, as the capacity of the cell as obtained by us is really that of the cell plus the leads. In the neighborhood of the dilute solution where the highest accuracy is desired, this accuracy is also obtained.

To make certain, however, that this error due to the leads capacity might also be safely neglected in the range of the more concentrated solutions, where we measured dielectric constants in the neighborhood of four, it was decided to check the apparatus by measuring the moment of a compound already known. *p*-Nitrotoluene was selected, having an electric moment of 4.50×10^{-18} e. s. u. as reported by Williams.[5] The value as determined by our method is within the limits of the precision of any method to measure electric moments. The capacity of these leads as calculated from the law of infinite cylinders was $1\mu\mu$ farad, a value small in comparison with the $1000–1500\mu\mu$ farads measured.

The method used to calculate the moment of a molecule was to make a saturated solution of the compound in benzene, the latter being a non-polar solvent. The dielectric constant was measured at each dilution five to seven readings being taken on each dilution and at various balanced capacities to check the readings. Variation here in capacity was as a maximum about $1.5\mu\mu$ farads, although in the diluted solutions the readings checked within $0.5\mu\mu$ farad. This represents an error of approximately 0.15% in the concentrated solutions. Densities were accurately determined by means of a specific gravity bottle, giving values accurate through the fourth decimal place.

The polarization of the solution was calculated by the method pointed out by Debye,[6] using the equation

$$P_{1,2} = P_1f_1 + P_2f_2 = \frac{\epsilon - 1}{\epsilon + 2}\cdot\frac{f_1M_1 + f_2M_2}{\rho}$$

where $P_{1,2}$ is molar polarization of the mixture; P_1, molar polarization of the solvent; P_2, molar polarization of the solute; f_1, mole fraction of the solvent; f_2, mole fraction of the solute; ρ, density of the solution; ϵ, dielectric constant of the solution. The values of P_2 were then obtained by plotting $P_{1,2}$ values as abscissas and F_2 values as ordinates. From this curve P_2 values were calculated, which were then plotted against f_2 and again extrapolated to infinite dilution, giving the value for the polarization of a single molecule between the plates of the condenser.

To obtain the values for the optical polarization (the polarization due to the deformation of the molecule) the individual atomic refractivities were added, proper allowances being made for the different types of linkages. This method was used as the refractive indices of the compounds under investigation have not as yet been determined. The difficulty we

---

[5] Williams, *Chem. Rev.*, **6**, 589 (1929).

[6] Debye, "Polar Molecules," Chemical Catalog Co., Inc., New York, 1929.

encountered in calculating this P_0 (optical polarization) is that no value is known for sulfur in the type of linkage we were interested in. The assumption was made that the values of sulfur from known compounds, e. g., sulfides, disulfides, could be used, where the atomic refractivity has a value of eight. Debye justifies an assumption of this kind, considering the possible precision of the value obtainable for the optical polarization.

From the values of the molar polarization P_2 of the polar molecule itself and the value P_0 for the optical polarization, the electric moment μ can be calculated as Debye shows by

$$\frac{4\pi}{3} N \frac{\mu^2}{3kT}$$

Substituting $N = 6.06 \times 10^{23}$ and $k = 1.372 \times 10^{-16}$, the equation becomes

$$\mu = 0.0127 \times 10^{-18} \sqrt{(P_2 - P_0)T}$$

where T is the absolute temperature.

The values obtained are shown in Table I together with the values for some related compounds which have been determined by other investigations.

Attempts were also made to measure μ for $C_6H_5SO_2CH_2C_6H_5$, and C_6H_5-$CH_2SOC_6H_5$, but their insolubility prevents an accurate determination of their electric moment by this method. All we can say is that they have a high moment, comparable to the simple sulfoxide and sulfone.

Discussion.—The results obtained indicate a surprisingly high value for the dipole moment of the semi-polar bond. This result seems to be established with certainty since the largest errors that may reasonably be assumed would not affect the results seriously. The value of 8.0 that was assumed for the atomic refraction of sulfur is a maximum; the correct value may be less. If this is the case the moments obtained are even larger.

It is to be expected of course that if the molecule has an approximately tetrahedral arrangement, the moment of the sulfone would not be much greater than that of the sulfoxide.

In Table II are given the accepted values for the electrostatic moments[7] of some compounds for comparison purposes. It will be noted that oxygen doubly bound to carbon has a moment much smaller than the semi-polar bond with sulfur.

One might be tempted to assume an even smaller moment for oxygen doubly bound to sulfur. If we assume a linear form for the sulfur dioxide molecule and that it contains one double bond and one semi-polar bond, then the moment of sulfur dioxide is about what would be expected. Great caution must be used, however, in drawing conclusions in this way

THE REACTION BETWEEN NITRITE AND IODIDE AND ITS APPLICATION TO THE IODIMETRIC TITRATION OF THESE ANIONS

BY CARLOS A. ABELEDO AND I. M. KOLTHOFF

RECEIVED MAY 11, 1931 PUBLISHED AUGUST 5, 1931

The reaction between nitrous acid and iodide

$$HNO_2 + I^- + H^+ \longrightarrow H_2O + NO + 1/2\ I_2$$

occurs only in acid medium. In the presence of oxygen the nitric oxide is oxidized to nitrogen dioxide which partly reacts with water, forming nitrous and nitric acid. With regard to the application of the reaction between nitrite and iodide to the iodimetric determination of these components, it was desirable to know at which hydrogen-ion concentration the reaction between the two takes place with a measurable speed. Moreover, it was of importance to study the reaction between iodide, dissolved oxygen and nitric oxide at various PH values.

To 10 ml. of Clark's buffer solutions, known amounts of potassium iodide and sodium nitrite were added and after definite times of standing the iodine was titrated with thiosulfate. Some results obtained at room temperature are given in Table I.

TABLE I

REACTION BETWEEN NITRITE AND IODIDE AT VARIOUS PH

PH of buffer, 10 cc.	Concn. I^- molatity	Concn. NO_2^- molarity	Time of standing, in minutes	0.1 *N* thiosulfate, cc.
3.4	0.2	0.2	5	2
4.0	.2	.2	5	1.5
4.0	.4	.2	5	2.5
5.0	.2	.2	5	0.4
5.0	.4	.2	5	.7

5.0	.2	.2	30	.20
5.6	.4	.2	5	.10
5.6	.4	.2	30	.40
6.0	.4	.2	5	.04
6.0	.4	.2	240	.09
7.0	.4	.2	30	00

From the results in Table I it may be concluded that under practical conditions at a PH larger than six, the reaction between nitrite and iodide takes place with a negligibly slow speed. This is not true for the reaction between nitric oxide, iodide and oxygen. Solutions of nitric oxide in buffers of various *PH* were treated with iodide in the presence of air. Even at a PH of 9.0 a trace of iodine is liberated very quickly; if the latter is titrated after five minutes no further reaction takes place upon standing. The same is true at *PH* values between 6 and 9, and the amounts of iodine liberated are relatively small even at a PH of 6. It should be mentioned, however, that the amount of iodine formed is not only dependent upon the PH, but also on the type of buffer used; in borate buffers more iodine is formed than in phosphate solutions of the same PH. Further studies for a better understanding of the reaction are in progress. Anyhow, the results obtained at PH values between 6 and 9 show definitely that the reaction between nitric oxide, iodide and oxygen at these low acidities cannot be interpreted by the hydrolysis of the oxidation product, nitrogen dioxide, to give nitrite and nitrate, since traces of nitrite do not react with iodide at a PH larger than 6. Therefore, it must be assumed that the nitrogen dioxide formed by the oxidation of nitric oxide reacts with iodide to liberate iodine. Even in stronger acid medium this kind of reaction must take place as it is impossible to interpret the results of the nitrite–iodide reaction on the sole assumption that the nitrogen dioxide formed by oxidation of the nitric oxide hydrolyzes to give nitrous and nitric acids.

For the analytical application of the reaction between nitrite and iodide it is of importance to know under what conditions nitrous acid and nitric oxide can be removed from the solution by addition of urea. In acetic acid medium the reaction is very incomplete even after a long time of standing. The best conditions are obtained if the solution contains at least 0.2 N hydrochloric or sulfuric acid and a large excess (1–2 g. was generally used) of urea. After fifteen minutes' standing no iodine is liberated on addition of potassium iodide.

On the basis of these preliminary experiments procedures were developed for the iodimetric titrations of iodide and nitrite.

Determination of Iodide.—Pure substances were used and the solutions standardized according to reliable methods of volumetric analysis.

Procedure.—Thc iodide solution is introduced into a 250-cc. glass-stoppered Erlenmeyer flask; about 1 *g*. of urea, 5 cc. of 0.5 molar sodium nitrite and 5 cc. of 4 N sulfuric acid are added. The flask is stoppered and allowed to stand with frequent shaking for about ten minutes, thereupon 1–2 g. of potassium iodide is added and the solution titrated with 0.1 N thiosulfate.

Note: 1. The amount of sodium nitrite given in the procedure is satisfactory for the oxidation of 25 cc. of 0.054.2 N iodide. It was found that in the presence of oxygen the nitrite will oxidize twice the theoretical amount of iodide. A large excess of nitrite is not harmful, provided urea has been added.

2. Since part of the nitric oxide formed is present in the gas phase, frequent shaking

is recommended to allow of all this gas reacting with urea. If at the end of the titration the color quickly comes back, the nitrogen oxide was not completely removed and the procedure must be repeated.

3. For the determination of very dilute solutions (25 cc., 0.01 to 0.001 *N*), 0.5 g. of urea, 1 cc. of 0.2 molar nitrite, 5 cc. of chloroform and 5 cc. of 4 *N* sulfuric acid were used and the liberated iodine titrated (after addition of some iodide) after thirty minutes' standing in the stoppered flask. Even in very dilute solutions accurate results are obtained (see Table II). It may be mentioned here that the iodide–nitrous reaction has already been applied by Grange[1] and later by Fresenius[2] to the determination of traces of iodide. The iodine is shaken out in carbon disulfide. Various authors have examined the method, but it cannot be recommended for the determination of traces of iodide, the chief reason being that the excess of nitrous acid or the nitrogen oxide formed interferes more or less. It was found by the present authors that the procedure is improved if the excess of nitrite and the nitrogen oxide formed are removed by urea. The iodine can be shaken out in chloroform, carbon tetrachloride, carbon disulfide, benzene, etc., and no difficulties are encountered.

4. Chlorides do not interfere with the iodide determination. Too high results are found if more than the equivalent amount of bromide is present. Improvement is obtained if the sulfuric acid is added in portions of 1 cc. at five-minute intervals (compare results in Table II).

5. Recently H. Szancer[3] applied the nitrite–iodide reaction to the determination of iodide. After the liberation of the iodine, the acid solution is neutralized with a slight excess of sodium bicarbonate and the iodine titrated with thiosulfate or arsenious-

[3] H. Szancer, *Arch. Pharm.*, 268, 263 (1930).

trioside. Under these conditions the nitrite does not react any more with iodide. However, in the slightly alkaline medium the iodine–thiosulfate reaction gives somewhat erratic results owing to a slight oxidation to sulfate. The results obtained by us with Szancer's method for this reason were 2 to 3% low. Probably the As_2O_3 titration will give better results; we have not tried it. Presence of bromide has the same effect in Szancer's method as in the procedure proposed by the authors.

Some results obtained are reported in Table II. The figures have been recalculated on the basis of a normality of the thiosulfate of exactly 0.1 N (0.01 N and 0.001 *N*, respectively).

Determination of Nitrite.—C. P. sodium nitrite was recrystallized twice from water and dried at 110°. Qualitative tests indicated its purity. The nitrite content was determined gravimetrically by treating with silver bromate and weighing as silver bromide.[4] The results indicated that the sodium nitrite contained 99.9–100.3% $NaNO_2$. Previous authors[5] have made use of the reaction between nitrous acid and iodide for the evaluation of nitrites. B. S. Davisson[6] has tested the various methods, but did not find them very satisfactory. He developed a method giving results accurate to within —1.5 and +2.5%. F. Dienert[7] described another elaborate procedure which, however, is no more accurate than to about 2% for 3 mg. of nitrite nitrogen. No experimental figures are given in his paper.

Proposed Procedure.—Ten to twelve grams of sodium bicarbonate, 3 g. of potassium iodide, 0.5 to 1 cc. of amyl alcohol and 25 cc. of water are introduced into a 250-cc. glass-stoppered Erlenmeyer flask, whereupon a measured volume of the nitrite solution is added. The contents of the flask are well mixed by shaking. After most of the sodium bicarbonate has settled, about 4 cc. of glacial acid is added from a pipet in such a way that the acid is well distributed through the solution, without shaking the flask. The latter is loosely stoppered and after the evolution of the carbon dioxide has nearly ceased gently rotated. After the sodium bicarbonate has settled, 6 to 7 cc. of 20 N sulfuric acid is added quickly without shaking the flask. The latter is loosely stoppered again, and after evolution of most of the carbon dioxide has ceased gently rotated to allow thorough mixing. The stopper is rinsed with water and the solution titrated with standard thiosulfate, using starch as an indicator.

After the end-point has been reached the stoppered flask is allowed to stand for ten minutes. If more than 0.1 to 0.2 cc. of 0.1 N iodine is formed (titration with thiosulfate), the procedure should be repeated.

NOTE: 1. A large excess of bicarbonate has to be used in order to remove all nitric oxide with the carbon dioxide during the reaction between nitrite and iodide. Potassium bicarbonate cannot be substituted for the sodium salt since the former is too easily soluble.

2. Since the presence of oxygen is very harmful during the reaction between iodide and nitrous acid, the air has to be removed from the reaction mixture before the strong acid is added. This is done by the addition of glacial acetic acid. At the low hydrogen-ion concentration in the acetate buffer formed no, or a very slight, reaction between nitrite and iodide takes place.

3. The addition of amyl alcohol is not essential, but is strongly recommended as it prevents overfoaming of the liquid during the evolution of carbon dioxide.

[7] F. Dienert, *Ann. chim. anal. chim. appl.*, [2] **1**, 4 (1919).

4. If the air is not removed completely the blue color returns after the end-point has been reached. To test the reliability of the result it is necessary to titrate the liquid ten to fifteen minutes after having reached the end-point. If more than **0.1** to 0.2 cc. of thiosulfate is then used, the result should not be accepted and the determination should be repeated.

5. Very dilute nitrite solutions can be titrated according to the recommended procedure. The accuracy is about 0.5%. (See Table III.)

6. Good results are obtained in the presence of no more than 2–3% of ethyl alcohol and of amyl alcohol. Therefore the procedure seems well adapted for the determination of nitrites in the presence of these organic substances (e. g., in amyl nitrite, spirit of ethyl nitrite U. S. P.) where the permanganate method cannot be applied.

Summary

The reaction between iodide and nitrite and nitric oxide, respectively, has been investigated at various PH values.

The optimum condition for the reaction between urea and nitrite and nitric oxide, respectively, has been determined.

Applications have been made to the iodimetric determination of iodide and nitrite, respectively. The Fresenius method for the determination of iodides has been improved.

The procedure described for the determination of nitrite can also be used in the presence of alcohols.

THE EMULSIFYING PROPERTIES OF GELATIN SYSTEMS

BY LEO FRIEDMAN AND DONALD N. EVANS

RECEIVED MAY 11, 1931 PUBLISHED AUGUST 5, 1931

That gelatin will act as an emulsifying agent is generally known, but extensive investigations of this property of gelatin have been very few. Holmes and Child,[1] in the study of emulsifying properties of gelatin, found that the maximum lowering of surface tension should be secured; that an excess of strong acids, bases or liquefying salt should not be added; and that the viscosity should not be greatly increased above that of water in order to obtain good emulsions. Working with kerosene–water emulsions, they did not find any convincing evidence that gelatin particles were withdrawn from the solutions to form adhesion layers about the oil droplets. Their conclusion was that the leading factor in an oil–water emulsion with the aid of gelatin is viscosity, not maximum, but the most favorable viscosity.

In this investigation it was desired to determine (a) how the emulsifying properties vary with the gelatin content, (b) the effect of PH on the emulsifying properties of gelatin, and (c) the extent of the adsorption of gelatin in the interface of the emulsion.

Experimental Procedure

The gelatin used (U. S Gelatin Company) was purified by first soaking in 1/128 molar acetic acid, then in distilled water, and finally electrodialyzing until a minimum current flowed. The solutions were made more acid or basic as required with hydrochloric acid or sodium hydroxide. The PH of the resulting solutions was measured electrometrically.

Emulsions were made with 5 cc. of the gelatin solution and 10 cc. of the immiscible liquid in a test-tube. Tubes with a diameter of 2 cm. were used for the study of the influence of *PH*, whereas tubes with a diameter of 3.5 cm. were used in the study of the influence of concentration of the gelatin. Because of the influence of the vessel on the emulsion process, this accounts for the fact that values from Table I do not coincide with those given in Table II. The tubes were stoppered and placed in a shaking machine for one hour, at the end of which time they were removed, given 100 shakes by hand, and set aside. Readings were taken from time to time showing the amount of stable emulsion remaining.

Experimental Results

Effect of Concentration of Gelatin.—The concentrations of the gelatin used varied from 0.25 to 1.5%. Experiments were carried out by mixing these gelatin solutions with eight different liquids in the manner described above. These liquids were ethyl acetate, n-butyl alcohol, ether, benzene, nitrobenzene, chloroform, carbon tetrachloride and cottonseed oil. The first three did not form emulsions.

Emulsions were also made using gelatin adjusted to PH 3, and to PH 6

Effect of P_H.—The results obtained for the influence of P_H on the emulsifying properties of gelatin are given in Table II. It is to be noted that practically all the experiments show a good stability near the P_H of the dialyzed gelatin, with a minimum and a maximum on each side. Near a P_H of 1 or of 12 there is a second drop in emulsifying properties and beyond this the gelatin loses its emulsifying properties. This effect is not shown in all of the experiments but is shown for at least one concentration of gelatin with each substance.

Cottonseed oil did not give a good emulsion in the 0.5% solutions, even with the most basic solution. In the 1% solution the emulsions were poorest at the most acid and the best at the most basic points.

The Adsorption of Gelatin at the Interface.—In order to determine the extent of adsorption of gelatin at the interface of the emulsions, analyses of the aqueous phase before emulsification were compared with analyses of the first few cc. of aqueous phase that separated from the emulsion as it started to break down. The micro-Kjeldahl method for nitrogen in proteins was used to determine the gelatin content. The results are shown in Table III. It is to be observed that gelatin had been removed from the aqueous phase and concentrated at the interface in the emulsions of carbon tetrachloride, chloroform and benzene with gelatin solutions at P_H 4.72. These emulsions were stable at the end of one hour after shaking. The chloroform emulsion with gelatin solution at P_H 8.13, and the carbon tetrachloride emulsion with gelatin solution at P_H 2.25 were not stable, and Table III shows that there was no adsorption of gelatin at the interface of these emulsions. Apparently gelatin will serve as an emulsifying agent only when conditions are such as favor adsorption at the interface.

TABLE III

Original	2.25	..	.8803	..
From carbon tetrachloride	2.25	0.5	.9058	−2.8

Discussion of Results

In the use of gelatin as an emulsifying agent for oil–water systems, it was found that the concentration of the gelatin between 0.25 and 1.5% at P_H 3, 4.7 and 6 was of little influence on the stability of the emulsion. The outstanding exception to this generalization was found in the case of

0.25% gelatin at PH 3, where the stability of four of the five emulsions was greatly decreased.

Examination of Table II showing the influence of PH on emulsifying properties of gelatin solutions shows that if PH of the gelatin solution is near the isoelectric point stable emulsions are formed. Addition of acid results in less stable emulsions at PH of about 3, another point of increased stability near 2.5 with a sharp drop when the PH is further decreased. Addition of alkali results in a sharp decrease in stability near PH of 6 with a maximum near PH of 10, and another decrease when PH rises above 11.

The factors which are generally considered important in the process of emulsification are: (1) mechanical treatment, (2) volume composition, (3) relative densities, (4) character of the walls of the container, (5) viscosity of the components and (6) the interfacial tension. In the experiments carried out the first four of these were kept as constant as possible, so that differences in stability of emulsions formed were probably due to changes in viscosity and interfacial tension. That such is the case can be seen from a comparison of the results obtained with curves showing the relation between viscosity of gelatin solutions and PH[2] and surface tension vs. PH.[3]

It is not to be expected that the maximum and minimum stabilities for one combination should exactly coincide with any other, for the nature of the interface is different in each case.

Summary

1. The emulsifying properties of gelatin for oil--water emulsions have been studied with reference to concentration of gelatin, PH of gelatin solution, and the possible adsorption of gelatin at the interface.

2. It has been found that variation of concentration between 0.25 and 1.5% has little effect at PH 3, 4.7, 6.

3. Changing the PH of the gelatin solution affects the emulsifying properties of the gelatin in a manner closely related to the changes of surface tension and viscosity of gelatin solutions with PH.

4. It has been found that whenever stable emulsions were formed, gelatin was concentrated at the interface.

DIPHENYLAMINE SULFONIC ACID AS A NEW OXIDATION–REDUCTION INDICATOR

BY L. A. SARVER AND I. M. KOLTHOFF

RECEIVED MAY 12, 1931 PUBLISHED AUGUST 5, 1931

Introduction

It was shown in a recent paper[1] that the first product of the oxidation of diphenylamine is the very insoluble white diphenylbenzidine, and that all but a trace of the indicator precipitates out with the completion of this stage of the reaction. The precipitate remains suspended in a finely divided condition, however, and is oxidized somewhat slowly by excess oxidant to the highly colored holoquinoid compound, diphenylbenzidine violet; but when the attempt is made to start with a solution of diphenylbenzidine, instead of producing it by the oxidation of diphenylamine, practically all of the indicator precipitates and settles out in large flocks. This suspension yields the violet color only after contact with a considerable excess of oxidant for several minutes. Therefore, while diphenylbenzidine is very satisfactory for reverse titrations, it does not work so well in direct titrations.

Furthermore, diphenylbenzidine violet reacts quickly with any unchanged diphenylbenzidine to form the very insoluble greenish-black meriquinoid compound, diphenylbenzidine green, which under certain circumstances imparts a muddy appearance to the solution, due to a mixture of considerable white and greenish-black precipitate with the violet solution. In addition, neither diphenylamine nor diphenylbenzidine give their color changes in the presence of even traces of tungstate,[2] a property which greatly limits their usefulness in the analysis of alloy steels. The present authors have ascertained that tungstate forms blue insoluble compounds with the colored oxidation products of diphenylamine, thus removing them from the solution. Hence, it was thought that some of the objectionable features might be corrected by introducing a strongly polar group like —SO_3H into the molecule, thereby increasing its solubility and that of its oxidation products.

I. Preparation of Barium Diphenylamine **Sulfonate.**—Equimolecular quantities of diphenylamine and acetic anhydride were treated with a few cubic centimeters of concentrated sulfuric acid and refluxed for one hour, after which the excess acetic acid was removed by washing with cold water and the acetyldiphenylamine recrystallized from ether and dried at 100°.[3] Then 200 g. of 20% fuming sulfuric acid was cooled to 5°, and

[3] A. Claus, *Ber.*, 14, 2365 (1881).

100 g. of the pulverized acetyldiphenylamine added in small portions, with constant stirring. The mixture was warmed to 45° on a water-bath for two hours, with continued stirring, then poured into 250 cc. of water and boiled for three hours to hydrolyze the acetyl compound, after which it was poured into a large volume of water and the unchanged diphenylamine filtered off. The filtrate was neutralized with barium carbonate, the barium sulfate filtered off[4] and the white barium diphenylamine sulfonate removed from barium acetate by fractional crystallization. The barium salt of diphenylamine sulfonic acid is sufficiently soluble for the preparation of indicator solutions, and has been used for subsequent work.

An analysis of the salt showed 21.88% barium, whereas the theoretical value for the anhydrous salt of the monosulfonic acid is 21.64%. Being primarily interested in the purity of the product, no attempt was made to secure a quantitative yield, though it may be mentioned that Gnehm and Werdenburg[4] obtained 80% of the theoretical amount of the monosulfonic acid, with 17% of the diphenylamine recovered unchanged.

II. Indicator Properties.—All the experimental evidence confirms the assumption that the mechanism of the oxidation of diphenylamine sulfonic acid is similar to that of diphenylamine; that it is first oxidized to diphenylbenzidine sulfonic acid, and then to diphenylbenzidine sulfonic acid violet, which forms a meriquinoid compound, diphenylbenzidine sulfonic acid green, with unoxidized diphenylbenzidine sulfonic acid.

Potentiometric titrations of diphenylamine sulfonic acid with potassium dichromate (similar to those of diphenylamine and diphenylbenzidine described in a previous paper[1]) were not very satisfactory from the stoichiometric point of view; nevertheless, it has been possible to determine the potential at which the color change takes place. Since the oxidation by dichromate is very slow in the absence of ferrous iron, it was more advantageous to add an excess of the dichromate to the acidified solution of diphenylamine sulfonic acid, and then titrate back with ferrous solution. For the details of the performance of these experiments the reader is referred to the previous paper. Further addition of ferrous solution after the reduction of the reddish-violet to diphenylbenzidine sulfonic acid green changes the color to a pale yellow, whereas diphenylbenzidine green was not affected by an excess of ferrous ions. The color change green to reddish-violet, and the reverse, takes place at a potential of about 0.59–0.60 v. (against the saturated calomel electrode, or 0.83–0.84 v., against the normal hydrogen electrode) in sulfuric acid solutions between 0.5 and 2.0 normal, whereas the color change for diphenylbenzidine occurs at about 0.51 v. (against the saturated calomel electrode, or 0.76 v., against the normal hydrogen electrode) under the same conditions. This difference of

[4] R. Gnehm and H. Werdenburg, Z. *angew. Chem*, **43**, 1027 (1899); V. Merz and W. Weith, *Ber.*, 5, *283* (1872), communicated by O. Meister.

oxidation potential was confirmed by the following experiment. A portion of a ferrous solution in normal sulfuric acid, but without any phosphoric acid, was titrated potentiometrically in one case, 20.23 cc. of 0.1 N dichromate being required; a similar sample showed a faint trace of color with 20.20 cc., and a good color with 20.25 cc., when diphenylamine sulfonic acid was used as indicator; but when diphenylamine was used as indicator in another similar sample, a muddy green precipitate appeared when about 19.00 cc. had been added, with more and more violet from 19.50 cc. on.

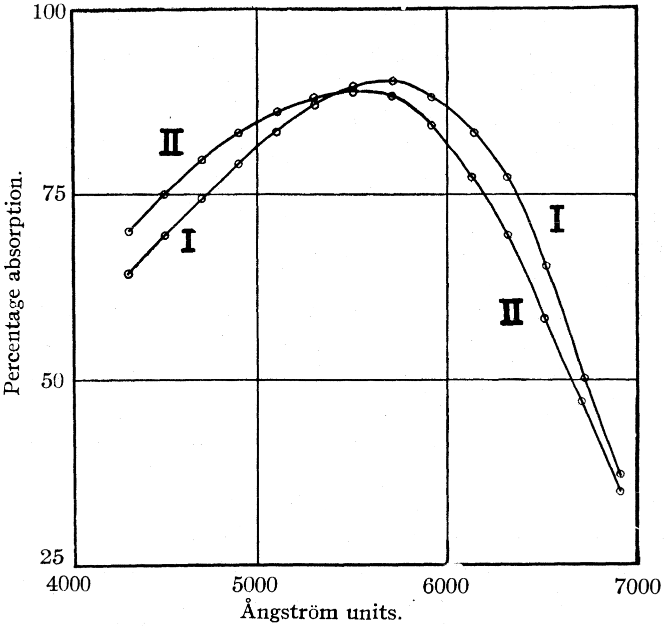

Fig. 1.—Absorption spectra of diphenylbenzidine violet and diphenylbenzidine sulfonic acid violet. I, diphenylbenzidine violet; II, diphenylbenzidine sulfonic acid violet.

The diphenylbenzidine sulfonic acid violet has a reddish-violet color resembling that of a dilute permanganate solution, and its absorption spectrum in the visible region resembles that of diphenylbenzidine violet (cf. Fig. 1), except that the former absorbs more in the red.

The speed of formation of the diphenylbenzidine sulfonic acid violet depends upon the oxidation potential of the solution, as is the case with diphenylamine and diphenylbenzidine. With permanganate or vanadate an acidified solution of the diphenylamine sulfonic acid is colored almost instantly; but with dichromate the coloration is very slow, even at high hydrogen-ion concentrations and with a relatively large excess of oxidant;

with this reagent the speed of oxidation is much less than in the case of diphenylamine or diphenylbenzidine. The presence of ferrous iron (see also the previous paper[1]) accelerates the oxidation of diphenylamine sulfonic acid tremendously; for example, with 0.1 cc. of 0.005 M indicator and 0.2 cc. of 0.01 N dichromate in 50 cc. of 2 N hydrochloric acid the violet color appeared within fifteen to twenty seconds in the case of diphenylaniine, and after two to three minutes in the case of diphenylamine sulfonic acid; but if 0.2 cc. of 0.01 *N* ferrous solution are first added to the acid solution of the latter indicator, and then 0.4 cc. of 0.01 N dichromate, the color appears after about one second with diphenylamine, and instantly with diphenylamine sulfonic acid.

The color change in the titration of ferrous iron by dichromate is very brilliant and sharply reversible; indeed, the coloring power of the substance is so great that titrations may be made in highly colored solutions where diphenylamine and diphenylbenzidine are not satisfactory. The presence of mercuric chloride has no influence upon the speed of formation of the reddish-violet oxidation product, whereas it retards the oxidation of diphenylamine and diphenylbenzidine very markedly. Finally—and this is the main advantage of the new indicator—its indicator properties are not affected by the presence of tungstate, whereas diphenylamine and diphenylbenzidine are useless in the presence of even traces of this substance.

The indicator corrections for diphenylamine, diphenylbenzidine and diphenylamine sulfonic acid in dilute solutions will be considered in a future paper.

Summary

Diphenylamine sulfonic acid has indicator properties similar to those of diphenylamine, but its color change is more sharp and brilliant. It can be used in the presence of tungstate, whereas diphenylarnine and diphenylbenzidine cannot. Ferrous iron has an enormous accelerating effect upon the speed of its oxidation, while mercuric chloride has no harmful effect. The absorption spectrum has been determined, and the electrochemical properties investigated.

INDICATOR CORRECTIONS FOR DIPHENYLAMINE, DIPHENYLBENZIDINE AND DIPHENYLAMINE SULFONIC ACID

BY L. A. SARVER AND I. M. KOLTHOFF

RECEIVED MAY 12, 1931 PUBLISHED AUGUST 5, 1931

Introduction

The reaction mechanisms of the oxidation of diphenylamine, diphenylbenzidine and diphenylamine sulfonic acid have been discussed in previous papers,[1] and it may be predicted from these that in the titration of reducing agents with potassium dichromate, diphenylbenzidine will require a negligible correction, whereas diphenylamine or diphenylamine sulfonic acid ought to consume an equivalent amount of reagent for their oxidation to the diphenylbenzidine state. In the titration of oxidizing agents with ferrous iron, however, it is hard to predict the size of the corrections, because of the instability of the colored holoquinoid compounds. Therefore an extensive study has been made of the analytical conditions and indicator corrections necessary for diphenylamine, diphenylbenzidine and diphenylamine sulfonic acid in the various titrations.

I. Indicator Solutions.—Each indicator was made up so as to be 0.005 molar (1.69 g. of diphenylamine per liter of concentrated sulfuric acid; 1.68 g. of diphenylbenzidine per liter of nine parts glacial acetic acid and one part concentrated sulfuric acid; 3.17 g. of anhydrous barium salt of diphenylamine sulfonic acid per liter of water), and to require theoretically an equal volume of 0.01 N oxidizing or reducing solution for each stage of the oxidation of the indicator.

II. Standard Solutions.—The dichromate solution was prepared by dissolving a given weight of pure potassium dichromate in water, and making up to a known volume. The ferrous and vanadate solutions were then standardized potentiometrically.

III. Titration of Ferrous Iron with Potassium Dichromate. 1. Recommended Conditions.—The solutions should be about 1.0 N with sulfuric or hydrochloric acid (the former being somewhat preferable), but they may vary between 0.5–2.0 N when diphenylamine or diphenylbenzidine is used as indicator, or between 0.25–3.0 N when diphenylamine sulfonic acid is used. About 10 cc. of 25% phosphoric acid should be present for each 50 cc. of volume, but considerable variation is permissible. Mercuric chloride renders color development slower with diphenylamine or diphenylbenzidine, but does not otherwise affect the accuracy of the titration; it has no appreciable effect upon the behavior of diphenylamine sul-

---

[1] I. M. Kolthoff and L. A. Sarver, THIS JOURNAL, 52, 4179 (1930); L. A. Sarver and I. M. Kolthoff, *ibid.*, 53, 2902 (1931).

fonic acid. In those cases where color development is slow, the oxidation of the indicator can be speeded up by warming to 50°, but the colors are then less permanent; diphenylbenzidine is generally less satisfactory than the other two for titrations of ferrous iron by dichromate, on account of the slowness of color development. No unnecessary excess of stannous chloride should be used in the reduction of the iron, because of the large amount of mercurous chloride precipitate obtained later. Stannic and manganous salts have no effect upon any of the three indicators, but only diphenylamine sulfonic acid can be used in presence of tungstate. Titrations can be made with 0.1, 0.01 or 0.001 N dichromate, but diphenylbenzidine is not recommended for the weaker solutions. Diphenylamine sulfonic acid is recommended for the micro-titration of ferrous iron, it being possible to determine 0.5 mg. of iron in a small volume within an accuracy of 1%. Especially when titrating with the weaker solutions, the volumes should not greatly exceed 50 cc., although they may be 100–250 *cc.* for 0.1 N dichromate.

2. Recommended Amounts of Indicators.—For titrations with 0.1 N dichromate in 100–250 cc. volumes, 5–6 drops of 0.005 molar indicator (7–10 drops of 0.1% diphenylamine or diphenylbenzidine or of 0.2% diphenylamine sulfonic acid barium salt) should be used. With 0.01 or 0.001 N dichromate in 10–50 cc. volumes, 0.02–0.05 cc. of 0.005 molar diphenylamine or diphenylamine sulfonic acid (0.03–0.06 cc. of 0.1% diphenylamine or 0.2% diphenylamine sulfonic acid barium salt) will give sharp distinct color changes.

3. Indicator Corrections.—Indicator corrections for titrations with 0.01 and 0.001*N* dichromate solutions, respectively, are given in Table I. It is seen that the excess of dichromate required for obtaining an end-point increases with increasing amounts of indicator; with diphenylamine, the corrections were found to be approximately the theoretical for amounts up to 0.3 cc. of 0.005 molar indicator, and 0.1 cc. of 0.01 *N* dichromate (or 1.0 cc. of 0.001 N dichromate) should be deducted for each 0.1 cc. of

TABLE I

INDICATOR CORRECTIONS FOR TITRATIONS OF FERROUS IRON WITH **0.01** OR **0.001** *N* POTASSIUM DICHROMATE SOLUTION

For each titration, 10 cc. of 0.01 or 0.001 N ferrous solution was added to a mixture of 10 cc. of 25% phosphoric acid, 1.2 cc. of concentrated sulfuric acid, 15 cc. of water and the stated volume of indicator.

Volume of 0.005 *M* indicator, cc.	Diphenylamine Excess of $K_2Cr_2O_7$ required, cc. 0.01 N	Diphenylamine Excess of $K_2Cr_2O_7$ required, cc. 0.001 *N*	Diphenylamine sulfonic acid Excess of $K_2Cr_2O_7$ required, cc. 001 N	Diphenylamine sulfonic acid Excess of $K_2Cr_2O_7$ required, cc. 0 001 *N*
0.02	0.01	0.21	0.02	0.21
.04	.04	.41	.05	.44
.10	.10	.95	.18	.93
.20	.21	1.90	.34	1.85
.30	.39	..	.51	3.48
.50	.63	..	0.75–0.90	..

indicator used (0.06 cc. and 0.6 cc., respectively, for each 0.1 cc. of 0.1% diphenylamine). With larger amounts of indicator, the presence of much diphenylbenzidine green interferes with the observation of the color. With diphenylamine sulfonic acid also, the corrections (expressed in terms of 0.01 N oxidizing solution) were found to be equal to the volume of 0.005 molar indicator (0.06 cc. of 0.01 *N* solution for each 0.1 cc. of 0.2% diphenylamine sulfonic acid barium salt) when less than 0.3 cc. was used and the titration made with 0.001 N dichromate solution; but when the titrations were made with 0.01 *N* dichromate solution, the corrections were somewhat larger than the theoretical.

IV. Titration of Dichromate or Vanadate Solutions with Ferrous Iron.—The same considerations as to titration volume, quantity of indicator and concentrations of phosphoric acid and sulfuric or hydrochloric acid, apply to the titration of 0.01 *N* dichromate or vanadate by 0.01 N ferrous iron. The presence of sodium acetate in the vanadate titration, as recommended by Willard and Young,[2] does not seem to be necessary, although the neutralization of the strong mineral acid does take away a disturbing color when much ferric iron is present. The violet color develops very slowly in acid dichromate solutions, especially when diphenylamine sulfonic acid is used as indicator, but a brilliant color appears instantly when the titration with ferrous iron is begun. In an acid vanadate solution the color develops rapidly without the addition of ferrous iron, so the titration can be started almost immediately after the addition of any of the three indicators.

TABLE II

INDICATOR CORRECTIONS FOR TITRATIONS OF DICHROMATE OR VANADATE SOLUTIONS WITH 0.01 N FERROUS IRON SOLUTION

For each titration, 10 cc. of 0.01 N dichromate or vanadate solution was added to a mixture of 10 cc. of 25% phosphoric acid, 1.2 cc. of concentrated sulfuric acid, 15 cc of water and the stated volume of indicator; the whole was then titrated at once with 0 01 *N* ferrous solution. The volumes given below should be added to the volume of 0.01 N ferrous solution used in any given titration.

Volume of 0 005 *M* indicator, cc.	Diphenylamine		Diphenylbenzidine		Diphenylamine sulfonic acid	
	Dichromate, cc.	Vanadate, cc.	Dichromate, cc.	Vanadate, cc.	Dichromate, cc.	Vanadate, cc.
0.02	0 04	0 03	0.02	0.03	0 05	0.03
.04			04	05	.13	.12
.10	.24	20	.10	.11	.31	.30
.20	..	.40	.17	.20	.58	.60
.30	.63	.63	.24	.29	.95	.95
50	..	..	.36		..	..

From the data in Table II it is seen that the indicator corrections are approximately the same in the dichromate and the vanadate titrations. If the titration is started immediately after the addition of the indicator

---

[2] H. H. Willard and Philena Young, *Ind. Eng. Chem.*, 20, 764 (1928).

0.1 cc. should be added to the volume of 0.01 *N* ferrous solution required for each 0.1 cc. of 0.005 *M* diphenylbenzidine (0.06 cc. for each 0.1 cc. of 0.1% diphenylbenzidine), 0.2 cc. for each 0.1 cc. of 0.005 *M* diphenylamine (0.12 cc. for each 0.1 cc. of 0.1% diphenylamine) and 0.3 cc. for each 0.1 cc. of 0.005 M diphenylamine sulfonic acid (0.18 cc. for each 0.1 cc. of 0.2% diphenylamine sulfonic acid barium salt). The correction is smaller for diphenylbenzidine than for diphenylamine, as could be expected. Diphenylamine sulfonic acid has the largest correction, but it is still recommended because it gives a sharp, brilliant color change, and can be used in the presence of tungstate. If the titration is not started immediately after the addition of the indicator, the corrections will be larger, on account of the decomposition of the holoquinoid compounds. This increase in the correction with time is negligible in the case of diphenylbenzidine when the titration is completed within fifteen minutes after the addition of the indicator, but it is appreciable in the case of diphenylamine sulfonic acid. For example, when a mixture of 10 cc. of 0.01 N vanadate solution, 10 cc. of 25% phosphoric acid, 1.2 cc. of concentrated sulfuric acid, 15 cc. of water and 0.2 cc. of 0.005 *M* diphenylamine sulfonic acid, was titrated with 0.01 N ferrous solution as quickly as possible, the correction was 0.55 cc. of 0.01 *N* solution; but after five, ten, fifteen and thirty minutes' standing, the corrections were 0.62, 0.68, 0.74 and 0.76 cc., respectively.

Summary

Analytical conditions (acidity, volume, amount of indicator, etc.) and indicator corrections have been given for the titration of 0.1, 0.01 and 0.001 N ferrous solutions with 0.1, 0.01 and 0.001 N potassium dichromate solutions, respectively, as well as similar information on the titration of 0.01 N dichromate or vanadate solutions with 0.01 N ferrous iron solution, using diphenylamine, diphenylbenzidine and diphenylamine sulfonic acid as indicators. Diphenylamine sulfonic acid is recommended because of its rapid brilliant completely reversible color changes, and its usefulness in the presence of tungstate.

THE KINETICS OF GAS EXPLOSIONS: THE THERMAL DECOMPOSITION OF OZONE SENSITIZED BY BROMINE VAPOR[1]

BY BERNARD LEWIS[2] AND W. FEITKNECHT[3]

RECEIVED MAY 12, 1931 PUBLISHED AUGUST 5, 1931

The kinetics of the thermal reaction between ozone and bromine below 13° was studied by Lewis and Schumacher.[4] It was found that bromine reacts with ozone quantitatively, forming a white crystalline oxide of bromine having the composition Br_3O_8 which is slowly deposited on the walls of the vessel. Following the complete disappearance of free bromine, the ozone decomposes into oxygen at a constant rate which is independent of the size and the kind of reaction vessel, ozone concentration (above a certain limit) and inert gases, but which depends on the quantity of oxide formed and on the temperature. Thus it was found that the rate of decomposition of ozone is directly proportional to the original concentration of bromine, namely

$$+\frac{dp}{dt} = k[Br_2]$$

and that the temperature coefficient has a value of **3.15** for 10° between 0 and 10°.

These investigators observed that if the temperature is raised to 20° no oxide of bromine is deposited. Instead there is a period of quiescence (lag period) during which no change in pressure occurs, followed by a sudden explosion which is accompanied with the evolution of light. This phenomenon, which involves only the decomposition of ozone into oxygen in the presence of the catalyst bromine, seemed to present a medium by which some light might be thrown on the concept of chain reactions.

The experiments in the transition range between temperatures at which solid oxide is formed and explosions occur are described elsewhere.[5] They are interpreted on the basis of the formation of an unstable adsorption compound of bromine and ozone at the wall which becomes increasingly more stable with decreasing temperature. The unstable compound, on decomposing, forms an active product which is ejected into the gas phase and starts reaction chains. By lowering the temperature the product of

this decomposition becomes less active as far as its ability to start reaction chains is concerned. This is shown by the gradually changing character of the reaction from a predominantly gas phase to a wall reaction.

Preliminary Experiments

In some early experiments, on mixing ozone and bromine in certain proportions, we were struck by the remarkably long lag periods which preceded explosions. Their duration was, in some instances, as long as one hour. The time was not easily reproducible.

It was soon discovered that these exceptionally long lag periods were caused by arsenous bromide. Due to the nature of the experimental technique, which involved repeated evaporation and freezing out of bromine on one side of a brass needle valve, arsenic in the latter was attacked and accumulated in the bromine reservoir as a white crystalline arsenous bromide ($AsBr_3$, melting point 31°). This compound was carried with the bromine into the reaction vessel and was adsorbed on the walls. Upon replacing the brass needle valve by a specially constructed stainless-steel diaphragm valve, the arsenic compound was eliminated completely and the lag periods were shortened to the order of one minute.

The length of the lag period is influenced by such factors as the ozone and bromine concentrations, the temperature and the activity of the vessel. As far as the lag period was concerned it made considerable difference whether ozone or bromine was admitted to the reaction vessel first. The lag times were shortened from minutes for the order bromine + ozone to several seconds for the order ozone + bromine.

The pressure of ozone just necessary to develop an explosion will be used as a measure of the explosion limit.[6] It was found to be influenced principally by temperature and the presence of inert gases. Moreover, the slow decomposition (in the event that the ozone pressure was below the explosion limit) was similarly affected.

These experiments led us to the belief that the wall of the vessel is of considerable importance for the development of explosions in this reaction, namely, that it is the seat of the initiation of chain reactions. Other investigators working with quite different systems have recently arrived at the same conclusion.[7,8]

---

[6] The term explosion limit in a two-component system at a definite total pressure. say atmospheric, is usually applied to the percentage combustible necessary to develop an explosion. In a one-component system, as in the present case, pressure is used as a measure of the explosion limit

Apparatus

The apparatus used in this investigation was described in its essential details in an earlier work.[4b] Certain additional features will be mentioned. In order to obtain pure and stable ozone, all greased stopcocks had to be eliminated and metal needle valves used in their stead. The needle valves used here are similar to those used previously with a slight modification to prevent the needle from sticking in the seat of the valve. The cone of the needle was made of a specially hard non-corrosive chrome–nickel–vanadium–tungsten steel. A stainless-steel diaphragm valve separated the bromine reservoir from the rest of the apparatus. It is similar in principle to that of Bodenstein and Dux,[9] but its principal parts consist of only two pieces, thus limiting the number of soldered joints to one. This joint is on the outside of the lapped-over rim of the diaphragm. The chief advantages of the valve are its simplicity of construction and freedom of exposure of corrosive gases to soldered joints.

The manometer system consisted of a Bodenstein quartz spiral manometer as a null instrument, backed by a mercury manometer and bromonaphthalene manometer (1 mm. Hg = 9.15 mm. bromonaphthalene). By means of a graduated scale in the telescope used for observing movements of the quartz spiral manometer pointer, a change of 0.02 mm. of mercury was observable.

Inert gases were stored in liter flasks. Before being used they were passed very slowly through a liquid-air trap (ether–carbon dioxide mixture for carbon dioxide gas) and a fine porous-plate Pyrex glass filter sealed into the Pyrex tubing to remove any possible suspended material. The filter is similar to the Jena porous-plate filter but is not obtainable commercially in Pyrex glass. Since the Jena filter could not be sealed into Pyrex tubing, a simple method[10] of making them of Pyrex glass was developed by one of us (B. L.) and they have been in use in this Laboratory for a year and a half with excellent results.

The reaction vessels used were two Pyrex glass bulbs (hereafter called vessels I and II) and a quartz bulb, each of 250 cc. capacity, and a number of cylindrical Pyrex glass tubes of various diameters. The experiments were conducted in a temperature-controlled water-bath. The reaction vessel was protected from light exposure.

Materials

The purest Kahlbaum bromine was used. It was distilled at a low temperature under high vacuum through anhydrous magnesium perchlorate and a Pyrex glass porous-plate filter directly into the bromine reservoir and sealed under vacuum.

---

[9] Bodenstein and Dux, Z. *physik. Chem.*, 85,297 (1913).

[10] Recently a similar filter and method was described by W. F. Bruce and H. E. Bent, THIS JOURNAL, 53, 990 (1931). Scrap Pyrex glass is ground to a fine powder. For a moderate-size grained filter, glass which passes a 60 mesh but not an 80 mesh sieve may be used. For finer filters, small particles should be ground to pass an 80 but not a 100 mesh sieve, etc. A layer of glass about 1.5 mm. deep is placed in a cylindrical mold such as described by Bruce and Bent or a mold made of platinum foil bent into shape as was used here. The procedure which was found satisfactory is to place the mold in a furnace at 890°. It is removed after twenty seconds and allowed to cool, after which the disk of glass separates easily from the mold. The disk is then placed on a small nickel or iron plate and once again heated in the furnace for forty seconds. The times will vary depending on the kind and size of mold. The technique is soon acquired after a little experimentation. The disk is smoothed with a file, placed in a tapered glass tube of the proper size and sealed in with a fine flame in the usual manner. Filters from 1 to 2.5 cm. in diameter have been made in this way.

Ozone was made and concentrated by the method of Riesenfeld and Schwab.[11] Pure dry electrolytic oxygen was passed through a Pyrex glass filter and a Siemens ozonizer into an evacuated flask containing a liquid-air trap. The oxygen in the mixture of liquid oxygen and ozone was pumped off and the ozone which remained had a purity of 99 to 100%. This was tested by noting the increase in pressure on exploding some of the pure ozone. The ozone was very stable in the temperature range of these experiments. At ordinary temperatures no increase in pressure could be observed over a period of several hours.

The inert gases used, namely, oxygen, nitrogen, helium, argon and carbon dioxide, were the purest obtainable in tanks. The helium and argon contained a little nitrogen and were 97% and 95.5% pure, respectively. Carbon dioxide was condensed in liquid air and the non-condensable gases were pumped off. It was then stored in the gas form.

Experimental Procedure

The principle of the measurements was to admit bromine and ozone separately into the reaction vessel at a definite temperature and to measure the increase in pressure with time caused by the reaction $2O_3 = 3O_2$. During the reaction the pressure of bromine remains unchanged. Before starting an experiment, all the ozone was allowed to evaporate in its reservoir and was then very carefully admitted to the reaction vessel by cracking the needle valve.[12] Unless otherwise stated, the order of entering the reaction vessel was bromine, inert gas (when used), ozone. Occasionally bromine was added last. The ozone was admitted rather rapidly and the time was taken when 10% was already in the vessel. When not in use both the ozone and bromine were maintained in liquid air in their respective reservoirs. Before each experiment the reaction vessel and also the ozone reservoir were pumped out with a diffusion pump to about 10^{-5} mm. For reasons which will become apparent later most experiments were conducted with 5 mm. of bromine.

In order to show the characteristic way in which bromine sensitizes the decomposition of ozone a number of experiments at 35° are plotted in Fig. 1 for different initial ozone pressures for the first three minutes of reaction. The experiments were made in the quartz vessel.

At low pressures of ozone the reaction commences slowly after the lag period. It then accelerates, goes through a maximum, after which it slows down. The form of the curve cannot be represented by a simple relationship. At higher ozone pressures the velocity is correspondingly greater. Above a definite pressure, in this case 32 mm. of ozone, the velocity rises so rapidly that an explosion results. Thirty-two mm. of ozone is therefore the explosion limit for these conditions. The curve for 30 mm. illustrates a mixture on the verge of explosion, the drop in pressure after the sudden rise being due to the dissipation of heat. The curve for 34 mm. represents an explosion. It will be observed that the lag period varies

---

[11] Riesenfeld and Schwab, *Ber.*, 55, 2088 (1922).

[12] Violent explosions take place if the needle valve is opened suddenly and too wide.

inversely as the ozone pressure and the rate of decomposition increases with the initial ozone concentration.

Activity of Vessel

Whilst the lag period, limit of explosion and rate of the slow reaction could vary in a given vessel to a considerable degree, they proved to be related to each other, namely, a short lag period corresponds to a low explosion limit and a high reaction rate.[13] It will be evident that these factors are really a measure of the activity of the wall of the vessel. The nature of this activity will be discussed later.

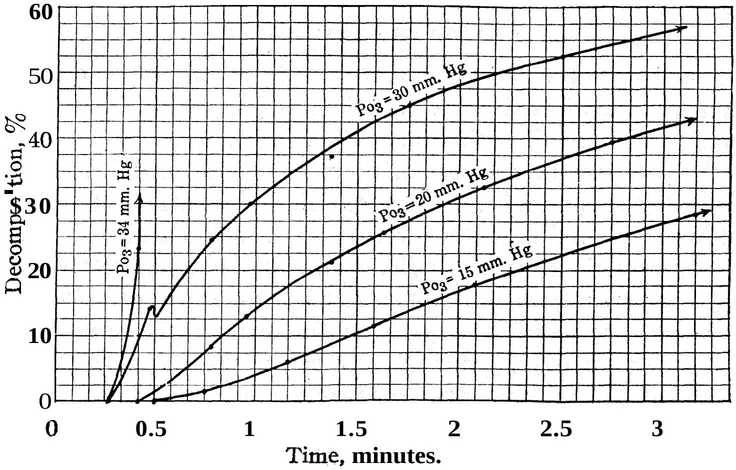

Fig. 1.—Typical curves showing decomposition of ozone: T, 35°; Br_2 pressure, 5 mm.

An inactive vessel could be made active by carrying out a reaction near the explosion limit or more effectively by admitting enough ozone to bring about an explosion. Extreme activity was never realized except by a succession of explosions. It therefore made some little difference from which side the explosion limit was approached, it being 1 to 2 mm. lower approached from the explosion or high ozone pressure side than from the slow reaction or low ozone pressure side. In all experiments the explosion limit was determined from the explosion side.

Deactivation of a vessel became more and more pronounced the longer it remained in disuse. For a moderate reversion to inactivity three or four days were required. It also became increasingly more difficult to reactivate. This is illustrated in Table I, in which are given data for different vessels which had remained unused for different periods of time.

---

[13] No such relationship was evident between the lag period and explosion limit when different vessels were compared. A vessel showing a long lag period could have quite a low explosion limit and vice versa (see Table II).

After each experiment the vessel was pumped out thoroughly and a fresh mixture admitted.

TABLE I

REACTIVATION OF VESSELS UNUSED FOR DIFFERENT PERIODS OF TIME

Vessel	Time unused	Temp., °C.	Mixture of gases	Expt.	Remarks
Glass bulb	17 days	25	5 mm. Br_2 16 mm. O_3	1	No change in 20 minutes
			(2 mm. above explosion limit)	2	Lag period 10 minutes; slow reaction
				3	Lag period 2 minutes; explosion
				4	Lag period 30 seconds: explosion (vessel very active)
Quartz bulb	I night	25	5 mm. Br_2 **23** mm. O_3	1	Lag period 1 minute, 15 seconds; slow reaction
			(2 mm. above explosion limit)	2	Lag period **32** seconds; explosion

A decrease in activity was also observed when air or inert gases which were not very carefully purified were admitted to the vessel. A much more marked but similar effect is observed with water vapor. **A** 0.1 mm. pressure of water vapor is sufficient to inhibit completely an explosion and to reduce the reaction velocity considerably. Even when the vessel was activated each day by the same method, it often showed slight differences in activity which affected not so much the explosion limit as the lag period and particularly the slow reaction at low ozone pressures. Thus for apparently the same conditions many experiments showed the same rate of decomposition whilst others differed considerably. Therefore it was necessary to make frequent tests of the activity of the vessel and to compare only those experiments which had been performed under similar conditions.

The differences in the activities observed may be due mainly to two causes: (1) active products formed during the decomposition or explosion of ozone remain adsorbed on the walls, thereby imparting more active properties to the latter (compare Farkas, Haber and Harteck).[7] *(2)* The activity is a property of the wall itself—that is, the surface consists of more or less active spots, according to the views of Taylor.

The experiments indicate, particularly when the activities of different vessels are compared (see Table 11), that it is the second factor which is of greater importance while the first exerts, if any, only a small influence. In this connection a highly active vessel which was heated to *ca.* 300° under high vacuum showed only a small decrease in activity. The inactivity of a new vessel or the deactivation of an active vessel by an impurity (such as $AsBr_3$ or unpurified air) may therefore be due to the adsorption of an impurity on the most active centers. The extreme activity which is observed to follow a number of intensive explosions seems to be due to a temporary change in the nature of the surface.

TABLE II

A COMPARISON OF THE ACTIVITY OF DIFFERENT VESSELS HAVING THE SAME SHAPE AND VOLUME

Vessel	State of activity	Lag period	Explosion limit
Glass I	New (moderate activity)	1'30"	14
Glass I	Very active	30"	12.5
Glass II	New (moderate activity)	1'10"	16
Quartz	New	35"	22
Quartz	Very active	30"	19.5

The experiments to be described and the data to be given in the following sections will be divided into two main parts: those dealing with the explosion limit and those concerning the slow decomposition below the limit.

Experiments on the Explosion Limit

1. Influence of Bromine on the Explosion Limit at **Different Temperatures.**—The main results are given in Fig. 2. The influence of bromine on the explosion limit varies with the temperature. Above 35° the limit is uninfluenced by the bromine concentration, even for a 100-fold variation. Below 35° a small influence is observed which becomes more pronounced as the temperature decreases. The limits were determined with an accuracy of ±0.5 mm. ozone pressure. At about 5 mm. of bromine the explosion limit curve goes through a minimum. For this reason this bromine pressure was used in nearly all subsequent experiments. Below 25° the change in the explosion limits with bromine concentration becomes still more marked, and the deposition of solid oxide becomes increasingly more probable. The phenomena are very different from those at higher temperatures and rather complex. Experiments in this range form the subject of a paper which is published elsewhere.[5]

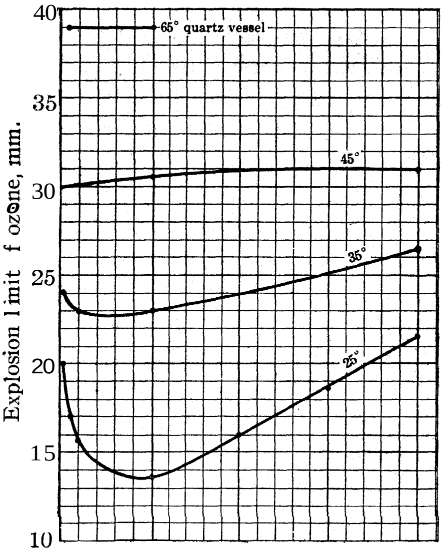

Fig. 2.—Influence of bromine on explosion limit.

2. Influence of **Temperature.** (a) Effect of Temperature on the **Lag** Period and the Decomposition Preceding Explosion.—The influence of temperature on the lag period and on the decomposition preceding an

explosion was studied for ozone pressures just above. the explosion limits and for a constant bromine pressure of 5 mm. The lag period and the length of time during which decomposition takes place before the explosion sets in decreases with increasing temperature (Fig. 3). Of special interest is the character of the curves. Above 25° the decomposition accelerates rapidly and continuously up to the explosion point, whereas below 25° the transition to the explosion is abrupt and increasingly so as the temperature is lowered.

Confining ourselves to temperatures above 25° the amount of ozone decomposed before explosion sets in depends on the temperature. It is greatest between the temperatures of 35 and 55°.

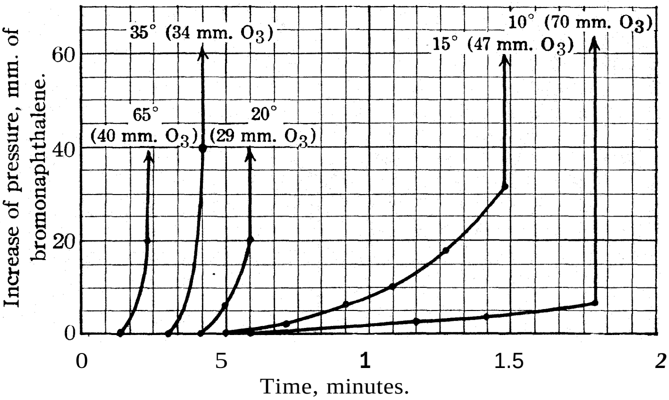

Fig. 3.—Influence of temperature on the reaction preceding explosion.

(b) **Effect of Temperature on Explosion** Limit.—Figure **4** shows that the explosion limit undergoes considerable change with temperature. It goes through a maximum at about 55° and a minimum at about 25°. Usually below 15° no explosions occur except when the vessel is in an exceptionally high state of activity.

A very active vessel may be rendered ineffective for developing an explosion below 15° by carrying out several experiments at an ozone pressure below the explosion limit. Solid oxide of bromine is gradually deposited on the wall, "conditioning" the vessel against explosions. In a vessel conditioned in this way, no explosions occur at 15° far above the normal explosion limit for an active vessel. However, the lag period is still short, indicating that the "conditioning" process does not affect the wall in the same way as the different kinds of deactivation described in a previous section.

3. Effect of Increasing the Surface on the Explosion Limit.—A new glass vessel (No. II) was completely filled with pieces of Pyrex glass tubing about 1 cm. long, 5 mm. outside and 3.6 mm. inside diameter. The actual change in surface was from 163 sq. cm. to 2067 sq. cm. and in volume from 195 cc. to 134 cc. for the empty and packed vessels, respectively. The increase in the ratio of surface to volume was 19 times. The greatest distance between any two surfaces was approximately 3.6 mm. The explosion limit in the empty vessel was about 16 mm. of ozone at 25°, but in the packed vessel no explosion was possible even up to 100 mm. of ozone. Anticipating our discussion later it is evident that although a large number of chains are started from the walls they are terminated by collisions with the surface before they can develop into an explosion.

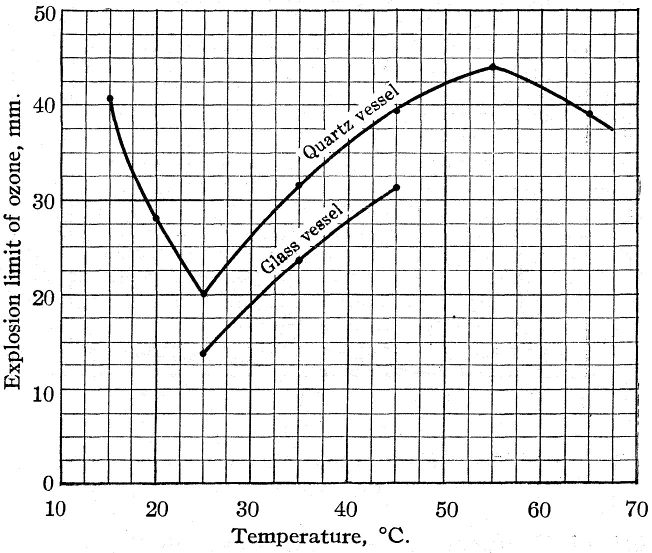

Fig. 4.—Effect of temperature on the explosion limit.

Half the number of glass pieces were now removed, so that half the volume was free. Here the explosion limit was about 29 mm. of ozone, some 13 mm. higher than in the empty vessel. It was found that 100% of the ozone had decomposed during the explosion, indicating that once the latter is started in a free space it travels unhindered through small openings. On several previous occasions the ozone reservoir was blown up due to the propagation of the explosion from the reaction vessel through a slightly opened needle-valve and capillary tubing about 0.1 mm. in diameter.[14] It was estimated that the speed of propagation was of the order of magnitude commonly found for a detonation in gases. From these facts it must be concluded that one is dealing here with detonations rather than

---

[14] Obviously the explosion will not travel through very small openings such as are encountered in a fine porous glass filter. (See also Riesenfeld and Wassmuth, *Z physik. Chem.*, **8B**, 314 (1930).)

slow inflammations. This explains the ineffectiveness of the packed half of the vessel in stopping the propagation. It is evident therefore that once the explosion is started the number of chains which terminate at the walls (even when the latter are close together) is insufficient to prevent practically infinite branching of chains.

In view of these results it was considered of importance to study the influence of the size of the vessel on the explosion limit.

4. Influence of Diameter of Vessel on the Explosion Limit.—From the above experiments it appears that under a given set of conditions reaction chains must travel uninterrupted (by walls) for some distance before a sufficient concentration of "reaction carriers"[15] can be developed by chain branching to lead to an explosion. To gain a more distinct idea of this distance the explosion limit was investigated in cylindrical vessels having the same length (12 cm.) but different diameters. Cylindrical instead of spherical vessels were chosen to obtain a greater volume.

Since the explosion limit is affected by the activity, all the vessels were first activated by a number of explosions. Their degrees of activity were similar, judging from the lag period and the rate of decomposition below the explosion limit. Therefore, the explosion limits in these vessels were comparable.

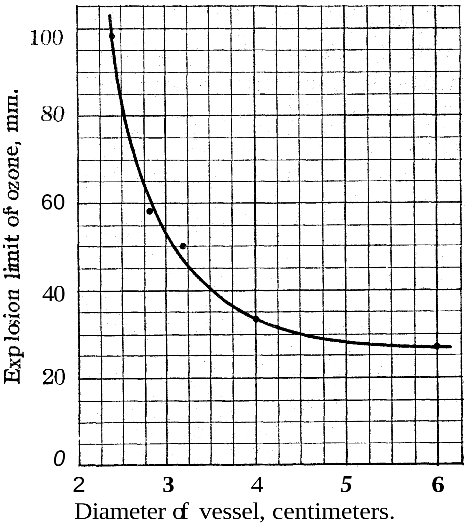

Fig. 5.—Relation between explosion limit at 25° and diameter of vessel.

In Fig. 5 the observed explosion limits at 25° are plotted against the diameter of the vessels. The curve so obtained corresponds to a rectangular hyperbola and is represented by the equation

$$(d - a)(p - b) = K$$

where d is the diameter of the vessel in mm. and p the explosion limit; a and b are constants which depend on the activity of the vessel. Deviations from this law are of the order that may be expected from the differences in activity from vessel to vessel. The curve is asymptotic to two lines parallel to the x and y axes whose coordinate values are represented by the constants b and a in the equation. Thus the value of b represents the

---

[15] By "reaction carrier" is meant one of the intermediate active products generated during the reaction through the medium of which the chains are carried on.

rxplosion limit for infinite diameter of vessels of this type which under these conditions is 20 mm. of ozone. The value of a represents the limiting diameter below which no explosion will take place, which under these conditions is found to be 20 mm.

Explosions of ozone alone by direct heating are also prevented in a similar way by proximity of the walls. Thus no explosion occurred in a 4-mtr. Pyrex glass tube containing 40 mm. of ozone when it was heated to 400°. (See also Ref. 14.)

Attention is directed to the existence of a similar hyperbolic law between the gas pressure and the condenser voltage when certain explosive mixtures such as $CO + O_2$, $H_2 + O_2$, $CS_2 + O_2$, are ignited by means of a discharge.[16] Although the method of ignition is quite different from that in our experiments the similarity in the results is striking.

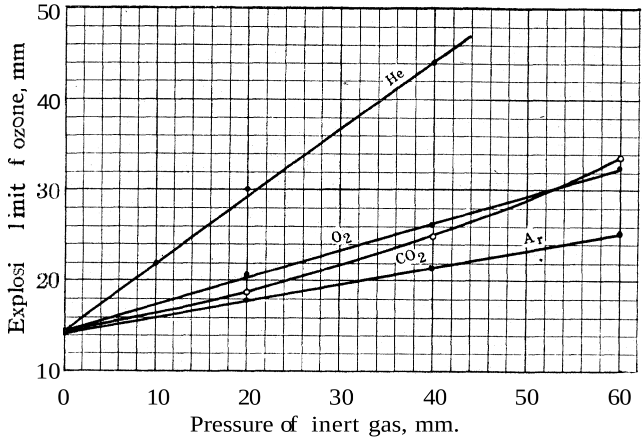

Fig. 6.—Effect of inert gases on the explosion limit at 25° (5 mm. of bromine).

5. Influence of Inert Gases on the Explosion Limit.—The experiments were carried out in the glass vessel I and the quartz vessel at 25°. Preliminary tests showed that the ozone was very stable in the presence of tho inert gases alone. The order in which the gases were admitted was: 5 mm. of bromine, varying amounts of inert gases, ozone.

In all cases the inert gas raises the explosion limit. Within the range of these experiments the limit increases directly proportional to the pressure of helium, argon, oxygen and nitrogen. With carbon dioxide the limit increases somewhat faster than by direct proportionality (see Fig. 6). The curve for nitrogen is not shown as it lies very close to and just above that for oxygen. All the curves meet in a common point, 14 mm. of ozone

---

[16] A. K. Brewer, *Proc. Nat. Acad. Sci.*, **13**, 689 (1927); THIS JOURNAL, 52, 4225 (1930); Finch and Cowen, *Proc. Roy. Soc.* (London), **A116**, 529 (1927).

at zero pressure inert gas. This is the explosion limit of pure ozone with 5 mm. of bromine at 25° in this glass vessel.

The effectiveness of inert gases in raising the explosion limit increases in the order, argon, carbon dioxide, oxygen, nitrogen, helium.[17] In the quartz vessel the effect is also in the same order but with helium the increase in the limit is now less than corresponds to direct proportionality.

The effectiveness in increasing the explosion limit is in the order of decreasing molecular weight. It is apparent that bromine should have little influence, which is in agreement with experiments described earlier.

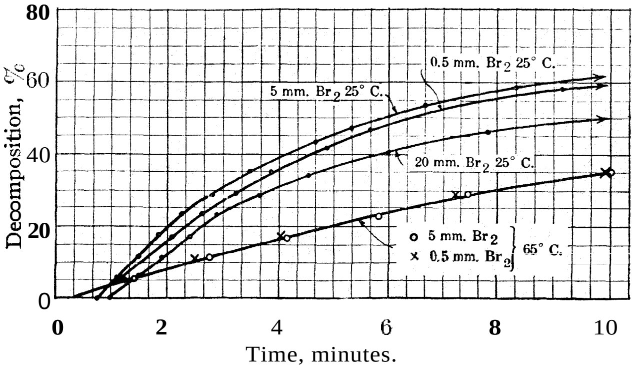

Fig. 7.—Influence of bromine on the rate of decomposition of ozone: pressure of ozone **15** mm.; quartz vessel (explosion limit 20 mm. of ozone).

The Decomposition of Ozone below the Explosion Limit

1. The Influence of Bromine on the Rate of Decomposition.—The influence of bromine on the decomposition of ozone below the explosion limit varies with the temperature. At 65° there is no difference in the rate between 0.5 and 5 mm. of bromine (see Fig. 7). At 35° a small effect can be observed. At 25° the reaction is fastest with 5 mm. of bromine, slower with 0.5 mm. of bromine, and still slower with 20 mm. of bromine. The parallelism between these experiments and those on the effect of bromine on the explosion limit is evident (refer to Fig. 2). For a given temperature the fastest rate corresponds to the lowest explosion limit. These facts indicate that the reaction is the same in principle for the slow decomposition as for the reaction leading to explosion.

---

[17] Experiments on the effect of inert gases on the inflammation limits of mixtures of methane–air, and carbon monoxide–oxygen have been conducted by Coward and Hartwell, *J. Chem. Soc.*, **1522 (1926)**; F. W. Stevens, This Journal, 50, **3244 (1928)**; and Jorissen, Booy and Van Heiningen, *Rec. trav. chim.*, *49*, *876* **(1930)**. A different order of effectiveness in raising the limit than in the present experiments was found. This is probably due to the entirely different chemical reactions and experimental conditions.

Below 25° the influence of bromine becomes very marked. The experiments are described fully elsewhere.[5]

2. The Effect of Temperature on the Rate of Decomposition.—The rate of decomposition of ozone was studied at different temperatures and at pressures below the explosion limit. One set of experiments is shown in Fig. 8 for 15 mm. of ozone and 5 mm. of bromine. To avoid crowding, only the temperature interval 25–70' is recorded. The results show that the rate of decomposition decreases as the temperature is raised from 25 to 55° and then increases above this temperature. From 15 to 25° the rate increases once more. Thus there are three distinct regions of temperature coefficients. The temperature coefficients for the first stages of the reaction for different temperature ranges are given in Table III.

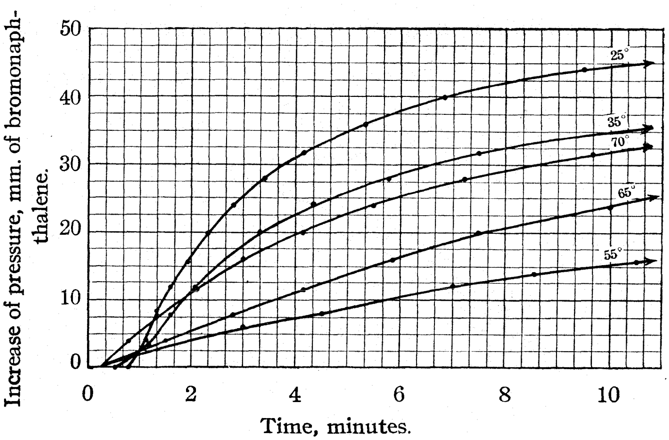

Fig. 8.—Decomposition of ozone at different temperatures: pressure of ozone, 1.5 mm.; bromine, 5 mm.

TABLE III

TEMPERATURE COEFFICIENTS IN DIFFERENT TEMPERATURE RANGES (15 MM. O_3; 5 MM. Br_2, QUARTZ VESSEL)

Temperature interval, °C.	Temperature coefficient[18]
65–55	1.7
55–45	0.6
45–35	.5
35–25	.7
25–15	1.5

---

[18] It has been customary to call temperature coefficients positive if they are greater than one, and negative if they are less than one. The term negative temperature coefficient is, we feel, a misnomer and confusing. We therefore suggest with Prof. A. F. Benton (statement at American Chemical Society Meeting, Indianapolis, March 30–April 3) that it be referred to as a temperature coefficient less than one.

The temperature coefficients are derived by dividing the rates of decomposition for short corresponding time intervals at different temperatures separated by 10°. At higher temperatures these temperature coefficients remain fairly constant during a reaction over a moderately long time.

These results show that the rates follow exactly the explosion limits. For different temperatures the lower the explosion limit the faster the rate of the slow reaction here considered (compare Fig. 4).

It is to be anticipated that the percentage decomposition in a given time will become more nearly the same at all temperatures as the initial pressure of ozone approaches the explosion limit. Table IV shows this clearly.

TABLE IV

COMPARISON OF AMOUNT OF OZONE DECOMPOSED AT DIFFERENT TEMPERATURES NEAR THE EXPLOSION LIMIT. QUARTZ VESSEL USED

Temp., °C.	Initial pressure, mm. of ozone	Explosion limit, mm. of ozone	Percentage ozone decomposed in 10 minutes
15	40	41	77
20	27	28	77
25	20	21	71
35	30	32.5	73
45	36.5	39	70
55	42.4	44	61
65	38	39	66

The somewhat greater decomposition below 25° is to be ascribed to a gradually changing type of wall reaction with decreasing temperature.[5]

Since no reaction constant can be calculated to which any significance can be attached, another means of comparing the rates at different temperatures and initial pressures is given. This is $\Delta p/\Delta t$ maximum, the change in pressure for an interval of ten seconds at the steepest portion[19] of each curve. For a given initial ozone pressure the steepest portion occurs soon after the reaction has set in (compare Fig. 1). In Fig. 9, therefore, $\Delta p/\Delta t$ maximum is plotted against the initial ozone pressure for different temperatures. Vertical lines represent the explosion limits at the various temperatures. As long as the pressure of ozone is far below the explosion limit, $\Delta p/\Delta t$ changes only slightly. On approaching the explosion limit it increases rapidly up to the explosion point, where it becomes practically infinite. These curves show graphically the suddenness with which the explosion sets in below 20° (see also reference 5).

3. Effect of Increased Surface on the Decomposition.—The decomposition was studied in the vessel packed with glass tubing used in previous experiments. It was mentioned above that no explosions are possible in the fully packed vessel. It is observed (Fig. 10) that regardless

---

[19] Here there is a minimum retarding effect due to oxygen set free in the decomposition.

of the initial ozone pressure the reaction proceeds to about 90% of completion in a comparatively short period of time, namely, about ten minutes. Furthermore, for a given set of conditions (temperature and ozone and bromine pressures) the decomposition in a certain time interval is greater in the packed than in the empty vessel (Fig. 11). However, this increase in the rate in the packed vessel in no way compares with the large increase in the ratio of surface to volume (19:1). This is shown in Fig. 11. The ratio of the reaction rates in the packed and empty vessels at 25°, 15 mm. of ozone, 5 mm. of bromine is calculated to be 1.3 and remains constant over the entire range of the reaction.

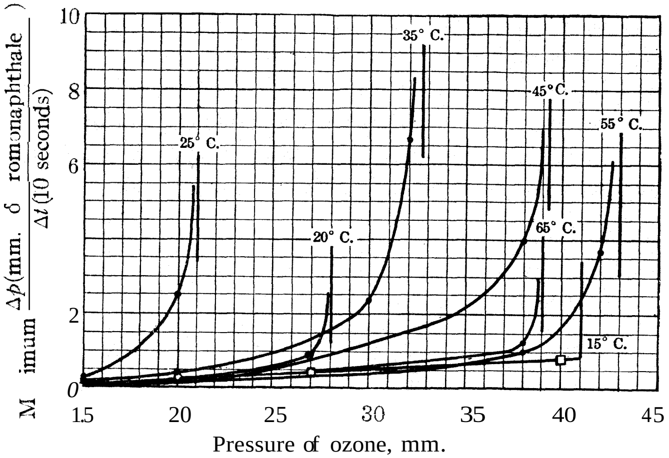

Fig. 9.—Maximum $\Delta p/\Delta t$ for different temperatures.

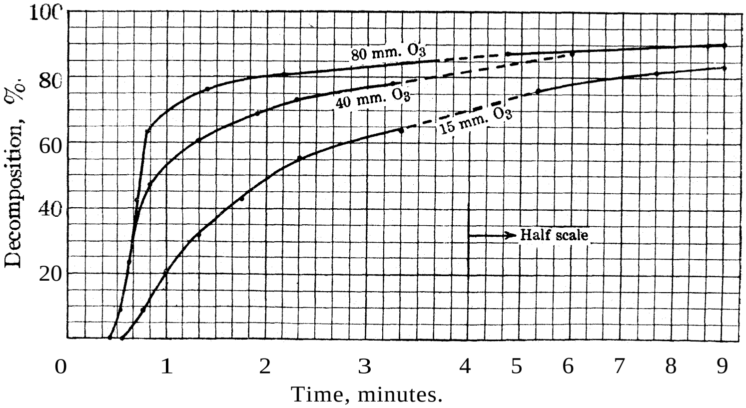

Fig. 10.—Decomposition of ozone in packed vessel at 25° and different ozone pressures.

The small increase in the rate of decomposition in the packed vessel over that in the empty vessel indicates that at 25° and above the larger part of the reaction takes place in the gas phase.

4. Temperature Coefficient in the Vessel Filled with Glass Tubing.—In Table V values for the temperature coefficients in the glass-filled vessel for different temperature intervals are given. Comparing these with the temperature coefficients in the empty vessel, it is a striking fact that whereas the value for the interval 15 to 25° in the empty vessel is 1.5 it is only **0.33** in the packed vessel. This means that the decomposition at the lower temperature is much faster in the packed vessel than in the empty vessel. The ratio of the rates in the packed and empty vessels can be calculated to be 5.25 at 15°. This can easily be understood when it is remembered that at lower temperatures the decomposition becomes more and more a wall reaction, whilst decomposition in the gas phase becomes smaller.[5] Owing to the greater rate of formation of the intermediate adsorption compound at 15° than at 25° the amount of ozone decomposed at the wall is greater at the former temperature; but as the number of active carriers shot out into the gas phase diminishes with decreasing temperature, the rate of decomposition at 15° in the empty vessel is smaller than in the packed vessel where the surface has been increased 19-fold. In fact the increase in surface is so great that the decrease of the reaction in the gas phase is more than overbalanced by the increase in the wall reaction. This is one of the first instances[20] to be recorded of a heterogeneous reaction possessing a temperature coefficient less than one.

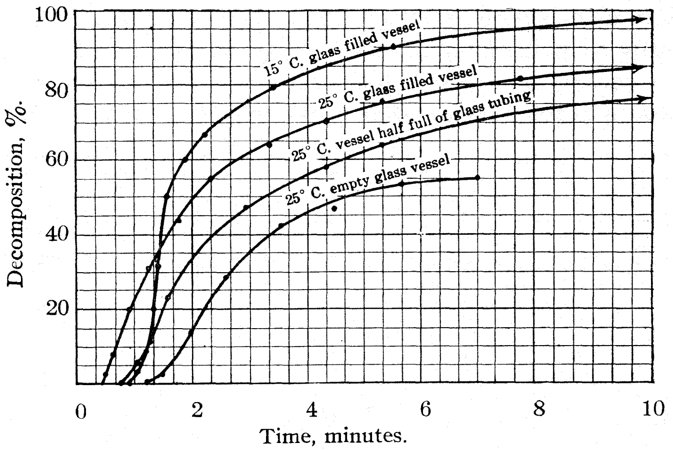

Fig. 11.—Decomposition of ozone: pressure of ozone, 15 mm.; bromine, 5 mm.

---

[20] Professor H. S. Taylor reported the discovery of another heterogeneous reaction with a temperature coefficient less than one in the catalytic surface conversion of ortho- and para-hydrogen (Meeting American Chemical Society, Indianapolis, March 30–April 3).

TABLE V

TEMPERATURE COEFFICIENTS IN PACKED VESSEL BETWEEN 15 AND 45°

$\Delta p_{t_2}/\Delta p_{t_1}$[21]	Temperature coefficient for initial pressure, 15 mm. of O_3
$\Delta p_{25}/\Delta p_{15}$	0.33
$\Delta p_{35}/\Delta p_{25}$	.72
$\Delta p_{45}/\Delta p_{35}$	1.05

As the temperature rises the temperature coefficient also rises until above 45° it is greater than one. This is due to the fact that the intermediate adsorption compound emits active carriers at the higher temperatures and gives rise to chains in the gas phase which multiply rapidly with increasing temperature. On the other hand the wall reaction rate decreases with increasing temperature owing to the decreased adsorption and consequently a smaller number of active carriers is emitted. It is obvious that due to these two factors the temperature coefficient should increase and will eventually reach a temperature at which it is greater than one.

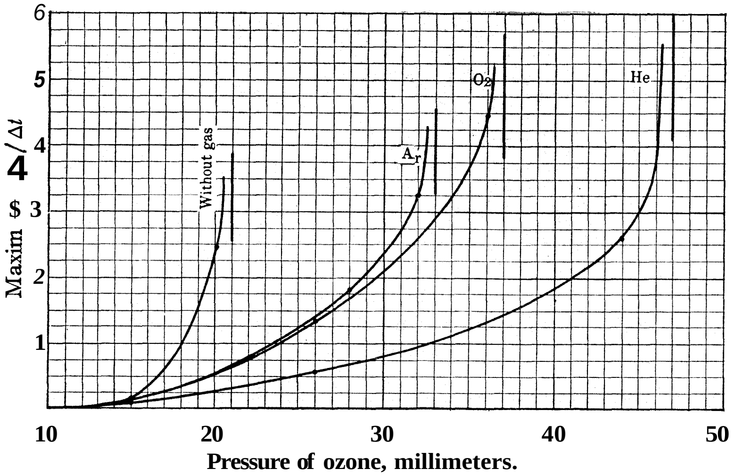

Fig. 12.—Comparison of the effects of inert gases on the maximum rate of decomposition of ozone: pressure of inert gas, 40 mm; bromine, 5 mm.; temperature, 25°.

5. The Effect of Inert Gases on the Decomposition.—The influence of inert gases on the explosion limit was shown to be greatest for those gases which have small atomic weights and high heat conductivities. To learn more about the mechanism of this influence, the decomposition of ozone below the explosion limit in the presence of like quantities of inert gases was studied. The following results were obtained in the quartz vessel at 25° with 5 mm. of bromine. They are shown graphically in Fig. 12, in

---

[21] The rise in pressure for an interval of ten seconds over the steepest portion of the curve was taken for comparing the rate.

which $\Delta p/\Delta t$ for the maximum speed is plotted against ozone pressure for 40 mm. of the inert gases, argon, oxygen and helium. A curve for pure ozone is also shown.

If the pressure of ozone is low, 15 mm.,[22] the inert gases exert very little influence on the rate of decomposition. As the ozone pressure is increased the influence of the inert gases becomes marked to a more or less degree depending on the gas. The rate is slowest for helium, faster for oxygen and fastest for argon. Since for like quantities of inert gases the explosion limit is lowest for argon, the rates become even more widely different as the explosion limit for argon is approached. For argon the rate approaches infinity, for oxygen it is slower and for helium very much slower. In the same way on approaching the explosion limit for oxygen the rate is very fast for the latter gas but still very slow for helium. Finally, if the rates of decomposition near the limits of explosion of all the inert gases (for different ozone pressures) are compared they are found to be nearly the same.

Mechanism and Discussion

This rather complex reaction can now be explained satisfactorily from the results of the experiments which have been described. In proposing the following mechanism, no unreasonable assumptions have been made but each step in the process is supported by or deduced from experimental facts.

The whole reaction may be divided into two distinct processes, one which takes place on the walls and the other in the gas phase. In point of view of time the wall reaction precedes the gas phase reaction.

(1) Before any increase in pressure can be observed some process must occur at the wall. The proof for this lies in the numerous observations made of the deactivation of the vessel by impurities such as $AsBr_3$ and impure air, the long lag periods occasioned by the latter, the gradual stepwise activation of a vessel by previous reactions and explosions, the marked differences in activity in different vessels and the effect of such activity on the slow decomposition and the explosion limit.

(2) This wall process is divided into three distinct phases.

(a) Both ozone and bromine are adsorbed on the walls. As far as the adsorption of ozone is concerned, this is shown very clearly by the marked shortening of the lag period when bromine is admitted to the vessel after the ozone. It will be recalled that here the lag period amounts only to some seconds whereas, when ozone is added after the bromine, the lag period involves minutes. The difference in these times is interpreted as the time taken by the ozone to displace part of the bromine adsorbed on the wall and to become adsorbed itself. Taylor[23] has pointed out that certain adsorp-

---

[22] This pressure is 5 to 6 mm. below the explosion limit of ozone in the absence of inert gases.

[23] H. S. Taylor, THIS JOURNAL, 53,578 (1931).

tion processes may be very slow. In the present case it is not possible to decide whether it is the replacement of bromine by ozone or the slow adsorption of ozone which accounts for this difference in the lag period. It would indeed be very difficult to account for the fact that the temperature coefficient between 25 and 55° is less than one were adsorption of ozone and bromine unnecessary.

(b) An intermediate unstable compound of ozone and bromine is formed at the walls. From general considerations, as both ozone and bromine are necessary for the decomposition or explosion and both constituents are adsorbed, it follows that some type of compound between ozone and bromine must be formed at the walls, apart from all considerations concerning its nature, stability or life-time as an entity. There is no clue to the chemical structure and composition of this oxide. It is not to be confounded with the solid crystalline oxide of bromine Br_3O_8 observed by Lewis and Schumacher,[4] nor with a volatile oxide of bromine, presumably Br_2O, recently described by Zintl and Reinäcker.[24] At 25° and above, the experimental results indicate that this oxide is very unstable. As the temperature is decreased below 25° a continuous increase in stability takes place. Already at a temperature of 15° under favorable conditions the once unstable oxide is observed to go over into the solid crystalline compound.[5]

(c) The unstable oxide decomposes immediately and expels or ejects into the gas phase energy-rich groups, most probably oxygen atoms or active oxygen molecules. The more stable adsorption compound at lower temperatures appears to eject groups which are too inactive to initiate further reactions in the gas phase. In support of this are the results showing that at lower temperatures the wall reaction increases and the gas phase reaction decreases and disappears (see also Reference 5).

(3) The active groups, which will be referred to as reaction carriers, on colliding with appropriate ozone molecules in the gas phase cause the latter to decompose and at the same time give rise to new active reaction carriers. In this way reaction chains build up and undergo branching or multiplication, the rate of which is dependent on the temperature, the ozone concentration, and the presence of inert gases. They spread out and propagate through the gas phase until they are broken up by collisions with the walls of the vessel. Individual links in the chain are also destroyed by unfavorable collisions with ozone or inert gas molecules. If the concentration of reaction carriers in an element of volume of the gas exceeds a critical value, the chains undergo practically unlimited branching and the reaction goes over into an explosion which leads to the complete decomposition of the ozone in the vessel. If the number of original reaction carriers shot out from the wall is too small (which is affected by tempera-

---

[24] E. Zintl and G. Reinacker, Ber., 63, 1098 (1930).

ture, ozone pressure and bromine pressure), the ozone concentration too low, or if a sufficient concentration of an inert gas is present, so that the critical concentration of reaction carriers is not attained, the reaction velocity after reaching a maximum slows down again long before all the ozone has decomposed.

(4) The actual reactions which occur in the chains are unknown. One probable mechanism may be suggested. It is supported to a certain extent by calculations of the velocity of propagation of a detonation wave in ozone. If the chain reaction theory of Lewis,[25] and the mechanism suggested by him are considered—namely

$$\begin{array}{l} O + O_3 = 2O_2^* \\ O_2^* + O_3 = 2O_2 + O \\ O + O_3 = 2O_2^* \\ \text{etc.} \\ \downarrow \\ O_2^* \end{array}$$

where O_2^* is an active molecule, the reaction carrier turns out to be an excited oxygen molecule with a total energy of 47.2 Kcal. of which 17.7 Kcal. is available as translational energy. (Heat of formation of $O_3 = 32$ Kcal. and heat of dissociation of $O_2 = 117$ Kcal.) The velocity of propagation is calculated to be 2150 meters/sec. Using the theory of Chapman and Jouguet,[26] which is strictly hydrodynamical and thermodynamical in character and does not consider the individual reactions at all, the velocity is calculated to be 2123 meters/sec. The speed of detonation of ozone has never been determined experimentally, but both theories have been able to account very closely for the velocities of detonations in other gas mixtures for which good experimental values are available. It may therefore be expected that the experimental value for the speed of detonation in pure ozone will be close to the value calculated above. It has been shown that the explosion of ozone in these experiments is in reality a detonation, which furnishes evidence for the probability of the above reaction mechanism.

The way in which branching occurs can be represented in the following scheme. We shall assume that the initial reaction carrier shot off from the wall is an active oxygen molecule. An oxygen atom might do just as well. As mentioned above, any one of the links in the branches may be terminated by unfavorable collisions with other molecules or with the wall. Chains may also terminate by a collision between two oxygen atoms and a third body to form an oxygen molecule. In a spherical vessel this may be a real factor due to the fact that chains start from all points on the wall, spread out spherically in all directions and overlap each other. The overlapping of the chains tends to accumulate reaction carriers and oxygen atoms, the

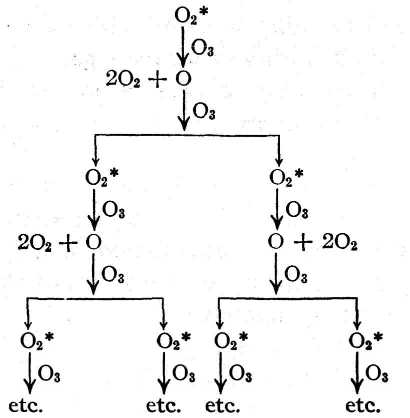
[26] Bernard Lewis and James B. Friauf, *ibid.*, 52, 3905 (1930), and references contained therein to papers by Chapman, Jouguet and others.



concentrations of which increase on approaching the center of the vessel. Obviously the formation of oxygen molecules from oxygen atoms is a slow process compared with the accumulation of reaction carriers. Referring to the experiments with different sizes of cylindrical vessels, it is obvious that the walls must be far enough apart to prevent the interruption of chains before a sufficient concentration of reaction carriers is built up. It is astonishing how far the carriers have to penetrate into the gas phase before this concentration necessary for explosion is reached.

(5) One may conclude from the results of studies on the photochemical decomposition of ozone that the chains are negligible or very short in the red region of the spectrum,[27] while in the ultraviolet[28] chains exist but they too are very short. The mechanism given by Schumacher[27] involves the formation of active oxygen molecules. These active molecules do not react further and start chains. It is believed that the chains in the present reaction are also propagated through the medium of active oxygen molecules. It is possible that the difference in behavior of the active oxygen molecules in both cases lies in the fact that the energy resides in the molecule in different forms. In this investigation a large amount of the energy is probably in the form of energy of translation which is in a more suitable form to react with ozone. In the photochemical reaction it may be that only a small amount of energy is available as energy of translation and that the efficiency of favorable collisions with ozone is much smaller. The writers realize the difficulties in the way of arriving at precise conclusions in this matter. Although the experiments do not indicate it, it may still be possible that bromine takes part in the chain mechanism in some unknown way. Further experiments are in progress.

(6) From these views, the reason for the influence of bromine on the

[28] E. Warburg, *Sitzb. preuss. Akad. Wiss.*, 644 (1913).

explosion limit and the slow decomposition below the explosion limit becomes clear. At the lower temperature, say 25°, if too little bromine is present, not enough bromine is adsorbed and too few reaction carriers are emitted from the wall. If too much bromine is present it displaces ozone from the walls and again too few carriers are formed. Somewhere there is an optimum bromine pressure at which a maximum number of carriers is formed. At higher temperatures the bromine has no effect because the surface is covered only partially and does not influence appreciably the ozone adsorbed. The number of carriers formed is therefore constant.

(7) The temperature coefficient of the reaction is divided into three parts. It is greater than one below 25°, less than one between 25 and 55°, and again greater than one above 55". These may now be explained on the basis of the mechanism given above. There are two main parts of the reaction which are affected by temperature, namely, the wall effect and the gas phase reaction. These gross effects are due to a number of separate causes.

A. Wall effect.
  1. Speed of adsorption with temperature.
  2. Amount of adsorption with temperature.
  3. Speed of formation of unstable intermediate adsorption compound.
  4. Speed of decomposition of unstable intermediate adsorption compound.
  5. Change of type of intermediate adsorption compound with temperature.

