FIRST REPORT OF THE COMMITTEE ON ATOMIC WIGHTS OF THE INTERNATIONAL UNION OF CHEMISTRY

BY G. P. BAXTER (*Chairman*), MME. M. CURIE, O. HÖNIGSCHMID, P. LE BEAU AND R. J. MEYER

RECEIVED APRIL 3, 1931 PUBLISHED MAY 6, 1931

In September, 1930, at the meeting of the International Union of Chemistry at Liege, the Committee on Elements which has functioned since 1923 was replaced by three committees, on Atomic Weights, Atoms, including isotopy and atomic structure, and Radioactive Constants. Hereafter the function of the first of these committees will be to prepare annually a table of atomic weights on the basis of the most recent evidence. National Committees on Atomic Weights are requested by the International Union to refrain from publishing tables of their own.

While it was impossible for the new committee to issue a report earlier this year. it is the intention of the committee normally to issue its report so far as possible in the first (January) number of current chemical and physical periodicals. These reports will cover the twelve months from October to September preceding.

Authors of papers bearing on the subject are requested to send copies to each of the five members of this committee at the earliest possible moment.[1]

Since the reports of the German and American committees[2] adequately cover the ground of progress during 1929, only investigations published since January 1, 1930, are reviewed in this report.

Batuecas, Schlatter and Maverick[3] have published new determinations

of $(PV)_0/(PV)_1$ by the expansion method. In Column I the assumption is made that the quantity varies lineally with the pressure; in Column II an equation of the second degree is used.

Nitrogen.—Moles and Batuecas[4] have redetermined the density of ammonia at various pressures. The gas was prepared (1) from ammonium oxalate and potassium hydroxide, (2) by synthesis (technical) from the elements, (3) by hydrolysis of magnesium nitride. After chemical purification the gas was fractionally distilled and in most cases was dried finally with phosphorus pentoxide. Correction for adsorption on the walls of the

globes was made. The results are expressed in the weight of the liter at 0° and 760 mm.

From the densities at various pressures the limiting density of ammonia is calculated by the method of differences to be 0.75990. The corresponding molecular weight of ammonia is then 17.032, and the atomic weight of nitrogen 14.009.

Phosphorus.—Ritchie[5] has determined the density of phosphine at different pressures. The gas was prepared from phosphonium iodide by means of potassium hydroxide and was fractionated.

Assuming a linear relation between P V and pressure, $(PV)_0/(PV)_1$ is calculated to be 1.0091.

If the normal liter of oxygen weighs 1.4290 g. and the coefficient of deviation from Boyle's Law per atmosphere is —0.00096, then $PH_3 = 34.000$ and $P = 30.977$. This value for phosphorus is appreciably lower than the chemical value.

Sulfur.—Hönigschmid and Sachtleben[6] have completed a synthesis of silver sulfide from its elements. The compound was found to be stable up to 300° but to lose sulfur by decomposition above this temperature. When reheated in sulfur vapor, partially decomposed sulfide takes up quantitatively the deficiency in sulfur. Excess sulfur is given up at 300°. To carry out a synthesis weighed quantities of the purest silver were heated in sulfur vapor until the reaction was complete and then the excess of sulfur was eliminated in a current of pure nitrogen at 280°. Constancy in weight of the sulfide was readily attained. The sulfur was prepared by precipita-

	Average	1.148621	32.066

Since all recent determinations of the atomic weight of sulfur have yielded a value not far from 32.06, this value has been adopted for the table.

Chlorine.—Scott and Johnson,[7] call attention to an error in the solubility of silver chloride at 0° assumed by Honigschmid and Chan[8] in their syntheses of silver chloride, which amounts to 0.002% in the weight of silver chloride.

Calcium.—Honigschmid and Kempter[9] purified calcium nitrate from marble by ten recrystallizations, and converted the product to chloride by precipitation of the carbonate and solution of the latter in hydrochloric acid (Sample I). Sample II was prepared from commercial nitrate by fifteen crystallizations. After recrystallization of the chloride it was prepared for weighing by dehydration and fusion in hydrogen chloride, and allowed

to solidify in nitrogen. The solutions of the weighed chloride were corrected for deviations from the neutral point by titration with $N/100$ solutions of acid and base and then were compared with silver in the usual way, and the silver chloride was collected and weighed. Weights are corrected to vacuum.