B. Gas phase reaction.
  1. Increase in chain length with temperature (speed of chain branching).
  2. Diffusivity of the carrier to the wall with temperature.

The temperature coefficients above 25° are explained as follows. (a) The amount of adsorption decreases with increasing temperature. We shall neglect the speed of adsorption, although this probably increases with increasing temperature. (b) Therefore, on the basis of mass effect alone, the speed of formation of the intermediate adsorption compound decreases with increasing temperature. (c) It is assumed that the intermediate compound decomposes fast enough so that the rate of emission of carriers is governed by (a). (d) The length of the chains of branching increases exponentially with the temperature. (e) The diffusivity of the active carriers to the wall increases as some power of the temperature, T^x, where $x = ca.\ 1.7$–2.

The effect of (a) and (e) is to slow down the rate as the temperature rises by decreasing the number of carriers emitted from the wall and by deactivating them (or others formed in the chains) on the wall. The effect of (d) is to speed up the rate as the temperature rises; (d) increases rather rapidly with temperature, faster than (e). It is possible, however, for the curves of the combined effect of (a) and (e) and that for (d) to possess such a character that they intersect at some temperature in the neighborhood of

55°. Thus between 25 and 55" the effects of (a) and (e) outweigh the effect of (d) and the temperature coefficient is less than one. Above 55° the effect of (d) outweighs the effect of (a) and *(e)* and the temperature coefficient is greater than one. In other words, when the gas phase reaction (branching of chains) becomes more extensive than the combined wall effects, the temperature coefficient is greater than one and ***vice versa.***

Concerning the temperature coefficient of less than one below 25°, it has been shown6 that as the temperature decreases below 25° the unstable intermediate compound goes over to a more stable form whose decomposition products are incapable of propagating chains in the gas phase. Therefore, as the temperature decreases the wall reaction becomes more pronounced and the gas phase reaction less. The combination of both effects result in a smaller total reaction occurring at the lower temperature. If the temperature and other conditions are such that solid bromine oxide is formed, the gas phase reaction disappears entirely.[4] The influence of temperature in the glass-filled vessel has been discussed above.

(8) It remains now to explain the effects of inert gases. At low ozone pressures where the reaction is normally very slow and the branching and spreading of chains is a minimum, the addition of moderate amounts of inert gases (10 to 60 mm.) will have very little effect on the already small branching. However, when the ozone pressure is raised to a point approaching the explosion limit (without inert gas), the branching of chains goes on to a marked degree and the addition of inert gases should produce a greater or smaller effect depending on the gas used. Moreover, whatever the inert gases used, the rate should be the same close to the explosion limit since here the branching becomes practically infinite. These limits are given in Fig. 6.

The manner in which the inert gases effect the branching of the chains may be understood as follows. Three different effects should be considered. These are: (1) the effectiveness of the inert gas in deactivating the reaction carrier. This is (for translational energy) a function of the mass of the inert gas. It is greatest for a mass similar to the carrier itself. (2) The number of collisions the inert gas makes with the carrier. Everything else being equal this is inversely proportional to the square root of the mass of the inert gas. The larger the number of collisions the greater the chance for deactivation. *(3)* The speed with which the heat energy liberated in the decomposition is transported to the wall—that is, heat conductivity. The heat conductivity of the inert gases used decreases in the order of increasing molecular weight. The greater the heat conductivity, the higher the explosion limit.

It is not possible to calculate quantitatively the exact influence of each inert gas. The combination of these three effects, however, checks well the order of the influence of the inert gases realized in the experiments.

The reason for the relatively small effect of bromine on the explosion follows from these considerations.

(9) It may be worth while to point out what new light this research throws on the general concept of chain reactions. First of all the experiments show that the conditions in the system ozone--bromine-surface are very complicated. The results, therefore, cannot be used for a precise formulation of the chain reaction mechanism, nor for the measurement of the length of the chains.

However, the reaction provides another example of chains starting and ending at the walls, that the chains are initiated by a wall adsorption compound. The results indicate that in this particular case the branching of chains in the gas phase occurs slowly and that it can become practically infinite only after the carriers and chains have penetrated a relatively great distance into the gas phase. Considerable decomposition as a result of branching of reaction chains also takes place under conditions where no explosions occur. The chains may be long or short depending on the conditions of the experiment. It is of interest to point out that as the explosion limit is approached they become gradually longer and longer. This and the fact that inert gases have an identical effect on the decomposition below and above the limit show that the reaction during the slow decomposition is identical with the reaction during explosion and furnishes unequivocal evidence for the chain theory of detonations in gas mixtures.

In contrast to this reaction are a number of other examples like the hydrogen–oxygen and carbon disulfide–oxygen systems.[8] In these latter reactions the transition from the non-explosive to the explosive stage occurs abruptly. Beyond the explosion limit only a slow reaction occurs (little or no branching of chains) which passes over suddenly at the limit to an explosion (practically infinite branching).

The dependence of the propagation of chains on the way in which the energy is distributed in the initial reaction carriers shot off from the wall or formed in the light reaction and the fact that the explosion involves a single molecule only, would seem to make the ozone explosion very suitable for a study of the fundamentals of gas explosions.

Summary

1. The decomposition of ozone sensitized by bromine vapor has been investigated. The reaction begins only after a lag period, following which an acceleration takes place which culminates in an explosion if the pressure of ozone exceeds a certain critical value. Below this explosion limit the reaction rate goes through a maximum and slows down again.

2. The lag period (ranging from a few seconds to an hour), the explosion limit, and the rate of the slow decomposition depend on the activity of the vessel. The activity is a property of the surface of the wall and can be

influenced by several factors which are discussed. Slow decomposition and particularly explosions render a vessel very active. A vessel so activated retains a considerable part of its activity even if unused for several days.

3. The concentration of bromine between rather wide limits has no influence on the explosion limit nor the slow reaction above 35°. Below this temperature an influence appears which becomes more marked with decreasing temperature. The explosion limit goes through a minimum and the slow reaction a corresponding maximum for 5 mm. of bromine.

4. For a definite bromine concentration the explosion limit goes through a minimum at 25° and a maximum at 55°. Corresponding to this the slow reaction has a temperature coefficient greater than one below 25°, less than one between 25 and 55° and greater than one above 55°.

5. No explosion is possible in a vessel filled with pieces of glass tubing. The results show that below 25° the reaction gradually becomes predominantly a wall reaction while above 25° the reaction takes place mainly in the gas phase. It is shown that the explosion is in reality a detonation.

6. The explosion limit increases with decreasing diameter of cylindrical vessels. A hyperbolic law is found to exist between the explosion limit and the diameter. Under certain experimental conditions no explosions are possible in a vessel smaller than 2 cm. in diameter. It is interesting to observe that reaction chains must travel a considerable distance into the gas phase before an explosion results.

7. The explosion limit is increased proportionally to the pressure of inert gases. The effect increases in the order argon, carbon dioxide, oxygen, nitrogen and helium. The slow reaction is affected similarly.

8. A mechanism based on the experimental facts is proposed. Reaction chains start at the wall due to the emission of an active product of a decomposing wall adsorption compound between bromine and ozone. The chains propagate in the gas phase and may terminate there or on the wall.

9. The photochemical decomposition of ozone is discussed in relation to the present investigation.

10. A method of making porous plate filters of Pyrex glass is described.

DETERMINATION OF SOLUBILITY OF SPARINGLY SOLUBLE LIQUIDS IN WATER

BY HARRY SOBOTKA AND JOS KAHN[1]

RECEIVED MAY 18, 1931 PUBLISHED AUGUST 5, 1931

During a biochemical investigation, we found it necessary to ascertain the solubility in water of several simple aliphatic esters, primarily the ethyl esters of the saturated normal monocarbonic and dicarbonic acids. Except for a few of these esters, no data could be found in the reference books of physical and organic chemistry. We therefore proposed to determine the water solubility of a number of these substances.

The quantitative estimation of sparingly soluble liquids in their saturated aqueous solutions sometimes meets with obstacles caused by difficulties in the analytical determination of small amounts of these substances. More often, however, the difficulty arises with the separation of the saturated solution to be analyzed. Depending on the attempted method of separation, losses by evaporation, adsorption to filters or other difficulties of mechanical nature may hamper the effectual and correct separation of a saturated solution from the excess of undissolved substance. The proximity of specific gravity of solvent and solute limits the choice of methods in many instances; in other cases a substance with relatively low refractive index will escape detection by inspection.

Schuncke and Bodtker[2] determined the mutual solubility in the system water-ether by mixing varying amounts of the two fluids and by observing the appearance of a second phase. Herz[3] applied the same principle to the estimation of the water solubility of a few other liquids as chloroform, benzene, etc. An improved method was used by Klobbie.[4] He added ponceau de xylidine, a dye insoluble in ether and soluble in water, to dry ether and then added water. As soon as the ether was saturated with water the formation of water droplets changed the appearance of the hitherto dry ponceau particles.

We were unaware of Klobbie's method when we devised the following procedure to overcome the difficulties mentioned above. It offers a quick and simple method of ascertaining data on solubility with 'an accuracy, satisfactory for various purposes, of ±0.001% (*i. e.*, 0.01 cc. in one liter).

Principle and Description of Method.—A few cc. of purified ester was stained with a minute quantity of Sudan IV, a water-insoluble lipoid-

soluble dye. It was then added drop by drop from a micro-buret with a capillary tip to 100, 250, or 500 cc. of distilled water of constant temperature (usually 20°) in a narrow-mouthed stock bottle provided with a well-ground glass stopper. The bottle was thoroughly shaken after each addition of ester. While the added ester was dissolved, the Sudan dye contained in the ester was also wholly or partially dissolved, imparting a pink tinge to the aqueous solution. When Sudan had been added in more liberal quantities a part of it was precipitated and floated on the surface in the form of dark brown solid particles. When the water was saturated with ester, a second liquid phase formed, consisting of transparent droplets of ester. These readily dissolved the solid phase if such had been formed. The last reading of the buret before appearance of the droplets was used for the computation of the solubility.

The end-point of this titration was improved by the following modification. Instead of adding the Sudan IV to the ester, one to five mg. of it is put into the water. The ester is run into the water drop by drop. The dilute solution, shaken frequently, assumes a pink color. When saturation is reached, one additional drop will suffice to convert the floating jagged indicator particles into dark transparent droplets.

In the case of the more soluble esters, a slightly larger amount of Sudan must be added. With less soluble homologs, the accuracy can be enhanced by using larger volumes of water.

The influence of trifling amounts of Sudan is as negligible in regard to the solubility to be measured as that of indicators on the stoichiometric relations in ordinary acidimetric procedures.

Solubility of Ethyl Esters of Mono- and Dicarbonic Acids.—This method was applied to the ethyl esters of the homologous series from propionic to capric acid and from malonic to sebacic acid. Most of these esters were supplied by the Eastman Kodak Laboratories, some were synthesized in our laboratory and all were purified by repeated distillation under reduced pressure. Their purity was checked refractometrically. The specific gravity had to be determined in the monocarbonic series above ethyl caprylate and the refractive indices above ethyl valerate; the refractive indices of the propionate and butyrate were redetermined. Our refractive indices for the dicarbonic esters tallied with those given by

Karvonen;[5] the specific gravities of these esters were taken from this author.

The molecular refractions derived from our observations according to the Lorentz–Lorenz formula agreed throughout with the theoretical values calculated from Eisenlohr's atomic refractions.[6] The theoretical value for ethyl propionate is 27.15, for laurate 68.70, for diethyl malonate 37.83 and for sebacate 70.16. The corresponding experimental figures (Tables I and II) are: 27.0, 68.8, 37.9 and 70.0.

[5] Karvonen, *Ann. acad. sci. Fenn., [A]10,* No 5, 12 (1916).

[6] Eisenlohr, *Z. physik. Chem., 75,* 585 (1910).

molecular weights, would yield a straight line if there was a geometric decrease of solubility.

The graph for the dicarbonic esters shows an irregularity between malonate and succinate. Further on, it follows a regular course with a sharper decrease of solubilities above azelate.

The solubility of the monocarbonic esters shows a slightly sharper decrease than that of the dicarbonic ones. A zig-zag in this series is caused by the relatively higher solubility of the esters with an odd number of carbon atoms. This oscillation may be observed up to pelargonate while the figure for the very slightly soluble caprate does not harmonize, probably because of the limitations of accuracy in this range.

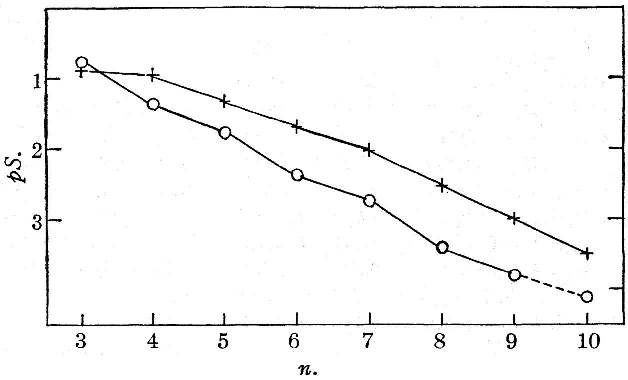

Fig. 1.—Solubility of ethyl esters of monocarbonic acids (○) and of dicarbonic acids (+) in water at 20°: *n*, number of carbon atoms; *pS*, − $\log_{10}$ of normality of saturated solution.

The solubility of the ethyl ester of a monocarbonic acid with *n* carbon atoms is between the solubilities of the diethyl esters of the dicarbonic acid with (n + 1) and that with (n + 2) carbon atoms.

Summary

1. A simple and inexpensive method is presented for the determination of the solubility in water of sparingly soluble liquids.

2. Complete data are given for the solubility at 20° of the ethyl esters in the monocarbonic series below capric (decanoic) acid and in the dicarbonic series below sebacic acid. The refractive indices of the monocarbonic esters were also determined.

THE RELATION BETWEEN THE RELATIVE STRENGTHS OF ACIDS IN TWO SOLVENTS

BY J. O. HALFORD[1]

RECEIVED MAY 26, 1931 PUBLISHED AUGUST 5, 1931

The expression, the strength of an acid, is frequently used in referring to either of two quantities between which a distinction should be made. In the general sense, the strength of an acid is a measure of its intrinsic tendency to lose protons, independent of the interference of a solvent. This property eludes specific evaluation. More frequently, the expression refers to a measured value in some solvent, expressed quantitatively on an arbitrary scale of proton potential, such as the P_H scale of aqueous solutions. We are concerned here not with acid strength in the general sense, but rather with a procedure by which to express the position of an acid on an arbitrary scale of strengths in one solvent in terms of its position on a similar scale in another.

Several years ago, Brönsted[2] made the statement that "Absolute comparison of the strengths of two acids or two bases is impossible because it requires the absence of any solvent medium." In other words, the three molecular species involved in the characteristic equilibrium of dissociation are affected differently and specifically by transfer from one medium to another, and the measured relative strength of two acids is, in general, dependent upon the solvent as well as the characteristics of the acids. For convenience, we may say that two effects require consideration when we compare the acidities of a series of substances in two solvents. The one, which involves the relation of the P_H scales, or their equivalent, we avoid by selecting these scales arbitrarily; the other is an irregular variation of relative strengths.

The dissociation of the three types of acids most frequently encountered may be represented by the equations

$$HA'' = A^- + H^+ \qquad (1)$$
$$HA^* = A + H^+ \qquad (2)$$
$$HA^- = A^{--} + H^+ \qquad (3)$$

The first includes the substances usually classed as weak acids, the second applies to acids of the type of ammonium ion and the third to the second dissociation of a polybasic acid. We may refer to these classes as different valence types. It is evident that in going from one solvent to another of different dielectric constant, the relative strength of two acids of different valence types will be considerably changed. For example, Reaction 1, in

---

[1] Alfred H. Lloyd Fellow in the Graduate School, University of Michigan.

[2] Bronsted, J. *Phys. Chem.*, **30**, 777 (1926).

which the ions appear only on one side of the equation, should be much more sensitive to the dielectric properties of the medium than Reaction 2, in which a singly charged positive ion appears on each side.

In the comparison of reactions of any one type, we find relative strengths fairly concordant, as in the summary by Hall[3] of reactions of type 2 in glacial acetic acid. However, minor variations occur, even within one valence type, and Hall's results indicate that they are usually within one pK unit.

Considering valence type 1, we find, in the measurements of Michaelis and Mizutani[4] in ethyl alcohol, water and their mixtures, that similar variations of relative strength occur, again of the order of one pK unit. The fact that these variations are small is ascribed by Hammett[5] to the circumstance that a solvent which is better for the free acid is also better for its salts. This is equivalent to a statement that the reaction of the ion A^- to forces other than those concerned with the ionic charge and its distribution is not greatly different from that of the free acid HA.

The relation between the ionization equilibria of an acid in two solvents and the distribution coefficients of the acid and its ions has been considered in detail by Bjerrum and Larsson.[6] They have employed solubility measurements in the evaluation of the distribution ratios of the ions. In this way, they have expressed the relation between the dissociation constants in two solvents in terms of the solubilities of the acid and its salts.

If we accept the importance of placing a large number of acid strengths on the same scale, such a relation becomes necessary, for it is improbable that we shall be able to make the required number of measurements in any one solvent. For example, acids which are classed as strong in water show differences in glacial acetic acid, while water is the better solvent for bringing out the differences between the stronger bases. In the selection of a solvent for the study of a given series of acids or bases, two main factors must be considered. The first is that the substances shall be sufficiently soluble to permit accurate measurement, and, if a potentiometric method is to be used, the solubility requirement also applies to the salts of the substances under investigation. The second requirement is that the solvent shall be sufficiently sensitive to variations of strength of the magnitude to be measured. The amphiprotic type of solvent is best suited to measurement, and it is this type which, because of its ability to reduce markedly the apparent strength of strong acids and bases, per-

[6] Bjerrum and Larsson, *Z. physik. Chem.*, 127, 358 (1927).

mits the narrowest range of application. In order to place the desired number of measurements on a comparative scale, more than one solvent, probably at least three, will be necessary, if the requirements of solvent power and range of application are to be met. Further, since at present we have no good reason for preferring one scale to another, it becomes desirable to compare results on several scales.

We present here a derivation of the relation between acid strengths in two solvents, in a form which, in our opinion, is more convenient than that of Bjerrum and Larsson. The concept of ion distribution coefficients is not directly involved. The following equations apply to valence type 1. Consider the dissociation constants, K_1 and K_2, of an acid in two solvents, distinguished by the subscripts 1 and 2.

Equation	ΔF	
$HA\text{(standard)} = HA_{(1)}$	$-RT \ln a_1$	(a)
$HA_{(1)} = H^+_{(1)} + A^-_{(1)}$	$-RT \ln K_1$	(b)
$HA_{(2)} = HA\text{(standard)}$	$RT \ln a_2$	(c)
$H^+_{(2)} + A^-_{(2)} = HA_{(2)}$	$RT \ln K_2$	(d)
$H^+_{(1)} = H^+_{(2)}$	B	(e)
$MA(s) = M^+_{(2)} + A^-_{(2)}$	$-RT \ln \sigma_2^2$	(f)
$M^+_{(1)} + A^-_{(1)} = MA(s)$	$RT \ln \sigma_1^2$	(g)
$M^+_{(2)} = M^+_{(1)}$	C	(h)

Since the sum of these equations is zero

$$RT \ln (a_2/a_1 \times K_2/K_1 \times \sigma_1^2/\sigma_2^2) = -(B + C) \qquad (4)$$

$$\frac{a_2\, K_2\, \sigma_1^2}{a_1\, K_1\, \sigma_2^2} = \text{constant} \qquad (5)$$

Here a_1 designates the activity, in solvent 1, referred to the usual standard state at infinite dilution, of the acid HA, when at equilibrium with HA (standard). For moderately soluble solid acids, this is approximately equal to the solubility. MA is the salt of the acid with the positive group M, and Equations f and g imply that the activity methods commonly employed with strong electrolytes are applicable. The quantity a is the mean activity of the ions, M^+ and A^-, in the saturated solution of the salt MA, the activity again so defined as to approach the concentration at infinite dilution. For slightly soluble salts, σ^2 is approximately equal to the solubility product. The quantity $B + C$, by which the constant of Equation 5 may be evaluated, should be the same for all acids of type 1. This is probably best determined by measurement, for at least one acid, of the other quantities in the equation. Also, it is directly related to the difference between the distribution coefficients, expressed logarithmically, of the ions H^+ and M^+.

Similar equations may be developed for each of the other types of dissociation equilibrium. We give here the result for type 2, representing the dissociation of such acids as ammonium ion

$$RT \ln (a_1/a_2 \times K_2/K_1 \times \sigma_2^2/\sigma_1^2) = -(B + D) \qquad (6)$$

$$\frac{a_1 K_2 \sigma_2^2}{a_2 K_1 \sigma_1^2} = \text{constant} \qquad (7)$$

Here *a* refers to the free base A, and a to the salt AHX, so that D applies to the work of transfer of the ion X^-. *C* and D have opposite signs, and the constants of Equations **5** and 7 are different. However, the corresponding equation for type ***3*** contains the same constant term as that for type 1. In order, then, to correlate the scales of two solvents for a number of acids involving all three valence types, it will be necessary to evaluate independently the constant terms of Equations **5** and 7.

These equations impose no restriction on the method of setting up the scale of acidities or *P*H values in any one solvent. Equations b and d imply that the scales are to be developed in the manner in which the PH scale of aqueous solutions has been established, so that the pK of an acid is equal to the negative logarithm of the dissociation constant. However, the appearance of the constant term in Equation ***5*** removes this apparent restriction. This is clearer if we examine the logarithmic form of the equation, employing the symbol pK, as defined above.

$$\log \frac{a_2 \sigma_1^2}{a_1 \sigma_2^2} + pK_1 = pK_2 + \text{constant} \qquad (5')$$

It is evident that either pK_1 or pK_2, or both, may be altered by the addition of an arbitrary constant, without interference with the validity of the equation. Such an alteration is equivalent to the use of an arbitrary PH scale. However, it will probably be most convenient, when circumstances are favorable, to employ the scale similar to that of aqueous solutions, in which the simple relation between pK and the dissociation constant is retained.

The shift of relative strength of two acids, in going from one solvent to another, is entirely a function of the quantities *a* and a. From Equation 5', for two acids, it follows that

$$\Delta pK_2 - \Delta pK_1 = \log \frac{a_2 \sigma_1^2}{a_1 \sigma_2^2}(\mathrm{A}) - \log \frac{a_2 \sigma_1^2}{a_1 \sigma_2^2}(\mathrm{B}) \qquad (8)$$

where A and B refer to the two acids compared, and $\Delta pK = pK(\mathrm{A}) - pK(\mathrm{B})$ in either solvent. In the first approximation, the calculation of the variation of relative strength is independent of the actual values of acid strength in either medium. However, the accurate evaluation of the activity of the undissociated part of the acid may require knowledge of its dissociation constant.

The above equations are exact if a and a are interpreted as activities. However, a useful approximation may be introduced by assuming that solubilities, when sufficiently low, may be employed to replace the activities. We have carried out this approximate calculation for several acids and their silver salts, in water and in 50% alcohol by volume, at 24 ± 1°. The solubility data have been taken from various sources. Where data on the free acids were lacking, we have obtained them by weighing the residue from evaporation of samples of the saturated solutions. The solubility of silver salicylate was determined as residue from evaporation, that of the other silver salts by titration of the saturated solutions with ammonium thiocyanate to a ferric thiocyanate end-point.

The results are summarized in Table I. The first column shows the acid, the second its solubility in water corrected for dissociation, the third its solubility in 50% alcohol, used without correction, the fourth and fifth the solubility of the silver salt in water and in 50% alcohol. Concentrations are expressed as moles per liter. The sixth column shows the quantity on the right side of Equation 8, the shift of acid strength relative to salicylic acid. The last column gives the corresponding measured value, taken from the following paper.[7]

TABLE I

DIFFERENCE OF STRENGTHS, RELATIVE TO SALICYLIC ACID, IN WATER AND IN 50% ALCOHOL BY VOLUME, AT 24 ± 1°

Acid	a_1	a_2	σ_1	σ_2	Diff. of rel. strength Calcd.	Measd.
Acetic	....	...	0.0670	0.0180	−0.20	0
Benzoic	0.0264	0.918	.0115	.00763	+ .56	0.5
Salicylic	.0142	.552	.0069	.0092	*0*	0
o-Nitrobenzoic	.0278	.898	.0291	.0204	.46	.5
α-Naphthoic	.00040	.0388	.00405	.00440	.60	.6

In the calculation for acetic acid, a_2/a_1 was taken arbitrarily as unity. The values in the last column, which were obtained by combining known relative strengths in water with measurements in 50% alcohol with the antimony electrode, may be in error by as much as 0.2 unit.

The writer is grateful to Professor James B. Conant, who suggested this problem and contributed valuable advice.

Summary

Equations which connect the relative strengths of acids in one solvent with those in another by means of solubility data, or their equivalent, have been discussed. Some applications to acids in water and in 50% alcohol are presented.

SOME EFFECTS OF HYDROCARBON GROUPS ON THE STRENGTH OF CARBOXYLIC ACIDS

BY J. O. HALFORD[1]

RECEIVED MAY 26, 1931 PUBLISHED AUGUST 5, 1931

In the preceding paper,[2] the quantitative relation between relative strengths of acids in different solvents has been discussed. The relative strength of two acids has been found, in general, to vary from one medium to another. The magnitude which this variation can attain becomes important, particularly to the organic chemist, for it determines the limits within which measurements of acid strength may be interpreted as truly characteristic of the acids. It has been useful, in correlating the properties of organic compounds, to consider the effect of substittitions and structural modifications on acid strength, to know, for example, how the dissociation varies through an homologous series, or how it is changed by the substitution of one group for another within the molecule. The use, for this purpose, of acid strengths measured by our present methods, involves the assumption that they evaluate a property of the acids. The variation of relative strength with the solvent shows that acid strength, as measured, depends on the solvent as well as the acid. It follows that the variation of acidity through a series of substances cannot be expressed in terms of other measured properties, such as distances between atoms, without taking into account the specific nature of the interaction of substance and solvent.

However, it should not be concluded that acid strengths, measured in one solvent, are entirely without significance in the correlation of the properties of series of related compounds. There can be little doubt that trichloroacetic acid is intrinsically stronger than acetic acid, or that phenol is weaker than benzoic acid. Our problem, then, is to decide what minimum difference of measured acidity may be interpreted as indicating a characteristic difference between the acids compared, or what is the maximum value of the uncertainty introduced by the irregular character of the solvent effect. An idea of the magnitude of this quantity can be obtained by measuring the strength of a sufficient number of acids in several solvents.

As an addition to the available experimental data, we have measured the strength of a number of acids, including some which are not readily studied in water because of low solubility, under conditions which permit the comparison of a relatively large number of substances. Following Michaelis and Mizutani,[3] we have employed 50% ethyl alcohol by volume

as solvent in some of the measurements, partly for the purpose of checking our procedure against theirs. However, we have given more attention to a solvent containing 60% by volume of butyl carbitol (diethylene glycol mono-butyl ether) and 40% of water. This solvent was selected because butyl carbitol–water solutions have somewhat more general solvent power than the corresponding alcohol–water solutions. For example, a solution of myristic acid and potassium myristate, each at a concentration of 0.0025 N, shows a precipitation in 50% alcohol, but does not come out of the butyl carbitol–water solution until the butyl carbitol content is reduced below 20%. The butyl carbitol content may be as high as 80% without serious interference with electrometric measurement. The selection of the 60% solution is arbitrary, but this figure is in the neighborhood of the optimum for high solvent power and ease of measurement.

Experimental

Procedure.—All measurements were made at 23 ± 1°. In order to examine the applicability of a titrimetric method, a set of titration curves was obtained, using the antimony or quinhydrone electrode against a saturated aqueous calomel cell. Having demonstrated in this way the greater reliability of the antimony electrode, it was adopted for the determination of acid strength. To obtain a measure of the strength of an acid, two solutions were made up, the one containing acetic acid, the other the unknown, each at a concentration of five millimoles per liter. To provide conductance, and standardize the salt effect, all solutions were 0.1 molal in lithium chloride. Each acid was then half neutralized with potassium hydroxide. The acetate buffer was introduced into the cell with the antimony electrode, and the potential against a saturated aqueous calomel cell determined. The procedure was repeated with the buffer of the unknown acid, followed by a repetition with the acetate buffer. In this way the electrodes were checked against previous measurements, and chance variation of electrode behavior directly following a determination was guarded against. Stirring was employed, but with the antimony electrode this was always gentle enough to prevent mixing large quantities of air through the solution.

Electrodes.—The hydrogen, antimony and quinhydrone electrodes were tested. None of these proved entirely satisfactory, at least by comparison with the precision attainable in aqueous solutions. The hydrogen electrode was too readily poisoned in the solutions containing butyl carbitol, the average life of those tried being about fifteen minutes. The quinhydrone electrode was better, but extraneous effects which cause small variations in water tend to introduce large errors in the mixed solvents, and it was difficult to obtain reproducibility within 20 mv. It was found possible to prepare sets of platinum electrodes by slightly different methods, such that satisfactory agreement within each set could be obtained, but large differences between different sets appeared. When used for the purpose of measuring equivalent weights, which depends on the sharpness of the break at the point of equivalence, the quinhydrone electrode was entirely satisfactory.

The antimony electrode, in the form of sticks of the metal, gave the most reproducible results. Regardless of age or previous treatment, it was exceptional to find two electrodes which differed by more than 2 mv. or failed to reproduce measurements by more than 5 mv. This statement applies to the measurement of acid strength by means of buffered solutions. We have no explanation of the behavior of these electrodes in titrations. The titration curves up to the point of equivalence were entirely satisfactory, but thereafter a drift back toward the initial readings set in, partially masking the break. However, the same electrodes gave good results, before or after such titrations, when used with buffered solutions in either the acid or alkaline range.

The experience of others[4] with the antimony electrode in aqueous solutions indicates that in the form of sticks it does not give the correct reversible potentials. However, it should be satisfactory in comparative work. In changing from water to a water–alcohol system, the potentials of the antimony electrode cannot be expected to follow those of the hydrogen electrode, for the latter is independent of the water activity, except for its influence on the hydrogen-ion activity, while with the former, water enters into the electrode reaction. If a given buffer in water shows a considerable difference of potential against the same buffer in 50% alcohol with hydrogen electrodes, a smaller potential should be observed with antimony electrodes. The difference between two buffers at constant water concentration, however, is practically the same with the two electrode systems.

Cells.—The cells were of the same type as those employed by Conant and Werner,' with a saturated potassium chloride–agar bridge, except that the junction from the bridge to the calomel cell was not stoppered. Antimony electrodes were suspended by copper or platinum wires.

Butyl Carbitol.—Commercial butyl carbitol was allowed to stand over lime for several days, then distilled at a pressure of 30 mm. No difficulty was experienced in obtaining a large fraction boiling within one degree, a 90% recovery from the commercial product being readily attained. This purification was made because the solvent, when mixed with water, was frequently 0.001 to 0.002 molar in an acid of about the strength of acetic acid. Even the purified solvent, when mixed with water and allowed to stand for several days, showed slight acidity. Apparently the acid was formed only in the solutions containing water, for the anhydrous solvent could be kept at least for several weeks without deterioration. Consequently, butyl carbitol–water solutions were made up shortly before use.

Acids.—The acids were mainly Eastman Kodak Co. products. Melting points of most of them are recorded in Table I. Stearic acid, a sample of unknown origin, gave the correct equivalent weight within one per cent. An attempted purification of tridecylic acid, which melts twelve degrees below the value given in "International Critical Tables," produced no increase of the melting point.

Results

Titrations with the Antimony Electrode in 60% Butyl Carbitol.—In order to obtain sufficiently sharp end-points with the antimony electrode it was necessary to employ acid concentrations of 0.05 to 0.1 molal, titrated with 1.0 molal potassium hydroxide. The results of several such titrations are plotted in Fig. 1, with potential as the ordinate against the function $\log(X/1 - X)$ as abscissa, where X represents the fraction of the acid neutralized. The slope of the lines is slightly higher than that obtained in aqueous solutions. Stearic acid was titrated at a smaller concentration, because of its low solubility. The order of the curves is the

same as in water, with the exception of benzoic acid, which in the water scale lies half-way between formic and acetic acids.

Titrations with the Quinhydrone Electrode in 60% Butyl **Carbitol.**—In Fig. 2 are shown the results of a number of titrations with the quinhydrone electrode. In this case, to show the character of the end-point, the potential is plotted as a function of the volume of standard alkali. The breaks are sharper, for the weaker acids, than those obtained with water as solvent.

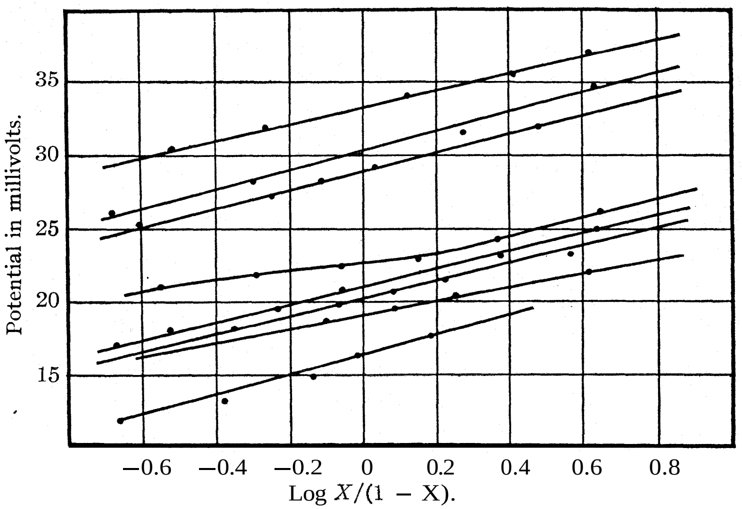

Fig. 1.—Titration curves with the antimony electrode in 60% butyl carbitol. 0.05 M acids titrated with 1.0 M KOH. In order, from the top, stearic, benzoic, acetic, formic, salicylic, chloroacetic, malonic, dichloroacetic (stearic acid at 0.005 M, titrated with 0.1 M KOH).

Strength of Acids.—In Table I the results of the determination of comparative strengths are summarized. The first column shows the acid, the second and third the melting point, measured and taken from "International Critical Tables,"[6] the fourth the *pK* value in water from the same source and the fifth the potential in volts, against a saturated aqueous calomel cell, of the half-neutralized solution of the acid in 60% butyl carbitol, as measured with the antimony electrode. The sixth column shows the strength, in *pK* units, on a scale in which the *pK* of acetic acid is arbitrarily taken as zero. The rate of change of potential with *P*H in water was determined with several electrodes to be 54 mv. per *P*H unit. The values of column six were obtained on the assumption that 54 mv. corresponds to one PH unit in the mixed solvent as well. Columns seven and eight are similar to five and six, for 50% alcohol.

Effect of Salt Concentration.—Before attempting to interpret these results, it is desirable to obtain some idea of the effect of total salt concentration on the measurements of acid strength. It is possible that the variation of relative strength between solvents, as measured, might be to some extent the result of irregular variations of the effect of total ionic strength. In the measurements an ionic strength of 0.1025 was maintained by means of lithium chloride. We have measured the relative strength, in 60% butyl carbitol, of acetic, myristic and benzoic acids, at ionic strengths from 0.0025 to 0.1025, with the result that, within the limits of error of the procedure, the total salt concentration introduces no uncertainty if it is constant through the series of measurements. Figure

3 illustrates the effect. For convenience, the curves are drawn to coincide at zero ionic strength. The coordinates are e. m. f. against the square root of the ionic strength. A small differential effect, about 0.1 *pK* unit, is observed, but this may not be real, since the probable error of measurement is of the same order of magnitude- If this quantity was applied as a correction to the relative strength of benzoic acid, its position with respect to acetic acid would deviate still further from that in water. In the working range the curves are nearly horizontal, showing that the potentials are not sensitive to small variations of lithium chloride concentration.

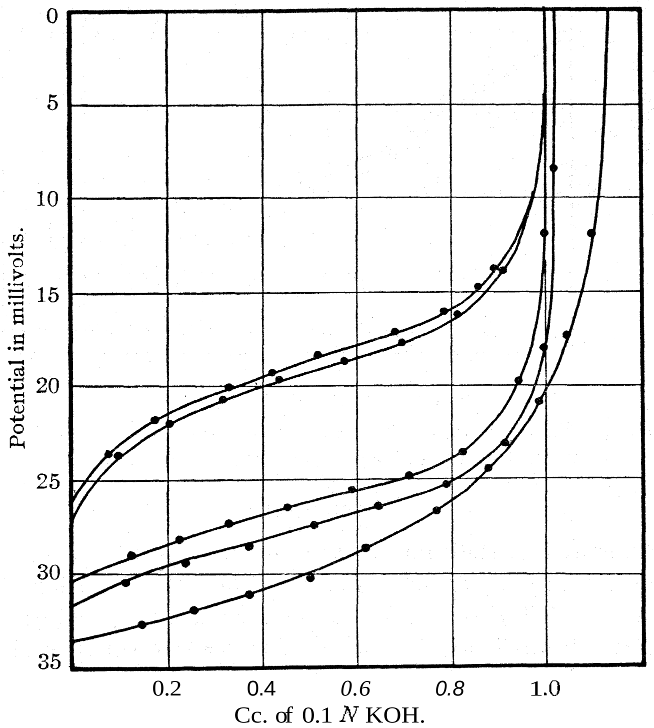

Fig. 2.—Titration curves with the quinhydrone electrode in 60% butyl carbitol. 0.005 M acids titrated with 0.1 M KOH. In order, from the top, acetic, benzoic, o-nitrobenzoic, chloroacetic, dichloroacetic.

Other Sources of Error.—The liquid junction between the aqueous calomel cell and the solution of the half-neutralized acid in the mixed solvent introduces an uncertainty of unknown magnitude. The junction potential should cancel out, in the evaluation of relative strength, if it remains constant in the separate measurements. We have attempted to minimize this error by employing a saturated potassium chloride bridge, and using the same initial acid concentration at all times. The high mole fraction of water in the mixed solvent should produce a tendency toward small junction potentials.

The variation of the potential between successive measurements of the same system is a second source of error. This variation, which is due to the antimony electrode, has been canceled, in part, by frequent measurements of the standard acetic acid system. The total error of measurement should be less than 0.2 *pK* unit.

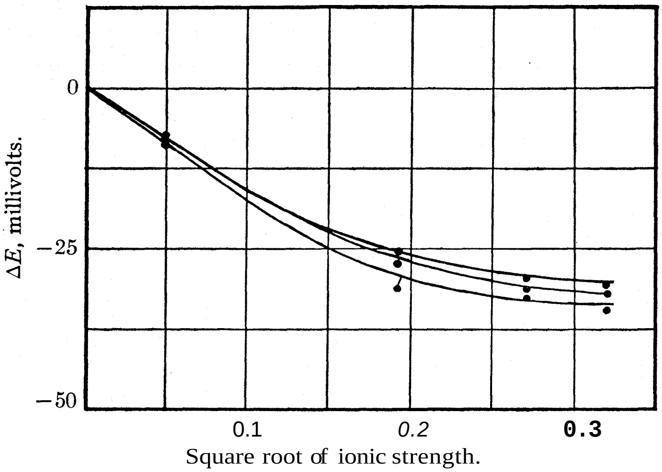

Fig. 3.—Effect of total salt concentration on apparent strength. In order, from the top, acetic, myristic and benzoic acids.

Discussion

We are indebted to Hall[7] for an excellent bibliography of measurements of acid strength in non-aqueous solvents. Since the variations of relative strength, as recorded by others, are of the same order of magnitude as those given here, the discussion will be sufficiently general if it is confined to the data of Table I.

The largest variation is that recorded for a-naphthoic acid, which in water is stronger by one *pK* unit than acetic, but in 60% butyl carbitol is weaker by 0.1 unit. Similarly, benzoic acid in water appears stronger by 0.6 unit than acetic acid, in 50% alcohol their strengths are equal, and in 60% butyl carbitol benzoic acid is the weaker by 0.3 unit. A similar variation is shown by *o*-nitrobenzoic acid. We are therefore unable to decide as to which of the three acids, benzoic, acetic and a-naphthoic, is intrinsically the strongest. Consequently, no specific deduction can be made concerning the relative positive or negative character of the methyl, phenyl and a-naphthyl groups. o-Nitrobenzoic acid appears in every case to be stronger than acetic acid, but we cannot say, within wide limits, how much stronger it is.

---

[7] Hall, *Chem. Rev.*, ***8***, **191** (1931).

Any general statement about the uncertainty which variable relative strength introduces into the interpretation of measured acid strengths is based on insufficient data. However, it appears dangerous, at present, to draw conclusions about the intrinsic properties of acids from measured relative strengths which differ by less than one *pK* unit, or a factor of ten in the dissociation constant. This means that the specific nature of the solvent effect introduces an uncertainty of that magnitude. Any deductions which can be made are essentially qualitative. The effect of future data on this conclusion will be, of course, to change the magnitude of the uncertainty. The most probable change is an increase. However, when the rather abnormal properties of water are considered, it is possible that future measurements may show that, by omitting aqueous values from consideration, a more specific set of relations may be deduced.

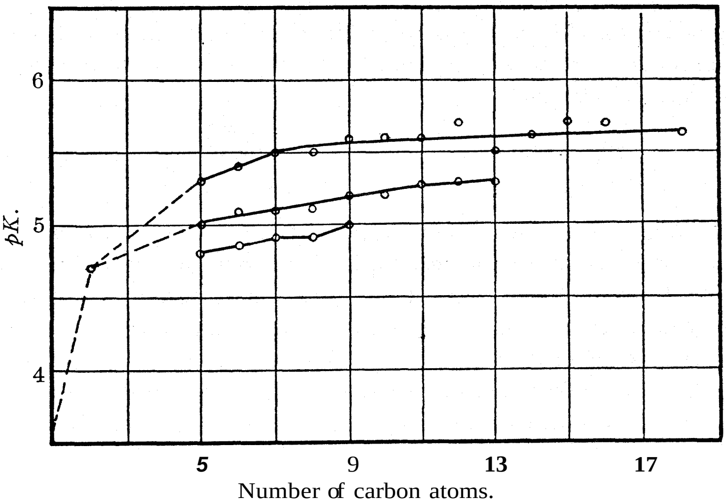

Fig. 4.—Strength (*pK*) of normal aliphatic acids as a function of the number of carbon atoms. Upper curve, 60% butyl carbitol; middle curve, 50% alcohol; lower curve, water.

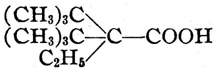
An interesting case arises in the comparison of acetic and chloroacetic acids. Regardless of the magnitude of the measured relative strength, we should feel justified in concluding that chloroacetic acid is the stronger because of the much greater strength of trichloroacetic acid.

Normal Aliphatic Acids.—In Fig. 4 the strength relations of the normal aliphatic acids in water, 50% alcohol and 60% butyl carbitol are plotted as a function of the number of carbon atoms. The curves are drawn to coincide at the point which gives the strength of acetic acid in water. The maximum difference, the relative strength of the higher fatty acids in 60% butyl carbitol, falls just within our limit of interpretation. The conclusion is, therefore, that, within this limit, all the normal aliphatic acids (except formic acid) have the same strength. However, this does not exclude the possibility that stearic acid may be weaker than acetic by one *pK* unit.

If it is assumed that the curve for water is analogous to the others, the *pK* value of stearic acid in water may be estimated as about 5.2. This quantity probably cannot be checked by direct measurement. Any mixture of water, stearic acid and sodium stearate will show much greater alkalinity because of the low solubility of the acid. The mixed solvents appear to increase differences which occur in aqueous solution.

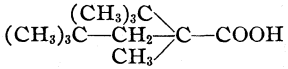
Branched Aliphatic Acids.—The measurements with isovaleric, isocaproic and methylethylacetic acids are inconclusive. However, it is improbable that such closely related substances are very differently affected by the solvent, and the measured values should be significant within rather narrow limits. Trimethylacetic acid is probably weaker than valeric.

The acids B and G, obtained from Mr. G. W. Wheland of this Laboratory, are isomers of lauric acid, and may be represented provisionally by the following structures



$$\left.\begin{matrix}(CH_3)_3C\\ (CH_3)_3C\\ C_2H_5\end{matrix}\right>C-COOH$$

B



$$\left.\begin{matrix}(CH_3)_3C\\ (CH_3)_3C-CH_2\\ CH_3\end{matrix}\right>C-COOH$$

G

The more highly branched B acid appears weaker than lauric acid, in the mixed solvents, by about one *pK* unit. The corresponding figure for the G acid is 0.6 unit. It is interesting to attempt a comparison of the three acids, acetic, lauric and B. Our limit of interpretation makes indefinite the comparison of either of the pairs, lauric and B acid, or lauric and acetic, but permits the conclusion that the B acid is definitely weaker than acetic acid. This means that either lengthening or branching the chain produces a definite weakening effect, but does not decide which of the effects is real. The probable answer is that both are significant.

Aromatic Acids.—The introduction of aromatic hydrocarbon radicals into acetic acid produces no effects large enough to be considered significant. Salicylic and o-nitrobenzoic acids are definitely stronger than benzoic acid.

The writer wishes to express his sincere appreciation of the advice and assistance of Professor James B. Conant, who suggested this problem.

Summary

The relative strength of thirty-one carboxylic acids in a solvent mixture containing, by volume, 60% of butyl carbitol and 40% of water, has been measured with the antimony electrode.

The significance of the variation of measured relative strength with the solvent has been considered, with the conclusion that a measured relative strength less than one *pK* unit, or a factor of ten in the dissociation constant, does not necessarily indicate a difference of intrinsic acidity. Future measurements in solvents other than water may increase this uncertainty.

Aromatic hydrocarbon radicals, when introduced into aliphatic acids, produce no measurable change of acidity.

Either the lengthening or the branching of the hydrocarbon chain in the aliphatic acids produces a definite weakening effect. Probably both effects are real.

A POTENTIOMETRIC STUDY OF WURSTER'S RED AND BLUE

BY L. MICHAELIS

RECEIVED JUNE 3, 1931 PUBLISHED AUGUST 5, 1951

In a rather large number of cases there have been found compounds intermediary, with respect to the level of oxidation, between a compound of the quinoid type and one of the hydroquinoid type. In a previous paper[1] it could be shown by a potentiometric method for three organic dyestuffs of the oxyphenazine series, that this intermediary compound is a molecule of the same size as either the holoquinoid form or the hydroquinoid form and differs from the hydroquinoid only by one oxidation equivalent (or hydrogen atom or electron). It must be considered as a radical-like compound with an odd number of electrons. Those three dyes offered a particularly favorable opportunity for the proof of such a statement because the intermediary compounds were very stable and permitted a thorough potentiometric study of the system, there being no drift in the potentials in time. The conclusions were based on observations of systems in a true thermodynamical equilibrium and therefore were scarcely liable to a misinterpretation.

This observation suggested the idea that other examples of half-reduced quinoid substances might be accessible to a similar potentiometric analysis. The difficulty in most of these cases is the fact that these intermediary compounds are as a rule not very stable in aqueous solution but undergo irreversible reactions and so cause a drift of the potentials. An attempt to utilize the potentiometric method for such a purpose was made by Clark, Cohen and Gibbs,[2] who studied the so-called meriquinones formed from aromatic diamines. They took for granted the current idea that these intermediary compounds are meriquinones according to Willstatter's[3]

definition as being molecular compounds of the holoquinoid and the hydroquinoid form.

For some years an increasing number of papers has been published advocating the formula of a free radical in such cases in which formerly double molecules were supposed to exist. In some of these cases an equilibrium between the free radical and its polymeric saturated form was assumed. This holds for instance for Gomberg's triphenylmethyl and for Wieland's biphenylnitride. In other cases the existence of the free radical without its polymerized form was assumed. This holds, for instance, for the case of the aromatic diamines, the subject also of this paper. Weitz and Fischer[4] showed by determination of the boiling point in solutions of such compounds that only the formula of a free radical is compatible with the data observed. A thorough compilation of the whole subject has been published by Weitz[5] in which many other examples are enumerated. Yet never has a potentiometric method been applied for the proof of such a contention. Such a method may not be applicable for every case, but in those cases in which it can be used this method is much superior to any other. All those assumptions with respect to incomplete dissociation which have to be considered in order to correct the boiling or freezing point data for electrolytes do not appear in the potentiometric method. This method whenever it is available may be considered as the best method for the determination of a molecular weight for an ionic compound.

The potentiometric analysis presented in this paper was suggested by, and is based on, a set of half-quantitative, preliminary observations which will first be described. These observations hold for asymmetric dimethyl-p-phenylenediamine and tetramethyl-p-phenylenediamine. There is no doubt that the method can be extended to other substances of this type but as we have to deal with very labile systems, each of these cases should be studied separately and may require long experimentation before a definite understanding is attained. Therefore this study will be restricted to the two substances mentioned.

When either of the two mentioned diamines is titrated with an oxidant such as bromine or chlorine, a deep color is developed, called Wurster's red in the case of the dimethyl compound and Wurster's blue for the tetramethyl one. When the titration is performed rather rapidly and farther extended, the color disappears again. When, after reaching the point of color discharge, the solution is allowed to stand, the color gradually turns back, though not to its maximum intensity, at a rate largely dependent on concentration and PH. The spectroscopic analysis shows that it is the same substance which reappears, as recognizable from the characteristic

---

[4] Weitz and Fischer, *Ber.*, *59*, 432 (1926).

[5] Weitz, Z. *Elektrochem.*, 34, 538 (1928).

double band, which differs in Wurster's red and blue only by the spectral location of the two bands. It should not be asserted, however, that the return of the color is due only to the reappearance of Wurster's red or blue. According to the conditions other dyes may or may not be developed besides.

The interpretation of this phenomenon is this. Wurster's red or blue differs from the mother substances, the respective diamines, only by one oxidation equivalent (or hydrogen atom, or electron) as Willstatter and his co-workers[3] have shown long ago. The disappearance of the color in the second step of titration indicates that the dye is oxidized to a higher level which has practically no, or very little, color. One might expect this substance to be the second step of oxidation, analogous to diiminoquinone, and very likely it is. But these substances are extremely labile, as Willstatter has shown; in aqueous solution they spontaneously undergo irreversible changes and are converted into substances to which we must attribute a great inclination to still further oxidation. So these secondary substances will reduce those molecules of the diiminoquinone still present in the solution, to Wurster's red (or blue) over again. From these rough observations we may expect that the second half of the titration is characterized by a very labile system which at no point of the titration is in any chemical equilibrium within reasonable time. So we may expect that even in the best case only in the first half of the titration steady potentials might be established.

This is exactly what happens. When during the titration the potential at a blank platinum electrode is read, there are sufficiently constant and reproducible potentials in the first half of the titration. This holds at least for a certain range of PH. The most suitable PH for constant potentials proved to be 4.6 for both substances. In the second part of the titration no constant potentials can be obtained under any condition. The potentials always drift back to the negative side as though the oxidized form (the diiminoquinone) would spontaneously and irreversibly disappear in time. When the second half of the titration is performed rather hastily, the potential will stay within a small, not very well reproducible, range and the end of the titration will sometimes be indicated by a sudden though often not very big jump, which, however, drifts back at a rate depending upon the conditions, such as the time required for the whole titration, the number of steps in which the whole titration had been subdivided and the pause between the successive steps. The color vansihes simultaneously with this potential jump and, on standing, reappears, simultaneously with the back drift. If it happens that no jump of the potential appears, no complete discharge of color will be observed either.

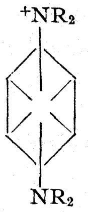
Thus the end-point of the first step of titration can, with a fair approximation, be recognized by the fact that the potentials, which were constant up to this point, begin to drift; and the end of the second step can be recognized, provided the titration in the second step is rapidly performed, by the point of coincidence of potential jump and transient discharge of color, if there is such a point at all. The amount of oxidant used for each of the two steps turns out to be the same, within the limits of error in such a labile system.

A theoretical analysis of the titration curve is, therefore, not difficult for the first half of the titration, but impossible at the present time for the second half. When the titration curve of the first step is analyzed, it turns out to be the curve for a regular reversible oxidation–reduction system, and the difference between the reduced and oxidized form turns out to be only one electron. It is very important to add that the mid-point potentials E_0 of this step of oxidation for different experiments, at the same PH, coincide, independently of the initial concentration of the diamine.[6] Hereby it is proved that Wurster's red or Wurster's blue differs from its particular diamine only by one electron, without any change in molecular size and that it is not a meriquinone according to Willstätter's definition, namely, a compound of one or several molecules of the holoquinoid form with one or several molecules of the completely reduced form. These two dyes, Wurster's red and blue, therefore are of the type of a half-reduced quinone, or semiquinone, a molecule with an odd number of electrons. We may also say that one of the two nitrogen atoms is bivalent as in Wieland's biphenylnitride. In contrast, however, to these biphenylnitrides, or to Gomberg's triphenylmethyl, the unsaturated radical-like compound does not seem to undergo to any measurable extent a polymerization to a double molecule in which the state of unsaturation is abolished. This radical-like compound in aqueous solution of a PH around 4.6, is, though not strictly stable, yet a fairly stable substance, provided there is no excess of oxidant which can oxidize it partly to a higher level. If this is the case, the whole system becomes unstable, and the radical-like compound will partake in the chemical processes which go on with greater or less rapidity. The radicals do not combine with each other to form double molecules or with the original diamine to form quinhydrones, but they undergo condensation or other reactions with the other molecules in the solution, especially with the very unstable substances which are on the oxidation level of diiminoquinones.

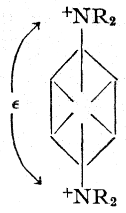
In formulating radicals of the described kind one may accept a point of view proposed already by Weitz, which is best presented in this way. In the static Formula I, where R is either a methyl group or hydrogen, it is indicated that one amino group has one electron less than would correspond to an electroneutral state.

---

[6] As to significance of the independence of E_0 of the initial concentration, see Ref. 1.



I



II

This static model should be replaced by a more dynamic one (Formula II). One electron has a circuit around both N atoms, or the two nitrogen atoms share one electron. This, then, is a chemical bond consisting in one shared electron, instead of the two in the ordinary chemical bond of G. N. Lewis.

Experimental

The purest commercial grades of the hydrochlorides of dimethyl-*p*-phenylenediamine and of tetramethyl-p-phenylenediamine (preparations of Eastman) were recrystallized by dissolving in methyl alcohol and precipitating with benzene. A suitable amount of the crystals was dissolved in deaerated water, and *a* suitable portion added to 15 cc. of acetate buffer of PH 4.62 (solution 0.1 normal both with respect to sodium acetate and acetic acid). A freshly prepared solution of bromine was used as oxidant, in such a concentration that 1 to 2 cc. was used to the complete titration of the first step. The titration was performed in a constant temperature chamber at 30° in a stream of nitrogen purified over copper at 450°, though this precaution might not have been imperative in working on such relatively positive potential ranges as we have to deal with here. Three blank platinum electrodes were immersed in the solution. Whenever the potential was steady it was observed for all three electrodes, without there ever being a difference of more than 0.1 millivolt. As soon as the potential began to drift, in the progress of titration, the readings had to be hastened and according to the circumstances only one electrode was used for the potential readings. In the diagrams all potentials, constant over a reasonable time within one or two tenths of a millivolt, are marked with plain circles. For all potentials with a drift the direction of the drift is indicated by an arrow. The short arrows indicate a drift of some tenths of a millivolt per minute; the long arrows indicate a drift of several millivolts per minute. The drawn out curves are those calculated according to

$$E = E_0 + 0.0601 \log \frac{X}{A - X}, \text{ volts}$$

where E_0 is a constant, X the amount of bromine solution in cc., and A that amount of bromine solution used up at the end of the first reversible step of the oxidation. The value of A was determined by the following three methods.

1. The first method is only roughly approximate and cannot be applied in every case; it can only be used when the second step of titration is performed within a few seconds without reading the potentials except for the very last part. This method can only be applied when the end of the second step of titration can be recognized by a transient complete discharge of color and a transient jump of the potential. These two phenomena coincide. On account of the unavoidable secondary reactions during the second half of titration even on rapid titration, the observed end-point, if there is one at all, will always come a little later in the curve than where the theoretical end-point should lie. If such an end-point can be recognized, one may assume that the amount of oxidant at this end-point is approximately equal to, or, more precisely speaking, is somewhat greater than, 2 *A*.

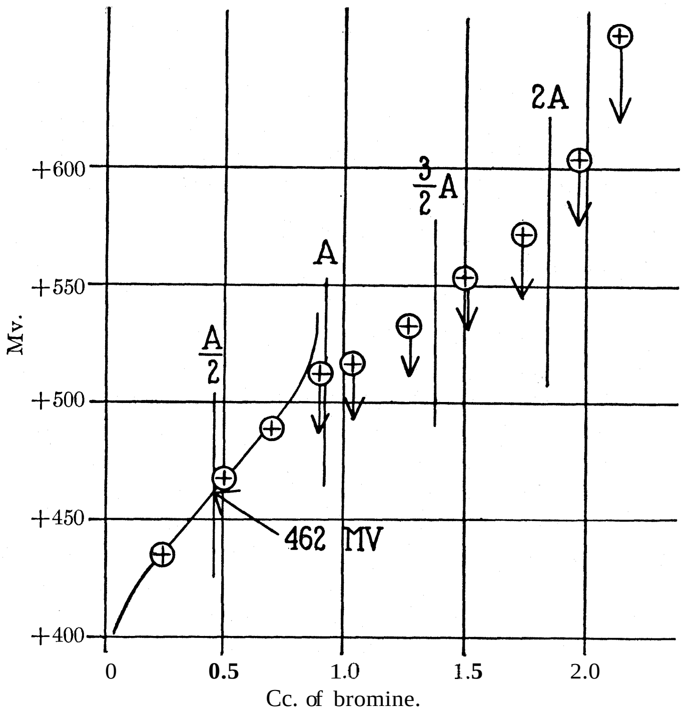


Fig. 1.—2×10^{-4} mole of dimethyl-*p*-phenylenediamine hydrochloride dissolved in 20 cc. of acetate buffer of PH = 4.62 (a solution 0.1 molar both for sodium acetate and for acetic acid) is titrated at 30 °C. with an aqueous solution of bromine. Abscissa, cubic centimeters of bromine. Ordinate, potentials, in millivolts, referred to the normal hydrogen electrode. Arrows signify drift of potential. Potentials without arrow are stable. A is the total theoretical amount of bromine used for the complete oxidation to the level of the semiquinone.

2. That point of titration where the previously steady potentials become inclined to a backward drift, can in the first approximation be taken as the value of A. This method, also, is an approximative one, because a little overlapping of the two steps of titration takes place. The correction of the true value for A lies in such a direction that the first drifting potential must occur somewhat before, but never after, the theoretically required amount, *A*, of the oxidant has been added. The result of this method agreed with that of the first within the limits to be expected, namely, that the first method furnished always a somewhat higher value for *A* than the second. The true value of A may be estimated as lying between those obtained with the first and those obtained with the second method.

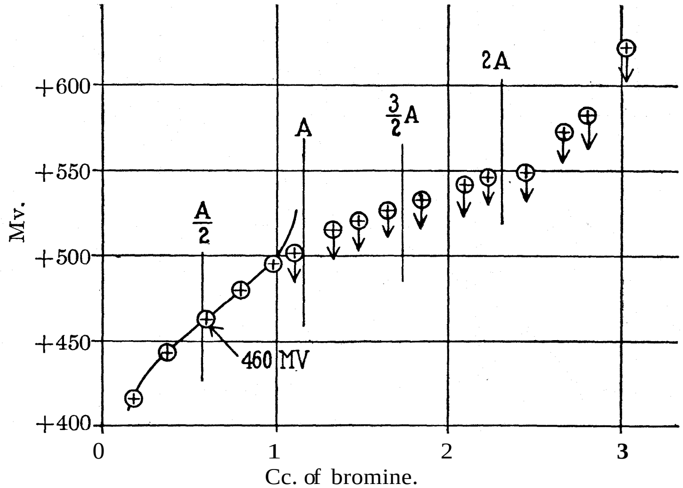

Fig. 2.—4 X 10^{-5} mole of dimethyl-*p*-phenylenediamine hydrochloride dissolved in 20 cc. of acetate buffer titrated with a bromine solution. Designations the same as in Fig. 1.

3. After the value of A had been evaluated approximately by one or both of these two methods, a correction was applied in the following way. By a graphical method of trial and error a value of A was chosen which furnished the best fitting curve for the first half of the titration where the potentials show no drift. It was postulated that there exists some value of *A* that will furnish an entirely fitting curve, and that this value of A should be very close to the one obtained with the two other methods, the deviation lying in the expected direction. This postulate was fulfilled in every case.

So the final and definite method is the third one, and the two others were only used to show that the value, A, obtained with this method can be shown, in suitable cases, to be compatible with those values which might have been approximately determined by the two others.

In any event, the third method furnished a theoretical curve which. except for the very end of this curve, for understandable reasons, fitted perfectly with the observations, and which furnished E_0 values agreeing satisfactorily for different experiments even on varying the initial concentration in the ratio 1:10. There is, then, every justification for utilizing these curves for an interpretation based on thermodynamical considerations.

There is a slight difference between the two amines with respect to the third method. In the tetramethyl compound the overlapping of the first and second steps of oxidation is somewhat greater than in the dimethyl compound. This is recognizable by the relatively earlier beginning of the drifting part of the curve. This disadvantage is, however, compensated by the fact that the potentials of the tetramethyl compound, before the drifting part of the curve begins, are even more stable than for the dimethyl compound. The tetramethyl compound, during the first, not drifting, part of the curve, can be titrated with the same leisure as any good reversible system; furthermore, even when the drift begins, this drift is so slow (within some tenths of a millivolt per minute) that the uncertainty of the potential value may lie only within one millivolt. Here the drift does not cause so much a time distortion of the curve, but

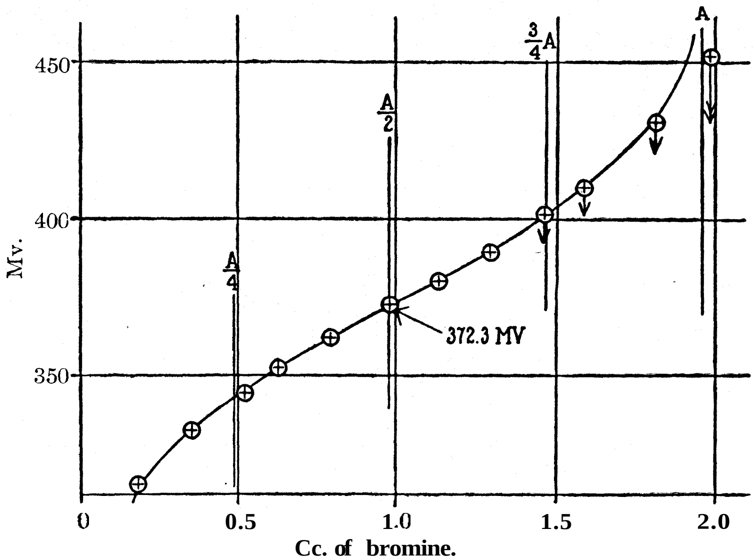

Fig. 3.—1.0 × 10^{-5} mole of tetramethyl-*p*-phenylenediamine hydrochloride dissolved in 15 cc. of acetate buffer and titrated with bromine. Designations as in Fig. 1. The short arrows signify a drift of the potential of about 0.1 millivolt per minute; the long arrow, a drift of several millivolts per minute. Potentials without arrow are perfectly stable.

rather shows the beginning of an overlapping and marks that part of the curve beyond which the potentials can no longer strictly obey the simple formula calculated for *a* one-step oxidation without overlapping.

These E_0 values must be considered as being strictly indicative of a free energy level of the system, and from the shape of the curve it can be decided with safety which one of the two reactions

$$\text{1 mole reduced form} \rightleftharpoons \text{1 mole oxidized form} + \epsilon \qquad (1)$$

(Wurster's red as semiquinone)

$$\text{2 moles reduced form} \rightleftharpoons \text{1 mole oxidized form} + \epsilon \qquad (2)$$

(Wurster's red as meriquinone)

(ϵ is one electron) takes place. The first of these two possibilities, then, is found to be the correct one.

Two titration experiments are shown for dimethyl-*p*-phenylenediamine graphically in Figs. 1 and 2. The initial concentrations differ in these two cases in the ratio 1:5, the greater one being 0.01 molar. Two experiments are shown for tetramethylphenylenediamine, one as a graph (Fig. 3) and another in the form of Table I. The initial concentrations in these two experiments differ in the ratio 1:7.5, the greater one being 0.003 molar.

Summary

It is shown by mathematical analysis of the potential curve obtained by oxidative titration with bromine that Wurster's red and Wurster's blue are not molecular compounds of one molecule of a quinoid type with another molecule of a hydroquinoid type, but true semiquinones, *i. e.*, radical-like compounds intermediary between quinone and hydroquinone and of the same molecular size as each of these two. Such a compound must possess an odd number of electrons. One may express the situation

by saying that the two nitrogen atoms of the dye are linked by a chemical bond which consists of a single electron instead of a pair.

NEW YORK, N. Y.

[COMMUNICATION NO. 64, EXPERIMENTAL STATION, E. I. DU PONT DE NEMOURS AND CO.]

THE REACTION BETWEEN OXYGEN AND ACETYLENE IN THE PRESENCE OF NITROGEN OXIDES

BY SAMUEL LENHER

RECEIVED JUNE 4, 1931 PUBLISHED AUGUST 5, 1931

Comparatively little work has been done on the catalyzed oxidation of the simple hydrocarbons. Study of the slow combustion of acetylene[1] led to isolation of the intermediate compounds, glyoxal, formaldehyde, and formic acid, and indicated the probable steps in the reaction. As the influence of a homogeneous catalyst is to lower the temperature at which measurable reaction begins, and thus to increase the stability of the partially oxidized products, study of the effect of gas catalysts in oxidations promised to give further information on the course of reaction.

The present investigation was a study of the effect of nitric acid vapor and its decomposition products on the slow thermal oxidation of acetylene. The oxides of nitrogen have been used repeatedly in the partial oxidation of the hydrocarbons.[2] It was assumed in these papers and patents that the action of the nitrogen oxides was catalytic, that is, that the nitrogen oxides were not destroyed in the reaction. This assumption was not directly tested, although Frolich, Harrington and Waitt[2f] stated that in the oxidation of methane with nitrogen peroxide and oxygen the loss of nitrogen peroxide by complete decomposition to elementary nitrogen was of the order of 1% per pass, and Bibb and Lucas[2g] indicated in an experiment that nitric acid was consumed in the oxidation of methane. It appears now from a recent paper by Smith and Milner[3] that in the partial oxidation of methane in the presence of nitrogen oxides the nitrogen oxides are consumed in the reaction and that their action cannot be considered catalytic. The writer has found in an investigation of the oxidation of ethylene, which will be communicated shortly, that nitrogen oxides react chemically with ethylene at the temperature of the slow oxidation reaction and that their action is not one of catalysis.

The catalytic action of nitrogen oxides in gaseous oxidations must be that of an active oxygen carrier which is alternately reduced in the reaction and oxidized by oxygen, or which can initiate long reaction chains from one primary reaction.

Experimental Results

The oxidation of acetylene in the presence of nitrogen oxides was studied by the flow method at atmospheric pressure. Oxygen and acetylene at a regulated rate of flow were mixed in a capillary at the entrance of the reaction vessel. Oxygen from a commercial cylinder was used without further purification. Acetylene (Prest-O-Lite) was passed through two spiral wash-bottles containing water to remove acetone and was dried with calcium chloride. Nitric acid vapor was introduced into the gas mixture by passing the oxygen through a wash-bottle containing 100 cc. of 90% nitric acid containing only 0.046% nitrogen peroxide. The concentration of nitric acid in the gas was controlled by the vapor pressure of the acid.[4] The temperature of the acid was kept constant to ±2° with a water-bath. The cylindrical Pyrex reaction vessel, 20 mm. in diameter, was heated in an electric tube furnace. Reaction temperatures were read by means of a chromel–alumel thermocouple in a thin-walled glass tube in the center of the vessel.

The reacted gases passed through a U-tube cooled in solid carbon dioxide–methanol mixture, and a spiral wash-bottle containing a standardized barium hydroxide solution to absorb carbon dioxide, and were collected in a water gasometer. The gas was analyzed as described by Kistiakowsky and Lenher (Ref. 1a, p. 3786). The organic products condensed in the cooled U-tube were practically negligible as determined by oxidation with standard potassium dichromate in strong sulfuric acid and back-titration with sodium thiosulfate. The U-tube contained appreciable amounts of nitric acid and nitrogen oxides, and in many experiments drops of inky blue nitrogen trioxide (N_2O_3) were seen. The organic acid content could not be determined because of the nitric acid. Quantitative analysis of the aldehyde content was not possible because of the very small amounts of both glyoxal and formaldehyde. Accordingly, after several tests showed that less than 3% of the acetylene went to formic acid and formaldehyde, the contents of the U-tube were omitted from further quantitative analysis. A solid deposit was formed in the exit tube of the reaction vessel at the end of the furnace. The amount of this deposit was determined by weighing. This deposit showed the general physical properties of trimeric glyoxal.[5] Monomeric glyoxal was prepared from a sample of one gram of

---

[5] Beilstein, "Handbuch der organischen Chemie," Julius Springer, Berlin, 1918, 4th ed., Vol. I, p. 759.

the deposit by heating it with phosphorus pentoxide[6] in a small distilling flask with a condenser cooled to −78°. On warming the flask the green vapor of glyoxal which condensed in the receiver to fine yellow needles was noted.

A weighed sample of the solid glyoxal product from several experiments was dissolved in 20 cc. of warm water. Thirty cc. of 50% acetic acid solution of *p*-nitrophenylhydrazine was added and thesolution was allowed to stand for thirty-six hours. The precipitate of the nitrophenylhydrazones was filtered on a small Biichner funnel, washed with warm 10% sodium carbonate solution and water, dried in powder form and weighed. The weighed precipitate was then extracted for two hours at room temperature with dry chloroform to dissolve the *p*-nitrophenylhydrazone of formaldehyde, and was then filtered, dried and .weighed. The weight of phenylhydrazones in one experiment was 0.6533 g. before treatment with chloroform and 0.6319 g. after extraction, which showed that the precipitate was 96.7% the di-*p*-nitrophenylhydrazone of glyoxal, whose melting point was 302°. The precipitate gave the characteristic Bamberger test of a blue coloration with alcoholic potassium hydroxide. The weights of glyoxal given in Table I are the actual weights of the solid deposit from the reaction on the assumption that the deposit was trimeric glyoxal.

A gas mixture containing equal volumes of acetylene and oxygen was used. The rate of flow of each gas was 0.05 cc. per sec., corresponding to an average time of contact of 180 seconds for the 30-cc. vessel at an average

temperature of 230°. One hundred and eighty cc. of acetylene–oxygen mixture was used. The nitric acid wash-bottle in the oxygen line was kept at 0° until the furnace was at the desired temperature and the gas flow was adjusted; then the acid was warmed to the temperature of the experiment. From Table I it is seen that the main products of the reaction are glyoxal and carbon monoxide with smaller amounts of carbon dioxide, hydrogen and water.

These experiments show that the principal reaction product is glyoxal, for the glyoxal recovered corresponds to 50–60% of the acetylene oxidized.

Experiments with a different time of contact and with different gas mixtures are given in Table II.

230	4 1	45	50	50	...	Explosion		

The rate of reaction in the presence of nitrogen oxides appears to depend on the concentrations of acetylene, oxygen and nitrogen oxides, as shown by the experiments with air and with different amounts of nitrogen oxides in Table I and with low acetylene concentrations and the same concentration of nitrogen oxides in Table II. The rate is not dependent on the square of the acetylene concentration, as in the uncatalyzed reaction,'" and the reaction is not retarded by an excess of oxygen or air.

In the above experiments with 4% of nitric acid in the gas mixture, reaction was observed below 170° by the formation of the solid deposit of glyoxal and the formation of carbon dioxide. Experiments carried out above 250° using over 2% of nitric acid vapor in the gases resulted in explosions. The sensitivity of gas containing nitric acid vapor varied with the time of contact; for example, numerous runs were made at 230° with times of contact from 90 to 180 seconds, but increasing the flow to give a time of contact of about forty-five seconds brought about explosions which shattered the reaction vessel. Dixon[7] observed that a lower ignition temperature was obtained when a gas mixture was passed rapidly into a hot tube than when the tube was gradually heated while the gas mixture was passing through it. It may be that the phenomenon noted here is caused by a lowering of the ignition temperature as observed by Dixon.

---

[7] Dixon, *Rec. trav. chim.*, 44, 305 (1925).

A number of experiments were carried out to see if nitrogen peroxide in small amounts lowered the explosion temperature of acetylene-oxygen mixtures as it did the explosion temperatures of hydrogen–oxygen mixtures[8] and of carbon monoxide–oxygen mixtures.[9] A 1 acetylene–1 oxygen mixture was used containing from 0.010 to 0.45% of nitrogen peroxide. Only the slow thermal reaction was observed in the range 260–315°. As a 1 acetylene–1 oxygen mixture exploded frequently at 325° and always at 340°, it was concluded that small amounts of nitrogen oxides (below 0.5%) did not lower the explosion temperature or the temperature range of the slow oxidation reaction.

Examination of the solid reaction product and the contents of the cooled trap by the sodium fusion test gave no evidence that the nitrogen oxides had entered into chemical combination, forming organic nitrogen compounds.

The reaction of nitric oxide and acetylene was studied under the conditions of the oxidation experiments in the absence of other nitrogen oxides and oxygen. Nitric oxide, which was stored over water, was passed through the system before the run to sweep out traces of nitrogen peroxide and oxygen. The reaction was tested using a mixture of 1 nitric oxide–1 acetylene with a time of contact of thirty seconds at 260°. No reaction was observed between nitric oxide and acetylene under these conditions; the gases leaving the reaction vessel were colorless, which showed the absence of nitrogen peroxide, there was no formation of carbon oxides, and the washings from the trap cooled to $-78°$ gave no evidence of the presence of organic oxidation products. As nitric oxide does not react with acetylene under the conditions of the reaction between acetylene and oxygen in the presence of nitric acid vapor (and its decomposition products), it was concluded that the nitrogen oxides are not reduced by acetylene beyond nitric oxide in the catalyzed oxidation.

Discussion

The presence of nitrogen oxides in concentrations greater than 0.5% by volume causes a marked lowering of the temperature of the slow thermal reaction between acetylene and oxygen; this lowering is as much as 80° for concentrations of 4% nitrogen oxides. As the rate of reaction is not greatly influenced by a change in the concentration of acetylene or oxygen, and as the rate of oxidation increases with increasing concentration of nitrogen oxides up to 4%, it appears that the rate-determining process is a reaction with a nitrogen oxide. At the temperature of these experiments, nitric acid vapor in the presence of oxygen is partially dissociated into water and nitrogen peroxide. The initial process is probably a reaction of

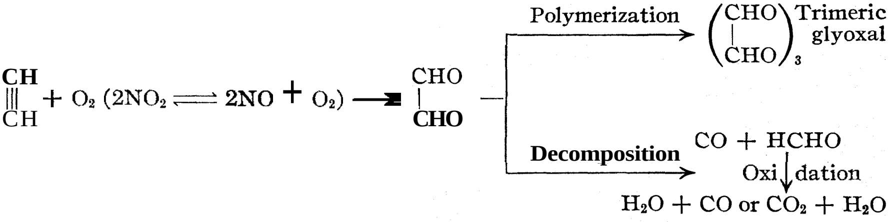
[9] Sagulin and Semenoff, *Chem. Reviews*, 6, 350 (1929).

nitrogen peroxide with acetylene. Acetylene is oxidized with the formation of nitric oxide. This nitric oxide is oxidized by oxygen to nitrogen peroxide. Thus the action of the nitrogen peroxide is one of true catalysis, involving alternate reduction with acetylene to nitric oxide and oxidation of the nitric oxide with oxygen to nitrogen peroxide.

The predominance of glyoxal as a reaction product indicates that its formation is a principal primary reaction. In fact, the yields of glyoxal of 50% or more of the acetylene oxidized suggest that it is the primary product. The occurrence of large amounts of carbon monoxide and of only traces of formic acid, formaldehyde and hydrogen points to the thermal decomposition of glyoxal to carbon monoxide and formaldehyde, $OHC—CHO \longrightarrow CO + HCHO$, as the main source of the carbon monoxide. The formaldehyde may be either oxidized to formic acid, which decomposes to water and carbon monoxide, $HCOOH \longrightarrow H_2O + CO$, or may be oxidized directly to water and carbon monoxide by nitrogen peroxide, $HCHO + NO_2 \longrightarrow CO + H_2O + NO$, in a reaction similar to the primary reaction of nitrogen peroxide with acetylene. The hydrogen and carbon dioxide may come from the decomposition of formic acid, $HCOOH \longrightarrow H_2 + CO_2$. The course of the reaction as shown by these experiments may be given by the scheme



Summary

The reaction between acetylene and oxygen in the presence of nitrogen oxides proceeds between 170 and 250° as a homogeneous reaction catalyzed by nitrogen peroxide. The main product is trimeric glyoxal; the other products are formaldehyde, formic acid, carbon oxides, hydrogen and water.

THE SYNTHESIS OF AMMONIA IN THE LOW VOLTAGE ARC

BY A. KEITH BREWER AND R. R. MILLER

RECEIVED JUNE 5, 1931 PUBLISHED AUGUST 5, 1931

A detailed study of the synthesis of ammonia in the glow discharge[1,2] has shown that the rate of formation is proportional to the current passing through the discharge, and is independent of the pressure between wide limits. The maximum rate of reaction was obtained for a $2H_2$–N_2 mixture.

From these considerations an electrochemical equivalence law was proposed for the glow discharge which is comparable to Faraday's laws for electrolytes. This law is expressed as $dP/dt = \propto \mathbf{I}$, where P is the equivalent ammonia pressure, I the current and $\propto$ a constant. This law has more recently been shown to have a universal application to the glow discharge.

The technique employed was such that a fair estimation of relative reactivities of atoms, excited molecules and positive ions could be made. The results showed that no reactivity could be assigned to active states other than positive nitrogen ions under the conditions of these experiments.

The present research was undertaken to test the following points: (1) Can the electrochemical equivalence law be applied to the low voltage type of arc? (2) Can any significance be given to the fact that a maximum rate was obtained for a $2H_2$–N_2 mixture? (3) What is the relative reactivity of the 16.8 volt nitrogen ion as compared to the 24.5 volt ion? (4) Can the presence of various active states other than N_2^+ ions be detected under conditions where the voltage of the exciting electron can be controlled?

The activation of nitrogen and hydrogen by controlled electron impacts has been studied by several investigators. Kunsrnan[3] obtained no reactivity for electron speeds under 17 volts. Storch and Olsen[4] report synthesis to start at about 15 volts. Their voltage–rate curves showed a sudden break near 23 volts and breaks for every four volts' increase thereafter. Caress and Rideal[5] detected a synthesis beginning at 13 volts with breaks at 17, 23, 30 and 34 volts. From this they assigned the reactive states to be H', N_2^+ and Nf, successively, the breaks at 30 and 34 volts being due to combinations of the lower voltages. Recently

Brett[6] has obtained voltage rate curves which he interprets as indicating breaks at 17, 18.5, 20.5, 24.5 and 27 volts, that correspond to the production of N_2^+, $H + H^+$, $N_2^{+\prime}$, $N + N^+$ and $N' + N^+$, respectively. He observed reactivity in the absence of an applied field. From these observations he assumes the mechanism of synthesis to be the interaction of atomic hydrogen with one or the other of the active states cited.

Apparatus and Method of Procedure

The tube and electrical hook-up used are illustrated in Fig. 1. The capacity of the tube was 300 cc, while that of the McLeod gage and leads was 175 cc. Both two- and three-electrode tubes were tried. The presence of a grid may be a help in the case of simple electron excitation; however, it only introduced complications in the presence of an arc. The results presented in this paper were taken with the two-electrode arc.

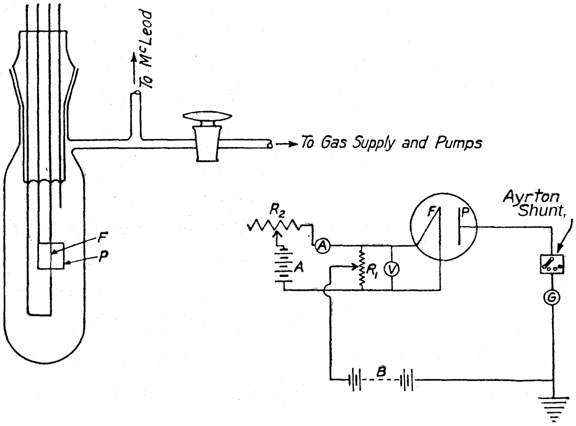

Fig. 1.—Tube with electrical connections.

Several types of filaments were tried, including tungsten, thoriated tungsten and barium and strontium coated platinum. The latter type obtained from the Bell Telephone Laboratories proved the most satisfactory. Most of the filaments were from 1 to 2 cm. in length, although longer filaments were used on occasions. The drop of potential along the filament was usually less than 0.5 volt. All filaments were thoroughly reduced in hydrogen before the experiments were started. The life of a filament was often as long as seventy-five runs with an average length of forty minutes each.

The $3H_2$–N_2 mixture was purified by passing over heated copper and glowing tungsten and through liquid air. Helium was purified by charcoal at liquid air temperature. Spectroscopically pure neon was used directly. The argon was purified by standing in contact with heated calcium for hours.

The method of procedure was essentially the same as that described for the glow discharge. The system was filled to the desired pressure with the gas mixture to be studied. The tube was then immersed in liquid air and an arc was struck between F and **P.** The pressure was thereafter read at regular intervals, usually five minutes; the decrease in pressure with respect to time was taken as the rate of ammonia synthesis. During each run both the current and liquid air level were maintained constant.

Results

The Effect of Pressure.—The influence of pressure on the rate of synthesis for a $3H_2$–N_2 mixture is illustrated by line 1 of Fig. 2. The line is identical to similar time–pressure curves obtained in the glow discharge in that the rate is independent of the pressure over a wide range. The rapid dropping of the rate to zero at some minimum pressure characteristic of the discharge tube is common also to both types of arcs. It will be noted that the rate remains constant to 0.04 mm. pressure while no synthesis could ever be detected under 0.02 mm. with a plate diameter of 1 cm. or less.

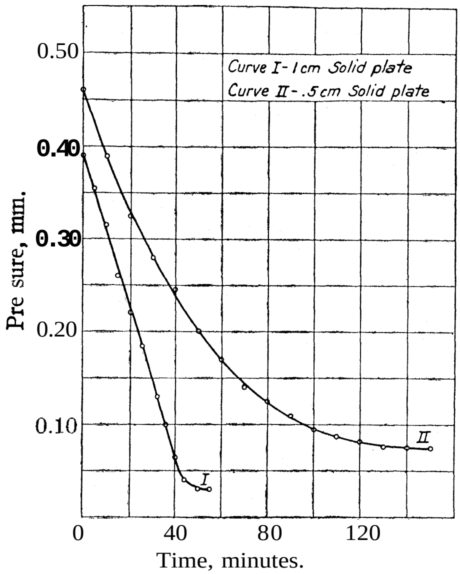

Fig. 2.

The Effect of Current.—The relationship between current and rate is illustrated in Fig. **3.** The low voltage arc is again similar to the glow discharge in that the rate of synthesis is proportional to the current flowing through the arc. The electrochemical equivalence law, $dP/dt = \propto I$, has, therefore, a general applicability to both types of discharges.

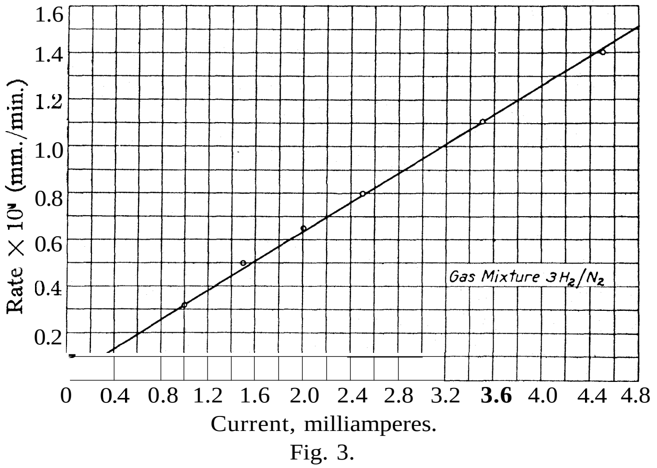

Fig. 3.

The Effect of Voltage.—The effect of varying the applied voltage between the filament and plate on the rate of clean-up is shown in Fig. 4.

The voltages given are not corrected for contact p. d. A direct measurement of the contact p. d. by voltage just necessary to stop electron emission showed the filament to be between 1.5 and 2.0 volts electronegative to the plate depending upon the conditions of the experiment. To obtain the correct voltages, therefore, the values given should be shifted about 1.5 volts to the right or raised by this amount.

These results were obtained with a filament which had been thoroughly reduced and on which over twenty runs had been made before any of the points given were taken. The general contour of curves obtained with new filaments is similar to that illustrated except that the total emissivity changes from time-to-time, tending to give breaks in the curve which in reality are due entirely to variations in the emissivity of the filament. These changes in emissivity are absent in a well worked-in filament.

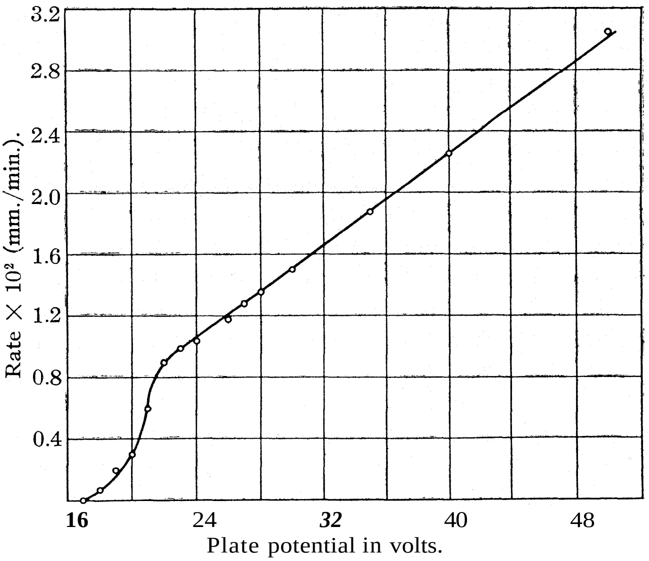

Fig. 4.

It will be seen from the curve that the reactivity at 17 volts is very small, no synthesis being detected at appreciably lower voltages. The rate increases rapidly with potentials between 17 and 23 volts, but thereafter the rate of change is linear over the range investigated.

In some instances a clean-up was detected under 17 volts, but the product frozen out on the walls invariably showed the vapor pressure of water. The clean-up could always be traced to an improperly reduced filament or to oxygen in the $3H_2$–N_2 mixture.

The Effect of the Filament.—The reactivity of a given filament appears to be affected both by its age and its length. Filaments 1 cm. in length gave a faster rate than did those 2 cm. in length, while 8-cm. filaments were even slower. The length of the region over which the arc played was not materially changed by lengthening the filament. It seems possible that the slower rates observed with the longer filaments are due to decomposition of the positive ion clusters on the heated filament. The enhanced rates obtained with old filaments are probably due to the changes in the potential gradient around the filament since it becomes smooth and thin with use; all visible oxide drops off after about fifteen runs and the base metal appears thin and bright.

The Effect of the Plate.—Various types and dimensions of plates were tried. Curve I of Fig. 2 was taken with a solid cylindrical nickel plate 1 cm. in length and 1 cm. in diameter, while curve II was taken with a similar plate except the diameter was 0.5 cm. Tests with several diameters showed that at high pressures the rate was approximately the same irrespective of the diameter. At low pressures, however, the rate decreased with the diameter, while the minimum pressure to which the synthesis could be carried was raised.

An increase in the length of the plate beyond the length of the filament had no appreciable effect on the rate, *i. e.*, Curve I of Fig. 2 would be the same whether the plate was 1 or 2 cm. in length. An increase in length of both the filament and plate apparently decreased the rate, for the reasons stated under the effect of the filament.

Both solid, screen and spiral wire plates were tried. The results were the same at the higher pressures irrespective of the type of plate. At the lower pressures, however, the rate was much more constant for the open plate, *i.* e., an open spiral plate of the dimensions used for Curve II of Fig. 2 gave a line quite similar to curve I. At the high pressures the arc for the spiral wire plates was entirely between the plate and the filament, while at the lower pressure it spread for an appreciable distance through and beyond the plate.

The Ratio of Hydrogen to Nitrogen.—The effect of varying the gas mixture on the rate of synthesis is illustrated in Fig. 5. These results were taken with comparatively new filaments to which the coating still adhered. For this reason the rates are somewhat lower than those given for the old filament in Fig. 4.

It will be seen that the maximum rate occurs in **a** mixture containing 83% nitrogen and 17% hydrogen for both the 19 and 30 volt arcs. In the case of the glow discharge the maximum rate was obtained with a mixture containing 33% nitrogen. The two arcs are similar, in that the rate in both cases is speeded up by excess nitrogen, although the acceleration is much more pronounced in the case of the low voltage arc.

Effect of Inert Gases.—The results obtained when helium, neon and argon are added to a $3H_2–N_2$ mixture are illustrated in Fig. 6. The rates in each case were measured at 0.3 mm. pressure, hence this point is taken as 100% added gas.

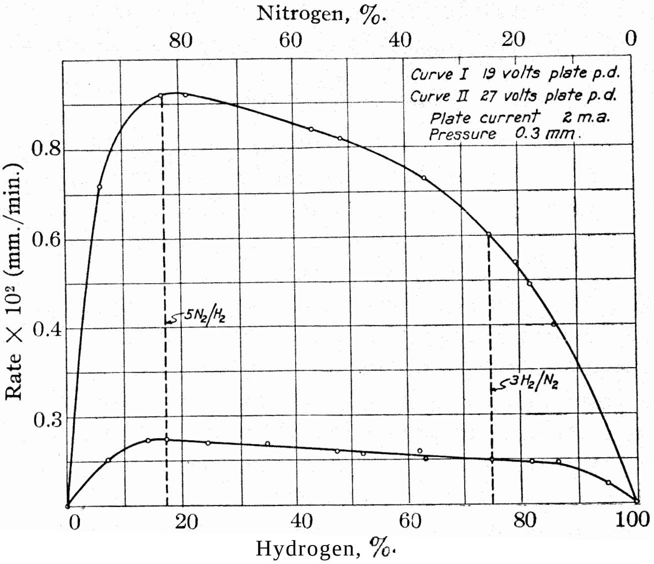

Fig. 5.

The helium and neon results could be duplicated without trouble, while argon, on the other hand, had a peculiar effect on the filament. After a run had been made with argon present, the rate for a pure $3H_2$–N_2 mixture

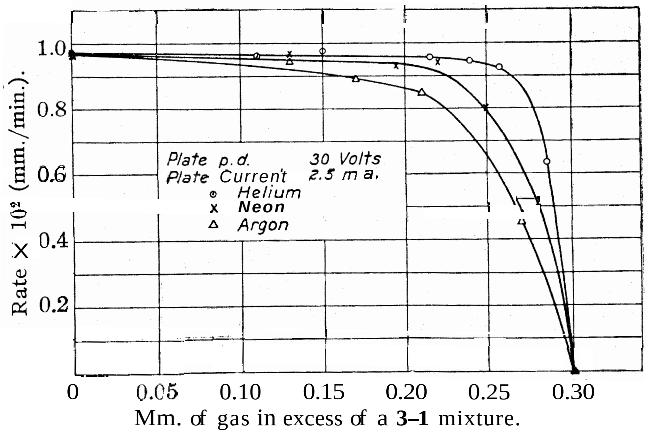

Fig. 6.

might be as much as twice that usually obtained; it returned to normal in the course of two or three runs in the absence of argon. For this reason the argon curve probably does not represent constant arc conditions.

The curve for helium is very similar to that obtained in the glow discharge, in that it shows no appreciable effect on the rate until the amount present is more than 80%. Argon in the glow discharge, however, slowed down the rate of reaction almost in proportion to the amount present.

Discussion of Results

The results just given are strikingly similar in nature to those presented previously for the glow discharge, in that the rate of synthesis (1) is proportional to the current flowing through the discharge, (2) is independent of the gas pressure over a wide range; and **(3)** is accelerated by excess nitrogen and retarded by excess hydrogen.

The similarities just mentioned necessitate the assignment of the same reaction mechanism to the two types of arcs. The fact that the electrochemical equivalence law ($dP/dt = \propto I$) holds for the low voltage arc is definite proof that the reaction is initiated by ions formed in the discharge, since the rate of production of atoms and excited molecules is neither proportional to the current nor independent of the pressure.[7]

Recent experiments in the glow discharge[8] have furnished direct proof that the oxidations of hydrogen, methane and carbon monoxide take place around positive ions formed in the discharge. Since the present reaction is similar in every respect, the mechanisms of reaction are evidently identical.

A comparison of line 1, Fig. 2, with similar lines for the glow discharge[2] shows that the synthesis may be carried to a much lower pressure in the low voltage arc, *i. e.*, 0.02 mm. for the arc as contrasted with 0.1 for the glow. This difference results from the fact that the life of an N_2^+ ion is much longer in the low voltage arc due to the absence of high fields driving ions to the electrodes and to the walls. The N_2^+ ion, therefore, is capable of making many more collisions with hydrogen molecules at a given pressure before becoming neutralized.

The acceleration in the rate of synthesis by the addition of excess nitrogen to the combining mixture, as shown in Fig. 5, is even more pronounced in the low voltage arc than in the glow discharge. This is again evidence in favor of the contention that the reaction is initiated primarily by N_2^+ ions and that H_2^+ ions are comparatively inert. The reason for the more pronounced effect of excess nitrogen in the present case lies in the fact, just pointed out, that the longer life of the N_2^+ ion enables the necessary collisions with hydrogen molecules to be made even when the partial pressure is very low.

The relationship between voltage and rate, as shown in Fig. 4, is a still

[7] Lowe, *Trans. Roy. Soc. Canada,* 20, 271 (1926); *Hughes* and *Skellett, Phys. Rev.,* 30, 11 (1927); *Crew* and *Hulbert, ibid.,* 29, 843 (1927); 30, 124 (1927).

[8] *Brewer* and Kueck, *J. Phys. Chem.,* 35, *1281* (1931); 35, 1294 (1931).

further proof that the reaction is initiated by N_2^+ ions, since no reactivity was detected under the ionization potential of nitrogen.

The present voltage–rate curves are in agreement with the results obtained by Kunsman[3] for electron bombardment in that no reactivity was detected under the ionization potential of nitrogen. Wansbrough-Jones[9] also obtained very similar results for the oxidation of nitrogen in the low voltage arc. The interpretation given his results is in complete agreement with that presented for the synthesis of nitrogen dioxide in the glow discharge.[10]

The results reported by Brett, however, are materially different from those presented in Fig. 4, not only in the presence of breaks but also in that he observed a clean-up even at zero voltage. The technique used in the two cases was not the same, which may account for the discrepancies. Brett made runs of but four minutes' duration; we were never able to obtain a temperature equilibrium under five minutes. His observed clean-up under 17 volts may have been due to temperature changes, or to an improperly reduced filament, or to oxygen in the $3H_2$–N_2 mixture. In regard to the breaks observed by Brett we have found that a given filament which has not had long use will be subject to changes even greater than those given. Further, no mention is made of the correction for contact potential, which is between −1.5 and −2.0 volts under the conditions of his experiments. Brett assumed breaks at 24.5 volts although his .curves show near breaks only at 23.5 and 26.5 volts. The break at 23.5 volts is doubtless the one due to the second ionization potential of nitrogen; the other breaks, therefore, must be shifted by a similar amount. In this event the assigning of active states to the possible breaks and the attributing of chemical reactivity to these states is highly speculative.

Calculation **of** M/N Ratio,--The computation of the number of ions formed per electron of current involves uncertainties as to the percentage of the current carried by positive ions, as to the number of positive ions formed per electron, and as to the distribution of ions between the nitrogen and hydrogen. Neglecting the positive ion current, which probably does not introduce an error of more than a factor of two, the total number of positive ions formed per electron of current can be estimated from the data of Langmuir and Jones.[11] The distribution of ions between the two gases can be calculated from the probability of ionization per collision as given by Compton and Van Voorhis[12] and the collision frequency as given by Hughes and Klein.[13]

[12] Compton and Van Voorhis, *ibid.*, 27, 724 (1926).

[13] Hughes and Klein, *ibid.*, 23,450 (1924).

The collision frequencies in nitrogen and hydrogen are of the ratio of 1.92 to 1.00; in a $3H_2$–N_2 mixture, therefore, an electron will make 1.56 collisions in hydrogen for every collision in nitrogen. A total of 1.5 ions for a 100 volt electron in a $3H_2$–N_2 mixture was taken as a standard from which the total number and distribution of ions was calculated from the probabilities of ionization for the various accelerating voltages. The results as computed from Fig. 4 are tabulated in Table I. $M/\text{min.}$ represents molecules per minute, M/e, molecules per electron, N_2^+/e, positive nitrogen ion per electron, and M/N_2^+ molecules of ammonia per nitrogen ion.

TABLE I

COMPUTED RESULTS

Volts	$M/\text{min.}$[a]	M/e	N_2^+/e	M/N_2^+
18	0.1366	0.0145	0.01127	1.288
20	0.5766	.0612	.0487	1.256
22	1.730	.1835	.0816	2.25
30	2.885	.306	.1945	1.57
40	4.350	.462	.345	1.34
50	5.770	.613	.487	1.258

[a] $\times 10^{-17}$.

It will be seen from the table that the M/N ratio rises rapidly to a maximum near the second ionization potential of nitrogen and thereafter decreases slowly with increasing voltage. Below 20 volts the ratio is practically constant.

The increase in rate between 18 and 20 volts is evidently due to an increase in production of N_2^+ ions. The decrease in the M/N_2^+ ratio above the second ionization potential of nitrogen is interesting in that it shows the effect of dissociation of N_2^+ ions on the rate of synthesis. A 24.5 volt N_2^+ ion while showing only a very slight dissociation on the primary impact dissociates into $N + N^+$ upon collision with neutral molecules. Since the N^+ ion is capable of forming but one ammonia molecule while an N_2^+ ion can form two, the decrease in rate is to be expected. This is further evidence for the relative inactivity of neutral atoms.

The value $M/N_2^+ = 2.25$ at 22 volts is evidently high since it is difficult to see how the ratio could exceed two on the basis of any mechanism that can be postulated. The error may be a general one arising from the manner of calculating N, or it may result from an added source of N_2^+ ions found above 18 volts, for instance, the ionization of nitrogen by collision of neutral molecules with the 18.2 volt hydrogen ion.

The Mechanism of Reaction.—The data presented in this paper, as well as correlative data obtained with the glow discharge, show clearly that the reaction mechanism may be divided into two parts: I, the formation of a positive nitrogen ion, and II, the interaction of the ion with neutral hydrogen molecules to form ammonia.

The evidence is definite regarding part I. It indicates that the reactivities of N_2^+ and N^+ are very great as compared to any other possible active state that might be present.

The process by which the ammonia molecule is built up around the positive ion is only indirectly indicated by the data in hand.

The results, on the whole, are entirely in line with the demands of a cluster mechanism, wherein hydrogen molecules are attached to the nitrogen ion. There is no indication of any intermediate compound formation. It seems probable from the *M/N* ratios obtained, that two molecules of ammonia are formed in the cluster about an N_2^+ ion, and one molecule about the N^+ ion cluster. This may be expressed by the equation for the N_2^+ ion

$$N_2^+ + 3H_2 = (N_2H_6)^+ \quad (1)$$

$$(NH)^+ + e = 2NH_3 \text{ (wall or gas phase)} \quad (2)$$

for the N^+ ion

$$N^+ + 2H_2 = (NH_4)^+ \quad (1)$$

$$(NH_4)^+ + e = NH_3 + H \quad (2)$$

It cannot be said that the above mechanism is the only one by which ammonia is formed in the arc. The results show definitely, however, that in the arc where atoms, excited molecules, metastables, and ions of both reactants are present, the reactivity around the nitrogen ions is so rapid that any possible reactivity of the other active states appears negligible in comparison. It is a matter of conjecture whether a mechanism of this type can be carried over to other conditions, such as the interaction of nitrogen and hydrogen on an iron catalyst. However, the possibility exists that the same work may be done by the surface forces in catalysis as is done by the electron in the arc.

The writers are indebted to Dr. C. H. Kunsman for the constructive interest he has taken in this research.

Summary

1. The synthesis of ammonia in the low voltage arc is shown to obey the electrochemical equivalence law, $dP/dt = \propto \mathbf{I}$, derived for the glow discharge, *i. e.*, the rate of ammonia formation is independent of the pressure between wide limits, and is proportional to the current flowing through the arc.

2. Synthesis does not take place for arc voltages under the ionization potential of nitrogen. Between 17 and 23 volts the rate increases rapidly with the voltage, while above 23 volts the increase is nearly linear.

3. A maximum rate of synthesis occurs in a mixture containing **83%** nitrogen. The addition of hydrogen to a $3H_2$–N_2 mixture decreases the rate almost in proportion to the amount of hydrogen added.

4. The effect of various inert gases is discussed.

5. The results are interpreted as indicating that the reaction takes place around N_2^+ and N^+ ions. H_2^+ ions, neutral atoms, and excited molecules are relatively inactive.

6. **A** method of calculating the rate of ion formation, as well as the distribution of ions between the nitrogen and hydrogen, is presented.

7. A ratio of $M/N_2^+ \sim 2$ is obtained below 23 volts (24.5 volts when corrected for contact p. d.). A ratio for $M/N^+ \sim 1$ seems the most probable for the monatomic ion.

8. It is suggested that the reaction goes to completion in a cluster of hydrogen molecules around the nitrogen ions.

VAPOR PRESSURES AND LATENT HEATS FOR THE SYSTEM: $BaCl_2 \cdot 8NH_3$–$BaCl_2$–NH_3

BY LOUIS J. GILLESPIE AND ELI LURIE

RECEIVED JUNE 6, 1931 PUBLISHED AUGUST 5, 1931

Introduction

In the experimental study of the thermodynamic properties of ammonia in gaseous solutions of ammonia and nitrogen[1] the substances $BaCl_2 \cdot 8NH_3$ and $BaCl_2$ were chosen as the materials to be used to avoid the necessity of a semipermeable membrane, because the high ammonia content of the octammine, the high decomposition pressures at temperatures below 50°, as well as the formation by barium chloride of only one ammine, are very desirable properties from an experimental standpoint.

Hüttig and Martin[2] had studied the 0° isotherm of barium chloride and ammonia, and had shown that barium chloride forms only one ammine, the octammine. They also determined the decomposition pressures of the octammine in the temperature range between 0 and —15.5°.

The large deviations of ammonia from the ideal gas law make the equilibrium an interesting one to study, and we have determined the pressures of ammonia in equilibrium with barium chloride and its octammine from 0 to 50°. One of us has recently discussed equations for representing, as a function of the temperature, the decomposition pressure of solid compounds capable of evolving a gas that deviates from the ideal gas law;[3] we have applied to our data the new equations for the pressures and the latent heats.

---

[2] Hüttig and Martin *Z. anorg. Chem.*, **125**, 269 (1922).

[3] **Gillespie,** ***Proc. Am. Amd. Arts Sci*****,** ***66 (No.***3), 153 (1930).

Preparation of Materials.—Liquid ammonia was treated with metallic sodium in a steel vessel. After it had been standing for several months, during which time gas was occasionally drawn off, ammonia was withdrawn and was fractionally distilled three times. After each distillation the ammonia was frozen by means of liquid air and any permanent gas removed by evacuation with a mercury diffusion pump backed with an oil pump. The middle fraction from the distillation was stored in a steel bomb as liquid ammonia.

"C. P." barium chloride was recrystallized from distilled water three times and dried at 110°.

Experimental Procedure and Measurements.—For the determination of the decomposition pressures above three atmospheres an all-steel apparatus was used. About one gram of dry barium chloride was placed in the steel reaction bomb and the entire system was evacuated. The reaction bomb was then connected through the proper steel stopcocks with a liquid ammonia reservoir and the ammine was prepared by causing ammonia to distil over into the reaction bomb. Before measuring the pressure, some ammonia gas was removed from the reaction bomb--enough to insure the presence of barium chloride as one of the phases. The pressures were measured by a piston gage and the temperatures by a platinum resistance thermometer.

The measurements at the lower temperatures and pressures were made using an all-glass apparatus and a mercury manometer. A thermostat of rather large dimensions was necessary in order to keep the temperature constant day and night.

In all cases the temperatures were constant to 0.02°.

The data were taken in three groups, the octammine being prepared separately (though from the same stock of barium chloride) in the three reaction vessels used at 0°, from 7.48 to 19.92°, and from 38.28 to 49.95'. The decomposition pressures are given in Table I in atmospheres, together with those (listed as "calcd. A") calculated by means of the simple equation

$$\text{Log}\, p = -1998.04/T + 7.13333 \qquad (1)$$

where p is the pressure in atmospheres, T is the absolute temperature (t + 273.13), and the logarithm is to the base ten. The percentage deviation is the observed minus calculated, divided by the observed, and multiplied by 100. The average percentage deviation without respect to sign is 0.21%.

In Table II are the decomposition pressures in millimeters of mercury obtained by Hiittig and Martin compared with the results from the same equation. Although the agreement at 0° is good, the divergence at lower temperatures is large, though irregular.

The Smoothing of the Pressures and the Calculation of the Heats.—As is well known, the linear relation between log @ and $1/T$ shown in equation (1) can be justified theoretically if we assume that the gas is an ideal gas, that the change of heat capacity attending the reaction is zero, and that the volume of the solids can be neglected. Gibbs[4] and others have given an equation for the case that the gas is ideal, and the change of heat capacity is not zero (though constant), and the volume of the solids is not zero (though constant). This equation is

$$\log p = A - B \log T - C/T \qquad (2)$$

In the present case the gas is ammonia, which deviates greatly from the ideal gas law, and the pressure rises above eight atmospheres. In such a case the deviation from the ideal gas law should probably be taken into account in the smoothing of the pressures, and is certainly important in the calculation of the heat absorbed in the decomposition of the ammine.

When the ideal gas law is used to calculate the molal volume of ammonia at the temperature and the corresponding vapor pressure of the ammine system, the errors are about 0.9, 2.7 and 7.6% at 0, 25 and 50°, respectively. In the calculation of the latent heat from the Clapeyron equation the error introduced by the use of the ideal gas law for computing the change of volume will be nearly as large. In the use of an equation which assumes the ideal gas law for smoothing the pressures and thus obtaining dp/dT there will be an error, which may be significant even when the linear equation (1) happens to appear satisfactory for the calculation of the pressures.[5]

These considerations apply with more force to the present data than to probably any previous data. Higher decomposition pressures have previously been measured, but not for a gas deviating so greatly from the ideal gas law as ammonia.

As a result of these considerations one of us has recently given general thermodynamic equations for the vapor pressures and latent heats as functions of the temperature, as well as special equations for the case of solids which can evolve a gas.[3] The approximate equations are

$$\log p = \log p_0 - \frac{M(C_p - \bar{c})}{R}\left[\frac{1}{M}\log\frac{T_0}{T} + 1 - \frac{T_0}{T}\right] + \frac{M\lambda_0}{R}\left[\frac{1}{T_0} - \frac{1}{T}\right] + M\left[\frac{\bar{v} - B_0}{RT} + \frac{A_0}{R^2T^2} + \frac{c}{RT^4}\right](p - p_0) \qquad (3)$$

$$\lambda = T\lambda_0/T_0 + \frac{T}{M}(C_p - \bar{c})\log\frac{T}{T_0} - \frac{RT}{M}\log\frac{p}{p_0} - Q\left[\frac{A_0}{RT} + \frac{3c}{T^3}\right](p - p_0) \qquad (4)$$

---

[4] Gibbs, "Scientific Papers I Thermodynamics," Longmans, Green and Co., New York, 1906 and 1928, footnote beginning on page 152.

[5] This statement would not be true, were we dealing with data of infinite precision. But when the precision of the data is limited and can only be judged by their consistency we can find more than one function, which will represent the body of data with practically the same average precision, though they will not represent any given datum with the same precision and the derivatives of the functions will in general differ at any given point. In such a practical case, we need what help can be obtained from rational equations.

In these equations T_0 is an arbitrary standard temperature, in the present case 0°C., p_0 is the corresponding vapor pressure (obtained from a preliminary smoothing of the data in any convenient manner), and λ_0 is the latent heat at the same temperature and pressure. M is the modulus of logarithms, common logarithms being denoted by log. The constants A_0, B_0 and c are the constants of principal importance in the Beattie–Bridgeman equation of state[6] and have for ammonia the values 2.3930, 0.03415 and 476.87×10^4, respectively, the units being liters per mole, atmospheres and degrees centigrade absolute ($T = t + 273.13$).[7] Q is the conversion factor: 24.2122 cal_{15}/liter-atm.[8] T, p and λ are the variable temperature, vapor pressure, and corresponding value of the latent heat, respectively. C_p is the molal heat capacity of the gas and $\bar{c}$ is the partial molal heat capacity of ammonia in the solids (equal to one-eighth of the excess of the molal heat capacity of the octammine over that of the barium chloride),[3] both at the constant pressure p_0. $\bar{v}$ is the partial volume of ammonia in the solids (equal to one-eighth of the excess of the molal volume of the octammine over that of the barium chloride). When equation (3) is applied to data in the manner previously discussed, λ_0 and $C_p - \bar{c}$ will be found in liter-atmospheres, and may be converted into calories by multiplication by Q. In the use of equation (4) it will be convenient to take the heats and heat capacities in calories, and for R the value 1.9869 cal_{15}, except when R occurs in the denominator of a fraction containing a constant of the equation of state, when it should be taken as 0.08206.[9]

Equations (3) and (4) are based on the following assumptions: (1) the equation of state used for the gas is the Beattie–Bridgeman equation in the volume form;[10] (2) the difference of heat capacities $C_p - \bar{c}$ is constant at the pressure p_0; **(3)** the partial molal volume of ammonia in the solids $\bar{v}$ is constant; and (4) terms involving squares and cubes of the pressures p and p_0, arising from the equation of state but not appearing in equations **(3)** and (4), are negligible. Such terms were found to affect the pressure by not more than 0.03% in any instance and to have a negligible effect on the latent heats.

Equation (3) looks more complicated than equation (2), but the difference is largely due to the fact that equation (2) is not in a form suitable for the graphic treatment of data when the coefficient B is unknown.

Equation **(3)** was applied to our data. The quantity $\bar{v}$ was known as

21.53 cc./mole at 25°.[11] The quantities λ_0 and $C_p - \bar{c}$ were treated as adjustable constants and were determined by drawing a straight line as explained in reference **3.** The value found for $C_p - \bar{c}$ is –7.050 cal., which corresponds to a value of $\bar{c}$ of about 16 calories per mole of ammonia in the solids. This appears to be a reasonable value, judging by the value $\bar{c} = 11$ calories per mole found for the system $AlCl_3 + AlCl_3{\cdot}6NH_3$, the only value obtainable from data for ammines reported in "International Critical Tables."[12] The value for λ_0 is 9074.0 cal_{15} per mole of ammonia, which may be compared with 9141, the value according to the simple equation (1).

The pressures thus calculated are entered as "calcd. (B)" in Table I. The average percentage deviation is 0.15. This may not seem to be a great improvement over equation (1), but the deviation for every point is less by equation **(3)** than by equation (1), provided that we do not count three cases in which equation (1) is closer by a negligible amount, 0.03% or less. **A** deviation plot shows that equation (1) fails to represent the slope at the higher temperatures, whereas equation **(3)** gives much improvement. Hence the latent heats calculated from equation (3) (by means of equation (4) should be much better than those calculable from equation (1), even if in the latter case an exact value of the volume change is computed for use in the Clapeyron equation.

As regards the data obtained by Hüttig **and** Martin for lower tempera-

tures, reference to Table II shows that equations (1) and (3) are in practical agreement at these temperatures. The distribution of the percentage deviations is such as to suggest that the fault lies in the experimental values. At lower temperatures it appears more difficult to obtain equilibrium. This interpretation is suggested also by the deviation plots of our own data.

Summary

The decomposition pressures of the system $BaCl_2{\cdot}8NH_3$–$BaCl_2$–NH_3, were measured from 0 to 50° with an average precision of about 0.2%. The results were interpreted by means of a vapor pressure equation previously derived,[3] which can be regarded as the equation $\log p = A - B \log T - C/T$ with added terms for the deviation of ammonia gas from the ideal gas law.

Interpolated values for the pressure and calculated values of the corresponding latent heat of decomposition are given in Table III.

THE KINETICS OF GAS REACTIONS AT CONSTANT PRESSURE

BY ARTHUR F. BENTON

RECEIVED JUNE 8, 1931 PUBLISHED AUGUST 5, 1931

The classical equations of reaction kinetics, relating the velocity of reaction to the concentrations of the reacting substances, were originally developed to describe the behavior of reactions occurring in liquid systems. In such systems the volume remains approximately constant. In the hands of van't Hoff, Bodenstein and others, the same equations were found to be applicable to gaseous reactions occurring at constant volume. In this period the kinetics of gas reactions were almost invariably studied by the so-called "static" method, in which the volume is maintained constant, and the progress of reaction is followed by noting the change in pressure.

In recent years there has been an increasing tendency to employ the flow method, which consists in streaming the gases through the reaction space, and determining the extent of reaction by analysis of the exit gases. This method differs essentially from the static method in that the reaction takes place at constant pressure. Nevertheless, it has been a common practice to apply to results obtained by this method the kinetic equations which hold for reactions at constant volume.

It is the object of the present paper to point out that kinetic equations for reactions at constant volume are not necessarily applicable to reactions at constant pressure, and to indicate how the latter are to be correctly treated.

Homogeneous, Unimolecular Gas Reactions.—Reactions of the first order are defined in two different ways, either (1) as those in which a constant fraction of the material reacts in unit time, or (2) as those in which the rate of change of concentration is proportional to the concentration of reacting substance. Accordingly, if n_A, n_B denote the number of moles of substances A and B, respectively, present in volume V, and c_A, c_B their respective concentrations, the rate of the reaction, $A \longrightarrow \nu B$, could be expressed in either of the following ways

$$-\frac{dn_A}{dt} = k_1 n_A \qquad (1)$$

$$-\frac{dc_A}{dt} = k_2 c_A = k_2 n_A/V \qquad (2)$$

If the reaction is carried out at constant volume, $dc_A(=d(n_A/V)) = (1/V)dn_A$, and the two expressions are equivalent. For reactions conducted at constant pressure, however, the volume does not remain constant (except in the special case where $\nu = 1$). Under this condition, therefore, Equations 1 and 2 are not equivalent. The difference between them can best be seen in their integrated forms

$$k_1t = \ln n'_A/n_A \qquad (1a)$$

$$k_2t = \ln c'_A/c_A = \ln \frac{n'_A}{n_A}\cdot\frac{V}{V'} \qquad (2a)$$

where the primes represent the conditions at zero time. If the gas consists of pure A at the start, V/V' varies from unity at $t = 0$, to ν at $t = \infty$. From this it can readily be shown that $k_2 = \nu k_1$ at $t = 0$, while at $t = \infty$, $k_2 = k_1$. Hence if either k_1 or k_2 is actually constant, the other will vary by a factor of ν during the course of the reaction.

While it is clear that these equations can not both be correct, they have been employed indiscriminately in the literature. Thus, for example, of three recent papers by different authors dealing with the homogeneous, unimolecular decomposition of hydrocarbons at constant pressure, one employs rate constants calculated by means of Equation 1 and two by means of Equation 2.

The generally accepted theory of homogeneous, unimolecular reactions leaves no doubt that Equation 1 rather than Equation 2 is the correct form. Of the total number of molecules of reactant, n_A, a given fraction are in the necessary activated state, and of this fraction a further fraction suffers reaction in unit time independent of the concentration.[1]

Homogeneous, Unimolecular Reactions in Flow Systems.—There are two methods by which reactions may be carried out at constant pressure, (1) the "flow" method, and (2) a method involving a closed system of variable volume. Equation 1a, obtained by direct integration of Equation 1, is obviously in suitable form for application to Method 2. On the other hand, its utility in the flow method is limited by the fact that the "time of contact" is not a directly measurable quantity. If the rate of flow of the entering gases is maintained constant, the time of contact t depends on the extent to which the volume changes during the progress of the reaction.

Let the volume of the reaction space be V_b, and let V' represent the volume of gas, at the temperature and pressure of the reaction space, entering per unit time. If there were no change in volume due to the reaction, the time of contact would be simply V_b/V'. However, in the reaction $A \longrightarrow \nu B$, the volume changes from $V' = (RT/P)n'_A$ to $V = (RT/P)(n_A + n_B) = (RT/P)(\nu n'_A - [\nu - 1]n_A) = V'(\nu - [\nu - 1]n_A/n'_A)$, where n'_A is the number of moles of A entering the reaction space per second, and n_A is the number passing any given point per second. If, under these conditions, we treat V_b as a variable, we may write

$$\frac{dV_b}{dt} = V = V'(\nu - [\nu - 1]n_A/n'_A)$$

Substitution of dt from this equation in Equation 1 gives

---

[1] Equation 1 probably applies strictly only to an ideal gas. In real gases it would seem that the fraction of the molecules in an activated state cannot be independent of the concentration, and it is further possible that the fraction of the activated molecules which decompose in unit time may also depend to some extent on concentration.

$$-V'\left(\nu - [\nu - 1]\frac{n_A}{n'_A}\right)\mathrm{d}n_A = k_1 n_A \mathrm{d}V_b$$

On integration,

$$k_1 V_b/V' = \nu \ln \frac{n'_A}{n_A} - (\nu - 1)\left(1 - \frac{n_A}{n'_A}\right)$$

where V_b is the volume of the whole reaction space, out of which n_A moles of *A* issues per second. If F represents the fraction of A which reacts, then

$$k_1 V_b/V' = \nu \ln \frac{1}{1 - F} - (\nu - 1)F \qquad (3)$$

In treating reactions in flow systems it has been the common practice hitherto to calculate the time of contact as the ratio of the volume of the reaction space to the average of the entering and exit rates of flow.[2] While this procedure gives a fair approximation when the fractional conversion is not too great, the simplicity and exactness of Equation 3 would seem to make approximations needless.

First Order, Catalyzed Reactions.—When we turn to first order gas reactions which are catalyzed by a solid surface, we find that when the volume varies neither Equation 1 nor Equation *2* is correct. This fact will be apparent from the following derivation.

We may assume that the reaction is of the first order either because (1) the velocity is determined by the rate of collision of (activated) molecules of reactant with the surface, or because (2) a small portion of the surface is occupied by adsorbed molecules, a given fraction of which are transformed in unit time. In Case (1) the rate of reaction, that is, the number of moles of reactant disappearing in unit time, is a given fraction of the number colliding with the surface, and this in turn is equal to $(v/4)Sc_A$, where S is the surface area, v is the average velocity of the molecules, and c_A is their concentration. Thus, at a given temperature

$$-\frac{\mathrm{d}n_A}{\mathrm{d}t} = k_3 \cdot \frac{v}{4} Sc_A = kSn_A/V \qquad (4)$$

It may be noted that this equation is dimensionally correct, since k_3 is dimensionless and both sides reduce to number per unit time.

In Case (2) the rate is proportional to the amount of gas adsorbed, and the latter is also determined by S and the concentration in the gas phase. Thus for small adsorption the result is the same as for Case (1). The principle is, of course, the same whether the adsorption is small or large, but in the latter event the order of reaction will differ from the first, and we should have to write

$$-\frac{\mathrm{d}n_A}{\mathrm{d}t} = k'S\frac{c_A}{1 + ac_A}$$

where a is the constant of the Langmuir adsorption equation.

---

[2] Pease [THIS JOURNAL, 51, 3470 (1929)] has, however, already elaborated the proper treatment of time of contact, and has applied it to the bimolecular polymerization of acetylene.

To integrate Equation 4 it is necessary to express V as a function of n_A. Let us assume that the reaction is $A \longrightarrow \nu B$, and that the gas entering the reaction space per second occupies the volume V', and is composed of n'_A moles of A and no B. Then, as before, $V = V'(\nu - [\nu - 1]n_A/n'_A)$ and $dt = (I/V)dV_b$, where V_b now represents the free space in the reaction tube not occupied by the catalyst. With these values of dt and V substituted in Equation 4, integration gives

$$\frac{kSV_b}{V'^2} = \nu^2 \ln \frac{n'_A}{n_A} - 2\nu(\nu - 1)\left(1 - \frac{n_A}{n'_A}\right) + \frac{(\nu - 1)^2}{2}\left(1 - \frac{n^2_A}{n'^2_A}\right)$$

Because of the somewhat complex nature of this exact expression, it is often preferable in practice to substitute an approximate equation previously suggested,[3] which may be written in the form

$$-\frac{\Delta n_A}{\Delta t} = kS\bar{c}_A$$

where $\bar{c}_A$ is the average concentration of A in the entering and exit gases, and At is V_b divided by the average rate of flow. This equation necessarily fails at high percentage conversions, but ordinarily involves only a negligible error for conversions up to at least 50%.

Bimolecular Reactions.—The treatment of homogeneous, bimolecular gas reactions at constant pressure is complicated to some extent because of the fact that the rate of collision in a gas whose volume is changing does not appear to have been studied, The correct form of velocity equation may readily be obtained, however, by considering a homogeneous, reversible reaction which is unimolecular in one direction and bimolecular in the other. Thus, in the reaction $A \rightleftarrows 2B$, the rate to the right is

$$-\frac{dn_A}{dt} = k_1 n_A$$

If we assume that the rate to the left is given by the expression

$$\frac{dn_A}{dt} = k_2 V c^2_B \qquad (5)$$

then, at equilibrium where the two rates are equal

$$k_1 n_A = k_2 V c^2_B, \text{ or } c^2_B/c_A = k_1/k_2 = K$$

where K is the equilibrium constant. Since, as may readily be shown, the usual ways of writing the bimolecular velocity equation do not give this necessary result, it may be assumed that Equation 5 is correct.

In the case of a catalyzed, bimolecular reaction, it may be shown by reasoning exactly analogous to that used in the corresponding unimolecular case that Equation 5 has the proper form. The equation can readily be applied by expressing n_A, V and dt in terms of n_B, V_b and the initial conditions, followed by integration. In practice, however, if the percentage conversion is not too great, it will usually be sufficient to employ the approximation

[3] Benton, *Ind. Eng. Chem.*, **19,494 (1927).**

$$\frac{\Delta n_A}{\Delta t} = k_2 \overline{V} \bar{c}_B^2$$

where $\overline{V}$ and $\bar{c}_B$ are the average volume and the average concentration of B, based on the entering and exit gases.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. V. THE POLYMETHYLENE BROMIDES

BY C. P. SMYTH AND S. E. KAMERLING

RECEIVED JUNE 10, 1931 PUBLISHED AUGUST 5, 1931

These measurements upon compounds containing two dipoles separated by a carbon chain of varying length were undertaken with the object of studying the effect of the carbon chain upon the positions of the dipoles relative to one another and thus of extending our knowledge of the shape and behavior of the chain. The bromide doublets were used as being simple dipoles obtainable in compounds with chains of different length. Subsequent measurements have been made upon the diethyl esters of dicarboxylic acids[1] and upon the glycols,[2] in both of which classes of compounds the dipoles are more complex.

Apparatus

The dielectric constants of the solutions of the substances under investigation have been measured with a capacity bridge, part of which was presented by the Bell Telephone Laboratories. This part consisted of two fixed resistance arms with small adjustable resistances and capacities for balancing small inequalities and shielded in-put and out-put transformers, the whole mounted in a case with the parts carefully shielded. The other two arms of the bridge consisted of two condensers with series resistances as used previously in this Laboratory.3 The source of current was a Western Electric Company variable oscillator, which was operated at a frequency of 50,000 cycles in these measurements. The balance of the bridge was obtained by passing the current through a six-tube amplifier with a detector and a multimeter, adjustable to read microamperes, as null instrument. The condenser in which the liquid was measured consisted of concentric gold-plated cylinders fitting closely into a small glass vessel similar to that used in earlier measurements.[4] The densities of the liquids were determined with a pycnometer of the type previously employed[5] and

the temperatures were controlled with a special form of thermostat also used before.[5] The solutions of ethylene bromide were measured at a wave length of 600 meters with a slightly more accurate bridge, which has been previously described,[6] and the measurements on decamethylene bromide were checked at 1000 meters on a heterodyne beat apparatus also previously described.[1,2]

Preparation of Materials

Heptane and benzene were purified as in earlier work.[7]

Ethylene Bromide.—Ethylene bromide from the Eastman Kodak Company was washed with cold concentrated sulfuric acid, sodium carbonate solution and water, and, after drying with calcium chloride, was fractionally distilled. The middle fraction, boiling at 131.0° (756 mm.), was used; n_D^{20} 1 53801; d_4^{20} 2.1760.

Trimethylene Bromide.—Trimethylene bromide from the Eastman Kodak Company was washed with sodium carbonate solution and water and, after drying with calcium chloride, was fractionally distilled under reduced pressure. The middle fraction, boiling constantly at 80.5° (50 mm.), was used; n_D^{20} 1.52319; d_4^{20} 1.9790.

Pentamethylene Bromide.—Pentamethylene bromide was loaned by Dr. Wallace H. Carothers of E. I. du Pont de Nemours and Company; b. p. 122–125° (36 mm.); n_D^{20} 1.5126.

Decamethylene Bromide.—Decamethylene bromide, loaned by Dr. Carothers. was distilled under reduced pressure (b. p. 172–174° (12 mm.)) and recrystallized.

Experimental Results

The dielectric constants, ϵ, and the densities, d, are given in Table I together with the polarizations, P_2, of the bromides calculated by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \quad \text{and} \quad P_2 = \frac{P_{12} - P_1}{c_1} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2 and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The dielectric constants were actually measured at intervals of about 10° and the densities at intervals of about 20°, with the exception of the measurements upon the benzene solutions of ethylene bromide which were made at the stated temperatures. Although the data were graphically interpolated to obtain values at definite 10° intervals, the results are shown, for the most part, at 20° intervals only, in order to save space. The values for the pure solvents, which have been repeatedly determined, are omitted also for the same reason.

The values of P_2 have been plotted against those of c_2 and extrapolated to $c_2 = 0$ to obtain the values of P given in Table II as P_∞. The values of P_∞ when plotted against $1/T$ should give a straight line, as required by the Debye equation, $P = a + b/T$, in which $a = P_E + P_A$, the sum of the electronic polarization, P_E, and the atomic, P_A, and $b = 4\pi N\mu^2/9k$, N

being the Avogadro constant, 6.061×10^{23}, μ, the electric moment, and k, the molecular gas constant, 1.372×10^{-16}. As the temperature range possible in these measurements is not as wide as might be wished for the accurate establishment of the $P_\infty - 1/T$ curves and as b is not constant for some of these substances, P_A is neglected and a set equal to MR_D. b is then obtained approximately as $(P_\infty - MR_D)T$ and the moment is calculated from the relation $\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - MR_D)T}$. At the bottom of the set of data for each substance in Table II, the very approximate values of P_A and of the moments obtained from the $P_\infty - 1/T$ curves are given in parentheses. The measurements of the decamethylene bromide solutions made with a heterodyne beat apparatus at 1000 meters wave length as a check gave values of the moment of 2.73×10^{-18} at 25° and 2.72×10^{-18} at 50° in excellent agreement with those in Table II.

Discussion of Results

The values of P_2 for ethylene bromide in dilute solution in heptane increase with rising temperature, pass through a maximum at about 30°, and then decrease, although, according to the Debye equation, P_2 should be a linear function of $1/T$. Obviously, it is useless to attempt to determine b as the slope of the $P_\infty - 1/T$ curve since b is not a constant. When the moment is calculated as $\mu = 0.0127 \times 10^{-18}\sqrt{(P_\infty - MR_{\text{D}})T}$, it is found to increase with rise of temperature. The measurements of ethylene bromide in benzene solution give much higher values of the polarization, a difference analogous to that found by Meyer in the case of ethylene chloride.[8] The polarizations in benzene solution also show a maximum at 30°, but, as the only values below this temperature were determined not far above the freezing point, where the tendency toward association is greater, great significance cannot be attached to this. The temperature range is here too short for an accurate determination of the moment from temperature variation, but the 30, 50 and 70° values lie on an approximately straight line, which gives $\mu = 1.12 \times 10^{-18}$ and $P_{\text{A}} = 17.5$. It is more satisfactory to use the refraction to obtain the values of the moment given in Table II, where the temperature variation of μ from 30 to 70° is negligible.

The polarizations of the higher bromides in dilute solution do not increase with rising temperature even at the lowest temperatures investigated, but the values of b obtained on the slope of the $P_\infty - 1/T$ lines give surprisingly large values of P_{A} and, consequently, low values of the moment. When the molar refraction is used in the calculation of the moment, the values obtained for trimethylene bromide show a small increase with rising temperature at the low temperatures. Pentamethylene bromide shows a more appreciable increase with temperature and decamethylene bromide a negligible increase. An increase in the moment with rising temperature, while tending to cause a departure from linearity in the $P_\infty - 1/T$ curve, would at the same time reduce the slope of the curve and hence reduce the value of b and increase P_{A}, which, as it is obtained by a long extrapolation, is very dependent upon the slope of the curve. The value of P_{A} for pentamethylene bromide which shows the most marked temperature variation of the moment, is the highest of the three, while that for decamethylene bromide, which shows negligible temperature variation of the moment, is much the lowest. Actually, one would expect the large molecule of decamethylene bromide to have the largest value of P_{A}. It appears probable,[9] therefore, that these apparent values of P_{A} are much too high, although the value for decamethylene bromide is less than double those found for some of the alkyl halides.[10] Considerable doubt must, however, exist as to whether these latter values are not too high.[9] Morgan and Lowry[11] obtained a value of 21.4 for the P_{A} of methyl bromide from the

temperature variation in solution and a value of 2.8 from the polarization of solid methyl bromide. The reason for this discrepancy is not apparent. In view, however, of the uncertainty which exists in regard to the P_A values for these bromides, it seems best to use the values of the moments calculated from $(P_\infty - MR_D)$. They are presumably a little high because of the neglect of P_A, but, for the most part, this cannot materially alter the conclusions to be drawn from them.

In order to interpret the results, it is necessary to know the moment of the dipole at each end of the carbon chain. The moment of methyl bromide reported by Morgan and Lowry[11] is 1.45×10^{-18}, but, in obtaining this value, they used the curve which gave the high value, 21.4, for P_A. As P_A has been neglected in the values of the moments which we are to interpret, it is best to use for our purposes the value of the moment obtained from a calculation in which the almost negligible value of P_A, 2.8, found from the solid, is used. The result of this calculation is 1.7×10^{-18}. Eucken and Meyer[12] have used a value of 1.5×10^{-18} for the moment of the C–Br bond obtained as the moment of bromobenzene and a value of 0.4×10^{-18} for that of the C–H bond calculated from that of toluene. The assumptions underlying the assignment of the values to these bonds are exceedingly doubtful in character, although the empirical method used by Eucken and Meyer is often effective in calculating moments. As the use of these bond moments gives the decidedly high value 1.9×10^{-18} for methyl bromide, it is best to adopt tentatively the value 1.7×10^{-18} as the moment of the dipole at each end of the carbon chain.

Williams[13] has treated the molecule XCH_2CH_2X as containing two dipoles, each of moment m, with their axes in the lines joining the carbon nuclei to the X groups, these lines making an angle with the extension of the line joining the carbon nuclei. The mean effective moment of the molecule is then calculated as $\mu = 1.41\ m \sin \theta$. The values which Williams observed for molecules of this type were all much lower than the calculated, a fact which he attributed to repulsion between the X groups and consequent decrease in θ. Meyer[8] has considered the mutual potential energies of the doublets and obtained a much more complicated expression, which, when the mutual potential energies are small in comparison with the energy of rotation of the dipoles around the C–C line, may be simplified to the equation given by Williams. When the distance between the doublets is small, the mutual potential energy is large, and it is only at very high temperatures, not practically obtainable, that the energy of rotation around the C–C line is sufficient to make the doublets independent of one another. As the mutual potential energy is a minimum when the doublets oppose one another, it is evident that the moment of the

---

[13] Williams, *Z. physik. Chem.*, [A] 138, 75 (1928).

molecule as a whole will increase as rising temperature gives a rotational energy which tends to overcome this effect of the mutual potential energy.

Meyer has found that the polarization of ethylene chloride in solution in hexane shows a variation with temperature in conformity with the requirements of his equation, deviating from the linearity required by the simple Debye equation. So many approximations and assumptions are necessary in a treatment of this sort that even an exact quantitative agreement between a single set of observed and calculated values is not necessarily convincing, but Meyer has experimentally demonstrated the success of his equation in predicting an increase in the moment of ethylene chloride with rising temperature. The results of the present work show a similar increase in the moment of ethylene bromide with rising temperature.

It is interesting to calculate the moment for the limiting case in which the rotational energy is large in comparison to the mutual potential energy of the doublets, or, expressed in another way, in which all positions in the rotation about the C–C bond are equally probable. Assuming the usual tetrahedral carbon valence angles and taking the moment of each dipole as $m = 1.7 \times 10^{-18}$, we may apply the simple equation of Williams to this limiting case: $\mu = 1.41 \times 1.7 \times 10^{-18} \sin 70° = 2.25 \times 10^{-18}$. The large difference between this value and those observed for ethylene bromide shows how far the actual conditions are from those assumed in the derivation of the equation. The reduction of the moment of each dipole by the inductive effect of the other has been neglected in this calculation. The moment of ethyl bromide has been found to be 1.86×10^{-18}.[5] The rounding off of this figure to 1.9×10^{-18} makes it comparable with the values of the moments in the calculation of which P_A has been neglected. The difference of 0.2×10^{-18} between this value and the moment of methyl bromide may be attributed mainly to the moment induced in the second carbon in the former.[10] This suggests that in ethylene bromide each dipole tends to induce a moment in the second carbon from it opposite to that induced by the other dipole. It would seem reasonable, therefore, to subtract a moment of at least 0.2×10^{-18} from the value 1.7×10^{-18} used for m in the calculation. If m is taken as 1.5×10^{-18}, the result obtained for μ is 2.0×10^{-18}, still much higher than the observed values, which should approach this value with rising temperature.

The temperature variation of the moment of ethylene bromide in benzene solution is small and uncertain and the moment is higher than that found in heptane solution. Meyer observed a similar difference in the case of ethylene chloride, finding a larger moment without temperature variation in the benzene solutions. The reason for this discrepancy probably lies in the effect of the benzene upon the forces between the dipoles in the molecule for results, as yet not published in detail,[14] confirm the tem-

---

[14] Smyth and Dornte, THIS JOURNAL, 53, 2005 (1931).

perature variation of the moment in the cases of ethylene chloride and ethylene chlorobromide, in at least qualitative conformity with the prediction of Meyer's equation.

In trimethylene bromide, the 110° valence angle of the central carbon should bend the chain thus, . This should tend to reduce the opposition between the dipoles at the ends of the chain and so increase the resultant moment. If we take 1.52 Å. as the internuclear separation of the carbons and 1.85 Å. as the separation of the carbon and the bromine nuclei,[15] we may calculate the distance which would separate the two bromine nuclei if they were able to lie on the inside of the angle of the carbon chain in the plane of the three carbon atoms, the 110° valence angles being maintained throughout. The result of this calculation, 1.53 Å., is considerably smaller than the atomic diameter of bromine, 2.18 Å., calculated from x-ray data,[16] which shows that this particular arrangement of the atoms in the molecule is impossible without great distortion of the valence angles. A similar calculation for ethylene bromide gives 2.79 Å. for the separation of the bromine nuclei when they lie on the same side of the molecule in the plane of the carbon atoms. Evidently there is reason to expect a moment for trimethylene bromide larger than that of ethylene bromide and showing some increase as the increasing energy of rotation about the C–C bonds accompanying rising temperature tends to overcome the effects of the mutual potential energy of the dipoles and the repulsion between the bromine atoms.

If the carbon chain in pentamethylene bromide were the zigzag structure, , with the carbons all in the same plane, its moment should differ from that of trimethylene bromide only as the result of an increase of 2.5 Å. in the separation of the two dipoles. This obviously should increase the moment and decrease its variation with temperature. Actually, there is no reason why there should not be turning about the other C–C bonds and it is easy to picture this turning as sometimes giving rise to a ring structure in which the dipoles overlap and oppose one another. This is somewhat analogous to the ring structure suggested to account for the lowering of the moment and its increase with rising temperature in the case of diethyl succinate.[1] The existence of a portion of the molecules in this ring structure, which would diminish with rising temperature, would account for the fact that the increase of moment on going from trimethylene to pentamethylene bromide is not greater and that the increase of moment with rising temperature is not inconsiderable. However, this must be regarded as a very tentative and speculative explanation rather than as definite evidence of ring formation. There is uncertainty in the experi-

---

[15] Pauling, *Z. Krist.*, **67**, 377 (1928).

[16] Huggins, *Phys. Rev.*, 28, 1086 (1926).

mental accuracy of the temperature variation of the moments of trimethylene and pentamethylene bromide. In the latter it may be merely that the mutual potential energy of the dipoles renders less probable those positions in which the chains are bent by turning around the C–C bonds so as to bring the two dipoles near together on the same side of the molecule and give increased moment. Increasing rotational energy with rising temperature would then overcome the effect of the mutual potential energy of the dipoles and increase the moment.

Probably in pentamethylene bromide and, certainly, in decamethylene bromide, it is justifiable to assign to the dipole at each end of the chain the moment of ethyl bromide, 1.9×10^{-18}, which has been found indistinguishable from that of heptyl bromide in value. If the carbon chain is rod-like with the 110° valence angles maintained, we can apply the simple equation used to calculate the limiting value of the moment of ethyl bromide, that is, $\mu = 1.41 \times 1.9 \times 10^{-18} \sin 70° = 2.5 \times 10^{-18}$. In decamethylene bromide, the dipoles are so far apart that we should expect no lowering of the resultant moment because of their mutual potential energy and, therefore, no temperature variation of the moment because of this effect. The difference between the observed and the calculated values of the moments is no greater than the possible absolute error in the observed value and the absence of appreciable variation of the values with temperature accords with the theoretical prediction. As any considerable permanent bending of the chain would cause a moment larger than that calculated and, probably, varying with temperature, which should affect the bending, it may be concluded that the long carbon chain in the liquid does not differ much from the rod-like shape commonly assigned to it. Another conclusion to be drawn is that the chain does not bend appreciably in the electric field used in measuring the dielectric constant, for such bending would increase the effect of the dipoles and give an apparent increase in the value of the electric moment observed.

In conclusion the writers wish to express their gratitude to the Bell Telephone Laboratories for a portion of the apparatus used in these measurements and to Dr. Wallace H. Carothers of E. I. du Pont de Nemours and Company for the loan of the pentamethylene and decamethylene bromide.

Summary

The dielectric constants and densities of heptane solutions of dibromides with two, three, five and ten carbon atoms between the bromines have been measured over a range of temperature and the results have been used to calculate the electric moments of the molecules.

The moment of ethylene bromide is found to increase with rising temperature in accordance witht heoretical predictions. The moments of methyl

and ethyl bromide are used to calculate the moments which might be expected in the molecules. The observed values are lowered by proximity of the two bromide dipoles, which also gives rise to the temperature variation of the moment. In decamethylene bromide the two dipoles are so far apart that the observed and calculated moments agree satisfactorily and the moment shows no variation with temperature.

Rotation around the C–C bonds probably causes some bending of the carbon chain, but there is no evidence of pronounced bending of the supposedly rod-like structures of the long chains, even in the external electric fields used in the measurement of the dielectric constants.

THE GLASS ELECTRODE. THE STUDY OF VARIOUS CHARACTERISTICS

BY H. KAHLER AND FLOYD DEEDS

RECEIVED JUNE 15, 1931 PUBLISHED AUGUST 5, 1931

Introduction

The theory of the glass cell which so far is the most widely accepted is that of Haber.[1] He derived several expressions for the potential difference across a glass membrane when the two surfaces are in contact with solutions whose hydrogen-ion concentrations (activities) are 1a and Ib. All of these expressions may be summarized into the equation E = RT log $(1a/1b) - F(G)$, where by $F(G)$ is meant a function of the glass, when immersed in different solutions.

The difference between the equations of Haber as well as between different hypotheses which have since been stated, arises from differences assumed for $F(G)$. When $F(G)$ is a small constant the glass is said to be "good," since it then has the theoretical slope for the calibration curve and also a small zero correction. Haber made the hypothesis that the glass is hydrated at its surfaces, this hydrated layer having the product $[H^+][OH^-]$ constant. In his paper, under certain conditions, $F(G) =$ RT log (IIa/IIb), where II*a* and II*b* are the hydrogen-ion concentrations (activities) in the two hydrated layers. $F(G)$ then is small only when II*a* is nearly equal to II*b*, which occurs when the hydrated layer is uninfluenced by the successive solutions coming in contact with the glass, or $[H^+]$ and $[OH-]$ are constant. Hughes[2] pointed out that this constancy could be attributed to the sodium silicate buffer system in the hydrated layer at the phase boundary. It is also evident that any increase in the buffer capacity of the hydrated layer improves the electrode performance.

Horovitz and collaborators[3] showed that certain glasses exhibited metal electrode functions for ions other than H^+ and OH^- when the glasses contained the metal whose ion was being measured in solution.

It has been observed by nearly every worker that thin glass electrodes give better results than thick glasses, though no one has shown any good reason for this. MacInnes[4] has gone so far as to use glasses only 1 micron thick, the membranes exhibiting interference colors. It is obvious from a practical standpoint that thick glasses having great mechanical strength would possess advantages in most applications.

We discuss thickness, resistance, zero correction, deviation and temperature coefficient, following the experimental technique generally employed by others as described in the literature. Following this, we show how some of these results may be greatly modified by using the methods outlined in this paper.

Chemical Composition of Glass.—On the basis of the work of Hughes and of MacInnes and Dole, the glasses we selected were those whose composition approached Corning Glass 015. Four such glasses are shown in Table I. The first glass to be used is unknown in origin and it has been designated "A." A second glass designated as 015 (Al) was obtained from the Corning Glass Company, and its designation is given the suffix Al because analysis showed the presence of aluminum. A third batch of glass called 015 is a sample of Corning soda lime glass and differs from 015 (Al) in that it yields electrodes having a calibration curve very close to the theoretical. Glass "M" is a sample prepared by Dr. G. W. Morey of the Geophysical Laboratory from c. p. ingredients.

sum of the reciprocal thicknesses was made $1/T = 1/t_1 + 1/t_2 + 1/t_3 + 1/t_4$ in order to compare with the resistance of several parallel resistances $1/R = 1/r_1 + 1/r_2 + 1/r_3 + 1/r_4$. On measuring the area of the bulb and its total resistance the specific resistance ρ could be obtained. The total resistance R was measured by an electrometer–capacity method as follows (Fig. 1).

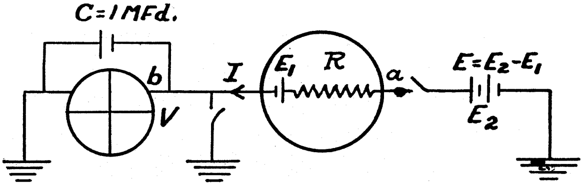

Fig. 1.—Resistance measurement: V, voltage of electrometer; E_1, potential difference across glass cell for zero current; E_2, voltage applied by potentiometer; E, excess potentiometer voltage for zero current; I, current; R, glass cell resistance.

The cell being first balanced by the null method, at a given time let the earth connection of b be broken and the excess potential R from the potentiometer applied so that the electrometer charges up at a certain time rate. This rate is observed and the resistance computed according to the equation

$$R = -\frac{t}{2.3C \log (E - V)/E}$$

R is the resistance, t is seconds where C is the capacity of the shunt condenser; E is the applied voltage, V is the electrometer voltage. This method has the great advantage that low applied voltages may be used and small currents flow, thus causing a minimum polarization.

As a result of such experiments the glass 015 Al gave a specific resistance of $2.0 \times 10^{+10}$ ohms/cm. cube, while glass "A" gave a specific resistance of $6.5 + 10^{+10}$ ohms/cm. cube. We estimate from the data of MacInnes and Dole for glass 015 that they would get about 1.2×10^{10}. For 015 we find $\rho = 3.6 \times 10^{10}$ at 22.3°. Horovitz obtained for various German glasses 10^{+7} to 10^{+10} for the specific resistance, the former of which seems remarkably low.

In some cases the glass electrode was provided with a guard ring and connected as in the well-known method. A check on the work is the graphs obtained for different cells of the same glass. These show that the resistance is proportional to the thickness of the glass. In passing it may be remarked that the guard ring is necessary for a short shanked glass electrode or a damp glass surface but for a well dried glass insulating surface in a fairly dry atmosphere and a length of shank of 10 cm. there is little need of the guard ring except in measurements of high precision or when the cell membrane has a very high resistance.

It can readily be seen that the leakage is related to the ratio of the surface resistance to the resistance of the glass membrane for electrolytic currents. If the latter be taken at 10^8 ohms, then the shank should be long enough so that the former would have a resistance of 10^{11} ohms with a humidity of 60%. The measurements were made at a measured humidity of 55%, the room being provided with an air dryer.

Resistance and Temperature.—The variation of resistance over the temperature range from 5 to 55° was ascertained. At 55° the resistance is only a fraction of the value obtained at 5°. Thus a cell which at 5° showed a resistance of over 1200 megohms at 55" had a resistance of only 12 megohms.

Potential Measurements.—In measuring potential differences across the glass membrane, the solution on each side of the membrane is electrically connected to a saturated calomel half cell by means of an agar–potassium chloride bridge. In the ensuing experiments a potentiometer and Compton type electrometer were used interchangeably with vacuum tube voltmeters. Three vacuum tube amplifiers were used. The first is of the previously described[6] type, using a 201-A tube critically balanced in the first stage for a minimum grid current, followed by a two-stage resistance coupled amplifier with a microammeter in the output of the last stage. The second amplifier was used with the FP-54 General Electric tube in the first stage followed by 222 and 212 tubes in successive stages. A third amplifier used the German Osram double grid (E series) tube with the control grid inserted in the tube through an amber plug, followed by 222 and 212 tubes.

In an electrometer–potentiometer system of small electrostatic capacity and small leakage the sensitivity of the system is independent of resistance in the circuit so long as a sufficient current flows to charge up the quadrant, since in the final steady state the current approaches zero. However, when leaks occur on the electrometer side of the potentiometer, the sensitivity of the equipment drops. The chief effect of increase in resistance is to increase the time necessary to get the final steady reading.

Similar considerations with regard to the glass cell, keeping the Haber theory in mind, might indicate that the resistance or thickness of the cell as such could play no part other than the time factor in the potential measured since, at the time of the final reading, there is no current flowing except that due to unavoidable insulation leakage.

However, experiments now to be described, as well as those previously reported in the literature, show that this is not the case, *viz.,* resistance (thickness) appears to affect the performance of the glass cell indirectly, at least under some conditions.

In measuring the hydrogen-ion activities of solutions, one of the first

---

[6] Kahler, DeEds, Rosenthal and Voegtlin, Am. *J. Phys.,* **91,** *225* (1930).

steps is to measure the potential when the same solution is on both sides of the glass. This gives the zero correction, also called the strain value by some writers, and the asymmetry value by other writers. By changing the solution simultaneously on both sides, a relation between the observed potential and the *P*H value of the solutions was obtained. This curve is shown in Fig. 2. This particular graph illustrates the manner in which a very poor cell may show a large change in zero correction with *P*H. The interpretation of this is that the slopes of the calibration curves on the two sides differ since the difference in slopes $S_2 - S_1 = Z_2 - Z_1$ the difference of zero corrections at two *P*H levels.

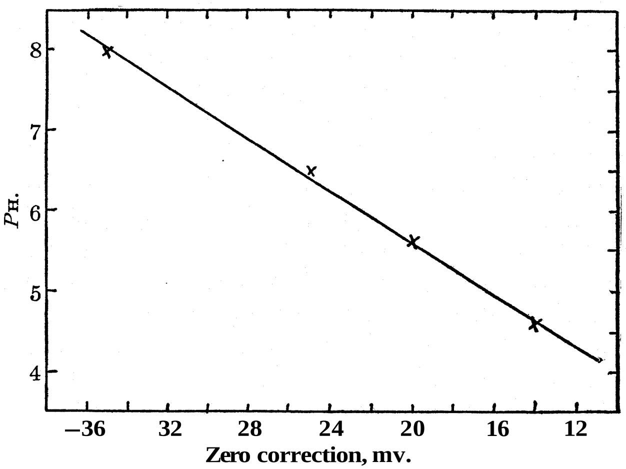

Fig. 2.—Glass "A," thick bulb.

Relation between Resistance (Thickness) and Zero Correction.—By taking a large number of cells of the Haber bulb type of the same kind of glass but differing in thickness and total resistance, it was shown that usually the higher resistant (thicker) cells have the larger zero corrections when using a liquid of *P*H 4 on each side if the outside surface is only immersed to the top of the bulb.

Deviation and Resistance (Thickness).—By keeping the fluid on the inside of the glass cell constant and varying the *P*H of the solution on the outside, a calibration curve for the cell outer surface may be obtained. It is found that as the resistance of the glass cell increases for the same glass composition, the curve for the glass cell markedly deviates from the theoretical relationship. In order to have a definite criterion for this effect, we take as a convenient measure of the deviation from the theoretical the difference between the hydrogen electrode and glass electrode reading for unit *P*H change: $E_H - E_G = \Delta(\text{H.G.})$. A perfect electrode has a difference of 0. MacInnes and Dole,[4] using thin membranes, were able to get a difference of zero over a range *P*H 1 to 9.8. At PH values for which the glass is attacked all glasses deviate markedly from the theoretical, as has been shown by many workers including Horovitz, Hughes, MacInnes and Dole.

The relation between Δ(H.G.) and thickness for different glasses on their outer surfaces is shown in Fig. 3. As can be seen, the "A" glass containing no aluminum is quite similar to 015(Al).

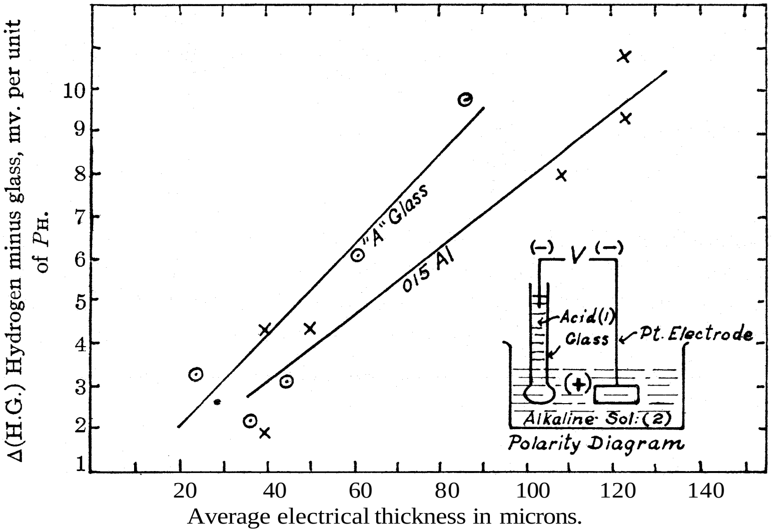

Fig. 3.—Polarity: when inside solution in glass cell is acid with respect to the outside—inside is negative. (Both calomel half cells are omitted in the diagram.)

For reasons to be pointed out later, it should be here stated that these measurements were all made when the outer glass surface was immersed only about 1 cm. below the surface of the solution.

Effect of Hydrofluoric Acid Treatment.—If the surfaces of the glass bulbs are etched with hydrofluoric acid, the thickness may be reduced at will. Experiments were performed with the idea of testing whether the zero correction and deviation from the theoretical would follow the thickness (resistance) deviation curves. The results for several glass cells are shown in Table II.

At this point it is well to make clear that all the above-mentioned experiments were made with a large area of wetted glass on one side of the membrane and a small area on the other side. The shank and bulb were of the same glass and the statement refers to the total combined areas. It seems likely that most of the work reported in the literature was done under somewhat comparable conditions.

Temperature.—Literature describing the use of the glass electrode for the measurement of H^+ has contained little discussion of the influence of temperature changes upon the observed potential. In making these measurements both the electrometer and a vacuum tube voltmeter were used. Curves showing the relationship between zero correction and temperature are shown in Fig. 4, these measurements being made with the electrometer. In Fig. 4, 08 is a thin electrode; N2 and N6 are thicker electrodes. Additional measurements on a good electrode in a buffer

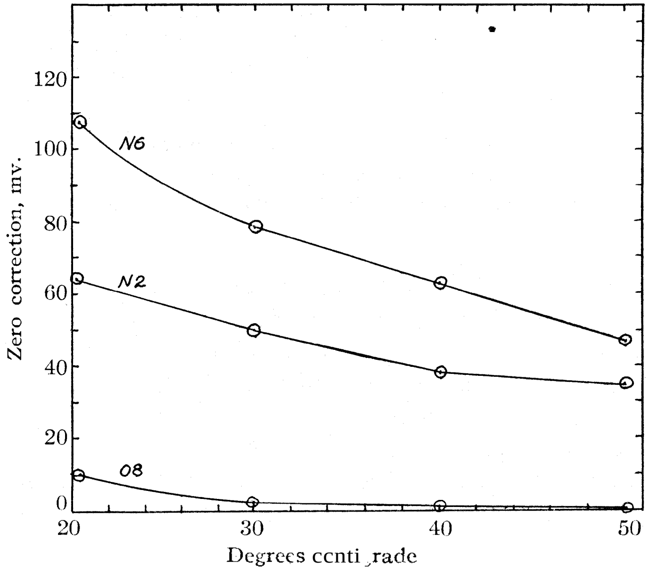

Fig. 4.

system at three different temperatures showed that as the temperature was elevated the slope of the calibration deviated a little more from the theoretical.

Effects of Surfaces upon Potential Measurements.—Experiments were performed to see if a given glass electrode gave the same calibration curve on the two sides of the bulb when the outside immersed surface was only a fraction of the inside wetted area. Although a difference in calibration on the two sides, without exception, was found on twenty electrodes, to conserve space we give the data on only a single electrode in the form of a matrix (Table III).

TABLE III

THICK ELECTRODE C 60. VOLTS MEASURED ON VACUUM TUBE VOLTMETER

Reading in volts

P_H outside	3.97 P_H Inside	748	Inside diff.
3.97	0.1842	-0.020	0.2042
748	.300	.096	.2040
Outside diff.	.1158	.1160	Theor. diff. = 0.2046 volt

This evidence shows clearly that an electrode may have different calibration curves on the two sides. A large number of experiments testing the importance of such factors as method of blowing the bulb, hydrostatic pressure at time of measurement and surface curvature gave negative results.

The important factor in determining the electrode characteristic was finally found to be the detailed conditions connected with the geometry of the wetted surfaces. Before discussing these details, however, it is first necessary to determine whether these phenomena are connected with states of non-equilibrium or equilibrium.

Time Required to Reach Equilibrium.—Most electrodes giving a poor performance show time lag in reaching a steady value. To study this, fourteen similar tube type electrodes were made, by sealing one end of 30-cm. lengths of 7-mm. diameter tubing of 1 mm. wall, and tested in buffer solutions. It was found that under similar experimental conditions all behaved alike. In going from one buffer to another, on the side of small immersion, the initial value was poor, improving on standing for the first and subsequent days (Table IV). This leaves little doubt that the de-

TABLE IV

24 hours	.980	.760	.220	0.252

viation effects are transient phenomena, disappearing when the system ultimately reaches equilibrium.

Potential Dependence on the Geometry of the Two Wetted Surfaces.—It was first established that in the tube type of electrode the larger surface gives the theoretical slope or something near thereto, and the smaller surface gives a calibration considerably under the theoretical. This effect is roughly proportional to the thickness. In the case where a glass tube electrode is partially immersed in a fluid so that the height is the same on both sides, the electrode also gives a good value (Table V).

TABLE V

EXPERIMENTAL DATA

[a] Close agreement with theoretical value when levels are equal. [b] Erratic value when levels are markedly different.

The most careful checks were made to test the influence of instrument leakage and it was definitely settled that the relations mentioned in the preceding paragraph were a function of the glass electrode itself and could not result from any deficiency of the measuring equipment.

The electrical capacity of the electrode was also eliminated as a factor in the deviations of the measurement from the theoretical value.

Next, tubes were made with equal areas on the two sides of the glass wall but in such a relationship to each other that no immersed surfaces would be directly opposite each other. Changing the solution inside gives the correct slope but changing the solution outside has practically no influence on the potential measured. Now an inspection of Figs. 5 and 6 showed that the current which flows through such an electrode must pass up a film on the surface of the glass, since the resistance through the glass would be several times the actually. measured value. This indicates the existence of an aqueous conducting film on the glass above the solution line which we simply call the deviation film, since we attribute most of the deviations to it.

Between this film and the glass there must be a phase boundary potential and between the film and main body of the solution a small diffusion potential. The deviation film through the process of diffusion gradually takes a PH value depending in part at least on the PH of the solution.

The measured potential difference is therefore the result of the parallel electromotive forces existing at the phase boundaries between the solution and glass and between the deviation film and glass, to the latter of which is added a small diffusion potential. In the simplest case of two parallel e. m. f.s, the measured potential, neglecting the diffusion potential, is $(Er + eR)/(R + r)$, where E, e and R, r are the potential differences and resistances in the two regions, respectively. Thus the higher the relative resistance of the submerged part of the electrode, the greater is the effect of the deviation film above the solution surface and hence the greater the deviation. This explains the resistance effects experimentally given in preceding paragraphs. A thick glass may therefore be used providing a large immersed area is used to lower the resistance.

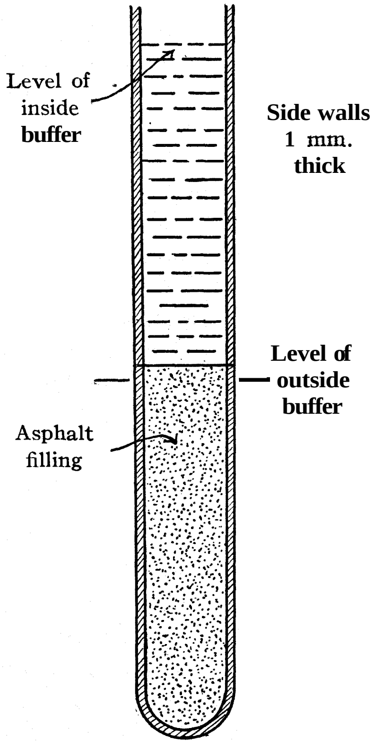

Fig. 5.

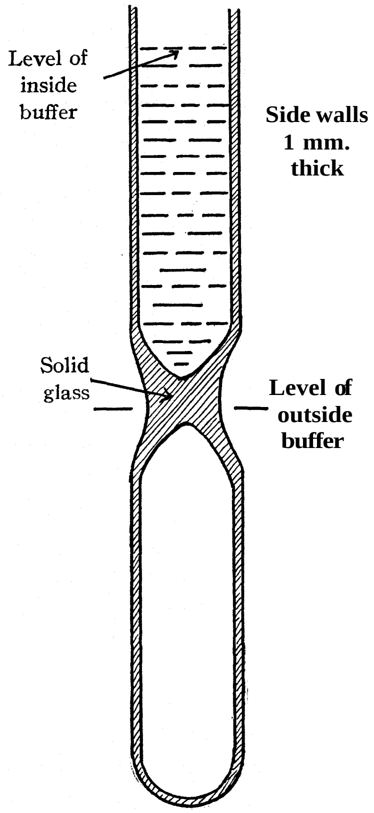

Fig. 6.

Two further tests of the deviation film hypothesis were (1) a tube which had stood in a solution for a week with a fixed level on the outside was found to give the theoretical difference for the solutions measured. The solution on the outside had been P_H 8.24. The tube was held horizontally and painted above the immersion line with a hydrochloric acid solution, care being taken to keep well above the line of top immersion. The tube was now wiped off with a towel and put back in the original position. The e. m. f. was now too low by 70 mv., showing the importance of the film above the liquid line. The value slowly recovered in the course of a day.

(2) If the deviations ordinarily found are to be attributed to films above the line, then by painting on a dry tube a layer of insulating paint, asphalt or paraffin, and just immersing to the edge of the coat, it should be possible to eliminate the spurious effects. A tube was so painted and it then gave the theoretical slope with only one-sixth the outside area immersed. This was verified in perhaps thirty cases.

Glass Cells with Solid Poorly Conducting Coats.—A few tests on the response of poorly conducting coats to change in *PH* of the solution were made. The coating should have two properties. (1) By simply adding resistance to the region covered it would give protection as pointed out in the preceding paragraphs. (2) If the coating itself does not respond to *PH* changes, it should give protection irrespective of resistance. In order to study the response of the coats to *PH* the entire bulb of a Haber–Klemensiewicz type electrode was coated with the material in question. Thin films of paraffin about 5μ thick, collodion, flexible collodion, oleic acid and stearic acid were put on the outer wall of the glass bulb as in Fig. 7. Shellac, DeKhotinsky cement and asphalt were also tried.

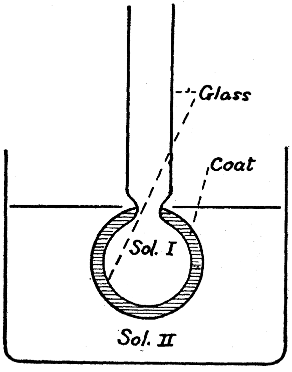

Fig. 7.

It was found that varying the *PH* of solution I in contact with the bare glass gave the usual calibration curve for a good electrode. The bulbs used in these tests were of large area and were quite thin (20μ). The resistance of the combination was usually measured. It was found that changing the PH of solution II in contact with these coatings had little effect on the potential of the chain, but changing the salt concentration in solution II had a marked influence on the readings. Table VI shows some typical experiments. The case of electrode **A-81** shows that readings can be duplicated from day to day.

An inspection of the table shows that for the coatings mentioned change of *PH* of the solution in contact with the coated side of the glass has little effect on the potentials measured. It is reasonable therefore to use such coatings in an attempt to cut out the change in potentials occurring above the level of immersion of the glass.

Practically we find that most paints are worthless after a few hours of immersion due to the fact that water penetrates between the paint and the soft alkaline glass.

Influence of Ions Other than Hydrogen and Hydroxyl.—There are statements in the literature to the effect that at least certain glasses, when made into thin membranes, are capable of measuring potential changes due to alterations in the concentration of ions other than hydrogen and hydroxyl. Horovitz and Schiller, in their widely known papers, showed for the special glasses they examined that sodium, potassium, silver and zinc electrode functions were exhibited. This is a matter of considerable significance, and we have, therefore, studied this phenomenon especially with reference to the sodium electrode function of the glasses in our possession.

For the purpose of studying the sodium electrode function, Horovitz in one case used a sodium acetate buffer. To this buffer varying amounts of sodium chloride were added. It was observed by him that the potential changes, indicated by the glass electrode, upon the addition of successive amounts of sodium chloride, could be accounted for by assuming that the glass membrane had a sodium electrode function.

In our work we found large sodium electrode effects, if we assumed that the PH of the buffer remained constant. On the basis of a consideration of ionic activities, such an assumption was not justified, and we therefore modified the experimental procedure as follows. A 50-cc. bottle was provided with a rubber stopper having holes to permit insertion of a hydrogen electrode, a glass electrode, an agar–potassium chloride bridge, an inlet for purified hydrogen gas and an escape for the gas. This arrangement made it possible to measure the potential of either the hydrogen electrode or the glass electrode in conjunction with a saturated calomel half-cell. Using this technique, the potentials were obtained on 25 cc. of a buffer solution, after all traces of oxygen had been eliminated as

[a] ΔEh and ΔEg are the changes in potential of the hydrogen and glass electrodes, respectively, due to the addition of the salt. [b] The PH column refers to the values before addition of the salt. [c] Buffer system composed of varying ratios of monosodium phosphate and disodium phosphate. [d] Buffer system composed of varying ratios of disodium phosphate and trisodium phosphate. These mixtures and the glycine series yield buffer mixtures having buffer capacities characteristic for each series; hence the difference in magnitude of salt effect noted on the hydrogen electrode.

judged by the constancy of the hydrogen electrode reading. A weighed amount of sodium chloride was then introduced and the potentials again observed. The data of a series of such experiments covering a PH range from 3.97 to 12.55 are given in Table VII.

Similar effects were obtained when electrodes were constructed so that equal areas were used on both wetted sides.

It is seen that the change in voltage at the glass electrode unaccounted for by the change in hydrogen-ion activity is definite but very small in the lower PH range. Only in alkaline solutions does the glass 015 show a significant sodium electrode function and even then it is far below the hypothetical magnitude. Similar experiments showed an even smaller effect produced by potassium.

The fact, here brought out, that the sodium effect becomes important only when the glass buffer properties begin to break down favors the idea that the salt is simply interfering with the hydrogen-ion measuring system.

Referring back to the introductory paragraph, it now appears that so far as Haber's theory is concerned, in the equation $E = RT \log (Ia/Ib) - F(G)$, $F(G)$ is probably the term involved in the deviation of the electrode calibration at extreme PH values, while the deviations at intermediate PH levels are due to the deviation film and have no special relation to the Haber hypothesis.

Conclusions and Summary

1. The specific resistances of several glasses were determined as well as decrease of resistance with rise of temperature.

2. It was shown that without waiting for the system to come to complete equilibrium, glasses give deviations from the theoretical calibration curve (volts against PH) which are roughly proportional to the thickness on the side of smaller fluid immersion. On the larger side the calibration is close to the theoretical.

3. This effect was shown to be caused by the formation of a hygroscopic deviation film on the glass surface above the water lie. It is suggested that the potential measured is the value of the spurious film potential and the true value of the immersed glass connected in parallel.

4. By changing the character of the film above the line, the values given by the electrode could be changed.

5. By suppressing the film through coats of dielectric paints, the deleterious effect could be practically eliminated as long as no water penetrated under the coating.

6. Potentials were measured through various thin semi-conducting coatings on glass bulbs. The potential on the coated side of the glass shows only a slight dependence on the PH of the solution and large salt effects. The opposite side of the glass wall, however, shows its usual calibration.

7. The change in salt effects for a PH range from 3.97 to 12.55 was determined. Specific salt effects over the secondary hydrogen ion change only become important in the extreme range of PH values.

WASHINGTON, D. C.

NOTES

The Atomic Weight of Chlorine. The Solubility of Silver Chloride.—I am grateful to Messrs. Scott and Johnson[1] for calling my attention to an erroneous statement in the paper by Hönigschmid and Chan[2] on the atomic weight of chlorine.

Our reason for deciding that it was unnecessary to apply a correction for the silver chloride removed in making the nephelometric tests, when the precipitate was subsequently to be weighed, was that we had assumed its solubility under the conditions of the analysis at 0° to be 0.05 mg. per liter. At that time we had not determined this value ourselves but, through an error in reading, had taken from the paper by Richards and Willard[3] this value instead of the true one, 0.5 mg. per liter. After reading the communication of Scott and Johnson, we determined this solubility in analyses both of sodium and potassium chlorides at the equivalence point, after the usual shaking and cooling in ice for several days. Portions of the perfectly clear solution were pipetted into nephelometer tubes and, after addition of silver and chloride ion, respectively, showed the same opalescence as a standard containing 0.53 mg. of silver chloride per liter, thus completely confirming the work of Richards and Willard. When an excess of 0.3 mg. of silver was added, the solubility was 0.42 mg. or only 80% as much. This common ion effect makes the correction uncertain.

The nature of the precipitate obtained by us was probably different from that obtained by Scott and Johnson, and this doubtless accounts for the lower solubility found by us. In making the correction we prefer to use our own value because we consider it more applicable.

A calculation of the correction to be applied was easily made by referring to the laboratory notebook which contained all the data. Usually only two or three tests were necessary, because the proper amount of silver was carefully weighed to within 0.1 or 0.2 mg. It was assumed that 100 cc. of the solution contained 0.05 mg. of silver chloride, as already determined, because although it may have been less in the first test, when an excess of one ion was present, this value is certainly a maximum. Each nephelometer tube contained 22 cc. The corrections are shown in Table I.

7	2.21357	6.73502	8.94863	− .04	.2473641	35.4562
8	3.04333	9.25949	12.30290	− .08	.2473669	35.4568
9	2.17711	6.62409	8.80133	− .13	.2473615	35.4558
	21.32439	64.88109	86.20632	− .84	.2473646	35.4563

The average value for the atomic weight of chlorine is 35.4563, and that obtained nephelometrically is 35.4567. The average deviation between the weight of silver chloride found and calculated is 0.10 mg. and the total for eight gravimetric determinations is 0.84 mg.

Because silver chloride retains traces of other salts, it is probable that the weight obtained in the gravimetric process tends to be too great and that an exact agreement between the gravimetric and volumetric methods, if it occurs, is due to a chance compensation of errors in both directions.

In most of our atomic weight determinations the error due to uncertainty in the amount of silver chloride removed for nephelometric tests is, as shown above, very small, because the solution is almost always so near the equivalence point that very few tests are necessary.

Note on the Third Law Calculation of the Entropy and Free Energy of Ammonia.—A calculation of the molecular entropy and free energy of formation of ammonia has been made by means of the third law of thermodynamics using the low temperature heat capacity data of this compound. The calculated molecular entropy and free energy of formation are, respectively, 46.7 entropy units, and —4150 calories at 298.1°K.

There has been considerable uncertainty regarding the proper value of the entropy of hydrogen to be used in thermodynamic calculations in combination with other molecular entropies obtained by means of the third law. For this purpose, Giauque[1] has recommended a value derived from the absolute entropy of ordinary hydrogen obtained from spectral data, modified by the principle of nuclear spin cancellation.[2] This value has been found satisfactory for systems of monatomic and diatomic substances, but has not been conclusively tested for larger molecules. Since the thermal data and equilibrium in the ammonia synthesis, $^1/_2N_2(g) + 1^1/_2H_2(g) = NH_3(g)$, are known with a high order of precision,[3] and since there are now sufficient measurements upon ammonia at low temperatures to permit a calculation of the molecular entropy, this substance serves as a test of the applicability of the third law, and more particularly of Giauque's value for the entropy of hydrogen.

The low temperature heat capacity measurements used in the present calculation are those of Clusius, Hiller and Vaughen,[4] also Eucken and Karwat.[5] Heats of vaporization and fusion were taken from the work of Eucken and Donath.[6] Extrapolation to 0°K. was carried out by the Debye function with $\Theta = 215$. For the heat capacity of the gas, the values of Osborne[7] and associates were used. The molecular entropy thus obtained is 46.7 entropy units at 298.1°K.

Assuming Giauque's value of 31.23 for the entropy of hydrogen, and 45.6 for that of nitrogen,[8] the entropy change accompanying the formation of ammonia is —22.9 E. U. The heat of formation, $\Delta H_{298.1}$, which is equal to —10,985 calories, is obtained from Lewis and Randall's equation[3]

$$AH = -9500 - 4.96T - 0.000575T^2 + 0.0000017T^3$$

The free energy of the ammonia synthesis can be derived from the above results by means of the second law, and is found to be: $\Delta F^{\circ}_{298.1} = -4150$,

which may be compared with the experimental ΔF°_{298} = —3910 given by Lewis and Randall.[8] If the previously accepted value[8] of 29.6 for the entropy of hydrogen be used instead of that later recommended by Giauque,[1] $\Delta F^\circ_{298.1} = -4900$ is obtained. It is obvious that Giauque's value gives the better agreement with experiment.

Villars[10] has calculated the molecular entropy of ammonia from spectroscopic data. His figure, 44.0 E. U., is not given on the same basis as the above value. When Villars' result is made comparable with the entropy of hydrogen used here (31.23), his value becomes 46.5, in close agreement with the 46.7 given above.

The Analysis of Chlorine Monoxide–Chlorine Mixtures.—Chlorine monoxide may be determined by absorption in potassium iodide solution and titration of the iodine liberated.

$$Cl_2O + H_2O + 4I^- \longrightarrow 2OH^- + 2Cl^- + 4I$$

It is necessary to acidify the solution before titrating with thiosulfate.[1]

$$Cl_2O + 4I^- + 2H^+ \longrightarrow 4I + 2Cl^- + H_2O$$

The liberation of OH− provides a further means for the determination of chlorine monoxide and indicates a method for the analysis of chlorine monoxide-chlorine mixtures.

$$Cl_2 + 2I^- \longrightarrow 2I + 2Cl^-$$

Excess of standard sulfuric acid is added and after titration of the total iodine with thiosulfate the excess acid is found by back titration with standard alkali. Bowen[2] used methyl orange as indicator. while Hinshelwood[3] used $N/10$ baryta and phenolphthalein. If x cc. of thiosulfate is used and then y cc. of sulfuric acid is required to neutralize the OH−; Cl_2O a y and Cl_2 a $x - 2y$. Acid, base and thiosulfate must all be of the same normality or correcting factors are necessary.

The analysis can be simplified by an adaptation of the method used by Bodenstein[4] for the analysis of chlorine-ozone mixtures.

As before, the gases are absorbed in potassium iodide solution and excess standard $N/10$ sulfuric acid added and the total iodine found.

[9] Giauque and Wiebe, THIS JOURNAL, 50, 121 (1928).

[10] Villars, *ibid.*, 53, 2006 (1931).

[1] Kistiakowsky, Z. *physik. Chem.*, 116, 371 (1925).

[2] Bowen, J. *Chem. Soc.*, 123, 1203 (1923).

[3] Hinshelwood, *Proc. Roy. Soc.* (London), A131, 177 (1931).

[4] Bodenstein, Schumacher and Padelt, Z. *physik. Chem.*, 5B, 209 (1929).

The excess sulfuric acid is estimated by addition of a slight excess of $N/10$ potassium iodate solution and titration of the iodine liberated.

$$IO_3^- + 51- + 6H^+ \longrightarrow 61 + 3H_2O$$

The acid may be standardized by addition of potassium iodide and a slight excess of $N/10$ potassium iodate solution, the results agreeing very well with those by other methods.

The agreement between this method and that used by Hinshelwood[3] may be seen by comparing the amounts of standard $N/10$ sulfuric acid used to neutralize the $OH-$ liberated by the chlorine monoxide contained in 5 cc. of a solution of chlorine monoxide-chlorine in carbon tetrachloride.

	Solution A	Solution B	Solution C
H_2SO_4 estimated by KIO_3 method, cc......	7.40	5.67	7.88
H_2SO_4 estimated by baryta method, cc......	7.42	5.74	7.89

Doing duplicate experiments showed an agreement to about one-half of one per cent. but the method could be brought up to the usual accuracy of iodine titrations using calibrated apparatus and greater care than in these preliminary experiments. The concentrations of chlorine monoxide and chlorine were between 0.05 and 0.30 g. moles per liter in these experiments.

This method would appear to have the advantage of speed, simplicity and a convenient end-point. Since the acid can be standardized in terms of the thiosulfate, only the latter need be determined absolutely and, furthermore, the ratio of chlorine to chlorine monoxide can be found without a knowledge of the actual normality of the thiosulfate.

The method could also be used for the analysis of chlorine dioxide–chlorine mixtures, the excess acid being determined as above by addition of potassium iodate solution.

$$ClO_2 + 51- + 4H^+ \longrightarrow Cl^- + 51 + 2H_2O$$

Bowen[2] analyzed chlorine dioxide–chlorine mixtures by absorption in potassium iodate solution, followed by thiosulfate titration in acid and in neutral solution according to Bray's[5] method.

$$ClO_2 + 51 + 4H^+ \longrightarrow Cl^- + H_2O + 51$$
$$3ClO_2 + 5I^- \longrightarrow 2IO_3^- + 3Cl^- + 31$$

The Ultraviolet Light Absorption of Ethyl Alcohol Purified by Different Methods.—According to Bielecki and Henri[1] the first ultraviolet absorption band of pure ethyl alcohol begins at about λ2500 Å., and extends, with increasing strength, down at least to 2100 Å. On the other hand, many of the impurities ordinarily found in ethyl alcohol (*e. g.*, aldehydes, resins, etc.), shows trong absorption bands at longer wave lengths. It follows that measurements of the absorption coefficients of ethyl alcohol in the threshold region, λ2500–3000 Å., should provide a very delicate method for the detection of impurities of this type.

We have observed a considerable variation in the absorption spectra in the threshold region of samples of ethyl alcohol purified by different methods, and believe that absorption measurements can be used to determine to some extent the efficiency of different methods of purification.

In Table I, and on Fig. 1, are compared the absorption coefficients of samples of ethyl alcohol which have been subjected to the following treatments. All distillations were made through a fractionating column, only the center portion of the distillate being collected in each case.

A. Stock 95% ethyl alcohol, without purification.

B. Alcohol "A" was dried over calcium oxide, then 1 g. of iodine added per liter of alcohol. The solution was allowed to stand for several days and then distilled. To this was added 1 g. per liter of pure powdered zinc, the mixture being refluxed for several hours and again distilled.[2]

C. To alcohol "A" was added, per liter, 25 cc. of 12 N sulfuric acid. The mixture was refluxed for several hours and distilled.

D The product from "C" was treated with 20 g. of potassium hydroxide and 10 g. of silver nitrate per liter, the mixture being refluxed and distilled.

E. Alcohol "D" was allowed to stand for one week over specially prepared pure calcium oxide, then distilled slowly on a water-bath.

F. Treatment same as in "E" except that the solid matter (calcium oxide and hydroxide) was filtered off before distillation.

G. Same as "E" except that the whole process, from first addition of calcium oxide, was carried out in an atmosphere of pure nitrogen.

H. Alcohol "D" was allowed to stand for one week over active aluminum amalgam, filtered and distilled.

The absorption measurements show clearly that the treatment of stock alcohol with dilute sulfuric acid, followed by distillation, produces a tremendous improvement in purity (curve C). Another marked improvement is produced by the treatment with alkaline silver oxide (curve D). This is no doubt due principally to the removal of aldehydes.

If the next step be distillation in air from calcium oxide, after standing, in the usual manner, a very pronounced increase in absorption is observed (curve E), indicating the formation of some absorbing impurity. Upon filtering off the calcium oxide before distillation, a less marked

increase in absorption is obtained (curve F), and upon keeping the alcohol in an atmosphere of nitrogen during the entire treatment and distillation, no change in absorption is observed (curve G).

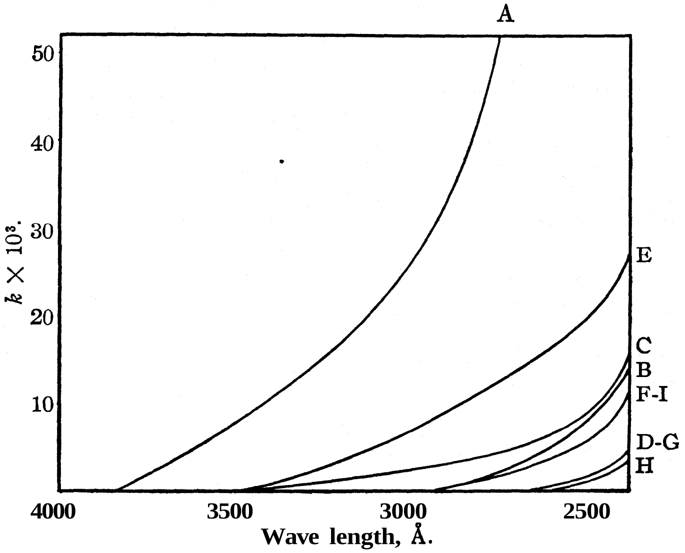

Fig. 1.—Absorption coefficients for various alcohol samples.

This suggests that the alcohol is oxidized by calcium oxide in the presence of air, the reaction proceeding very slowly at room temperature, and much more rapidly during distillation. The oxidation does not occur in the absence of oxygen, and hence the drying of ethyl alcohol over calcium oxide should be carried out in nitrogen.

Drying over aluminum amalgam gives the lowest absorbing, and hence the purest alcohol of any of the methods used here. It should be pointed out, however, that non-absorbing impurities, such as water, are not detected by absorption measurements. The electrical conductivity may be used to detect the presence of small amounts of water, and a comparison of the conductivities of the different samples indicated that aluminum amalgam is fully as efficient a drying agent as calcium oxide. Metallic calcium, used as a drying agent, failed to give any better results than calcium oxide, either for light absorption or conductivity.

The iodine–zinc method of purification (curve B) does not give quite as good results as the other methods.

It is of interest that the absorption measurements of Bielecki and Henri (column I) which are the lowest hitherto reported, agree almost exactly with our alcohol F, while our samples D, G and H show a lower absorption in this threshold region.

In short wave lengths, however, where alcohol itself absorbs strongly, one would expect the difference between the various samples to be slight.

Summarizing, light absorption measurements indicate that the standard practice of drying ethyl alcohol over calcium oxide should be carried out in an oxygen-free atmosphere. The highest degree of purity, as measured by the absorption spectrum, is obtained by the use of aluminum amalgam for drying.

SOME FACTORS AFFECTING THE CATALYTIC ACTIVITY OF COBALT OLEATE IN THE AUTOXIDATION OF PENTENE-2[1]

BY JULIUS HYMAN AND C. R. WAGNER

RECEIVED DECEMBER 12, 1930 PUBLISHED AUGUST 5, 1931

(A) Introduction

In a paper published some months ago,[2] the authors noted the catalytic activity of certain substances on the autoxidation of cracked gasolines. It was ascertained at that time that hydrogen chloride, for example, was a strong autoxidizing catalyst, whereas acetic acid was almost without effect. These reactions, as well as numerous other indications, prompted the authors[2,3] to propose a new theory of autoxidation based on the acidic

[1] Presented before the Petroleum Division of the American Chemical Society at Cincinnati, Ohio, September 9–13, 1930.

[3] Hyman and Wagner, J. *Inst. Pet. Tech.*, 15, 645 (1929).

character of the autoxidation catalysts, as well as on the possibility of oxonium compound formation in the cases where peracids were felt to act as catalysts.

Among the compounds showing a decided catalytic activity was reported a mixture of cobalt and nickel acetate crystals, despite their apparent insolubility in gasoline. In work reported in a recent paper,[4] the authors have made use of this fact, using cobalt oleate as a catalyst in the autoxidation of the pentenes. Cobalt oleate (provided it is not removed too completely from its original solvent) is readily soluble in hydrocarbons.

Since the time that certain compounds were discovered to have a positive catalytic effect on the formation of pseudo-gum in cracked gasoline, the authors have felt that "promoted" autoxidation (*i.e.*, autoxidation which has been promoted by a foreign substance purposely added) could be brought under the same viewpoint as the "unpromoted" autoxidation. It is believed that the material to be presented in this paper tends to justify such an opinion.

The cobalt soaps have for years been used as "driers" in paints and varnishes and, according to various authorities,[5] are the most active of all the soaps in this respect. Kissling[6] recognized the action of the drying of an oil film to be in part, at least, an oxidation, and Fahrion[7] was quick to apply Engler and Weissberg's extension of the original Engler-Bach theory of autoxidation[8] to this problem. According to Fahrion's interpretation, the metals may act as carriers of atmospheric oxygen, transferring this oxygen either between two "acceptors"—olefin bonds of a drying oil—or else allowing half the oxygen to combine with water to form hydrogen peroxide. The manner in which such transfer was to take place was left moot, although Fahrion believed that the metal-oxygen combination was in the form of a metallic peroxide or hydro-peroxide. The theory, regarding the action of driers, which appears to have gained the most popularity is that of Ingle.[9]

Ingle's theory is an alteration and extension of Fahrion's theory, the most striking point of which is the postulation that only those metals act as siccatives (in the form of their soaps) which possess multiple valence states, and only then when the salts corresponding to the lower valence state are more stable than those corresponding to the higher state. In

order to distinguish between the drying activities of the various metals possessing multiple valence states, Ingle further postulated that the more valence states a metal could assume, the more active it would be as a drier.[10]

That Ingle's scheme cannot express the action of driers completely is obvious, as its author admitted.[9b] For example, cobalt, having but two valence states is more active (in its soaps) as a drier, than is vanadium, with at least four. Furthermore, soaps of aluminum, calcium, sodium and silver act as driers to some extent, despite the fact that these metals possess but one valence state. The authors believe, with Ingle,[9] that their use of metal catalysts with unsaturated hydrocarbons parallels to quite an extent the use of such catalysts with the vegetable oils. In fact, metal catalysis in atmospheric oxidation does not seem to be limited to these fields at all, but appears to play a very important role in other branches of chemistry as well, as for example, in physiological chemistry.[11]

As a matter of fact, in the petroleum industry, metal catalysis in autoxidation is undoubtedly present. As a very minor but immediate example, the use of a copper dish for gum determination leads to inordinately high gum values, which can be accounted for only by assuming a catalytic activity of the copper, *i. e.*, the copper compounds formed by interaction of the acids present in the oxidized gasoline with the copper dish.