The average of both series, 40.085, is slightly higher than that found earlier by Richards and Honigschmid, 40.071. For the present 40.08 is recommended.

A. V. and O. Frost[10] claim to have discovered a concentration of Ca^{41} by beta-ray emission from K^{41} in a potassium feldspar containing 0.042% of calcium oxide. Only 0.15 g. of calcium oxide was available. From the ratio $CaCl_2:CaBr_2$ the atomic weight of calcium was found in two experiments to be 40.23. Similar experiments with ordinary calcium which had been purified in the same way gave 40.10.

Honigschmid and Kempter[11] attacked the same problem with calcium extracted from sylvin by von Hevesy. After preliminary purification the average atomic weight through the chloride was found to be 40.22. Spectroscopic investigation, however, revealed the presence of strontium. After removal of this impurity by fractional precipitation of the oxalate, the observed atomic weight was lowered to 40.093. The material still contained 0.015 atom per cent. of strontium so that the value to be expected is 40.091. Since the sylvin is a geologically younger mineral than the feldspar, a smaller concentration of Ca^{41} is to be expected, so that the question as to appreciable variation of Ca^{41} in nature is still an open one.

Vanadium.—Scott and Johnson,[12] have analyzed vanadyl trichloride. This was made by heating purified vanadium trioxide in a current of chlorine, and the product was purified by vacuum distillation, after removal of excess chlorine with mercury and sodium. Portions for analysis were removed in sealed glass bulbs in the later stages of the distillation. After being weighed the bulbs were broken under either nitric acid or ammonia.

[12] Scott and Johnson. THIS JOURNAL, 52, 2638 (1930).

In the former case the glass was washed with nitric acid and collected on a filter. In the latter, after the supernatant liquid had been filtered, the precipitate was dissolved in nitric acid and the glass was washed and collected. The solutions were then compared with silver in the usual way, and in some cases the silver chloride was collected. The analyses are arranged in the order of decreasing volatility of the chloride samples. Weights are corrected to vacuum.

THE ATOMIC WEIGHT OF VANADIUM

Acid Hydrolysis

	Average	.535519	50 945		.403072	50 955

Experimental evidence was found that the nephelometric end-point was slightly affected by the presence of vanadic acid, but the effect on the atomic weight of vanadium is less than 0.005. The average of the comparisons with silver, 50.948, agrees almost exactly with the recent results obtained by McAdam, and by Briscoe and Little.

Chromium.—Gonzales[13] has applied to chromyl chloride the recently developed method of preparing volatile inorganic compounds by fractional distillation in vacuum. The compound was prepared by the action of concentrated sulfuric acid on a mixture of sodium chloride and potassium bichromate and after fractional distillation under low pressure was collected in sealed glass bulbs. The bulbs were broken under water and the halogen was determined by comparison with silver in the usual way. Ultimately the silver chloride was determined. Weights are corrected to vacuum.

THE ATOMIC WEIGHT OF CHROMIUM

Wt. of CrO_2Cl_2, g.	Wt. of Ag, g.	Ratio CrO_2Cl_2:2Ag	Atomic wt. of chromium	Wt. of AgCl, g.	Ratio CrO_2Cl_2:2AgCl	At. wt. of chromium

---

[13] Gonzales, *Anales soc. españ. fís. quím.*, *28,* 579 (1930).

The average result 52.02 is only 0.01 unit higher than the current one and no change is recommended for the present.

Arsenic.—Krepelka[14] has published details of the analysis of arsenic trichloride noted earlier.[15] Recrystallized arsenic trioxide was reduced with sugar charcoal and the metal resublimed. Conversion of the metal to chloride was followed by repeated vacuum distillation of the latter. Samples were collected for weighing in sealed evacuated bulbs. Hydrolysis with ice water was followed by comparison with silver in the usual way. In two cases the silver chloride was collected and weighed. Vacuum weights are given.

THE ATOMIC WEIGHT OF ARSENIC

	Average	.560219	74.938		.421638	74.938

[a] Calculated with Cl = 35.457. The figures given by the authors are calculated with Cl = 35.458.