(B) Preliminary Preparations

It is now common knowledge that aldehydes such as benzaldehyde and acetaldehyde, when exposed to sunlight in the presence of oxygen, are converted partially at least into peroxides. In the absence of light a somewhat similar but much slower reaction takes place.

If, however, acetaldehyde is dissolved in alcohol to which a crystal of cobalt acetate and a few drops of acetic acid have previously been added, and if such a solution is permitted to stand under oxygen in the dark, the peroxide formation is even more rapid than in sunlight. During the reaction, the light pink solution is changed to olive-green. This reaction suggests that one of the reasons for the autoxidation of acid-free aldehydes in the dark may lie in the presence of traces of metallic salts as impurities.

It was decided to prepare a sample of cobalt oleate, free from solvent. This was tried both by methods of fusion and precipitation. The former method, however, never made a product free from fatty acid, and therefore the latter method was used throughout the work. The general method of preparation was, first, to make the potassium soap by allowing U. S. P. oleic acid, diluted with alcohol, to react with a 10% excess of potassium hydroxide dissolved in a large portion of distilled water. To this solution,

---

[10] Fokin[5] also assumed this latter generalization.

[11] O. Warburg, *Ber.*, *58*, 1001 (1925).

after being filtered, was added either a slight excess or a slight insufficiency of C. P. $Co(C_2H_3O_2)_2\cdot 4H_2O$, also previously dissolved in considerable distilled water, and filtered. The precipitate of the cobalt soap formed immediately upon mixing. It was taken up in as little ether as possible, centrifuged, the ether extract filtered, and alcohol added until an ether–soap layer formed. A cobalt oleate solution, such as the layer just mentioned represents, is a deep purple, very heavy solution which hardens immediately on contact with air. The hardening is not due to oxidation, apparently, but rather to evaporation of the ether. If the ether–soap solution is evaporated in *vacuo*[12] a solid substance is formed, which, however, is not the pure soap but a combination of soap, alcohol and ether. If this material is heated on the water-bath in vacuum until the odor of alcohol is gone, a purple colored rubbery substance is formed which appears to be the cobalt oleate itself. The fact that it shows a cobalt content of 10.2–10.3% (the cobalt soap being ignited to the oxide, which is then reduced to metallic cobalt by hydrogen, and weighed as such), whereas theoretically cobalt oleate should contain but 9.48% of the metal, indicates that the U. S. P. oleic acid contains acids of molecular weights lower than that of pure oleic acid.[13] However, for the purposes of this work, it was necessary only to avoid the presence of free fatty acid, and therefore no attempt was made to purify the oleic acid further.

For the preparation of the cobalt oleate used in the main experiments, it was found advantageous to use chloroform instead of ether as a solvent, chiefly because of the very low solubility of water in the former. It was also found unnecessary to wash the chloroform extract with alcohol; thus, the chloroform solution was evaporated *in vacuo* in a water-bath heated to 60°, and the danger of decomposing the soap, consequently, considerably reduced. Such soap also shows a cobalt content of 10.2–10.3%. In the work herein reported the cobalt oleate was never freed from the original chloroform solvent but, rather, more chloroform was added to the solution.

(C) Experimental

If cobalt oleate catalyzes the autoxidation of the olefin bond, it should be an autocatalyst of itself, that is, it should hasten its own oxidation. Indeed, the induction period in this particular autoxidation should disappear entirely, for it is impossible to imagine a negative catalyst present in so large an amount as to prevent completely, even for a very short while,

---

[12] A simple and satisfactory arrangement for vacuum evaporation consists of a heavy-walled lipless Pyrex dye beaker, a funnel whose rim fits the inner part of the rim of the beaker, and a ring of thin sheet rubber, used as a gasket. The suction pump hose is connected to the stem of the funnel. Care must be taken to prevent excessive foaming of the soap solution.

[13] Of course, there is always the possibility of the formation of a mixed soap, namely, cobalt aceto-oleate, in fairly constant proportions.

the autoxidation of so fairly pure a soap solution as the cobalt oleate solution prepared by us. Cobalt oleate, however, is not oxidized immediately, if exposed to oxygen in the dark. In fact, the oxidation does not become noticeable until a lapse of twelve to fifteen hours. The oxidation of cobalt compounds in organic media is readily visible by the color change. The original purple color changes first to brown, and then rapidly to an olive green. The experiment previously alluded to was carried out by allowing several drops of a chloroform solution of cobalt oleate to drop onto a piece of quantitative filter paper. The chloroform was evaporated by blowing with compressed oxygen, and the paper then placed in a four-ounce oil bottle, which was filled with oxygen and kept in the dark. The results obtained indicate quite clearly that some compound other than cobalt oleate is the real catalyst in the reaction. This compound seems to form slowly in the soap, induced perhaps through traces of impurities; for once oxidation has begun, it appears to proceed very rapidly. It usually appears to begin at the fringes of the spot of cobalt oleate. A drop of distilled water in the bottle seems to delay oxidation slightly; a trace of acetic acid appears to hasten the oxidation considerably; on the other hand, a drop of aqueous ammonia retards the oxidation for several days. The authors believe these exploratory experiments to be of considerable importance, for while the present-day tendency might be to interpret these results solely in the light of surface activity and hydrogen-ion concentration, the authors feel that a simpler and more fundamental viewpoint lies in assuming, on the one hand, the interaction of fatty acid and the cobalt oleate, at least minutely, to produce a complex acid possessing catalytic powers, while the ammonia, on the other hand, would tend to bind these acids, or even form amine-cobalt complexes so as to prevent the formation of complex acids.[14] The experiments previously spoken of were continued by determining the rate of autoxidation of pentene-2 in the presence of cobalt oleate alone, as well as in the presence of stearic acid and triethylamine. Pentene-2 was prepared from *sec.*-amyl alcohol and sulfuric acid.[15] It is the simplest of the amylenes to prepare with a fair degree of purity and has been shown by the authors[4] to be oxidized by molecular oxygen with comparative ease. The manner of carrying out the experiments and the mode of titration used was the same as that used by the authors in the paper just referred to.

The results in Table I substantiate the results obtained by noting the action of acetic acid and ammonia on drops of cobalt oleate solution taken up by filter paper (see page 3022). A very interesting point to note in Table I, however, is the initial "induction period," during which time oxida-

---

[14] Mackey and Ingle[5] suggested that partial valences of the soap ions might play a part in the catalytic action of metal driers.

[15] Norris and Joubert, THIS JOURNAL, 49, 873 (1927).

tion does not appear to take place (see the first column of Table I). If the idea of complex acid formation is adhered to, it is at once apparent that the tremendous catalyzing influence of cobalt soaps cannot depend on the action of a complex cobaltous acid in such quantities as might be found by simply mixing a cobaltous soap with a fatty acid. The remaining possibility is the activating influence of a complex cobaltic acid.

The fact that normal cobaltic salts are quite unstable excepting in strongly acid solution makes the preparation of cobaltic soaps by precipitation a rather difficult task. Fusion methods were felt by the authors to be unsatisfactory for this work, because of the possibility of formation of decomposition products which might mask the character of the results. It was therefore decided to oxidize a chloroform solution of cobaltous oleate, in the presence of oleic acid, using hydrogen peroxide of 10% strength as the oxidizing agent. The calculated amount of oleic acid was used, and 50% more hydrogen peroxide than the theoretical equation would require. The resulting product, which is of an olive-green color, was washed repeatedly with water, to remove the excess hydrogen peroxide, then heated for a half hour on the water-bath, any excess oleic acid removed by repeated extraction with ethyl alcohol, and the remaining ethyl alcohol and chloroform evaporated in *vacuo* as previously described. A cobalt determination gave the very surprising result of 13.4% cobalt in the new product, whereas the cobaltous material showed only 10.3% cobalt. The cobaltic material made without the addition of the oleic acid showed a similar analysis.

The most plausible explanation for the above-mentioned analysis lies in the assumption that the cobaltic compound formed from the oxidation of cobaltous oleate immediately splits off oleic acid, a certain amount of which is removed by alcohol extraction. A simple analogous experiment may be conducted as follows.

Dissolve a few crystals of cobalt acetate in a little 95% alcohol. Add a few drops of 10% hydrogen peroxide. The purple solution becomes olive-green so rapidly that the intermediate brown state is scarcely perceptible. If a little of this clear solution is poured on a piece of fine filter paper, the color distributes itself evenly over the entire blot. As the alcohol evaporates, the odor of acetic acid may be noticed. After standing overnight, the solution will have turned brown, and if a few drops are poured onto a piece of filter paper, the brown color will not spread with the liquid. This indicates that the (apparently) basic cobaltic acetate has hydrolyzed completely to form colloidal cobaltic hydroxide. It is logical to assume that a similar series of changes takes place with the oxidized cobaltous oleate. The complete hydrolysis, however, seems to take place very slowly, if at all. If a piece of cobalt oleate is exposed to the air for several days, the surface becomes sticky. If the surface is washed with alcohol, and the alcohol evaporated, a pale yellow film, evidently of oleic acid, remains behind.

In this way, then, the oxidation of a cobalt soap may produce its own fatty acid. Numerous series of tests similar to that recorded in Table I have been made, using a chloroform solution of the green cobalt*ic* oleate compound as a catalyst. A representative run appears in Table II. Because of the fact that only those values at the beginning of the runs are of immediate interest, only these have been noted. As the runs continued, the values for the various titrations merge into one another.

TABLE II

DATA OF A REPRESENTATIVE RUN

		Cc. of 0.01 N Na_2SO_3 used after		
	Material	**4 hrs.**	**28 hrs.**	**78 hrs.**
1	Pentene-2, blank	0.00	0.00	0.00
2	No. 1 + 2 drops 8.2% soln. of Co^{+++} compound in $CHCl_3$ + 4 drops pure $CHCl_3$	0.80[a]	5.20	10.00
3	No. 1 + 2 drops Co^{+++} soln. + 4 drops 10% stearic acid soln. in $CHCl_3$	0.90	5.55	11.95
4	No. 1 + 2 drops Co^{+++} soln. + 4 drops normal soln. NH_3 in $CHCl_3$	0.00[b]	0.00	7.10

[a] No. 2, titrated at the beginning of the test, showed practically no iodine liberation.

[b] Two drops of N ammonia solution added to sample after portion for first titration had been removed, to allow for ammonia lost by evaporation. No ammonia added thereafter for the remainder of the run. The amount of ammonia used at the beginning in series No. 4 was approximately double that needed to form a compound $(Co(NH_3)_6)X_3$.

The results of the experiments recorded in Table II attract attention in more than one respect. The most striking feature is the lack of an induction period in series 2 and 3.

Again, the influence of acidic and basic substances is apparent, quite in accordance with the authors' viewpoint. The fact that the plain cobaltic solution shows a high initial catalytic influence the authors would ascribe to the formation of a fairly stable complex cobaltic acid during the preparatory oxidation. The powerful inhibiting effect of ammonia leads the authors to the conclusion that so long as a strong free base is present, cobaltic soaps will not function as catalysts. As a concluding remark relevant to these experiments, therefore, it appears probable that when a cobalt soap acts as a catalyst, the oxidized soap is the active principle; furthermore, the most apparent explanation for the nature of this active principle is to assume the formation of a complex cobaltic acid.

(D) Theory

Provided one may then assume the active principle of a cobalt soap to be a complex cobaltic acid, and provided, furthermore, that one may generalize the case of cobalt soaps to driers in general, a logical picture of "promoted autoxidation" may be gained, somewhat as follows.

If the metals, present in their soaps, have several valence states, and if the metals were present originally in their lowest valence states, then the peroxides formed by autoxidation may raise the metals to higher valences. For example, Co^{++} will be raised to Co^{+++}, Mn^{++} will be raised to Mn^{++++} or higher and Pb^{++} will be raised to Pb^{++++}, which will be the normal valence states for these metals so long as any peroxides are present. If, therefore, complex acids are to be formed, the nuclear atoms will be Co^{+++}, Mn^{++++} and Pb^{++++}. Now, although Mn^{++++} and Pb^{++++} have not received much investigation regarding their complex-forming tendency, Co^{+++} is known as the ion possessing the greatest tendency in this respect. Cr^{+++}, which also possesses a high complex-forming tendency, is oxidized by peroxides to a higher valence state. Pt^{++++}, another complex-forming ion, acts as a rather good drier in the form of its soaps.

In 1899, Abegg and Bodländer[16] made the important observation that, in general, metallic cations form complexes more readily, the weaker their electro-affinities. This is equivalent in the case at hand to saying that the greater the oxidation potential exerted when a metallic ion existing in the presence of peroxides is reduced to its next lower valence state, the greater will be the tendency of that ion to form complexes. The very incomplete data on this subject[17] indicate clearly that the active siccative ions possess high potentials, the cobaltic ion heading the list. Thus, a bridge may be formed between the tendency toward complex formation and the drying powers of metallic soaps. It can hardly be doubted, however, that the stabilities of the individual acids (formed under the conditions of the autoxidation) play an important role in determining the activity of the soap in question.

As to the acidity of such complex acids, they all[18] belong to the class known as true acids, that is, compounds showing acidic tendencies even in so-called non-ionizing media, as distinct from the pseudo-acids,[19] to which category the plain fatty acids belong.

[19] Ref. 18, p. 227.

Conductivity experiments made some time ago in their laboratory by the authors has shown that vapor-phase gasoline which had undergone oxidation possessed to a very appreciable degree the ability to conduct the electric current. Hence, it is apparent that ions actually are present in such *a* medium. This information has been of value to the authors in explaining the results of their investigation on the autoxidation of the amylenes,[4] assuming that the atmospheric oxidation of amylenes also produces ions, or maintains ionization.

(E) Summary

1. Cobalt soaps of oleic acid have been prepared, and their catalytic effects studied.
2. It has been shown that the cobaltic soap is responsible for the great catalytic activity of cobalt soaps in promoting autoxidation.
3. It has further been shown that bases exert a negative whereas fatty acids exert a positive catalytic effect on autoxidation in the presence of a cobalt soap.
4. The activity of cobalt soaps has been explained on the assumption of the formation of a complex cobaltic acid.

SALTS OF THE AMMONO-ENOLIC MODIFICATION OF QUINALDINE[1]

BY F. W. BERGSTROM

RECEIVED MARCH 11, 1931 PUBLISHED AUGUST 5, 1931

Introduction

Since the group —CH=N— is related to ammonia as —CH=O is related to water,[2] it follows that the heterocyclic nitrogen compounds, pyridine, quinoline, isoquinoline and quinoxaline are aldehyde-acetals of an ammonia system. The aldehydic properties of pyridine, quinoline and isoquinoline are not marked, because of the stability of the six-membered ring they contain. Nevertheless, Mr. McAllister and the author have shown that all three of these compounds react with the Grignard reagent in ether at 150°.[3] Ziegler and his co-workers have quite recently

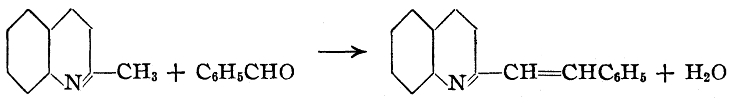
[1] Presented at the Berkeley, California, meeting of the National Academy of Sciences, September, 1930, and at the Eugene, Oregon, meeting of the A. A. A. S., June, 1930. Abstract in *Science*, **72, 402** (1930).

[2] This is not strictly true, since nitrogen is trivalent, while oxygen is divalent. The third valence of the nitrogen in the —CH=N— group may be attached to an alkyl or aryl radical, giving all of the ammono aldehydes the dual character of aldehyde-acetals [Strain, THIS JOURNAL, 49, 1559 (1927)].

[3] Bergstrom and McAllister, *ibid.*, **52**, **2845** (1930)

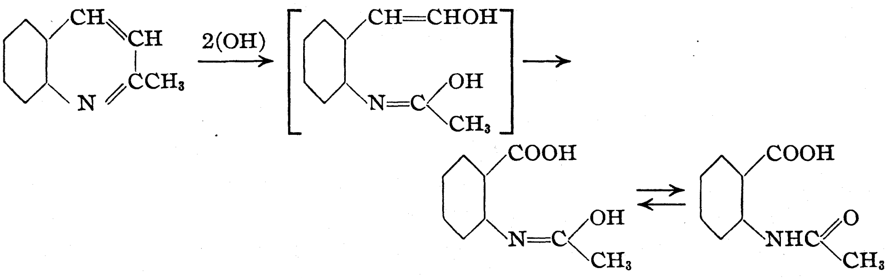
shown that the lithium alkyls and aryls, in ethereal solution, add very readily to the —CH=N— bond of these cyclic aldehyde acetals at ordinary temperatures[4] Quinoxaline, in distinction from pyridine, quinoline and isoquinoline, reacts with ethereal solutions of the Grignard reagent under ordinary conditions.[5] Quinoxaline therefore more closely resembles the familiar aquo aldehydes in its behavior.

If quinoline be regarded as a cyclic ammono aldehyde (-acetal) it follows that 2-methylquinoline (quinaldine) is a cyclic ammono ketone (-acetal) because it contains the grouping —N=C(CH_3)—.[6] In harmony with this view, quinaldine has been found to condense readily with benzaldehyde in the presence of zinc chloride to form benzylidene-quinaldine[7] in accordance with the equation



Clearly this type of reaction, which is by no means restricted to benzaldehyde and quinaldine, can be compared to the union of benzaldehyde with acetone to form dibenzalacetone. Reactions of this nature have led Mills and Smith[8] to compare quinaldine with the ketones of the water system.

The oxidation of quinaldine with potassium permanganate[9] yields N-acetylanthranilic acid, perhaps in accordance with the equation



The rupture of the carbon chain has occurred between the carbon of the ammono carbonyl group, =C=N—, and an adjacent carbon of the ring. The aliphatic aquo ketones on oxidation are similarly broken apart on one side or the other of the carbonyl group.

Many ketones of the water system are tautomeric, in that they exist

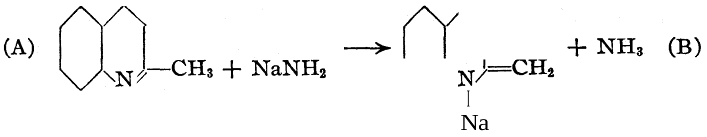
in a ketonic and an enolic modification, both of which are often capable of independent existence. In cases where both modifications cannot be isolated as such, derivatives of both forms may be known. This is true of quinaldine, since the ammono-keto form is the only one that has been obtained, although many reactions are best explained by the ammono-enolic formula, No. B below, in which Na is replaced by H.[8,10] The N-alkyl derivatives of this form (B) represent a rather reactive but definitely known class of compounds, the N-alkyl-2-methylene-1,2-dihydroquinolines.[11] The replacement of the N-hydrogen atom of formula B by potassium, sodium or other metals should likewise give fairly stable derivatives of the ammono-enol (enamic)[12] modification. It was for the purpose of preparing some of these compounds that the present investigation was undertaken. Ziegler and Zeiser[13] have already announced the preparation of the N-lithium salt of quinaldine ammono-enol (compare formula B) which was effected by the action of lithium phenyl upon quinaldine in ethereal solution. In the present work it is desired to bring to completion the study of the action of the alkali amides upon quinaldine in liquid ammonia, as reported in part last year by the author.'

Preparation of Salts of the Ammono-enolic Modification of Quinaldine.—In a preliminary fashion, it was found that the amides of potassium, sodium and lithium reacted readily with a solution of quinaldine in liquid ammonia at *+20* or −33° to form opaque rich red solutions of the ammono-enolic (enamic) modification of quinaldine. Thus sodium amide and quinaldine react in accordance with the equation

(I)



The isolation of the sodium salt in a state of fair purity is illustrated by the following typical experiment.

In one limb of a two-legged reaction tube[14] was placed 0.36 g. of metallic sodium, together with a coil of iron wire to serve as a catalyst for the reaction of sodium with the solvent to form sodium amide. The other leg contained 1.0 cc. of quinaldine, that is, approximately half the amount required by the above equation. After the disappearance of the blue color of the sodium solution, the quinaldine was washed into the leg containing the resultant sodium amide, whereupon an opaque red solution formed at once with a slight evolution of heat. To insure the completeness of reaction, the solu-

tion above the remaining sodium amide was concentrated to a small volume and the tube set aside for a day. The concentrated red solution was carefully decanted into the clean leg of the reaction tube and evaporated to dryness by permitting the liquid ammonia to evaporate from the tube, since it proved impossible to induce crystallization of the salt even at −78°. The ammono-enol salt so prepared unavoidably contained the sodium amide that was simultaneously transferred in solution. Since the solubility of sodium amide in ammonia is of the order of a gram a liter at 20°, this error is not serious. The reaction tube, prepared in the customary manner for analysis, was evacuated at 20° and at 100–150°. The reddish-brown ammono-enolate solidified to a voluminous froth at the lower temperature. The loss of ammonia at the higher temperature is evidently attended with a slight ammonolysis of the salt, since a few very small droplets of liquid (quinaldine) condensed on the cooler portions of the tube. The specimen, after heating, was hydrolyzed overnight with water vapor, a yellowish very viscous liquid of somewhat sharp odor being formed. This was dissolved in dilute hydrochloric acid and analyzed for sodium.[15] A second aliquot was made alkaline with sodium hydroxide, the liberated base extracted with ether, the ether evaporated and the residue taken up in alcohol. From this alcoholic solution a picrate was prepared which could not be obtained in a pure state. Obviously quinaldine was not formed in any quantity by the hydrolysis of its heated potassium salt. This was not unexpected, since the heated salt was insoluble in ether, while the unheated material was readily soluble.

Quinaldine could be isolated when unheated specimens of the potassium and sodium salts of the ammono-enol were hydrolyzed. Apparently, the free ammono-enol first liberated in the hydrolysis is only partially converted to the ammono-keto form (ordinary quinaldine), the rest perhaps being polymerized to products of indefinite nature.

The lithium and barium salts of quinaldine ammono-enol were prepared in the same manner from quinaldine and the amides of lithium and barium, which were made by the catalytic action of iron wire upon liquid ammonia solutions of these metals. In neither of these cases does the reaction appear to be quite complete, since small amounts of quinaldine were always unattacked. Calcium amide reacts only to a very slight extent with quinaldine.

The potassium salt of the ammono-enol, prepared by the action of potassium amide upon quinaldine, could not be crystallized from ammonia solution at −78°.[16] Therefore, in order to accomplish its isolation, the product of the action of an excess of potassium amide solution upon quinaldine was freed from solvent ammonia (the liquid ammonia was evaporated from the tube and the latter evacuated) and extracted in the reaction tube with anhydrous ether.[17] The salt remaining after evapora-

---

[15] One aliquot portion ($^{1}/_{4}$) was evaporated dry and gently ignited to carbonize the organic matter. Then sulfuric acid was added and after ignition the precipitate was weighed as sodium sulfate.

[16] Potassium amide is soluble in liquid ammonia to about the same extent.

[17] The stopcock of the evacuated reaction tube was immersed in ether and opened to allow the introduction of the required amount of ether. The stopcock was then closed. The ether in the tube, under its own vapor pressure, could be evaporated from one leg to the other in the same manner as liquid ammonia (procedure of E C. Franklin, unpublished work).

tion of the ether retained a small amount of both ether and ammonia at 20° in a vacuum. This was given off at 100°, but the salt simultaneously suffered some decomposition.

In duplicate experiments, in which the loss of weight occasioned (cf. Equation I) by the reaction of weighed quantities of potassium amide and quinaldine was determined,[18] it was found that the potassium salt of the ammono enol retained less than 0.1 mole of ammonia in a vacuum at 20°. Conversely, it was found that the sodium salt of quinaldine retained 0.561 mole of ammonia after intermittent evacuation at room temperatures for a period of two days. Ammonia in excess of half a molecule, at least, cannot be held by the salt as true solvent of "Crystallization."

TABLE I

ANALYSES OF QUINALDINE SALTS

Salt	Metal, % At 20°	Metal, % At 100–50°	Calculated for Anammonous salt	Calculated for Salt xNH$_3$	x
K	20.3, 20.2[b]	22.4, 21.5	21.6		
Na	12.3	13.9	13.9	12.6	0.5
Li[a]	3.74	3.80	4.66	3.80	2
Ba[a]	27.2	27.9	32.6	28.1	4
Ca	Reaction very slow and incomplete				

[a] These figures merely represent the maximum amount of lithium amide or barium amide dissolved by quinaldine, and do not quite correspond to definite compounds, since a little quinaldine was unattacked.

[b] Both ammonia and ether retained by salt. Two specimens analyzed.

An attempt to prepare the zinc and silver salts of the ammono-enol of quinaldine by metathesis in liquid ammonia resulted in failure. The precipitates obtained by adding a solution of the sodium salt of the ammono-enol to a solution of zinc cyanide or to silver iodide when washed proved to be, respectively, an impure zinc amide and a slightly impure metallic silver. Evidently the ammono-enolic modification of quinaldine is a very weak acid, since its zinc and silver salts are so completely ammonolyzed. The appearance of metallic silver instead of silver amide in the above reaction is probably due to a reduction of the latter to metal and the equivalent nitridation of the ammono-enol.

Preparation of Salts of Quinaldine in Other Solvents

Since the use of liquid ammonia is inconvenient for many laboratories, attempts were made to prepare the potassium and sodium salts of quinaldine in other solvents. It was found that quinaldine was unaffected by a solution of sodium ethylate in absolute alcohol at 20°, since the characteristic red color of the enolate failed to develop. The potassium and sodium salts of quinaldine were very slightly soluble in benzene and toluene but readily soluble in anhydrous ethyl ether and in quinaldine

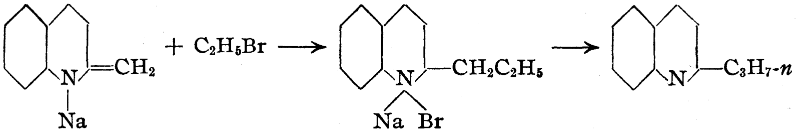
---

[18] *Cf.* Kraus and Greer, THIS JOURNAL, 45, 3079 (1923).

itself. Preliminary experiments indicated the feasibility of preparing these salts from sodium or potassium amide and quinaldine in absolute ether, but not in benzene or in toluene. The products must necessarily contain ammonia since a molecule of ammonia is liberated in the reaction. (Equation I.)

The Action of Alkyl and Aryl Halides upon Ether and Liquid Ammonia Solutions of the Salts of Quinaldine Ammono-Enol.—Since the sodium salt of the enolic modification of acetoacetic ester reacts with alkyl halides to form alkylated homologs of the keto form, it seemed probable that the related potassium and sodium salts of the ammono-enolic modification of quinaldine would behave similarly—and yield homologs of quinaldine with a lengthened side chain, in accordance with the type equation[19]

(II)



2-Ethyl, 2-n-propyl, 2-n-butyl and 2-ω-phenylethylquinolines were thus prepared by the action of methyl idodide, ethyl bromide, n-propyl bromide or benzyl bromide, respectively, on liquid ammonia or absolute ethereal solutions of the potassium salt of quinaldine. These reactions were conveniently carried out in a preliminary fashion in liquid ammonia reaction tubes. For the preparation of larger quantities of these homologs of quinaldine, it was necessary to adopt a different procedure, which may be illustrated by describing the preparation of 2-n-propylquinoline.

A Pyrex tube, 32 cm. long, 4.5 cm. in diameter and closed at one end was placed inside of a Dewar vessel of slightly larger internal dimensions. The top of the Dewar tube vessel was closed by a rubber stopper through which passed (1) a tube reaching to the bottom of the Pyrex tube lining the Dewar, (2) a short tube bent at right angles for introducing liquid from a tank of commercial anhydrous ammonia, (3) a similar bent tube for venting the ammonia that evaporates within the Dewar to the waste and (4) the tip of a 20-cc. buret, the latter passing through a hole in the center of the stopper. This arrangement is similar to that described by Wooster and Mitchell,[20] but differs from it in the use of a removable Pyrex tube to line the Dewar and in the use of a current of ammonia, introduced through tube (1), for stirring the reaction mixture. The use of a mechanical stirrer in these reactions was found to be unnecessary.

---

[19] Since Rosenhauer, Hoffmann and Unger[11] have found that ethyl iodide and N-methyl-2-methylene-1,2-dihydroquinoline react to form 2-n-propylquinoline methiodide, the addition represented by the above equation has been assumed to proceed in a like manner. (A primary 1,3-addition to the enonium conjugated system of Decker,  $CH_2{=}C{-}\underset{|}{N}{-}$ [*Helv. Chim. Acta*, 13, 666 (1930).] Ziegler and Zeiser (Ref. 13) have discussed reactions of this type, and have prepared, among other compounds, 2-n-butyl- and 2-w-phenylethylquinoline by the action of *n*-propyl bromide and benzyl chloride, respectively, on the lithium salt of quinaldine.

[20] Wooster and Mitchell, THIS JOURNAL, 52, 691 (1930).

The Pyrex inner tube fitting the Dcwar having been filled approximately half full of liquid ammonia from the tank, the stopper was removed for a short while and 6.2 g. of metallic potassium introduced together with 0.1 g. of ignited ferric oxide to serve as a catalyst for the conversion of the liquid ammonia solution of potassium to potassium amide. When the conversion of the potassium to potassium amide was complete—as shown by the disappearance of the blue color of the metal solution—19.5 cc. (21.5) g. of quinaldine (0.9 equivalent) was slowly introduced from the buret, while ammonia gas was passed through tube (1) to stir the solution.[21] After standing for two or three hours to make sure that all of the quinaldine had been converted to the potassium salt, ethyl bromide was slowly run into the solution from the buret with stirring until the deep red color of the solution had disappeared. The reaction was fairly vigorous. The reaction product, 2-n-propylquinoline, partly separated as a liquid phase denser than the solvent. The Pyrex tube lining the Dewsr was now removed, the mouth loosely plugged with cotton, and the ammonia allowed to evaporate off under the hood (tube wrapped with toweling to prevent too rapid volatilization of the ammonia). The residue was treated with water to dissolve the potassium bromide and extracted twice with ether to remove the n-propylquinoline. The liquid remaining after evaporation of the ether was distilled in a vacuum, the fraction boiling at 124.5–126° (uncorr.) at 6 mm. being saved as the product; yield, 19.3 g. or 75% of the theoretical.[22]

Picrate, yellow crystals from alcohol, m. p. 162–163° (corr.);[23] mixed melting point with the picrate of 2-n-propylquinoline, prepared by the method of Meisenheimer and Schütze (m. p. 162–163°) is 162–163°, proving their identity.[24]

Methiodide, m. p. 181.7–182.7° (corr.):[24] Analysis of the dried picrate (Dumas): 0.1223 g. gave 13.70 cc. of nitrogen under standard conditions. Calcd. for $C_{18}H_{16}N_4O_7$: N, 14.0. Found: N, 14.0. Analysis of the free base: 0.2823 and 0.2580 g. gave 18.78 and 16.78 cc. of nitrogen under standard conditions. 0.1654 g. gave 0.5111 g. CO_2 and 0.1174 g. H_2O. Calcd. for $C_{12}H_{13}N$: C, 84.16; H, 7.66; N, 8.19. Found: C, 84.28; H, 7.94; N, 8.30, 8.13.

The results of the reactions of other alkyl and aryl halides with the potassium salt of quinaldine are summarized in Table II.

Experiments 1–6, inclusive, and 9 and 12 were carried out in the manner described under the larger scale preparation of 2-*n*-propylquinoline. About 10 g. of quinaldine

---

[21] In order that the quinaldine may flow into the reaction cell, it was necessary to connect the top of the buret with the waste ammonia line, which, of course, was directly attached to one of the tubes (3) leading into the cell.

[22] It appears that 2-ethyl-, 2-n-propyl- and 2-n-amylquinolines undergo a slow change (absorption of small amounts of oxygen from the air?) over long periods of time, since analyses of old preparations of these substances (after redistillation in a vacuum) are invariably low in carbon (*cf.* analysis of 2-ethylquinoline). Therefore freshly prepared specimens of 2-n-propyl- and 2-n-amylquinolines were analyzed with the result that the percentages of carbon rose almost to the theoretical. (These analyses are included in the present article.)

The purity of all of the alkylated quinolines prepared in the present article was markedly lowered by using potassium amide much in excess of the amount required by Equation I. The excess of potassium amide appears to react with some of the alkylated quinoline produced in the reaction to form a potassium salt, which in turn is alkylated by treatment with an alkyl halide (*cf.* Ziegler and Zeiser, Ref. 13).

[23] 163–164° according to Meisenheimer and Schiitze, Ber., **56B**, 1356 (1923).

[a] Some gaseous NH_3 always remained dissolved in the ether.

was used in each experiment, together with 1.1 equivalents of potassium. All other experiments were performed on a smaller scale in ammonia tubes. Where ether was used as a solvent, the potassium salt of quinaldine was first prepared in liquid ammonia, the latter evaporated and absolute ether added. The desired alkyl halide was introduced into this solution.

Notes on Identification

(1) **2-Ethylquinoline.**—Picrate, yellow needles from alcohol, m. p. 149–151°, (corr.).[25] Analysis of free base: 0.2537 g. gave 18.02 cc. of nitrogen under standard conditions. 0.1697 g. gave 0.5203 g. CO_2 and 0.1082 g. H_2O. Calcd. for $C_{11}H_{11}N$: C, 84.02; H, 7.06; N, 8.92. Found: C, 83.62; H, 7.13; N, 8.89.

(4) ***n*-Butylquinoline.**—Picrate, separating slowly from alc. soln., m. p. 163–165°, (corr.). The picrate of 2-n-butylquinoline melts at 162–163°.[26] Analysis of base: 0.3132 g. gave 19.62 cc. of nitrogen under standard conditions. 0.1692 g. gave 0.5224 CO_2 and 0.1266 H_2O. Calcd. for $C_{13}H_{15}N$: C, 84.26; H, 8.17; N, 7.57. Found: C, 84.25; H, 8.37; N, 7.84.

(5) ***n*-Amylquinoline.**—Picrate, yellow needles separating slowly from alcohol, m. p. 108.5–109.5° (corr.). Analysis of this picrate: 0.1240 g. gave 13.18 cc. of nitrogen under standard conditions. Calcd. for $C_{20}H_{21}N_4O_7$: N, 13.1. Found: N, 13.30. Analysis of the free base: 0.2935 and 0.3105 g. gave 16.18 and 17.53 cc. of nitrogen under standard conditions. 0.1536 g. gave 0.4748 g. CO_2 and 0.1201 g. H_2O. Calcd. for $C_{14}H_{17}N$: C, 84.36; H, 8.61; N, 7.04. Found: C, 84.31; H, 8.76; N, 6.89, 7.06.

For purposes of comparison, an independent synthesis of 2-n-amylquinoline was carried out by Mr. P. S. Winnek, who followed the method of Spath and Pikl[27] with a slight

---

[25] Mulliken, Vol. II, p. 155, gives 146–147° (148°) as the melting point.

[26] Ziegler and Zeiser, Ann., 485, 184 (1931).

[27] Spath and Pikl, Ber., 62B, 2249 (1929).

modification. Butylidene quinaldine was prepared, in accordance with the directions of these authors, by condensing *n*-butyraldehyde with quinaldine; b. p. 162–165° at 5 mm.; 11.5 g. of this product was dissolved in absolute alcohol and reduced with gaseous hydrogen in the presence of platinum oxide according to the directions of Adams.[28] The calculated amount of hydrogen (one mole per mole of butylidene quinaldine) was absorbed in half an hour; b. p. of product saved, 150–151° at 5–7 mm.; yield, 5 g. or 43% of the theoretical. Analysis showed this fraction to have the composition of a slightly impure amylquinoline; picrate, m. p. 107.5–109.0' (corr.); mixed melting point with the picrate of n-amylquinoline prepared in liquid ammonia (m. p. 108.5–109.5") is 108.2–109.0°, showing their identity. The cause of the difference between the preparation of Spath and Pikl and the two specimens of amylquinoline prepared in the present work has not been determined.

(9) **2-ω-Phenylethylquinoline.**—Pale yellow liquid as first distilled, almost all boiling at 210" (uncorr.) (9 mm.). Most of the liquid solidified on standing. The crystals were freed from mother liquor by pressing on a porous plate, m. p. 28.5–29.5°, corr.[29] *Anal.* 0.1408 and 0.1652 g. gave 7.13 and 7.84 cc. of nitrogen under standard conditions. 0.1098 g. gave 0.3520 g. CO_2 and 0.0663 g. H_2O. Calcd. for $C_{17}H_{16}N$: C, 87.50; H, 6.49; N, 6.01. Found: C, 87.43; H, 6.69; N, 6.33, 5.93. Picrate, yellow needles, m. p. 131–132°, (corr.).[30] Analysis of this picrate: 0.1684 g. gave 16.41 cc. of nitrogen under standard conditions. Calcd. for $C_{23}H_{19}N_4O_7$: N, 12.1. Found: N, 12.2. In addition to this picrate there was obtained another picrate in smaller amount, melting at 120.5–121.5". Analysis of this picrate: 0.0538 g. gave 5.30 cc. of nitrogen under standard conditions. Calcd. for $C_{23}H_{19}N_4O_7$: N, 12.1. Found: N, 12.3. Therefore the two picrates have the same composition.

(10)–(16) Quinaldine, if reported as a product of the reactions summarized in the above table, was always identified as the picrate (m. p. 194–195°) and the identification confirmed by determining the mixed melting point of this with some known quinaldine picrate, m. p. 194–195°. The mixed melting points in no cases were changed. Quinaldine in these experiments did not appear to be formed quantitatively.

(16) **Cyclohexylmethylquinoline** (?).—The chief basic product of the action of cyclohexyl bromide on the potassium salt of quinaldine in liquid ammonia was quinaldine itself. A picrate, prepared from the higher boiling fraction (above 140° at 10 mm.) melted at 146.5–147.8° (corr.) after several crystallizations. *Anal.* 0.2679 g. gave 27.36 cc. of nitrogen under standard conditions. Calcd. for $C_{22}H_{23}N_4O_7$: N, 12.3. Found: N, 12.8. Perhaps this was the picrate of the expected 2-w-cyclohexylmethylquinoline. It was obtained in very poor yield.

Discussion

The reactions enumerated in Table II are evidently complicated to some extent by the ammonia retained by the potassium salt of quinaldine, this perhaps accounting for the partial regeneration of quinaldine in experiments (10) to (15) inclusive. If we assume that the potassium salt of quinaldine is slightly ammonolyzed in solution to potassium amide and quinaldine, the observed reactions may be due to the combination of potassium amide with the paraffin polyhalide. The alkyl mono halides

[30] M. p. of the picrate of 2-ω-phenylethylquinoline according to Ziegler and Zeiser,[26] is 132°.

on the other hand must preferentially add to the enonium conjugated system, $CH_2{=}C{-}NK{-}$[19] in the manner of Equation II.

In this connection it is of interest to find that the potassium salt of the enol of acetophenone, prepared in liquid ammonia according to the directions of Strain,[31] reacts with ethyl bromide (the ammonia tube was cooled to −40° to permit the introduction of the ethyl bromide)[32] to form some acetophenone, but none of the expected butyrophenone. In the absence of liquid ammonia, alkylated acetophenones are formed in excellent yield.[33]

The Action of Heat upon the Salts of Quinaldine.—It has been previously recorded in this article that quinaldine may be recovered in fair yield from the products of hydrolysis of the unheated sodium and potassium salts of quinaldine. The failure to find quinaldine (except in two cases) in the mixture resulting from the hydrolysis of the heated potassium, sodium and lithium salts of the ammono-enol strongly suggests that these salts are thermally unstable.

In order to test this supposition, 5.2 g. of quinaldine was heated in a bomb tube with the potassium amide from 1.5 g. of potassium (1.0 equivalent) for six hours at 150°.[34] At the end of this time, the ammonia in the bomb was distilled off and the Pyrex tube containing the heated potassium salt immersed in a bath of liquid ammonia. Fresh ammonia was distilled into the tube, but the enolate was not completely soluble. Furthermore, ethyl bromide in excess of the calculated amount did not react vigorously with the opaque red solution, nor did it cause the complete decolorization of some reddish mud in the bottom of the reaction tube. The material remaining after evaporation of the ammonia was extracted with ether and the extract distilled. No picrate of 2-n-propylquinoline could be isolated in a pure state from any of the fractions. It is clear then that heating destroyed most of the potassium salt.

Attempt to Prepare the Ammono-enolic Form of Quinaldine.—A solution of the potassium salt of quinaldine ammono-enol, prepared in an ammonia reaction tube at ordinary temperatures, was decanted into a solution of an excess of ammonium bromide. The red color of the enolate did not completely disappear for a few seconds. This would indicate that the ammono-enol form of quinaldine or its ammonium salt has a transitory existence in ammonia solution at room temperatures. Ordinary quinaldine was recovered after evaporation of the solvent am-

[34] Blair, THIS JOURNAL, 48, 91 (1926). The interior of the bomb was lined with a Pyrex tube closed at one end only. The formation of potassium amide and of the potassium salt of quinaldine in this tube was accomplished in the same manner as in the larger scale preparation of 2-n-propylquinoline, described above. The ammonia was evaporated from this reaction tube, which was allowed to warm up to room temperature before introduction into the bomb. Then, with the head of the bomb tightened, the desired amount of ammonia was distilled in and the bomb heated in an upright electric

monia and identified as the picrate, m. p. 194–195°, mixed melting point with authentic quinaldine picrate (m. p. 194–195°), 194–195°.

Nitridation of the Potassium Salt.—It was hoped that the addition of iodine to a liquid ammonia or absolute ethereal solution of the potassium salt of quinaldine would produce either 1,4-diquinolylbutane, or 2-o-iodoquinaldine. Neither of these compounds could be isolated as a product of the reaction. Large quantities of a reddish-black tar were formed, together with smaller amounts of quinaldine, irrespective of whether the reaction was carried out in ammonia or in ether. Bromine reacted in a similar fashion with a solution of potassium quinaldine ammono-enolate in ether with the formation of the same products.

Attempted Preparation of Quinaldine-2-acetic Acid.—It was hoped that this compound would be formed by passing dry carbon dioxide through a solution of the potassium salt of quinaldine in absolute ether.[35] The only organic product isolated in any quantity was quinaldine, while the potassium appeared to be converted to potassium aquocarbonate. No cyanamide (ammonocarbonic acid) or cyanate (mixed aquo-ammonocarbonic acid) was formed in the reaction. Ziegler and Zeiser[4b] obtained only quinaldine by the action of carbon dioxide on the lithium salt.

The Action of Acetophenone on the Potassium Salt of Quinaldine.—Acetophenone reacts with a liquid ammonia solution of potassium quinaldine ammono-enolate to form a precipitate of the sparingly soluble potassium acetophenone enolate[31] and quinaldine (the latter identified as picrate). The solution becomes colorless, indicating the complete disappearance of the quinaldine salt.

Notes on the Use of Iron and Cobalt Oxides as Catalysts in the Reaction between Potassium and Ammonia.—In one of the preceding experiments, a liquid ammonia solution of several grams of potassium was converted within a few minutes to potassium amide by the catalytic action of 0.1 *g.* ignited ferric oxide.[36] The latter is therefore a much more effective catalyst for this reaction than either metallic iron or platinum. The use of oxide catalysts in small quantity for the preparation of potassium amide at −33° is perfectly justified, provided the reaction is not influenced by the iron oxide or by traces of potassium oxide in solution. As a catalyst in ammonia tube experiments where one desires a potassium amide of highest purity, ferric oxide is not to be recommended. The following experiments illustrate the point in mind.

Three-tenths gram of freshly ignited ferric oxide was brought into contact with the potassium amide from 0.44 g. of potassium in an ammonia reaction tube at room temperatures. At the end of a day, the oxide, originally red, was coated with a thin black

---

[35] The potassium salt still retained a small amount of ammonia.

[36] C. A. Kraus and students have long used ferric oxide as a catalyst for this reaction.

layer which slowly increased in depth during the next three and a half months. After this time had elapsed, the mixture of unchanged ferric oxide and the iron–nitrogen–potassium compound was washed with ammonia dried in a vacuum and dissolved in dilute sulfuric acid. *Anal.* Fe (in solution), 35.9; N, 9.1; K, 28.7; Fe_2O_3 (not dissolved by the dilute acid), 17.0. The precipitate reacted vigorously with water, and therefore resembled the iron–nitrogen–potassium compounds previously described.[37] Nearly all of the potassium oxide (or hydroxide) formed in this reaction was transferred to the other leg as a result of washing the black precipitate. This is to be expected only if the action of potassium amide on ferric oxide yields potassium monoxide, which Kraus and Whyte[38] have shown to be slightly soluble in ammonia.

Potassium hydroxide, if formed, would be slightly soluble in potassium amide solution, as the following experiment indicates: a strong solution of potassium amide, which had been in contact with a stick of potassium hydroxide in one leg of an ammonia reaction tube at room temperatures, was decanted into a much larger volume of pure ammonia in the other leg of the tube. There resulted immediately a precipitate of fine white needles. These were washed with ammonia and analyzed. Calcd. for KOH: K, 69.7. Found: K, 69.6; N, a trace. Apparently the reaction of Kraus and Whyte, expressed by the top arrow in the following equation, is reversible

$$K_2O + NH_3 \rightleftharpoons KNH_2 + KOH$$

Ignited cobalt oxide (Co_3O_4) also proved to be an excellent catalyst for the potassium–ammonia reaction. Like ferric oxide, the oxide of cobalt was very slowly attacked by the potassium amide solution that resulted.

Summary

1. Quinaldine reacts readily with the amides of sodium, potassium and lithium and more slowly with barium amide to form salts of the ammono-enolic form. In this respect quinaldine behaves as a cyclic ammono ketone (ketone-acetal).

2. The potassium salt of quinaldine reacts with methyl iodide, ethyl bromide, n-propyl bromide and benzyl bromide to form, respectively, 2-ethyl-, 2-n-propyl-, 2-n-butyl- and 2-o-phenylethylquinoline. With n-butyl bromide, a base having the composition of an amylquinoline is formed in poor yield. Polyhalides of methane and ethane, in so far as investigated, react with the potassium salt in the presence of ammonia to regenerate quinaldine. Iodine and bromine convert the potassium salt largely to a tar.

3. The potassium salt of quinaldine has been shown to decompose in liquid ammonia solution at 150°. Decomposition likewise takes place in the absence of solvent at 100–150°.

4. Potassium amide in liquid ammonia solution reacts slowly with ferric and cobalto-cobaltic oxide to form potassium oxide or hydroxide and iron- or cobalt–potassium–nitrogen compounds. Potassium amide dissolves potassium hydroxide in small quantities, probably to form potassium oxide.

CERTAIN AMINO DERIVATIVES OF LAURIC ACID

BY D. M. BIROSEL

RECEIVED MARCH 25, 1931 PUBLISHED AUGUST 6, 1931

The literature records a few amino derivatives of lauric acid. By coupling lauryl chloride with certain amino acids, Bondi[1] prepared lauryl-glycine and lauryl-alanine. By the same procedure, Guerin[2] obtained lauryl-toluidines. Condensing a-bromolauryl chloride with certain amino acids in the presence of sodium hydroxide and displacing the halogen atom with an amino group through the action of ammonia, Hopwood[3] and Weizmann prepared certain dipeptides. A search in the literature reveals the lack of reference on the preparation of a-aminolauric acid. This paper describes the preparation, characteristics of a-aminolauric acid and other amino derivatives of this long chain fatty acid.

Experimental Part

Source and Preparation of Lauric Acid.—Lauryl glyceride is the principal constituent of coconut oil, a Philippine produce of great importance. The mixed methyl esters of the fatty acids in the oil were prepared and fractionated under reduced pressure. The portion distilling at 148–155" under 18 mm. pressure was collected. This fraction was redistilled and the water-white liquid ester was preserved for use. The acid obtained from the ester melted at 43–44°.[4]

Preparation of α-Aminolauric Acid.—The method adopted by Adams and Marvel[5] in preparing α-amino-*n*-caproic acid was found applicable in the synthesis of α-aminolauric acid. To fifty grams of melted lauric acid were added 7.5 cc. of phosphorus trichloride and 11 cc. of bromine. The solution was refluxed in an all-glass apparatus provided with a trap to dispose of the escaping hydrobromic acid. Digestion was continued for eight hours, increasing the temperature of the bath to 100° toward the end. The yellow precipitate of phosphorous acid was allowed to settle and the clear liquid product was decanted gently.

Ten grams of the brominated acid chloride was hydrolyzed to obtain the free α-bromolauric acid. The acid was extracted with ether and after evaporating the solvent. a liquid residue was obtained. When cooled the product solidified but at room temperature it became liquid; 9.2 g. of this liquid product was treated with ammonia at 58° for several hours. A white precipitate separated. It was filtered by suction, washed with distilled water and afterward with methyl alcohol. The colorless powder was dried in the oven at 100" and about a 51% yield was obtained.

Acetyl-α-aminolauric Acid.—A trial experiment was undertaken to see whether acetic anhydride has any effect on α-aminolauric acid. A solid was obtained which melted

very much lower than the original compound. The experiment was repeated using 2 g. of the amino acid. It was digested for a few minutes with an excess of acetic anhydride. When all the solid amino acid had dissolved, the volume of solution was doubled by adding water. An oil separated which solidified. The solid was filtered, washed with water, crystallized from alcohol and dried.

Picrate of α-Aminolauric Acid.—Two grams of a-aminolauric acid was treated with 10 cc. of a concentrated alcoholic solution of picric acid. After digestion for a few minutes, the solid amino acid was completely dissolved. After diluting the alcoholic solution to twice its volume with water, a solid compound precipitated. It was filtered and washed with dilute alcohol. It was crystallized from 50% alcohol, giving pale yellowish crystals.

TABLE I

CONSTANTS AND ANALYTICAL DATA[a]

Compound	M. p., °C.	Formula	Nitrogen analyses, % Calcd.	Nitrogen analyses, % Found
a-Aminolauric acid	263 (dec.)	$C_{12}H_{25}O_2N$	6.50	6.60 6.66
Acetyl-a-aminolauric acid	93-94	$C_{14}H_{27}O_3N$	5.44	5.46 5.50
α-Aminolauric acid picrate	255–256 (dec.)	$C_{18}H_{27}O_9N_4$	12.60	12.20
Methyl a-aminolaurate	241–242 (dec.)	$C_{13}H_{27}O_2N$	6.11	6.27

Lauryl m-nitranilide	78	$C_{18}H_{28}O_3N$	8.75	8.74

[a] The writer is indebted to Professor Alfredo Santos of the School of Pharmacy, University of the Philippines, for the determination of nitrogen by micro analysis for the last six compounds.

Lauramide.—The amides of lower fatty acids have been prepared by treating their methyl esters with concentrated ammonium hydroxide and it was expected that lauramide could be obtained in this way. It was found, however, that ammonia had no effect on methyl laurate either at room temperature or at 60°. The compound was finally obtained by condensing the acid chloride with ammonia. Ten grams of lauryl chloride was added in small streams to a concentrated solution of ammonium hydroxide which was continually stirred. Methyl alcohol was added to the semi-gelatinous mass. A white solid separated from the alcoholic solution and from the filtrate two more crops of crystals were obtained when the volume of solution was reduced. Recrystallization from alcohol gave a product which was found to melt at 99–100°.[6]

When the residual filtrate was evaporated, a gelatinous mass was obtained. It was dissolved in alcohol and a compound was obtained which melted at 74–75°.[7] When the mixed melting point of this compound was taken with ammonium laurate obtained by passing ammonia into an absolute alcoholic solution of lauric acid, no depression in the melting point was noted. From the filtrate a very small amount of oily substances was obtained.

---

[6] Blaise and Guérin, *Bull. soc. chim.*, **29**, 1209 (1903). reported lauramide as melting at 98–99°. The literature records from 97 to 103°.

[7] Falicola, *Gazz. chim. ital.*, **40**, II, 425 (1910), reported 75° as the melting point of ammonium laurate.

[8] Blaise and Guérin, Ref. 6, obtained a small quantity of oily substance when they prepared lauramide by condensing lauryl chloride and ammonia. They characterize it as lauronitrile.

Esters of α-Aminolauric Acid

Methyl a-hinolawate.— Methyl α-bromolaurate was prepared first by condensing 5 g. of a-bromolauryl chloride with methyl alcohol. The ester was purified by washing its ethereal solution with dilute sodium hydroxide. After evaporating the solvent, a liquid residue was obtained. The ester was acted upon by concentrated ammonium hydroxide for several hours at 58°. The white solid compound which separated was filtered, washed with methyl alcohol and dried in the oven at 100°.

Isopropyl **α-Aminolaurate.**—The a-bromolaurate of isopropyl alcohol was prepared by starting with 5 g. of a-bromolauryl chloride and excess alcohol. The purified liquid ester was treated with concentrated ammonium hydroxide at 58° for several hours. The white solid that separated was filtered, washed with methyl alcohol and dried in the oven at 100".

***n*-Propyl α-Aminolaurate.**—Five grams of the a-bromolauryl chloride prepared above was treated with excess propyl alcohol. The purified liquid ester was treated with ammonia at 58° for several hours. The white solid compound was filtered, washed with methyl alcohol and dried.

Isobutyl α-Aminolaurate.—Five grams of the a-bromo acid chloride was condensed with excess isobutyl alcohol. The liquid ester was purified by washing its ethereal solution with dilute sodium hydroxide. The halogen of the ester was displaced by an amino group when the ester was acted upon by ammonia at 58° for several hours. The amino compound separated as white precipitate from the solution. It was filtered, washed with methyl alcohol and dried.

Nitranilides

Lauryl-*p*-nitranilide.—One gram of *p*-nitraniline was condensed with a little excess of lauryl chloride. Upon warming the mixture, the solid nitraniline dissolved. The product was extracted with ether and washed with dilute alkali, afterward with distilled water. When the solvent was evaporated, a solid residue was obtained. The solid was crystallized from alcohol, giving fine short white needle crystals.

Lauryl-*m*-nitranilide.—Two grams of m-nitraniline was condensed with a little excess of lauryl chloride. The solid m-nitraniline dissolved when the mixture was warmed. The ethereal solution of the compound was washed with dilute sodium hydroxide and afterward with water. A solid residue was left when the solvent was evaporated. Crystallization from alcohol gave fine short needle crystals.

Summary

1. The preparation of a-aminolauric acid has been described.
2. Nine amino derivatives of lauric acid have been prepared.

THE NUMBER OF STRUCTURALLY ISOMERIC ALCOHOLS OF THE METHANOL SERIES

BY HENRY R. HENZE AND CHARLES M. BLAIR

RECEIVED APRIL 13, 1931 PUBLISHED AUGUST 5, 1931

Although several attempts have been made by Cayley and others[1] to calculate the number of isomeric hydrocarbons of the methane series, little attention has been given to the similar problem of calculating the number of isomeric alcohols of the methanol series. This limited treatment[1g] undoubtedly depended upon the fact that the methanol homologs were considered as typical mono-substitution products of the paraffins; hence, it was logical to assume that the number of isomeric alcohols should be conditioned by the number of hydrocarbons from which, theoretically, the former might be derived. Such formulas as have been advanced for determining the number of isomeric alcohols of any given carbon content actually prove to be inadequate and erroneous. Hence, it seemed desirable to derive a formula which would estimate accurately the number of isomeric alcohols.

Our initial attempt sought to establish a simple mathematical relationship between the total number of isomers and their carbon content. It was soon realized that no such simple relationship exists, and the problem was solved only by recognition of the fact that the alcohols might be classified according to simple types, for each of which the number of isomers could be computed. The types into which the alcohols were divided were those commonly recognized in organic chemistry, namely, (1) primary, (2) secondary and (3) tertiary. The scheme for calculating the number of isomers of each type depends upon the method of forming their structural formulas.

(1) The structural formulas of the primary alcohols, RCH_2OH, of n total carbon atom content, may be formed from those of the alcohols of $n - 1$ carbon atoms, ROH, by removing the OH group from each and attaching the resulting alkyl radical, R—, to the —CH_2OH group. Obviously, the number of primary alcohols that may be formed in this way will equal the total number of alcohols of all types containing $n - 1$ carbon atoms. This may be expressed as

$$p_n = T_{(n-1)} \qquad \text{(I)}$$

where p_n is the number of primary alcohols of n carbon atoms, and T_{n-1} is the total number of alcohols of all types containing $n - 1$ carbon atoms.

[1] (a) Cayley, *Ber.*, 8, 1056 (1875); (b) Schiff, *ibid.*, 8, 1542 (1875); (c) Hermann, *ibid.*, 13, 792 (1880): 30, 2423 (1897); 31, 91 (1898); (d) Tiemann, *ibid.*, 26, 1605 (1893); (e) Delannoy, *Bull. soc. chim.*, [3] 11, 239 (1894); (f) Losanitsch, *Ber.*, 30, 1917, 3059 (1897); (g) Goldberg, *Chem.-Ztg.*, 22, 395 (1898); (h) David, *Rev. gen. Sci.*, 39, 142 (1928); (i) Trautz, "Lehrbuch der Chemie," Berlin, 1924, Vol. III, p. 23.

(2) The structural formulas of the secondary alcohols, RR′ >CHOH, of n total carbon atom content, may be formed from those of the alcohols ROH and R′OH (the carbon content of R— plus R′— always equaling $n - 1$) by removing the OH group from each and attaching the resulting alkyl radicals, R— and R′—, to the >CHOH group. The number of secondary alcohols that may be thus formed will equal the total number of possibilities, without exception or repetition, of combining simultaneously with the >CHOH group every value of R— taken one at a time and every complementary value of R′— also taken one at a time. These possibilities are theoretically of two types: (a) in which the two alkyl radicals, R— and R′—, are of unequal carbon content; and (b) in which these are of equal carbon content. Type (b) is actually impossible with an alcohol of an even number of carbon atoms for in that type $n - 1$ should be divisible by two. The number of isomeric secondary alcohols may be calculated by the following (finite) recursion formulas according to whether the carbon content is even or odd.

Even $$s_n = T_1 \cdot T_{(n-2)} + T_2 \cdot T_{(n-3)} + \ldots + T_{(n-2)/2} \cdot T_{(n/2)} \qquad \text{(IIa)}$$

Odd

$$s_n = T_1 \cdot T_{(n-2)} + T_2 \cdot T_{(n-3)} + \ldots + T_{(n-3)/2} \cdot T_{(n+1)/2} + \frac{T_{(n-1)/2} \cdot (1 + T_{(n-1)/2})}{2} \qquad \text{(IIa}'\text{)}$$

where T is the total number of alcohols of all types containing the number of carbon atoms represented by its subscript. Note that the subscripts in each term add up to $n - 1$, and that the number of terms is $(n - 1)/2$ for odd carbon atom content and $(n - 2)/2$ for even.

(3) The structural formulas of the tertiary alcohols, RR′ >C<OHR″, of n total carbon atom content, may be formed from those of the alcohols ROH, R′OH and R″OH (the carbon content of R— plus R′— plus R″— always equaling $n - 1$) by removing the OH group from each and attaching the resulting alkyl radicals, R—, R′— and R″—, to the >C<OH group. The number of tertiary alcohols that may be thus formed will equal the total number of possibilities, without exception or repetition, of combining simultaneously with the >C<OH group every value of R— taken one at a time and all complementary values[2] of R′— and R″— also taken one at a time. These possibilities are theoretically of three types: (a) in which the three alkyl radicals are of different carbon content; (b) in which two of the alkyl radicals are of equal carbon content and different from that of the third; and (c) in which the three alkyl radicals are of equal carbon content. Type (c) is actually possible only when $n - 1$ is divisible by three. The number of alcohols of each type may be calculated by the following (finite) recursion formulas for that particular type:

---

[2] The values of R′— and R″— complementary to R— satisfy the relationship that the total carbon content of R— plus R′— plus R″— equal $n - 1$.

The number of isomeric tertiary alcohols of type (a) equals

$$\Sigma T_i \cdot T_j \cdot T_k \qquad \text{(IIIa)}$$

where i, j and k are integers, distinct, and greater than zero; $i + j + k = n - 1$; $i > j > k$.

The number of terms of type (a) depends on whether n is even or odd. Even: if $n/6$ or $(n - 2)/6$ is an integer, the number of terms of type (a) is $(n - 2)(n - 6)/12$; and if $(n + 2)/6$ is an integer the number of terms is $(n - 4)^2/12$.

Odd: if $(n + 1)/6$ or $(n + 3)/6$ is an integer, the number of terms is $(n - 3)(n - 5)/12$; and if $(n - 1)/6$ is an integer the number of terms is $(n^2 - 8n + 19)/12$.

The number of isomeric tertiary alcohols of type (b) equals

$${}^1/_2 \Sigma T_i \cdot (1 + T_i) \cdot T_j \qquad \text{(IIIb)}$$

where i and j are integers, distinct, and greater than zero, and $2i + j = n - 1$.

The number of terms of type (b) also depends on whether n is even or odd. Even: if $n/6$ or $(n - 2)/6$ is an integer, the number of terms of type (b) is $(n - 2)/2$; and if $(n + 2)/6$ is an integer, the number of terms is $(n - 4)/2$.

Odd: if $(n + 1)/6$ or $(n + 3)/6$ is an integer, the number of terms is $(n - 3)/2$; and if $(n - 1)/6$ is an integer, the number of terms is $(n - 5)/2$.

The number of isomeric tertiary alcohols of type (c) equals

$$\frac{T_i(1 + T_i)(2 + T_i)}{6} \qquad \text{(IIIc)}$$

where i is an integer, greater than zero, and $3i = n - 1$.

Obviously, there will never be more than one term of type (c) for any given value of n.

Grateful acknowledgment is made to Dr. Leo Zippin[3] and to Professor Orrin Fink, Jr., of Pennsylvania State College for their aid in checking the recursion formulas.

The actual use of these formulas may be illustrated in the calculation of the number of isomeric heptyl alcohols, $C_7H_{15}OH$.[4] Primary alcohols: $n = 7$

$$p_7 = T_6 = 17$$

Secondary alcohols: number of terms equals $(n - 1)/2 = 3$

$$s_7 = T_1T_5 + T_2T_4 + T_3(1 + T_3)/2$$
$$= 1.8 + 1 \cdot 4 + 2 \cdot 3/2 = 15$$

Tertiary alcohols: type (a), number of terms (for $(n - 1)/6$ = an integer) equals $[(n - 4)^2 + 31/12 = 1$

---

[3] National Research Fellow in Mathematics.

[4] It is of interest to note that the total number of heptyl alcohols is erroneously stated as being 38 in Richter's "Organic Chemistry" (Spielmann), second edition, Vol. I, p. 121.

$$T_3 \cdot T_2 \cdot T_1 = 2 \cdot 1 \cdot 1 = 2$$

Type (b), number of terms (for (n − 1)6 = an integer) equals (n − 5)/2 = 1

$$T_1(1 + T_1)T_4/2 = 1(1 + 1)4/2 = 4$$

Type (c), number of terms (for (n − 1)/3 = an integer) equals 1

$$T_2(1 + T_2)(2 + T_2)/6 = 1(1 + 1)(2 + 1)/6 = 1$$

$$t_7 = 2 + 4 + 1 = 7$$

$$T_7 = p_7 + s_7 + t_7 = 17 + 15 + 7 = 39$$

The following table indicates the number of isomeric alcohols of the methanol series as calculated by the use of the recursion formulas.[5]

TABLE I

NUMBER OF ISOMERIC ALCOHOLS

Carbon content	Primary	Secondary	Tertiary	Total
1	1	0	0	1
2	1	0	0	1
3	1	1	0	2
4	2	1	1	4
5	4	3	1	8
6	8	6	3	17
7	17	15	7	39
8	39	33	17	89
9	89	82	40	211
10	211	194	102	507
11	507	482	249	1,238
12	1,238	1,188	631	3,057
13	3,057	2,988	1,594	7,639
14	7,639	7,528	4,074	19,241
15	19,241	19,181	10,443	48.865
16	48,865	49,060	26,981	124,906
17	124,906	126,369	69,923	321,198
18	321,198	326,863	182,158	830,219
19	830,219	849.650	476,141	2,156,010
20	2,156,010	2,216,862	1,249,237	5,622,109

Summary

1. No direct or simple relationship appears to exist between the total number of isomeric alcohols of the methanol series and their carbon content.

2. Formulas of the (finite) recursion type are advanced which permit the calculation from their carbon content of the number of primary, secondary and tertiary alcoholic isomers. In using these recursion formulas to calculate the total number of such alcohols of any given carbon content, the total number of isomers of every lesser carbon content must be known.

3. The totals so obtained agree exactly through the dodecyl alcohols

---

[5] The structural formulas of the homologs of methanol, inclusive of the dodecyl alcohols, were written in connection with the derivation of these recursion formulas. The totals obtained from actual count of these structural formulas agreed exactly with those derived from the use of the recursion formulas.

with the numbers required by theory as tested by actually writing all the possible structural formulas.

4. The usefulness of the formulas advanced is not limited to the calculation of the number of structurally isomeric alcohols. Since the latter are typical mono-substituted derivatives of the paraffins, the figures recorded in Table I more generally represent the number of structurally isomeric mono-substitution products of the saturated hydrocarbons inclusive of the eicosanes.

SOME ORGANIC ACIDS IN BARLEY, MAIZE, OATS AND RYE PLANTS

BY E. K. NELSON AND H. H. MOTTERN

RECEIVED APRIL 23, 1931 PUBLISHED AUGUST 5, 1931

In continuation of the work on the organic acids of cereal plants, which began with a study of the acids of wheat plants,[1] an investigation has been made of the non-volatile acids in the green parts of the growing plants of barley, maize, oats and rye. The maize was raised in the field. The barley, oats and rye plants were grown in the greenhouse. All plants were beginning to head when cut. As in the case of wheat plants the investigation was confined to the non-volatile acids, extracted by boiling water from the dried, ground plants. These have not been previously reported in the literature.

Aconitic acid, previously reported as present in sugar cane[2] and in sorghum[3] and found in the wheat plant,[1] is present also in these plants of the grass family. Other acids in some of these plants which have not been found in numerous investigations of the acids of fruits are tricarballylic acid and malonic acid.

The Acids of Barley Plants.—The acids were separated from one hundred pounds of barley plants and converted into the ethyl esters, yielding 84 g. of crude esters. Fractionation at 10 mm. yielded: 1, 80–95°, 0.4 g.; 2, 95–105°, 0.6 g.; 3, 105–115°, 1.5 g.; 4, 115–125°, 5.2 g.; 5, 125–135°, 42.2 *g.*; 6, 135–150°, 1.1 g.; 7, 150–165°, 2.8 g.; 8, 165–173°, 21.9 g.; residue, 8 g.

Fraction 1 yielded oxalic dihydrazide, melting at 235° and further identified by optical crystallographic data.[4] The filtrate, seeded with malonic hydrazide, yielded a second crop of crystals, melting at 148–149° and further identified as malonic hydrazide by optical data.

[2] Behr, *Ber.*, 10, 35 (1877).

[3] Parsons, Jahresb., 1444 (1882).

[4] Optical crystallographic examinations were made by G. L. Keenan of the Food and Drug Administration.

Fractions 4 and 5 yielded malic hydrazide melting at 179°.

Fraction 7 was seeded with tricarballylic hydrazide, but the result was negative. Malic hydrazide was obtained instead, and was identified as such by its melting point.

Fraction 8 yielded a small quantity of hydrazide melting at 186°. When this was mixed with tricarballylic trihydrazide, the melting point was between that of tricarballylic trihydrazide and 186°. Optical crystallographic data showed it to be slightly impure tricarballylic trihydrazide.

The filtrate from tricarballylic hydrazide was seeded with citric hydrazide. On standing, citric trihydrazide separated. It melted at 108°, and was identified by the optical method. The yield of tricarballylic hydrazide was small as compared with that of the citric hydrazide, showing the fraction to consist mainly of ethyl citrate.

Aconitic acid was obtained from the ether extraction of the acids previous to esterification. The ether extraction afforded about 2 g. of crystals contaminated with an oily material. On purification the crystals melted at 180–181° and were further identified as aconitic acid by optical crystallographic examination.

Oxalic acid was determined by the method of Arbenz[5] and 0.019% was found on the basis of the green plants.

The Acids of Maize Plants.—The acids, separated as lead salts from ninety-six pounds of fresh maize plants in the roasting-ear stage of maturity, were converted into the ethyl esters, yielding 83 g. of crude esters.

Fractionated four times at 10 mm. the following fractions were obtained: 1, 85–95°, 2.1 g.; 2, 95–105°, 3.6 g.; 3, 105–115°, 2.8 g.; 4, 115–125°, 3.5 g.; 5, 125–135°, 20.2 g.; α_D −10.5"; 6, 135–145°, 1.8 g.; 7, 145–155°, 3.3 g.; 8, 155–165°, 11.1 g.; 9, 165–179°, 6.2 g.; residue, 28.0 g.

The hydrazides were prepared from these fractions. Fraction 1 yielded an immediate precipitate of oxalic dihydrazide, melting at 235° and further identified by optical crystallographic examination. The filtrate from oxalic dihydrazide was seeded with malonic dihydrazide, but with a negative result.

Fraction 2 yielded a mixture of oxalic and malic hydrazides; fraction 3, impure malic hydrazide; and fractions 4 and 5, pure malic hydrazide melting at 179°. From fraction 6 a few crystals of malic hydrazide were obtained. Fraction 8 afforded an oily hydrazide. The acid, isolated from the ester after saponification, melted at 180–181°, and was unsaturated. It was identified as aconitic acid by optical aystallographic data.

Fraction 9 gave an immediate precipitate of a crystalline hydrazide which after recrystallization from 75% alcohol melted at 182°, and which by optical crystallographic data was further identified as tricarballylic trihydrazide.

Citric acid was identified in this fraction by the Stahre[6] reaction, in which pentabromoacetone was formed. Oxalic acid, which was determined by the Arbenz method, amounted to 0.029% on the fresh basis.

The Acids of Oat Plants.—The acids, isolated as lead salts from one hundred pounds of oat plants, were brought into a rather concentrated water solution and extracted with ether in a continuous extraction outfit. The ether solution was washed three times with 5-cc. portions of water, and the washings were added to the aqueous solution of acids.

On evaporation, 9.42 g. of yellow, crystalline acids was obtained. This was recrystallized from ethyl acetate. It was mainly aconitic acid, as shown by optical crystallographic data and by the color reaction given by aconitic acid on heating with acetic anhydride.

The acids left after ether extraction were esterified, affording 13.5 g. of crude esters,

---

[5] Arbenz, Mitt. *Lebensm. Hyg.*, 8, 98 (1917).

[6] Stahre, *Nord. Farm. Tidskrift.*, 2, 41 (1895).

which, on fractionating at 10 mm., yielded the following fractions: 1, 95–125°, 2.0 g.: 2, 125–130°, 8.7 g.; 3, 130–150°, 0.6 g.; 4, 150–160°, 0.5 g.

Fraction 1, on refractionating, gave fraction 1a, 90–110°; 1b, 110–120°; 1c, 120–125°. Hydrazides were prepared from these fractions.

From fraction 1a, a small quantity of malonic hydrazide was separated. There was not enough for a melting point determination, but it was identified by optical crystallographic data.

Fractions 1b, 1c and 2 yielded malic hydrazide. Fraction 3 yielded a mixture of malic and an oily hydrazide, and from fraction 4 a few crystals, identified by the usual methods as citric hydrazide, were obtained. These were associated with the oily hydrazide resulting, no doubt, from aconitic acid which had remained unextracted by ether. The content of oxalic acid, determined by the Arbenz method, was found to be 0.04% on the basis of the fresh material.

The Acids of Rye Plants.—The acids from one hundred pounds of rye plants, separated as lead salts and esterified, yielded 43 g. of crude esters.

Fractionation at 10 mm. afforded the following fractions: 1, 90–100°, 1.4 g.; 2, 125–135°, 14.9 g., α_D −9.75°; 3, 135–145°, 2.5 g.; 4, 145–155°, 0.9 g.; 5, 155–165°, 8.8 g.; 6, 165–175°, 4.0 g.; residue, 3.7 g.

The hydrazides were prepared from these fractions.

Fraction 1 afforded an immediate precipitate of a hydrazide, crystallizing in needles and melting at 235°, which corresponds to the hydrazide of oxalic acid. The filtrate from oxalic hydrazide was examined for malonic hydrazide, but none was found.

Fractions 2, 3 and 4 yielded malic hydrazide, melting at 178–179°.

Fraction 5 did not yield a pure crystalline hydrazide. It was, therefore, saponified and the acid separated. The acid was not completely soluble in water. Aconitic acid was identified in the water-soluble portion by optical crystallographic data and the color reaction with hot acetic anhydride. The water-insoluble fraction, a sirupy acid, was not identified.

Fraction 6 afforded an impure hydrazide. This fraction was then redistilled, and the hydrazide obtained from the redistilled fraction, melting at 104–105°, was further shown to be citric trihydrazide by optical crystallographic data. A determination of oxalic acid gave 0.048% on the basis of the fresh material.

Summary

Barley plants were found to contain aconitic, malic, citric, malonic, tricarballylic and oxalic acids. A determination of oxalic acid showed that it contained 0.019% on the basis of the fresh material.

Maize plants were found to contain aconitic, malic, citric, tricarballylic and oxalic acids. The percentage of oxalic acid in the fresh material was found to be 0.029.

Oat plants were found to contain aconitic, malic, citric, malonic and oxalic acids. 0.04% of oxalic acid was found in the fresh plants.

Aconitic, malic, citric and oxalic acids were found in rye plants. The undried plants contained 0.048% of oxalic acid.

The occurrence of aconitic acid in these members of the grass family, as well as in sugar cane and sorghum, is noteworthy.

THE VAN SLYKE METHOD FOR PROTEIN ANALYSIS AS AFFECTED BY FATS[1]

BY SIGFRED M. HAUGE

RECEIVED APRIL 29, 1931 PUBLISHED AUGUST 5, 1931

The Van Slyke method[2] for protein analysis was designed for the differentiation of pure proteins by the determination of chemical groups characteristic of certain amino acids. Wishing to investigate the distribution of amino acids in naturally occurring protein materials, numerous investigators attempted to use this method for the determination of the nitrogen distribution of various materials containing not only proteins but carbohydrates, fibers, fats and various other constituents present in plant and animal substances. The confusion arising from this work led Van Slyke[3] in 1915 to call attention again to the fact that his method was devised to be used with pure proteins, not accompanied by other substances.

The effect of carbohydrates and fiber on the Van Slyke method has been thoroughly investigated, especially by Gortner and his co-workers.[4] They have shown that these substances materially affect the nitrogen distribution of this method and have ascribed the effect to the action of the aldehyde group.

Although considerable work has been done on the effect of carbohydrates, a survey of the literature has failed to disclose any similar work having been conducted on the effect of fats and related compounds on the Van Slyke method. However, Morrow[5] stated: "The Van Slyke method of analysis for the determination of certain amino acids is limited in its application to pure proteins, to solutions of practically pure proteins, or to protein substances comparatively free from carbohydrates, fibers, fats, etc."

It therefore seemed desirable to make a critical study of the effect of the presence of fat and related compounds on the nitrogen distribution of proteins as determined by the Van Slyke method.

Experimental

Throughout this investigation, the technique for the Van Slyke method as summarized in Morrow's text, "Biochemical Laboratory Methods,"[5] was used. A description of the materials hydrolyzed as well as the results of the analyses are given in tables. The figures for each individual treatment represent the average of two, three or more determinations made from individual hydrolyses.

In the first series of experiments, the protein used was casein (Hammersten). Three grams of casein was hydrolyzed alone; in the presence of butter fat; in the presence of individual representative constituents of fat, such as glycerol, stearic acid, representing the saturated group of fatty acids, and oleic acid representing the unsaturated groups; and, finally, in presence of carnauba wax, which is not a triglyceride. The amounts of materials used and the results of the analyses obtained from these hydrolysates are given in Table I.

TABLE I

THE EFFECT OF THE PRESENCE OF FAT, GLYCEROL, STEARIC ACID, OLEIC ACID AND CARNAUBA WAX ON THE VAN SLYKE ANALYSIS OF CASEIN (AVERAGE RESULTS)

Material hydrolyzed, 3 g. of casein +	Ammonia nitrogen, mg.	Humin nitrogen			Basic nitrogen			Non-basic nitrogen		Nitrogen recovered, mg.
		Acid insol., mg.	Acid sol., mg.	P. T. A., mg.	Amino, mg.	Non-amino, mg.	Arginine, mg.	Amino, mg.	Non-amino, mg.	
	41.02	3.01	6.65	2.10	66.76	35.16	33.42	243.15	16.95	414.80
2 g. butter fat	41.42	2.59	10.34	3.54	61.62	36.64	29.96	230.72	20.28	407.15
2 g. glycerol	41.23	2.48	10.36	4.87	58.55	43.72	24.52	186.10	58.82	406.13
3 g. glycerol	41.46	2.79	19.39	5.60	54.95	53.43	21.68	174.66	60.54	412.82
3 g. stearic acid	41.20	2.73	6.58	2.14	68.92	35.24	33.08	240.96	13.84	411.61
3 g. oleicacid	41.37	3.23	6.36	2.00	66.38	34.42	33.32	237.42	15.92	407.10
3 g. carnauba wax	41.20	2.57	5.32	2.10	64.29	33.71	30.80	234.10	19.40	402.69

It will be noted that the ammonia nitrogen remained about constant in all cases. This was true also of the acid-insoluble humin. In the samples hydrolyzed in the presence of butter fat, there was an increase in the acid-soluble humin, the phosphotungstic acid humin and a decrease in the amino nitrogen of both the basic and non-basic fractions. As a consequence of the decrease in amino nitrogen, there is an increase in the non-amino nitrogen of these fractions because these values are obtained by the difference between the total nitrogen and the amino nitrogen. There is also a significant decrease in the arginine nitrogen value. The values for the other amino acids found in the basic nitrogen fraction are omitted because cystine is present only in small amounts and any values calculated for histidine and lysine which were based on such decreased amino and arginine values as obtained in the presence of fat, would be of no significance.

Since the Van Slyke method was found to be affected by fat, the next step was to determine the constituent responsible for this action. In the tests with glycerol, stearic acid and oleic acid, it was found that the fatty acids were without effect, while glycerol affected the same groups that were affected by the butter fat but to a greater extent. Thus it appears that glycerol is the reactive agent responsible for the effects produced.

The tests with carnauba wax were conducted for the purpose of determining the effect of wax, and especially of a material which is not a triglyceride, upon the Van Slyke method. The results show that carnauba wax had little, if any, effect on the nitrogen distribution.

These effects produced by fats and glycerol on the results of the Van Slyke analyses are in some respects similar and in others unlike that produced by carbohydrate material. Unlike the action of carbohydrates, glycerol or fats do not cause the formation of acid-insoluble humin, but in respect to the other fractions, the effects are similar. Gortner[4c] observed that in addition to the formation of acid-insoluble humin, carbohydrate material caused an increase in the acid-soluble humin, phosphotungstic acid humin and non-amino nitrogen, and a decrease in the arginine nitrogen and amino nitrogen, similar to that obtained in these experiments with fat and glycerol.

In the second series of experiments, gelatin (Bacto-Gelatine, Difco Standardized) was used as the protein. Since gelatin contains little or no tyrosine, tryptophane, cystine and histidine, it was thought that analyses of this protein with and without additions of glycerol might give an insight into the amino acid involved in the formation of the acid-soluble and phosphotungstic acid humins, as well as show what effect the absence of a number of amino acids might have on the other fractions. The results are given in Table II. It is to be observed that the results are quite different from those obtained with casein. There is no increase in the acid-soluble humin and phosphotungstic acid humin nitrogen. However, the amino nitrogen and arginine fractions are decreased in a similar manner as before.

TABLE II

THE EFFECT OF THE PRESENCE OF GLYCEROL ON THE VAN SLYKE ANALYSIS OF GELATIN (AVERAGE RESULTS)

		Humin nitrogen			Basic nitrogen			Non-basic nitrogen		
Material hydrolyzed	Ammonia nitrogen, mg.	Acid insol. mg.	Acid sol., mg.	P.T.A., mg.	Amino, mg.	Non-amino, mg.	Arginine, mg.	Amino, mg.	Non-amino, mg.	Nitrogen recovered, mg.
3 g. gelatin	18.18	0.29	1.48	5.38	110.80	61.53	67.76	209.21	53.37	459.24
3 g. gelatin + 3 g. glycerol	18.35	.31	1.38	5.20	80.90	88.90	56.4	190.22	71.48	455.74

The third series of experiments were performed to determine the effect of glycerol on arginine, tyrosine and tryptophane. These amino acids were Pfanstiehl products used without further purification. The results of these analyses are given in Table III. In the case of arginine, the arginine value and amino nitrogen were decreased by the presence of glycerol, Concerning the ammonia and humin nitrogen fractions, the differences were not large enough to be significant. For the unexpected presence of nitrogen in the non-basic fraction, no explanation is offered.

TABLE III

THE EFFECT OF GLYCEROL ON THE NITROGEN DISTRIBUTION OF SOME AMINO ACIDS (AVERAGE RESULTS)

Material hydrolyzed	Ammonia nitrogen, mg.	Humin nitrogen Acid insol., mg.	Acid sol., mg.	P.T.A., mg.	Basic nitrogen Amino, mg.	Non-amino, mg.	Arginine, mg.	Non-basic nitrogen Amino, mg.	Non amino, mg.	Nitrogen recovered, mg.
3 g. arginine	0.07	0.07	0.07	1.26	21.11	55.19	77.44	5.46	2.26	86.49
3 g. arginine + 3 g. glycerol	.14	.21	.21	1.94	17.28	57.76	61.04	3.98	4.67	86.19
2 g. tyrosine	.0	.0	.0					23.44	.0	23.44
2 g. tyrosine + 3 g. glycerol	.16	.0	4.52					14.30	4.22	23.20
3 g. tryptophane	.07	.70	0.42					20.69	19.35	41.21
3 g. tryptophane + 3 g. glycerol	.12	.80	1.12					17.95	22.26	42.25

The experiments with tyrosine clearly indicate that tyrosine hydrolyzed in the presence of glycerol tends to form acid-soluble humin. It is interesting to note that tyrosine has also been found to be responsible for the formation of acid-soluble humin when hydrolyzed in the presence of aldehyde~. There was a definite decrease in amino nitrogen.

Unlike the action of aldehydes on tryptophane,[4c] glycerol does not cause the formation of acid-insoluble humin. However, there is some indication that it does contribute some nitrogen to the acid-soluble humin. Again, it will be observed that glycerol caused a decrease in amino nitrogen.

Summary

1. The Van Slyke method for protein analysis is affected by the presence of fat.

2. The reactive constituent of the fat molecule is glycerol; the fatty acids such as stearic acid, representing the saturated group, and oleic acid representing the unsaturated groups, are without effect.

3. The significant effects produced by fat or glycerol are: an increase in the acid-soluble humin, in the phosphotungstic acid humin, and in the non-amino nitrogen, and a decrease in the amino nitrogen and arginine values.

4. Carnauba wax, which is not a glyceride, had little, if any, effect on the Van Slyke method.

THE CHEMISTRY OF ORGANIC GOLD COMPOUNDS. III. DIRECT INTRODUCTION OF GOLD INTO THE AROMATIC NUCLEUS

(PRELIMINARY COMMUNICATION)[1,2]

BY M. S. KHARASCH AND HORACE S. ISBELL

RECEIVED APRIL 30, 1931 PUBLISHED AUGUST 5, 1931

Introduction

In previous papers by Kharasch and Isbell[3] the applicability of the Grignard reagent in the preparation of gold carbon compounds is discussed. The authors point out that in their experience the use of the Grignard reagent is definitely limited to the preparation of gold compounds of the ethyl radical and radicals that lie below the ethyl radical in the Table of Electronegativity of Radicals.[4] This limitation of the Grignard reagent, as well as the inapplicability of other indirect methods, to the preparation of aromatic gold compounds forced us to investigate the direct action of anhydrous gold chloride on aromatic compounds.

Fortunately, the direct action, whenever possible, of anhydrous auric chloride upon aromatic substances leads to the introduction of the gold into the aromatic nucleus and the formation of a compound $RAuX_2$. Our preliminary results indicate that direct "auration" is as general a reaction as nitration, halogenation or mercuration, except that it is a much faster reaction and the products of the reaction are much less stable.

Previous Work.—The action of aqueous solutions of auric chloride upon organic substances has been studied exhaustively.[5] The results of these studies may be summarized as follows: first, the reduction of a water solution of gold chloride by organic substances is a function of the hydrogen-ion concentration and in general the reduction is more rapid in alkaline solution. Second, organic substances may be divided into three classes based upon their behavior toward a water solution of gold chloride: (1) a class of substances which neither reduce nor extract gold chloride from a water solution (the saturated hydrocarbons belong in this class); (2) organic substances which are oxidized by a water solution of gold chloride

with the consequent precipitation of metallic gold; (3) a class of substances which extract the gold chloride from a water solution.

Behavior of Anhydrous Gold Chloride toward Organic Reagents.—Our studies of the behavior of anhydrous gold chloride toward organic substances make it quite evident that the solvents belonging in Class 3, cited above, in reality do not extract gold chloride from water but a hydrated complex. Furthermore, our experience indicates that aromatic substances, as well as oxygen-containing aliphatic compounds, either react with anhydrous gold chloride to give, at least as intermediates, gold carbon compounds or combine with that reagent to form complexes. Saturated hydrocarbons and alkyl halides in the aliphatic series, and nitrobenzene in the aromatic series, appear to be the only compounds unaffected by anhydrous gold chloride. Nitrobenzene, incidentally, in spite of the appreciable solubility of anhydrous gold chloride in it, is thus far the only aromatic compound which we have found not to interact or form very stable complexes with that reagent.

The above conclusions are based upon the following considerations: (1) the behavior of anhydrous auric chloride toward benzene and other substances; (2) the behavior toward benzene and other aromatic substances of hydrated auric chloride or anhydrous auric chloride previously treated with small quantities of ether, alcohol, glacial acetic acid, etc.

The Reaction of Anhydrous Auric Chloride and Benzene,—When dry benzene is added slowly to anhydrous auric chloride, a vigorous reaction ensues—hydrogen chloride is evolved and 1,2,4,5-tetrachlorobenzene and aurous chloride may be isolated from the mixture. On the other hand, if finely divided anhydrous auric chloride is added to a large quantity of dry benzene (thiophene free), an immediate evolution of hydrogen chloride takes place and the solution acquires a red color which in a few minutes turns brown. If allowed to stand for a few moments longer, a bright yellow precipitate is formed. The precipitate thus formed is aurous chloride and the solution contains phenyl chloride.[6] The yield is 97.7% of the calculated amount.

However, if the reaction given above is stopped at the point where the brown precipitate is formed, a different result is obtained. This may be accomplished by the addition of ether, a few cc. of acetic acid, alcohol, ethyl acetate or other reagents containing oxygen. If an equal volume of ether is added a yellow solution results, without the formation of any aurous chloride. Upon evaporation of the ether–benzene mixture yellow crystals are obtained. These may be separated from the adhering gold chloride by

[6] In this connection the statement of Lenher, This Journal, 35, 552 (1913), is quite pertinent: "It has not been possible to produce aurous type of compounds (inorganic) by the use of an organic reducing agent." Under anhydrous conditions the formation of aurous chloride is quite the usual occurrence.

thorough washing with water and crystallization from alcohol. Beautiful, long, narrow crystals, which are almost colorless, are thus obtained. The analysis and behavior of the compound indicate that it is phenyl auric dichloride. The yield is 0.41 g. from 2 g. of auric chloride.

Anal. Subs. (dried over P_2O_5), 0.0597: Au, 0.0342. Calcd. for $Au(C_6H_5)Cl_2$: Au, 57.14. Pound: Au, 57.17.

The compound is difficultly soluble in water, readily soluble in salt solution, very soluble in alcohol, difficultly soluble in ether, insoluble in benzene and petroleum ether. It decomposes at 73–75" or upon long standing.

The first step of the reaction may therefore be postulated as follows

$$C_6H_6 + AuCl_3 \longrightarrow C_6H_5AuCl_2 + HCl \qquad (1)$$

It is quite likely that the molecule of phenyl auric dichloride reacts then with another molecule of benzene to give diphenyl auric chloride and hydrogen chloride.

$$C_6H_5AuCl_2 + C_6H_6 \longrightarrow (C_6H_5)_2AuCl + HCl \qquad (2)$$

The compound diphenyl auric chloride is evidently an exceedingly unstable substance and in the presence of hydrogen chloride the following decomposition takes place

$$(C_6H_5)_2AuCl + HCl \longrightarrow C_6H_5Cl + AuCl + C_6H_6 \qquad (3)$$

Our assumption of the instability of diphenyl auric chloride is based upon our attempts to prepare this substance directly from auric chloride and the Grignard reagent, and some rather extensive experiments to prepare the compound from phenyl auric dichloride and phenyl magnesium bromide. In all of the above experiments we were unable to isolate the compound diphenyl auric chloride.

The evidence adduced points to the conclusion that the addition of ether to the mixture of anhydrous auric chloride and benzene, at a point where the brown color is formed, effectively blocks the interaction of the phenyl auric dichloride with benzene by forming a stable complex between the ether and the phenyl auric dichloride.

Additional evidence regarding the combination of ether with anhydrous auric chloride lies in the fact that when we add ether to the benzene solution prior to the addition of gold chloride, no phenyl auric dichloride is formed. Furthermore, neither chloroauric acid nor hydrated gold chloride gives any gold organic compound when treated with benzene, as in the formation of phenyl auric dichloride. That this inhibiting effect of the ether is not due to a dilution effect is shown in a most striking manner by the fact that one drop of benzene in 10 ec. of petroleum ether reacts vigorously with dry auric chloride, while pure benzene will not react with anhydrous auric chloride which is simply moistened with ether.

Effect of Substituents upon Reactivity of Aromatic Substances and Anhydrous Auric Chloride.—Thus far the following gold–carbon compounds have been prepared by direct auration: phenyl auric dichloride, tolyl auric dichloride, diphenyl auric dichloride, methylsalicylate auric dichloride and o-nitroanisole auric dichloride. The latter substance has not been analyzed as yet. Only a preliminary study has been made of the action of gold chloride and of different types of radicals, their rates of reaction and the stability of the products. The time interval before the addition of the ether depends upon the particular compound into which gold is being introduced. If a reaction takes place with a high speed, obviously it is extremely difficult to stop that reaction at one of the intermediate stages.

Very negative radicals react very vigorously with auric chloride. Thus in a qualitative way we might arrange the aromatic hydrocarbons in the following order according to the vigor of their reaction with auric chloride: naphthalene, diphenyl, toluene and benzene. This arrangement of the substances is the same as that found for the electronegativity of the radical~. The instability of these organo-auric dichlorides is also in perfect accord with the hypothesis developed in the preceding section, that slightly electronegative radicals should form more stable compounds toward hydrolytic agents than the compounds of the more electronegative radicals.

The influence of different substituents in the benzene nucleus on the rate of reactions with anhydrous gold chloride is quite marked. Strongly electronegative groups, *i. e.*, NH_2, $-N(CH_3)_2$, OH, increase the speed of reaction and decrease the stability of the products. Weakly electronegative groups have the opposite effect. Thus the reaction between phenol and auric chloride is almost instantaneous, while the reaction with nitrobenzene is extremely slow, at ordinary temperature. Combinations of the two types of effects, for example, methyl salicylate and *o*-nitroanisole react to give fairly stable products. Between the substances which react extremely rapidly with auric chloride and lead to very unstable substances and those that react slowly are a large number of compounds which in the future will form the foundation for a chemistry of organic gold compounds.[7]

Gold Chloride as a Halogen Carrier.—If benzene is added dropwise to anhydrous gold chloride, a vigorous reaction takes place and 1,2,4,5-tetrachlorobenzene may be isolated from the residue. On the other hand, if a large quantity of benzene is added at one time, phenyl chloride is formed. We have shown previously that an intermediate compound, phenyl auric dichloride, is formed. This compound, similar to other

---

[7] Not only do the aromatic compounds undergo direct auration but aliphatic compounds containing active hydrogen atoms undergo a similiar reaction. Thus, malonic acid reacts with anhydrous auric chloride with the liberation of hydrogen chloride and the formation of a gold organic compound. The latter resembles in properties phenyl auric dichloride. These reactions are being investigated.

organo-metallic compounds, reacts with chlorine gas to give auric chloride and phenyl chloride. In the presence of chlorine gas auric chloride can thus function as a halogen carrier. In actual experiments benzene was rapidly chlorinated when auric chloride was used as a catalyst. The chlorine was practically completely absorbed and one or more chlorine atoms easily introduced into benzene. Phenylauric dichloride reacted equally well as a catalyst.

This definite mechanism of the catalytic effect of auric chloride is of interest particularly when one bears in mind similar catalytic activity on the part of other metal catalysts where no such intermediates have been isolated, *i.* e., iron and aluminum. It is hard to see, however, in view of the difference in position of these metals in the electromotive series, how the isolation of the intermediate gold organic substances helps the theory of intermediate compound formation as applied to the other catalysts.

The gold halides may also be employed as condensing agents in the Friedel and Craft syntheses in place of the aluminum halides.

Properties of Aryl Gold Dichlorides.—Upon heating, the aryl gold dichlorides decompose at their melting points. They are instantly acted upon by strong reducing agents, such as stannous chloride or hydroquinone, and metallic gold is formed. This behavior of the aryl gold dichlorides is similar to that of the alkyl gold dichlorides and strikingly different from that of the dialkyl gold chlorides, which are very stable to reducing agents.

With thiosalicylic acid the aryl gold dichlorides react like auric chloride, namely, the auro-thiosalicylic acid is formed. The aryl gold dichlorides are also insoluble in water but quite soluble in sodium chloride solution, probably forming the chloroaurate complexes $Na^+(RAuCl_3)^-$.

In the case of phenyl gold dichloride the complex with sodium chloride, while stable toward heat in 0.4 M concentration, is rapidly decomposed in alkaline solution with the separation of metallic gold.

The analyses of the aryl gold dichloride offered some difficulty. Since they had to be washed with water to extract the unchanged gold chloride, they most likely combined with that reagent to form the complex $H^+(RAuCl_2OH^-)$, an assumption suggested by the ready solubility of the aryl gold dichlorides in sodium chloride. In view of the fact also that the substances were rather unstable, they had to be analyzed rapidly. The phenyl gold dichloride, which is the most stable of the aryl gold dichlorides we had prepared thus far, could be dried in *vacuo* to constant weight over phosphorus pentoxide. In the case of the other compounds, we had to work much more rapidly and thereby dry the materials less thoroughly. The analyses therefore indicate that while all solvents of crystallization had been completely removed from them, they all still contained a molecule of water of hydration. With better facilities, however, than we had available at the time, the water of hydration undoubtedly could be removed readily.

Experimental Part

The Reaction between Phenyl Auric Dichloride and Phenylmagnesium Chloride.—To 1.726 g. of phenylauric chloride dissolved in 200 cc. of anhydrous ether at −10°, the Grignard reagent from 1.044 g. (1.25 equivalents) of phenyl bromide was added drop by drop. During the addition of the reagent a small amount of gold precipitated. When the reaction seemed to be complete, 200 cc. of petroleum ether was added. The excess of Grignard reagent was then decomposed and the ether extract washed repeatedly with water and finally dried with sodium sulfate. The ether extract contained considerable gold. Upon evaporation of the ether, gold was precipitated. The product of the reaction was unstable and we were unable to isolate a gold–carbon compound.

The Preparation of Tolyl Auric Dichloride.—Tolyl auric dichloride is obtained by the action of auric chloride on toluene. Finely divided auric chloride is mixed with a small amount of toluene, whereupon hydrogen chloride is evolved, a brown precipitate separates, and the solution acquires a deep red color. After a few minutes ether is added, as in the case of benzene. Upon evaporation of the solvent the residue is washed with petroleum ether and then water. It is then crystallized from ether.

Anal. Subs., 0.0688: Au, 0.0364. Calcd. for $C_7H_7AuCl_2H_2O$: Au, 52.30. Found: Au, 52.91.

The compound is yellow and crystalline. It is soluble in alcohol, ether and benzene, and insoluble in carbon tetrachloride and petroleum ether. It darkens very quickly on exposure to strong light.

The addition of toluene to a nitrobenzene solution of auric chloride at −15° gave light yellow crystals whose properties were the same as those of tolyl auric dichloride.

An ethyl acetate solution of auric chloride did not react with toluene.

The Preparation of Diphenyl Auric Chloride.—Diphenyl auric dichloride, $C_{12}H_9AuCl_2$, was prepared from a petroleum ether solution of diphenyl and anhydrous auric chloride by essentially the same method that was used for the preparation of phenyl auric dichloride. The yield from two grams of auric chloride was 0.127 g. of diphenyl auric dichloride.

Anal. Subs., 0.0430: Au, 0.0192. Calcd. for $C_{12}H_9AuCl_2H_2O$: Au, 44.91. Found: Au, 44.95.

The compound is yellow and crystalline. It decomposes at about 65°. It is soluble in alcohol and ether, insoluble in petroleum ether and water. It is soluble in sodium chloride solution.

The Preparation of Methyl Salicylate Auric Dichloride.—Methyl salicylate auric dichloride was prepared by dissolving one gram of methyl salicylate in 50 cc. of petroleum ether. After the addition of 4 g. of auric chloride, the method for the preparation of gold compounds by direct "auration" as previously given was used.

Anal. Subs., 0.0993: Au, 0.0455. Calcd. for $C_8H_7O_3AuCl_2H_2O$: Au, 45.11. Found: Au, 45.82.

The compound is light yellow and crystalline. It is quite stable and melts and decomposes at 107°. It is soluble in alcohol and ether, insoluble in petroleum ether and water. It is soluble in sodium chloride solution. An alcoholic solution of the compound is decomposed very rapidly when treated with an alkali or sodium bicarbonate solution. Metallic gold separates in all cases.

o-Nitroanisole Auric Dichloride.—*o*-Nitroanisole when treated in cyclohexane solution with auric chloride reacted to give a crystalline compound. This was worked up in the usual manner. The compound was insoluble in petroleum ether, cyclohexane and water; it dissolved readily in alcohol.

Summary

1. It is pointed out that anhydrous auric chloride reacts rapidly, at ordinary temperatures, with aromatic compounds except nitrobenzene, with the liberation of hydrogen chloride and the formation of compounds $RAuCl_2$.

2. It is shown that anhydrous auric chloride reacts with most oxygen-containing substances, forming complexes.

3. Nitrobenzene is shown to be the only solvent, thus far discovered, which dissolves gold chloride without undergoing a reaction with that reagent.

4. The effect of substituents in the benzene ring on the speed of reaction of the compounds with gold chloride is discussed.

5. The behavior of aryl gold dichlorides toward reducing reagents is discussed.

6. It is shown that the aryl gold dichlorides, while insoluble in water, dissolve in sodium chloride solution probably forming complexes of the chloroaurate type.

7. The effect of gold chloride as a halogen carrier is discussed from the standpoint of the intermediate compounds that have been isolated, and the further reaction of those substances and chlorine.

8. The preparation and properties of the following aryl gold dichlorides are described: phenyl auric dichloride, tolyl auric dichloride, diphenyl auric dichloride, methyl salicylate auric dichloride and o-nitroanisole auric dichloride.

THE CHEMISTRY OF ORGANIC GOLD COMPOUNDS. IV. GOLD IMIDE COMPOUNDS[1]

BY M. S. KHARASCH AND HORACE S. ISBELL

RECEIVED APRIL 30, 1931 PUBLISHED AUGUST 5, 1931

Introduction

The elements of the first sub-group in the periodic system, *i.* e., copper, silver and gold, form two distinct classes of imide salts. Thus, copper in alkaline solution gives the well-known "biuret"[2] reaction with biuret and reacts readily also with other compounds which contain an imide group. Specifically, with succinimide, a complex salt,[3] $K_2Cu(C_2H_2O_2N)_4$

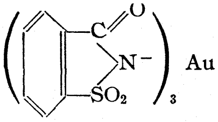
is formed. However, silver forms a normal salt with succinimide ($Ag(C_2H_4O_2N)$).[4]

The tendency of gold to form compounds of the chloroaurate type[5] is clearly shown by a new class of gold imide compounds which we have prepared.

Previous Work.—There are no gold carbonyl imides described in the literature. The sulfinimides, which are more acidic, form metallic salts more readily and a process has been described for the preparation of gold sulfinimides.[6] The method consists in treating the alkali salt of the sulfinimide with auric hydroxide. In the case of saccharin a compound of the following type is claimed



According to the disclosure in the patents, these gold sulfinimides give "the well-known gold reactions with stannous chloride or oxalic acid." Obviously these gold sulfinimides furnish an appreciable concentration of auric ions in solution. The patents further state that "the formation of these compounds is surprising, since by the use of aromatic carbonyl imides as for example, phthalimide, this reaction does not take place."

Our experience differs fundamentally from that of the above authors in the following respects: (1) we have been able to prepare gold carbonyl imide complexes. (2) The structures of the gold imide complexes are different from those assumed in the German patents. *(3)* The stability of our gold imide complexes is very great, for they do not give, at ordinary temperatures, tests for gold when treated with such reagents as stannous chloride or oxalic acid.

Properties of Imido-auric Acids.—The compounds of gold imides which we have prepared may be represented by the general formula $H^+[Au(imide)_4]^-$. We have designated them as imido-auric acids because their structures are similar to the structure of chloroauric acid. They give colorless solutions which are characterized by great stability toward both heat and reducing agents. Thus, neutral solutions of these compounds may be warmed without reduction with hydroquinone, stannous chloride or other powerful reducing agents, while strongly acid or alkaline solutions of the substances are only reduced upon warming. This great stability of the gold compounds toward reducing agents indicates that they do not ionize to give an appreciable quantity of gold ions.

---

[4] Bunge, Ann. *Suppl.*, 7, 119 (1870); Ley and Werner, *Ber.*, 38, 2199 (1905); 40, 705 (1907)

[5] This tendency has been stressed in our previous papers, THIS JOURNAL, 53, 2701 (1931); 53, 3053 (1931).

[6] German Patents 347,139 and 348,070.

These complex salts of gold imides are also very stable toward mineral acids at ordinary temperatures. The addition of a mineral acid to a salt of the gold imides usually leads to the separation of the imido-auric acids. This behavior of the salts of gold imides is in striking contrast to the behavior of the salts of copper imides, which are decomposed instantly even by such weak acids as acetic.

The imido-auric acids are definitely acidic, forming well-characterized salts and reacting acid to indicators. In particular succinimido-auric acid is a relatively strong acid. It decomposes carbonates and turns Congo red blue Even more remarkable is the fact that ammonium succinimido-aurate may be crystallized from hot glacial acetic acid without decomposition. The acid properties of this succinimido-auric acid cannot be attributed to succinimide, for the latter is a very weak acid.

The alkali and alkaline earth salts of the imido-auric acids are extremely soluble in water, but insoluble in alcohol. On the other hand, ammonium succinimido-aurate is crystalline and difficultly soluble in water but more soluble in alcohol than the corresponding alkali salts. The presence of other salts, particularly salts of halides, such as sodium chloride, produces a great change in the solubility of some of these compounds. Thus, the difficultly soluble ammonium succinimido-aurate dissolves easily in dilute aqueous salt solutions of chlorides and bromides. The desirability of avoiding the presence of large quantities of salts in the preparation and crystallization of these compounds is obvious.

Some of the free acids are very soluble in water, for example succinimido-auric acid; others are difficultly soluble, such as the phthalimido-auric acid.

The Preparation of Imido-auric Acids.—The imido-auric acids are best prepared by the direct combination of gold hydroxide and the desired imide. In some cases the reaction takes place by simply heating an aqueous mixture of auric hydroxide and the imide. Usually, however, the reaction takes place more readily in the presence of a small quantity of a halogen salt or a mineral acid. The halogen salt or acid serves as a means of obtaining an appreciable quantity of auric ions in solution. This is particularly desirable since auric hydroxide is practically insoluble in water. In general, any substance which increases the concentration of auric ions in solution would increase the rate at which the imido-auric acids are formed. An excess of auric hydroxide is also employed and serves as a buffer to regulate the acidity. In some cases, due to the insolubility of the imide, it is necessary to use other solvents besides water, *i. e.*, a mixture of alcohol and water. A soluble salt of the imide may be used, but this increases the difficulty in the separation of the products of the reaction.

The Structure of Ammonium Succinimido-aurate.—Since the reaction between auric hydroxide and imides takes place slowly, the solution must be kept warm for a considerable period. This long heating may result in the hydrolysis of a portion of the imide, liberating ammonia, which may lead to the production of the ammonium salt of the imido-auric acid. Its formation in the presence of succinic acid indicates that the imido-auric acid is a relatively strong acid; otherwise it would not deprive succinic acid of the ammonium radical.

In order to establish the structure of ammonium succinimido-aurate, it was converted into the corresponding barium salt. This was accomplished by heating a solution of the ammonium salt with barium hydroxide, when ammonia was liberated and upon concentration of the solvent pure barium succinimido-aurate separated. Subsequently the barium salt was decomposed with the calculated quantity of sulfuric acid and the crystalline free acid was obtained. This crystalline free acid was then changed back into the ammonium salt by treating it with ammonium hydroxide. Furthermore, succinimide was recovered, practically quantitatively, by the reduction of ammonium succinimido-aurate with zinc.

Experimental Part

1. Ammonium **Succinimido-aurate, $NH_4Au(C_4H_4O_2N)_4 \cdot 4H_2O$.—To** 117 g. of succinimide and one gram of auric chloride dissolved in 500 cc. of water, moist auric hydroxide (equivalent to 40 g. of auric oxide) was added. The mixture was warmed on the steam-bath for forty-eight hours. Most of the auric hydroxide dissolved and a colorless product formed. Sufficient boiling water was then added to dissolve the crystals which had formed and the hot solution filtered. Upon cooling the filtrate, colorless crystals of ammonium succinimide-aurate separated. Sixty-six grams of solid was thus obtained. The product was crystallized from hot water and subsequently air dried at room temperature.

Anal. Subs., 0.1022: Au, 0.0296. Calcd. for $AuC_{16}H_{20}O_8N_5 \cdot 4H_2O$: **Au,** 29.02. Found: **Au,** 28.96.

Crystalline ammonium succinimido-aurate became anhydrous after drying for several months in *vacuo* over phosphoric anhydride. Samples were also dehydrated by drying for eight hours at 80° in *vacuo*.

Anal. Subs., 0.3624: Au, 0.1373; N, 29.5 cc. of $N/10$ acid. Calcd. for $AuC_{16}H_{20}O_8N_5$: Au, 32.47; N, 11.51. Found: Au, 32.51; N, 11.40.

The salt separates from water in transparent prismatic crystals, frequently in the form of almost regular hexagons but sometimes elongated; when viewed from the ends they are rectangular and from the sides trapezoidal.

An 0.1-g. quantity of the substance heated in a crucible, detonated violently. In a melting point tube, it decomposed at 270 to 280°, gradually turning purple and finally black, without melting.

The compound is difficultly soluble in water or dilute alcohol, insoluble in ether, benzene, chloroform and most organic solvents. It is fairly soluble in hot glacial acetic acid, crystallizing upon cooling. It gives colorless solutions in concentrated sulfuric acid which decompose when heated, with the precipitation of metallic gold. It is soluble in sodium carbonate solution or in alkalies, forming the corresponding alkali salts.

Two grams of ammonium suecinimido-aurate was dissolved in **50** cc. of hot glacial acetic acid. Upon cooling the filtrate **1.3** g. of crystalline ammonium succinimido-aurate separated, This was washed with ether and dried at 70° *in vacuo.*

Anal. Subs., **0.1062;** Au, **0.0345.** Calcd. for $AuC_{16}H_{20}O_8N_5$: Au, **32.47;** Found: Au, **32.49.**

A second lot of crystalline succinimido-aurate was obtained by the addition of ether to the mother liquor. The crystals weighed **0.6** g.

Barium Succinimido-aurate, $Ba[Au(C_4H_4O_2N)_4]_2$.—Two grams of ammonium succinimido-aurate was dissolved in **29** cc. of cold *N*/10 barium hydroxide. After solution the odor of ammonia was observed. The solution was concentrated in vacuo to about **5** *cc.,* when a small quantity of unchanged ammonium succinimido-aurate had separated. The clear filtrate was diluted with methyl alcohol until it turned slightly turbid, when crystallization of the substance occurred. After several hours the crystals were collected on a filter. It was crystallized from a mixture of alcohol and water. The pure product was dried at 70° *in vacuo* to the constant weight of **0.7514** g.

Anal. Subs., **0.0712:** Au, **0.0212;** $BaSO_4$, **0.0126.** Calcd. for $BaAu_2C_{32}H_{32}O_{16}N_8$: Au, **29.97;** Ba, **10.44.** Found: Au, **29.93;** Ba, **10.40.**

The crystals separated from dilute alcohol or water in long slender needles which formed in fan-like clusters. They were very soluble in water but insoluble in organic solvents. In a melting point tube the compound decomposed at 268–270°. **A** water solution was not reduced by aqueous solutions of hydroquinone or stannous chloride.

Succinimido-auric Acid, $HAu(C_4H_4O_2N)_4$.—To **0.5** g. of barium succinimido-aurate dissolved in **15** cc. of water, **7.6** cc. of *N*/10 sulfuric acid was added slowly while the solution was shaken vigorously. The barium sulfate which precipitated was collected on a **filter.** The clear filtrate was evaporated *in vacuo* to a sirup, which was brought to crystallization by the addition of a small quantity of alcohol. The crystals were collected on a filter, washed with alcohol, followed by ether, and finally dried at 80° in *vacuo.* The weight of material was **0.35** g.

Anal. Subs., **0.0464: Au, 0.0154.** Calcd. for $HAuC_{16}H_{16}O_8N_4$: **Au, 33.19. Found:** Au, **33.19.**

When crystallized from dilute alcohol or water, succinimido-auric acid is obtained in the form of very fine needles. These needles are easily soluble in water, difficultly soluble in alcohol and insoluble in ether and ethyl acetate. In a melting point tube this compound decomposed at **210–240°,** depending upon the rate of heating.

A water solution of succinimido-auric acid was neutralized with a solution of ammonium hydroxide. **A** precipitate of ammonium succinimido aurate formed immediately. The crystals were collected on a filter and dried in *vacuo.*

Anal. Subs., **0.1056:** Au, **0.0342.** Calcd. for $NH_4AuC_{16}H_{16}O_8N_4$: Au, 32.47. Found: Au, **32.38.**

Separation of **Succinimide** from Ammonium **Succinimido-aurate.**—One gram of anhydrous ammonium succinimido-aurate, $(NH_4)Au(C_4H_4O_2N)_4$, was partially dissolved at room temperature in **25** cc. of water which contained **0.2** g. of sodium chloride, and one gram of granulated zinc was added. The mixture was allowed to stand at room temperature. After twenty-four hours considerable gold had been deposited and the solution had become distinctly alkaline. Dilute acetic acid was then added until the solution was neutral. Then the mixture was set aside for another twenty-four hours, when the hydrogen-ion concentration was adjusted again. After standing for about ten days all the gold had been reduced to the metal. The succinimide was then isolated in the usual manner. The weight of material was **0.6** g. and the melting point **116°.** After a single crystallization the melting point rose to 124°.

Barbital **Imido Auric** Acid  $\overset{+}{H}\cdot 3H_2O$.—Barbital (di-ethylbarbituric acid) in water solution reacts with auric hydroxide very slowly to give a silky precipitate. A water solution of barbital on standing for two months with four grams of auric hydroxide formed less than 0.5 g. of this silky precipitate. Even on warming on a steam-bath the rate of formation was very slow. The addition of a small amount of auric chloride or a drop of hydrochloric acid, however, greatly accelerated the rate of formation; other chlorides had the same effect.

0.01 mole of auric hydroxide was mixed with 0.04 mole of barbital and 50 cc. of water and two drops of concentrated hydrochloric acid was added. After digestion on the steam-bath for forty-eight hours, practically all the gold hydroxide had been changed to a white silky precipitate. Upon crystallization from 50% alcohol a pure compound resulted.

Anal. Subs., 0.1122, 0.1164, 0.1449, 0.0466, 0.0916: Au, 0.0232, 0.0236, 0.0294, 0.0096, 0.0188. Calcd. for $HAuC_{32}H_{44}O_{12}N_8\cdot 3H_2O$. Au, 20.41; N, 11.59. Found: Au, 20.68, 20.27, 20.29, 20.60, 20.52; average 20.47; N, 11.74, 11.42; average 11.57.

The compound is white and crystalline. It is soluble in dilute alcohol, very difficultly soluble in water and 95% alcohol, insoluble in ether, benzene and petroleum ether. It is not readily reduced by hydroquinone or sodium hydrosulfite. It decomposes at 200° to a black liquid.

Sodium Salt of Barbital **Imido** Auric Acid.—Barbital imido auric acid dissolves in sodium hydroxide solution forming a sodium salt which may be precipitated by the addition of alcohol. This salt is very soluble in water. It is very stable toward reducing agents. A water solution of this salt, after careful acidification with hydrochloric acid, gives a precipitate of barbital imido auric acid.

Benzoic Sulfinimido-auric Acid $\overset{+}{H}$  $\cdot 3H_2O$.—Auric hydroxide reacts much more readily with saccharin than with any other compound which we tried, to form a complex imide. Due to the greater acidity of this group it is not necessary to add gold chloride or other substances in order to accelerate the reaction.

0.01 mole of auric hydroxide was digested with 0.04 mole of saccharin in water solution. A yellow crystalline compound resulted. After crystallization from 50% alcohol and drying for eighteen hours over phosphoric anhydride, the following analyses were obtained.

Anal. Calcd. for $HAuC_{28}H_{16}O_{12}N_4S_4\cdot 3H_2O$. Au, 20.41; N, 5.69. Found: Au, 20.14; N, 5.41.

The compound is difficultly soluble in dilute alcohol, almost insoluble in water and 95% alcohol, insoluble in organic solvents, slightly soluble in salt solutions but soluble in alkalies. It decomposes gradually without melting at 135°.

Sodium Phthalimido-aurate $\overset{+}{Na}$  $\cdot 3H_2O$.—The **reac-**

tion with phthalimide proceeds slowly and the addition of gold chloride or other salts is necessary. The separation from the reaction product of any unchanged phthalimide is difficult, due to the low solubility of the latter.

The sodium salt was prepared by the reaction between sodium carbonate, auric hydroxide and phthalimide. It was crystallized several times from alcohol–water mixtures.

Anal. Subs., 0.0938: Au, 0.0220; Na_2SO_4, 0.0094. Calcd. for $NaAuC_{32}H_{16}O_8N_4\cdot 3H_2O$: Au, 22.95; Na, 2.70. Found: Au, 23.45; Na, 3.24.

The compound is difficultly soluble in water, insoluble in alcohol, acetone, ether and slightly soluble in dilute alcohol. It was not reduced by hydroquinone or sodium hydrosulfide. It begins to decompose at 185°, gradually becoming black as the temperature rises.

This product was not quite pure, and it probably contained a small amount of sodium phthalimide, which resulted in a high sodium content. However, there is no doubt as to the identity of this compound, as its physical and chemical properties indicate that the compound is sodium phthalimido-aurate.

The authors wish to acknowledge their indebtedness to Dr. Carl Voegtlin of the National Institute of Health of the United States Public Health Service for his interest and the encouragement he has given them throughout the work on gold compounds.

Summary

1. It is shown that gold hydroxide reacts with carbonvlimides as well as with sulfinimides to give compounds of the chloro-aurate type. These compounds have been designated as imido-auric acids and are represented by the general formula $^{+}H[Au(imide)_4]^{-}$.

2. The great stability of the imido auric acids, as well as their salts, toward powerful reducing agents is discussed.

3. The acid character of succinimido auric acid $\overset{+}{H}[Au(succinimide)_4]^{-}$ is emphasized. It is shown that this acid is a stronger acid than carbonic acid.

4. The following representatives of a new class of gold carbonyl imides are described: succinimido-auric acid, ammonium succinimido-aurate, barium succinimido-aurate, barbitalimido-auri acid and sodium phthalimido-aurate.

5. A sulfinimide derivative, saccharinimido-auric acid, is described.

THE MECHANISM OF SULFUR LABILITY IN CYSTEINE AND ITS DERIVATIVES. I. SOME THIO ETHERS READILY SPLIT BY ALKALI

BY BEN H. NICOLET

RECEIVED MAY 4, 1931 PUBLISHED AUGUST 5, 1931

It is the purpose of the present paper, first, to describe the behavior of certain ketonic derivatives of thio ethers which are somewhat remarkably labile toward alkali, and, afterward, to point out a probable relation between the behavior of these compounds and the problem of "labile sulfur" in materials of biological interest.

Generally speaking, the thio ethers, RSR', are very stable toward all hydrolytic agents. Even the mercaptans of hydrocarbon radicals are quite stable toward acids and alkalies. Recently Billheimer and Reid[1] have shown that certain aliphatic mercaptans, when heated for two hours at 260° with 3 N alkali, are only partially hydrolyzed, and these results may perhaps be taken as typical. Vorlander[2] found, not unexpectedly, that triphenylmethyl mercaptan was rather readily hydrolyzed.

Really striking lability of the single bond[3] between carbon and divalent sulfur, however, is to be found only in derivatives containing other substituents, suitably located, and of these the most effective appears to be the keto group.

The α-keto derivatives, $RCOCH_2SR'$, show in some cases considerable instability of the sulfur–carbon bond, particularly toward alkaline and reducing reagents, and it is of interest that no compound of the type $RCOCH_2SH$ appears to have been isolated in a state of purity. The hydrolytic splitting of such compounds seems, however, to have little relation to the common reactions of biological sulfur compounds, as it is frequently, if not generally, attended by the oxidation of the sulfur[4] and its replacement by hydrogen.

Particular attention must be paid, however, to the β-keto sulfides, $RCH(SR')CH_2COR''$. A number of these compounds have been made, chiefly by Ruhemann[5] (see also Posner[6]). The reaction involved is the

[1] Billheimer and Reid, THIS JOURNAL, 52, 4338 (1930).

[2] Vorlander and Mittag, *Ber.*, 46, 3450 (1913).

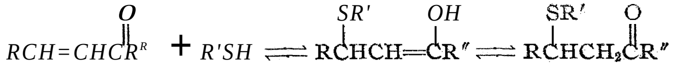
[3] The thio acids and their esters, as well as thiourea derivatives, are substances, the hydrolysis of which is well known and fairly well understood. They are expressly omitted from the present discussion.

[4] The compound $C_6H_5COCH(SCH_2COOH)C_6H_5$ (desylthioglycolic acid), for instance, deposits desoxybenzoin when dissolved in cold dilute alkali. This reaction is being studied and the results will be reported later.

[5] Ruhemann, J. Chem. *Soc.*, 87, 461 (1905).

[6] Posner, *Ber.*, 35, 809 (1902).

addition of a mercaptan to an a,@-unsaturatedketone, preferably with the aid of an alkaline catalyst, as in Equation A and is doubtless to be considered as a 1,4-addition to the conjugated series of double bonds.



$$RCH{=}CH\overset{O}{\overset{\|}{C}}R + R'SH \rightleftharpoons R\overset{SR'}{C}HCH{=}\overset{OH}{C}R'' \rightleftharpoons R\overset{SR'}{C}HCH_2\overset{O}{\overset{\|}{C}}R'' \qquad (A)$$

Ruhemann and Posner were both primarily interested in the sulfones to be obtained by the oxidation of their products, and neither appears to have noticed that, in the presence of alkali, the reaction represented in Equation A is quite easily reversed, and the initial products regenerated.[7]

Reading from right to left, Equation A represents this reversal as a 1,4-elimination from the enol form, with regeneration of the original conjugated unsaturated system. Easy reaction would accordingly be expected also for a substance of the type $RCH(SR')CH{=}CHCH_2COR''$, from the enol form of which 1,6-elimination of H and SR' should take place. But this latter case seems to have no present biochemical significance.

In the Experimental Part the preparation of certain of these β-keto sulfides and their behavior when treated with alkalies are described. Two examples may be discussed briefly at this point.

From benzalacetophenone and thioglycolic acid, the sulfide acid C_6H_5-$CH(SCH_2COOH)CH_2COC_6H_5$(I) was prepared. It does not dissolve in dilute caustic alkalies to give a clear solution, because of the ease with which benzalacetophenone is liberated. In 0.1 *N* sodium carbonate solution at room temperature it is more than one-third decomposed in one hour, as measured by the weight of crystalline benzalacetophenone of correct melting point obtained when the solution is filtered. The reaction goes to completion on longer standing. The ease of splitting is here very strikingly greater than that of the "labile sulfur" of, for instance, insulin, as determined by Abel and Geiling.[8]

In the case of β-*p*-tolylmercapto-benzylacetophenone, $C_6H_5CH(SC_6H_4CH_3)CH_2COC_6H_5$ (11), and similar compounds, the lack of a carboxyl group makes experiments in water difficult, as the substances dissolve appreciably neither in water nor in alkali. When, however, the substance II is dissolved in alcohol together with an excess of lead acetate (no reaction occurs at this stage) and treated with sufficient sodium hydroxide solution to make the final alkali concentration 0.1 molar, the yellow lead salt of *p*-tolylmercaptan is rapidly precipitated at room temperature. If the reaction is stopped after one minute by the addition of an excess of acetic acid, the decomposition is found to have been nearly quantitative,

---

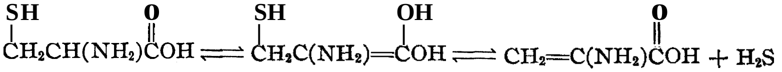
[7] Kohler and Reimer [Am. *Chem.* J., 31, 163 (1904)] have, however, made brief mention of the fact that the analogous sulfones are readily split by alkali to give sulfinates and unsaturated ketones.

[8] Abel and Geiling, *J. Pharmacol.*, 25,423 (1925).

as measured by the weight of the pure lead salt obtained. Other analogous derivatives were correspondingly reactive. Moreover, the substance II, when warmed on a steam-bath with a slight excess of phenylhydrazine in acetic acid, readily gives the sulfur-free 1,3,5-triphenylpyrazoline.

It should, perhaps, be emphasized here that the combined work of Ruhemann,[5] Kohler[7] and Posner[6] leaves no reasonable doubt as to the structures of thio ether derivatives of the type described.

Suggested Mechanism of the Reaction of Cysteine with Alkali.—In the previous section the action of alkalies on certain β-keto thio ethers has been discussed, but inspection of the formula of cysteine shows that it also has its —SH group attached in the β-position with reference to a —CO— group, and although the latter forms part of a carboxyl group, there is at least a formal analogy between the two types of compounds. Equation B is thus analogous to Equation A, above, reversed.



$$\overset{\text{SH}}{\overset{|}{\text{C}}}\text{H}_2\text{CH(NH}_2)\overset{\text{O}}{\overset{\|}{\text{C}}}\text{OH} \rightleftharpoons \overset{\text{SH}}{\overset{|}{\text{C}}}\text{H}_2\text{C(NH}_2)\!=\!\overset{\text{OH}}{\overset{|}{\text{C}}}\text{OH} \rightleftharpoons \text{CH}_2\!=\!\text{C(NH}_2)\overset{\text{O}}{\overset{\|}{\text{C}}}\text{OH} + \text{H}_2\text{S} \quad \text{(B)}$$

Equation B thus represents the idea that the removal of sulfur from cysteine by alkalies is due primarily to the presence of the sulfur in the position β- to the carboxyl group, and suggests that it takes place as a 1,4-elimination of hydrogen sulfide[9] from an intermediate enolized form. Various reasons for such a view will now be given.

That alkaline decomposition of cysteine (or cystine) involves the removal of H_2S (or H_2S_2) from the molecule, rather than simple hydrolysis (replacement of —SH by —OH), seems fairly certain and, incidentally, constitutes a striking analogy to the reaction of the β-keto sulfides. Clarke and Inouye[10] have recently given additional reasons for believing that aminoacrylic acid is one of the early products of the reaction. Baumann[11] long ago stated that S-phenylcysteine loses phenylmercaptan when heated with alkali, at least as rapidly as cysteine loses hydrogen sulfide under similar conditions.

It is, on the other hand, a well-known fact that the tendency to enolization of a carboxyl group is likely to be very small indeed compared to that of a keto group. Is the tendency in this particular case sufficient to justify the theory presented? Fortunately, evidence is available to test this point. There is very little doubt that the racemization of an optically active α-amino acid by alkali, when it occurs, is due to just this enolization process. Most of the common amino acids of biochemical interest show very little tendency to racemize except under quite extreme conditions. But serine (Daft and Coghill[12]) is apparently very readily

---

[9] From cystine, RSSH, or eventually H_2S_2, would be split out.

[10] Clarke and Inouye, *J. Biol. Chem.*, 89, 399 (1930).

[11] Baumann, Ber., 15, 1733 (1882).

[12] Daft and Coghill, *J. Biol. Chem.*, 90, 341 (1931).

racemized by surprisingly dilute alkali, and the careful measurements of Andrews[13] on its analog, cystine, show that the latter is slowly racemized even by cold alkali, and at a rate several times (but not many times) more rapid than the rate of sulfur loss under the same conditions. This is as it should be, for enolization must cause racemization, but need not necessarily lead, in any given instance, to the loss of sulfur,

The loss of sulfur in alkaline cystine solutions is a relatively slow reaction. With boiling normal alkali, in the presence of excess lead oxide, it is about half complete in an hour (Clarke and Inouye[10]). The decomposition of the β-keto sulfides is so enormously more rapid than this that there seems to be no difficulty on this ground in accepting the suggested mechanism, as represented by Equation B.

But certain derivatives of cysteine and of cystine are known in which the sulfur is very much more labile than in the amino acids themselves. Referring only to substances of known constitution, glutathione shows very strikingly greater sulfur lability than does cysteine (Hopkins[14]). Dialanylcystine loses hydrogen sulfide (and sulfur) somewhat more readily than cystine, but very much less readily than does its anhydride.[15,16] Derivatives of cystinehydantoin[17,18] also show conspicuous reactivity. These results are of interest in relation with the fact that many proteins (and, of course, insulin) contain a portion of their sulfur in a form conspicuously more labile than that of cystine itself.

In this connection, attention must be called to the fact that modifications of the carboxyl group such as ester or amide formation are well known to increase the tendency toward enol formation with the hydrogen of the a-carbon atom. Applications of this fact in the biochemical field may be seen in the work of Dakin[19] and Levene[20] on the racemization of peptides and diketopiperazine derivatives. A detailed discussion of this point does not seem to be called for here, but it has already been pointed out that increased ease of racemization (of a cysteine or cystine residue) and increased ease of desulfurization should be expected to go together.

The conclusion to be drawn is that, on the basis of the theory presented in this paper, it would be expected that certain cystine derivatives should be more sensitive to desulfurization by alkali than cystine itself; and this expectation of increased sensitivity would apply specifically to those

derivatives in which the carboxyl group of cystine is in peptide or analogous combination. Cystine peptides in which the carboxyl group remains free should, on the whole, be distinctly less reactive, not necessarily than cystine itself, but than somewhat similar peptides in the formation of which the cystine carboxyl takes part.[21] As glutathione (the reduced form) is known[22] to be γ-glutamyl-cysteyl-glycine, its special sensitivity is in accord with this expectation.

The existence of decidedly "labile" sulfur in many biological products has suggested to a number of workers in the past that these products must contain a portion of their sulfur in some unknown form, certainly different from cysteine. It should be pointed out that, as cysteine derivatives are known which show greatly increased sulfur lability, and as their behavior is only what would be expected on the basis of the ideas here presented, "labile sulfur" is scarcely to be considered as an indication of the presence of novel types of sulfur compounds.

Experimental

Benzylacetophenone-β-thioglycolic Acid, $C_6H_5CH(SCH_2COOH)CH_2COC_6H_5$, (I).—**Thioglycolic** acid (2.0 cc.) was dissolved in 25 cc. of absolute alcohol, and 2 N sodium ethylate (in absolute alcohol) added until 0.5 cc. more was present than necessary for neutralization to phenolphthalein. One mole of benzalacetophenone (5.2 g.) was then added, and the solution allowed to stand overnight. It was then just neutralized with acetic acid, poured into 100 cc. of 3% sodium carbonate solution and filtered promptly with suction from a gelatinous precipitate into a flask containing an excess of acetic acid. A crystalline precipitate formed, which melted at 120° and after two recrystallizations from five parts of alcohol melted constantly at 129°. The yield was about 40%.

Anal. Calcd. for $C_{17}H_{16}O_3S$: S, 10.67. Found: S, 10.72, 11.12 (Parr bomb).

If more alkali is used in the condensation, the amount of the precipitate is larger, and the acid cannot readily be obtained crystalline. The gelatinous precipitate dissolved with some difficulty in hot alcohol and after five recrystallizations melted at 199–200°. It was tentatively identified as the low-melting form of 1,3,5-tribenzoyl-2,4-diphenylpentane.

Hydrolysis of the Acid, I.—Half a gram of the pure acid was added to 25 cc. of normal sodium hydroxide. The solution was turbid from the beginning and soon deposited a heavy precipitate of crystalline material. On filtration after fifteen minutes a good yield of benzalacetophenone, melting at 55.5°, was obtained.

Even in 0.1 N sodium carbonate, a really clear solution of the acid could not be obtained. On standing at room temperature, the turbidity of the solution gradually increased, and after one and one-half hours filtration separated more than half of the calculated amount of benzalacetophenone. On longer standing, a further quantity separated. The solution contained thioglycolic acid. It is thus apparent that even under

---

[21] It is almost obvious that the adjacent amino group would also exert an influence on the firmness of the sulfur bond. Modification of the amino group would therefore have its effect. It is, however. believed that the effect of the carboxyl, and particularly of the carboxamido group, is of decidedly greater importance.

[22] Nicolet, *J. Biol. Chem.*, 88, 389 (1930); Kendall, Mason and McKenzie, *ibid.*, 88, 409 (1930); Grassmann, Uyckerhoff and Eibler, *Z. physiol. Chem.*, 189, 112 (1930).

these very mild conditions the material breaks down to give the substances from which it was formed. It was to prevent, in so far as possible, a similar decomposition, that the crude solution of the sodium salt, in the preparation of the acid, was filtered directly into acetic acid

Benzylacetone-β-thioglycolic Acid, $C_6H_5CH(SCH_2COOH)CH_2COCH_3$.—This acid nas prepared essentially as described above, but from benzalacetone. It has not yet been obtained in crystalline condition, and its detailed description is therefore postponed

Benzylacetophenone - β - p - tolylsulfide, $C_6H_5CH(SC_6H_4CH_3)CH_2COC_6H_5$ (**II**)[5].—Molar proportions of benzalacetophenone (8 4 g.) and *p*-tolylmercaptan (5.0 g.) were dissolved in 40 cc of benzene, and a little 2 N sodium ethylate solution added (0.5 cc more than required to give a pink color with phenolphthalein). After standing overnight, 2 cc. of acetic acid and 25 cc. of alcohol were added. The product (crude yield 86%) was best purified by solution in its own weight of warm chloroform and addition of warm alcohol. It is soluble in hot alcohol to the extent of 7–8%, but quite difficultly soluble in cold alcohol. It melts at 113°.

Anal. Calcd. for $C_{22}H_{20}OS$: S, 9.64. Found: S, 9.72, 9.72 (Parr bomb).

When this sulfide was dissolved in acetic acid and warmed on the steam-bath with a slight excess of phenylhydrazine, p-tolylmercaptan was split out and 1,3,5-triphenylpyrazoline was easily formed in good yield. The product was identical with that formed from benzalacetophenone and phenylhydrazine.

Benzylacetone - β - *p* - tolylsulfide, $C_6H_5CH(SC_6H_4CH_3)CH_2COCH_3$ (**III**).—The preparation from benzalacetone followed closely that for its analog, II. The reaction was stopped by the addition of acetic acid without alcohol, the benzene solution evaporated, and the quite soluble residue crystallized from a small volume of alcohol. The pure substance melts at 64°.

Anal. Calcd. for $C_{17}H_{18}OS$: S, 11.85. Found: S, 11.96, 11.81 (Parr bomb)

Alkaline Hydrolysis of the Sulfides II and 111.—Due to the insolubility of these substances in water and in alkali, it was necessary to use alcoholic solutions, but since the reaction with alkali is reversible, an idea of its rate can only be got when one of the products is removed as it is formed. Accordingly, the following procedure was used.

One gram of the sulfide II was dissolved in 86 cc. of warm alcohol, and the solution rapidly cooled to 30–35° (it is then supersaturated). Twice the calculated amount of 20% lead acetate solution was then added (no coloration or precipitate was produced) followed by sufficient 6 *N* alkali to neutralize the acetic acid from the acetate and leave the solution 0 5 N with regard to alkali. A yellow precipitate began to form at once and after ten minutes an excess of acetic acid was added to stop the reaction. The orange precipitate soon became yellow and crystalline. It weighed 0.6 g. and was practically pure $Pb(SC_6H_4CH_3)_2$, melting at 205–208° to an orange-red oil. On treatment of the lead salt with potassium iodide and iodine, di-p-tolyl disulfide was obtained in good yield (m. p. 45.5") and fully identified.

When alkali concentrations as low as 0.1 N were used, an equally good yield of the lead mercaptide was obtained, and this was still true when the time of action of the alkali was reduced to one minute. Control experiment3 showed that reaction occurred only while the solution was alkaline.

The behavior of the sulfide III was similar in all respects.

Summary

Certain @-ketonicsulfides have been described which are split by alkali with rather extreme ease to give mercaptans and a,@-unsaturatedketones.

A structural analogy between these compounds and cysteine or cystine has been pointed out, and some of the reasons have been given for considering the action of alkali on the two classes of compounds as analogous. From these considerations, a mechanism for the alkaline decomposition of cysteine has been developed and reasons have been indicated for the anticipation of greatly increased reactivity in certain specified types of cysteine and cystine derivatives.

ROTENONE. XIII. OXIDATION OF METHYLDERRITOLIC ACID AND THE SYNTHESIS OF 2,3,5- AND 2,3,6-TRIMETHOXYBENZOIC ACIDS AND THEIR DERIVATIVES

BY L. E. SMITH AND F. B. LAFORGE

RECEIVED MAY 9, 1931 PUBLISHED AUGUST 5, 1931

As reported in previous articles,[1] derritol methyl ether is converted by catalytic hydrogenation into methylderritolic acid, which is oxidized by hydrogen peroxide in alkaline solution to a compound of the formula of a trimethoxyphenylacetic acid. We have also reported that this trimethoxyphenylacetic acid is oxidized by permanganate to a trimethoxybenzoic acid melting at 78–80.'

Four of the six trimethoxybenzoic acids have been definitely described in the literature, but since the properties of none of the known acids agree with those of the oxidation product of the trimethoxyphenylacetic acid from derritol methyl ether, it seemed necessary to prepare the two missing members, that is, the 2,3,5- and 2,3,6-trimethoxybenzoic acids.

Orthovanillin was used as the starting material, the methylation of which was carried out according to the method of Spath and Mosettig.[2] The methyl ether was nitrated by the method of Perkin and Robinson[3] and the isomeric 2,3-dimethoxy-5-nitro and 2,3-dimethoxy-6-nitrobenzaldehydes were separated by means of their *p*-toluidides.[4]

The first-mentioned compound was converted into 2,3-dimethoxy-5-hydroxybenzaldehyde, which was then methylated and oxidized to the 2,3,5-trimethoxybenzoic acid, which melted at 105'.

The 2,3,5-trimethoxyphenylacetic acid was prepared from the corresponding aldehyde by the Mauthner synthesis.

The 2,3,6-trimethoxybenzoic acid was prepared by first oxidizing the 2,3-dimethoxy-6-nitrobenzaldehyde and then replacing the nitro group

[4] Perkin, Robinson and Stoyle, ibid., 125, 235 (1924).

by the hydroxyl group with subsequent methylation to the trimethoxy derivative.

The melting points of the six theoretically possible trimethoxybenzoic acids are given in the following table:

Trimethoxybenzoic acid	Melting point, °C.	Trimethoxybenzoic acid	Melting point, °C.
2,3,4	97-99	2,4,5	144
2,3,5	105[a]	2,4,6	142–144 (decomposition)
2,3,6	145–146	3,4,5	168–170

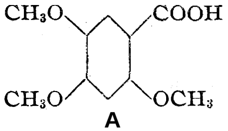
[a] For a compound which they assume to have this formula, Faltis and Neumann, *Monatsh.*, 42, 372 (1921), report a melting point of 141–143°.

As the properties of none of these acids agreed with those of the oxidation product of the trimethoxyphenylacetic acid from derritol methyl ether, it seemed probable that our supposed trimethoxybenzoic acid was an impure substance. Therefore, we have repeated our oxidation experiments and found that the product obtained under the conditions employed was in fact a mixture containing considerable quantities of unchanged starting material from which we were unable to isolate the oxidation product.

We have now, by an indirect method, obtained the trimethoxybenzoic acid corresponding to the natural trimethoxyphenylacetic acid in a pure condition and found it to melt at 145°.

The procedure followed was to convert the trimethoxyphenylacetic acid into its ethyl ester, from which the trimethoxybenzyldiphenylcarbinol was prepared by the Grignard reaction. The carbinol was then dehydrated to the corresponding alkene, which yielded the trimethoxybenzoic acid by permanganate oxidation.

This acid is identical with the trimethoxybenzoic acid recently prepared by Clark[6] by the methylation of the dimethoxyhydroxybenzoic acid obtained by the oxidation of dehydrodeguelin and identified as asaronic acid of formula (A), melting at 145°. When mixed with this acid the trimethoxybenzoic acid from derritol methyl ether showed no depression of the melting point, but it showed a very marked depression when mixed with 2,3,6-trimethoxybenzoic acid, which also melts at 145°. Dihydroderritol methyl ether also gave asaronic acid when oxidized in acetone solution with permanganate and from derritol a small yield of the dimethoxyhydroxybenzoic acid was obtained which was identical with the oxidation product of dehydrodeguelin.[5]



A

It is established, therefore, that the three methoxyl groups in derritol methyl ether occupy the 2,4,5-positions, and that this compound contains the grouping (B).

Experimental

2,3-Dimethoxy-5-hydroxybenzaldehyde.[6]—Three grams of 5-nitro-o-vanillin methyl ether was dissolved in 5.25 cc. of 30% sodium bisulfite and the solution diluted with 25 cc. of water. This solution was slowly added to a boiling mixture of 22.5 g. of calcium carbonate (from 23 5 g. of calcium chloride and 37.5 g. of potassium carbonate) and 60 g. of ferrous sulfate in 150 cc. of water. The mixture froths considerably especially in the early stages of the reaction. The boiling was continued for one and one-half hours, after which the dissolved amino aldehyde, which proved to be unstable in the free state, was filtered into 12 cc. of concentrated hydrochloric acid diluted with two or three parts of water. This solution was cooled to 3° and 0.93 g. of sodium nitrite in 75 cc. of water was added. The solution of the diazo compound was warmed to room temperature and then left on the steam-bath for two hours. After boiling for ten minutes with decolorizing carbon the solution was filtered and extracted with ether. The ether extracts after drying over anhydrous sodium sulfate were evaporated. The crystalline residue of 2,3-methoxy-5-hydroxybenzaldehyde was recrystallized from water; m. p. 152". The yield varied somewhat but was usually about 0.5 g.

Anal. Subs., 0.0569: CO_2, 0.1240; H_2O, 0.0283. Calcd. for $C_9H_{10}O_4$: C, 59.34; H, 5.49. Found: C, 59.43; H, 5.52.

Methylation of **2,3-Methoxy-5-hydroxybenzaldehyde.**—Two grams of the aldehyde was dissolved in 4 cc. of 33% sodium hydroxide and 12 cc. of water in a three-necked flask fitted with a mechanical stirrer. Four cc. of methyl sulfate was slowly added, followed by 2 cc. of 33% sodium hydroxide. After stirring for three hours on a water-bath, the mixture was filtered, and the separated crystals were washed with water. The 2,3,5-trimethoxybenzaldehyde was recrystallized from 50% ethyl alcohol; m. p. 71°; yield, 1.2 g.

Anal. Subs., 0.0209: AgI, 0.0763. Calcd. for $C_{10}H_{12}O_4$: $3CH_3O$, 47.44. Found: CH_3O, 47.58.

Oxidation of **2,3,5-Trimethoxybenzaldehyde.**—Thirty-five hundredths gram of the aldehyde was suspended in 50 cc of water containing 0.1 g. of potassium hydroxide. The mixture was oxidized on the steam-bath with 8 cc. of 3% potassium permanganate. The solution was filtered from the manganese dioxide, acidified with dilute hydrochloric acid and extracted with ether. The ether extracts after drying over anhydrous sodium sulfate were evaporated, leaving the crystalline 2,3,5-trimethoxybenzoic acid, which was then recrystallized from water; m. p. 105"; yield, 0.15 g.

Anal. Subs., 0.0735: CO_2, 0.1521; H_3O, 0.0367. Calcd. for $C_{10}H_{12}O_5$: C, 56.6; H, 5.66. Found: C, 56.43; H, 5.54.

Azlactone of **2,3,5-Trimethoxybenzaldehyde.**—One and two-tenths grams of the aldehyde, 1.5 g. of hippuric acid and 0.6 g. of anhydrous sodium acetate were intimately mixed in a mortar. The mixture was placed in a 50-cc. Erlenmeyer flask, 3.5 cc. of acetic anhydride added, and the mixture heated on the steam-bath for two hours. After cooling, 5 cc. of water was added, the mixture allowed to stand for an hour, filtered and the product washed with water and then with ethyl alcohol. The azlactone was recrystallized from ethyl alcohol; m. p. 181–183°. The yield was nearly quantitative.

Anal.[7] Subs., 3.892 mg.: CO_2, 9.625 mg.; H_2O, 1.737 mg. Subs., 7.099 mg.; N, 0.260 cc. Calcd. for $C_{19}H_{17}O_5N$: C, 67.25; H, 5.01: N, 4.13. Found: C, 67.56; H, 4.96; N, 4.16.

[7] We are indebted to Mr. J. R. Spies of this division for carrying out the micro analyses reported in this paper.

2,3,5-Trimethoxyphenylacetic Acid.—One and eight-tenths grams of We azlactone was boiled for one and one-half hours with 14 cc. of water containing 2.8 g. of potassium hydroxide. After cooling. 1.3 cc. of 30% hydrogen peroxide was added, the solution was allowed to stand for one and one-fourth hours and then warmed for fifteen minutes on the steam-bath. After acidifying with hydrochloric acid, the solution was extracted with ether. The ether extracts after drying over anhydrous sodium sulfate were evaporated, and the products were kept in an oven at 105° overnight to remove benzoic acid. The remaining substance was recrystallized from water, m. p. 83°. When mixed with the trimethoxyphenylacetic acid from methylderritolic acid, the melting point was depressed to 60–65°

Anal. Subs., 4.130 mg.: CO_2, 8.873 mg.; H_2O, 2.296 mg. Calcd. for $C_{11}H_{14}O_5$: C, 58.40; H, 6.15. Found: C, 58.46; H, 6.13.

Reduction of **2,3-Dimethoxy-6-nitrobenzoic** Acid.—Nine grams of ferrous sulfate was dissolved in 25 cc. of water and an excess of concentrated ammonium hydroxide was added. The mixture was heated to 92° and 1 g. of the acid dissolved in ammonium hydroxide was added in small portions. The solution was boiled for one hour, then filtered and cooled. As the resulting amino acid proved to be unstable, the solution was cooled to 5°, made acid with an 8 cc. excess of concentrated hydrochloric acid, and 0.66 g. of sodium nitrite dissolved in 25 cc. of water was added in small portions with constant stirring. The solution was allowed to warm to room temperature and then boiled for ten minutes with decolorizing carbon. After filtering, the solution was cooled and extracted with ether. The ether extract, after drying over anhydrous sodium sulfate, was evaporated and the resulting 2,3-methoxy-6-hydroxybenzoic acid was recrystallized from water. It consists of long needles of m. p. 82°; yield, 0.25 g.

Anal. Subs., 0.0683: CO_2, 0.1365; H_2O, 0.0311. Subs., 0.0206: AgI, 0.0487. Calcd. for $C_9H_{10}O_5$: C, 54.54; H, 5.05; $2CH_3O$, 31.31. Found: C, 54.49; H, 5.06; CH_3O, 31.23.

Methylation of **2,3-Methoxy-6-hydroxybenzoic** Acid.—One gram of the acid was dissolved in 40 cc. of 5% potassium hydroxide and to this solution 2 cc. of methyl sulfate was added with mechanical stirring. The stirring was continued for three hours, after which the solution was made acid with hydrochloric acid and extracted with ether. After drying over anhydrous sodium sulfate, the ether extracts were evaporated. The 2,3,6-trimethoxybenzoic acid was recrystallized from water, m. p. 145–146°.

Anal. Subs., 0.0580: CO_2, 0.1208; H_2O, 0.0297. Subs., 0.0194: AgI, 0.0647. Calcd. for $C_{10}H_{12}O_5$: C, 56.6; H, 5.66; $3CH_3O$, 43.86. Found: C, 56.78; H, 5.69; CH_3O, 44.05.

Amide of **2,4,5-Trimethoxyphenylacetic** Acid from Methylderritolic Acid.—Five-tenths gram of the acid was dissolved in 10 cc. of benzene and to this solution 0.5 g. of phosphorus pentachloride was added. After boiling off the hydrogen chloride, the solution was cooled in an ice-bath and saturated with dry ammonia. Water was then added and the benzene removed by boiling. The amide was recrystallized from water; m. p. 169°; yield, 0.4 g.

Anal.[7] Subs., 3.481 mg.; CO_2 7.498 mg.; H_2O, 2.050 mg. Subs., 3.396 mg.; N, 0.186 cc. Calcd. for $C_{11}H_{15}O_4N$: C, 58.67; H, 6.67; N, 6.22. Found: C, 58.74; H, 6.54; N, 6.22.

Ethyl Ester of the **2,4,5-Trimethoxyphenylacetic** Acid from Methylderritolic Acid.—Two and two-tenths grams of the acid, 5 cc. of absolute ethyl alcohol and 0.5 cc. of concentrated sulfuric acid was refluxed for three hours. After dilution with two volumes of water, the solution was made alkaline with solid potassium carbonate and extracted with ether. The ether solution was extracted with water and after drying over anhydrous sodium sulfate was evaporated. The crude ester was not purified further but was treated directly with the Grignard reagent.

2,4,5-Trimethoxybenzyldiphenylcarbinol.—The phenylmagnesium bromide was prepared in the usual manner, with 1.34 g. of magnesium turnings and 8.34 g. of bromobenzene. Four and one-half grams of the crude trimethoxyphenylacetic ester in ether solution was added to the Grignard reagent over a period of forty-five minutes, with constant stirring. The mixture was then refluxed for an hour and, after cooling, hydrolyzed with dilute sulfuric acid with slight warming to complete the reaction. The ether layer was separated and after drying over anhydrous sodium sulfate was evaporated. The resulting carbinol was recrystallized from ethyl alcohol, m. p. 130–131°.

Anal. Subs., 0.0700: CO_2, 0.1942; H_2O, 0.0419. Calcd. for $C_{23}H_{24}O_4$: C, 75.82; H, 6.59. Found: C, 75.65; H, 6.65.

α-2,4,5-Trimethoxyphenyl-β-diphenylethylene.—One-half gram of 2,4,5-trimethoxybenzyldiphenylcarbinol was heated with a trace of iodine in an Abderhalden drier at 138° until the evolution of water ceased. On cooling, the oily residue became crystalline and was recrystallized from dilute ethyl alcohol; m. p. 101–103°; yield, 0.35 g.

Anal. Subs., 0.0667: CO_2, 0.1951; H_2O, 0.0386. Calcd. for $C_{23}H_{22}O_3$: C. 79.76; H, 6.35. Found: C, 79.77; H, 6.43.

2,4,5-Trimethoxybenzoic Acid.—Three-tenths gram of α-2,4,5-trimethoxyphenyl-β-diphenylethylene was dissolved in 25 cc. of acetone and small amounts of finely ground potassium permanganate were added over a period of several days until a permanent purple color was obtained. The solution was filtered, the precipitate washed with acetone and after drying digested with boiling water. After filtering from the manganese dioxide, the solution was made acid with dilute hydrochloric acid and extracted with ether. The ether extracts after drying over anhydrous sodium sulfate were evaporated. The resulting 2,4,5-trimethoxybenzoic acid was recrystallized from water, m. p. 145–146°. A mixed melting point with 2,4,5-trimethoxybenzoic acid prepared by Dr. E. P. Clark of this Laboratory gave no depression.

Anal.[7] Subs., 3.356, 4.572 mg.: CO_2, 6.959, 9.447 mg.; H_2O, 1.658, 2.252 mg. Calcd. for $C_{10}H_{12}O_5$: C. 56.6; H, 5.66. Found: C, 56.55, 56.35; H. 5.49, 5.47.

Oxidation of Dihydroderritol Methyl Ether.—Five grams of dihydroderritol methyl ether was dissolved in 200 cc. of anhydrous acetone neutral to permanganate. The solution was cooled in an ice-bath, and 16 g. of finely powdered potassium permanganate was added in small portions with mechanical stirring. Several days were required to complete the reaction. The mixture was filtered and the precipitate digested with 300 cc. of water and filtered from manganese dioxide. The filtrate, after concentrating to a small volume under reduced pressure, was made acid and extracted with ether. The ether extract was dried over anhydrous sodium sulfate and evaporated. The residue was recrystallized from water, m. p. 145°. The yield was 0.4 g. A mixed melting point with asaronic acid showed no depression.

Oxidation of Derritol.—Five grams of derritol was oxidized and the reaction product isolated in the manner described above. The reaction was complete in about five hours. The product was washed with a small amount of dilute methyl alcohol and then recrystallized from water, m. p. 211–212° with decomposition. When mixed with the hydroxydimethoxybenzoic acid, which Clark obtained from dehydrodeguelin, the melting point showed no depression.

Summary

The preparation and properties of 2,3,5 and 2,3,6-trimethoxybenzoic acids are described. The addition of these two missing members completes the series of six possible acids of this type.

The 2,3,5-trimethoxyphenylacetic acid was prepared from the corresponding 2,3,5-trimethoxybenzaldehyde.

The trimethoxyphenylacetic acid obtained from derritol methyl ether was converted into its ethyl ester, which yielded the diphenylcarbinol by the Grignard reaction. This carbinol was dehydrated to the corresponding trimethoxyphenyldiphenylethylene, which was oxidized to a trimethoxybenzoic acid. This acid proved to be identical with 2,4,5-trimethoxybenzoic acid (asaronic acid).

The same acid was obtained by direct oxidation of derritol methyl ether and derritol itself yielded a dimethoxyhydroxybenzoic acid.

THE NUMBER OF ISOMERIC HYDROCARBONS OF THE METHANE SERIES

BY HENRY R. HENZE AND CHARLES M. BLAIR

RECEIVED MAY 11, 1931 PUBLISHED AUGUST 5, 1931

At various times attempts have been made by both mathematicians and chemists to derive a formula by which the number of isomeric hydrocarbons of the methane series could be calculated.

Apparently the first attempt to derive such a formula was made by the English mathematician Cayley[1] in 1875. He recognized that the number of isomers for a given carbon content was dependent upon the number of those of lesser carbon contents, and thus he obtained successively for every magnitude an expression for the fundamental chains common to all of magnitude N. This function led to the building of "centric and bicentric trees," and with the help of the same he predicted the number of isomeric hydrocarbons inclusive of a carbon content of thirteen. However, his predictions of the number of isomers for the carbon contents of twelve and thirteen were in error.

Almost simultaneously with this attempt of Cayley was that of Schiff.[2] Using a method involving combinations and permutations, he calculated the number of isomeric hydrocarbons through the dodecanes, obtaining for the dodecanes, however, the same erroneous value as that of Cayley.

This error, along with that of Cayley as to the number of tridecanes, was first corrected by Hermann[3] about five years later. The latter divided the structural formulas of the isomers into types, according to the number of branches attached to the fundamental chain of each, and attempted to relate the number of isomers of each type to the total number

[1] Cayley, *Ber.*, 8, 1056 (1875).

[2] Schiff, *ibid.*, 8, 1542 (1875).

[3] Hermann, *ibid.*, 13,792 (1880); 30,2423 (1897); 31, 91 (1898).

of hydrocarbons. His results were limited to the series CH_4 $C_{13}H_{28}$ and the utilization of his method of calculation does not allow one to predict accurately the number of isomers of the hydrocarbons more complex than the tridecanes.

In 1893, Tiemann[4] also recognized the existence of various types of isomers (monomethyl, dimethyl, monoethyl, etc.), and using an abbreviated numerical system of writing these isomers, counted their number. He recorded the results inclusive of the decanes, but his totals for the nonanes and decanes were incorrect.

This problem of calculating the number of isomeric hydrocarbons was attacked by Delannoy[5] at about the same time but from an entirely different angle. He developed an empirical formula in which an additional term was brought into use with each unit increase in the carbon content. This formula served to calculate the number of isomers through the tridecanes, but it does not hold for those of higher carbon contents.

Another effort at solution of this problem by use of combinations, permutations and variations was that of Losanitsch,[6] who attempted to apply these in determining the number of isomers of each of the types into which he divided the hydrocarbons. We tabulated the number of isomers of certain types through $C_{20}H_{42}$ but summed these so as to obtain the total number of isomers only inclusive of $C_{14}H_{30}$. It is to be noted that his results for $C_{12}H_{26}$ and $C_{14}H_{30}$ are in error.

Goldberg,[7] in 1898, observing that the previously advanced formulas were complicated and difficult to apply, attempted to derive a simpler formula for calculating the number of hydrocarbons. He developed such a formula but, unfortunately, it did not hold above $C_{10}H_{22}$, the totals calculated becoming increasingly below the actual number of isomers. Goldberg recognized this drawback, and, desiring to obtain the number of isomers for higher carbon contents, adopted the Geneva system to number the branch chains and wrote, in an abbreviated form, the structural formulas of all isomers inclusive of the undecanes, but made no predictions for any higher homologs.

For the period of twenty-five years following the work of Goldberg no further reference to this problem is to be found recorded in the literature. The next work appearing is that of Trautz,[8] who in 1924 published a rigorous mathematical treatment of this question. However, this work, combinatorial in nature, was centered upon the substituted hydrocarbons rather than upon the paraffins themselves and cannot be used inaccurately predicting the number of isomers except for those of low carbon content.

[7] Goldberg, *Chem.-Ztg.*, 22, 395 (1898).

[8] Trautz, "Lehrbuch der Chemie," Berlin, 1924, Vol. III, p. 23.

The most recent attempt recorded in literature is that of David[9] in **1928.** His formula is only a slight modification of that of Delannoy, in which an additional term was added for each unit increase in carbon content, and is of no value in calculating the number of isomers for carbon contents greater than eleven.

It is seen, therefore, that the mathematical formulas which have been advanced for calculating the number of isomeric hydrocarbons, when tested by actual writing and counting of the structural formulas, are found to be correct only inclusive of that carbon content for which they were derived and are in error in predicting the number of isomers for higher carbon contents. The cause for these errors is readily seen, for a formula based upon a "centric" or a "bicentric" center of symmetry will obviously become in error when the carbon content increases so that additional centers of symmetry are introduced. Similarly, formulas so derived that an additional term must be added for each unit increase in the carbon content will also be in error for all carbon contents greater than that for which the additional terms can be definitely established.

It seemed desirable, therefore, to derive a formula which would accurately estimate the number of isomeric hydrocarbons. Attempts to derive such a formula soon showed that no simple mathematical relationship exists between the total number of isomers and their carbon content. The problem was solved only by establishing a relationship between the number of isomeric hydrocarbons of a given carbon content and the previously calculated number of isomeric alcohols of lesser carbon contents. This relationship is in direct contrast to the idea held by previous workers who considered the number of alcohols to be conditioned by the number of hydrocarbons from which, theoretically, the former might be derived.

Theoretical Discussion

In this treatment we find it desirable to separate the hydrocarbons into classes according to whether their carbon content is even or odd. Those hydrocarbons whose carbon content, N, is an even number, are further divided into two groups: A, consisting of those hydrocarbons whose graphic formula may be divided into two parts of $N/2$ carbon atoms each; and B, the remaining isomeric hydrocarbons whose graphic formula cannot be so divided. Division of the graphic formula into two parts signifies breaking the single bond between two adjacent carbon atoms, thus obtaining two alkyl radicals.

Likewise, the hydrocarbons whose carbon content, N, is an odd number, are also divided into two groups: **A,** consisting of those hydrocarbons whose graphic formula can be divided into two parts, one of $(N + 1)/2$ carbon atoms and the other of $(N - 1)/2$ carbon atoms; and B, con-

---

[9] **David, *Rev. gén. sci.*, 39, 142 (1928).**

sisting of the remaining hydrocarbons whose graphic formula cannot be so divided.

For the hydrocarbons of even carbon content, in calculating the number of isomers in group **A,** two factors are utilized: **(I)**, the number of possible alkyl radicals of $N/2$ carbon atoms, and (11), the number of possibilities, without exception or repetition, of combining the alkyl radicals of $N/2$ carbon atoms with those of $N/2$ carbon atoms.

(I). The number of paraffin alkyl radicals of a given carbon content is equal to the number of isomeric alcohols of that carbon content. The method of calculating this number has been previously determined.[10]

(II). If two alkyl radicals of $N/2$ carbon atoms each are combined, a hydrocarbon of N carbon atoms is obtained. Therefore, the number of hydrocarbons of N carbon atoms that may be obtained will depend upon the number of alkyl radicals of $N/2$ carbon atoms; and, since each isomeric alkyl radical is a distinct substance, the number of combinations of the $T_{N/2}$ alkyl radicals of $N/2$ carbon atoms, taken one at a time, with the $T_{N/2}$ alkyl radicals of $N/2$ carbon atoms, taken one at a time, may be calculated by the mathematical formula for this type of combination, that is

$$T_{N/2}(1 + T_{N/2})$$

For the hydrocarbons of odd carbon content, in calculating the number of isomers in group **A,** two factors are also utilized: (I), the number of possible alkyl radicals of $(N + 1)/2$ carbon atoms and of $(N - 1)/2$ carbon atoms, and (11), the number of possibilities, without exception or repetition, of combining the alkyl radicals of $(N + 1)/2$ carbon atoms, taken one at a time, with those of $(N - 1)/2$ carbon atoms, also taken one at a time. In order to prevent duplication in determining the number of these combinations, it is necessary to recognize that part of the alkyl radicals of $(N + 1)/2$ carbon atoms may be derived from the alkyl radicals of $(N - 1)/2$ carbon atoms by the addition to the free valence of the latter, of the $—CH_2—$ group. Hence, the hydrocarbons resulting from combining such portion of the alkyls of $(N + 1)/2$ carbon atoms, that may be so derived, with the alkyls of $(N - 1)/2$ carbon atoms are considered as being formed by joining the alkyls of $(N - 1)/2$ carbon atoms to the alkyls of $(N - 1)/2$ carbon atoms through an intermediate carbon atom, and the number of such possible combinations will equal $T_{(N-1)/2}(1 + T_{(N-1)/2})$, where T is the total number of alcohols of all types containing the number of carbon atoms represented by its subscript. The combination of the remaining portion of the alkyls of $(N + 1)/2$ carbon atoms with the alkyls of $(N - 1)/2$ carbon atoms will form the balance of the isomeric hydrocarbons of group **A,** and the calculation of their number will be made by the mathematical formula

$$T_{(N-1)/2}(T_{(N+1)/2} - T_{(N-1)/2})$$

---

[10] Henze and Blair, THIS JOURNAL, 53, 3042 (1931).

The total number of hydrocarbons in group A will consist, therefore, of the sum of the number of hydrocarbons obtained in these two ways. Hence, the number of isomers in group A will equal

$$\frac{T_{(N-1)/2}(1 + 2T_{(N+1)/2} - T_{(N-1)/2})}{2} \cdot$$

If the graphic formula of the hydrocarbons of even carbon content cannot be divided into two parts of $N/2$ carbon atoms each there must be in the formula one carbon atom, and only one, to which are attached branches none of which may contain more than $(N/2 - 1)$ carbon atoms. Obviously, there must be at least three branches, and since carbon has only four valences, there cannot be more than four branches.

Similarly, for those hydrocarbons of odd carbon content whose graphic formulas cannot be divided into two parts, one of $(N + 1)/2$ carbon atoms and the other of $(N - 1)/2$ carbon atoms, there must be in each of such formulas one carbon atom, and only one, to which are attached branches none of which may contain more than $(N - 3)/2$ carbon atoms. By a treatment similar to that already utilized in the case of the hydrocarbons of even carbon content, it may be shown that this specified carbon atom must have attached to it either three or four branches.

Hence, the isomeric hydrocarbons of group B, both even and odd, will be of two types: (a), those in which three branches are attached to the specified carbon atom, and (b), those in which four branches are attached to the specified carbon atom. The total number of isomers of group B will be obtained by a summation of types (a) and (b).

Type (a) would seem to consist of three possible cases: (1), in which all three branches were of different carbon content; (2), in which two branches were of the same carbon content and different from the third; (3), in which all three branches were of the same carbon content. All three of these cases are actually possible but all will not necessarily be present with every value of N. The number of isomers in each case may be calculated by the following mathematical formula for that particular case.

Case (1) $\Sigma T_i \cdot T_j \cdot T_k$ (a_1)

where $i + j + k = N - 1$; i, j and k are integers, distinct, and greater than zero; $i > j > k$; i, for even carbon content, is never greater than $(N/2 - 1)$; i, for odd carbon content, is never greater than $(N - 3)/2$.

Case (2) $^1/_2\Sigma T_i \cdot T_j(1 + T_i)$ (a_2)

where $2i + j = N - 1$; i and j are integers, distinct, and greater than zero; for even carbon content, neither i nor j may be greater than $(N/2 - 1)$; for odd carbon content, neither i nor j may be greater than $(N - 3)/2$.

Case (3) $^1/_6T_i(1 + T_i)(2 + T_i)$ (a_3)

where $3i = N - 1$; i is an integer greater than zero.

Type (b) would seem to consist of five possible cases: (1), in which all four branches are of different carbon content: (2). in which two branches are of the same carbon content and each of the others of different content; (3), in which three branches are of the same carbon content and different from the fourth; (4), in which all four branches are of the same carbon content; (5), in which the four branches can be divided into two sets of two branches each, the individual members of each set being of the same carbon content but differing in content from the members of the other set. It will be seen that cases (4) and (5), though theoretically possible for hydrocarbons of both even and odd carbon content, are actually possible only for the latter, for in case (4) $(N - 1)$ should be divisible by four, and in case (5) $(N - 1)$ should be divisible by two. The number of isomers in each case may be calculated by the following mathematical formula for that particular case.

Case (1) $$\Sigma T_h \cdot T_i \cdot T_j \cdot T_k \tag{b$_1$}$$

where $h + i + j + k = N - 1$; h, i, j and k are integers, distinct, and greater than zero; $h > i > j > k$; h, for even carbon content, is never greater than $(N/2 - 1)$; h, for odd carbon content, is never greater than $(N - 3)/2$.

Case (2) $$\tfrac{1}{2}\Sigma T_i \cdot T_j \cdot T_k(1 + T_i) \tag{b$_2$}$$

where $2i + j + k = N - 1$; i, j and k are integers, distinct, and greater than zero.

Case (3) $$\tfrac{1}{6}\Sigma T_i \cdot T_j(1 + T_i)(2 + T_i) \tag{b$_3$}$$

where $3i + j = N - 1$; i and j are integers, distinct, and greater than zero.

Case (4) $$\tfrac{1}{24}T_i(1 + T_i)(2 + T_i)(3 + T_i) \tag{b$_4$}$$

where $4i = N - 1$; i is an integer greater than zero.

Case (5) $$\tfrac{1}{4}\Sigma T_i \cdot T_j(1 + T_i)(1 + T_j) \tag{b$_5$}$$

where $2i + 2j = N - 1$; i and j are integers, distinct, and greater than zero; $i > j$.

The total number of hydrocarbons of N carbon atoms may be determined by adding to the number of isomers calculated in group A the summation of the number calculated in each of the cases of group B.

The actual meaning and use of these recursion type formulas[11] may be illustrated in the calculation of the number of isomeric tetradecanes.[12]

Sample Calculation

Group **A.** $N = 14;\ N/2 = 7$

$T_7 \cdot (1 + T_7)/2 = 39 \cdot (1 + 39)/2 = 780$

---

[11] Grateful acknowledgment is made to Dr. Leo Zippin, National Research Fellow in Mathematics, for his aid in checking the recursion formulas.

[12] The number of isomeric tetradecanes erroneously calculated as being 1855, first by Losanitsch and later by Trautz, has been accepted without further substantiation and appears in certain recent textbooks of organic chemistry.

Group B. $N-1 = 13;\ N/2-1 = 6$

Type (a)

Case (1)

$T_6 \cdot T_5 \cdot T_2 = 17 \cdot 8 \cdot 1 = 136$
$T_6 \cdot T_4 \cdot T_3 = 17 \cdot 4 \cdot 2 = 136$

Case (2)

$T_6 \cdot T_1 \cdot (1 + T_6)/2 = 17 \cdot 1 \cdot (1 + 17)/2 = 153$
$T_5 \cdot T_3 \cdot (1 + T_5)/2 = 8 \cdot 2 \cdot (1 + 8)/2 = 72$
$T_4 \cdot T_5 \cdot (1 + T_4)/2 = 4 \cdot 8 \cdot (1 + 4)/2 = 80$

Case (3)

This case is not actually possible for this carbon content

Type (b)

Case (1)

$T_6 \cdot T_4 \cdot T_2 \cdot T_1 = 17 \cdot 4 \cdot 1 \cdot 1 = 68$
$T_5 \cdot T_4 \cdot T_3 \cdot T_1 = 8 \cdot 4 \cdot 2 \cdot 1 = 64$

Case (2)

$T_5 \cdot T_2 \cdot T_1 \cdot (1 + T_5)/2 = 8 \cdot 1 \cdot 1 \cdot (1 + 8)/2 = 36$
$T_4 \cdot T_3 \cdot T_2 \cdot (1 + T_4)/2 = 4 \cdot 2 \cdot 1 \cdot (1 + 4)/2 = 20$
$T_3 \cdot T_6 \cdot T_1 \cdot (1 + T_3)/2 = 2 \cdot 17 \cdot 1 \cdot (1 + 2)/2 = 51$
$T_3 \cdot T_5 \cdot T_2 \cdot (1 + T_3)/2 = 2 \cdot 8 \cdot 1 \cdot (1 + 2)/2 = 24$
$T_2 \cdot T_6 \cdot T_3 \cdot (1 + T_2)/2 = 1 \cdot 17 \cdot 2 \cdot (1 + 1)/2 = 34$
$T_2 \cdot T_5 \cdot T_4 \cdot (1 + T_2)/2 = 1 \cdot 8 \cdot 4 \cdot (1 + 1)/2 = 32$
$T_1 \cdot T_6 \cdot T_5 \cdot (1 + T_1)/2 = 1 \cdot 17 \cdot 8 \cdot (1 + 1)/2 = 136$

Case (3)

$T_4 \cdot T_1 \cdot (1 + T_4)(2 + T_4)/6 = 4 \cdot 1 \cdot (1 + 4)(2 + 4)/6 = 20$
$T_3 \cdot T_4 \cdot (1 + T_3)(2 + T_3)/6 = 2 \cdot 4 \cdot (1 + 2)(2 + 2)/6 = 16$

Thus, the number of isomeric tetradecanes equals 1858.

In Table I is to be found a summary of the number of terms actually present in all theoretically possible cases of types (a) and (b) through a carbon content of forty. Since the number of alkyl groups (*i. e.*, the total number of isomeric alcohols) through C_{20} is recorded in a previous contribution, it is now possible to calculate the number of isomeric hydrocarbons of double this carbon content. Hence, to calculate the total number of isomeric hydrocarbons of the methane series of higher carbon content it would become necessary to make a preliminary calculation of the total number of isomeric alcohols of the methanol series of $N/2$ and lesser carbon contents.

The number of isomeric paraffins, as calculated by the use of these recursion type formulas, for certain selected carbon contents is shown in Table II. It should be noted that the data utilized in deriving these recursion formulas were the totals of the isomers of the series C_4H_{10} to $C_{10}H_{22}$ inclusive as obtained by actual writing of their structural formulas. Since the total number of isomeric tridecanes and tetradecanes, as calculated by

the recursion formulas, differed from the totals previously accepted in the literature, it seemed desirable also to write and count all the structural formulas, as required by theory, of the undecanes, dodecanes, tridecanes and tetradecanes. The numbers so obtained agree exactly with the totals as calculated by the use of the mathematical formulas.

TABLE II

NUMBER OF ISOMERIC HYDROCARBONS OF THE METHANE SERIES

30	4,111,846,763
40	62,491,178,805,831

Summary

1. No direct or simple relationship appears to exist between the total number of isomeric hydrocarbons of the methane series and their carbon content.

2. By means of a separation of the isomeric hydrocarbons of each specified carbon content into types, arbitrarily chosen upon the basis of their structural formulas, a relationship may be established between the number of hydrocarbons and the alkyl groups of which the former may be considered to be composed. Mathematical formulas of the (finite) recursion type are advanced which permit of the calculation, from their carbon content, of the number of isomeric hydrocarbons in each of these structural types. In using these recursion formulas to calculate the total number of such hydrocarbons of any given carbon content, the total number of alkyl groups (*i. e.,* the total number of isomeric alcohols) of $N/2$ and **all** lesser carbon contents must be known.

3. The totals obtained by use of these mathematical formulas agree exactly through the tetradecanes with the numbers required by theory as tested by actually writing all the possible structural formulas.

THE INFLUENCE OF THE ARSONO GROUP ON THE ACTIVITY OF NUCLEAR CHLORINE

BY R. E. ETZELMILLER[1] AND CLIFF S. HAMILTON

RECEIVED MAY 14, 1931 PUBLISHED AUGUST 5, 1931

It has long been known that halogens in the benzene nucleus can neither be removed nor replaced by the ordinary reagents which act upon them in the aliphatic series. Nevertheless, the presence of certain groups such as nitro, cyano, carboxyl, etc., loosens the attachment and promotes substitution. Most of the experimental work in the study of replacement reactions has been done with halogeno-nitro compounds. However, as early as 1892, Heidenreich and Victor Meyer[2] showed that o-bromobenzoic acid and ammonia reacted at 200° to give diphenylamine. Later, Ullmann[3] made a study of the condensation of o-chlorobenzoic acid with aniline and found that a catalyst was necessary, the salts of copper being most effective. The addition of potassium carbonate and the use of nitrobenzene as a solvent were also found to increase the yields.

Since the arsono group is similar in structure to the nitro, carboxyl, and sulfonic acid groups, and is meta directing, halogen in the ortho

[3] Ullmann, *Ann.*, 355, 312 (1907).

position, by analogy, should be reactive. In fact, Gibson and his coworkers[4] have successfully applied the method of Ullmann to condensation reactions of o-bromophenylarsonic acid with various aromatic amines.

Thus it was suggested to make a study of the reactivity of the halogen of o-chlorophenylarsonic acid and to determine the value of its application to the synthesis of new arsenicals.

Condensations of the arsonic acid with primary aliphatic and aromatic amines and with ammonia were found to take place readily when they were heated in amyl alcohol with a copper catalyst and potassium carbonate. Secondary amines, benzamide and potassium phthalimide did not condense under like conditions while alcohols or alcoholates were found to replace the chlorine with the formation of the corresponding ethers.

Experimental[5]

General Procedure for the Preparation **of** Alkylamino-phenylarsonic Acids.—Ten grams of o-chlorophenylarsonic acid, 10 g. of anhydrous potassium carbonate, a trace of cuprous iodide, 6 cc. of the primary alkylamine and 25 cc. of amyl alcohol in a 50-cc. Erlenmeyer flask, fitted with a condenser with ground-glass connection, were heated in an oil-bath at 130–135° for fifteen hours, the reaction mixture being well stirred. The excess amine and amyl alcohol were removed by steam distillation, and the resulting solution was treated with decolorizing carbon. On acidification to Congo red paper with dilute hydrochloric acid, a grayish mass separated, which was crystallized from dilute acetic acid. Recrystallization from 75 cc. of hot 3 *N* hydrochloric acid gave a fine white precipitate which was identified as an alkoxyphenylarsonic acid (described later). After filtering, the alkylaminophenylarsonic acid was recovered by almost neutralizing the filtrate to Congo red paper with dilute sodium hydroxide. The portion insoluble in hydrochloric acid solution was treated again with 50 cc. of 3 N hydrochloric acid, and more amino compound recovered. The total yield of the alkylaminophenylarsonic acid obtained varied from 20–49% while the total yield of the ether varied from traces to as much as 7%. For analysis the amino compound was reprecipitated from a smaller amount of 3 N hydrochloric acid and crystallized from dilute acetic acid.

[5] The potentiometric method of Cislak and Hamilton, THIS JOURNAL, 52, 638 (1930), was used for the quantitative determination of arsenic in the compounds prepared. The analyses are given in duplicate when the proof of the structures of the compounds hinged upon the arsenic analyses, and the amount of the purified sample permitted.

o-Arsonophenyl-N-butyl-nitrosamine.—To 5 g. of o-n-butylaminophenylarsonic acid in 100 cc. of 3 *N* hydrochloric acid, a solution of 8 g. of sodium nitrite in 25 cc. of water was slowly added, with stirring. The nitrosamine which formed was filtered, washed with water and dried. It was purified by treating with 40 cc. of hot ethyl acetate, cooling, and then crystallizing the residue from 400 cc. of hot water; yield 4.57 g. The cream-colored needle-like crystals melted with decomposition at 147° (corr.).

Anal. Calcd. for $C_{10}H_{15}O_4N_2As$: As, 24.73. Found: As, 24.82, 24.73.

Reaction with Ammonium Carbonate in Sealed Tubes.—Ten grams of *o*-chlorophenylarsonic acid, 10 g. of anhydrous potassium carbonate, 0.5 g. of copper acetate and 25 cc. of amyl alcohol were placed in a bomb tube and thoroughly mixed while heating in a steam-bath. After cooling, 10 g. of ammonium carbonate was mixed with the contents and the tube sealed. The tube was heated in a bomb oven for fifty hours at 135°. The mixtures from three tubes, prepared and treated as above, were combined and steam distilled, and the remaining solution decolorized and strongly acidified. The tarry substance (see below) which formed was removed, and the solution made just alkaline to Congo red paper (acid to litmus), and evaporated to dryness. The solid residue was extracted with portions of hot absolute alcohol which were combined, and the alcohol removed by evaporation. The oily substance which remained was dissolved in a small amount of water, decolorized and the water allowed to evaporate. At first an oil separated, followed by white crystals. By gently warming with a little water, the crystals dissolved, leaving most of the oily substance. By two such extractions a small amount of white needle-like crystals was obtained which melted at 151–152° (corr.). The melting point of o-arsanilic acid given by Jacobs, Heidelberger and Rolf[6] is 153°. A solution of the crystals when diazotized gave an orange dye with R-salt.

Anal. Calcd. for $C_6H_8O_3NAs$ (*o*-arsanilic acid): As, 34.54. Found: As, 34.34.

The. tarry substance (see above), which was insoluble in the acid solution, was treated with boiling 6 N hydrochloric acid. It formed a clear solution from which a small quantity of a non-identified substance slowly separated (from hot solution) as white needles. The substance did not melt below 240°, was soluble in dilute sodium hydroxide, but insoluble in hot 6 N hydrochloric acid. A qualitative test showed the presence of nitrogen and the absence of chlorine. The arsenic content was found to be 27.64%. The filtrate from the acid treatment above was allowed to cool. Long white needles separated which were recrystallized from hot 6 N hydrochloric acid, dissolved in alkali, decolorized and reprecipitated with acid. When air dried, the substance melted at 132–136° with foaming. However, when dried in *vacuo* over sulfuric acid, or in the oven at 100°, the substance melted at 198–200° (corr.). A test for nitrogen was positive, while one for chlorine was negative. The arsenic analysis corresponded to that for diphenylamine-*o*,*o*′-diarsonic acid.

Anal. Calcd. for $C_{12}H_{13}O_6NAs_2$: As, 35.95. Found: As, 36.00, 36.02.

Reaction with **Monomethylaniline.**—A mixture of 10 g. of o-chlorophenylarsonic acid, 12 g. of anhydrous potassium carbonate, copper powder and 30 cc. of monomethylaniline (no solvent) was heated for fifteen hours at 140–150°, with stirring. After removing the methylaniline by steam distillation, the resulting solution was decolorized and acidified. The substance which separated was treated with hot acetone, cooled and filtered. The portion insoluble in acetone was further purified by dissolving in alkali, decolorizing, and reprecipitating with acid. The substance was dried in a desiccator over sulfuric acid and there was no further loss in weight on drying for ten hours in an oven at 100°. The yield was 1.65 g. A qualitative analysis showed the absence of ni-

---

[6] Jacobs, Heidelberger and Rolf, THIS JOURNAL, 40, 1583 (1918).

trogen and chlorine. The arsenic analysis corresponded to diphenyl ether *o,o'*-diarsonic acid. The substance softened and darkened at 240°.

Anal. Calcd. for $C_{12}H_{12}O_7As_2$: As, 35.87. Found: As, 35.97, 35.97.

General Procedure for the Preparation of Alkoxyphenylarsonic Acids.—Ten grams of o-chlorophenylarsonic acid, 10 g. of anhydrous potassium carbonate, a little copper powder, and 35 cc. of an alcohol containing 1.6 g. of potassium (or an equivalent amount of sodium) were heated at 130–135° for fifteen hours with stirring. After steam distillation and treatment with activated charcoal the alkoxyphenylarsonic acid was precipitated by acidifying with concd. hydrochloric acid. The yield was 30–49%.[7]

TABLE II

ALKOXYPHENYLARSONIC ACIDS

-Phenylarsonic acid	Yield, %	M. p., °C. (corr.)	Arsenic analyses, % Calcd.	Found
o-n-Butoxy-	30	200	27.55	27.56
o-Isoamoxy-	43	201	26.02	26.00
o-Phenoxy-	49	174	25.49	25.40

Discussion

In beginning a study of the reactions of o-chlorophenylarsonic acid, a series of about sixty condensation reactions with aniline was carried out under different experimental conditions. Specific examples have been chosen from this series to show the various effects. In general, 5 g. of the arsonic acid, 5 g. of anhydrous potassium carbonate, a trace of copper powder, and 20 cc. of aniline (no solvent) were heated in the apparatus described in the Experimental Part for fifteen hours, at 135°. In the tables only the conditions or amounts which differ from the general procedure are given. The yields indicated are based upon the amounts obtained after steam distillation, acidification, and a single crystallization from acetone and water.

Only two catalysts, copper and cuprous iodide, were tried in this series of reactions. Cuprous iodide gave a better yield but the product obtained when using copper was found to be purer. No yield was obtained in the absence of a catalyst. Freshly prepared cuprous iodide was more efficient than that which had been kept for some time.

TABLE III

THE EFFECT OF CHANGES IN TEMPERATURE

Time, hrs.	10	10	10	10
Yield, %	Trace	56	7	Trace

---

[7] In the case of o-phenoxyphenylarsonic, acidification with concd. hydrochloric acid gave an oil. The water layer was removed and the oily substance treated with ether. A white crystalline precipitate formed which was dissolved in the cakd. amount of dilute sodium hydroxide, decolorized with charcoal and reprecipitated by the slow addition of hydrochloric acid. The product was further purified by recrystallization from an acetone–water solution.

As indicated in Table III, the best yields were obtained at a temperature of about 135°.

TABLE IV

THE EFFECT OF CHANGES IN REACTION TIME

Time, hrs.	3	5	10	20
Yield, %	52	58	56	52

From the data in Table IV, apparently the reaction was finished in from three to five hours.

TABLE V

THE EFFECT OF SOLVENTS (Cu_2I_2 WAS USED AS THE CATALYST)

Aniline, cc.	Solvent	Yield, %
15	None	61
25	None	61
15	Amyl alcohol (4 cc.)	69
15	Amyl alcohol (8 cc.)	65
5	Amyl alcohol (25 cc.)	68
15	Nitrobenzene (8 cc.)	56
15	Nitrobenzene (25 cc.)	Small
15	Amyl alcohol (25 cc.) and water (1 cc.)	60
15	Amyl alcohol (25 cc.) and water (5 cc.)	48
15	Water (5 cc)	48

Slightly better yields were obtained using amyl alcohol as the solvent. The action of nitrobenzene was unfavorable. Small amounts of water, which hinder the ordinary Ullmann reaction, did not greatly affect the yield.

Condensations did not take place when sodium carbonate or sodium acetate was substituted for the potassium carbonate. In no case was a triphenylamine-diarsonic acid isolated. Theoretically such a compound could be formed by the reaction of two molecules of o-chlorophenylarsonic acid with one molecule of aniline.

Incidentally, it was found that o-chlorophenylarsonic acid, when heated to boiling with water containing a slight excess of aniline, formed a crystalline aniline salt. Aniline was liberated again on treating with alkali.

A series of condensations was also carried out with primary aliphatic amines. The amines (iso- and n-amyl, n-butyl, and n-propyl) readily condensed with *o*-chlorophenylarsonic acid under the conditions found favorable in the experiments with aniline. The products, after the usual recrystallizations, etc., were found to be mixtures. This was indicated by slight changes in the melting points on recrystallization and also by the fact that nitrogen determinations were consistently low. By crystallizing from hot 3 N hydrochloric acid, a white crystalline substance separated on cooling which did not contain nitrogen and which corresponded in properties to a compound (*o*-amoxyphenylarsonic acid) obtained by treating o-chlorophenylarsonic acid with potassium amylate, under the usual experimental conditions. Smaller yields were obtained with butyl- and propylamines, probably due to their lower boiling points and to the greater solubilities of their condensation products. A sealed tube reaction with ethylamine was carried out and a small quantity of a substance obtained which melted at 126–127°. The melting point given in the literatures for o-ethylaminophenylarsonic acid is 128–129°.

Ethanolamine (b. p. 168°, uncorr.) in the absence of a solvent condensed very readily with o-chlorophenylarsonic acid to form *o*-β-hydroxyethyl-aminophenylarsonic acid. This product has previously been prepared by Rodewald and Adams[9] by treating o-arsanilic acid with β-chloroethyl-chlorocarbonate and hydrolyzing the resulting product with alkali. The nitrosamine was prepared to prove an amino rather than an ether linkage.

Glycine condensed, in the presence of amyl alcohol, to give fair yields of phenylglycine-o-arsonic acid. To avoid steam distilling, the amyl alcohol was removed by extractions with ether.

It was desired to include in this study the reaction of o-chlorophenylarsonic acid with ammonia. This reaction was carried out in sealed tubes using ammonium carbonate as the source of ammonia. Copper acetate was used as the catalyst, since due to its solubility it was easily dispersed throughout the reaction mixture. Theoretically one, two, or three hydrogen atoms of ammonia could be replaced by phenylarsonic acid radicals to give (1) o-arsanilic acid, (2) a diphenylamine-diarsonic acid, and (3) a triphenylamine-triarsonic acid. From the reaction mixture, o-arsanilic acid was identified by means of its melting point, its reaction with R-salt, and by its arsenic analysis. A small amount of a second substance containing nitrogen was obtained which was soluble in hot 6 *N* hydrochloric acid, but crystallized on cooling. Its arsenic analysis corresponded to that calculated for a diphenylamine-diarsonic acid. A third product was isolated which contained nitrogen and arsenic (27.64%) which was insoluble in hot 6 *N* hydrochloric acid, and did not melt below 240°. The nature of this substance was not determined.

All attempts to condense with secondary aliphatic amines (di-isoamyl-, di-*n*-butyl-, and diethylamines) were unsuccessful. The reactions were carried out at various temperatures in the absence of a solvent, but no reaction product was obtained. When amyl alcohol was used as a solvent, amoxyphenylarsonic acid was formed in yields as high as 20%.

Although Gibson and Johnson[10] have found it possible to condense *o*-bromophenylarsonic acid with monomethylaniline, the reaction under similar conditions with *o*-chlorophenylarsonicacid gave no product containing nitrogen. When heated under the usual conditions to 140–150° with monomethylaniline (no solvent), a product was obtained which was insoluble in acetone or dilute hydrochloric acid but was readily soluble in alkali. The arsenic content wss found to correspond to that calculated for a diphenyl ether diarsonic acid. Theoretically this could be formed if part of the *o*-chlorophenylarsonic acid were hydrolyzed to form o-hydroxyphenylarsonic acid, which in turn reacted with some of the remaining o-chlorophenylarsonic acid. The latter reaction would be probable since phenol was found to react readily to form diphenyl ether *o*-arsonic acid. While no evidence has been obtained of the formation of o-hydroxyphenylarsonic acid in any of the reactions studied thus far, still it is possible that certain reagents may bring about the hydrolysis of o-chlorophenylarsonic acid. In fact, Tuttle[11] found that o-chlorobenzoic acid when heated with piperidine yielded salicylic acid, but none was obtained when heated with a potassium hydroxide solution. Since the usual methods of splitting ethers are not applicable to diphenyl ethers, and since no suitable derivative

with known constants could be found, no final proof of the structure of this compound was made.