This value is slightly lower than the value which has been in use for some time, and slightly higher than that found by Aston with the mass spectrograph after correction for the presence of O^{18}, 74.927. The value 74.93 is adopted in the table of atomic weights.

Tantalum.—Krishnaswami[16] has analyzed the chloride and bromide of tantalum. Metallic tantalum was first obtained by reducing purified potassium tantalum fluoride with sodium in an atmosphere of argon. When examined spectroscopically the metal appeared to be free from impurities, although it contained a small percentage of oxide. The metal was converted to halides by the action of pure dry halogens and the halides were twice distilled in vacuum and collected in sealed glass bulbs. After being weighed the bulbs were broken under ammonia and the solutions filtered to remove glass and tantalic acid. To find the weight of the glass the tantalic acid was dissolved in oxalic acid and the glass was collected on a weighed crucible. The solutions were then compared with silver, and

3.49922	5.26278	.66490	181 36	6 99201	.50046	181.39
	Average	,66485	181.34		.50044	181.37

The average value, 181.36, is lower than that found by Balke in 1910, 181.50. Balke's method, in which the ratio $TaCl_5:Ta_2O_5$ was determined, has been found to be unreliable because of the uncertain composition of most oxides. The new value therefore has been adopted.

Rhenium.—Hönigschmid and Sachtleben[17] have taken advantage of the increased quantities of rhenium now available by analyzing silver perrhenate. Three specimens of material were prepared. (I) Potassium perrhenate was recrystallized and the silver salt precipitated. Retained potassium was removed by reprecipitation and crystallization. (II) Metallic rhenium was burned to heptoxide in oxygen, and after solution of the oxide in water, silver perrhenate was precipitated with silver nitrate. (III) The third sample was prepared by dissolving silver oxide in perrhenic acid.

THE ATOMIC WEIGHT OF RHENIUM

Sample	Wt. of $AgReO_4$, g.	Wt. of AgBr, g.	Ratio $AgReO_4:AgBr$	Atomic weight of rhenium
I	5.36365	2.81186	1.90751	186.34
11	7.83577	4.10795	1,90747	186.33
11	8.55829	4.48684	1.90742	186.33

		Average	1.90735	186.31

---

[17] Hönigschmid and Sachtleben, Z. *anorg. Chem.*, 191,309 (1930).

The silver salt was prepared for weighing by fusion in air of a mixture of the perrhenate with an excess of acid. Weighed amounts of salt were dissolved in water and the silver was precipitated as silver bromide. Weights are corrected to vacuum.

This result is 2.4 units lower than the preliminary value found by W. and I. Noddack by analysis of the disulfide, but in view of the inferiority of the latter method and the small quantities weighed, the new value 186.31 is adopted for the table.

Thallium.—Honigschmid and Striebel[18] prepared thallous bromide by precipitation from a solution of the purified sulfate. After distillation in nitrogen the salt was weighed in a quartz tube. Solution in hot water was followed by hot precipitation with a nearly equivalent amount of silver The end-point was found with a nephelometer in the usual way. Weights are corrected to vacuum.

THE ATOMIC WEIGHT OF THALLIUM

Preliminary Series

Wt. of TlBr, g.	Wt. of Ag, g.	Ratio TlBr:Ag	Atomic weight of thallium
3.86281	1.46582	2.63526	204.38
3.78429	1.43583	2.63561	204.41
3.96949	1.50639	2.63510	204.36
3.94471	1.49669	2.63562	204.42
	Average	2.63540	204.39

Final Series

Wt. of TlBr, g.	Wt. of Ag, g.	Ratio TlBr:Ag	Atomic weight of thallium
4.01222	1.52251	2.63527	204.377
3.97142	1.50692	2.63546	204.397
3.90498	1.48170	2.63547	204.399
4.07193	1.54509	2.63540	204.391
3.68886	1.39974	2.63539	204.390
4.04739	1.53580	2.63536	204.387
	Average	2.63539	204.390

This value agrees exactly with that found earlier by Honigschmid, Berckenbach and Kothe through the analysis of thallous chloride.