In the course of this work a few other reactions were attempted which were unsuccessful. The formation of ethers from alcohols or alcoholates, and the work of Hurtley,[12] who, in studying the replacement of halogen in o-bromobenzoic acid, condensed that acid with malonic ester, acetoacetic ester and benzoylacetone, suggested like condensations with o-chlorophenylarsonic acid. However, under similar conditions the corresponding reactions did not take place. Benzamide and potassium phthalimide also failed to react under conditions similar to the amino condensations or at higher temperature.

Summary

1. A study was made of the effects of changes in the reaction conditions, such as temperature, time, catalyst, solvent, etc., on the reaction of *o*-chlorophenylarsonic acid with aniline.

2. o-Chlorophenylarsonic acid was condensed with a series of aliphatic amines and amino compounds, namely, isoamyl-, n-butyl-, n-propyl-, and ethanolamines, and with glycine. The nitrosamine derivatives of n-butyl-, and β-hydroxyethylaminophenylarsonic acids were also prepared.

3. A sealed tube reaction with ammonium carbonate gave a reaction mixture from which o-arsanilic acid, and diphenylamine-*o,o'*-diarsonic acid were isolated.

4. Attempts to condense o-chlorophenylarsonic acid with monomethlyaniline yielded a product which analyzed for diphenyl ether *o,o'*-diarsonic acid.

5. The alcoholates of isoamyl and n-butyl alcohols and also phenol were condensed with o-chlorophenylarsonic acid to give isoamoxy-, n-butoxyphenylarsonic acids, and diphenyl ether *o*-arsonic acid, respectively.

THE CHEMICAL REACTIVITY OF THE FUSED BASES. II. THE ACTION OF FUSED POTASSIUM AMIDE UPON ALIPHATIC NITRILES[1]

BY R. A. FULTON AND F. W. BERGSTROM

RECEIVED MAY 25, 1931 PUBLISHED AUGUST 5, 1931

Introduction

The preparation of methane may readily be accomplished in the laboratory by heating sodium acetate with sodium hydroxide or, better, with soda lime.[2] Unfortunately, the methane so prepared is never quite pure, since it is generally contaminated with hydrogen and with other gases that may arise from the decomposition of the sodium acetate alone.[2(d-h)] Unsuccessful attempts have been made to generalize this reaction and to prepare the lower hydrocarbons of the methane series by heating the sodium salt of an acid containing one more carbon atom than the desired product with soda lime. The following equation expresses the anticipated reaction

$$\mathrm{R{-}COONa + NaOH = R{-}H + Na_2CO_3} \qquad (A)$$

Although some elementary organic textbooks still give this as a general method for the preparation of aliphatic hydrocarbons, it is now recognized that these reactions are rather complex and yield, besides sodium carbonate and hydrogen, quantities of hydrocarbons containing fewer carbon atoms than would be expected.[3] Nevertheless, by distilling a mixture of sodium ethylate and the sodium salt of stearic, palmitic, elaidic or oleic acid in a vacuum, Mai[4] has been able to obtain fair yields of the hydrocarbons that would be anticipated if the reaction followed the course of Equation **A.**

In the related field of nitrogen compounds, Miss Fulton[5] and Mr. E. C. Cornell[6] have found that a number of fatty acids of the ammonia system, $\mathrm{R{-}C}\begin{smallmatrix}\mathrm{=NH}\\ \mathrm{-NH_2}\end{smallmatrix}$, yielded hydrocarbons when heated with potassium amide, the reactions proceeding qualitatively in accordance with the equation

$$R{-}C\begin{matrix}=NH\\ -NHK\end{matrix} + KNH_2 = R{-}H + NH_3 + NCNK_2 \qquad (B)$$

The acid amidines, $R{-}C\begin{matrix}=NH\\ -NH_2\end{matrix}$, themselves not being readily available were prepared for the most part by the action of potassium amide on the corresponding acid anammonide (acid nitrile) as represented by the equation

$$R{-}CN + KNH_2 = R{-}C\begin{matrix}=NH\\ -NHK\end{matrix} \qquad (C)$$

The similarity between equations (A) and (B) is to be especially noted. In each case there results a hydrocarbon that contains one less carbon atom than the fatty acid entering the reaction. In the first case, potassium aquo carbonate, K_2CO_3, is formed; in the second case, a potassium ammono carbonate, dipotassium cyanamide, $NCNK_2$.

The quantitative formation of the hydrocarbon to be expected from equation (B) is scarcely to be anticipated if these reactions are strictly analogous to the decomposition of the salts of the aquo fatty acids by heated soda lime or sodium hydroxide. Therefore it becomes desirable to repeat the work of Miss Fulton and Mr. Cornell on a larger scale and under more carefully regulated conditions. To this end a number of the nitriles of the lower fatty acids were passed through molten potassium amide, in the cell described in the next section, to convert them to the potassium salts of the corresponding *ammono* fatty acid, in accordance with equation (C). These salts—in the presence of the heated potassium amide in the cell—were at once decomposed into di-potassium cyanamide and a mixture of hydrocarbon gases, which were collected and analyzed.

Apparatus and Manipulation

The apparatus used in the present work is shown in Fig. 1. It was fabricated entirely of nickel, since this metal appears to be unattacked by the fused amides even at temperatures well in excess of 400°.[7] The two small needle valves were made of monel metal.

The fusion chamber F is made of a 20-cm. length of seamless nickel tube, 3.75 cm. in internal diameter and 3 mm. in thickness. A thick plug of nickel, Q, is silver soldered into the bottom of the tube in such a manner that about two-thirds of the plug projects outside. Two parallel flats are milled on this portion to permit the plug to be clamped in a vise while the hexagonal head G is being screwed into place or removed.

The nitrile is dropped from a small buret, S, into the tube P from which it is carried by a current of dry ammonia through the needle valve, A, and thence through the fused potassium amide in the bottom of the cell. The enlargement near the bottom of H is designed to prevent the fused amide from backing up into the smaller tube and solidifying. The tube T-N-H is broken at L with a compression joint, the threads on which have the same pitch as the threads on the top of F. This allows the hexagonal cap, *G*, to be removed at the end of a run, leaving H embedded in the solidified potassium amide. The lock-nut N allows the tip of the tube H to be adjusted at any suitable height from the bottom of the fusion chamber. Since the two valves A and D are

---

[7] Fernelius and Bergstrom, J. Phys. *Chem.*, 35, 742 (1931).

rather close together, it would be very difficult to screw both into place if it were not for the union at T.

The gases liberated in the reaction are vented through D and passed through a mercury bubbler, U, into a gas collector, V, containing dilute sulfuric acid,[8] where the ammonia is absorbed. The unabsorbed gases are then passed through a drying tube, W, into a modified Shepherd–Porter apparatus where they are analyzed.[9] The use of the apparatus may best be illustrated by the description of a typical run.

The thoroughly cleaned cell, assembled as in Fig. **1,** is placed in a large electric crucible furnace, K, and heated to a temperature of **300**" while a current of dry ammonia[10] is passed through it for about half an hour. The cell is now thoroughly dry. The plug B is unscrewed and valve D closed, allowing a stream of ammonia to escape from B. Through this hole was inserted a short length of capillary sealed to the bottom of a 25-mm. test-tube. Approximately **3** g. of metallic potassium was placed in this test-tube and the top closed by a stopper through which passed a tube leading to a supply of ammonia under pressure (ammonia tank).[7] The potassium was melted by carefully applying a flame to the outside of the test-tube. The molten potassium was then forced into the cell by judicious application of ammonia pressure, the oxide remaining behind. The weight of the tube plus the potassium less the weight of the tube containing only the residual oxide equaled the weight of the potassium introduced into the cell. This generally varied between **3** and **3.5** g.

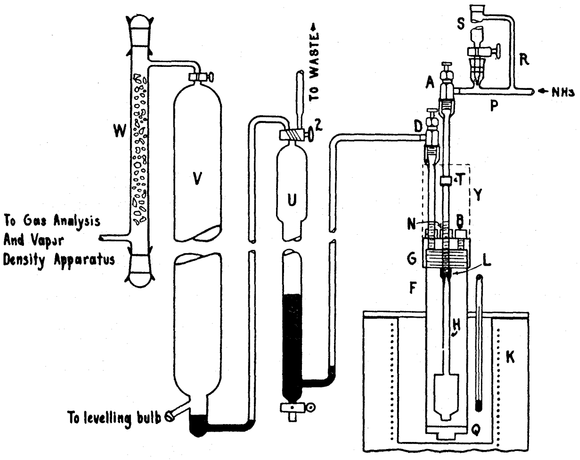

Fig. 1.

After the introduction of the potassium, B was replaced and the water jacket Y screwed into position (shown in dotted lines in Fig. 1). The jacket was kept about two-thirds full of water for the purpose of keeping the valves cool, thus facilitating their manipulation. The lock nut *N* was loosened and the ammonia inlet tube H adjusted so that its tip was, by calculation, about 2 mm. below the surface of the molten

potassium. Then *N* was tightened. The temperature of the cell was raised to about 400° and a rapid current of ammonia passed through to convert the potassium to potassium amide (stopcock *2* was opened to the waste). This generally required about half an hour to an hour. The complete conversion was recognized by the cessation of the evolution of hydrogen. (Stopcock **2** turned to direct ammonia into the absorption tower.)

The nitrile was now introduced into the cell by means of the buret in the manner already described. Duplicate runs are comparable, since the amount of potassium used in each experiment was very closely the same and since the opening at the lower end of I was kept at approximately the same distance underneath the surface of the molten amide. All nitriles were passed through the cell at a rate of about 0.1 cc. per minute, that is, at such a rate that all of the nitrile reacted with the potassium amide. The weight of nitrile entering the reaction varied between one-half gram and two grams (see Table I). A more rapid rate of addition of nitrile caused the production of tar.

The gases formed in the reaction and collected in the gasholder, V, were passed through a barium perchlorate tube, W, and thence to a slightly simplified Shepherd–Porter gas analysis apparatus. The modification consisted in the use of a single tube, with indentations like a Vigreux column, for the condensation of the hydrocarbons gases by liquid air. Since the volume of gas formed in the reactions seldom exceeded one liter, a fairly complete separation of the constituents of the mixture was effected by removing the nitrogen–hydrogen, methane, ethane, propane and butane fractions with a Topler pump, the condensation tube being held at the temperatures recommended by Shepherd and Porter. Thus, none of the hydrocarbons were re-fractionated, as in the original method to which reference was made. The efficiency of separation of the hydrocarbon gases was verified by burning them in the slow combustion pipet of the Shepherd–Porter apparatus, and by determining their vapor density. To this end the individual hydrocarbon fractions, which were collected in the graduated delivery tube of the Topler pump, were passed through a phosphorus pentoxide drying tube and thence into an evacuated vapor density bulb. The gas so collected was weighed under a known pressure, indicated by a manometer attached to the system. The higher hydrocarbons, liquid at ordinary temperatures, were separated by repeated distillations from a small flask with a fractionating column.

The cell containing the non-volatile reaction products, together with the excess of potassium amide, was cooled in ice water and half filled with benzene. Water was then slowly introduced until the contents of the cell were completely hydrolyzed. The resulting strongly alkaline aqueous solution was separated from the benzene, diluted and almost neutralized with dilute nitric acid (cooling). Then an excess of ammonia water was added and this was followed by an aqueous solution of silver nitrate to precipitate the yellow di-silver cyanamide (silver ammono carbonate), which was filtered off, dried in *vacuo* at 60° and weighed.

It is evident that this procedure will give only an approximately accurate measure of the amount of cyanamide formed, since this is known to be slowly converted to urea in strongly alkaline solution. Buchanan and Barsky[11] have found that normal solutions of sodium hydroxide slowly and quantitatively convert cyanamide to urea. The rate of hydrolysis of the cyanamide is almost independent of the hydrogen-ion concentration in the more strongly alkaline solutions, the velocity constant for a first-order reaction being (0.74–0.96) 10^{-2}. The amount of cyanamide converted to

urea during the hydrolysis of the potassium amide fusions here discussed should not exceed a very few per cent. The analytical results for cyanamide are thus only approximately correct, especially since the di-silver cyanamide precipitates are often impure.

Results of the Experiments

The experiments described in this paper were all performed in duplicate, the conditions of the two sets of runs being as nearly identical as possible. The analyses of the gases formed in the two runs checked to within a few tenths of one per cent. in nearly all cases. Undoubtedly alteration in the speed of addition of the nitrile and in the height of fused potassium amide through which the nitrile was passed would alter the relative proportions of the hydrocarbons that were formed. The average values are given.

Table I shows the weight of the nitrile entering the reaction at the three temperatures of the experiments (300, 360 and 400") (column **A**); the total volume of gas formed (column B); the molecular weight of the hydrocarbon fractions as determined by the vapor density method (column C); the calculated molecular weights of these hydrocarbons (column D); the weight of di-silver cyanamide obtained from the hydrolyzed solid reaction product (column E), and the number of moles of di-silver cyanamide obtained per mole of the reacting nitrile (column F).

Tables II, III and IV summarize the results of the analyses of the gases whose volumes are given in column B of Table I.

TABLE II

THE DECOMPOSITION OF NITRILES BY POTASSIUM AMIDE

(Temp., 300°)[12]

	Hydrogen	Methane	Ethane	Propane	Butane	Iso-butane	Iso-pentane

$(CH_3)_2CHCH_2CH_2CN$	59.3	Trace	2.5			9.5	28.7

Discussion

It is evident that potassium amide and acetonitrile react at all three temperatures to form methane and dipotassium cyanamide in almost theoretical yields, in accordance with the type equation B. Propionitrile and solid potassium amide react at 300° to form a gas which is 65% ethane,

---

[12] The nitrogen–hydrogen–methane fraction, pumped from the solidified hydrocarbon gases at liquid air temperatures, was analyzed by combustion in a slow combustion pipet, the amount of methane being determined from the carbon dioxide formed in the reaction. The remainder of the combustible gas, as calculated from the contraction in volume on burning with air was hydrogen. However, since nitrogen was not obtained in significant amounts in the preliminary runs, the hydrogen in the above tables was determined by difference, the volume of methane being known.

16.4% methane and 18.6% hydrogen. All of the higher nitriles behave similarly, that is, the expected hydrocarbon is formed, together with varying amounts of all of the hydrocarbons down to and including methane. Hydrogen is always formed at the same time.

The yields of the lower hydrocarbons and of hydrogen increase with increasing temperature of fusion (Tables III and IV), while the yield of the expected hydrocarbon (equation A) decreases. This points most obviously to a catalytic decomposition or cracking of the expected hydrocarbon which increases with increasing temperature. The nickel of the cell at the temperatures of the reactions was found to have little effect on vapors of the hydrocarbons below pentane, when these were passed through the empty cell. The potassium amide itself must therefore have caused the decomposition or cracking of the anticipated hydrocarbons. This was indeed found to be the case, since the hydrocarbons from n-heptane down to ethane were partially cracked when passed through molten potassium amide under the conditions of the present experiments. This work will be discussed in detail in a forthcoming paper.

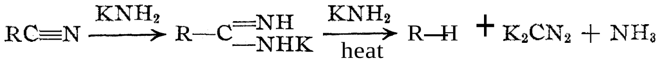
In an entirely analogous manner it was found that n-pentane was cracked readily by soda lime at a temperature of 400°, yielding hydrogen and a mixture of the lower hydrocarbons with a large preponderance of methane. This will perhaps account for the impracticability of preparing ethane and its higher homologs in accordance with the generalized reaction of equation A.

The decomposition of some of the higher nitriles by fused potassium amide (Table I) has given more than one mole of cyanamide per mole of reacting nitrile. It is known that carbon may be converted by the fused amides to cyanamide.[13]

Summary

1. A nickel apparatus has been devised for carrying out reactions in pure fused sodium or potassium amides.

2. The ammono fatty acid anammonides—that is, the nitriles of the fatty acids—react with fused potassium amide in accordance with the type equation



$$RC\equiv N \xrightarrow{KNH_2} R-C{=NH \atop -NHK} \xrightarrow[\text{heat}]{KNH_2} R-H + K_2CN_2 + NH_3$$

In other words, the salts of the fatty acids of the ammonia system are decomposed by heating with a base of the same system into a hydrocarbon and a sodium ammono carbonate (di-sodium cyanamide). The hydrocarbon R—H is cracked by the molten amide to simpler hydrocarbons and hydrogen, the degree of decomposition increasing with increase in the temperature of the fusion.

3. The failure to obtain the expected hydrocarbon in the reaction $R-COONa + NaOH$ (heated) $= Na_2CO_3 + R-H$ appears to be due in part at least to the cracking of the expected product R—H to lower hydrocarbons and hydrogen under the catalytic influence of soda lime or sodium hydroxide.

THE CONSTITUTION OF MELEZPTOSE AND TURANOSE

BY EUGENE PACSU

RECEIVED MAY 25, 1931 PUBLISHED AUGUST 5, 1931

Investigations[1] have shown that when the natural non-reducing trisaccharide melezitose is gently hydrolyzed by weak acid solutions, there results as one of the products the reducing disaccharide, turanose. This sugar is the first known true isomer of sucrose and was first obtained in a pure crystalline condition by C. S. Hudson and the present author.[2] The failure in the past to secure a crystalline turanose has compelled investigators to use melezitose as the starting material in their efforts to solve the problem of the constitution of these two sugars.

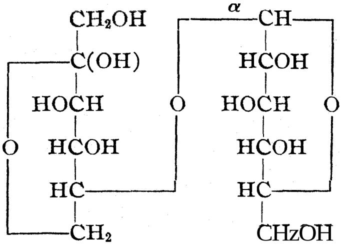
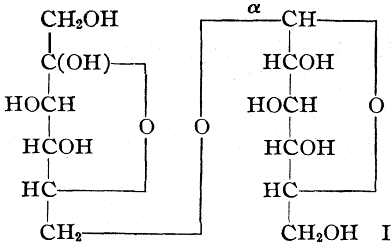
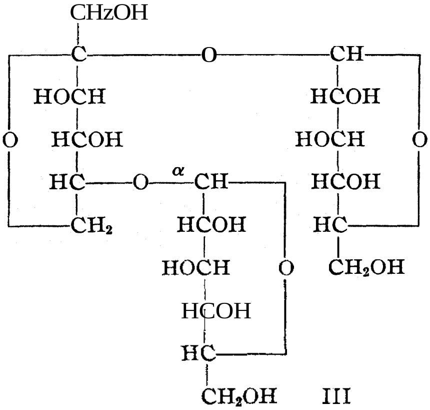
At the present time two different formulas are assigned for both turanose (I and II) and melezitose (III and IV):



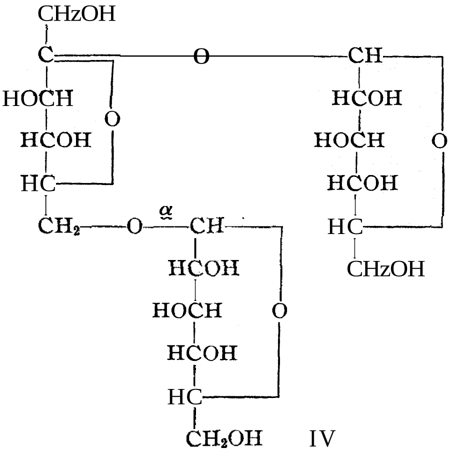
I



II



III



IV

It is my purpose to show that now we can ascribe a definite constitution for these two sugars based on methylation studies of former investigators and on new evidence recently obtained in this Laboratory using crystalline turanose as a starting material.

It is now quite beyond question that the general composition of melezitose is a-glucopyranose<fructose<>glucopyranose, where the reducing disaccharide, a-glucopyranose<fructose< is turanose. The α-glycosidic linkage in turanose has been proved by Bridel and Aagaard,[3] but the identity of the other potential disaccharide fructose<>glucopyranose is not as certain. Unlike turanose it cannot be isolated in a free state. It may be sucrose or a ring isomer of sucrose. Neither will methylation experiments answer this question. A completely methylated melezitose would yield on hydrolysis 2,3,4,6-tetramethylglucopyranose and a trimethylfructose. The structure of this fructose derivative would be the key to the true constitution of melezitose and turanose. Unfortunately, however, none of the theoretically possible isomeric trimethylfructoses has

---

[3] M. Bridel and T. Aagaard, *Bull. soc. chim. biol.*, 9,884 (1927); T. Aagaard, *Tids. Kemi Bergwesen*, *8*, *5*, *16*, 35 (1928).

so far been prepared, and therefore this direct method of comparison is not available.

If we assume with Zemplén and Braun[4] that the fructose fragment of melezitose contains the same 2,6-oxide linkage as it was believed exists in the fructose part of sucrose, their conclusion that their partially methylated fructose has the structure of 1,3,4-trimethylfructose<2,6> leads to (I) for the structure of turanose and (III) for melezitose. However, Haworth and Hirst[5] have shown that the fructose constituent of sucrose does not belong to the normal fructopyranose type and they have suggested the presence of a fructofuranose in sucrose. If such a sucrose be the constituent of melezitose then we must agree, as Zemplén[6] points out, that the structure of the trimethylfructose is 1,3,4-trimethylfructose<2,5> and therefore turanose and melezitose should be represented by (II) and (IV), respectively. The trimethylfructose in question has been methylated by Leitch[7] and 1,3,4,6-tetramethylfructose<2,5> was obtained. This same fructose derivative is claimed by Haworth to be found when octamethylsucrose is hydrolyzed. According to Leitch this result is evidence that Zemplén's assumption that sucrose is the non-reducing potential disaccharide of melezitose is correct and that therefore the structure of turanose and melezitose must be (II) and (III). However, reflection will show that this conclusion is not justified. If we consider the possibility that 1,3,4-trimethylfructose may easily acquire two different rings,[8] it is possible that the non-reducing disaccharide in melezitose is not the common sucrose but rather a ring isomer containing a 2,6-oxygen bridge in the fructose component. The completely methylated derivative of such a melezitose (III) still may yield on hydrolysis 1,3,4-trimethylfructose<2,5> because the expected 1,3,4-trimethylfructose<2,6> may easily shift its pyranoid ring into a furanoid ring.

Further evidence which leads us to doubt that ordinary sucrose is a constituent of the melezitose molecule is found in certain investigations of Bridel and Aagaard[3] on the hydrolysis of melezitose by various enzymes.

It therefore appears that the "proved structures of melezitose and turanose are still questionable. Indeed experiments which I am now reporting indicate that the structures originally assigned to these sugars by Zemplén and Braun are the more probable.

It has been shown by Helferich[9] in his studies on triphenylmethyl deriva-

[6] G. Zemplén, *Ber.*, 59, 2539 (1926).

[7] Grace Leitch, *J. Chem. Soc.*, 588 (1927).

[8] This is a logical assumption since the potential ketone group as well as the fifth and sixth OH groups are free.

[9] B. Helferich and J. Becker, *Ann.*, 440, 1 (1924); B. Helferich, L. Moog and A. Jünger, *Ber.*, 58, 872 (1925).

tives of the sugars and glucosides that triphenylchloromethane reacts only with the primary alcoholic groups in these compounds. It is evident, therefore, that triphenylchloromethane may be used to advantage in investigating the structure of turanose. The quantity of this reagent taken up by the sugar will give us an indication of the number of primary alcoholic groups present in the molecule. This method has been used by Josephson[10] in his studies on maltose, sucrose and raffinose. He has shown that hydrogen bromide dissolved in glacial acetic acid easily removes the triphenylmethyl residue as triphenylbromomethane and, if this be determined quantitatively, the number of primary alcoholic groups can be readily ascertained.

If we apply this method of analysis to turanose, certain possibilities suggest themselves. If formula (II) be correct, a di-(triphenylmethyl)-turanose will be obtained. However, if the correct structure of turanose be that represented by formula (I), a tri-(triphenylmethyl)-turanose may result inasmuch as the sixth OH group of the fructose residue though involved in ring formation may become free due to a shift of the ring. That such a ring shift may be expected is justified by the observation of Josephson.[10] This investigator has shown that both arabinose and xylose in their normal forms react slowly with triphenylchloromethane in pyridine solution.

Experiments carried out with crystalline turanose show that this sugar readily combines with triphenylchloromethane to give a tri-(triphenylmethyl)-turanose which on acetylation yields a pentaacetyl derivative. These facts point clearly to the conclusion that the glucose residue in the turanose molecule cannot be attached to the sixth carbon atom of the fructose constituent. This obviously rules out formula (II) for the constitution of the turanose component in melezitose and also indicates that the true constitution of melezitose is as represented by formula (III). Such a formula for melezitose confirms the above statement that the potential nonreducing disaccharide in the molecule is not sucrose but rather a ring isomer of it. As regards the structure of the free turanose we can state with some degree of certainty that it is a 5-α-glucosido$<1,5>$fructose containing a 2,4-ring in its fructose part or a 2,6-ring which in solution shifts into the 2,4-position. That such a ring shift takes place is supported by evidence which will be published later. If turanose be acetylated in acetic anhydride solution at room temperature in the presence of the catalyst zinc chloride, three well-defined crystalline octaacetates are produced instead of the two foreseen by theory if a ring shift is excluded.

Finally it may be added that the fact that all the known disaccharides are linked either to the fourth or sixth carbon atom and never to the fifth position should not concern us seriously if it be observed that the fifth

---

[10] K. Josephson, *Ann.*, **472,230** (1929).

carbon atom of fructose where the glycosidic linkage in the turanose molecule occurs is in reality the fourth carbon atom counted from the potential reducing group of the fructose component.

Experimental Part

Preparation of **Tri-(triphenylmethyl)-turanose.**—Three and a half grams of crystalline turanose was dissolved in 60 cc. of hot pyridine and to the cooled solution 14 g. of triphenylchloromethane was added. On standing for a short time at room temperature a white crystalline material was deposited from the solution which in all probability is triphenylmethyl pyridine chloride. After four to five days the solution was cooled in an ice-bath and water was added to it drop by drop. When the double compound went into solution, more water was carefully added until cloudiness developed. The liquid was kept below 0° for several hours and the triphenylcarbinol which separated during this time removed by filtration. The clear filtrate was poured under vigorous stirring into one and one-half liters of ice water. The gummy precipitate so obtained was allowed to stand for several days in water which was occasionally renewed. At the end of this time the gummy precipitate had changed into a white, solid mass. This was collected at the pump, dissolved in alcohol, the solution decolorized with charcoal and stirred into a large amount of ice water. After standing for two days in the ice box the treatment was repeated. Finally it was filtered and dried for several days at room temperature over phosphorus pentoxide in a vacuum desiccator to constant weight; yield, 2–3 g. of colorless, white powder. The specific rotation was found to be $[\alpha]^{20}_{D}$ 30.87° (0.7046 g. in 25 cc. of chloroform solution rotated 1.74° to the right in a 2-dm. tube). No mutarotation of the solution could be observed. This material melted at 105–115°, a phenomenon which is due to the presence of the α- and β-forms. It is insoluble in water and petroleum ether but is readily soluble in the common organic solvents.

Anal. Calcd. for di-(triphenylmethyl)-turanose, $C_{50}H_{50}O_{11}$: C, 72.60, H, 6.10; for tri-(triphenylmethyl)-turanose, $C_{69}H_{64}O_{11}$: C, 77.50, H, 6.04. Found: C, 77.06; H, 6.21.

Preparation of **Tri-(triphenylmethyl)-turanose Pentaacetate.**—Two grams of tri-(triphenylmethyl)-turanose was dissolved in 10 cc. of pyridinc and to the ice-cold solution 6 cc. of acetic anhydride was added. On standing for two days at room temperature a few drops of water were carefully added to the cooled solution and after half an hour it was stirred into 500 cc. of ice water. The sirup which was precipitated very soon turned into a solid. This was allowed to stand for several days in water which was occasionally changed. The filtered substance was then dissolved in alcohol, the solution decolorized with charcoal and stirred into ice water. After repeating this treatment the filtered substance was dried in a vacuum desiccator over phosphorus pentoxide and solid sodium hydroxide to constant weight: yield, 2.2 g. of colorless fine powder having a specific rotation in chloroform of $[\alpha]^{20}_{D}$ 75.85" (0.6889 g. in 25 cc. of chloroform solution rotated 4.18° to the right in a 2-dm. tube). The substance does not possess a sharp melting point as it begins to sinter at about 85° and melts at 95–105°. It is insoluble in water but is soluble in the common organic solvents except petroleum ether.

Anal. Calcd. for di-(triphenylmethyl)-turanose hexaacetate, $C_{62}H_{62}O_{17}$: C, 68.98; H, 5.79; for tri-(triphenylmethyl)-turanose pentaacetate, $C_{79}H_{74}O_{16}$: C, 74.14; H, 5.83. Found: C, 73.92; H, 5.93.

In an acetyl estimation made by the method of Kunz,[11] 0.4060 g. of substance was dissolved in 80 cc. of pure acetone to which 24.6 cc. of 0.1 N sodium hydroxide was sub-

---

[11] A. Kunz and C. S. Hudson, THIS JOURNAL, 48,1982 (1926).

sequently added. The acetylated triphenylmethyl derivative of turanose neutralized 16.8 cc. of decinormal alkali, whereas the value calculated for tri-(triphenylmethyl)-turanose pentaacetate is 15.9.

The triphenylmethyl estimation was carried out by the method of Josephson,[10] 0.1525 g. of substance was dissolved in 0.5 cc. of cold glacial acetic acid and mixed with 0.4 cc. of glacial acetic acid saturated at 0° with hydrogen bromide. After a transitory halochromic coloration due to the formation of a double compound between triphenyl carbinol and hydrogen bromide, triphenylbromomethane separated from the cold liquid. The crystals were collected on a Jena glass filter and washed by means of a pipet with 0.4 cc. of glacial acetic acid. After being dried over solid potassium hydroxide in a vacuum desiccator to constant weight, the triphenylbromomethane formed weighed 0.1088 g., which is 94.13% of the theoretical amount required for tri-(triphenylmethyl)-turanose pentaacetate.

Summary

Two different formulas for both turanose and melezitose are recorded in the literature. Evidence is submitted to show that turanose has three primary alcoholic groups in its molecule in that a tri-(triphenylmethyl)-turanose and its pentaacetate could be prepared. This fact together with certain methylation experiments of former investigators leads to the conclusion that the formulas of turanose (I) and melezitose (III) originally suggested by G. Zemplén and G. Braun should be chosen for these rare compound sugars.

STEREOCHEMISTRY OF DIPHENYL COMPOUNDS. THE RESOLUTION OF 8,8'-DICARBOXY-1,1'-DINAPHTHYL

BY W. M. STANLEY[1]

RECEIVED MAY 28, 1931 PUBLISHED AUGUST 5, 1931

The resolution of 2,2'-dicarboxy-1,1'-dinaphthyl[2] (I) demonstrated that the 2,2'-carboxyl groups and the 8,8'-hydrogen atoms are sufficiently large to interfere with each other and thus allow resolution into optical isomers. This indicates that a carboxyl group and a hydrogen atom are large enough to interfere across the space AB (III) which may be calculated as 2.51 Å. by assuming the usual angles in the benzene ring. The fact that this compound was found to be quite stable toward racemization indicates that this interference is fairly large. The compound in which the carboxyl groups and the hydrogen atoms are interchanged, 8,8'-dicarboxy-1,1'-dinaphthyl (II), should also be resolvable, since the 8,8'-carboxyl groups and the 2,2'-hydrogen atoms should interfere across the space AB as in the previous compound, assuming that no additional fac-

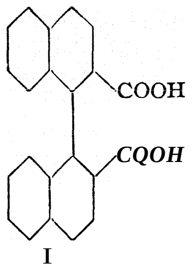
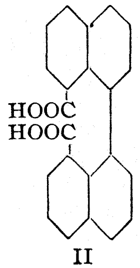
[2] Kuhn and Albrecht, Ann., 464, 282 (1928).

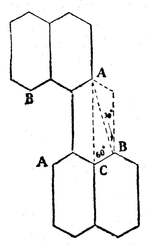
tors enter the case. This compound (II) is of unusual interest since it may be readily seen that it is an example of an α,α'-disubstituted diphenyl derivative. Although the resolution of α,α'-disubstituted diphenyl derivatives has been predicted,[3] attempts at resolution, up to the present time, have been unsuccessful.



I



II



III

In the present investigation 8,8′-dicarboxy-1,1′-dinaphthyl was resolved into its optical isomers by fractionation of the monoquinine salt from benzene. Pyridine solutions of the d- and I-acids gave $[\alpha]_D^{20}$ + 198.1° and $[\alpha]_D^{20}$ − 185.8°, respectively. Practically complete racemization occurred in pyridine solution on standing for five weeks at 19°, and complete racemization occurred in 2 N ammonium hydroxide solution on standing at 19° for fifteen hours. The optically active acids were also completely racemized by heating in pyridine solution at 100° for thirty minutes or by heating in 0.1 *N* sodium hydroxide at 90° for thirty minutes.

The correct explanation as to why 8,8′-dicarboxy-1,1′-dinaphthyl is readily racemized while 2,2′-dicarboxy-1,1′-dinaphthyl is quite stable toward racemization is not yet clear. The difference in stability may be due to the fact that the peri-substituted carboxyl groups in 8,8′-dicarboxy-1,1′-dinaphthyl render the molecule more labile and more capable of distortion than when the carboxyl groups are in the 2,2′ positions.

The set of interference values which has been suggested3 was designed primarily to enable estimation of the interferences between 2,6 and 2′,6′ groups in diphenyl derivatives. In such compounds the interfering groups were assumed to be at an angle of 60" from the line of nearest approach (AC). However, in the case of 8,8′-dicarboxy-1,1′-dinaphthyl the 2,2′- and the 8,8′-groups cause the interference and these groups may be assumed to be at an angle of 30" from the line of nearest approach (AB). The effective diameter of the groups would probably be a little larger since they are directed more toward each other (by 30°); consequently in compounds of this type the interference values would probably need to be slightly increased.

The author wishes to express his sincere thanks to Professor Ludwig Kalb for the 8,8′-dicarboethoxy-1,1′-dinaphthyl used in this investigation.

[3] Stanley *and Adams,* THIS *JOURNAL, 52,* 1200 (1930); 53,2364 (1931).

Experimental Part

8,8′-Dicarboxy-1,1′-dinaphthyl.—A mixture of 0.65 g. of 8,8′-dicarboethoxy-1,1′-dinaphthyl[4] and 2 g. of potassium hydroxide in 50 cc. of amyl alcohol was refluxed for seven hours. About 45 cc. of alcohol was then removed by distillation under vacuum and 100 cc. of water added to the residue. The acid was then precipitated by the addition of concentrated hydrochloric acid, removed by filtration and dissolved in 50 cc. of dilute aqueous ammonia. This solution was treated with animal charcoal to give a colorless solution, from which the acid was precipitated by the addition of hydrochloric acid. The yield was 0.5 g. (91%) of a product melting at 298–300° to a red liquid. Upon recrystallization from ethyl alcohol the melting point was raised to 306–307°. The 8,8′-dicarboxy-1,1′-dinaphthyl is insoluble in xylol, acetone, ether and chloroform, slightly soluble in ethyl alcohol, ethyl acetate and acetic acid, and soluble in pyridine and hot acetic anhydride. The ester was only partially saponified by the use of methyl or ethyl alcoholic potassium hydroxide.

Anal. Subs., 5.025 mg.: CO_2, 14.20 mg.; H_2O, 1.89 mg. Calcd. for $C_{22}H_{14}O_4$: C, 77.17; H, 4.12. Found: C, 77.07; H, 4.21.

Resolution of 8,8′-Dicarboxy-1,1′-dinaphthyl.—To a cloudy solution of 0.4367 g. of 8,8′-dicarboxy-1,1′-dinaphthyl in 150 cc. of absolute ethyl alcohol was added 0.4138 g. (1 equivalent) of quinine. The solution, which became perfectly clear upon the addition of the quinine, was evaporated to dryness. The mono-quinine salt is very soluble in methyl alcohol, ethyl alcohol, acetone and chloroform, slightly soluble in benzene and insoluble in ether and water. The mono-quinine salt was taken up in 20 cc. of benzene and a few drops of ethyl alcohol was added to make the solution clear. The solution was then boiled for five minutes and allowed to stand. After standing for two days at room temperature, the clear solution was decanted from a thin glassy film (0.24 g.) which had formed on the sides and bottom of the Bask.

Rotation. 0.0566 g. made up to 3 cc. with chloroform at 20° gave α_D −0.45"; $l = 1$; $[\alpha]^{20}_D$ −23.9".

After standing two more days a mass of fine crystals (0.25 g.) and two large clusters of fine needles (0.1 g.) had separated from the decanted solution. These were removed and dried. The melting point of the 0.1-g. portion was 195° with sintering at 175".

Rotation of the 0.1 g. portion: 0.0548 g. made up to 3 cc. with chloroform at 20° gave α_D −3.1°; $l = 1$; $[\alpha]^{20}_D$ −169.7'.

The 0.1-g. portion was recrystallized from benzene. The melting point was unchanged.

Rotation. 0.0292 g. made up to 2 cc. with chloroform at 20" gave α_D −2.42'; $l = 1$; $[\alpha]^{20}_D$ −165.8'.

Rotation of the 0.25-g. portion: 0.0604 g. made up to 3 cc. with chloroform at 20° gave α_D −2.75'; 1 = 1; $[\alpha]^{20}_D$ −136.6".

Anal. Calcd. for $C_{42}H_{38}O_6N_2$: C, 75.64; H, 5.75. Found: C, 75.47; H. 5.71.

The remaining salt solution was evaporated to dryness and gave 0.25 g. of salt which sintered at 173° and melted at 190°.

Rotation. 0.0570 g. made up to 3 cc. with chloroform at 20° gave α_D = +3.65°; $l = 1$; $[\alpha]^{20}_D$ +192.1°.

The first portion (0.24 g.) of salt which was obtained in the fractionation consisted mainly of the *d,l*-salt. Upon refractionation from benzene the partially pure d- and *l*-salts were obtained.

***d*-8,8′-Dicarboxy-1,1′-dinaphthyl.**—To 0.24 g. of salt having a rotation of +192.1° in chloroform was added 10 cc. of 0.5 *N* hydrochloric acid. After stirring for ten

---

[4] Kalb, Ber., 47, 1724 (1914).

minutes the mixture was filtered. This treatment was repeated twice and the precipitated acid was dissolved in 15 cc. of 0.1 N sodium hydroxide and extracted twice with 5 cc. of chloroform. The active acid was then precipitated from the alkaline solution with dilute hydrochloric acid. After drying, the product melted to a red liquid at 305–306°.

Rotation. (a) 0 0210 **g.** made up to 2 cc. with pyridine at 20° gave α_D +2.08°; 1 = 1; $[\alpha]_D^{20}$ +198.1°. **(b)** 0.0336 g. made up to 15 cc. with 0.1 *N* sodium hydroxide gave a, —0.28'; 1 = 0.5; $[\alpha]_D^{20}$ —250.0°. (c) 0.0190 g. made up to 5 cc. with **2** *N* aqueous ammonia gave a, —0.35°; *l* = 0.5; $[\alpha]_D^{20}$ —184.2".

A portion of the d-salt having a rotation of +44.5° in chloroform was hydrolyzed in a similar manner to give partially pure d-acid.

Rotation. (a) 0 02.50 g. made up to 9 cc. with 0.5 N aqueous ammonia gave a, —0.12"; *l* = 1; $[\alpha]_D^{20}$ —43.2'. (b) 0.0240 g. made up to 2 **cc.** with pyridine at 20° gave α_D +0.88°; 1 = 1; $[\alpha]_D^{20}$ +73.1°.

It was necessary to use dilute alkaline solutions of the d-acid since concentrated alkaline solutions of the d-acid were always cloudy. Repeated solution in alkali, extraction with chloroform and precipitation with hydrochloric acid did not change this property.

***l*-8,8'-Dicarboxy-1,1'-dinaphthyl.**—A portion of I-salt having a rotation of **—169.7°** in chloroform was hydrolyzed by treatment with three 5-cc. portions of 0.5 *N* hydrochloric acid and extraction of the alkaline solution with chloroform. The Z-acid so obtained melted to a red liquid at 304.5–305.5°.

Rotation. 0.0240 g. made up to 2 cc. with pyridine at 20° gave α_D **—2.25°; *l* = 1;** $[\alpha]_D^{20}$ —185.8'.

Anal. Subs.. 4.447 mg.: CO_2, 12.57 mg.: H_2O, 1.68 **mg. Calcd.** for $C_{22}H_{14}O_4$: C, 77.17; H, 4.12. Found: C, 77.02; H, 4.23.

A portion of 1-salt having a rotation of —136.6° in chloroform was hydrolyzed ***by*** treatment with three 10-cc. portions of 0.5 *N* hydrochloric acid, solution in 0.5 *N* aqueous ammonia and immediate precipitation with dilute hydrochloric acid.

Rotation. 0.0225 **g.** made up to 2 cc. with pyridine at 20° gave α_D —2.02"; *l* = **1;** $[\alpha]_D^{20}$ —179.6'.

The I-acid was precipitated from the pyridine solution by the addition of concentrated hydrochloric acid at 0°. The rotation was again taken.

Rotation. 0.0187 g. made up to **2** cc. with 2 *N* ammonium hydroxide at 20° gave α_D +0.31°; *l* = 1; $[\alpha]_D^{20}$ +33.1°.

Racemization Experiments

1. **A** solution of 0.0210 g. of d-acid in 2 cc. of pyridine at 20° gave a, +2.08°; *l* = 1; $[\alpha]_D^{20}$ +191.1°. Heating the solution at 100° for thirty minutes caused complete racemization of the acid.

2. **A** solution of 0.0240 g. of I-acid in 2 cc. of pyridine at 20° gave a, —2.25"; 1 = 1; $[\alpha]_D^{25}$ —185.8". Standing for five weeks at room temperature caused almost complete racemization since the rotation was —5°: a, —0.06°; 1 = 1; $[\alpha]_D^{20}$ —5.0°.

3. A solution of 0.0187 g. of *l*-acid in 2 cc. of 2 *N* aqueous ammonia at 20° gave α_D +0.31°; 1 = 1; $[\alpha]_D^{20}$ +33.1°. After standing at 19° for fifteen hours the rotation was zero.

4. A solution of Eacid in 2 *N* aqueous ammonia having a, +0.24° was allowed to stand at 19°; after two hours a, +0.18°; after four hours a, +0.13°; after six hours α_D +0.08; after ten hours a, 0°.

5. A solution of 0.0336 g. of d-acid in 15 cc. of 0.1 N sodium hydroxide gave α_D —0.28"; *l* = 0.5; $[\alpha]_D^{20}$ —250.0". After heating the solution at 90° for thirty minutes the rotation was zero.

6. A portion of 0.0314 g. of acid having a rotation of −179° in pyridine was added to 3 cc. of acetic anhydride. The mixture was heated to boiling during one minute to effect solution and then immediately cooled to 20°. The rotation of the acetic anhydride solution was zero. The acetic anhydride was removed below 20° by means of a stream of air under vacuum and the residue dissolved in 2 cc. of pyridine. The rotation of the pyridine solution was zero.

The material recovered from the pyridine solution was recrystallized from benzene and had a melting point of 179–180°. It was insoluble in cold alkali and but slowly soluble in hot alkali, from which solution the original acid of m. p. 306–307° was obtained upon acidification. An analysis proved it to be the mixed acid anhydride of one molecule of 8,8′-dicarboxy-1,1′-dinaphthyl and two molecules of acetic acid.

Anal. Subs., 5.063 mg.: CO_2, 13.66 mg.; H_2O, 1.89 mg. Calcd. for $C_{26}H_{18}O_6$: C, 73.21; H, 4.25. Found: C, 73.68; H, 4.18.

When this mixed acid anhydride was heated above its melting point (180°) bubbles were evolved from the light yellow liquid and at 198–202° the liquid was converted to a red colored solid. After washing with hot dilute sodium hydroxide and recrystallization from chloroform this material melted at about 340°. This compound proved to be the anthanthron which was previously prepared by Kalb[4] by the action of concentrated sulfuric acid on 8,8′-dicarboethoxy-1,1′-dinaphthyl. Solution in concentrated sulfuric acid caused a bright green coloration.

Anal. Subs.: 2.619 mg.: CO_2, 8.26 mg.; H_2O, 0.77 mg. Calcd. for $C_{22}H_{10}O_2$: C, 86.25; H, 3.29. Found: C, 86.01; H, 3.29.

Summary

1. 8,8′-Dicarboxy-1,1′-dinaphthyl has been resolved into optical isomers by fractionation of the monoquinine salt from benzene.

2. This compound is the first α,α'-disubstituted diphenyl derivative which has been resolved.

3. The optically active acids were readily racemized.

SIGNIFICANT TEMPERATURES IN THE PYROLYSIS OF CERTAIN PENTANES AND PENTENES[1]

BY JAMES F. NORRIS AND GEORGE THOMSON

RECEIVED MAY 29, 1931 PUBLISHED AUGUST 5, 1931

Previous determinations in this Laboratory of the temperatures at which certain ethers[2] and a number of alkyl derivatives of malonic acid[3] begin to decompose when heated under definite conditions showed that these temperatures could be determined in independent experiments that gave results which agreed within ±2 degrees. The values obtained made it possible to correlate the temperatures at which certain bonds were broken

---

[1] From the thesis presented by George Thomson in partial fulfilment of the requirement for the degrer of Doctor of Philosophy, 1930.

[2] Norris and Young, THIS JOURNAL, 52, 753 (1930).

[3] Norris and Young, *ibid.*, 52, 5066 (1930).

by pyrolysis with the rates at which these bonds were broken in a chemical reaction. The results showed, also, the effect of the structure of the alkyl radicals present on the temperature of pyrolysis.

The satisfactory results obtained in the earlier experiments led to the study in a similar way of the temperatures at which certain pentanes and pentenes begin to decompose when heated. With this information it would be possible to effect the pyrolysis of the hydrocarbons at or near their cracking temperatures and thus obtain the products first formed in their decomposition. It was expected that the results would lead to a better understanding of the mechanism of pyrolysis and to added knowledge of the effect of structure on the lability under the influence of heat of the carbon-carbon and carbon–hydrogen bonds in hydrocarbons.

This 'method of investigating the cracking of hydrocarbons seemed worthy of study, because previous work in this field has been carried out at such temperatures that profound decomposition resulted, and the number of products formed was so large that it was impossible to draw any definite conclusions as to the mechanism of the many reactions involved. For example, the pyrolysis of pentane and isopentane have been studied by Calingaert[4] at 600° and by Hague and Wheeler[5] at temperatures between 600 and 850°. Calingaert determined quantitatively eight products of the pyrolysis.

It is shown in this paper that normal pentane begins to pyrolyze at 391° and isopentane at 383°. Experiments now in progress indicate that at ten degrees above these temperatures a simple decomposition takes place as the result of the breaking of a single carbon–carbon linkage in each case. These experiments will be reported later. This paper is confined to the consideration of the temperatures at which the hydrocarbons begin to pyrolyze and the rates at which the reactions proceed at different temperatures.

In the determination of the temperature at which pyrolysis begins, the hydrocarbon was heated for about one hour, at a definite temperature, in a glass apparatus in which the expansion that occurred under approximately atmospheric pressure could be measured. At temperatures below that of decomposition no expansion was evident after thermal equilibrium had been established. As the temperature at which the vapor was held was raised, step by step, a temperature was reached at which expansion due to pyrolysis continued throughout the hour. From the increase in the volume of the vapor in a measured time, the rate of expansion at this temperature was calculated. The values of these rates at different temperatures were plotted against the temperatures. Figure 1 shows the results of an experiment when n-pentane was used.

---

[4] Calingaert, THIS JOURNAL, *45*, **130** (1923).

[5] Hague and Wheeler, *J. Chem. Soc.*, **378** (1929).

It is seen that intersecting straight lines can be drawn through the points. In the case of this hydrocarbon at temperatures up to 389° there was no expansion when the hydrocarbon was held at these temperatures for an hour. Above 389° expansion continued throughout the hour at the rates indicated.

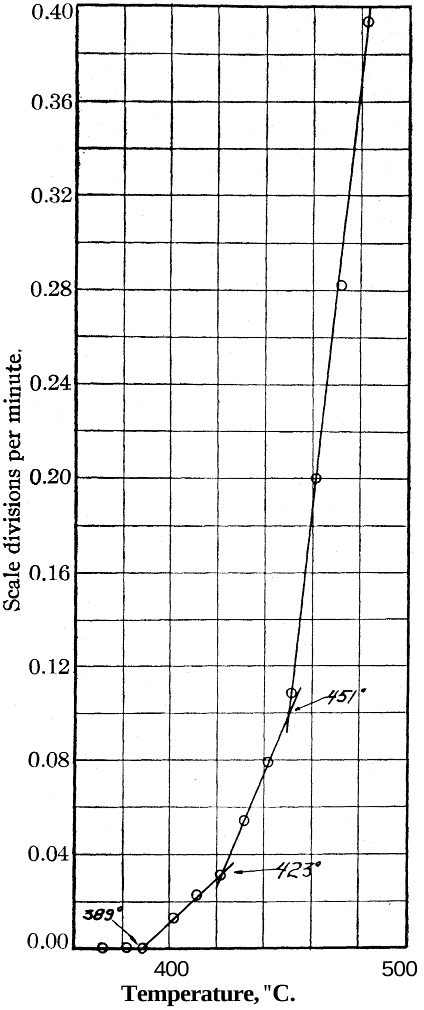

Fig. 1.—n-Pentane cracking rate curve: 1 Scale div. = 0.09 cc. at 40°.

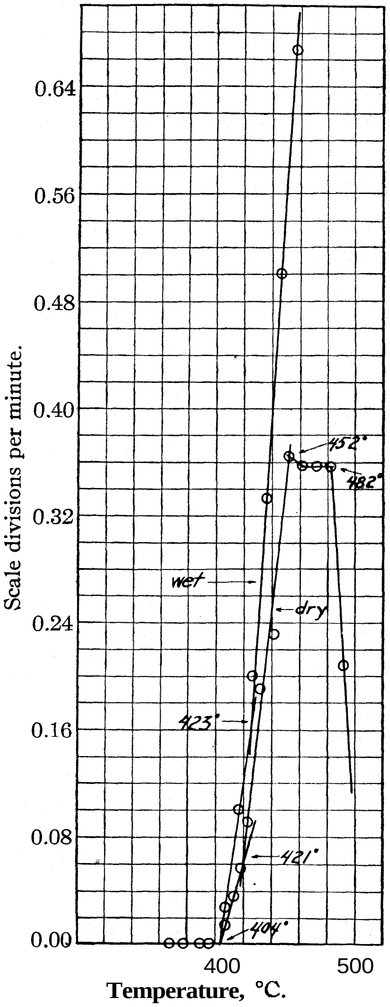

Fig. 2.—Pentene-2 cracking rate curve: 1 Scale div. = 0.09 cc. at 40°.

It appeared probable that between 389 and 423° one type of decomposition was taking place and that between **423** and 451° another type had set in. Above 451° the increased rate indicated more profound decomposition.

To determine whether or not the breaks in the lines represent real changes in the way in which the hydrocarbon undergoes pyrolysis, Mr. George Standley is now investigating the products formed at temperatures within the ranges indicated. It can be said at this time that the results are in accord with the view put forward above.

In the case of the unsaturated hydrocarbons the results were similar to those obtained with the paraffins, except that an additional significant temperature was observed. Above a certain temperature the rates of expansion either remained constant, or decreased as the temperature was increased. It is evident that at these higher temperatures two types of reactions are taking place simultaneously, namely, pyrolysis, which causes expansion, and another change which leads to contraction.

The examination of the cooled vessel in which the hydrocarbon had been pyrolyzed above the temperature at which the rate of expansion began to decrease (reversal temperature) showed that there had been formed a yellowish-brown oil less volatile than the hydrocarbon used. Below the reversal temperature there was little or no high-boiling oil formed. These observations indicate that the decrease in the rate of expansion is associated with the formation of polymers.

The behavior of pentene-2 is shown in Fig. 2 by the lines marked "dry," which record the rates of decomposition when the hydrocarbon was free from moisture. By plotting the rates it is possible to discover a temperature at which no expansion occurs (reversal temperature), since at this temperature the rates of the two types of reactions are the same.

The reversal temperatures of the three pentenes studied were from 53 to 65° above the temperatures at which the hydrocarbons began to decompose.

The influence of a trace of water in the pyrolysis of pentene-2 was investigated. The results are shown in Fig. 2. There appeared to be no influence on the pyrolysis temperature, but the rate of decomposition was doubled. Reversal in the rate, indicating polymerization, did not occur with the wet hydrocarbon at about ten degrees above the reversal temperature of the dry hydrocarbon.

The results obtained with the hydrocarbons studied are given in Table I.

The tabulated results show that n-pentane begins to decompose at a temperature higher than that at which its isomer with a branched chain begins to decompose; that pentane-2 and pentene-1 crack at about the same temperature; that pentene-2 is more stable to heat than pentene-1, and that the increase in the number of radicals joined to doubly linked carbon atoms in trimethylethylene leads to increased thermal stability.

In Table II are given for each hydrocarbon the percentage expansion per hour at ten degrees above the significant temperatures recorded in Table I and the increase in these values per ten degrees within the stated temperature intervals.

TABLE I

SIGNIFICANT TEMPERATURES IN THE PYROLYSIS OF THE HYDROCARBONS LISTED

	Initial cracking temp., °C.	Second break, °C.	Third break, °C.	Reversal temperature, °C.
Isopentane	383	419	449	
	383	426	450	
	383 Average	423 ± 3.3	45010.5	
Pentene-1	387	418		457

TABLE II

THE FIGURES REFER TO THE ACTUAL EXPANSION OF THE HYDROCARBON VAPOR AT THE TEMPERATURE INDICATED

Hydrocarbon	Expansion 10° above initial break, %/hr.	Expansion Increase per 10°, %/hr.	Expansion 10° above sec. break, %/hr.	Expansion increase per 10°, %/hr.	Expansion 10 above third break, %/hr.	Expansion Increase per 10°, %/hr.	Maximum expansion, %/hr.
Isopentane	0 22	0 22 (383–423°)	1.6	0 7 (423–450°)	4.6	1 7 (450–485°)	
Pentene-1	.67	0 67 (389–420°)	4.4	2.1 (420–456°)			10.4 (456°)
n-Pentane	.22	0.22 (391–426°)	1.6	0.7 (426–450°)	5.1	2 5 (450–482°)	
Pentene-2	.68 (Dry)	0 68 (Dry) (400–421°)	3.7 (Dry)	2.4 (421–453°)			
	1.36 (Wet)	1.36 (Wet)	6.3 (Wet)	3.6 (421–459°)			8.8 (453°)
Trimethylethylene	1.2	1.2 (433–448°)	4.1	2.2 (448–475°)			9.9 (493°)

The results show that pentene-1 and pentene-2 decompose three times as rapidly as n-pentane and isopentane when the hydrocarbons are heated ten degrees above their respective cracking temperatures. Trimethylethylene decomposes about twice as fast as the straight-chain olefins and six times as fast as the paraffins at ten degrees above their respective cracking temperatures. Within the same temperature range (433–448°), it decomposes about twice as fast as the pentanes. Other significant facts which can be drawn from the table will be considered in a subsequent paper in which the study of the products of pyrolysis will be reported.

The work is being extended to other hydrocarbons. It is planned to investigate the influence of increased surface per volume of vapor, and of the presence of catalytic agents on the temperatures of pyrolysis. The theoretical aspect of the subject will be considered later.

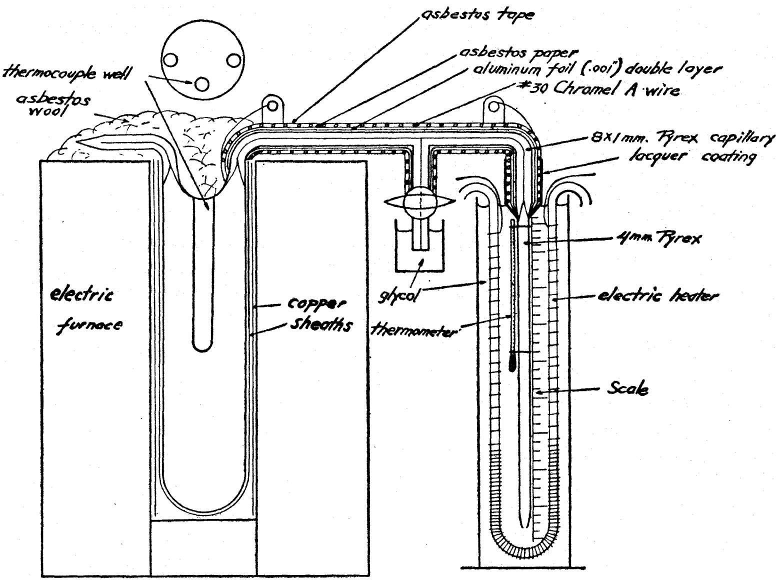

Fig. 3.

Experimental Part

Apparatus.—The apparatus consisted of an electric furnace in which was inserted a Pyrex bulb of about 52 cc. capacity connected by capillary tubing to a manometer arrangement as shown in Fig. 3. The bulb contained a thermocouple well and had another capillary opening to facilitate cleaning. Two copper sheaths surrounding the bulb in the furnace produced uniform temperature distribution. A double layer of aluminum foil underneath the electric heater on the capillary tube leading to the manometer served the same purpose.

The manometer tube was made of 4-mm. Pyrex tubing and was immersed in a hydrometer jar filled with ethylene glycol kept at a constant temperature of 40° by an electric heater. An experiment had shown that the vapors of the hydrocarbons were insoluble in glycol. The hydrometer jar was provided with a scale for reading the liquid level in the manometer tube. To prevent the glycol from soaking up into the electric heater on the capillary tube, the end of the heater was covered with several coats of lacquer.

In order to bring the manometer level to the zero mark, the stopcock on the capillary tube could be opened and gas allowed to escape.

A calibrated chromel–alumel thermocouple connected to a Leeds and Northrup portable potentiometer was used to measure the temperature of the hydrocarbon gas.

Since the olefins absorb oxygen to form peroxides on standing in bottles containing air, and the saturated hydrocarbons absorb some moisture, each hydrocarbon was distilled over sodium, just before each determination, directly into an 8 mm. × 14 cm. tube until from 1 to 1.5 cc. of hydrocarbon had collected. Chips of freshly cut sodium were then dropped in until there was enough to reach the surface of the liquid. The tube was then slipped over the end of the manometer tube on the apparatus and made tight with a short piece of pressure tubing. After surrounding the hydrocarbon with carbon dioxide snow and acetone, the apparatus was evacuated to less than 1 mm. pressure while at the same time the electric heater on the side arm was turned on and the bulb baked out with a Bunsen burner for several minutes. The heater was then turned off and the bulb allowed to cool. It was then immersed in ice and water and the carbon dioxide snow and acetone substituted by glycol at about the same temperature as the boiling point of the hydrocarbon. This caused the hydrocarbon to distil slowly over and condense in the bulb, which was then inserted in the electric furnace and the tube containing the sodium residue immersed in the hydrometer jar filled with warm glycol so that the rubber connection was just covered. As soon as the temperature of the bulb reached the boiling point of the hydrocarbon, this tube with its rubber connection was pushed off with a pair of tongs and the hydrometer jar raised to the position shown in the sketch. The sweeping action of the excess hydrocarbon boiling out was an added assurance of the absence of air.

When pentene-2 was run wet, the hydrocarbon was distilled over sodium into the 8 mm. tube as before but instead of adding chips of sodium a drop of water was added. The rest of the procedure was the same as when *dry*.

If, after holding the bulb at constant temperature for one hour, no expansion occurred, the temperature was raised 10° and again held constant for one hour. Eventually a temperature was reached at which expansion was appreciable. Scale readings were then taken over a period of sixty to eighty minutes. As the rate became greater this period was shortened until at 80 to 100° above the initial temperature readings were taken over a period of twenty minutes. These readings (4 at the higher temperatures, 8–9 at the lower temperatures) when plotted against time fell on straight lines the slopes of which were plotted against the corresponding temperatures. The intersection of this curve with the zero rate line fixed the initial temperature more accurately.

Materials

Pentene-1 was prepared in this Laboratory by Dr. R. L. Wakeman from ethylmagnesium bromide and allyl bromide. Final distillation over sodium gave a boiling point of 30.0–30.1" (corr.),[6] d_4^{20} 0.641.

Pentene-2 was made by dehydrating secondary amyl alcohol with sulfuric acid according to the method of Norris ["Organic Syntheses," Vol. VII, p. 76]. After drying and distilling over sodium it boiled at 36.3–36.4° (corr.).

2 Methylbutene-2 was obtained from tertiary amyl alcohol by dehydrating with oxalic acid. The mixture of 2-methylbutene-2 and 2 methylbutene-1 after many distillations through a Davis' column gave about a 12% yield of 2-methylbutene-2, b. p. 38.3–38.4° (corr.).

---

[6] Kirrmann, [Bull. *soc. chim.*, 39, 988 (1926)] gives the b. p. as 30.5–31.0° but Hyman and Wagner, [THIS JOURNAL, 52, 4346 (1930)] found the b. p. to be 30.0" (corr.).

[7] H. S. Davis, *Ind. Eng. Chem., Analytical Edition*, 1, 61 (1929).

***n*-Pentane.**—By hydrogenating the above pentene-2, using nickel catalyst and purifying the product with sulfuric acid, very pure pentane was obtained, boiling at 36.1–36.2° (corr,).

Isopentane was obtained in a manner similar to that used for n-pentane but using the amylene mixture from the dehydration of *tert.*-amyl alcohol. The final product boiled at 27.9–28.0° (corr.).

Summary

1. The temperatures have been determined at which n-pentane, isopentane, pentene-1, pentene-2 and trimethylethylene begin to decompose when heated in a Pyrex glass vessel for one hour.

2. The determination of the rates at which these hydrocarbons decompose showed that for each hydrocarbon the increase in rate per ten degrees was constant within certain temperature limits and that this increase in rate was greater within the higher temperature limits. It appears probable that the limiting temperatures of the several ranges are the temperatures at which certain bonds undergo pyrolysis.

3. It was found that a trace of moisture had no effect on the cracking temperature of pentene-2, but that it doubled the rate at which the hydrocarbon decomposed.

4. When the olefins were heated at increasing temperatures, a temperature was found at which no expansion took place. The results indicate that at this point the expansion which results from pyrolysis is equal to the contraction resulting from polymerization.

THE STRUCTURE AND SOME DERIVATIVES OF PARA-DIMETHYLAMINO-PARA-CHLOROBENZOIN

BY SANFORD S. JENKINS[1]

RECEIVED MAY 29, 1931 PUBLISHED AUGUST 5, 1931

The object of this report is to present the experimental evidence in support of a structure which is assigned to *p*-dimethylamino-*p*-chlorobenzoin[2] and to describe the preparation and some properties of a number of related compounds.

The starting material was prepared by condensing *p*-dimethylaminobenzaldehyde and *p*-chlorobenzaldehyde by means of potassium cyanide. The substance thus prepared melts at 128° and is readily oxidized with Fehling's solution to the corresponding benzil, which fuses at 144.5°.

Several methods have been employed for determining the structures

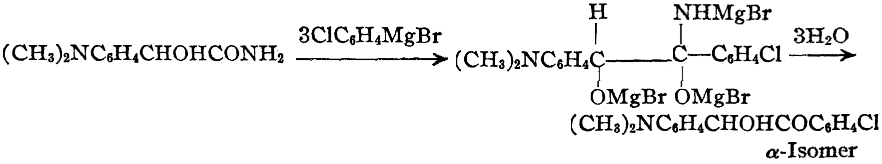
---

[1] Grafflin Scholar, 1930–1931.

[2] Staudinger, Ber., 46,3538 (1913).

of unsymmetrical benzoins. For example, Meisenheimer and Jochelson[3] obtained benzanisoin by the action of alkali on a-bromobenzyl *p*-methoxyphenyl ketone. Tiffeneau and Levy[4] have determined the structures of a number of these substances by fission with potassium hydroxide and more recently the method of Werner and Detscheff,[5] which makes use of the Beckmann rearrangement of the benzoin oximes has been extended by Buck and Ide.[6] The foregoing, however, cannot be classed as direct methods since other standards are required for comparison. Other methods,[7] in which the Grignard reaction is used, are directly applicable to studies of this nature, since they lead to the synthesis of isomers of known structure and hence direct comparison with the original material is possible.

Thus, with the aid of the Grignard reaction[7'] both of the isomeric *p*-dimethylamino-*p'*-chlorobenzoins were prepared and studied. *p*-Dimethylaminomandelamide was condensed with *p*-chlorophenylmagnesium bromide and after hydrolysis of the resulting complex *p*-dimethylamino-α-hydroxybenzyl *p'*-chlorophenyl ketone was obtained and for convenience will be called α-*p*-dimethylamino-*p'*-chlorobenzoin. This melted at 104.5° and on oxidation with Fehling's solution it produced the same benzil as did the "starting material" with like treatment; however, a mixed melting point determination with the latter substance showed a large depression. It is thus evident that α-*p*-dimethylamino-*p'*-chlorobenzoin is different from but isomeric with the starting material. In order to obtain the other or β-isomer, *p*-chloromandelamide[8] was reacted with *p*-dimethylaminophenylmagnesium bromide and p-chloro-a-hydroxybenzyl *p'*-dimethylaminophenyl ketone was obtained. This substance melted at 128,° produced the above benzil on oxidation and when mixed with the starting material showed no depression of the melting point. Thus it is seen that *p*-dimethylamino-*p'*-chlorobenzoin as produced by condensing the respective aldehydes is the β-isomer and has the structure $(CH_3)_2NC_6H_4COCHOHC_6H_4Cl$. The reactions are



$$(CH_3)_2NC_6H_4CHOHCONH_2 \xrightarrow{3ClC_6H_4MgBr} (CH_3)_2NC_6H_4\underset{\underset{OMgBr}{|}}{\overset{\overset{H}{|}}{C}}-\underset{\underset{OMgBr}{|}}{\overset{\overset{NHMgBr}{|}}{C}}-C_6H_4Cl \xrightarrow{3H_2O}$$

$$(CH_3)_2NC_6H_4CHOHCOC_6H_4Cl$$

α-Isomer

β-Isomer

A very interesting observation was made during the study of the above isomers. It was found that the a-derivative readily produced the β-compound when heated for a short time with alcoholic potassium cyanide. An investigation of this reaction is being made, the results of which will be published in the near future.

As was stated above *p*-dimethylamino-*p*′-chlorobenzil was obtained when either a- or β-*p*-dimethylamino-*p*′-chlorobenzoin was oxidized with Fehling's solution. On reduction with tin and hydrochloric acid the α-benzoin produced a compound melting at 140° which was found to be *p*-dimethylaminobenzyl *p*′-chlorophenyl ketone, and for convenience will be designated α-*p*-dimethylamino-*p*′-chlorodesoxybenzoin. When the @-benzoin was reduced in a similar manner, not only the a-desoxy derivative was isolated but another substance melting at 170° was obtained. The latter proved to be p-chlorobenzyl *p*′-dimethylaminophenyl ketone, which will be called β-*p*-dimethylamino-*p*′-chlorodesoxybenzoin. These compounds were readily separated since the a-isomer was much more soluble in acid solution than the @-derivative. Furthermore, on reduction with sodium amalgam β-*p*-dimethylamino-*p*′-chlorobenzoin formed the corresponding hydrobenzoin, melting at 180,° which, when heated with a mixture of acetic and hydrochloric acids, readily lost water and formed α-*p*-dimethylamino-*p*′-chlorodesoxybenzoin in good yield. No attempt was made to reduce the a-benzoin under similar conditions since only a small quantity of this material was available.

The oximes were obtained by heating the desoxybenzoins in pyridine solution with an excess of hydroxylamine hydrochloride. a-@-Dimethylamino-*p*′-chlorodesoxybenzoin oxime melted at 150.5° while β-*p*-dimethylamino-*p*′-chlorodesoxybenzoin oxime was found to melt at 152°. An interesting observation was made in preparing the a-oxime—in the reaction mixture a substance was always found, in small percentage, which melted at 229° and proved to be *p*-dimethylamino-*p*′-chlorostilbene (described below). This unusual side reaction is being studied further.

The structure of β-*p*-dimethylamino-*p*′-chlorodesoxybenzoin was deduced in the following manner. *p*-Dimethylaminobenzaldehyde was condensed with *p*-chlorobenzylmagnesium bromide and p-chlorobenzyl-*p*′-dimethylaminophenylcarbinol was obtained, which melted at 112°. When the β-desoxy derivative was reduced with sodium amalgam, this carbinol was also produced. The following reactions will make this clear.

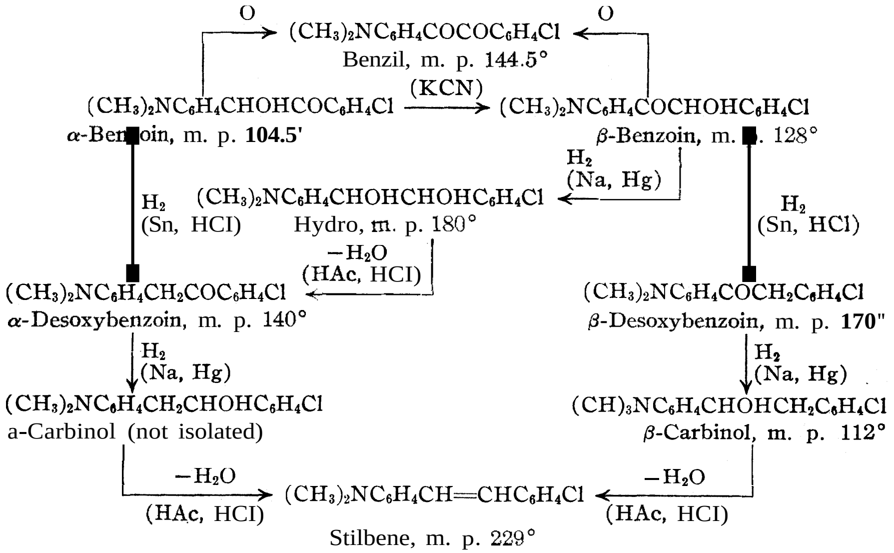
$$(CH_3)_2NC_6H_4CHO \xrightarrow{ClC_6H_4CH_2MgBr} (CH_3)_2NC_6H_4CH(OMgBr)CH_2C_6H_4Cl \xrightarrow{H_2O} (CH_3)_2NC_6H_4CHOHCH_2C_6H_4Cl \quad (I)$$

$$(CH_3)_2NC_6H_4COCH_2C_6H_4Cl \xrightarrow[(Na,\ Hg)]{H_2} (CH_3)_2NC_6H_4CHOHCH_2C_6H_4Cl \quad (II)$$

When dehydrated by the acetic–hydrochloric acid mixture the above carbinol, produced by either method (I or II), lost water and formed *p*-dimethylamino-*p'*-chlorostilbene, melting at 229°. When α-*p*-dimethylamino-*p'*-chlorodesoxybenzoin was likewise reduced with sodium amalgam, an isomeric carbinol was produced which also readily lost water in an analogous manner with the formation of this stilbene. Thus it is seen that the a- and β-desoxy derivatives are isomeric and have the structures

$(CH_3)_2NC_6H_4CH_2COC_6H_4Cl$ and $(CH_3)_2NC_6H_4COCH_2C_6H_4Cl$
α-*p*-Dimethylamino-*p'*-chlorodesoxybenzoin β-*p*-Dimethylamino-*p'*-chlorodesoxybenzoin

The reactions which have been described above are represented in the following diagram



The writer wishes to thank Dr. E. Emmet Reid for his interest and help in this work.

Experimental

α-*p*-Dimethylamino-*p*-chlorobenzoin.—A mixture of **15** g. of *p*-chlorobromobenzene, **2** g. of magnesium turnings and **50** cc. of anhydrous ether was refluxed for three hours. Then **3 g.** of *p*-dimethylaminomandelamide,[7c] finely powdered, was added in small portions, over a period of thirty minutes. After heating over a twenty-five watt light for eight hours, the solution was poured into **200** g. of water and crushed ice containing **20** g. of concentrated sulfuric acid. The ether was removed and the aqueous layer extracted with two 100-cc. portions of ether. The extracts were discarded. The acid solution was then neutralized with ammonia and the yellow precipitate which formed was separated, dissolved in 50 cc. of alcohol and filtered hot. On cooling a mass of yellow needles separated which weighed 2.0 g. and melted at 96–98". After two crystallizations from ligroin (Skellysolve "C") the product melted at 104.5° (corr.).

β-*p*-Dimethylamino-*p*′-chlorobenzoin

First Method.—To a solution of 28.7 g. of *p*-dimethylaminobenzaldehyde and 28.1 g. of *p*-chlorobenzaldehyde dissolved in 140 cc. of 95% alcohol was added 5 g. of potassium cyanide dissolved in 60 cc. of water. The mixture was refluxed for one hour and allowed to cool. The crystalline material was separated, washed twice with water and once with a small portion of alcohol; yield, 21 g. To the filtrate was added 3 g. more of potassium cyanide. The solution was then heated for an hour, allowed to cool and the solid filtered. After washing with water and alcohol it weighed 6 g. The two crops of crystals were then combined and recrystallized twice from alcohol. The almost white needles melted at 128" (corr.).

Second Method.—A mixture of 20 g. of *p*-bromodimethylaniline, 3 g. of magnesium and 100 cc. of anhydrous ether was refluxed for forty-eight hours. After the heating, 1.3 g. of finely powdered *p*-chloromandelamide[8] was added in small portions over a period of thiiy minutes. The solption was then refluxed for an additional eight hours and poured into 200 g. of crushed ice and water containing 20 g. of concentrated sulfuric acid. The mixture was stirred until all of the solid matter had dissolved. The clear solution was then extracted with six 50-cc. portions of ether. In this case the water layer was discarded. The ether solution was washed first with a 2% solution of sodium carbonate and then with water. The ether was distilled. The solid was then dissolved in a small amount of alcohol, filtered hot and allowed to crystallize; weight, 0.50 g. After two further crystallizations from alcohol, it melted at 128° (corr.).

Third Method.—Five-tenths of a gram of the a-benzoin and 0.10 g. of potassium cyanide dissolved in 20 cc. of 70% alcohol were heated for thirty minutes and allowed to cool. The crystalline material was filtered off, washed with water and recrystallized from a small portion of alcohol. It weighed 0.40 g. and melted at 128" (corr.). When this material was mixed with that obtained by the other methods, there was no depression of the melting point; when a mixed melting point determination was made with the a-benzoin, however, there was a depression of 10–15°.

***p*-Dimethylamino-*p*′-chlorobenzil.**—This material was obtained from α- or β-*p*-dimethylamino-*p*′-chlorobenzoin in 90% yield when an alcoholic solution of either of these substances was heated for half an hour with an excess of concentrated Fehling's solution on the water-bath. The benzil crystallized from alcohol in thin orange-colored needles which melt at 144.5° (corr.).

***p*-Dimethylamino-*p*′-chlorohydrobenzoin.**—To 15 g. of *p*-dimethylamino-*p*′-chlorobenzoin was added 200 cc. of alcohol. The benzoin was dissolved by heating to 50–60° on the water-bath. To the solution was added 20 cc. of water and 150 g. of 4% sodium amalgam in portions, over a period of one hour. The mixture was kept at 50–60° for four hours while a steady stream of carbon dioxide was passed into it. Small portions of acetic acid were added at intervals but at no time was the mixture allowed to become acid. The mixture was occasionally shaken. After standing overnight at room temperature, 200 cc. of water was added and the suspended matter was decanted from the mercury onto a filter. After washing several times, the solid was recrystallized from alcohol; yield, 7.5 g.; m. p. 180° (corr.). There was another substance present which was quite soluble in the dilute alcohol, perhaps the isohydrobenzoin, but no attempt was made to purify it.

α-*p*-Dimethylamino-*p*'-chlorodesoxybenzoin

First Method.—To 1 g. of the hydrobenzoin (prepared in the above manner) were added 15 cc. of glacial acetic acid and 5 cc. of concentrated hydrochloric acid. The mixture was boiled for ten minutes, after which 50 cc. of water was added. The solution was then neutralized with 10% sodium carbonate solution allowed to stand for a few minutes and filtered. The solid was washed several times with water and crystallized from alcohol. The product was obtained in a yield of 0.80 g. and melted at 140° (corr.).

Second Method.—A mixture of 0.50 g. of α-*p*-dimethylamino-*p*'-chlorobenzoin, 0.50 g. of mossy tin, 3 cc. of concentrated hydrochloric acid, a small crystal of copper sulfate and 10 cc. of alcohol was heated for five hours. The solution was filtered hot, 50 cc. of water added and neutralized with sodium carbonate. The mixture was allowed to stand for a while, after which the precipitate was filtered, washed several times with water, sucked dry and extracted twice with hot alcohol (25-cc. portions). The extract was evaporated to a volume of about 15 cc. and cooled; yield, 0.30 g. After two crystallizations from alcohol the substance melted at 140° (corr.).

Third Method of Preparing **α-*p*-Dimethylamino-*p*'-chlorodesoxybenzoin.**—The filtrate from which the β-desoxy compound (described below) had been obtained was made slightly alkaline with sodium carbonate. After standing for a while the solid was separated, washed several times with water and extracted three times with 100-cc. portions of alcohol. The solution was then evaporated to a volume of about 50 cc. and allowed to cool. The solution deposited 3.50 g. of substance which after two crystallizations from alcohol formed almost white plates and melted at 140° (corr.). Mixed melting point determinations with the substance made by methods ***one*** and ***two*** showed no depression.

β-*p*-Dimethylamino-*p*'-chlorodesoxybenzoin.—A mixture of 11 g. of β-*p*-dimethylamino-p'-chlorobenzoin, 10 g. of mossy tin, 0.50 g. of copper sulfate, 20 cc. of concentrated hydrochloric acid and 40 cc. of alcohol was refluxed for five hours. The hot solution was filtered and 10 cc. of water added. On cooling the solution deposited 5 g. of fine white prisms. To the filtrate 40 cc. of water was added and 0.50 g. more of the same material was obtained. After two recrystallizations from alcohol the substance melted at 170° (corr.).

p-Chlorobenzyl-*p*'-dimethylaminophenylcarbinol

First Method. (β-*p*-**Dimethylamino-*p*'-chlorostilbene** Hydrate.)—A mixture of 20 g. of p-chlorobenzyl bromide, 2.50 g. of magnesium turnings and 100 cc. of ether was refluxed for three hours. A solution of 14 g. of p-dimethylaminobenzaldehyde in 100 cc. of ether was then added slowly over a period of forty-five minutes from a dropping funnel. The solution was heated for two hours and poured into 200 cc. of crushed ice and water containing 20 g. of concentrated sulfuric acid. The ether layer was separated and discarded. The water layer was made slightly alkaline with ammonium hydroxide and extracted twice with 100-cc. portions of ether. The ether solution was dried over anhydrous sodium sulfate and the ether distilled off. A yield of 20 g. of crude material was obtained. After two crystallizations from 80% alcohol the substance was obtained as white needles melting at 112° (corr.).

Second Method.—A mixture of 1.0 g. of β-*p*-dimethylamino-*p*'-chlorodesoxybenzoin, 50 cc. of alcohol (90%) and 25 g. of sodium amalgam was warmed to 50–60° while a slow stream of carbon dioxide was admitted. The reaction was allowed to proceed for four hours at this temperature. During this time the mixture was frequently shaken. The solution was then decanted from the mercury and diluted with 100 cc. of water. The solid was filtered off and washed with water, after which it was recrystallized from a small amount of 80% alcohol. A yield of 0.40 g. of product melting at 109–111° was obtained. When this was mixed with the carbinol obtained by the first method, there was no depression of the melting point.

***p*-Dimethylamino-*p*'-chlorostilbene.**—The carbinol above as made by either method readily lost water when heated with a mixture consisting of 80% glacial acetic acid and 20% concentrated hydrochloric acid and produced *p*-dimethylamino-*p*'-chlorostilbene. A mixture of 10 g. of the carbinol, 40 cc. of glacial acetic acid and 10 cc. of concentrated hydrochloric acid was heated for ten minutes on the hot-plate The solution was diluted with 200 cc. of water and neutralized with sodium carbonate. The solid matter was separated, washed with water and dried; weight 8.0 g. After two crystallizations from benzene it formed almost white scales and melted at 229° (corr.)

The above stilhene was also obtained by reducing α-*p*-dimethylamino-*p*'-chlorodesoxybenzoin with sodium amalgam and dehydrating the resulting product with the acetic–hydrochloric acid mixture. A mixture of 1.0 g. of the a-desoxy compound, 25 cc. of alcohol and 25 g. of sodium amalgam was warmed to 50–60° and occasionally shaken. At intervals small portions of 50% acetic acid were added, but not enough to make the solution acid. After four hours 100 cc. of water was added, the solid filtered, washed with water and recrystallized from dilute alcohol; yield, 0.50 g. This material was heated with 10 cc. of the acetic–hydrochloric acid mixture for a few minutes, the solution then diluted with 50 cc. of water and neutralized with sodium carbonate. The solid was filtered, washed with water and recrystallized twice from alcohol. It weighed 0.20 g. and melted at 229". When mixed with p-dimethylamino-*p*'-chlorostilbene, the melting point was not depressed.

α-*p*-Dimethylamino-*p*'-chlorodesoxybenzoin Oxime.—A mixture of 1.0 g. of the or-desoxy compound, 1.0 g. of hydroxylarnine hydrochloride and 10 cc. of pyridine was heated on the water-bath for four hours. The solution was then diluted with 10 cc. of water, cooled in ice water for a while and the solid which formed separated. On recrystallization from alcohol it melted at 227–229° and proved to be p-dimethylamino-p'-chlorostilbene. It weighed 0.20 g.

The filtrate was diluted with 30 cc. of water and the precipitate which formed on standing was separated, washed with water and dried. It weighed 0.7 g. and after two crystallizations from ligroin (Skellysolve "C") it formed white prisms melting at 150.5° (corr.).

β-*p*-Dimethylamino-*p*'-chlorodesoxybenzoin Oxime.—This oxime was obtained in a manner similar to the or-compound. In this instance, however, not a trace of the

β-$(CH_3)_2NC_6H_4C{=}NOHCH_2C_6H_4Cl$	Colorless needles	152	9.70	9.85	12.28	12.35

stilbene was obtained. This oxime could be crystallized from alcohol but ligroin proved to be a better solvent. A yield of 0.80 g. was obtained which crystallized in long colorless needles and melted at 152° (corr.). A mixed melting point determination showed that the oximes were unlike.

Summary

1. By means of the Grignard reaction both isomeric (a and β) *p*-dimethylamino-*p'*-chlorobenzoins have been synthesized. The benzoin as prepared by condensing *p*-dimethylaminobenzaldehyde and *p*-chlorobenzaldehyde was found to be *p*-chloro-α-hydroxybenzyl *p'*-dimethylaminophenyl ketone (β isomer) and has the structure $(CH_3)_2NC_6H_4$-$COCHOHC_6H_4Cl$.

2. Under the influence of potassium cyanide, α-*p*-dimethylamino-*p'*-chlorobenzoin was found to rearrange and produce the 6-isomer.

3. Upon reduction under suitable conditions, the a-benzoin produced *p*-dimethylaminobenzyl *p'*-chlorophenyl ketone. Under similar treatment, however, the β-benzoin produced the above ketone and also its isomer, *p*-chlorobenzyl *p'*-dimethylaminophenyl ketone. Nine new substances were prepared and characterized in the course of this work.

THE AUTOXIDATION OF ALPHA NORMAL-AMYLCINNAMIC ALDEHYDE. CIS- AND TRANS-ALPHA-NORMAL-AMYLCINNAMIC ACIDS

BY MARSTON T. BOGERT AND DAVID DAVIDSON[1]

RECEIVED JUNE 8, 1931 PUBLISHED AUGUST 5, 1931

Introduction

In the course of our study of the rates of autoxidation of commercial aldehydes,[2] we were led to examine the products resulting from the action of air on α-*n*-amylcinnamic aldehyde, $C_6H_5CH{=}C(Am)CHO$. Since, in general, the action of air or oxygen on an aldehyde leads to the formation of the corresponding acid through the intermediate per-acid, thus[3]

$$RCHO + O_2 \longrightarrow RCOOOH \qquad (+RCHO) \longrightarrow 2\,RCOOH$$

and, since unsaturated aldehydes such as crotonaldehyde and cinnamic aldehyde behave in accordance with this formulation, we expected that this aldehyde would yield a-amylcinnamic acid. Investigation revealed, however, that, when blown with air, a-amylcinnamic aldehyde undergoes

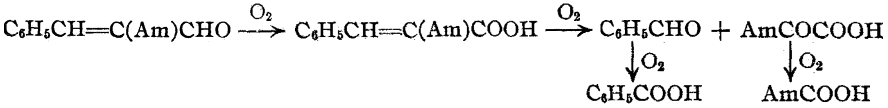
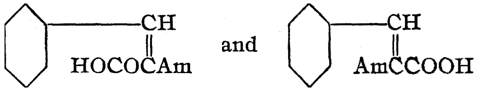
a complex autoxidation reaction leading to the formation of caproic acid, benzoic acid and a form of a-amylcinnamic acid melting at 40°, as well as benzaldehyde and other, as yet unidentified, neutral substances. The production of the three acids mentioned indicates that both the aldehyde and the ethylene functions are attacked by oxygen, perhaps as follows



$$\mathrm{C_6H_5CH{=}C(Am)CHO} \xrightarrow{O_2} \mathrm{C_6H_5CH{=}C(Am)COOH} \xrightarrow{O_2} \underset{\substack{\downarrow O_2\\ \mathrm{C_6H_5COOH}}}{\mathrm{C_6H_5CHO}} + \underset{\substack{\downarrow O_2\\ \mathrm{AmCOOH}}}{\mathrm{AmCOCOOH}}$$

Two Alpha-Amylcinnamic Acids.—Since a-amylcinnamic acid had not previously been described in the literature, it was desirable to prepare it in order to compare it with the product obtained in the autoxidation of the aldehyde. Four methods of synthesis were employed: (1) the condensation of benzaldehyde with sodium heptoate (Perkin–Stuart),[4] (2) the condensation of benzaldehyde with methyl heptoate by means of sodium (Claisen),[5] *(3)* the condensation of benzal chloride with sodium heptoate[6] and (4) the condensation of benzaldehyde with methyl hexyl ketone by means of hydrogen chloride, followed by oxidation with sodium hypochlorite. In each case an α-amylcinnamic acid was obtained which melted at 80° and was entirely distinct from that obtained by the autoxidation of the aldehyde.

The Configuration of the Alpha-Amylcinnamic Acids.—$\mathrm{C_6H_5CH{=}C(Am)COOH}$ may be represented by the two space formulas



"trans"

In harmony with the configurations of the two cinnamic acids we shall designate as "cis" that form of a-amylcinnamic acid in which the phenyl and carboxyl groups are cis.

The 40° acid differs from the 80° acid in that it forms an insoluble aniline salt in petroleum ether. By analogy with the behavior of the cis- and trans-a-methylcinnamic acids,' this marks the 40° acid as the cis form. Striking confirmation of this configuration is obtained in the behavior of the two acids toward concentrated sulfuric acid. While the 80° acid dissolves readily to form a colorless solution from which it is precipitated unchanged by water, the 40° acid forms a deep blue solution from which ice precipitates a yellow, sweet-smelling oil, freezing at 4° (a-amylindone).

[7] Stoermer and Voht, *Ann.*, **409,** 36 (1915).

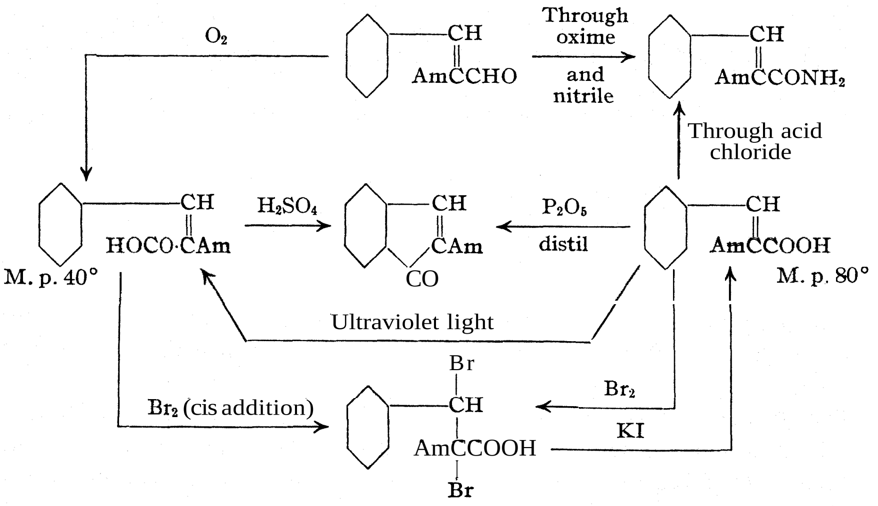
Although the 80° acid is unattacked by cold concentrated sulfuric acid, it yields this same amylindone when distilled with phosphorus pentoxide. That the two acids yield the same indone but with different ease at once establishes their isomerism and their respective configurations. The 40° acid, because of the readiness with which ring formation occurs between the ortho position in the benzene ring and the carboxyl group, is, therefore, the *cis*, while the 80° acid is the *trans* form.

Further confirmation of the isomerism of the two acids is obtained in their yielding the same dibromide, melting at 143–144.° Since the latter can be reduced to the *trans* acid melting at 80° by means of potassium iodide, a means was had of converting the *cis* acid melting *at* 40° to its geometric isomer, thus

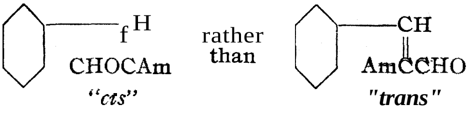
$$\textbf{\textit{Cis} form (m. p. 40°)} \xrightarrow{Br_2} \text{Dibromide} \xrightarrow{KI} \textbf{\textit{Trans}} \text{ form (m. } p. \text{ 80°)}$$

The reverse transformation of the *trans* to the *cis* form was accomplished by means of ultraviolet light. The reactions just discussed are summarized in Chart I.

Chart I



The Configuration of Alpha-Amylcinnamic Aldehyde.—Having established the configuration of the α-amylcinnamic acids beyond a reasonable doubt, and recalling that the *cis* form of the acid had been obtained by autoxidation of the aldehyde, it appeared that the commercial aldehyde possessed the *cis* configuration



Further investigation, however, showed that commercial a-amylcinnamic aldehyde is really closely related to the trans-a-amylcinnamic acid, m. p. 80°, and that, therefore, it has the trans configuration.

Thus, direct oxidation of the aldehyde to the acid by means of silver oxide yielded trans-a-amylcinnamic acid, identical with that obtained by other syntheses. Furthermore, the series of reactions, $RCHO \longrightarrow RCH{=}NOH \longrightarrow RCN \longrightarrow RCONH_2$, yielded an a-amylcinnamamide, melting at 117°, which was also obtained from trans-a-amylcinnamic acid through the acid chloride.

We are forced to the conclusion that although ordinary a-amylcinnamic aldehyde is the trans form, it reacts with oxygen to give (among other products) the cis form of a-amylcinnamic acid.[8] This inversion accompanying autoxidation may be explained by means of the following considerations. Stoermer and his co-workers have demonstrated that the trans forms of cinnamic acids are converted into the less stable cis forms by ultraviolet light.[9] On the other hand, several investigators have found that the autoxidation of aldehydes is a chemiluminescent reaction.[10] We may assume, therefore, that the radiation (or energy) emitted by the autoxidation of a-amylcinnamic aldehyde is absorbed by the product, namely, trans-a-amylcinnamic acid, which is thereby converted into its geometric isomer.

It is true that the experimental results do not enable us to decide whether this rearrangement of *trans* to cis configuration occurs wholly or partly in the initial aldehyde, the per-acid, or the trans acid stage but, in the absence of such evidence, we have assumed what seems to us the simplest interpretation of our observations.

Acknowledgments.—The authors are indebted to Mr. John Adriani for his assistance in the syntheses of a-amylcinnamic acid while he was a Senior student at Columbia College, to Dr. Eric C. Kunz, Vice President of the Givaudan–Delawanna Co. for a generous supply of a-amylcinnamic aldehyde, and to the Research Department of the American Manufacturers of Toilet Articles for financial aid.

Experimental

Autoxidation of α-*n*-**Amylcinnamic** Aldehyde.—In a darkened chamber 136.1 g. (0.675 mole) of freshly distilled a-amylcinnamic aldehyde, boiling at 161–163° at

16 mm., contained in a gas wash bottle, was blown with air, the issuing gas being passed through a second wash bottle containing dilute sodium carbonate. The increase in acidity was determined occasionally by titrating 0.3 cc. of the oil dissolved in 25 cc. of alcohol with standard sodium hydroxide solution using phenolphthalein as an indicator. The progress of the reaction is indicated in Fig. 1. After forty-two days the residual oil weighed 131.5 g. (not allowing for 2.4 cc. which had been removed for titration) and contained approximately 0.47 mole of monobasic acids. The oil was agitated with a solution of 52 g. of sodium carbonate in 500 cc. of water and then treated with ether to aid in the separation of the neutral oil from the aqueous extract. A small amount of sodium bicarbonate separated and was filtered off. The aqueous layer was extracted a second time with ether and the ether layers combined (E).

The aqueous layer was distilled to remove ether and volatile non-acidic constituents, about 300 cc. of water being collected. A mixture of 100 cc. of hydrochloric acid and 100 cc. of water was then added to the residue, and the distillation resumed, water being added from time to time. About 800 cc. of distillate (D) was collected, which contained a volatile oily acid (caproic). The residue (R) crystallized partially on standing overnight. D was made alkaline, concentrated by evaporation, acidified and distilled. The residue yielded crystals of a solid acid (benzoic). The distillate was treated as before, the oily acid finally being separated, dried over phosphorus pentoxide, and distilled (b. p. 201–208°; yield, 18.5 g.). When esterified with methyl alcohol and hydrogenchloride gas it yielded a fruity ester, boiling at 148–151°, which, when allowed to stand for two weeks with an equal volume of concentrated ammonia, yielded an amide, m. p. 99–100°. The acid was, therefore, n-caproic.

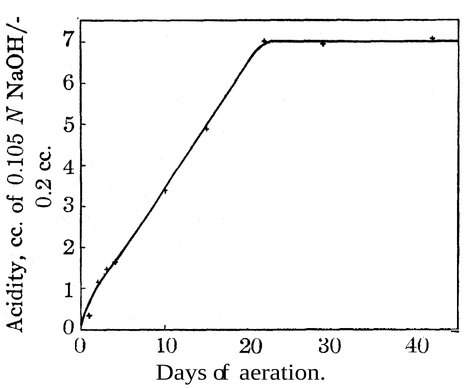

Fig. 1.

The residue (R) was filtered and the solid acid combined with the solid obtained in the purification of the caproic acid. When recrystallized from water, it yielded 7.5 g. of glistening platelets, melting at 121–122°. It was identified as benzoic acid by means of a mixed melting point, and examination of the methyl ester and amide.

The filtrate from residue (R) contained a dark oil which was distilled under diminished pressure giving the following fractions: (1) 6.7 g. partly solid, b. p. 130–190° at 18 mm., (2) 17.1 g. of a viscous yellow liquid, b. p. 190" at 18 mm., 215° at 14 mm., and a residue of 6.8 g. Fraction (1) was dissolved in dilute sodium hydroxide and the solution distilled to remove any non-acidic products formed in the distillation. The residue was then acidified with hydrochloric acid. The resulting oil yielded 2.9 g. of crude benzoic acid when extracted with hot water. Fraction (2), when chilled, deposited 2.8 g. of crystals melting at 38–39°. The filtrate was distilled, boiling mainly at 194° at 15 mm. The distillate yielded 3.6 g. of acid, m. p. 38–39", while a further quantity was obtained from the oily filtrate and other residues by dissolving in petroleum ether and precipitating with aniline. The acid was purified by precipitating the aniline salt, m. p. 65°, decomposing the latter with dilute hydrochloric acid, separating the acid, dissolving in dilute sodium hydroxide, clarifying with norite, and finally liberating the acid. This separated as an oil which slowly crystallized (m. p. 40°). Further precipitation of the aniline salt did not affect the melting point. The acid is exceedingly soluble in all common organic solvents.

Titration. 154 mg. required 8.56 cc. of standard alcoholic sodium hydroxide (0.0828 *N*). 155 mg. required 8.57 cc. Equivalent weight: calcd., 218. Found: 218, 219.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.0; H, 8.3. Found: C, 76.9; H, 8.3.

These results indicate the substance to be an a-amylcinnamic acid.

The ether layer (E) which contained the oil from which the acids had been extracted with sodium carbonate was shaken twice with half-saturated sodium bisulfite solution. The bisulfite layers were combined and treated with hydrochloric acid, the sulfur dioxide removed by warming, and the resulting oil separated. It boiled at 174–177° and had the odor of ***benzaldehyde;*** yield, 1.3 g.[11] Its identity was confirmed by treating it with alcohol and concentrated ammonia, when colorless crystals, melting at 103°, were obtained (hydrobenzamide).

The ether layer from which the benzaldehyde had been separated was washed with sodium carbonate, dried with calcium chloride, and the ether evaporated. The residual oil weighed 61.7 g. It distilled with some decomposition at 17 mm., 49.0 g. yielding 25.6 *g.* of material boiling below 180° and 23.2 g. of a dark viscous residue. Redistillation yielded 12.2 g., boiling at 110–150° at 15.5 mm. (mainly at 143–150°) and 6.0 g. boiling at 150–170° at 15.5 mm. Both fractions yielded a small amount of a solid semicarbazone which has not been obtained sufficiently pure to be identified.

Syntheses of **α-Amylcinnamic** Acid, m. p. 80°. **(1)** Perkin–Stuart Method.—A mixture of 25 g. of benzaldehyde, 35 g. of sodium heptoate and 67 g. of heptoic acid was refluxed for thirty hours. The mixture was then distilled at 20 mm. from a bath at 180°. The residue was dissolved in boiling water and acidified with hydrochloric acid, the oil separated, the water layer extracted with ether, and the extract combined with the oil. The ether solution was extracted with sodium carbonate, the water layer extracted several times with ether to remove resinous material, warmed with norite on the hot-plate, and filtered. The almost colorless solution of sodium salts was then acidified, the oil extracted, the extract dried with sodium sulfate, the ether evaporated, and the oil distilled at 2 mm. Much heptoic acid was recovered and finally 1.6 g (3.2%) of a-amylcinnamic acid boiling at 161° at 2 mm. and melting at 69° was obtained. When purified through the sodium salt the melting point rose to 74°, and from 75% acetic acid to 80°.

(2) Claisen Method.—The directions given in "Organic Syntheses" for the preparation of ethyl cinnamate[12] were adapted for the production of methyl α-amylcinnamate by substituting methyl heptoate for ethyl acetate. The excess of methyl heptoate was removed at 20 mm. and the residue distilled at **2 mm.** The fraction boiling at 130–180° at 2 mm. and weighing 20 g. was saponified with methyl alcoholic potassium hydroxide and the acid separated. After steam distilling to remove heptoic acid, several recrystallizations from dilute alcohol yielded 6.5 g. (8%) of a-amylcinnamic acid melting at 76°. Further recrystallization from 75% acetic acid gave a product melting at 80".

(3) Badische Method.—Seven grams of sodium **was** dissolved in 65 g. of heptoic acid, 16.1 g. of benzal chloride added and the mixture refluxed for thirty hours. The product was isolated as in (1); yield, 6.0 g. (28%), m. p. 80".

---

[11] Much of the benzaldehyde produced must have been lost during the aeration, since a pronounced odor of benzaldehyde was noted in the issuing air after seventeen days.

[12] "Organic Syntheses," John Wiley and Sons, Inc., New York, **1929,** Vol. IX, p. **38.**

(4) The most satisfactory method of preparation of a-amylcinnamic acid involves the condensation of benzaldehyde with methyl hexyl ketone, followed by oxidation of the intermediate methyl a-amyl styryl ketone with hypochlorite. The details of this method will appear in a subsequent paper; yield, about 70%, m. p. 80°.

Titration. 151 mg. required 8.34 cc. of standard alcoholic sodium hydroxide (0.0828 N). 149 mg. required 8.24 cc. Equivalent weight. Calcd., 218. Found: 219. 218.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.0; H, 8.3. Found: C, 77.0; H, 8.2.

Oxidation of a-Amylcinnamic Aldehyde **with Silver** Oxide.—To a boiling mixture of 5 g. of silver nitrate in 3 cc. of water, 2 g. of a-amylcinnamic aldehyde and 30 cc. of alcohol was added a hot solution of 2.5 g. of potassium hydroxide in 30 cc. of alcohol. The boiling was continued, water being added to replace the volatilized alcohol. After thirty minutes the alcohol was entirely removed. The clear straw-colored supernatant layer was decanted from the silver and the latter leached several times with boiling water. The combined liquors were acidified with acetic acid, whereupon slightly discolored trans-a-amylcinnamic acid, m. p. 78°, separated; yield, 1.7 g. (77%). Recrystallization from 75% acetic acid gave needles melting at 80°.

α-Amylcinnamaldoxime.[13]—50.5 g. of a-amylcinnamic aldehyde, 100 cc. of alcohol, 17.5 g. of hydroxylamine hydrochloride, and 34 g. of sodium acetate trihydrate were refluxed for an hour. On cooling and diluting with water, 44.2 g. of oxime, m. p. 74°, was obtained. It was recrystallized by dissolving in alcohol and diluting with water.

α-Amylcinnamonitrile.—27.5 g. of the oxime was boiled for three hours with one and one-half moles of acetic anhydride and one gram of anhydrous sodium acetate. The mixture was cooled and cautiously treated with dilute sulfuric acid to decompose the excess of acetic anhydride. It was then largely diluted with water, the nitrile extracted with benzene, the extract washed with sodium carbonate solution and dried over sodium sulfate. The benzene was removed and the residue distilled. The product was practically pure a-amylcinnamonitrile, b. p. 173° at 18 mm., 165° at 13 mm. and 135° at 3 mm.; yield, 21 g. (83%).

Anal. Calcd. for $C_{14}H_{17}N$: C, 84.4; H, 8.5. Found: C, 84.4; H, 8.5.

α-Amylcinnamamide.—1.7 g. of the nitrile was refluxed for eight hours with a solution of 2 cc. of 50% sodium hydroxide and 15 cc. of n-propyl alcohol. Dilution of the alcoholic solution gave a solid, which was recrystallized from dilute alcohol and finally from ethyl acetate–petroleum ether, giving silky needles, m. p. 117°, identical with the product obtained below.

Anal. Calcd. for $C_{14}H_{19}ON$: C, 77.4; H, 8.8. Found: C, 77.4; H, 9.0.

α-Amylcinnamamide from **α-Amylcinnamic** Acid.—One gram of a-amylcinnamic acid, m. p. 80°, was heated under reflux at 80–90° for one hour with 5 cc. of thionyl chloride. The excess of thionyl chloride was then distilled off and the residue treated with concentrated ammonia. The solid obtained was recrystallized from dilute alcohol and finally from ethyl acetate–petroleum ether, giving silky needles, m. p. 117°, identical with the product obtained above.

Action of Sulfuric Acid on 40 and 80° a-Amylcinnamic Acids.—1.09 g. of cis-a-amylcinnamic acid, m. p. 40°, was added to 11 cc. of chilled concentrated sulfuric acid. The acid readily dissolved, giving a deep blue solution. The mixture was stirred for a few minutes to complete solution and then poured on ice. The yellow oil was extracted with ether, the extract washed with water and then with 10% sodium carbonate. Evaporation of the ether gave 0.9 g. of a brown oil. Distillation at 20 mm.

---

[13] Rutovski and Korlev, *J. prakt. Chem.*, 119, 272 (1928).

gave 0.65 g. of a golden brown oil, which solidified to a yellow solid, m. p. 4°, when placed in a freezing mixture. The oil had an odor resembling amyl salicylate. For identification and analysis, the substance was converted into its oxime; 0.65 g. of the indone gave 0.53 g. of golden yellow leaflets, which, when recrystallized from 80% methanol, melted at 75° and were identical with the product obtained below.

Anal. Calcd. for $C_{14}H_{17}ON$: C, 78.1; H, 7.9. Found: C, 78.4; H, 8.2.

A parallel experiment with 1.09 g. of trans-a-amylcinnamic acid, m. p. 80°, and 11 cc. of concentrated sulfuric acid gave a colorless solution, which when thrown on ice precipitated a colorless solid. Recrystallized from 75% acetic acid, this yielded 0.94 g. of needles, m. p. 80". A mixture with trans-a-amylcinnamic acid also melted at 80".

Formation of a-Amyl Indone from *Trans*-α-amylcinnamic Acid.—5.45 g. of *trans*-a-amylcinnamic acid, m. p. 80°, and 8 g. of phosphorus pentoxide were placed in a Claisen flask and well mixed by shaking. Distillation with a free flame at 17 mm. gave a golden brown distillate, b. p. 157–158° at 17 mm., which froze at 1–2° to a yellow solid. When added to concentrated sulfuric acid it formed a deep blue solution. Its odor was reminiscent of amyl salicylate; yield, 4.0 g. (80%). It was identified as a-amyl indone by conversion to the oxime according to the method of Schmidt and Söll.[14] One gram of the indone was refluxed for one and one-half hours with 0.35 g. of hydroxylamine hydrochloride and 0.5 g. of barium carbonate powder in 15 cc. of methanol. The mixture was then cooled, filtered and diluted with water; 0.77 g. of yellow leaflets, m. p. 74°, were obtained and 0.28 g. of further material upon further dilution of the mother liquor. Recrystallization from twenty parts of methanol and five parts of water gave golden yellow leaflets, m. p. 75°, identical with the product obtained above.

Action of Bromine on *Trans*-α-amylcinnamic Acid.—2.18 g. of *trans*-α-amylcinnamic acid, m. p. 80°, was dissolved in 25 cc. of carbon tetrachloride, and 0.6 cc. of bromine added to the solution in diffused daylight. Decolorization soon occurred, whereupon the carbon tetrachloride was removed by means of a current of air and the residue treated with petroleum ether and chilled; 2.3 g. of a dibromide m. p. 137–139° was obtained. Recrystallization from carbon tetrachloride–petroleum ether raised the melting point to 143–144°.

Anal. Calcd. for $C_{14}H_{18}O_2Br_2$: C, 44.5; H, 4.8. Found: C, 43.7; H, 4.6.

Transformation of *Cis*-α-amylcinnamic Acid, m. p. 40°, to *Trans*-α-amylcinnamic Acid, m. p. 80°.—1.09 g. of cis-a-amylcinnamic acid, m. p. 40°, was dissolved in a few cc. of petroleum ether and excess of bromine added to the solution in diffused daylight. As the bromine was absorbed, heat was evolved, a little hydrogen bromide appeared and a crystalline deposit formed on the walls of the flask. After four hours the flask was chilled, the mother liquor poured off and the crystalline deposit washed with petroleum ether; 1.13 g. of a flesh-colored cake was obtained which melted at 139–140". Recrystallization from carbon tetrachloride-petroleum ether gave a colorless product, m. p. 143–144°. A mixture with the product obtained above also melted at 143–144°; 0.95 g. of this product, 1.7 g. of potassium iodide and 10 cc. of alcohol were refluxed for twenty minutes. The mixture was then diluted with dilute sodium bisulfite solution, whereupon a precipitate of 0.57 g. of crude trans-a-amylcinnamic acid was obtained, which, when recrystallized from 75% acetic acid, gave 0.39 g. of needles, m. p. 80° (mixed melting point). The acid obtained gave a colorless solution in concentrated sulfuric acid.

Transformation of *Trans*-α-amylcinnamic Acid, m. p. 80°, to *Cis*-α-amylcinnamic

---

[14] Schmidt and Söll, Ber., 40, 2455 (1907).

Acid, m. p. **40°.**—2.18 g. of *trans*-α-**amylcinnamic** acid, m. p. 80°, spread out on a plate and placed at a distance of about fifteen inches from a Hanovia quartz mercury arc was irradiated for about 120 hours. The acid then melted at about 70° and gave a deep blue color with concentrated sulfuric acid. It was triturated with petroleum ether and filtered. The residue weighed 1.1 g., melted at 80° and gave a practically colorless solution in sulfuric acid. The petroleum ether extract was treated with several drops of aniline and seeded with the aniline salt of cis-a-amylcinnamic acid. A crop of long felted needles, m. p. 66° and weighing 0.41 g., was obtained. On decomposing the latter with dilute hydrochloric acid, 0.28 g. of cis-a-amylcinnamic acid, m. p. 38–39' (mixed melting point), was obtained. The product gave *a* deep blue color with sulfuric acid.

Summary

1. The a-amylcinnamic aldehyde of commerce is the trans isomer, since it is converted into trans-a-amylcinnamic acid by means of silver oxide, and into trans-a-amylcinnamamide through the oxime and the nitrile.

2. Autoxidation of a-amylcinnamic aldehyde proceeds readily at room temperature in the dark. Profound attack of the aldehyde ensues, leading to the production of caproic acid, benzoic acid and *cis*-α-amylcinnamic acid, m. p. 40°. The inversion of the trans to the cis form is accounted for by the chemiluminescence of the primary autoxidation.

3. Four methods of synthesis of a-amylcinnamic acid led to the same trans form, m. p. 80°.

4. The cis configuration of the 40° form of α-amylcinnamic acid is established by its ready formation of an indone. The trans form undergoes the same reaction, but only under much more vigorous conditions.

5. Cis-a-amylcinnamic acid is converted into the trans form through the dibromide.

6. Trans-a-amylcinnamic acid is converted to the cis form by means of ultraviolet light.

DIASTEREOMERS OF α,α',β,β'-TETRABROMOETHYL ETHER

BY WILLIAM L. RUIGH AND RANDOLPH T. MAJOR

RECEIVED JUNE 3, 1931 PUBLISHED AUGUST 5, 1931

One of the products obtained by the bromination of paraldehyde is the so-called "Tetrabromobutyraldehyde" that was first obtained by Freundler.[1] Hibbert, Perry and Taylor[2] reported that this compound was identical with the product which they obtained by the bromination of divinyl ether. They offered further evidence to show that this compound was α,α',β,β'-tetrabromoethyl ether, $CH_2BrCHBrOCHBrCH_2Br$, and that it was not tetrabromobutyraldehyde, $CH_2BrCHBrCHBr_2CHO$.

The divinyl ether obtained by Ruigh and Major[3] was an apparently much purer product than that investigated by Hibbert, Perry and Taylor. From the description of the preparation of divinyl ether which was published by the latter authors the presence of acetaldehyde in their product was quite possible. It seemed desirable, therefore, to repeat and amplify the work of these authors and for the bromination of divinyl ether to use a product of known purity.

We have found that when pure divinyl ether was brominated in chloroform or carbon tetrachloride solutions two distinct crystalline products were obtained together with a small amount of a highly lachrymatory oil. When, however, the bromination was carried out in the presence of powdered calcium carbonate, using carbon tetrachloride as the solvent and carefully dried materials, a quantitative yield of the two solid products only was obtained. The oil obtained in the earlier brominations was probably a mixture containing bromination products of acetaldehyde, since divinyl ether is readily hydrolyzed to acetaldehyde in the presence of moisture and acids.

We were unable to effect a quantitative separation of the mixture obtained in these brominations; we were, however, able to isolate pure samples of the two products which formed this mixture. One of the products crystallized in the form of prisms, while the other formed long fine needles.

The identity of the prisms with the compound obtained by Freundler by the bromination of paraldehyde, was shown by a mixed melting point determination. This is in harmony with the view of Stepanov, Preobrashenski and Shchukina[4] that Freundler's "tetrabromobutyraldehyde" was in reality α,α',β,β'-tetrabromoethyl ether. Our analytical results

---

[4] Stepanov, Preobrashenski and Shchukina, *Ber.*, 59B, 2533 (1926).

confirmed the results of Hibbert, Perry and Taylor, which favored the latter structure. These authors also showed that the compound condensed with ethylene glycol to give bromoethylidene glycol, a fact which they presented as additional evidence in favor of the ether structure of the compound.

It was further found that acetaldehyde was formed when the compound was treated with sodium in xylene or zinc dust in acetic acid. By the action of *p*-nitrophenylhydrazine on the compound in acetic acid we obtained the *p*-nitrophenylosazone of glyoxal. The four carbon chain that is in tetrabromobutyraldehyde would not be expected to give a derivative of glyoxal under these conditions.[5] Dworzak and Prodinger[6] showed that $\alpha,\alpha',\beta,\beta'$-tetrabromoisobutyl ether, obtained by the bromination of isobutyraldehyde, gave a-hydroxyisobutyraldehyde when treated with a dilute solution of sodium bicarbonate. When our prisms were treated in a similar manner we found that the resulting solution contained glycolaldehyde or possibly bromoacetaldehyde.

On the basis of the evidence outlined, there seems to be no reason to doubt that this compound has the structure $\alpha,\alpha',\beta,\beta'$-tetrabromoethyl ether.

The other product of the bromination of divinyl ether which crystallized in the form of needles was obtained in pure form and free from the prisms only with great difficulty. Its melting point was only a few degrees below that of the prisms and the solubilities of the two compounds in various solvents were very much the same. The melting point of a mixture of the two compounds was considerably lower than that of either. The results obtained from analytical and molecular weight determinations of the needles corresponded with the values calculated for tetrabromoethyl ether. When treated with *p*-nitrophenylhydrazine in acetic acid, a quantitative yield of the *p*-nitrophenylosazone of glyoxal was obtained. By heating the needles above their melting point, they were converted into the isomeric prisms. This conversion also took place on long standing in solution in ether at room temperature. In petroleum ether, however, the needles were apparently perfectly stable.

The two a-carbon atoms of $\alpha,\alpha',\beta,\beta'$-tetrabromoethyl ether are asymmetric and theoretically there should exist two inactive forms, the meso and the racemic. On the basis of the evidence here presented, it appears that the two bromination products of divinyl ether are diastereomeric forms of $\alpha,\alpha',\beta,\beta'$-tetrabromoethyl ether. Although it is possible that the needles are also a product of the bromination of paraldehyde, we have not been able to isolate it from the products of this reaction.

A study of the quantitative bromination of divinyl ether by the method of McIlhiney[7] was undertaken. The amount of bromine absorbed represented about 95% of that theoretically required. However, when the iodate correction was applied, the amount of bromine added to the unsaturated groups varied from 76 to 82% of the theoretical requirements. Buckwalter and Wagner[8] have recently shown that the McIlhiney method for the determination of the amount of unsaturation in organic compounds gives erratic and erroneous results. The method developed by these authors is not applicable to a determination of the amount of unsaturation in divinyl ether due to the low boiling point of the ether.

Experimental Part

Bromination of Divinyl Ether.—Five grams of pure divinyl ether in 20 g. of chloroform was chilled to −15° and 22.8 g. of bromine in 50 g. of chloroform was slowly added with stirring. All but about 0.5 cc. of the bromine solution was absorbed before a slight permanent yellow color appeared. This color was removed by the addition of a drop of divinyl ether. The solution was evaporated down to an oil (37.1 g.), which was mixed with an equal volume of petroleum ether. The solid which crystallized out was filtered off; the filtrate when chilled yielded more solid. The total yield of solid was 21.7 g. or 78% of the theoretical amount of α,α',β,β'-tetrabromoethyl ether. When 50 g. of divinyl ether was brominated in carbon tetrachloride, 222.3 g. or an 80% yield of the solid was obtained. The highly lachrymatory oil which remained after the solid products of the reaction had been removed was not investigated.

The solid from the reaction consisted of a mixture of prisms and needles. It was not possible to effect a quantitative separation but apparently about 20% of the solid consisted of the needles. When 10 g. of divinyl ether was brominated with 46 g. of bromine at −20° in the presence of an excess of calcium carbonate (precipitated chalk) in dry carbon tetrachloride solution, a quantitative yield of the mixed forms was obtained. No oil was formed in this experiment. Under these conditions, by inspection under the microscope, the needles formed about 50% of the total solid.

The prisms were fairly readily obtained when the mixture slowly crystallized from petroleum ether. The first fraction consisted of the practically pure prisms.

The needles, however, were obtained in a pure condition only with great difficulty. In order to do this the needles were allowed to grow rapidly and the ligroin solution, which was supersaturated with respect to the prisms, was decanted. Five grams of the pure needles was obtained in this manner.

In ethyl ether a slow isomerization of the needle to the prism form took place, which was complete after the mixture had stood for three weeks at room temperature. Solutions of the bromination products in acetone gradually decomposed after several days and gave a black tar. The compounds appeared to be quite stable, however, in petroleum ether.

The prisms melted at 65–66°; a mixture of these crystals with the compound obtained by Freundler by the bromination of paraldehyde also melted at 65–66°.[1]

[8] Buckwalter and Wagner, THIS JOURNAL, 52, 5241 (1930).

The needles melted at 62–63°; a mixture of the needles and prisms melted at 45–57°.

Anal. Calcd. for $C_4H_6Br_4O$: C, 12.32; H, 1.56; Found: C, 12.41, 12.48; H, 1.37, 1.41.

Mol. wt. Calcd. for $C_4H_6Br_4O$, 389.7. Found: 376.3, 378.2 (Menzies–Wright ebullioscopic method).

Action of Zinc Dust and Acetic Acid on the Prisms.—About 0.5 g. of the prisms was dissolved in 15 cc. of dilute acetic acid and several grams of zinc dust was added in small portions while the reaction mixture was warmed on the water-bath. The solution was filtered, diluted with water to a volume of about 50 cc., just neutralized with sodium carbonate and distilled. The distillate reduced Tollens' reagent. A small portion of the distillate when treated with p-nitrophenylhydrazine gave the *p*-nitrophenylhydrazone of acetaldehyde; m. p. 128–129°. A mixture of this material with the *p*-nitrophenylhydrazone of acetaldehyde melted at 128–129°.[9]

Action of Sodium on the Prisms.—In a 50-cc. flask were placed 10 g. of the prisms, 4 g. of sodium and 25 cc. of dry xylene. An 8-mm. bent glass tube served as a condenser and the receiver was a flask cooled with a solid carbon dioxide–acetone mixture. The xylene was heated just to the boiling point and after about half an hour about 0 5 cc. of liquid had collected in the receiver. The distillate had a strong odor of acetaldehyde, reduced Tollens' reagent and gave the p-nitrophenylhydrazone of acetaldehyde; m. p. 128–129°. A mixture of this material with the p-nitrophenylhydrazone of acetaldehyde melted at 128–129°.[9]

Hydrolysis of Prisms.—One gram of the prisms and 100 cc. of a 2% solution of sodium bicarbonate were warmed until the prisms melted. After the mixture had been shaken for about forty-five minutes, practically all of the solid material had disappeared. The solution was then cooled and saturated with carbon dioxide. A portion of this solution reduced Fehling's solution rapidly at room temperature, a red precipitate being formed after four minutes. The solution also gave the p-nitrophenylosazone of glyoxal, m. p. 309–310°, when it was treated with p-nitrophenylhydrazine in acetic acid. When equal quantities of this solution and a 50% solution of potassium hydroxide were warmed, a yellow color developed.[10]

Action of *p*-Nitrophenylhydrazine on Prisms and Needles.—A solution of 0.5 g. of the prisms and 1 g. of p-nitrophenylhydrazine in about 50 cc. of 50% acetic acid was warmed on the water-bath for an hour. After the solution had been cooled the precipitate was removed by filtration; yield, 0.49 g. The crude product was dissolved in 40 cc. of hot pyridine from which red needles separated on cooling; m. p. 309–310°. It gave a deep blue color with a concentrated solution of potassium hydroxide to which had been added a few drops of alcohol. These facts together with the analysis identified this compound as the p-nitrophenylosazone of glyoxal.[11]

Anal. Calcd. for $C_{14}H_{12}N_6O_4$: N, 25.61. Found: N, 25.63.

A quantitative yield of 0.09 g. of the p-nitrophenylosazone of glyoxal was obtained when 0.1 g. of the needles was warmed in a 50% acetic acid solution of *p*-nitrophenylhydrazine for several hours at 50–60°.

Transformation of the Prismatic to the Needle-like Form of Tetrabromoethyl Ether.—Two-tenths of a gram of the needles was heated in a test-tube for four minutes at 100°. A slight decomposition accompanied by the evolution of hydrogen bromide took place. This was shown by the white fumes produced when a stopper wet with ammonia was held near the mouth of the test-tube used. The product obtained was

---

[9] E. Hyde, *Ber.*, **32,** 1813 (1899).

[10] Fischer and Landsteiner, *ibid.*, 25,2552 (1892).

[11] Dakin and Dudley, Biochem. J.,15, 127 (1913).

recrystallized from ligroin; yield, 0 15 g. of the prisms. Evaporation of the mother liquor yielded a mixture of both needles and prisms. The crude prisms after one crystallization from ligroin melted at 64–65°. A mixture of this product with another sample of the prisms melted at 65°

Titration of Divinyl Ether by Means of Bromine.—Samples of divinyl ether were enclosed in sealed glass bulbs and broken in the presence of a standard solution of bromine in stoppered flasks chilled on ice. The flasks were kept at 0° for an hour in the dark and then allowed to stand at the temperature of the laboratory. For analyses "A" and "B" of Table I the flasks stood for twenty-four hours before the addition of the solution of potassium iodide and the titration with sodium thiosulfate, while analyses "C" and "D" stood for two hours before the titration.

The results given in Line 1 of Table I express the percentage of the theoretical amount of bromine required by divinyl ether used that was actually absorbed. Line 2 gives the results in percentage of the theoretical amount of bromine actually absorbed after the iodate correction had been made.

We are greatly indebted to Mr. Douglass Hayman, who made most of the analyses recorded in this paper.

Summary

1. It has been shown that the bromination of pure divinyl ether gives two distinct crystalline compounds. Evidence is given to show that these compounds are diastereomers of $\alpha,\alpha',\beta,\beta'$-tetrabromoethyl ether.

2. The prismatic form of $\alpha,\alpha',\beta,\beta'$-tetrabromoethyl ether has been shown to be identical with the bromination product of paraldehyde that was first obtained by Freundler and that was called by him "tetrabromobutyraldehyde."

THE ISOMERS IN "DIISOBUTYLENE." I

BY FRANK C. WHITMORE AND S. N. WRENN

RECEIVED JUNE 3, 1931 PUBLISHED AUGUST 5, 1931

The material known as diisobutylene was first reported by Butlerow.[1] It was prepared by him from isobutylene and sulfuric acid in a sealed tube and by heating tertiary butyl alcohol with dilute sulfuric acid. Similar methods of preparation have since been used by other workers.[2] Similar materials have been prepared by heating tertiary butyl alcohol with quinoline hydrochloride for three days at 160°;[3] by the action of ferric chloride on isobutyl alcohol at 200° for 24 hours;[4] by heating tertiary butyl iodide with metallic oxides in a sealed tube;[5] by the reaction of tertiary butyl chloride and isobutylene in the presence of zinc chloride at room temperature;[6] by the action of zinc chloride on isobutyl alcohol in the presence of hydrogen chloride or traces of isobutyl chloride;[7] and by the polymerization of isobutylene at high temperature and pressure or in the presence of catalysts.[2b,8]

It was early recognized that diisobutylene probably consisted of the two isomeric octylenes, 2,4,4-trimethylpentene-1 and 2,4,4-trimethylpentene-2. Oxidation experiments indicated the presence of these olefins in varying amounts according to the results of different investigators.[9] It was not until the work of McCubbin and Adkins that the actual presence of these olefins and their relative proportions were clearly determined.[2c] They showed that there is about four times as much 2,4,4-trimethylpentene-1 as of its pentene-2 isomer in diisobutylene as prepared by heating tertiary butyl alcohol with approximately 50% sulfuric acid.

The literature contains little information on the physical properties of diisobutylene. The boiling point is given over ranges between 101 and 113° with the most generally accepted values near 103°. The density at 20° is given from 0.715 to 0.7195. Only one reference to the refractive index is given, n_D^{20} 1.41123.[2b] The melting point is given as

−101°.[10] The present investigation grew out of attempts to make addition products of "diisobutylene." It was soon found that the mixtures obtained were unsatisfactory for study. Many unsuccessful attempts were made to synthesize the individual isomers said to be contained in diisobutylene. It was then decided to attempt the separation of diisobutylene into its isomers by careful fractional distillation. This method proved to be fully as difficult as the results of earlier workers would indicate but has been carried to the point where there is no longer any doubt of its possibility. The results to date are being published because this phase of the work has been interrupted by the departure of one of the authors. The separation is being continued with the use of even more efficient columns than those used in the present study.

A total amount of 19 liters of diisobutylene was subjected to 29 careful fractional distillations during 291 hours of actual distillation.

The purest samples of each isomer obtained have the following properties.

	Boiling point (corr.), Cottrell apparatus, °C.	d_4^{20}	n_D^{20}
Lower isomer	100.1–100.2 (736 mm.) 101.2–101.3 (760 mm.)	0.710	1.408
Kigher isomer	103.0–103 4 (736 mm.) 104.1–104.5 (760 mm.)	0.715	1.415

Since the lower isomer is found in much larger amounts than the higher one and in view of the results of McCubbin and Adkins,[2b] there can be little doubt that the lower isomer is 2,4,4-trimethylpentene-1 and that the higher isomer is 2,4,4-trimethylpentene-2.

Special experiments showed that diisobutylene does not polymerize or depolymerize on standing in glass bottles exposed to light for over a year or on refluxing at atmospheric pressure for six hours.

In order to make sure that the different properties of the "higher isomer" were not due to impurities of triisobutylene,[7] a 1:1 mixture of the lower isomer and triisobutylene was fractionated by means of column "H" (see below). No difficulty was experienced in separating the two substances in a single distillation. Since the column used was distinctly inferior to the two columns used in the fractionations of the two isomeric diisobutylenes, the properties of the higher isomer cannot be ascribed to impurities of triisobutylene not removed during the distillations.

Experimental

Preparation **of Diisobutylene.**[11]—Individual runs were made in 12-liter flasks provided with reflux condensers. To a cold mixture of 3300 cc. of water and 2700 cc. of C. P. sulfuric acid was added 2500 g. of commercial tertiary butyl alcohol. The thor-

---

[10] Parks and Huffman, private communication.

[11] Based on directions supplied by W. W. Hartman of the Eastman Kodak Company.

oughly shaken mixture was heated on the steam-bath for twenty to thirty hours. Shortly after the heating started an oil began to separate on the surface. The oily layer was removed, washed with water and dilute potassium carbonate solution, dried over calcium chloride for several days and finally refluxed over metallic sodium for five hours. At the end of this treatment fresh sodium retained its metallic luster even after heating in the mixture for an hour. The usual yield was 2100 cc. This, on fractionation through column "J" (see below), gave 1500 cc. of the diisobutylenes boiling at 100–105" (738 mm.) and 500 cc. of residue of triisobutylene and higher polymers. Usually several runs were worked up together.

During the course of the work some diisobutylene was kindly supplied by Dr. Graham Edgar of the Ethyl Gasoline Corporation. This boiled at 98–108° (760 mm.). It had been prepared from material obtained by absorbing cracked refinery gases in sulfuric acid. This diisobutylene was refluxed over metallic sodium and given a preliminary distillation through column "J." Neither in this nor in subsequent distillation was any difference noted between the diisobutylene made in this Laboratory from tertiary butyl alcohol and that made by the Ethyl Gasoline Corporation from cracked gases containing isobutylene.

Description of Columns.[12]—Three columns were used. All were well insulated and were operated with total condensers and variable take-offs. Usually the take-off was adjusted at about 5 cc. per minute and the heat supplied was adjusted to give maximum reflux without flooding the columns.

	Height, cm.	Diameter, cm.	Material	Insulation (magnesia pipe cover)	Packing
Column "H"	120	2	Pyrex glass	3.8 cm. with electrical heating	6 × 6 mm. glass rings
Column "J"	180	3.6	Cast iron	8.9 cm.	Same
Column "W"	260	1.8	Brass	5.1 cm.	6 X 6 mm. brass rings

With columns H and J, Pyrex glass flasks were used as stills. These were heated in oil-baths. Column W was fitted with a 1500-cc. brass pot electrically heated. The boiling points were taken on a short Anschütz thermometer with the mercury thread entirely in equilibrium with the condensing vapor.

Distillations.—At first careful fractionations were carried out in the usual way according to the boiling points of the fractions. It was soon found that the refractive indices changed much more rapidly than the boiling points. Thus fractions from different distillations but having similar refractive indices were combined and refractionated. In all the distillations fractions of 50–60 cc. were taken even when the boiling point did not vary. During the early distillations such successive fractions showed changing refractive indices. In later distillations fractions were obtained which on redistillation gave successive fractions with the same boiling points and the same refractive indices.

Since the various fractionations gave over five hundred fractions, it is obviously impossible to give all the details. The fractionations are summarized in the following table. Distillations 1–17 were carried out in column J and distillations 18–29 in column W.

---

[12] The design of these columns was according to suggestions by M. R. Fenske, who is in charge of the investigations on Pennsylvania petroleum in this Laboratory.

Possible Changes of Diisobutylene on Standing and during Distillation.—Several samples of diisobutylene of various refractive indices were allowed to stand for over a year and then examined again. No change was observed in their refractive indices. This showed that no appreciable polymerization or oxidation had taken place under the conditions used, namely, storage in glass bottles with cork stoppers and exposure to ordinary daylight. The oxidation and polymerization products of diisobutylene all have higher indices of refraction[2]"

In order to determine the possibility of the dissociation of diisobutylene during distillation, a sample of known refractive index was refluxed through column "W" (the tallest of the columns) for six hours with total reflux. Arrangements were made to catch any escaping isobutylene in a solution of bromine in carbon tetrachloride. When the bromine was removed by sodium thiosulfate and the carbon tetrachloride was distilled, no high boiling material was obtained. A blank using known isobutylene showed there was no difficulty in detecting even a small amount of the dibromide, b. p. 146–148° (738 mm.). The material in the pot showed no change in refractive'index, thus showing that it contained no dissolved isobutylene formed during the refluxing and that it had not suffered any appreciable change during its contact with the brass column and packing. **A** small amount of dissolved isobutylene lowers the refractive index of diisobutylene notably.

Separation of Diisobutylene and **Triisobutylene.**—The possibility of separating these materials by the type of columns used was definitely settled by the following experiment. A large amount of the residues from the fractionation of crude diisobutylene was distilled from an ordinary distilling flask and the 1500 cc. boiling at 160–200° was redistilled through column "H" with the column heated to 150–160°. A fraction amounting to 850 cc. boiled at 173–174° (726 mm.). This was distilled again through column "H" as before. Twenty fractions were taken with boiling points at 738 mm. from 175.5 to 178.8' and refractive indices from 1.4300 to 1.4338. Fractions 2–14 were used for the distillation experiment with diisobutylene. These fractions ranged in boiling point from 175.7 to 176.4° (738 mm.) (corr.) and in refractive index from 1.4300 to 1.4305. A sample of the mixture on distillation through column H gave the following results, 170.6–175°, 8.5 cc.; 175.0–176.2°, 419 cc., n_D^{20} 1.4300; 176.2–176.6° (flask dry), 95 cc., n_D^{20} 1.4308.

Diisobutylene, fractions 14 to 18 of Distillation 20, b. p. 100.0–100.1° (727–729 mm.), n_D^{20} 1.4087–1.4088, was distilled through column "H." Practically all (97%) distilled at 99.8–100.0° (734 mm.) and had a refractive index of 1.4085.

The above diisobutylene (156 cc.) and triisobutylene (156 cc.) were distilled through column "H" with the results given in the following table.

Bar., mm.	Time, min.	B. p., °C.	Fraction	Vol., cc.	Ref. index	% Distilled (total)
733	0	99.6				
	18	99.8	1	4.5	1.4085	1.3
732.5	85	99.8	2	99	1.4086	34.7
	130	99.8	3	17	1.4087	40.4
	190	99.8	4	20	1.4087	47.1
	200	100.0	5a	2		47.7
	235	101.0	5b	6	1.4090	49.8
Heat on column	245	110.0	6a	4		
	254	127.0	6b	1		
	257	132.0	6c	0.5	1.4099	51.6
	292	171.0	7	7	1.4210	54.0
	314	175.0	8	8	1.4288	56.6
732	328	175.4	9	13	1.4300	61.0
	388	175.8	10	94	1.4300	92.4
	400	175.8	11	22	1.4303	100.0

The flask was dry at the end of the distillation. The hold-up and loss amounted to 14 cc.

Physical Properties.—The boiling points were determined at various pressures near **735** mm. in a Cottrell boiling point apparatus with a standardized Anschiitz thermometer having the mercury thread entirely exposed to the vapor. The value of $\Delta p/\Delta$ b. p. for each isomer was found to be about 21.8 mm. per degree C. The boiling points at 760 mm. were calculated from this relation.

The refractive indices were determined to four places with an Abbé refractometer with prism kept at a constant temperature by water from a bath held at 20.0°. Observations taken at different times on the same samples checked within one or two in the fourth decimal place.

When larger amounts of the pure isomers are available they are to be submitted to various physical chemists and physicists to be measured accurately as was done in connection with the classical researches of Edgar, Calingaert and Marker on the isomeric heptanes.

Summary

1. By repeated fractionation through improved laboratory columns of the adiabatic, total condensation, variable take-off type, "diisobutylene" can be separated into 2,4,4-trimethylpentene-1 and 2,4,4-trimethylpentene-2, the former being present in much the larger amount.

2. The boiling points, densities and refractive indices of the isomers have been determined.

NITRATION OF ACYLANILINES

BY L. CHAS, RAIFORD AND JACOB NELSON WICKERT

RECEIVED JUNE 6, 1931 PUBLISHED AUGUST 5, 1931

Nitration of phenol and the cresols, except the para compound, gives isomeric mononitro derivatives. Zincke and collaborators[1] found that when an acetic acid solution of a brominated cresol is treated with sodium nitrite, the halogen atom, if it occupies a favorable position, may be replaced by the nitro group. In this way they obtained from the meta series a product in which the halogen atom para to hydroxyl was replaced, while in the ortho and para series the atom ortho to hydroxyl was substituted. In no case did they record the formation of isomeric nitro compounds in a single nitration.

Work in this Laboratory and elsewhere by Raiford and students[2] has proved that when halogenated phenols containing bromine or iodine as substituents are nitrated by this method they may exchange halogen in the ortho and para positions for the nitro group and thus give rise to isomeric mononitro derivatives.[3] On this account it was desired to study halogen substitution products of benzene in which position 1 is occupied by some radical other than hydroxyl. Aniline derivatives suggested themselves.

When an acyl or alkyl aniline is subjected to bromination or nitration,[4] the new substitueat usually enters the anilide rather than the other radical, if either of the *o,o,p*-positions is available. Replacement of halogen by the nitro group in such products is extremely rare. Hiibner[5] obtained a monobromodinitro derivative by nitration of benzoyl-2,4-dibromoaniline with fuming nitric acid, but the structure of the product was not determined. Treatment of *p*-bromodimethylaniline with nitrous acid[6] gave *p*-bromophenylmethylnitrosamine, and *p*-nitrodimethylaniline. When the starting material contained chlorine instead of bromine, no replacement of halogen was observed, but the products were *p*-chlorophenylmethylnitrosamine and 3-nitro-4-chlorodimethylaniline.

[3] All attempts to replace chlorine in this way have been unsuccessful. Thus, when Raiford and Heyl [*Am. Chem. J.*, *43*, 397 (1910)] and Raiford [*ibid.*, 46, 425 (1911)] subjected *sym.*-trichlorophenol and 2,4,6-trichloro-*m*-cresol, respectively, to the action of nitrous acid under the conditions indicated, only starting material could be recovered. More vigorous treatment of the cresol derivative with fuming nitric acid removed chlorine from the para position and gave a quinone instead of a nitro compound.

Borrelli[7] treated benzoyl-2,4,6-tribromoaniline with fuming nitric acid, and obtained two products that melted at 227 and 272–273°, respectively, and which were recorded on the basis of analyses[8] for nitrogen and bromine as isomeric dinitrotribromobenzanilides. Since the structures of these compounds were not proved either by synthesis[9] from the required amines and acid chlorides, or by the study of their possible hydrolysis products, it was of interest to consider them further.

In the present study Borrelli's work has been repeated by following his brief directions as closely as possible. The results obtained did not agree entirely with what he reported. The nitration product was a mixture of substances with different solubilities in benzene, as the previous author found. The two least soluble ones that melted at 242 and 266°, respectively, were isolated.[10] Analyses indicated that they were mononitro derivatives, and hydrolysis gave, in each case, *sym.*-tribromoaniline, which showed that in the anilide the nitro group was attached to the benzoyl radical. The lower melting anilide was identified (see experimental part) as the *m*-nitrobenzoyl derivative, and the higher one as the ortho isomeride. Theory requires the existence of four mononitro and ten dinitro derivatives of benzoyl-2,4,6-tribromoaniline. To learn whether Borrelli's products might be included in that list all possible isomers were synthesized and examined. The identity of each was further established by study of its hydrolysis products. None of them corresponds in terms of physical constants with either of the compounds recorded by Borrelli.

When an acetanilide instead of a benzanilide substitution product was nitrated isomers were again obtained. Treatment of acetyl-2,4-dibromoaniline[11] with fuming nitric acid alone gave an 86% yield of the corresponding 2,4-dibromo-6-nitro compound.[12] When the starting material was first dissolved in concentrated sulfuric acid and fuming nitric acid was added to this solution, the reaction was much more rapid than before and required cooling to control it. Fractional crystallization of the product gave the 6-nitro compound mentioned above and the isomeric acetyl-2,4-dibromo-5-nitroaniline.[13] This behavior is, in part, in accordance with the observation of others.[14]

[d] Colorless needles after repeated crystallization from alcohol. " Obtained from 2,4,6-tribromo-3.5-dinitroaniline that was prepared in 52% yield by Blanksma's method [*Rec. trav. chim.*, 21, 255 (1902)]. [f] Colorless needles from alcohol.

extracted with sodium carbonate solution and finally crystallized from a suitable solvent. The composition of these products is shown by analytical data in the accompanying tables, and the structure of each was further established by hydrolysis and identification of the corresponding acid and amine.

Summary

1. Nitration of benzanilide or its halogen substitution products in the absence of sulfuric acid introduces the new substituent into one of the *o,o,p*-positions of the anilide residue if either of them is available. When the benzoyl derivative of *sym.*-tribromoaniline is used the substituent enters the acyl radical and gives a mixture of the isomeric 2-nitro- and 3-nitrobenzoyltribromoanilides.

2. When the acetyl derivative of 2,4-dibromoaniline was nitrated in the presence of concentrated sulfuric acid a mixture of the isomeric 5-nitro- and 6-nitrodibromo compounds was obtained.

3. In none of the aniline derivatives here studied was halogen replaced by the nitro group.

4. All mono- and dinitro substitution products of benzoyl-2,4,6-tri-

bromoaniline demanded by theory have been synthesized and their structures determined.

5. Further work is in progress in this Laboratory.

BENZALPYRUVIC ACID DIBROMIDE

BY MARIE REIMER

RECEIVED JUNE 6, 1931 PUBLISHED AUGUST 5, 1931

The action of sunlight on β-bromobenzalpyruvic acid has been the subject of study in this Laboratory for several years.[1] The fact that large quantities of this unsaturated bromo compound have been required has led to improved methods of preparation of benzalpyruvic acid and of its dibromide from which the unsaturated bromo compound is prepared and to the observation that a marked characteristic of the dibromide is the ease with which it forms addition compounds with various solvents. In view of a recent paper by Musajo[2] in this same field it seems advisable to publish results already obtained.

The melting points of different samples of benzalpyruvic acid dibromide prepared in the early work varied from 125 to 142° and this variation was ascribed to contamination of the substance with the unsaturated bromo compound formed from it by loss of hydrogen bromide. It has now been found that the dibromide readily forms a hydrate in the presence of even traces of moisture and that the purest sample of the dibromide described previously contained enough of this hydrate to lower the melting point although not enough to affect the analytical results. In the present work, in which benzalpyruvic acid and the reagents used in the bromination reaction were thoroughly dried, the crude dibromide, obtained in 92 to 97% yield, has been found to melt at 148–150°; recrystallized from dried benzene, at 150–151°. The compound described by Musajo as melting at 147–150° is probably this substance and is certainly not a racemic isomer of the acid melting at 142° as he suggests. Under the conditions used in this Laboratory for the bromination no isomer is formed.

Experimental Part

Preparation of Benzalpyruvic Acid.—For the preparation of pure samples of the acid its methyl ester, obtained readily from crude acid and easily purified, was hydrolyzed in methyl alcoholic solution with potassium hydroxide. The marked insolubility of the potassium salt of the acid in methyl alcohol suggested the following procedure for the condensation reaction which is found to give better yields of pure product and in a much shorter time than the former method adapted from that of Erlenmeyer.

---

[1] Reimer, THIS JOURNAL, 48, 2454 (1926).

[2] Musajo, *Gazz. chim. ital.*, **60**, 669 (1930).

Seventeen and six-tenths grams (0.2 mole! of pyruvic acid was mixed with 21.2 g. (0.2 mole) of benzaldehyde, the mixture cooled and 55 cc. of a 25% solution of potassium hydroxide (0.24 mole) in methyl alcohol added slowly with constant shaking and cooling. The solution became dark reddish yellow but there was no evidence of condensation as long as the mixture was kept at or below 10°. As the temperature rose, crystals of the potassium salt of benzalpyruvic acid slowly separated and the solution became warm. After twelve hours at room temperature there was an almost solid mass of crystalline potassium salt. This was filtered, washed with a few cubic centimeters of methyl alcohol and with ether and air dried. From 70 to 80% yields of analytically pure salt were obtained.

Anal. Calcd. for $C_{10}H_7O_3K$: K, 18.22. Found: K, 18.42.

From the alcoholic filtrates, after spontaneous evaporation of the alcohol and acidification of the aqueous solution of the residue, a dark reddish-yellow oil was obtained This is evidently a mixture containing the oily acid described by Claisen and Claperède.[3]

From cooled, concentrated solution of the potassium salt iced hydrochloric acid precipitated benzalpyruvic acid in more than 90% yield. To prevent the separation of the acid as an oil which subsequently solidifies in impure condition, it was found advisable to seed the potassium salt solution with crystals of the acid before acidification. The product was dried over sulfuric acid and recrystallized from benzene; melting point, 61–62°.

Reaction with Bromine.—The bromination was carried out in carefully dried chloroform with bromine freshly distilled from phosphorus pentoxide. To 10 g. of the dried acid in 60 cc. of chloroform, cooled with ice, 3.03 cc. of bromine was added slowly. The solid that separated toward the end of the reaction was filtered and washed with cooled chloroform. From the filtrate the chloroform was evaporated almost completely in a current of dry air. The yield of dibromide from both sources was 92 to 97%. When the bromination was carried out with air-dried acid, a considerable portion of the substance in the chloroform filtrates was found to be the unsaturated acid, β-bromobenzalpyruvic acid. The crude dibromide is faintly yellow. It softens in the melting point tube at 147° and melts with vigorous decomposition at 149–150°. It crystallizes slowly from dried benzene in fine, stiff, almost colorless needles melting at 150–151° with effervescence.

Anal. Calcd. for $C_{10}H_8O_3Br_2$: C, 35.71; H, 2 38. Found: C, 35.92; H, 2.47.

The hydrate was formed by dissolving 1 g. of the dibromide in 15 cc. of warm benzene to which 0.3 cc. of water had been added. From the moist benzene solution, very fine shining soft white needles separated almost immediately. The crystals soften markedly at about 90°. If the heating is rapid, the substance melts, with vigorous decomposition, at about 140°. If heated slowly, the decomposition may take place at as low a temperature as 120°.

Anak. Calcd. for $C_{10}H_8O_3Br_2 \cdot H_2O$: C, 33 89; H, 2.82. Found: C, 33 78; H, 2.99.

A sample of this substance sealed in a specimen bottle was unchanged after many months. On exposure to the air, even after four months, the substance softened at 90° and melted at 142–143°.

With methyl alcohol the dibromide also forms a solid addition product which separates from solution when almost all the solvent alcohol has evaporated. The solid softens between 70 and 80° to an opaque mass which melts at about 125° with slow evolution of gas above this temperature. This behavior is unchanged after many weeks.

Anal. Calcd. for $C_{10}H_8O_3Br_2 \cdot CH_3OH$: C, 35.86; H, 3.26. Found: C, 36 18; H, 3.15.

---

[3] Claisen and Claperède, Ber., 14, 2472 (1881).

The stability of this product suggests that it is a hemi-acetal and is in marked contrast with that of the methyl alcoholic addition product of β-bromobenzalpyruvic acid. This addition compound separates from methyl alcohol solution in large transparent prisms which almost immediately became opaque through loss of methyl alcohol.

Anal. Calcd. for $C_{10}H_7O_3Br \cdot CH_3OH$: C, 45.99; H, 3.83. Found: C, 46.10; H, 4.10.

When benzalpyruvic acid dibromide is boiled with methyl alcohol for five or ten minutes, the methyl ester previously described, melting at 117°, is formed in good yield. There is no loss of hydrogen bromide as is the case when the dibromide is boiled with water[1] nor is there replacement of bromine with methoxyl as with the dibromide of 2,4-dimethoxy-5-bromocinnamic acid.'

In **ethyl** alcohol the dibromide is readily soluble in the cold and does not separate from the solution on spontaneous evaporation of the solvent. The yellow oil remaining gave analytical results indicating it to be a mixture. After standing for several days, the oil deposited a few crystals which melted at 61-62' and were proved to be the ethyl ester of benzalpyruvic acid dibromide by a mixed melting point determination with that substance. The ester was readily obtained in quantity by bromination of ethyl benzalpyruvate.6 The product crystallizes from ether in very pale yellow stocky needles melting at 61-62°.

Anal. Calcd. for $C_{12}H_{12}O_3Br_2$: C, 39.56; H, 3.29. Found: C, 39.22; H, 3.39.

The ester crystallized from ethyl alcohol in less pure condition, and, after standing in contact with alcohol for several days, the product was a yellow oil which analyses showed to be a mixture of the ester with that substance in combination with alcohol.

The ease of esterification of benzalpyruvic acid dibromide is interesting when contrasted with the behavior of the unsaturated @-bromobenzalpyruvic acid. The unsaturated acid cannot be esterified directly, crystallizing unchanged after standing for many hours in solution in alcohol saturated with hydrogen chloride.

Summary

Improved methods of preparation of benzalpyruvic acid and of benzalpyruvic acid dibromide have been described as well as addition compounds of the dibromo compound with various solvents.

ACTION OF HYDROGEN CHLORIDE ON STANNANES OF THE TYPE $R_2SnR'_2$

BY RALPH H. BULLARD AND FRANCIS R. HOLDEN

RECEIVED JUNE 10, 1931 PUBLISHED AUGUST 5, 1931

In a previous paper[1] the action of halogens on some mixed stannanes was discussed. It was shown that the replacement series of some organic groups in decreasing order of ease of removal from tin by halogen is phenyl, benzyl, methyl, ethyl and n-propyl. F. B. Kipping,[2] on halogenating certain mixed stannanes, found that the ease with which various radicals are removed by iodine from a molecule containing two or three different groups decreases in the order: o-tolyl, *p*-tolyl, phenyl and benzyl. Hence the replacement series based on the halogenation reaction becomes: o-tolyl, *p*-tolyl, phenyl, benzyl, methyl, ethyl and n-propyl.

It was considered of interest to ascertain whether or not this order is observed when mixed stannanes are treated with dry hydrogen chloride. Kipping states that the order in which the groups are removed from his unsymmetrical stannanes by warm or hot concentrated hydrochloric acid solutions is in general the same as that with iodine. He notes one exception: tribenzylethylstannane when refluxed with hydrochloric acid yields tribenzylstannyl chloride.

To simplify the problem it was decided in this investigation to prepare symmetrical stannanes of the type $R_2SnR'_2$ and to treat these with dry hydrogen chloride under conditions such that two groups, and only two groups, would be removed. Examination of the resulting dichloride would then show which groups had been removed. For this purpose dimethyldiethylstannane, diethyldi-n-propylstannane, and diphenyldiethylstannane were prepared and treated with dry hydrogen chloride at temperatures such that two groups were removed. If the above replacement series of groups is valid in connection with this reaction, one would predict (1) that both methyl groups would be removed from dimethyldiethylstannane, (2) that both ethyl groups would be removed from diethyldi-n-propylstannane, and (3) that both phenyl groups would be removed from diphenyldiethylstannane. A study of the reaction products showed them to be (1) methylethylstannyl dichloride, (2) ethyl-n-propylstannyl dichloride and (3) diethylstannyl dichloride. In the first two instances the two groups substituted by the chlorine of the hydrogen chloride were one of each kind.

Experimental Part

Preparation of the Stannanes.—Dimethyldiethylstannane, $(CH_3)_2(C_2H_5)_2Sn$, was prepared by the Grignard reaction from methylmagnesium iodide and diethylstannyl

---

[2] F. B. Kipping, *J. Chem. Soc.*, 131, 2365 (1928).

dichloride. It was purified by distilling under reduced pressure. It distilled at 32° under 14 mm. pressure and at 132° under atmospheric pressure; yield of the pure stannane, 75% of the theoretical.

Anal. Subs., 0.1351: SnO_2, 0.0986. Calcd. for $(CH_3)_2(C_2H_5)_2Sn$: Sn, 57.40. Found: Sn, 57.48. *Mol. wt.* Subs., 0.2248, 0.1334, 0.2418: C_6H_6, 21.42, 19.78, 21.47: *At*, 0.261, 0.167, 0.279. Calcd. for $(CH_3)_2(C_2H_5)_2Sn$: mol. wt., 206.8. Found: mol. wt., 205.9, 206.6, 206.6.

Diethyldi-n-propylstannane, $(C_2H_5)_2(n\text{-}C_3H_7)_2Sn$, was similarly prepared by the Grignard reaction using n-propyl bromide and diethylstannyl dichloride. It was purified by distilling under reduced pressure. It boiled at 84.5° under 10 to 11 mm. pressure. Under atmospheric pressure it distilled at 205 to 207° with slight decomposition; yield of the pure stannane, 88% of the theoretical.

Anal. Subs., 0.2282, 0.2534: SnO_2, 0.1307, 0.1448. Calcd. for $(C_2H_5)_2(n\text{-}C_3H_7)_2$, Sn: Sn, 45.15. Found: Sn, 45.11, 45.01. *Mol.* wt. Subs., 0.1570, 0.3976: C_6H_6, 20.15, 19.82: *At*, 0.155, 0.406. Calcd. for $(C_2H_5)_2(n\text{-}C_3H_7)_2Sn$: mol. wt., 262.9. Found: mol. wt., 257.4, 253.0.

Diphenyldiethylstannane, $(C_6H_5)_2(C_2H_5)_2Sn$, was likewise prepared by the Grignard reaction from ethylmagnesium bromide and diphenylstannyl dichloride. It was purified by distilling under reduced pressure. It boiled at 155–157° at 4 mm. pressure; yield of the pure stannane, 78.5% of the theoretical.

Anal. Subs., 0.3513, 0.3457: SnO_2, 0.1601, 0.1575. Calcd. for $(C_6H_5)_2(C_2H_5)_2Sn$: Sn, 35.88. Found: Sn, 35.90, 35.89.

Treatment of **Dimethyldiethylstannane** with Dry Hydrogen Chloride.—Dry hydrogen chloride was bubbled through 10.89 g. of the stannane contained in a round-bottomed flask. An oil-bath was placed around the flask and the temperature was gradually raised to 140–145° over a period of two hours. The temperature was then maintained at this point for two hours more. On cooling, the contents of the flask solidified. The product was recrystallized from hot petroleum ether; 10.67 g. was obtained. The crystals melted at 52°; yield, calculated as methylethylstannyl dichloride, $(CH_3)(C_2H_5)SnCl_2$, 86.7% of the theoretical.

Anal. Subs, 0 1812, 0 2100: SnO_2, 0.1167, 0.1356. Subs., 0.2015, 0.2724: AgCl, 0.2438, 0.3319. Calcd. for $(CH_3)(C_2H_5)SnCl_2$: Sn, 50.80; Cl, 30.35. Found: Sn, 50.73, 50.86; Cl, 29.93, 30.14. *Mol. wt.* Subs., 0.2323, 0.3860: C_6H_6, 20.44, 20.44: *At*, 0.248, 0.405. Calcd. for $(CH_3)(C_2H_5)SnCl_2$: mol. wt., 233.7. Found: mol. wt., 234.6, 238.7.

Some of the methylethylstannyl dichloride was converted into the oxide by dissolving it in water and treating this solution with sodium hydroxide solution. The resulting precipitate was filtered, washed with water, alcohol, ether, and then dried.

Anal. Subs., 0.3652, 0.2618: SnO_2, 0.3065, 0.2202. Calcd. for $(CH_3)(C_2H_5)SnO$: Sn, 66.40. Found: Sn, 66.10, 66.25.

Methylethylstannyl dichloride was converted into **trimethylethylstannane** by treatment with sodium and methyl iodide in liquid ammonia. On dissolving 0.5049 g. of the dichloride in liquid ammonia, a clear solution was obtained. Sodium, in weighed amounts, was added to this solution. When 0.0913 g., approximately two atoms of sodium per molecule of dichloride, had been added a yellow gummy precipitate had formed. This was presumably the methylethyltin free group. The further addition of 0.0454 g. of sodium, approximately one more atom of sodium per molecule of dichloride, caused the free group to dissolve and gave a yellow solution. The addition of a further 0.0449 g. of sodium resulted in the formation of a deep red solution of the disodium methylethylstannide, $Na_2Sn(CH_3)(C_2H_5)$. A very small amount of sodium in addition gave a deep blue solution, showing that the end-point of the reaction had been passed with this last addition. Methyl iodide was then added until a clear colorless solution was obtained. This produced a white precipitate. On evaporating the ammonia and vapor distilling with ammonia gas through a condenser cooled with liquid ammonia, a few drops of a liquid boiling at 109° (uncorr.) was obtained. Trimethylethylstannane, $(CH_3)_3(C_2H_5)Sn$, boils at 108.2° corr.[3] The reactions involved in the above transformations are therefore

$$
\begin{aligned}
(CH_3)(C_2H_5)SnCl_2 + 2Na &= (CH_3)(C_2H_5)Sn + 2NaCl \\
(CH_3)(C_2H_5)Sn + 2Na &= Na_2Sn(CH_3)(C_2H_5) \\
Na_2Sn(CH_3)(C_2H_5) + 2CH_3I &= (CH_3)_3(C_2H_5)Sn + 2NaI
\end{aligned}
$$

The identification of the trimethylethylstannane formed by these reactions gives rather conclusive proof that the product of the action of hydrogen chloride on dimethyldiethylstannane is methylethylstannyl dichloride.

Treatment of **Diethyldi-*n*-propylstannane** with Dry Hydrogen Chloride.—Dry hydrogen chloride was bubbled through 4.778 g. of the stannane for four hours at 100°. The solid product was recrystallized from hot petroleum ether; 3.25 g. was obtained; yield, calculated as ethyl-n-propylstannyl dichloride, 68.9% of the theoretical. The reaction had not been run quite to completion because the piercing odor of a monohalide was present. The purified substance melted at 53°.

Anal. Subs., 0.1653, 0.1761: SnO_2, 0.0961, 0.1021. Subs., 0.2045, 0.2465: AgCl, 0.2247, 0.2691. Calcd. for $(C_2H_5)(n\text{-}C_3H_3)SnCl_7$: Sn, 45.35; Cl, 27.10. Found: Sn, 45.79, 45.67; Cl, 27.18, 27.01.

Treatment of **Diphenyldiethylstannane** with Dry Hydrogen Chloride.—Dry hydrogen chloride was bubbled for forty minutes through 15.6 g. of the stannane heated at 150–160°. The escaping vapors were passed through a small water condenser. A liquid was obtained which was identified as benzene. The solid residue in the reaction flask was crystallized from petroleum ether; 10.46 g. was obtained; yield, calculated as diethylstannyl dichloride, 89.6% of the theoretical. The purified crystals melted at 84°. Diethylstannyl dichloride melts at 84–85°.[4]

The authors wish to acknowledge their indebtedness to the Warren Fund of the American Academy of Arts and Sciences for a grant which assisted in defraying the expenses of this investigation.

Summary

The preparation of dimethyldiethylstannane, diethyldi-n-propylstannane and diphenyldiethylstannane has been described.

On treating dimethyldiethylstannane with dry hydrogen chloride under conditions such that two groups are substituted by chlorine, one methyl group and one ethyl group are removed with the resulting formation of methylethylstannyl dichloride.

Diethyldi-n-propylstannane on similar treatment yields ethyl-n-propyl stannyl dichloride.

Diphenyldiethylstannane, however, on similar treatment yields diethyl stannyl dichloride.

THE FRIEDEL AND CRAFTS REACTION WITH MALEIC ANHYDRIDE AND RESORCINOL DIMETHYL ETHER. THE ADDITION OF AROMATIC ETHERS TO UNSATURATED SUBSTANCES

BY GRACE POTTER RICE

RECEIVED JUNE 11, 1931 PUBLISHED AUGUST 5, 1931

Several examples of the reactivity of maleic anhydride in addition reactions have been recorded in the literature in recent years. Diels and Alder[1] have studied the reactions which this anhydride and other substances, having extremely reactive double linkages, undergo when treated with a large and varied list of unsaturated substances. So specific is this type of reaction that it has been used by Windaus[2] to prove that a conjugated system of double linkages in an ergosterol derivative is destroyed by irradiation, since the irradiated product failed to react with maleic anhydride.

Kuhn and Wagner-Jauregg[3] have studied the addition of maleic anhydride to polyenes and very recently Conant and Scherp[4] have obtained evidence that a reaction takes place between maleic anhydride and free radicals.

In this Laboratory it has now been found that maleic anhydride combines with resorcinol dimethyl ether in the presence of aluminum chloride to give a saturated anhydride, dimethoxyphenylsuccinic anhydride (I). This reaction can be explained by a mechanism involving a 1,4-addition to maleic anhydride. The anhydride I was unexpectedly obtained, along with other substances, when the Friedel and Crafts reaction with maleic anhydride and resorcinol dimethyl ether was carried out for the purpose of preparing dimethoxybenzoylacrylic acid, II. The fact that this unsaturated acid has been shown to form an addition product with resorcinol dimethyl ether in the presence of aluminum chloride may account in part for the low yield.

$(CH_3O)_2C_6H_3COCH{=}CHCO_2H + C_6H_4(OCH_3)_2 \longrightarrow$

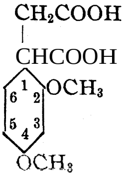
II

$(CH_3O)_2C_6H_3COCH_2CHCO_2H$

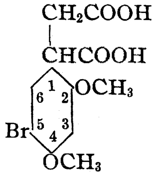
III

Certainly a diminished yield of unsaturated acid II accompanies an increased yield of the ketonic acid III in the Friedel and Crafts reaction.

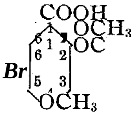
That the substituting group in III is in the a-position to the COOH group rests on the analogy with the mode of addition of various addends to benzoylacrylic ester and its substitution products.[5] That the point of union of the substituting group is that indicated at carbon atom 1 in III is based on the proof of the point of union of this same substituting group in dimethoxyphenylsuccinic acid IV, obtained from the anhydride I by hydrolysis. It is as follows



IV

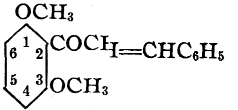


V



Dimethoxyphenylsuccinic acid IV forms one monobromo substitution product and it has not been possible to prepare a dibromo compound from this acid. If the side chain were at carbon atom 3 or at carbon atom 6, both of those substances would be expected to form dibromo substitution products since both of them have two hydrogen atoms which are alike. The bromodimethoxysuccinicacid obtained from IV gives a known product on oxidation, 5-bromo-2,4-dimethoxybenzoic acid.[6] The position of the side chain in IV must, therefore, be that indicated.

The structure of the acid IV is interesting in view of the fact that cinnamyl chloride is reported to react with resorcinol dimethyl ether to form the compound[7] (A).



A

The ketonic acid III could be formed in the Friedel and Crafts reaction from the anhydride I as well as from the unsaturated acid II; in fact it has been shown to be formed when this anhydride is treated with resorcinol dimethyl ether and aluminum chloride, but along with the

[7] Simonis and Danischewski, Ber., 59,2914 (1926).

acid III there is also obtained about an equal quantity of an isomeric acid,[8] $(CH_3O)_2C_6H_3COCHCH_2(COOH)C_6H_3(CH_3O)_2$. Since not a trace of the isomeric acid has been detected in the reaction with maleic anhydride and resorcinol dimethyl ether, it seems probable that the ketonic acid III is formed from the unsaturated acid and not from the anhydride.

Numerous examples have been reported of the use of aluminum chloride and of sulfuric acid to bring about addition reactions between unsaturated substances and benzene, toluene, phenol, resorcinol, and hydroquinol.[9] The reaction between resorcinol dimethyl ether and maleic anhydride, however, is not brought about by either hydrogen chloride or sulfuric acid but only by aluminum chloride. In view of the fact that anisole does not add to the unsaturated ketone, $C_6H_5CH{=}CHCOC_6H_4OCH_3$,[10] even in the presence of aluminum chloride, it seems of interest to attempt to determine how general is the reaction between aromatic ethers and unsaturated substances with unusually reactive conjugated systems of double linkages such as maleic anhydride and substituted benzoylacrylic acids. An investigation of this subject is under way in this Laboratory.

Experimental Part

The Friedel and Crafts Reaction.—Freshly distilled maleic anhydride,[11] 53.6 g., which was recrystallized from chloroform immediately before using, was dissolved in 71.5 g. of resorcinol dimethyl ether. This solution, which had a characteristic dark, yellow-green color,[12] was treated with 150 g. of carbon disulfide slowly while being stirred rapidly with an electric stirrer in order that the maleic anhydride might separate in as small crystals as possible. The mixture was cooled with ice, 80 g. of finely powdered aluminum chloride was added gradually and the stirring continued until the dark red product turned to a solid mass. This was decomposed with ice and concd. hydrochloric acid and the granular solid which separated was filtered by suction and left to dry; 111 g. of product melting at 105–130° was obtained. This solid was powdered and extracted several times with small quantities of ether, which removed most of the resorcinol dimethyl ether and left 76 g. of a slightly yellow product melting at 135–160°. When this was dissolved in acetone, dimethoxyphenylsuccinic anhydride I (37.4 g.) crystallized in fine, colorless needles; the residue from the acetone filtrate was boiled with a small quantity of toluene, which left undissolved 3.7 g. of yellow dimethoxybenzoylacrylic acid, II. The toluene solution held a mixture of anhydride and yellow acid. Part of the residue from the toluene was separated by taking advantage of the fact that the yellow acid creeps from a benzene solution of the mixture and leaves the anhydride in solution; the rest of the residue from toluene was dissolved in 50% acetic acid. The yellow acid crystallized in almost pure condition and the filtrate deposited dimethoxyphenylsuccinic acid IV formed by hydrolysis of the anhydride; 49.2 g. of anhydride,

5.6 g. of unsaturated acid and 5.2 g. of dimethoxyphenylsuccinic acid were separated in pure condition. The residue left after evaporation of the ether used for washing the crude solid was distilled with steam; this removed resorcinol dimethyl ether and left a dark red oil from which no solid could be separated.

Dimethoxyphenylsuccinic Anhydride I, $(CH_3O)_2C_6H_3\overline{CH—CH_2CO—O—CO}$.—The anhydride crystallizes from acetone, benzene, toluene, chloroform and a mixture of chloroform and ether in colorless needles melting at 147°. It is readily obtained by warming dimethoxyphenylsuccinic acid with acetyl chloride and by distilling the acid in a vacuum. On boiling with water or 50% acetic acid it gives the corresponding acid.

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.08. Found: C, 61.07; H, 5.01.

Dimethoxyphenylsuccinic Acid IV, $(CH_3O)_2C_6H_3CH(COOH)CH_2COOH$.—The acid crystallizes from water, methyl alcohol, acetone and 50% acetic acid in large, transparent crystals which melt at 160°, leaving a purple coloration in the top of the melting point tube.

Anal Calcd. for $C_{12}H_{14}O_6$: C, 56.69; H, 5.51; CH_3O, 24.40. Found: C, 56.87; H, 5.79; CH_3O (Pregl), 24.86.

Dimethoxybenzoylacrylic Acid II, $(CH_3O)_2C_6H_3COCH{=}CHCO_2H$.—The acid is sparingly soluble in toluene and boiling water, readily soluble in chloroform, acetone and boiling methyl alcohol; it separates in fine yellow needles which lose their color at 180° and then darken and melt at 189° with decomposition.

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.08. Found: C, 60.63: H, 5.01.

Methyl Dimethoxybenzoylacrylate, $(CH_3O)_2C_6H_3COCH{=}CHCO_2CH_3$.—A poor yield of the ester was obtained by refluxing a methyl alcohol solution of the acid with concd. sulfuric acid. It forms yellow needles which melt at 85° after two recrystallizations from methyl alcohol.

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60. Found: C, 62.80; H, 5.77.

The unsaturated acid gives a product containing nitrogen when treated with diazomethane; this reaction as well as a method for the preparation of the ester in good yield is still under investigation.

α-Dimethoxyphenyl-β-dimethoxybenzoylpropionic Acid III, $(CHO_3)_2C_6H_3COCH_2—CH(COOH)C_6H_3(CH_3O)_2$.—When the Friedel and Crafts reaction was repeated under as nearly the same conditions as was possible, only 0.4 g. of unsaturated acid was separated. In this case the crystalline solid, left after removal of the anhydride and unsaturated acid, was treated with cold methyl alcohol; 9.7 g. of substance melting at 125–147° was obtained. By fractional recrystallization from 50% acetic acid this mixture was separated into two acids; the more soluble one was dimethoxyphenylsuccinic acid IV and the less soluble one an acid which melted at 160° on recrystallization from methyl alcohol; it is α-dimethoxyphenyl-β-dimethoxybenzoylpropionic acid, III. From 9.7 g. of solid, 4.7 g. of IV and 3.7 g. of III were obtained in pure condition. The residue from the ether used for washing the crude product deposited 2 g. of III when it was treated with methyl alcohol.

Anal. Calcd. for $C_{20}H_{22}O_7$: C, 64.17; H, 5.88; CH_3O, 33.15. Found: C, 64.38; H, 5.92; CH_3O (Pregl), 33.67.

The Friedel and Crafts reaction has been carried out fourteen times under a variety of conditions, using carbon disulfide as solvent, petroleum ether as solvent and using no solvent and the temperature has been varied over a wide range. One reason that the best yield in these many reactions was only 60% of all products together is the lack of solubility of maleic anhydride at the temperature at which the reaction gives the smallest quantity of unmanageable oil. The solid anhydride becomes coated with the viscous aluminum chloride addition product and is not attacked. When the reaction was carried out without a solvent it was extremely vigorous and a large amount of oil was obtained from which only a few grams of the products described could be separated. From this reaction a fifth substance melting at 185–187° was isolated which may be a result of demethylation, in the presence of aluminum chloride, of one methoxyl group in each aromatic nucleus of the acid III. It has not Wen possible, however, to change it into III by methylation with dimethyl sulfate.

Anal. Calcd. for $C_{18}H_{18}O_7$: C, **62.42; H,** 5 **20.** Found: C, **61.83**; H, **5.87.**

Perkin and Robinson[13] have found that an analogous reaction takes place when resorcinol dimethyl ether and succinic anhydride are treated in the molten condition with aluminum chloride. It is probable that a large part of the untractable material is formed as a result of the demethylating action of aluminum chloride. No reaction, however, could be made to take place between maleic anhydride and resorcinol dimethyl ether by using gaseous hydrogen chloride or sulfuric acid in place of aluminum chloride.

5-Bromo-2,4-dimethoxyphenylsuccinic Acid, V, $(CH_3O)_2C_6H_2BrCH(COOH)CH_2$-COOH.—Dimethoxyphenylsuccinic acid was brominated in carbon disulfide, chloroform, glacial acetic acid and ether. The same product was always obtained and this could not be induced to react with a second molecule of bromine in boiling glacial acetic acid or in the sunlight. The crude product, after washing with ether, was a chalk-white powder melting at 219°; yield, 88%.

Anal. Calcd. for $C_{12}H_{13}O_6Br$: C, **43.24;** H, **3.90.** Found: C, **43.54;** H, **3.99.**

One gram of this acid was refluxed for fifteen hours in acetone solution with potassium permanganate. On acidifying the aqueous solution obtained by boiling the oxides of manganese with water, **0.3** g. of solid melting at **186–193"** was precipitated. After recrystallization from acetone the solid showed no depression of melting point when mixed with a specimen of 5-bromo-2,4-dimethoxybenzoic acid.

Dimethyl Dimethoxyphenylsuccinate, $(CH_3O)_2C_6H_3CH(COOCH_3)CH_2COOCH_3$.—This ester, prepared by refluxing a methyl alcohol solution of the acid IV with concd. sulfuric acid, could not be induced to crystallize before it was distilled in a vacuum (b. p. 231° at **31** mm.). The solid separates from methyl alcohol in heavy transparent plates which melt at 60°; yield of pure product, **92%.**

Anal. Calcd. for $C_{14}H_{18}O_6$: C, **59.57; H, 6.38.** Found: C, **59 66; H, 6.34.**

Methyl **5-Bromo-2,4-dimethoxyphenylsuccinate,** $(CH_3O)_2C_6H_2BrCH(COOCH_3)$-$CH_2COOCH_3$.—This ester a a s brominated in order to determine whether it is possible to obtain isomeric monobromo derivations or a dibromo derivative in spite of the fact that only one bromine compound is formed from the corresponding acid. Bromination in chloroform solution gave a quantitative yield of bromo ester which melted at 90° after two recrystallizations from methyl alcohol.

Anal. Calcd. for $C_{14}H_{17}O_6Br$: C, **46.53;** H, **4.70.** Found: **C, 46.22; H, 4.70.**

α-Dimethoxyphenylethane-α,β-dicarbonic Acid-&methyl Ester, $(CH_3O)_2C_6H_3CH$-$(COOH)CH_2COOCH_3$.—A solution of **17.2** g. of dimethoxyphenylsuccinic anhydride in **200** cc. of methyl alcohol was refluxed for three hours and the solution evaporated to 150 cc., **2** g. of anhydride separated and on further evaporation the filtrate deposited **12.4** g. of ester melting at **139–141.5'; yield, 72%.** After recrystallization from methyl alcohol the colorless needles melted at 142.5°. This ester was first obtained in the course of purifying a Friedel and Crafts product, as the acid IV is readily esterified by boiling it with methyl alcohol.

---

[13] **Perkin** and Robinson, **J.** *Chem. Soc.,* **93,509 (1908).**

α-Dimethoxyphenylethane-α,β-dicarbonic Acid-a-methyl Ester, $(CH_3O)_2C_6H_3CH(COOCH_3)CH_2COOH$.—This ester is obtained from the dimethyl ester of IV by allowing it to stand for two hours at room temperature with a methyl alcohol solution of potassium hydroxide. The product from hydrolysis of 5.5 g. of dimethyl ester was poured onto ice, the dimethyl ester (2.1 g.) was filtered off and the filtrate extracted with ether; evaporation of the ether left a solid (2.3 g.) melting at 100–115°. By repeated recrystallizations from methyl alcohol, 0.3 g. of pure ester melting at 117" was separated. Analysis indicated that the rest was a mixture of the two isomeric mono esters. On hydrolysis with aqueous potassium hydroxide it gave a quantitative yield of the acid IV.

Anal. Calcd. for $C_{13}H_{16}O_6$: C, 58.20; H, 5.97. Found: subs. (117°), C, 58.06; H, 5.90; mixture: C, 58.03; H, 6.12.

The structures of these two isomers are inferred from analogy with the corresponding esters of phenylsuccinic acid.

The ketonic acid III is formed as the only product of reaction when resorcinol dimethyl ether is treated with dimethoxybenzoylacrylic acid and aluminum chloride.

Methyl **α-Dimethoxyphenyl-β-dimethoxybenzoylpropionate,** $(CH_3O)_2C_6H_3COCH_2CH(COOCH_3)C_6H_3(CH_3O)_2$.—This ester was prepared by saturating a methyl alcohol solution of the acid with hydrogen chloride. The solid, obtained in quantitative yield, crystallizes in clusters of silky needles melting at 140°.

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.94; H, 6.18. Found: C, 65.07; H, 6.37.

Semicarbazone of α-Dimethoxyphenyl-β-**dimethoxybenzoylpropionic** Acid, $(CH_3O)_2C_6H_3C({=}NNHCONH_2)CH_2CH(COOH)C_6H_3(CH_3O)_2$.—The ketonic acid gives a 90% yield of semicarbazone on standing for twelve hours with semicarbazide; after washing with boiling methyl alcohol, the powder melted at 204°.

Anal. Calcd. for $C_{21}H_{25}O_7N_3$: C, 58.46; H, 5.80. Found: C, 58.52; H, 6.13.

α-5-Bromo-2,4-dimethoxyphenyl-β-bromo-β-(5-bromo-2,4-dimethoxybenzoyl)-propionic Acid, $(CH_3O)_2C_6H_2BrCOCHBrCH(COOH)C_6H_2(CH_3O)_2Br$.—The ketonic acid, suspended in carbon disulfide and cooled with ice, was treated with three molecular equivalents of bromine. On removal of the solvent the crude, colorless solid forms a cerise-colored coating which was removed by washing with cold methyl alcohol. The acid then melts (dip) with decomposition at 213° to a cherry-red melt.

Anal. Calcd. for $C_{20}H_{19}O_7Br_3$: C, 39.28; H, 3.10. Pound: C, 39.26; H, 2.97.

The methyl ester of this bromo acid was prepared by bromination of the ester of the ketonic acid (140°) in carbon disulfide solution. After washing with cold methyl alcohol, the crude product melted at 161–181° and decomposed at 191°.

Anal. Calcd. for $C_{21}H_{21}O_7Br_3$: C, 40.32; H, 3.36. Found: C, 39.91; H, 3.37.

The crude bromo ester is a mixture of two substances, one melting at 210° and the other at 165–173° and not pure. From the analysis of the crude product it may be concluded that these are probably racemic compounds as the ester has two unequal asymmetric carbon atoms.

And. Subs. (210°). Calcd. for $C_{21}H_{21}O_7Br_3$: C, 40.32; H, 3.36. Found: C, 40.34; H, 3.41.

The Friedel and Crafts Reaction with Resorcinol Dimethyl Ether and Dimethoxyphenylsuccinic Anhydride

β-Dimethoxyphenyl-β-dimethoxybenzoylpropionic Acid and Methyl **β-Dimethoxyphenyl-β-dimethoxybenzoylpropionate,** $(CH_3O)_2C_6H_3COCH(CH_2COOH)C_6H_3(CH_3O)_2$ and $(CH_3O)_2C_6H_3COCH(CH_2COOCH_3)C_6H_3(CH_3O)_2$.—A solution of 29 g. of resorcinol dimethyl ether in 70 cc. of carbon disulfide was treated with an intimate mixture of 10

g. of the anhydride I and 20 g. of aluminum chloride, both finely powdered. The mixture was warmed in a water-bath and stirred vigorously as long as there was evidence of reaction; the orange-colored viscous mass was decomposed with ice and concd. hydrochloric acid and the product filtered off and washed with cold benzene when dry; yield, 12.7 g. of substance melting at 90–135°. The crude solid can be partially separated with 50% acetic acid as a solvent. The first crop of crystals is the ketonic acid III (160°) and the second crop a new acid melting at 157° after a second recrystallization; the mixture of III and this substance melts at 140–145°.

Anal. Calcd. for $C_{20}H_{22}O_7$: C, 64.17; H, 5.88. Found: C, 64.22; H, 6.17.

The residue after these two crops had been removed persistently separated as a mixture, so it was turned into a mixture of esters which could be separated.

The aqueous solution left after filtering off the solid formed in the reaction was mixed with the residue left after removal of the benzene used to wash this solid and the mixture distilled with steam. The insoluble residue which failed to crystallize was esterified and the solid product dissolved in methyl alcohol. The ester of the acid III separated first; from the filtrate the ester of the isomeric acid was obtained as a solid melting at 104° after washing with ether.

Anal. Calcd. for $C_{21}H_{24}O_7$: C, 64.94; H, 6.18. Found: C, 65.26; H, 6.46.

The yield of pure products (65%) was as follows: 4.9 g. of acid III, 1.2 g. of the ester of acid III, 0.3 g. of isomeric acid and 3.9 g. of the ester of the isomeric acid. After this isomeric acid and its ester had become familiar substances, the residues from two Friedel and Crafts reactions with maleic anhydride were examined most carefully but the acid (157°) could not be found nor could its ester be identified when a residue was esterified. If this acid is formed in the Friedel and Crafts reaction with maleic anhydride, it has defied isolation.

Summary

In the presence of aluminum chloride resorcinol dimethyl ether combines with maleic anhydride to form dimethoxyphenylsuccinic anhydride, which may be interpreted as the result of a 1,4-addition reaction. Along with this anhydride four other substances are formed in the Friedel and Crafts reaction. These have been identified, their formation explained and derivatives of them have been prepared.

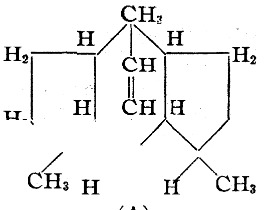
THE SYNTHESIS OF 5,6-DIHYDROPYRINDINE

BY WILLARD C. THOMPSON

RECEIVED JUNE 12, 1931 PUBLISHED AUGUST 5, 1931

Introduction



(A)

In connection with American Petroleum Institute Project 20 there appeared recently a paper describing a hydroaromatic base of the formula $C_{16}H_{25}N$[1] to which was assigned provisionally the structure shown (A). This substance, the first hydroaromatic base to be obtained from petroleum in pure form, is now being investigated in the Texas Laboratory in order to clear up certain doubtful features in connection with the above formula.

5,6-Dihydropyrindine  was discovered in shale oil by Takashi Eguchi[2] in 1927 but, because of the failure of Chemical *Abstracts* to abstract that part of the Eguchi paper[3] dealing with the base in question, this work was overlooked until after the Thompson and Bailey paper had been submitted for publication. Therefore, the assignment of the pyrindacine structure to the $C_{16}H_{25}N$ compound was in no way influenced by the discovery of the Japanese chemist.

At the suggestion of Professor Bailey the author has synthesized 5,6-dihydropyrindine, following a method suggested by von Braun's synthesis[4] of 5,6,7,8-tetrahydroquinoline, and thus confirmed the structure originally assigned to the C_8H_9N shale oil base.[5] The fact that Eguchi obtained quinolinic acid on oxidation of his product excluded the isopyridine structure,  and leaves no doubt as to the discovery of the first base of this type to be found in nature.

In recent preliminary experiments in the Texas Laboratory in connection with the bases occurring in California crude kerosene distillates, the procedure for the isolation of a number of these in pure form has been developed. Their refractivity indicates both aromatic and hydroaromatic types, and, along with the difficulty of resolution of the .distillation

[4] Von Braun and Lemke, *Ann.,* 478, 191 (1930).

[5] For other syntheses in the pyrindine series, see T. Zincke, *Ann.,* 290, 321 (1896); Curt Striegler, *J. prakt. Chem.,* [2] 86, 241 (1913).

fractions into individual components, the wide range of 180 to 335° in their boiling points suggests an exceptionally complex mixture. In line with the cyclopentane structure, so typical of many petroleum hydrocarbons and naphthenic acids, it may be expected that, even if the Eguchi base does not occur among the kerosene bases, numerous hydrides of pyrindine or methylated pyrindines, or it may be isopyrindines, will be encountered.[6]

Since the method employed in the synthesis of 5,6-dihydropyrindine is analogous to that followed by von Braun for 5,5,7,8-tetrahydroquinoline, an outline of von Braun's procedure is subjoined. (1) 2-Hydroxymethylenecyclohexanone (A) results in the Claisen condensation of cyclohexanone with amyl formate.[7] (2) Product (A) with cyanacetamide yields 2-hydroxy-3-cyano-5,6,7,8-tetrahydroquinoline (B) and 2-keto-3-cyano-8a-hydroxy-1,2,3,5,6,7,8,8a-octahydroquinoline (C).[8] (3) Products (B) and (C) yield on heating with concentrated hydrochloric acid 2-hydroxy-5,6,7,8-tetrahydroquinoline, (D).[9] (4) With phosphorus pentachloride product (D) is converted to 2-chloro-5,6,7,8-tetrahydroquinoline, (E).[4] (5) Finally product (E) is reduced to 5,6,7,8-tetrahydroquinoline, (F).[4]

Could a similar series of reactions be carried out, with cyclopentanone replacing cyclohexanone in the first step, it is obvious that in step *(5)* 5,6-dihydropyrindine would result. Here the only part of the synthesis previously effected involves the condensation of cyclopentanone with amyl formate to yield hydroxymethylenecyclopentanone.[10] Steps corresponding to (1), (2) and (4) when applied to the synthesis of 5,6-dihydropyrindine, under the conditions employed by the author, result in poor yields; the other reactions proceed smoothly. The dihydropyrindine, although not prepared in an amount sufficient for purification through fractional distillation, was analyzed in the form of picrate. In accordance with the method of Skraup the synthetic product was oxidized to quinolinic acid and this proved to be identical with quinolinic acid made from quinoline. Furthermore, its physical properties are entirely in agreement with those determined by Eguchi on the shale oil base.

The various reactions involved in the synthesis as outlined can be elucidated through the following structural formulas

---

[6] The Texas Laboratory has obtained recently three barrels of kerosene bases, extracted from 9000 barrels of crude kerosene distillate, from the Union Oil Company of California, and a search will be instituted in fractions in the 200° zone for the C_8H_9N shale-oil base as soon as this large supply has been submitted to exhaustive fractional distillation.

Experimental Part

2-Hydroxymethylenecyclopentanone, I.—In this preparation the procedure of Steindorff[10] was followed with minor modifications. To a cooled solution of 20 g. of cyclopentanone and 17.6 g. of ethyl formate in 100 cc. of anhydrous ether was added 5.5 g. of sodium in small pieces. Most of the sodium reacted within an hour and, after standing in the ice box overnight, the mixture was treated with 100 cc. of ice water. The aqueous layer was extracted with ether, the reaction product precipitated as an oil with the required amount of acetic acid, and the oil taken up in ether. On evaporation of the ether solution, previously dried over calcium chloride, the hydroxymethylenecyclopentanone was obtained as a viscous liquid which, after sublimation at 100° in a vacuum, melted at 73°. A 15 to 20% yield was obtained. The use of isoamyl formate instead of ethyl formate did not give an increase in yield.

2-Keto-3-cyano-7a-hydroxy-1,2,3,5,6,7a-hexahydropyrindine, 11.—Enough alcohol to effect solution was added to a mixture of 8.4 g. of cyanacetamide, 11.2 g. of hydroxymethylenecyclopentanone, 2 cc. of piperidine and 35 cc. of water. After standing for several days at 40°, 4 g. of a crude crystalline condensation product separated. This was decolorized by boiling its acetic acid solution with animal charcoal and after several recrystallizations from hot glacial acetic acid it was obtained as microscopic, rhombic prisms which did not melt even at 310°. The substance is only slightly soluble in water, alcohol and ether.

Anal. Calcd. for $C_9H_{10}O_2N_2$: C, 60.68; H, 5.62; N, 15.73. Found: C, 60.23; H, 5.72; N, 15.62.

2-Hydroxy-5,6-dihydropyrindine-3-carboxylic Acid, 111.—Product II was heated with concentrated hydrochloric acid in a sealed tube at 120–130° for two hours. The solution was diluted with an equal volume of water and boiled with animal charcoal. After filtering and cooling the acid separated in a 50% yield as a white solid and was recrystallized from boiling water, from which it separated as fine slender needles, melting at 272° with decomposition. It is slightly soluble in cold but readily soluble in hot water and alcohol. Its aqueous solution gives a red coloration with ferric chloride and a yellow coloration with ferrous sulfate. A silver salt, insoluble in cold water and soluble in hot water, is formed with silver nitrate.

Anal. Calcd. for $C_9H_9O_3N$: C, 60.32; H, 5.06; N, 7.82. Found: C, 59.87; H, 5.20; N, 7.95. *Equivalent weight.* Calcd. for $C_9H_9O_3N$: 179. Found: 170.

2-Hydroxy-5,6-dihydropyrindine, IV.—Five grams of product II and 15 cc. of concentrated hydrochloric acid were heated for two hours at 120–130° and then at 150 160° for three hours. From the acid solution, diluted with an equal volume of water and boiled with animal charcoal, there separated on cooling 3.5 g. of the hydroxy base as fine slender rods. After several recrystallizations from hot water the base was obtained as a white product, melting at 187–188". It is slightly soluble in cold water and cold alcohol but dissolves readily in ether, hot water and hot alcohol. The hydroxy compound gives a red coloration with ferric chloride and yields a picrate that can be recrystallized from alcohol in the form of small, flat, right prisms, melting at 164°.

Anal. Calcd. for C_8H_9ON: C, 71.08; H, 6.71; N, 10.36. Pound: C, 70.79; H, 6.85: N. 10.46.