Lead.—Baxter and Bliss[19] have determined the atomic weight of two specimens of RaG. The first was extracted from Swedish kolm, the second from uraninite from Wilberforce, Ontario, Canada. Purification was effected by precipitation as chromate and sulfate and crystallization as nitrate and chloride. After resublimation the chloride was fused preparatory to weighing, Comparison with silver was carried out as usual. Weights are corrected to vacuum.

The kolm lead has a lower atomic weight than any other specimen yet examined and seems to consist almost entirely of the isotope Pb^{206}.

Aston[20] has extended the usefulness of the mass spectrograph to the determination of the chemical atomic weight of complex elements by microphotometric measurements of the intensities of the isotopic lines in a mass spectrogram. The following table gives the percentages of the components, as well as the packing fractions and the atomic weights calculated on the basis of chemical oxygen.

	Isotopic weights and percentages											Packing fraction	Atomic wt. 0 = 16.0000
Chromium	50	52	53	54									
	4.9	81.6	10.4	3.1								-10×10^{-4}	52.011

THE CRYSTAL STRUCTURE OF SOME FORMS OF GLUCOSE. A PRELIMINARY PAPER

BY O. L. SPONSLER AND W. H. DORE

RECEIVED JUNE 18, 1930 PUBLISHED MAY 6, 1931

In anticipation of throwing more light upon the atomic arrangement of the cellulose unit, several crystalline forms of glucose have been under investigation. The structural relationship between cellulose and the beta modification of the amylene oxidic ring form of glucose has been pointed out by the authors.[1] In order to gain a clearer conception of cellulose it has seemed desirable to determine the structure of the crystals of the beta form and also of other forms of glucose. The present report deals with some preliminary results on the alpha and the beta forms of d-glucose ($C_6H_{12}O_6$) and on the alpha glucose monohydrate ($C_6H_{12}O_6 \cdot H_2O$).

The first two forms were prepared[2] by the method of Hudson and Dale[3] and the monohydrate by that of Hudson and Yanovsky.[4] The fine crystals so obtained were examined by the powder method of x-ray crystal analysis. Radiation from a molybdenum target Coolidge tube was employed for obtaining the diffraction patterns. The existence of crystallographic data for the two alpha forms made it possible to determine the lattice dimensions and to assign space groups to these forms. The absence of similar data for beta glucose precluded those deductions regarding its structure, but the diffraction patterns made it evident that the alpha and beta forms have different crystal structures.

After this paper was written Hengstenberg and Mark[6] reported a lattice for "d-glucose" without stating whether the alpha or beta form was used. They employed a single crystal rotation method. The agreement of their data with those appearing in this paper, together with the method they used for preparing their material, makes it clear that they were working with alpha d-glucose.

Alpha d-Glucose.—Taking 130decker's[6] value of 1.5384 for the specific gravity, 180 for the molecular weight and Avogadro's constant as 6.062 X 10^{23}, the molecular volume of alpha d-glucose is

$$\frac{180}{1.54} \times \frac{1}{6.062 \times 10^{23}} = 193 \times 10^{-24} = 193 \text{ cu. Å.}$$

Groth[7] described d-glucose as orthorhombic bisphenoidal with axial ratios: $a : b : c = 0.794 : 1.000 : 0.335$. The determination of these ratios by Becke[8] was made on material which, from the method of its preparation, was clearly the alpha modification.

Assuming four asymmetric molecules in the elementary cell (the minimum for the rhombic bisphenoidal class), the volume is 4 × 193 or 772 cu. Å., corresponding to cell dimensions: a = 10.45 Å., b = 14.85 Å., c =

Alpha d-Glucose Monohydrate.—Taking Bodecker's value of 1.5714 for the specific gravity and 198 for the molecular weight, the molecular volume of alpha glucose monohydrate is

$$\frac{198}{1.5714} \times \frac{1}{6.062 \times 10^{23}} = 207.9 \times 10^{-24} \text{ or } 207.9 \text{ cu. Å.}$$

Groth[7] describes alpha glucose monohydrate as monoclinic sphenoidal with axial ratios: $a:b:c = 1.735:1:1.908$, with the angle between inclined axes, $\beta = 97'59'$. An elementary cell containing two molecules as a minimum has dimensions: a = 8.72 Å. b = 5.03 Å., and $c = 9.59$ Å., $\beta = 97°59'$, when based on the volume and axial ratios given. A comparison of the interplanar spacings from those dimensions and from the x-ray data is presented in Table II. From crystallographic data the crystal is shown to be monoclinic; from chemical data the molecule is known to be asymmetric. In the absence of x-ray data from a single crystal, those two considerations would place the structure in space group C_2^2. That space group[8] demands two molecules per unit cell and requires that the (010) spacing be halved. Our interpretation is in agreement with both requirements.