2-Chloro-5,6-dihydropyrindine, V.—Four grams of 2-hydroxy-5,6-dihydropyrindine, 4 g. of phosphorus oxychloride, and 15 g. of phosphorus pentachloride were heated at 120–130° under pressure for four hours. The chlorodihydropyrindine, admixed with a considerable amount of tarry material, was treated with ice water, made alkaline and steam distilled. About 0.5 g. of a white solid, insoluble in water, was obtained. After several recrystallizations from 50% alcohol the product separated in the form of colorless rhombic prisms melting at 70–71°.

Anal. Calcd. for C_8H_9NCl: N, 9.12. Found: N, 8.87.

5,6-Dihydropyrindine, VI.—Three grams of 2-chloro-5,6-dihydropyrindine was heated with 15 g. of zinc dust and 60 cc. of concentrated hydrochloric acid for six hours. The solution was then diluted with an equal volume of water, filtered, made alkaline and steam distilled. The distillate was extracted with ether, which, on evaporation, yielded 2–3 cc. of a base having a pyridine-like odor. The product was distilled under reduced pressure, a middle fraction of about 0 3 cc. heing reserved for refractive index and boiling point determinations. The freshly distilled base is colorless but soon darkens on standing. The following physical constants were determined: b. p. at 750 mm 199°; n_D^{25} 1 5407. The corresponding constants of the Fguchi base are: b. p at 761 mm. 199.8"; n_D^{25} 1.541.

The first runnings and residue in the distilling flask were dissolved in alcohol and the base precipitated as picrate. After several recrystallizations from alcohol the yellow picrate was obtained in the form of flat rhombic prisms melting at 181–182°. The picrate of the shale-oil base as described by Eguchi crystallizes in "flat needles," soluble in hot alcohol and melting at 181°.

Anal. Calcd. for $C_8H_9N{\cdot}C_6H_2OH(NO_2)_3$: C, 48.28; H, 3.45; N, 16.09. Found: C, 48.36; H, 3.63; N, 16.05.

Oxidation of **Dihydropyrindine.**—To 0.2 g. of the base, in 25 cc. of water and heated under reflux in a boiling water-bath, 1.5 g. of potassium permanganate was added in small portions over a period of eight hours. Finally the solution was heated to boiling, filtered and evaporated to dryness. The residue was dissolved in water and the quinolinic acid precipitated as silver salt, from which it was recovered in the usual way. The acid was recrystallized from alcohol and on heating in a capillary tube a vigorous evolution of gas took place at 180–190°. As the heating was continued, the product solidified at about 200° and melted at 231°. A mixture of this product with a sample of quinolinic acid, prepared according to the directions of Skraup,[11] showed the same behavior on heating. With copper sulfate solution the acid gave a blue precipitate, insoluble in boiling water and boiling acetic acid, and with ferrous sulfate an orange coloration, characteristic properties of quinolinic acid.

Conclusion

The discovery in the Texas Laboratory of a petroleum base of the formula $C_{16}H_{25}N$, which is probably a hydro-pyrindacine, has directed

---

[11] Skraup, *Monatsh.*, 2, 147 (1881); Hoogewerff and Van Dorp, *Rec. trav. chim.*, **1**, 107 (1882).

attention to the possibility of cyclic nitrogen bases occurring in petroleum distillates of the pyrindine type. The structural relationship of pyrindine to pyrindacine is similar to that between quinoline and acridine.

The occurrence of 5,6-dihydropyrindine in shale oil distillates and the $C_{16}H_{25}N$ base in crude kerosene distillates contributes to the importance of the five-membered carbon ring and will direct the attention of the chemist toward a further search for natural products of these types. Furthermore, it is to be expected that further research in the Texas Laboratory on the kerosene bases will develop a relationship between petroleum bases and naphthenic acids, more especially as concerns cyclopentane structure.

A synthesis of 5,6-dihydropyrindine seemed desirable in confirmation of Eguchi's interpretation of his C_8H_9N base, although the proof of structure furnished by the Japanese chemist was apparently conclusive. It is realized that the method of preparing this substance, as described in the present paper, must be improved in several steps before 5,6-dihydropyrindine becomes available in quantity for further research.

THE C_4-SACCHARINIC ACIDS. V. THE PREPARATION OF 2,3-DIHYDROXYBUTYRIC ACID LACTONE. 3-HYDROXYISOCROTONIC ACID LACTONE. AN ATTEMPT TO PREPARE 2,2'-DIHYDROXYISOBUTYRIC ACID[1]

BY J. W. E. GLATTFELD, GLADYS LEAVELL, GEORGE E SPIETH AND DONALD HUTTON

RECEIVED JUNE 15, 1931 PUBLISHED AUGUST 5, 1931

The resolution of 2,3-dihydroxybutyric acid (hereafter called "2,3-acid") has already been reported in a paper from this Laboratory.[2] The acid used for the resolution experiments was prepared in accordance with the procedures of the two previous workers, Hanriot, and Nef.[3] As neither of these authors was interested specifically in this acid, they did not make a very extended study of its preparation. No mention is made by them, for instance, of the simultaneous formation of an unsaturated acid, 3-hydroxyisocrotonic acid, although the formation of this acid is mentioned by Carré.[4] This unsaturated acid was formed to some extent in every one of our runs, in some cases even to the exclusion of the desired 2,3-acid. It was isolated in the form of its lactone in large quantities during

---

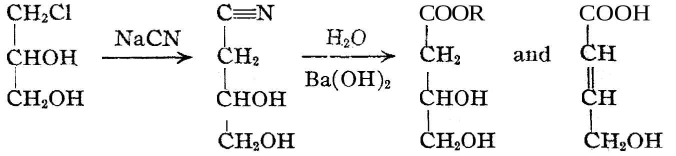
the work of preparation reported below. It is a very valuable by-product as it serves as a source for erythronic acid, which it yields when oxidized with permanganate,[5] or with barium or silver chlorate.[6] Although many experiments were carried out in an attempt to prevent the formation of the unsaturated acid, none of them was entirely successful. During this work, however, a satisfactory procedure for the preparation of the 2,3-acid and its separation from the unsaturated acid was developed and is given below because no detailed directions are at present available in the literature. By following these directions a reasonably good yield of the 2,3-acid (28%) may be obtained. This procedure does not differ in principle from that of Nef, but it does differ in some important details. It may be outlined as follows



CH_2Cl–CHOH–CH_2OH $\xrightarrow{NaCN}$ C≡N–CH_2–CHOH–CH_2OH $\xrightarrow[Ba(OH)_2]{H_2O}$ COOR–CH_2–CHOH–CH_2OH and COOH–CH=CH–CH_2OH

Glycerol-a-chloro-hydrin

Nitrile of 2,3-dihydroxybutyric acid

2,3-Dihydroxy-butyric acid

3-Hydroxyisocrotonic acid

2,3-Dihydroxybutyric Lactone

Glycerol-α-chlorohydrin.—As indicated above, glycerol-a-chlorohydrin is the starting product in this synthesis. It was prepared by the action of 1350 cc. of hydrochloric acid of sp. gr. 1.18 on 1 kg. of glycerol in the presence of 48 cc. of glacial acetic acid. The reaction mixture was introduced into pressure bottles, heated in an oil-bath at 120° for seven hours, and then fractionated at 15 mm. The 110–160° fraction was refractionated at 3 4 mm. The average yield of the fraction of b. p. 101–105" at 3–4 mm. in five runs was 707 g., or 59% (Cl, calcd., 32.08; found, 32.24, 32.14).

Preparation of the Lactone.—A solution made by the addition of 32.6 g. of potassium cyanide (or the equivalent in sodium cyanide) in 50 cc. of water, to 55 g. of glycerol-a-chlorohydrin in 225 cc. of 95% alcohol, was kept with occasional shaking in a closed towel-wrapped pressure bottle (tested citrate of magnesia bottle) in a water-bath at room temperature for thirty-six hours. The water-bath was then heated to boiling and so maintained for two and one-half to three hours, the bottle cooled and contents subjected to filtration to remove salts. The filtrates in two such experiments were combined and the solvents removed as completely as possible with water pump (15–20 mm.) and water-bath at 60". The residue was treated with 200 cc. of 95% alcohol, the mixture warmed, subjected to filtration and the salts washed with alcohol. The filtrate was again concentrated under the conditions mentioned above. The residue was dissolved in 200 cc. of water and added to a mixture of 160 g. of hydrated barium hydroxide in 800 cc. of water. The mixture was then kept in a boiling water-bath for four hours while a stream of air, washed by passage through sodium hydroxide solution, was drawn through it (evaporated water not replaced). The hot mixture was then added to a hot solution made up of 166 cc. of 6 *N* sulfuric acid in 2 liters of water, and the mixture kept hot while

[6] Géza Braun, THIS JOURNAL, 51, 235, 246 (1929).

the final quantitative precipitation of the barium was effected by the use of a dilute solution of sulfuric acid. The barium sulfate was removed and the filtrate and washings from the barium sulfate, which contained a trace of barium ion, were subjected to distillation (at 15–20 mm. and water-bath finally at 90°) to remove the water completely; the residue was extracted with absolute alcohol, the alcohol solution decanted and the salts thoroughly washed by decantation. The alcohol was removed from the extract and washings by distillation at 15–20 mm. with water-bath finally at 90°. The residue was then transferred to a Claisen flask and distilled at 3–8 mm., from an oil-bath by the use of an oil pump. The material which boiled below 60° was discarded and two fractions 60–140° and 140–200° collected. The average yields of these two fractions in thirty experiments were 21 g. and 55 g., respectively. These two fractions were twice refractionated and the final fractions, 70–110° and 135–160° at 2–5 mm., averaged in twenty-six experiments, 19.6 g. and 33.5 g. The 70–110° fraction (Fraction I) consisted chiefly of 3-hydroxyisocrotonic lactone and the 135–160° fraction (Fraction II) chiefly of 2,3-dihydroxybutyric lactone; 23 and 28% of the theoretical, respectively.

Purification of the Lactone.—Fraction II gave a test for chloride ion which was due largely, but apparently not entirely, to the presence of a small amount of ammonium chloride. It was found that solution in ten parts of dry ethyl acetate (or 5 parts ethyl acetate and 2–3 parts ether) and allowing to stand overnight caused the precipitation of the salt. The salt was removed by filtration through a folded filter, and the ethyl acetate by distillation (water-bath finally at 100°)*. The residue was dissolved in water and portions of a suspension of pure silver oxide in water added until a white precipitate ceased to form. The filtered solution now failed to give a chloride ion test. The water was removed by distillation with the water pump (15–20 mm. and water-bath finally at 100°), the residue fractionated with the oil pump and the 135–160° fraction at 2–5 mm. again collected. This fraction again tested for chloride ion. The process from the point indicated by the asterisk above was repeated three or four times. While it was easy to get a product that gave only a faint test for chloride, the complete removal of the impurity required ten to fourteen repetitions of the process. Evidently chloride ion is freed during the distillations and a perfectly pure lactone can be obtained only when the source of contamination is destroyed.

The pure lactone boiled under the conditions here used (Claisen flask with long arms, oil-bath and 20 drops of distillate per minute) at 148–150° at 2–4 mm.

Anal. Subs., 0.2190, 0.2639: H_2O, 0.1234, 0.1472; CO_2, 0.3775, 0.4522. Calcd. for $C_4H_6O_3$: **H,** 5.92; **C,** 47.08. Found: **H,** 6.31, 6.24; C, 47.03, 46.82. ***Molecular weight*** determinations gave the following: 104.1, 106.9, 102.2, 104.6, average 104.4. Calculated for $C_3H_6O_3$, 102.05.

Crystallization of the Lactone.—A sample of the pure lactone in a test-tube was cooled in a carbon dioxide snow–acetone bath. Stirring of the sample and scratching of the sides of the test-tube soon caused the entire sample to solidify. This solid sample was saved for inoculation purposes. It was soon found that the lactone could be recrystallized. Thus one volume of lactone in three volumes of a one to one acetone–ether mixture was cooled to about −35° by immersion in a carbon dioxide–acetone mixture, inoculated with the solid mentioned above, and thoroughly stirred for ten minutes. The solution had then set to a pasty mass of crystals. After a half hour the mother liquor was drawn off by the insertion of a glass tube with cotton plug to the bottom of the flask and the application of suction to the tube. There was left in the flask a beautiful mass of white crystals which melted at 22.5–26°. The crystals were three times subjected to the crystallization process outlined above except that only one-half volume of acetone–ether mixture was used and the mixture of crystals and mother liquor was kept in an ice-salt mixture for one-half hour before removal of the mother liquor. The crystals still melted over the same range. They were allowed to melt and the liquid subjected to distillation at 5 mm.; the temperature rose at once to 150" and practically all of the sample distilled between 150 to 151°.

Titration. Subs., 0.2174, 0.2028: 21.38, 19.98 cc. of 0.1 N alkali (phenolphthalein). Calcd. for C_4-saccharinic acid lactone: 21.28, 19.84 cc.

The **Phenylhydrazide.**—The melting point of this compound was found to be higher than that reported by Nef (99°), and by Glatffeld and Miller (100–101°).

Apparently the pure phenylhydrazide is not always formed when the usual procedure for hydrazide formation (addition of phenylhydrazine to the lactone in ethyl acetate solution followed by short heating and letting the reaction mixture stand for several days) is followed. A product, recrystallized from ethyl acetate until the melting point no longer rose, of m. p. 105 5° was obtained by this usual procedure. Analysis of this product showed it not to be the pure phenylhydrazide (calcd. for $C_{11}H_{14}O_3N_2$: N, 13.33; found: 14.64, 14.63, 14.43). The true phenylhydrazide was obtained, however, when a mixture of 12 g. of lactone (b. p. 150–155" at 6 mm.) and 13 g. of phenylhydrazine, without solvent, was heated for two hours on the boiling water-bath and then allowed to stand for forty-eight hours; yield 13 g. Three recrystallizations from ethyl acetate yielded 7 g. of lustrous white plates with a constant melting point of 109°.

Anal. Subs., 0.1025, 0.1053: N_2, 12.25 cc. (24°, 738 mm.), 12.4 cc. (23°, 748 mm.). Calcd. for $C_{10}H_{14}N_2O_3$: N, 13.33. Found: 13.04, 13.08.

3-Hydroxyisocrotonic Acid Lactone

This lactone does not seem to have been studied extensively. Lespieau[7] prepared it by heating 2,3-dichlorobutyric acid and also[8] by the treatment of 2,3-dichlorobutyric acid with sodium carbonate. Lespieau reports the boiling point as 95–96' at 13 mm. and melting point as +4°. As mentioned above, Carré[4] reports that it was formed in his reduced pressure distillation of 2,3-dihydroxybutyric acid.

This unsaturated lactone appeared in all of our distillations of the crude 2,3-dihydroxybutyric acid. We confirmed the observation of Carré that the unsaturated lactone is not formed in the distillations of the pure 2,3-acid lactone; this latter lactone is perfectly stable once it is formed and distils at 2–4 mm. with no apparent decomposition. The unsaturated lactone must therefore be formed at some stage before the 2,3-acid has changed to its lactone.

Purification of Lactone.—About 150 g. of Fraction I (see above) was twice fractionated and the lower fractions (one-tenth of whole) discarded both times. The portion of b. p. 70–75° at 2–3 mm. pressure was cooled in a freezing mixture until about three-fourth of it was solid. The solid was separated by rapid suction filtration, melted, again partly frozen, the solid separated, etc. This process was carried out seven times; 10 g. of material which contained only 0.04% chlorine was obtained. It melted at +5°.

Anal. Subs., 0.2071, 0.1716: H_2O, 0.0925, 0.0750; CO_2, 0.3232, 0.3592. Calcd. for $C_4H_4O_2$: H, 4.79; C, 57.13. Found: H, 5.00, 4.89; C, 56.95, 57.11.

Attempts to titrate the purified lactone indicated that it contained no free acid; the first drop of 0.1 N alkali colored the solution (phenolphthalein). The results of ti-

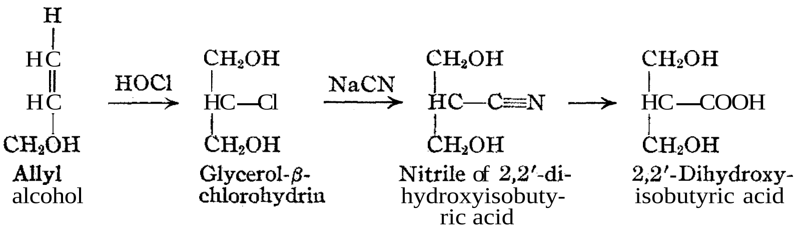
trations carried out in the usual manner (boiling out carbon dioxide after addition of excess acid) gave varying results; apparently the lactone undergoes some change in structure during titration in the hot solution.

Compound Formed **with Phenylhydrazine.**—The lactone reacts with phenylhydrazine but the yield of product is small if a solvent is used. A mixture of 14.5 g. of lactone (b. p. 75–77° at 3 4 mm.) and 22 g. of phenylhydrazine, heated for three hours on the water-bath, however, yielded (transferred with ether) 18 g. of crude product which, after repeated recrystallization from ethyl acetate, melted at 183°. Crystals from other preparations also melted at the same point. The substance was very stable (one sample did not show signs of decomposition in eighteen months) and seemed to be a characteristic derivative of 3-hydroxyisocrotonic acid. Analysis showed that it was not the simple phenylhydrazide, however; figures for carbon, hydrogen and nitrogen were all high (calcd. for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.29; N, 14.57. Found: *C*, 68.16, 68.24; H, 6.79, 6.79; N, 17.44, 17.24).

Attempted Preparation of 2,2′-Dihydroxyisobutyric Acid

This acid has not yet been reported in the literature. As it is one of the C_4-saccharinic acids according to our definition,[9] its preparation was attempted by the process indicated below.



The experimental procedures followed for preparation and purification were exact duplicates of those outlined above for the preparation and purification of 2,3-dihydroxybutyric lactone except that the β- instead of the a-chlorohydrin of glycerol was used. Again two products were formed, a low and a high boiling product. The former was shown to be 3-hydroxyisocrotonic acid and the latter was at first thought to be the desired 2,2′-iso acid[10] mainly because of the fact that reduction of the product yielded some isobutyric acid. Further study, however, showed that if the 2,2′-iso acid was present at all, it was much contaminated by the 2,3-acid lactone. This raised the question as to the source of the 2,3-acid lactone. The most obvious explanation of the presence of the latter was that the β-chlorohydrin that had been used in the preparation work was contaminated with α-chlorohydrin. A search of the literature showed that the β-glycerol chlorohydrin prepared from allyl alcohol contains a large quantity of the α-chlorohydrin.[11] The pure α- and β-glycerol chlorohydrins

[11] Smith, *Z. physik. Chem.*, 92,727 (1918); 94, 723 (1920).

were therefore prepared and these then used in the preparation procedures. Both yielded the same products, 3-hydroxyisocrotonic and 2,3-dihydroxybutyric acid lactones. This shows that the reaction between the chlorohydrins and sodium cyanide is not *a* simple double decomposition reaction. A possible explanation is that both chlorohydrins under the experimental conditions used give the same glycidol, which then adds hydrogen cyanide to form the nitrile of the 2,3-acid practically exclusively.

Pure a- and β-Glycerol Chlorohydrins.—It has long been known[12] that the α-chlorohydrin of glycerol forms a stable condensation product (isopropylidene-a-chlorohydrin) with acetone. It is also known[13] that if the two hydroxyl groups necessary for condensation with acetone are in the 1,3 (as in β-chlorohydrin of glycerol) and not the 1,2 position (as in a-chlorohydrin of glycerol), the condensation proceeds with great difficulty if at all. These facts were taken advantage of in effecting the separation of the *a*- from the β-chlorohydrin of glycerol and the purification of the two compounds. The mixture of chlorohydrins obtained by the addition of hypochlorous acid to allyl alcohol was repeatedly condensed with acetone until no more condensation occurred. The purified condensation product then yielded the pure a-chlorohydrin and the uncondensed residue the pure β-chlorohydrin of glycerol as shown below.

The only property known to us by means of which the purity of given samples of *a*- and @-chlorohydrins of glycerol can be determined is their reaction rate with alkali. In dilute aqueous solution, alkali decomposes both into glycidol but at remarkably different rates Smith[14] showed that the a-isomer is 50% decomposed in much less than one-tenth the time it takes the β-isomer to become 50% decomposed. He used the bimolecular reaction rate equation in his calculations and found that with the pure a-isomer the equation gave a fairly good "constant" but that when mixtures of a- and @-isomers were used the "constant" dropped rapidly with time. He showed, however. that the "constants" at 50% decomposition (K 50) are very good measures of purity and that K 50 for the pure a-isomer at 25° in 0.015 *N* barium hydroxide solution was 11.1 and that for the pure β-isomer about 0.81. For the work in hand it was not necessary to use 100% pure a- and @-isomers. No difficulty was experienced in obtaining samples of the two isomers that were at least 90% pure.

A mixture of 300 *g*. (K 50 = 5.26; % Cl = 36.54) of the chlorohydriu made by the method of Reed and Hurst (allyl alcohol + HOCl),[15] 200 g. of anhydrous sodium sulfate, 1200 cc. of acetone and 18 cc. of concd. sulfuric acid was introduced into a bottle which was then corked and placed in a "revolving" machine. This machine kept the sodium sulfate at all times suspended in the liquid. The machine was operated for twenty-two hours continuously, at the end of which time 75 g. of lead carbonate and 50 g. of sodium carbonate were added to the reaction mixture, the bottle put back on the machine and again rotated for six hours. The bottle was then opened, the liquid decanted and the salts washed by decantation with acetone. The acetone was removed by distillation at ordinary pressure with the water-bath finally at 100°. The residue was thoroughly extracted three or four times with low-boiling ligroin. The combined extracts were dried over sodium sulfate, fractionated at ordinary pressure, and the fraction of boiling range 145–165° saved. This was practically pure isopropylidene-a-chlorohydrin

(209 g.). The residues insoluble in ligroin from two such experiments were now combined and put through exactly the same condensation process again; the quantities of reagents noted above were used. Again a quantity of isopropylidene-a-chlorohydrin (70 g.) and a chlorohydrin residue insoluble in ligroin were obtained. The residue was again condensed as before but proportionately smaller quantities of reagents now used. The process was repeated twice more; quantities of isopropylidene-a-chlorohydrin obtained were 60 g. and 33 g. The final crude residue weighed about 90 g. It was added to corresponding material from other runs and then fractionated with oil pump and oil-bath. Usually three or four fractionations were sufficient to give a colorless product whose boiling range was 110–114° at 3–4 mm. The yield of this purified product was about 10–15%; K 50, 0.70–0.80 and % Cl, 31.30–31.80. The combined isopropylidene-a-chlorohydrin weighed 372 g., a 45% yield. Almost half of the chlorohydrin started with is unavoidably lost in the many experimental manipulations necessary in this process.

The experiment outlined above was repeated many times. The isopropylidene-α-chlorohydrin thus prepared was twice fractionated at ordinary pressure and samples then hydrolyzed by addition of three parts of dilute sulfuric acid (0.1 to 0.15 *N*) to one part of product. The mixture was placed on the revolving machine overnight, during which time the oily condensation product completely dissolved. The sulfuric acid was quantitatively removed by means of barium hydroxide solution (an excess of base must be avoided). The reaction mixture (slightly acid) was then subjected to distillation (barium sulfate not removed) from a water-bath and with a water pump until no more distillate came over, then fractionated with oil pump and oil-bath. The product thus obtained usually boiled at about 111–114° at 7–8 mm. and had K 50 about 9 and percentage of Cl, 31.5–31.8. Repeated fractionation gave a product which was perfectly colorless and which possessed a K 50 of between 9.5 and 10.00.

Phenylurethans of a- and β-Glycerolchlorohydrins.—Rider and Hill[16] have recently prepared these compounds and report the melting points as 128–129° for the α-isomer and 133" for the 8-isomer. We prepared them from our purified products according to the directions of Rider and Hill with results as follows: 17 g. of each chlorohydrin with 13 g. of phenyl isocyanate gave 2.5 g. of crude product in the case of the a-isomer and 3 g. in the case of the 8-isomer. Recrystallization from acetone–high boiling ligroin (1 to 10) yielded finally, in the case of the a-isomer, 0.6 g. of m. p. 127–129, and, in the case of the β-isomer, 2 g. of m. p. 133–136°.

Reaction of the Pure Chlorohydrins with Cyanide.—The highly purified a- and 0-glycerol chlorohydrins prepared as indicated above were each now treated with sodium cyanide and the reaction mixtures put through the synthesis indicated above for the preparation of the 2,3-acid lactone. In each case 55 g. of the chlorohydrin was used and the corresponding quantities of reagents as used in the previous work. In the case of the 0-isomer 18 g. (35%) of product of boiling range 148–150° at 4 mm. was obtained. A sample of this titrated correctly for a dihydroxybutyric lactone (subs., 0.3274: calcd. 31.87 cc. of 0.1 N alkali; found, 31.20). It solidified when cooled with carbon dioxide, could be recrystallized from acetone–ether and melted at 22.5–25.5°. These data show that it was the lactone of 2,3-dihydroxybutyric acid. In the case of the a-isomer, 20 g of product (39%) of boiling range 146–149° at 4 mm. was obtained. It also solidified when sufficiently cooled, could be recrystallized from acetone–ether, after which it melted at 22.5–26". It titrated for a dihydroxybutyric lactone (subs., 0.2174: calcd., 21.31 cc. of 0.1 N alkali; found, 21.28 cc.). These data offer convincing evidence that the products in the two cases were identical and that both were samples of 2,3 dihydroxybutyric lactone.

---

[16] Rider and Hill, THIS JOURNAL, 52,1525 (1930).

Summary

Directions are given for the preparation in about 28% yield of 2,3-dihydroxybutyric lactone from glycerol monochlorohydrin. The lactone has been obtained in crystalline form of melting range 22–26°. The phenylhydrazide melts at 109°.

A valuable by-product, 3-hydroxyisocrotonic lactone, was isolated in 23% yield. The compound which this lactone forms with phenylhydrazine (not the simple phenylhydrazide) melts at 183°.

2,2'-Dihydroxyisobutyric acid cannot be prepared by treatment of glycerol-β-chlorohydrin with sodium cyanide followed by hydrolysis. The product is 2,3-dihydroxybutyric lactone whether the α- or the β-chlorohydrin of glycerol is used in the synthesis.

STUDIES IN THE CHLOROPHYLL SERIES. VI. THE MECHANISM OF THE PHASE TEST

BY CATHERINE C. STEELE[1]

RECEIVED JUNE 20, 1931 PUBLISHED AUGUST 5, 1931

The essential change in allomerization and phase test saponification in the derivatives of chlorophyll *a* is the dehydrogenation of the grouping —CHOHCO— to —COCO—, and it has now been shown that the two hydrogen atoms are removed by oxygen from the air.[2] If the phase test saponification of methyl phaeophorbide a or chlorin *e* trimethyl ester is carried out in a modified Warburg apparatus[3] the amount of oxygen absorbed can be measured. Since the products are the "unstable chlorins," the oxidation is also shown to take place in the alkaline medium, and not in the subsequent acidification nor in the conversion of the chlorins to the phaeopurpurins.

The inherent difference between Willstätter's methods of "phase test" and "hot quick" saponification, whereby he obtained either phytochlorin *g* or chlorin *e* from phaeophorbide a, is now apparent.[4] Phase test saponification is an atmospheric oxidation process: with phaeophorbide a it also opens a ring but effects only partial saponification of the methyl group,

---

[1] Commonwealth Fund Fellow at Radcliffe College.

[2] A preliminary statement of these results appeared in a Communication to the Editor, THIS JOURNAL, 53, 1615 (1931), and the allomerization experiments are discussed in detail in Paper V, *ibid.*, 53, 2382 (1931). In this present paper are discussed the corresponding experiments in the phase test.

[3] Hyde and Scherp, *ibid.*, 52,3359 (1930).

[4] Willstätter and Stoll, "Investigations on Chlorophyll," translated by Schertz and Merz, Science Printing Co., 1928, p. 263.

since the product is a mixture of unstable chlorins which change to the two phaeopurpurins, one of which (7) still retains a methoxyl group.[5] Hot quick saponification of phaeophorbide *a* is an hydrolysis (or complete demethylation) process, and it is now obvious that the reason why the methyl alcoholic solution must be kept boiling during the entire process is that the alcoholic vapors above the solution eliminate practically all the air from the reaction, and hence hydrolysis is accomplished before the material has had a chance to oxidize. Conant and Moyer[6] found that in the phase test on phaeophorbide, the formation of chlorin e can be suppressed completely by substituting ethyl or n-propyl alcohol for methyl alcohol in the solution of potassium hydroxide, or by keeping the reaction mixture at $-10°$. In the latter case, hydrolysis is inhibited by the low temperature, and the oxidation has time to go to completion. In the former case it is well known that concentrated ethyl and n-propyl alcoholic alkali solutions absorb oxygen readily with the possible formation of peroxides, and therefore accelerate the oxidation in the phase test. This is borne out by the fact that, in the measurement of the oxygen absorbed in the phase test, it was found impossible to obtain an initial equilibrium in the Warburg apparatus by the use of propyl alcoholic alkali, due to its continued absorption of oxygen (see experimental portion of this paper).

Previously, several attempts to inhibit the phase test by using an atmosphere of nitrogen were made, but these were unsuccessful, owing to the minute quantity of oxygen necessary for the reaction (0.008 millimole = 0.16 cc. for 5 mg. of methyl phaeophorbide *a*). The use of oxygen absorbers was then tried; here it was found possible on a small scale to treat methyl phaeophorbide a with 25% methyl alcoholic potash in an atmosphere of nitrogen and in the presence of sodium stannite, and obtain alkali-soluble products which on methylation with diazomethane gave chlorin *e* trimethyl ester and methyl phaeophorbide a and no phaeopurpurin 7. Similarly chlorin *e* trimethyl ester gave an alkali-soluble product which on methylation gave back chlorin *e* trimethyl ester. The hydrolyzed product was apparently a monomethyl chlorin *e*, as it contained one methoxyl group.

In connection with this work, the difference in the time and optimum temperatures for the phase test on chlorin e ester and phaeophorbide *a* was noted, and led to a comparison of the rate of hydrolysis of several esters under phase test conditions (including both those which do and those which do not undergo the phase test). While these results cannot be entirely explained, we append in the following table a summary of the results obtained; the figures represent averages of several runs and are probably significant within 20%.

The usual procedure was to dissolve 5 mg. of ester in about 0.5 cc. of

[5] Paper V, THIS JOURNAL, 53,2382 (1931).

[6] Paper III, *ibid.*, 52,3014 (1930).

pyridine and transfer it to 15 cc. of ether in a 50-cc. Erlenmeyer flask. When the solution had attained the required temperature, 1.5 cc. of 25% methyl alcoholic potash was added and the mixture stirred mechanically. It was then shaken up with water and ether, and the material in the alkaline layer transferred to fresh ether (and methylated, where the products were the unstable chlorins). The amounts of hydrolyzed and unhydrolyzed material were determined in a Zeiss comparison spectroscope. Where the two solutions were of the same material (*e. g.*, porphyrins) the ether solutions were compared directly. It was found to be immaterial whether the hydrolyzed solution was remethylated or not. Where the solutions were of different compounds, the amount of substance in mg. in each was obtained by comparison with a standard solution of the material in question.

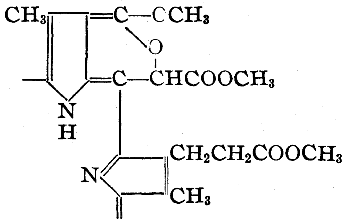
TABLE I

COMPARATIVE RATES OF HYDROLYSIS UNDER PHASE TEST CONDITIONS

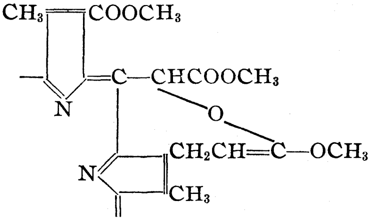
	Percentage hydrolyzed in 5 min. at −8°	30 min. at −8°	15 min. at 20°	Products
Pyrroporphyrin monomethyl ester		0	50 56	Pyrroporphyrin
Phylloporphyrin monomethyl ester		0	52 43	Phylloporphyrin
Rhodoporphyrin dimethyl ester		0	57 52	Rhodoporphyrin (spectrum)
Chlorin *a* trimethyl ester		20	100	Chlorin *a* (spectrum)
Chlorin *e* trimethyl ester		28	100	Dimethyl phaeopurpurin 7 after methylation
Dehydrophaeophorbide *a* methyl ester	87	100	100	Dimethyl phaeopurpurin 7 after methylation
Phaeophorbide *a*	51	100	100	Dimethyl phaeopurpurin 7 after methylation
Phaeophorbide *a* monomethyl ester	28	100	100	Dimethyl phaeopurpurin 7 after methylation
Phaeopurpurin 7 dimethyl ester	100	100	100	Phaeopurpurin 7 (spectrum)
Phaeopurpurin 18 monomethyl ester	100	100	100	Chlorin *a*

Pyrroporphyrin and phylloporphyrin esters contain only the propionic ester group; this apparently cannot be hydrolyzed under the phase test conditions at −8° for thirty minutes. Rhodoporphyrin ester, which has in addition a methyl group on the β-carboxyl, hydrolyzes at about the same rate. Hydrolysis under phase test conditions for five minutes at −8° of methyl phaeophorbide a, phaeophorbide a, and methyl dehydrophaeophorbide a gave the following percentages of dimethyl phaeopurpurin 7 after methylation (this represents the total alkali-soluble material): 28, 51 and 87%. Demethylation and oxidation, oxidation without demethylation, and demethylation alone are the corresponding reactions involved. These results show that the group which gives alkali solubility is a grouping which is more easily hydrolyzed than the ester groups of the porphyrins. If one considered only these results, the conclusion would be that hydrolysis of the propionic ester group is not involved in the phase test; but we know that the propionic ester group is hydrolyzed in the case of methyl phaeophorbide because the product, phaeopurpurin 7, is a monomethyl compound with the methyl group on the carboxyl directly attached to a pyrrole ring. (The proof of this follows from its pyrolysis to monomethyl chlorin f and is supported by the fact that phaeophorbide *a* also yields phaeopurpurin 7.) These results indicate that the hydrolysis of the propionic ester is not the first result of the action of alkali: it is more likely that the anhydride ring (or a lactam ring) in phaeophorbide a first opens.[5] If this is the case, no comparison can be drawn between the hydrolysis rates of the propionic ester in a neutral porphyrin and that in a compound in which a potentially acidic group has already been converted into a salt.

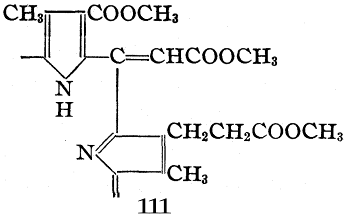
Hydrolyses of phylloporphyrin ester and methyl phaeophorbide *a* were carried out in homogeneous methyl alcoholic solution, using the same proportion of methyl alcoholic potassium hydroxide as in the phase test, and the phylloporphyrin ester was completely unhydrolyzed after thirty minutes at −8°, while the methyl phaeophorbide gave *25.5%* (compare 28% in ether) of hydrolyzed material in five minutes. The presence of a two-phase system consisting of the ether and the alcoholic layer of the potassium salt of phaeophorbide is therefore not responsible for the differences shown in Table I between the porphyrins and the phaeophorbides. The following formulas are suggested as possibilities for the trimethyl ester of chlorin *e*



I



II



111

Formula II contains a more labile form for the propionic ester grouping than I or III, which require the peculiarly rapid hydrolysis of the propionic ester group as discussed above in the case of the phaeophorbide. The extraordinary rapidity with which dimethyl phaeopurpurin 7, methyl phaeopurpurin 7 and methyl phaeopurpurin 18 hydrolyze under phase test conditions (five minutes at −8°, 100% alkali soluble) is surprising. The formula for phaeopurpurin 7 must contain the grouping (IV), or the corresponding enol modification (IVa) and hydrolysis of the trimethyl ester (dimethyl phaeopurpurin 7) must again involve hydrolysis of a propionic ester group. That there is some difference in the ease of hydrolysis of the two ester groups was shown by stirring dimethyl phaeopurpurin 7 with phase test alkali at −8° for five minutes; the resulting product had a methoxyl content of 7% (calcd. for 1 (OCH_3): 4.95; for 2 (OCH_3): 9.65). It is interesting to note that although dimethyl phaeopurpurin 7 hydrolyzes under phase test conditions to phaeopurpurin 7, long standing or shaking of the dimethyl ester with phase test alkali converts it back to the unstable chlorins.

Experimental

Absorption of Oxygen in the Phase Test.—The oxygen absorption during the phase test was demonstrated by using a modified Warburg apparatus. The use of propyl alcoholic alkali was abandoned after it was found impossible with equal volumes present to equalize the pressures in the two arms of the apparatus, due to an increasing absorption of oxygen by the alkali alone. The improved yields of phase test products by the use of propyl alcoholic alkali is therefore due to the latter acting as an oxygen absorber.[7] Equilibrium was easily obtained by using methyl alcoholic potassium hydroxide and carbon dioxide-free air.

(a) Methyl Phaeophorbide *a*.—Twenty-three cc. of 25% methyl alcoholic potash was placed in one of the bottles of the absorption apparatus, and a glass bulb having a long capillary end and containing methyl phaeophorbide a (509 mg. = 0.008 millimole) was carefully inserted in the alkali. The other bottle contained a corresponding amount of alkali to equalize the volumes. The apparatus was placed in a water-bath at 20° and shaken for ten or fifteen minutes until a constant difference in the pressure readings was obtained. The apparatus was then removed from the bath, the bulb broken by a quick shake, the apparatus replaced, and shaken continuously. Pressure readings were recorded during five-minute intervals for the first hour, subsequently at longer intervals. The number of moles of gas absorbed was calculated from a previously determined factor (1 cc. of manometer liquid = 0.0017 millimole of gas). The course of the reaction is indicated by the following figures, which give the millimoles of gas absorbed at different times: ten minutes, 0.0027; thirty minutes, 0.0046; one hour, 0.0086; one and one-half hours, 0.0102; two hours, 0.0117; two and one-half hours, 0.0129; three hours, 0.0137.

---

[7] Paper III, THIS JOURNAL, 52, 3016 (1930).

That the reaction proceeds at a progressively diminishing rate is shown by the following values in 10^{-6} mole per hour for the amount of gas absorbed during successive thirty-minute intervals: 9 2, 8 0, 3 2, 3.0, 2.4, 1.6. The maximum for the rapid absorption of oxygen is in eighty-seven minutes when 0.01 millimole of oxygen has been absorbed, this corresponds to the absorption of one mole of oxygen per mole of phaeophorbide with the formation of hydrogen peroxide.

(b) Chlorin *e* Trimethyl Ester.—In an experiment with 5.92 mg. of chlorin *e* ester (=0.01 millimole), the amount of gas in millimoles absorbed at different times was as follows: ten minutes, 0.0027; thirty minutes, 0.0047; one hour, 0.0062; one and one-half hours, 0.0068; two hours, 0.0071. The rates in 10^{-6} mole per hour for the amount of gas absorbed during successive thirty-minute intervals are therefore 9.2, 3.0, 1.2, 0.6.

In a second experiment with 4 mg. of chlorin *e* ester (=0.0067 millimole) the amount of gas in millimoles absorbed was 0.0014 in ten minutes; in thirty minutes, 0.0038; in one hour, 0 0054; in one and one-half hours, 0.0065; in two hours, 0.0073. The rates in 10^{-6} millimole per hour for absorption during thirty-minute intervals is therefore 7.6, 3.2, 2.2, 1.6. The limit to the amount of oxygen absorbed is clearly one mole of oxygen per mole of chlorin *e* trimethyl ester.

In both (a) and (b) the products were the unstable chlorins, which on standing gave mixtures of phaeopurpurins 7 and 18, or on methylation with diazomethane gave dimethyl phaeopurpurin 7.

In a control experiment, phaeopurpurin 7 was used in the bulb, and no absorption was observed during 1 hour's shaking with the alkali.

Inhibition of the Phase Test

(i) Methyl Phaeophorbide a.—Twenty cc. of 25% methyl alcoholic potassium hydroxide and 1 g. of stannous chloride were placed in the long arm of a Thunberg tube, and 20 mg. of methyl phaeophorbide a was placed in the short arm. The tube was alternately evacuated and filled with nitrogen about eight times, then shaken for seven minutes. The solution was deep green in color. Water was added immediately the tube was opened, and the alkaline solution, on being shaken with ether, retained all the material. It was transferred by acidification to fresh ether, and washed with water. In one experiment the solution was methylated with diazomethane; no change in color was observed, and the product was a mixture of chlorin *e* ester (extracted with 8% acid) and of methyl phaeophorbide *a*, acid number 18. These were identified by spectrum in acid and ether; there was twice as much chlorin *e* as phaeophorbide a, and no phaeopurpurin 7 was obtained.

(ii) Chlorin *e* Trimethyl Ester.—In similar experiments on chlorin *e* ester, most of the material was alkali-soluble after fifteen minutes' shaking; the alkali solution was yellow-green. On transference to ether, methylation with diazomethane gave back the trimethyl ester of chlorin *e*, identified by acid number and spectrum in acid and ether. No phaeopurpurin 7 was obtained. Fractionation of the unmethylated solution resulted in the extraction of all the material with 5 to 6% hydrochloric acid; it had the spectrum in acid and ether of chlorin *e* but contained one methoxyl group (OCH_3: found, 5.76; calcd., 4.95).

Action of Phase Test Alkali on Esters

A few typical experiments are given below (see theoretical section of this paper for table of all the results).

Phylloporphyrin Ester.—Five mg. of ester was dissolved in pyridine, transferred to 15 cc. of ether, and 1.5 cc. of *25%* methyl alcoholic potassium hydroxide added. The mixture was stirred mechanically for fifteen minutes at 20°; then, after addition of water and ether, the alkaline layer was separated and acidified in the presence of fresh ether. The two ether solutions were compared in the spectroscope and gave the ratio hydrolyzed:unhydrolyzed material:: 19.6:20. The volumes of the two solutions were measured and the ratio became 19.6×95 cc.:20×87 cc. The percentage of hydrolyzed material is therefore 51.7%. The hydrolyzed fraction was methylated with diazomethane, washed and dried. On comparing it again with the unhydrolyzed ester the ratio was 20×46 cc.:19.2×50 cc., and the percentage hydrolyzed was 49.6.

Methyl Phaeophorbide a.—(i) Five mg. of ester dissolved in pyridine and transferred to ether was cooled to −8° in an ice–salt bath and 1.5 cc. of methyl alcoholic potassium hydroxide added. The mixture was stirred for five minutes, then water and ether were added. The alkaline layer was acidified under fresh ether and immediately methylated with diazomethane to convert the unstable chlorins to dimethyl phaeopurpurin 7. This was compared with a standard solution of dimethyl phaeopurpurin 7 (50 mg. per liter) and the amount determined was 1.11 mg. The original ether solution containing the unhydrolyzed material was compared with a standard solution of methyl phaeophorbide a. The amount obtained was 2.8 mg.; hence the percentage of hydrolyzed material was 28%.

(ii) Five mg. of ester in pyridine was added to 15 cc. of methyl alcohol in a 50-cc. flask, the solution was cooled to −8° and stirred for five minutes with 1.5 cc. of 25% methyl alcoholic potassium hydroxide. Water and ether were added and the alkaline layer was washed several times with ether, then acidified under fresh ether. This was methylated, and was found to contain 1.2 mg. of dimethyl phaeopurpurin 7. The percentage of unhydrolyzed material was 25.5.

Phaeophorbide a.—Five mg. of phaeophorbide a in pyridine and ether was stirred for five minutes at −8° with 1.5 cc. of 25% methyl alcoholic potassium hydroxide. Water and ether were added, the alkaline layer rapidly acidified under fresh ether, and the product methylated. A fractionation with 14% hydrochloric acid removed the dimethyl phaeopurpurin 7 and this was compared with a standard solution. The amount found was 2.4 mg. The residue from the fractionation, which consisted of unphased phaeophorbide, was washed, dried and compared with a standard solution of methyl phaeophorbide a. The amount was 2.3 mg.; hence the percentage of phaeophorbide phased was 51.

Methyl Dehydrophaeophorbide a.—Five mg. in pyridine–ether was stirred with alkali for five minutes at −8°. The alkaline layer was acidified under fresh ether and the solution methylated. It was compared with a standard solution of dimethyl phaeopurpurin 7, and contained 1.2 mg. The original ether, containing unhydrolyzed material, was compared with a standard solution of methyl dehydrophaeophorbide a (15 mg. per liter). It contained 0.6 mg.; hence the percentage hydrolysis was 87%.

Summary

1. The phase test on chlorophyll derivatives involves oxidation by atmospheric oxygen. The amount absorbed was measured in the case of methyl phaeophorbide *a* and chlorin e trimethyl ester.

2. This oxidation can be prevented by the use of sodium stannite with an atmosphere of nitrogen.

3. A comparison of the rates of hydrolysis under "phase test" conditions of various esters in the "*a*" series is given.

STUDIES OF CONJUGATED SYSTEMS. IX. THE ADDITION OF HYPOCHLOROUS AND HYPOBROMOUS ACIDS TO VINYLACRYLIC ACID

BY IRVING E. MUSKAT AND LESLIE HUDSON

RECEIVED JUNE 22, 1931 PUBLISHED AUGUST 5, 1931

In a recent paper Muskat and Northrup[1] have developed a theory to interpret the addition reactions of conjugated systems. This theory is based on the supposition that conjugated systems differ from non-conjugated systems only in so far as the former may exhibit 1,3-rearrangement, while the latter cannot exhibit this phenomenon. It further assumes that the addition of both components of the addendum to an ethylenic double bond does not occur simultaneously but rather, as has been suggested by Stieglitz,[2] that the essential feature is the attraction of the positive substituting group to the negative carbon valences irrespective of complete saturation. By the application of this theory these authors have shown that in the halogenation of vinylacrylic acid a 1,3-rearrangement is not possible and consequently only 3,4-halogenation can occur. This is in accord with the work of Muskat, Becker and Lowenstein,[3,4] who have shown that in the chlorination and bromination of vinylacrylic acid only 3,4-addition products are formed. As a corollary to the mechanism proposed by these authors, the hypohalous acids should add to vinylacrylic acid in exactly the same manner as do the halogens. The work reported in this paper was undertaken to test this point and contains the results of an investigation on the addition of hypochlorous and hypobromous acids to vinylacrylic acid.

Thiele[5] proved that vinylacrylic acid is reduced, by means of sodium amalgam in alkaline medium, in the 1,4-positions, and not in the 1,2-positions as claimed by Doebner.[6] Ingold and Burton[7] have shown that if vinylacrylic acid is reduced by means of sodium amalgam in acid medium, then 18% of the vinylacrylic acid is reduced in the 1,2-positions while the remainder is reduced in the 1,4-positions. Muskat and Knapp[8] have recently shown that vinylacrylic acid is hydrogenated catalytically in the 3,4-positions. These last investigators have proposed a theory to interpret these varying reduction reactions of conjugated systems.

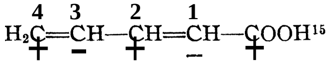
Kohler and Butler,[9] while studying the relative ease of 1,4- and 1,6-addition, showed that sodium malonic ester combines with the esters of vinylacrylic and sorbic acids to give 1,6-addition products, while phenylmagnesium bromide reacts with the same esters to give first the corresponding ketones, which react further to give 1,4-addition products.

Muskat, Becker and Lowenstein[10] have studied the chlorination and bromination of vinylacrylic acid and found that both chlorine and bromine are absorbed in the 3,4-positions. They also found that 3-chloro- and 3-bromovinylacrylic acids absorb chlorine and bromine, respectively, in the 3,4-positions. These are the only addition reactions of vinylacrylic acid that have been reported in the literature.

Mokiewsky[11] was the first investigator to study the addition of hypohalous acids to conjugated systems.[12] He prepared the dichlorohydrin and dibromohydrin of isoprene but did not determine the structure of these compounds. Muskat and Grimsley[13] have made a detailed study of the addition of hypochlorous and hypobromous acids to phenylbutadiene. They have found that these acids are added to phenylbutadiene in the 3,4-positions to give 3-hydroxy-4-chloro-1-phenylbutadiene and 3-hydroxy-4-bromo-1-phenylbutadiene, respectively. They also prepared the dichlorohydrin and dibromohydrin of phenylbutadiene.

Braun[14] recently attempted to add hypochlorous acid to vinylacrylic acid and reported that "vinylacrylic acid is easily oxidizable with hypochlorous acid." However, he did not isolate any products. In our investigation we had no difficulty in preparing and isolating crystalline monohalogenhydrins and dihalogenhydrins of vinylacrylic acid.

The addition of hypochlorous acid to vinylacrylic acid was first studied. It was found that vinylacrylic acid very readily absorbs one molecule of hypochlorous acid to form a monochlorohydrin, m. p. 71–74°. The structure of the monochlorohydrin was determined by ozonization. Six monochlorohydrins are theoretically possible, depending on whether 1,2-, 1,4- or 3,4-addition takes place and also on the relative positions of the Cl and OH groups.



$$\overset{4}{\underset{+}{H_2C}}{=}\overset{3}{\underset{-}{CH}}{-}\overset{2}{\underset{+}{CH}}{=}\overset{1}{\underset{-}{CH}}{-}\underset{+}{COOH}^{15}$$

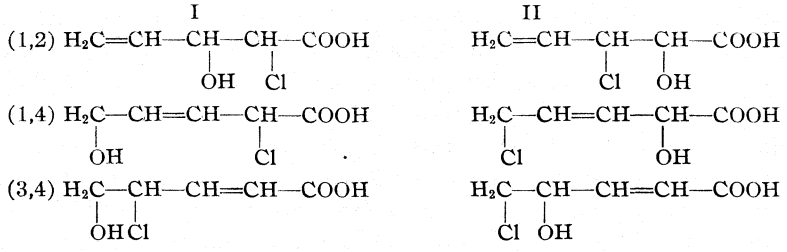
[15] The plus and minus signs do not imply a complete transfer of an electron from



I

(1,2) $H_2C{=}CH{-}\underset{OH}{CH}{-}\underset{Cl}{CH}{-}COOH$

(1,4) $\underset{OH}{H_2C}{-}CH{=}CH{-}\underset{Cl}{CH}{-}COOH$

(3,4) $\underset{OH}{H_2C}{-}\underset{Cl}{CH}{-}CH{=}CH{-}COOH$

II

$H_2C{=}CH{-}\underset{Cl}{CH}{-}\underset{OH}{CH}{-}COOH$

$\underset{Cl}{H_2C}{-}CH{=}CH{-}\underset{OH}{CH}{-}COOH$

$\underset{Cl}{H_2C}{-}\underset{OH}{CH}{-}CH{=}CH{-}COOH$

However, since in all of its addition reactions hypochlorous acid reacts as if it has the electronic structure $\overset{-}{HO}\,\overset{+}{Cl}$, and since the electronic structure of vinylacrylic acid has been shown to be $\overset{+}{CH_2}{=}\overset{-}{CH}{-}\overset{+}{CH}{=}\overset{-}{CH}{-}\overset{+}{C}OOH$,[4] it seems altogether probable that the structure of the monochlorohydrin is represented by series I rather than by series II.

On ozonizing the vinylacrylic acid monochlorohydrin it was possible to isolate oxalic acid as one of the oxidation products. This proves that hypochlorous acid adds to vinylacrylic acid in the 3,4-positions to give the chlorohydrin $CH_2OH{-}CHCl{-}CH{=}CH{-}COOH$.

On distilling the monochlorohydrin under reduced pressure, decomposition occurred with the elimination of water. A lower-boiling fraction distilled over but it was not possible to identify any definite products.

An ethereal solution of the monochlorohydrin was treated with phosphorus pentoxide. Water was eliminated, as could be easily seen, by the warming of the solution and the appearance of the phosphoric anhydride. A polymer was obtained which appeared to be the polymer of 3-chlorovinylacrylic acid but no definite proof could be obtained.

The monochlorohydrin of vinylacrylic acid readily absorbs a molecule of hypochlorous acid to form a dichlorohydrin, m. p. 143°. Its structure was not determined but it most probably had the structure $CH_2OH{-}CHCl{-}CHOH{-}CHCl{-}COOH$.

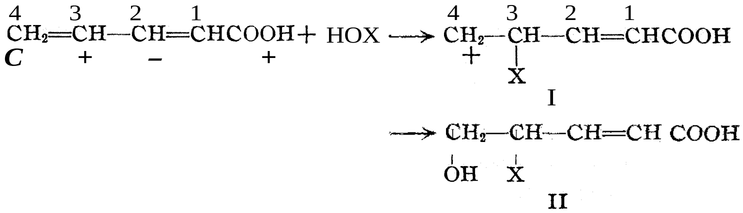
The addition of hypobromous acid to vinylacrylic acid was then studied. It was found that vinylacrylic acid readily absorbs one molecule of hypobromous acid to form a monobromohydrin, m. p. 92–93'. The structure of the monobromohydrin was determined in a manner entirely analogous to that used for the chlorohydrin. The isolation and identification of oxalic acid as one of the oxidation products of the bromohydrin proved that it also was a 3,4-addition product of vinplacrylic acid.

Vinylacrylic acid bromohydrin readily absorbs a molecule of hypobromous acid to form a dibromohydrin, m. p. 148–149". Its structure was not determined but it most probably had the structure $CH_2OH{-}CHBr{-}CHOH{-}CHBr{-}COOH$.

---

one atom to another. They indicate merely a displacement of the pair of valence electrons from the central position.

The addition of the hypohalous acids to vinylacrylic acid in the 3,4-positions therefore confirms the theory of Muskat and Northrup[1] regarding the addition reactions of conjugated systems. The first step in the addition of $\overset{-}{H}\overset{+}{O}\overset{+}{X}$ to vinylacrylic acid, is the addition of the positive halogen X^+ to the 3-carbon atom to give the intermediate I.



$$\begin{array}{l} \overset{4}{\underset{C}{CH_2}}{=}\overset{3}{\underset{+}{CH}}{-}\overset{2}{\underset{-}{CH}}{=}\overset{1}{\underset{+}{CH}}COOH + HOX \longrightarrow \overset{4}{\underset{+}{CH_2}}{-}\overset{3}{\underset{\underset{X}{|}}{CH}}{-}\overset{2}{CH}{=}\overset{1}{CH}COOH \quad \text{I} \\ \longrightarrow \underset{\underset{OH}{|}}{CH_2}{-}\underset{\underset{X}{|}}{CH}{-}CH{=}CH\ COOH \quad \text{II} \end{array}$$

This intermediate cannot undergo a 1,3-rearrangement, and the negative hydroxyl group must therefore add to the terminal carbon atom to give the 3,4-addition product, II.

Experimental Part

Vinylacrylic Acid Chlorohydrin.—Vinylacrylic acid was prepared according to the method of Muskat, Becker and Lowenstein,[3] by the condensation of acrolein with potassium bisulfite and treatment of the resulting addition product with malonic acid. Hypochlorous acid was prepared according to the method of Reformatsky,[16] by passing chlorine into a finely divided suspension of mercuric oxide in water at about −5°. The hypochlorous acid was distilled under reduced pressure to free it from dissolved mercuric salts. A 3–5% solution of hypochlorous acid, free from chlorine, was used in these experiments.

Vinylacrylic acid in chloroform solution was treated with one mole of a dilute hypochlorous acid solution. The hypochlorous acid must be added very slowly and under continuous stirring and cooling in an ice-bath; otherwise, the reaction becomes too violent. The hypochlorous acid is absorbed almost instantaneously. The reaction mixture was then extracted several times with chloroform, in which vinlyacrylic acid is very soluble but the chlorohydrin of vinylacrylic acid is insoluble. The water solution was then thoroughly extracted with ether, the ethereal solution dried over anhydrous sodium sulfate, and the ether removed by vaporization. A yellowish oil remained which crystallized on standing. The crystals were brought onto a porcelain suction filter and thoroughly washed with a chloroform–benzene (3–1) solution. The crystals melted at 71–74". The chlorohydrin is soluble in water, alcohol, acetone, glacial acetic acid, ethyl acetate, pyridine, ether, benzene and toluene. It is insoluble in ligroin, chloroform and carbon tetrachloride.

Anal. Calcd. for $C_5H_7O_3Cl$: Cl, 23.56. Found: Cl, 23.70, 23.59. Calcd. for $C_5H_7O_3Cl$: mol. wt., 150.5. Found (by acid–base titration): mol. wt., 156.0.

The vinylacrylic acid chlorohydrin, dissolved in water, was subjected to ozonization for twenty-four hours. The process of ozonization and the method of working up the oxidized fractions are amply described by Muskat and Becker.[4] It was possible to isolate oxalic acid from the ozonization products, which proved that hypochlorous acid had added to vinylacrylic acid in the 3,4-positions. A number of ozonizations were made,

---

[16] Reformatsky, *J. prakt. Chem.*, 40,396 (1889).

using glacial acetic acid as the solvent for vinylacrylic acid. In every case oxalic acid was the only product that was isolated.

A portion of the vinylacrylic acid chlorohydrin was distilled under reduced pressure. Decomposition occurred with the elimination of water. A lower boiling fraction (100–130° under 12 mm. pressure) distilled over, from which a small amount of a solid, m. p. 137–141°, was isolated. It appeared to be the γ-lactone,  $\mathrm{CH_2{=}C{-}CH{=}CH{-}C{=}O}$ (ring closed through O), which was obtained by the distillation of the dichloride and dibromide of vinylacrylic acid. However, this was not verified.

An anhydrous ethereal solution of the chlorohydrin was shaken with phosphorus pentoxide. The reaction mixture became quite warm and the phosphorus pentoxide became sticky and gave all the indications of having taken up water from the chlorohydrin. The solution was filtered, and the ether was removed by vaporization. A solid remained which appeared to be the polymer of 3-chlorovinylacrylic acid. However, this could not be verified.

$$\mathrm{CH_2OH{-}CHCl{-}CH{=}CH{-}COOH} \xrightarrow[\text{agent}]{\text{dehydrat.}} \mathrm{CH_2{=}CCl{-}CH{=}CH{-}COOH}$$

A number of efforts were made to chlorinate the vinylacrylic acid chlorohydrin, but with no success. Only a small amount of chlorine seemed to be absorbed. This fact is of interest since the 3,4-dichloride of vinylacrylic acid would not absorb chlorine to form the tetrachloride of vinylacrylic acid.[4]

Vinylacrylic Acid Dichlorohydrin.—Vinylacrylic acid chlorohydrin, in water solution, was treated with one mole of a dilute hypochlorous acid solution. Absorption took place fairly readily and the solution became warm. The water solution was extracted a number of times with ether. The ethereal solution was dried over anhydrous sodium sulfate and the ether was removed by vaporization. A yellowish oil remained which crystallized on standing. The crystalline mass was triturated with a small amount of ether and filtered by means of suction. Snow white crystals remained on the filter. The pure crystals melted sharply at 143°. The dichlorohydrin is very soluble in alcohol, acetone and hot water; moderately soluble in ether; and insoluble in ligroin, benzene, chloroform and carbon tetrachloride.

Anal. Calcd. for $\mathrm{C_5H_8O_4Cl_2}$: Cl, 34.936. Found: Cl, 34.89, 34.62. Calcd. for $\mathrm{C_5H_8O_4Cl_2}$, mol. wt., 202.98. Found (by acid–base titration): mol. wt., 205.99.

Vinylacrylic Acid Bromohydrin.—Vinylacrylic acid was treated with one mole of a dilute hypobromous acid solution. Its method of preparation is identical with that described for the preparation of the chlorohydrin. It is essential in this preparation that the hypobromous acid be distilled under reduced pressure to free it from dissolved mercuric salts. The bromohydrin may easily be recrystallized from benzene. The pure bromohydrin melts at 92–93°. It is very soluble in ether, alcohol, glacial acetic acid; somewhat soluble in hot benzene, chloroform, carbon tetrachloride, water; and insoluble in cold benzine and ligroin.

Anal. Calcd. for $\mathrm{C_5H_7O_3Br}$: Br, 40.99. Found: Br, 40.94, 40.78.

The vinylacrylic acid bromohydrin, in water solution, was subjected to ozonization and the ozonide thus formed was worked up in a manner entirely analogous to that described for the chlorohydrin. It was possible to isolate oxalic acid as one of the oxidation products which was identified by its melting point and the melting point of a mixture with a sample of known origin. It was not possible to obtain even the slightest indication of the presence of any of the aldehydes or acids to be expected from the oxidation of compounds formed by the 1,2- or 1,4-addition of hypobromous acid.

Vinylacrylic Acid Dibromohydrin.—Vinylacrylic acid bromohydrin, in ethereal solution, was treated with one mole of a dilute hypobromous acid solution. Its method of preparation is identical with that described above for the dichlorohydrin. The pure crystalline dibromohydrin melts at 148-149°. It has approximately the same solubilities as the monobromohydrin.

Anal. Calcd. for $C_5H_8O_4Br_2$: Br, 54.76. Found: Br, 54.84.

Summary

1. Vinylacrylic acid absorbs hypochlorous and hypobromous acid in the 3,4-positions to form 3-chloro-4-hydroxyvinylacrylic acid and 3-bromo-4-hydroxyvinylacrylic acid, respectively.

2. Vinylacrylic acid chlorohydrin absorbs a molecule of hypochlorous acid to give a dichlorohydrin. In the same way vinylacrylic acid bromohydrin absorbs a molecule of hypobromous acid to give a dibromohydrin.

3. These addition reactions of vinylacrylic acid are found to be in perfect agreement with the general theory on the addition reactions of conjugated systems as previously developed.

CHICAGO, ILLINOIS

NOTES

A Simplified Method of Preparation of Alpha Amino Acid Amides.[1]—It has been generally recognized by investigators of the chemistry of alpha amino acids that good yields of the amides of these acids are difficult to obtain. Fischer,[2] Koenigs[3] and Bergell[4] were leaders in this field of work. The Fischer method and that of Koenigs for obtaining the amides consists in treatment of the alpha amino acid esters with liquid ammonia in sealed tubes at room temperature for from ten days to three months. Bergell, Heintz,[5] and others obtained the amides by treatment of the alpha halogen fatty acid esters or amides with alcoholic ammonia at fairly high temperatures. The yields of amides obtained by the use of these methods were not particularly satisfactory.

The authors undertook the preparation of certain alpha amino acid amides as a preliminary to the study of the chemistry of their biuret reactions[6] A simplification of the older methods for obtaining the amides was accomplished. The esters of glycine, d-alanine and dl-leucine were treated separately in a shaking device with methyl alcohol which had been saturated previously with ammonia at 0°. The reactions were allowed

to proceed at room temperature for a number of hours, and the excess of alcohol and ammonia was then removed under reduced pressure, the amides remaining in the form of white crystals, or as oils which solidified when placed in the refrigerator. This treatment of the esters named produced the amides in good yield. Table I shows at a glance the conditions used by us and the advantages of this plan as compared with the methods and results of previous workers. Glycine amide[7] and d-alanine amide were purified by solution in chloroform and reprecipitation from this solution by means of dry ether. dl-Leucine amide was purified by recrystallization from benzene. The glycine amide, d-alanine amide and dl-leucine amides obtained by us melted at 67–68° (uncorr.), 71–72° (uncorr.) and 105–106° (uncorr.), respectively.

TABLE I

THE PREPARATION OF ALPHA AMINO ACID AMIDES

	Present method		Previous methods	
Amide	Conditions	Yield	Conditions[8]	Yield, %
Glycine amide	Glycine ester (20 g.), CH_3OH satd. with ammonia (300 cc.), shaking 20 hrs.	(8 g.) 55.7%	Liquid ammonia, bomb, 10 days	33
d-Alanine amide	Alanine ester (3.5 g.), CH_3OH satd. with ammonia (60 cc.), shaking 50 hrs.	(2.6 g.) 83.7%	Liquid ammonia, bomb, 1 mo.	53
dl-Leucine amide	Leucine ester (4.9 g.), CH_3OH satd. with ammonia (75 cc.), shaking 80 hrs.	(3.6 g.) 88.5%	Liquid ammonia, bomb, 3 mo.	80–85

The Reaction of Acetophenone Derivatives with Sodium Hypochlorite.—It has long been known that acetophenone, when treated with sodium hypochlorite, is changed into benzoic acid. Likewise benzalacetone is decomposed into cinnamic acid.[1] The literature, however, gives very little information regarding the general scope of this procedure for the synthesis of aromatic acids.

The lowered cost of aluminum chloride provides an inexpensive method for the synthesis of certain acetophenone derivatives by means of the Friedel–Crafts reaction. The oxidation of these derivatives with sodium hypochlorite is, however, restricted to compounds which do not contain

---

[7] During the preparation of glycine amide some glycine anhydride separated and was removed from the reaction mixture at the conclusion of the reaction by filtration.

Resacetophenone		199	0
Nitroresacetophenone		215	0
p-Hydroxyacetophenone	.....	158	0

Five to 10 gram samples were used in each case.

[a] From Richter "Lexikon" and Beilstein.

Compounds which are not easily halogenated may be treated by passing chlorine slowly into a suspension of the compound in sodium hydroxide solution. Those which easily react with halogens, such as *p*-methoxyacetophenone, may be treated by adding a cold alkaline hypochlorite solution to a methyl alcohol solution of the compound. The latter solvent may frequently be used to increase the solubility of the acetophenone derivative and thereby increase the speed of the reaction. A considerable excess of hypochlorite must be used to ensure complete reaction. At the end of the reaction acetone or sulfur dioxide was added to destroy the excess halogen before the solution was acidified. The free chlorine is easily detected by adding a few drops of the solution to a solution of potassium iodide. Hypochlorite proved much more efficient and convenient than the hypobromite or iodite. With the latter reagents the reaction was much slower and less complete. Furthermore, the separation of bromoform or iodoform from the reaction was often difficult. The general procedure used may be illustrated as follows.

p-Chlorobenzoic Acid.—Five grams of p-chloroacetophenone was dissolved in 25 cc. of methyl alcohol and 50 cc. of 20% sodium hydroxide was then added to the solution. Chlorine was passed into the solution while stirring rapidly. The cloudy solution soon began to clear as the temperature rose to about 80°. More alkali was added from time to time until a total volume of 100 cc. had been used. When the solution was practically clear, the chlorine addition was stopped and the solution stirred for about fifteen minutes longer. A small amount of acetone was added to react with the excess chlorine. The solution was treated with a small quantity of Norite and filtered. Upon acidifying with hydrochloric acid the organic acid was precipitated. The product was practically pure, but was further purified by reprecipitating it from dilute sodium hydroxide. The yield was 93%, m. p. 234–236°.

Correction. Para-Nitrophenyl Carbamyl Chloride and Para-Nitrophenyl Isocyanate.—In a recent paper it was stated that the product of the action of phosgene on *p*-nitraniline was p-nitrophenyl carbamyl chloride.[1] While this is the primary product of the reaction mixture, it has been found that after recrystallization from hot carbon tetrachloride as recommended in the procedure, the final purified product is then free from halogen and is p-nitrophenyl isocyanate, m. p. 57.° The analysis given is incorrect. Determination of the nitrogen by the micro Dumas method gave the following results.

Anal. Subs., 3.322 mg.: N_2 gas, 0.577 cc. at 31° and 744 mm. Calcd. for $C_7H_4O_3N_2$: N, 17.07. Calcd. for $C_7H_5O_3N_2Cl$: N, 13.97. Found: N, 17.09.

The purified product with m. p. 57° is therefore p-nitrophenyl isocyanate[2] and is the reagent from which the urethans were prepared. It is evident that the *p*-nitrophenyl carbamyl chloride lost hydrogen chloride during the recrystallization from boiling carbon tetrachloride.

INTERATOMIC FORCES IN BINARY ALLOYS

Sir:

Under this title, N. W. Taylor has recently published [THIS JOURNAL, 53, 2423 (1931)] a test of Langmuir's theory of non-electrolyte solutions which seems to me unfortunate in three respects. Following Hildebrand and Sharma [*ibid.*, **51**, 467 (1929)], he has confused Hildebrand's definition [*ibid.*, **51**, 66 (1929)] of a "regular solution," for which at constant composition T log a_1/N_1 is independent of the temperature, with that of a "symmetrical system," for which at constant temperature log $(a_1/N_1)/N_2^2$

---

[1] Shriner and Cox, THIS JOURNAL, 53, 1601 (1931).

[2] This has also been noted by van Hoogstraten, Doctor's Dissertation Rijks University, Leiden, June 30, 1931.

is independent of the composition. His method of comparison is to compare one quantity calculated by means of an extrapolation with another calculated by an integration from a few experimental points and involving the first extrapolation and also a second one. He considers that the agreement with Langmuir's equation supports Langmuir's assumptions, but he does not give a comparison with the equations of Heitler and of Van Laar.

The test can be made directly with the experimental data, and the accompanying table shows the comparison for cadmium–lead alloys [Taylor, *ibid.*, 45, 28 (1923)]. The results for the other alloys, which are essentially the same, are omitted for the sake of brevity. The solutions appear not to be "regular," but the values of T log a_1/N_1 decrease with increasing temperature somewhat more than the irregularities of the individual measurements. They are constant enough to make the use of their average in the comparison which follows preferable to the use of the measurements at any one temperature, even though the temperatures are not the same for all the compositions.

I have discussed elsewhere [Chemical Reviews, 8, 321 (1931)] the various theories as to the relation of the change in free energy to the composition. Heitler's theory gives "symmetrical systems" or T log $a_1/N_1 = \alpha N_2^2$ (1); Langmuir's theory gives T log $a_1/N_1 = \beta S_1[N_2S_2/(N_1S_1 + N_2S_2)]^2$ (2); Van Laar's theory and the more general theory I proposed give T log $a_1/N_1 = \gamma V_1[N_2V_2/(N_1V_1 + N_2V_2)]^2$ (3). The S's are the molecular (or molal) surfaces, and the V's the corresponding volumes, and α, β and γ are constants. The comparison of these three equations is given in the last three rows of the table, with constants calculated for the most dilute

alloys. Although the physical theories are quite different, the resulting equations do not differ greatly for molecules so similar in size as these metals. The agreement of equation (1) with the experiments is distinctly poorer than that of the other two equations, but the difference between these two is too small to choose between them, and either one checks the measurements almost within the experimental error. The results with the other alloys are equally indecisive. In fact, I know of no measurements, in systems for which the agreement might be significant, which agree distinctly better with the equation of Langmuir than with that of Van Laar, or *vice versa*. The choice of theory must rest on a more fundamental analysis, a further contribution to which I hope to publish shortly.

THE FORMATION OF HYDROGEN PEROXIDE FROM HYDROGEN AND OXYGEN

Sir:

I have recently reported [THIS JOURNAL, 52, **5106–5110** (1930)] that hydrogen peroxide is formed, along with water, when hydrogen–oxygen mixtures at atmospheric pressure are passed through a Pyrex reaction tube at 500–550°. Thermodynamic data [Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923, p. 496] indicate that the peroxide cannot have been formed via water

$$H_2 + {}^1/_2\, O_2 \longrightarrow H_2O \qquad (1)$$

$$H_2O + {}^1/_2\, O_2 \longrightarrow H_2O_2 \qquad (2)$$

but must have been produced directly

$$H_2 + O_2 \longrightarrow H_2O_2 \qquad (3)$$

Since hydrogen peroxide dissociates to give water, the question arises as to whether all the water formed passes through the peroxide stage, or whether a part comes direct from the elements.

An attempt was made to answer this by determining the ratio of peroxide to water formed under conditions leading to successively lower total conversions. If hydrogen peroxide were the only primary product, one should obtain something approaching pure peroxide in the limit. As the experimental results were on the whole inconclusive, it seems unnecessary to report them in full. However, a representative set of data may be of interest.

The data of the table refer to experiments in which $19H_2{:}1O_2$ mixtures were passed through a spherical Pyrex reaction vessel of 4.3 cm. diameter. The gases passed from flowmeters to traps cooled to −79°, then through the reaction bulb and then through a weighing U-tube also cooled to −79.° Total product was determined by weighing; the peroxide was then titrated with 0.05 N potassium permanganate; and water was obtained by difference.

Temp. °C.	Approx. heating, sec.	Part press. in off-gas in 0.001 atm. H_2O_2	H_2O	Ratio H_2O_2/H_2O	H_2 reacting, %
550	0 5	0 068	0.37	0.18	0.046
550	1	.21	1.7	.12	.20
540	1	.19	0.76	.25	.10
530	1	.056	0 21	.27	.028

In spite of the extremely small total conversions (less than 0.2% H_2), the best result obtained was one mole of peroxide to four moles of water. The possibility of independent, direct formation of water from the elements is thus by no means excluded.

SURFACE REACTIONS OF ATOMS AND RADICALS

Sir:

Recently we[1] have found that water vapor, dissociated in a discharge tube, will oxidize carbon monoxide to carbon dioxide. Since atomic oxygen is not very effective in causing this oxidation we are led to believe that the carbon dioxide is formed as the result of a reaction involving the hydroxyl radical. Assuming that this is the case, we can use the oxidation of carbon monoxide as a test for OH and in this way determine whether it is affected by certain catalytic surfaces.

By observing the effect of different catalysts on the yield of carbon dioxide, we have found that a dehydrogenation catalyst is inefficient in causing the H + OH combination while a dehydration catalyst is quite efficient. This result is in accord with the work of Taylor and Lavin[2] and shows, as might be expected, that a strictly dehydrogenation catalyst is only effective in causing the recombination of hydrogen atoms.

In light of the fact that we are able to observe the oxidation of carbon monoxide after practically all of the hydrogen atoms have been removed (by the dehydrogenation catalyst) it seems that we have here a method for the separation of H and OH.

THE ROLE OF HYDROGEN BONDS IN CONDUCTION BY HYDROGEN AND HYDROXYL IONS

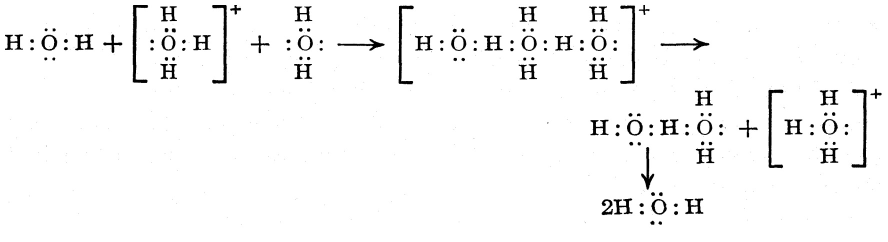
Sir:

The abnormally high conductance of hydrogen and hydroxyl ions in water solution is well known.' To account for this it has been proposed[2] that "an interchange takes place between the ions and the solvent molecules with the result that the mean path over which these ions travel is reduced in proportion to the effective diameter of the solvent molecules which are concerned in this interchange^{M}—a modification of Grotthuss' chain theory of conduction.

Against this hypothesis it has been pointed out[1] that similar abnormally high conductances would be expected for solvent ions in solvents such as ammonia, whereas this is not the case. Recourse is then had to the assumption that the abnormal speeds of the solvent ions in water are due to their relatively low hydration.

I shall attempt to show now that the concept of "hydrogen bonds," first proposed by me in 1919 and shortly thereafter independently by Latimer and Rodebush, furnishes a satisfactory mechanism for chain conduction by the solvent ions in water but not in ammonia.

Let us assume, for simplicity, that hydrogen ions are  $\left[\begin{matrix} & \mathrm{H} & \\ \mathrm{H}: & \ddot{\underset{\cdot\cdot}{\mathrm{O}}} & :\mathrm{H}\end{matrix}\right]^{+}$ in water and  $\left[\begin{matrix} & \mathrm{H} & \\ \mathrm{H}: & \ddot{\underset{\cdot\cdot}{\mathrm{N}}} & :\mathrm{H} \\ & \mathrm{H} & \end{matrix}\right]^{+}$ in ammonia. The hydrogen kernels are held quite tightly to the oxygen and even more tightly to the nitrogen. In the case of H_3O^+ the force holding each hydrogen will be greatly decreased if another hydrogen, say in an H_2O molecule, approaches the lone pair in the oxygen valence shell. If at the same time an oxygen lone pair in another water molecule should approach one of the H_3O^+ hydrogens, that hydrogen might well be transferred to this second water molecule, making it an H_3O^+ ion. Diagrammatically



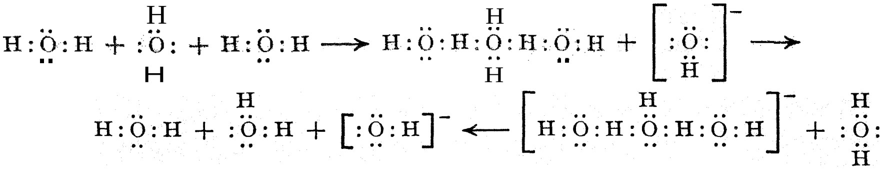
Such a mechanism is obviously impossible with NH_4^+ ions, for no lone pairs are available to aid in the "loosening" of the NH bonds.

---

[1] Cf. Kraus, "Properties of Electrically Conducting Systems," The Chemical Catalog Co., Inc., New York, 1922, p. 206.

[2] Lumsse. Thesis, Clark University, 1920.

Analogously, an OH– ion can remove a hydrogen from a water molecule if the oxygen in the latter has around it three other hydrogens



Although one might postulate hydrogen bonds between NH3 molecules so as to produce nitrogen atoms surrounded by four hydrogens, these hydrogens would be more tightly held than each of four hydrogens surrounding an oxygen (NH_4^+ is more stable than OH_4^{++}) and apparently they cannot easily be removed by NH_2^- ions.

It seems likely, moreover, that N : H : N bonds are not readily formed. ((: F : H : F :)– is quite stable; O : H : O bonds are weaker but common in crystals and probably in liquid water and temporarily during many reactions, whereas no examples whatever of N : H : N or C : H : C bonds are known to me.) If so, this in itself suffices to account for the lack of abnormally large conductances of NH_4^+ and NH_2^- in ammonia.

The conductance data for other solvents also seem to be in agreement with the ideas here expressed, but I shall not now take the space to discuss them.

HEXAFLUORODISILANE

Sir:

Up to the time of the present writing the only binary fluoride of silicon that has been identified definitely is the tetrafluoride, SiF_4. Methods leading to the formation of so-called subfluorides, several of which have been reported, have failed when repeated by later experimenters. Nevertheless, the presumption remained that binary fluorides other than the tetrafluoride should be capable of existence, since certain of the corresponding compounds of carbon have been isolated.

We have now succeeded in preparing hexafluorodisilane, Si_2F_6, by gently warming hexachlorodisilane with anhydrous zinc fluoride, followed by condensation and fractionation of the products. The substance is gaseous under ordinary conditions of temperature and pressure, but may be condensed to a snow white solid, melting at –18.5° under 780 mm. pressure.

The vapor pressure of the substance has been determined from –79 to –4°; the pressure becoming 760 mm. at –19°. Gas density determinations upon the same product lead to the molecular weight 173.8 (calcd. for Si_2F_6, 170.1). Inasmuch as the product has been shown to be quite pure, not only by the rectilinear character of the vapor pressure curves when log p is plotted against $1/T$, but also by the observed sharpness of the melting point, and by the absence of any appreciable amounts of chloride, we feel that there can be little doubt concerning the actual composition of the substance.

When in contact with moist air or water, the substance is instantly hydrolyzed, the products formed including hydrogen, hydrofluoric acid, "silico-oxalic acid"—or 1,2-bis-(oxy-oxo)disilane—silicic and fluosilicic acids, the proportions of the several substances varying with experimental conditions. The quantitative study of this hydrolysis, which will also make possible the analysis of the original substance for silicon and fluorine, is now in progress, and will be described in the detailed account of this investigation in a later issue of THIS JOURNAL.

It may be added that the analogous preparation of hexafluoroethane, C_2F_6, by the interaction of zinc fluoride with hexachloroethane, has failed to give satisfactory results at ordinary pressure.

THE DECOMPOSITION OF PYROSULFURYL CHLORIDE, A HOMOGENEOUS UNIMOLECULAR REACTION

Sir:

According to the literature, given to date in Mellor's "Treatise on Inorganic and Theoretical Chemistry," Vol. X, p. 683, pyrosulfuryl chloride, $S_2O_5Cl_2$, decomposes at its boiling point and above at a rate which should be convenient for study. The molecule is sufficiently large that one might expect, in accord with present theories, that the decomposition might be unimolecular. The vapor phase decomposition has been investigated, and found to be homogeneous and unimolecular.

The reaction has been followed by the pressure-increase method in a Pyrex bulb, both empty and when filled with glass tubing. The pressure approximately doubles during the reaction, which is considered to be one yielding SO_3 and SO_2Cl_2, and which, at 179° has a half-time of seven minutes in the empty bulb. When the surface is increased four times by packing, the half-time is approximately fifteen minutes.

Other temperatures are now being used, and the reality of the apparent decrease in rate with increased surface is being studied. The full report of the experiments will be submitted as soon as possible.

Radioelements and Isotopes: Chemical Forces and Optical Properties of Substances. By KASIMIR FAJANS, University of Munich. The George Fisher Baker Non-Resident Lectureship in Chemistry at Cornell University. The McGraw-Hill Book Company, Inc., 370 Seventh Ave, New York, 1931. x + 125 pp. Illustrated. 15.5 × 23.5 cm. Price, $2.50.

This volume, for the most part, contains the subject-matter of Professor Fajans' lectures given in the spring of 1930 at Cornell University as George Fisher Baker Non-Resident Lecturer. The systematic discussions of Radioactivity and of Isotopes given in these lectures have been omitted as they are covered fully in other publications of the author.

Part I of this volume is devoted to The Origin of the Actinium Series and the Stability of Isotopes; Part II to Chemical Forces and Optical Properties. Part II is much the longer and is particularly useful as a presentation in brief and convenient form of the important researches of Professor Fajans upon these subjects.

Both in content and in physical appearance this volume maintains the high standard of excellence characteristic of the earlier volumes of this series.

ARTHUR B. LAMB

Atlas der physikalischen und anorganischen Chemie. Die Eigenschaften der Elemente und ihrer Verbindungen in graphischer **Darstellung** auf 29 **Tafeln.** (Atlas of Physical and Inorganic Chemistry. The Properties of the Elements and their Compounds Graphically Illustrated on 29 Charts.) By PROF. DR. A. VON ANTROPOFF and DR. M. VON STACKELBERG, University of Bonn. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1929. 64 pp. 19 figs. 29 × 36 cm. Price, RM. 40, cardboard, KM 42, cloth binding

This Atlas consists of a collection of 29 charts, each 11 by 14 inches and provided with a key printed in English, German and Spanish. These charts cover the important physical and chemical properties and the distribution of the elements. An explanatory text in German of 64 pages containing many tables and diagrams accompanies the charts.

This Atlas should be very useful to the teacher in presenting vividly the numerical data characteristic of the chemical elements, and to the professional chemist as a means of quick and ready reference.

ARTHUR B. LAMB

Introduction à l'étude de la mécanique ondulatoire. (An Introduction to the Study of Wave Mechanics.) By Lours DE BROGLIE, Maître de Conférences à la Sorbonne Libtairie Scientifique Hermann et Cie., 6, Rue de la Sorbonne, Paris, France, 1930. xvi + 292 pp. Illustrated. 16 X 25 cm. Price, unbound, 85 fr.; bound, 95 fr.

Wave mechanics from its beginning has been a many-sided science, and the side to which de Broglie has contributed, and which he writes about, is the connection of wave mechanics with classical mechanics. For that aspect of the subject, the present book gives a very complete and readable discussion. On the other hand, the specific problems of atomic and molecular dynamics for which wave mechanics has proved so valuable are treated to only a very slight extent by de Broglie. For this reason, the book is less likely to appeal to a chemist or experimental physicist than many other works which have appeared. On the other hand, the reader interested in analytical mechanics will enjoy the clear account of the relation of wave mechanics to the methods of Lagrange, Hamilton and Jacobi, a relation which is made the basis of the author's treatment. The discussions of wave packets, of the uncertainty principle, and of various other branches of the subject are valuable. The book is, however, mathematical throughout, and could hardly be read with profit except by one who already had some familiarity with the subject.

JOHN C. SLATER

Handbook of Chemical Microscopy. Vol. II. Chemical Methods and Inorganic Qualitative Analysis. By ÉMILE MONNIN CHAMOT, B.S., Ph.D., Professor of Chemical Microscopy and Sanitary Chemistry, Cornell University, and CLYDE WALTER MASON, A.B., Ph.D., Assistant Professor of Chemical Microscopy, Cornell University. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1931. ix + 411 pp. Illustrated. 15 × 23.5 cm. Price, $4.50.

In Volume II, "The inclusive field of 'microchemistry,' which comprises all chemical procedures dealing with small amounts of material, is discussed only as regards those portions of it which involve microscopical qualitative reactions." After two introductory chapters which give clear and detailed descriptions of the necessary technique, the specific tests used in the detection of the various elements are discussed, under the groups of the periodic table. In addition to the detailed description of the procedure by which the various crystalline products are obtained, and to the verbal description of the products themselves, excellent photomicrographs of the characteristic crystals are given. The reviewer regrets that the optical constants of these various characteristic crystals are not given; the need of such constants is often felt, and they may be of positive aid in the identification of poorly formed crystals. A curious slip was found on page 156: in the thallium alums it is the alkali, not the aluminum, that is replaced by thallium, hence it is incorrect to state that "Its analogy to aluminum is shown by its property of forming alums." The discussion of the detection of anions is especially good. The "Handbook of Chemical Microscopy" will be found an indispensable aid to those who use the microscope in chemical problems; and the clear exposition of the technique given therein should greatly increase the number of those who make use of these rapid and satisfying methods.

GEORGE W. MOREY

Berl-Lunge **Taschenbuch für** die anorganisch-chemische **Grossindustrie.** (Berl-Lunge Handbook of Inorganic Industrial Chemistry.) Edited by E. BERL, Ph.D., Professor of Industrial and Electrochemistry at the Technical High School of Darmstadt. Seventh, revised, edition. Second part, Nomograms, Verlag von Julius Springer, Linkstrasse **23–24,** Berlin W **9,** Germany, **1930. 31** tables, with legends and descriptions. **23.5** X **31** cm. Price, **RM.** 37.50.

This publication consists of thirty-one unbound nomographic charts which are designed to be useful in the control laboratories of manufacturers or users of inorganic heavy chemicals. The charts are well printed and will doubtless permit interpolations and interpretations of the observed data with greater speed and less danger of blunders than by the use of tables or computations.

GRINNELL JONES

The Terpenes. Vol. **I.** The Simpler Acyclic and Monocyclic Terpenes and their Derivatives. By J. L. SIMONSEN, D.Sc., F. I. C., Professor of Chemistry, University College of North Wales. The Macmillan Co., **60** Fifth Ave., New York, **1931.** xv + **420** pp. **14** X **22.5** cm.

The author states in his preface that, while the constituents of the various essential oils have been adequately dealt with in the English language by Parry, "The Chemistry of the Essential Oils," and by Finnemore, "Essential Oils," with the exception of Brooks' monograph, "The Non-Benzenoid Hydrocarbons," which covers a somewhat wider field, no book is available which deals with the chemistry of the terpenes.

In order to supply this deficiency the author has written this work. Special attention has been directed to the methods used in the determination of constitution and synthesis.

The author has traced the development of the views on the constitution of the various terpenes in a clear and pleasing manner, and with adequate references.

Where further research is desirable he has so indicated, and his comments are valuable and to the point and show a broad knowledge of his subject. Structural formulas have not been spared, and the student of terpene chemistry will find no difficulty in following the trend of thought.

The work is well written and will be of value to those interested in this fascinating field of organic chemistry.

Very few errors in printing were noted.

E. K. NELSON

The Carbon **Compounds.** A Textbook of Organic Chemistry. By C. W. PORTER, Professor of Chemistry in the University of California. Second revised edition. Ginn and Company, **15** Ashburton Place, Boston, Massachusetts, **1931.** ix + 469 pp. Illustrated. **15.5** × 24 cm. Price, $4.00.

The latest edition of this well-known text is not only revised but is, to a very large extent, rearranged and rewritten. In almost all cases the changes have been in the direction of simplification and clarification.

"In this edition the structure of sucrose has been revised on the basis of the researches of Haworth and his associates. Thyroxine and two other amino acids have been added to the list of the hydrolysis products of proteins. The discussion of Robertson's theory of protein salt formation has been replaced by a statement setting forth the views of Osborne, Cohn, Vickery and Schmidt. Dissociation constants of acids and bases have been added."

In addition to these major changes and additions all the tables of constants have been revised according to the latest data. The two indexes have been combined in one. The Questions and Problems have been almost entirely changed and have been somewhat expanded.

Very few adverse criticisms can be made. The carbon tetrahedron on page 15 is wrongly constructed. The explanation of the Geneva system of naming substances with complex side chains remains unsatisfactory. Occasional loose statements creep in, like that on page 92 regarding the hydrolysis of cyanides.

The author has taken full advantage of the opportunity to improve an already excellent text.

FRANK C. WHITMORE

Jahrbuch der organischen Chemie. (Yearbook of Organic Chemistry.) By Professor Dr. JULIUS SCHMIDT, Stuttgart. Vol. 16, 1929. Verlag von Franz Deuticke, Vienna, Austria, 1931. xvii + 299 pp. 17 × 26 cm. Price, M. 30, unbound: M. 33, bound.

The sixteenth annual report on Organic Chemistry deals with the publications of 1929. The material is organized in the same manner as in previous reports but the new volume is somewhat larger, mainly because it contains an additional chapter which deals with "glucosides, resins and organic colloids." Author and publisher are evidently making a praiseworthy effort to have these reports appear more promptly.

E. P. KOHLER

The Development of Physiological Chemistry in the United States. By RUSSELL H. CHITTENDEN, Professor of Physiological Chemistry in the Sheffield Scientific School of Yale University, 1882–1922. American Chemical Society Monograph Series. Published by The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1930. 427 pp. 15.5 × 23.5 cm. Price $6.00.

Professor Chittenden has undertaken the difficult task of writing an account of *a* half-century's progress in this country in the field of physiological chemistry. The task is difficult because it is not always possible with our perspective to distinguish between progression and retrogression, between the important and the unimportant. Nevertheless this monograph will be a valuable source of information to the advanced student, to the teacher and to that future historian who will write a critical review of science in this era.

It is particularly fitting that Professor Chittenden should be the author of such a monograph. The lead taken by his laboratory in the study of physiological chemistry is indicated by the fact that of the twelve chapters, No. 10 and significant parts of six others deal with researches at New Haven. The author points out that Yale has had 93 successful candidates for the degree of Ph.D. in physiological chemistry up to 1927 and of these, 57 hold or have held important positions in American universities or medical colleges.

One can make few criticisms of a specific character. In view of the author's association with Osborne it is surprising to read (p. **93)** that zein "constitutes nearly one-half of the maize kernel." A statement that smacks of radio science appears on p. 151 where reference is made to Reichert's 600 photomicrographs of hemoglobin crystals "coming from the blood of every conceivable species of animal." Presumably because the literature references, with but few exceptions, terminate with 1927, no reference is made to Fiske's work on phosphocreatine. Many will be disappointed because of the decision to confine the monograph to the United States. If the author, like our scientific societies, had disregarded the Canadian boundary he would not have excluded that happy patriarch of physiological chemistry in America, A. B. Macallum.

D. B. DILL

The Vitamins. By H. C. SHERMAN, Mitchill Professor of Chemistry, Columbia University, and S. L. SMITH, Senior Chemist, Office of Experiment Stations, United States Department of Agriculture. American Chemical Society Monograph Series. Second edition. The Chemical Catalog Company, Inc., 419 Fourth Avenue, at 29th Street, New York, 1931. 575 pp. Illustrated. 15.5 X 23.5 cm. Price, $6.00.

To those interested specifically in the field of nutrition, Dr. Sherman's book presents in available form excellent abstracts of the most important investigations. Many chemists wish to obtain a survey of this field and Dr. Sherman has most carefully, and in his usual unbiased critical manner, presented a well classified, chronological review of the fundamental contributions in the field of vitamins. The large number of citations makes the book exceedingly valuable as a reference book and as an aid to research.

It is believed that the excellent subdivisions of each chapter will enable students to classify, for the first time, the problems in the respective fields. It is unfortunate that the nomenclature was not definitely standardized. To those not directly concerned in vitamin research, a critical correlation of the various researches would be helpful. The evidence more recently published indicating the presence of several new factors in yeast, wheat and casein deserves a fuller discussion.

This book differs greatly from his first edition. It consists of **336** pages of text, 184 pages of literature containing over 3000 citations. Eighteen pages are devoted to author index and **24** to subject index. **A** number of excellent photographs are included. No illustrations on vitamin D are given. The original chapter on B is divided into two chapters, vitamin B and vitamin G. There is an excellent chapter on vitamin E **and** also one on vitamin D. The chapter on "Vitamins in the Problem of Food Supply," has been omitted and the material combined with the other chapters.