TABLE III

Beta d-Glucose.—The powder data for beta glucose are not capable of interpretation without the support of crystallographic data, but the observed interplanar spacings are here placed on record in Table III in order to point out a difference between the crystals of the beta and alpha forms.

Summary

The crystal structures of three forms of glucose (alpha and beta anhydrous glucose and alpha glucose monohydrate) have been studied by the x-ray powder method. The interplanar spacings of the three forms are given. The data for anhydrous alpha glucose correspond to an orthorhombic unit cell having dimensions: $a = 10.45$ Å., $b = 14.85$ Å., $c = 4.97$ Å., and meet the requirements of space group V^4. The data for alpha glucose monohydrate agree with the requirements of a monoclinic unit cell having dimensions: $a = 8.72$ Å., $b = 5.03$ Å., $c = 9.59$ Å., $\beta = 97°59'$ and correspond to space group c_2^2.

OXIDATION–REDUCTION POTENTIALS.
IV. THE DETERMINATION FROM EQUILIBRIUM DATA.
B. FERRIC–FERROUS ELECTRODE

BY STEPHEN POPOFF, VERNON B. FLEHARTY AND EDWIN L. HANSON

RECEIVED AUGUST 20, 1930 PUBLISHED MAY 6, 1931

The determinations of oxidation–reduction potentials from equilibrium data are considered to be more reliable[1] than those from e. m. f. measurements because in the former one attains true equilibrium, while in the latter one cannot always be certain that an inert electrode will always record the true potential, especially in dilute solutions. E. m. f. measurements are further complicated by liquid junction potentials, which cannot, theoretically at least, always be entirely eliminated. In equilibrium data it is also possible to work with the more dilute solutions in which the principle of ionic strength can be considered to hold—thus the activity coefficients of the ions can be calculated from the limiting case of the Debye–Hückel equation.

When metallic mercury comes in contact with ferric perchlorate solution, the following reaction takes place

$$2Fe(ClO_4)_3 + 2Hg \rightleftharpoons 2Fe(ClO_4)_2 + Hg_2(ClO_4)_2$$

This reaction is of special interest because, at equilibrium, the substances are present in comparable amounts which can be suitably analyzed. It is therefore possible to determine the equilibrium constant by purely

---

[1] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 411.

chemical means, to calculate the oxidation–reduction potential of the ferric–ferrous electrode, and to compare the latter with that obtained from e. m. f. measurements.

The equilibrium of this particular reaction has not been studied chemically, although Noyes and Brann[2] determined the equilibrium constant of the reaction

$$Ag + Fe(NO_3)_3 \rightleftharpoons AgNO_3 + Fe(NO_3)_2$$

The perchlorates, mercury and perchloric acid were considered to be better suited for the determination of the equilibrium constant than the nitrates, silver and nitric acid, because in the latter case it is difficult to prepare pure metallic silver in a fine and suitable state of subdivision possessing the same energy content, and because of the possible oxidizing action of nitric acid.

In our investigation sufficiently dilute solutions were employed to be able to use the principle of ionic strength in the calculation of the equilibrium constant. The equilibrium constant was also calculated from total concentration by suitable mathematical and graphical treatments.

As a result of this experimental study the oxidation–reduction potential of the ferric–ferrous electrode was calculated to be —0.7473 v. Popoff and Kunz[3] obtained —0.7477 v. by e. m. f. measurements.

Preparation of Materials

(1) All water was redistilled from an alkaline permanganate solution.

(2) Ferric perchlorate was prepared by treating J. T. Baker c. p. ferric chloride with successive portions of G. Frederick Smith perchloric acid, and heating until no test for chloride ion was obtained. It was then recrystallized four times from 0.1 M perchloric acid.

(3) Mercury was purified by passing it through a column of dilute nitric acid six times; through redistilled water six times; distilling, filtering and passing through nitric acid and water as before.

(4) Potassium permanganate, silver nitrate, preventive, hydrochloric acid and perchloric acid solutions were made from the best chemicals obtainable.

Analytical Methods

All analyses were made using weight pipets and burets.

(1) The potassium permanganate solution was standardized electrometrically against Bureau of Standards sodium oxalate using McBride's conditions.[4]

(2) The silver nitrate solution was standardized electrometrically using a silver–silver chloride electrode with recrystallized potassium chloride as the standard.

(3) The total iron in the ferric perchlorate solution was determined electrometrically by the Zimmerman–Reinhardt method making the solution 0.5 *M* with respect to perchloric acid.

(4) The concentration of perchloric acid in the ferric perchloric solution was determined volumetrically using methyl orange as the indicator, by adding an excess of sodium hydroxide, filtering, and titrating the excess base with a standard acid solution.

[3] Popoff and Kunz, ibid., 51, 382 (1929).

[4] McBride, *ibid.*, 34, 393 (1912).

(5) and **(6)** The weight ratio between the silver nitrate and sodium chloride solutions was determined electrometrically using silver-silver chloride electrodes.

(7) The perchloric acid solution was standardized volumetrically using phenolphthalein as the indicator, against a carbonate-free solution of sodium hydroxide which had been standardized against constant boiling hydrochloric acid solution.

(8) Analysis of the equilibrium mixture.

(a) The ferrous iron was determined by precipitating the mercurous ion with an excess of sodium chloride, filtering, adding **20** cc. of preventive solution and enough perchloric acid to make the acid concentration approximately **0.5** M. The solution was then titrated electrometrically with potassium permanganate.

(b) The mercurous mercury was determined by adding an excess of sodium chloride and titrating the excess electrometrically with the silver nitrate, using a silver–silver chloride electrode.

(c) The ferric iron was obtained by difference between the total iron and ferrous iron found.

Table I expresses the results of these analyses. Concentration (*C*) is expressed in moles per thousand grams of water in vacuum in all tables.

The Relation between Equilibrium Constant and Oxidation–Reduction Potential.—The reaction

$$2Fe^{+++} + 2Hg \rightleftharpoons 2Fe^{++} + Hg_2^{++} \qquad (A)$$

occurs in the cell

$$Pt \mid Fe(ClO_4)_3, Fe(ClO_4)_2 \mid Hg_2(ClO_4)_2 \mid Hg$$

The equations for the potentials at each electrode at 25° are

$$E_{\mathrm{Fe}} = E_{0\mathrm{Fe}} - 0.05915 \log \frac{a_{\mathrm{Fe}^{+++}}}{a_{\mathrm{Fe}^{++}}}$$

$$E_{\mathrm{Hg}} = E_{0\mathrm{Hg}} - \frac{0.05915}{2} \log a_{\mathrm{Hg_2}^{++}}$$

At equilibrium, the potential of the cell will be zero, and

$$E_{0\mathrm{Hg}} - \frac{0.05915}{2} \log a_{\mathrm{Hg_2}^{++}} = E_{0\mathrm{Fe}} - \frac{0.05915}{2} \log \frac{a^2_{\mathrm{Fe}^{+++}}}{a^2_{\mathrm{Fe}^{++}}}$$

Transposing, one gets

$$E_{0\mathrm{Hg}} - E_{0\mathrm{Fe}} = \frac{0.05915}{2} \log a_{\mathrm{Hg_2}^{++}} - \frac{0.05915}{2} \log \frac{a^2_{\mathrm{Fe}^{+++}}}{a^2_{\mathrm{Fe}^{++}}}$$

$$- \frac{0.05915}{2} \log \frac{a^2_{\mathrm{Fe}^{++}} \times a_{\mathrm{Hg_2}^{++}}}{a^2_{\mathrm{F_2}^{+++}}}$$

However, $a^2_{\mathrm{Fe}^{++}} \times a_{\mathrm{Hg_2}^{++}}/a^2_{\mathrm{Fe}^{+++}}$ is the equilibrium constant of reaction (A)

$$E_{0\mathrm{Hg}} - E_{0\mathrm{Fe}} = \frac{0.05915}{2} \log K$$

in which K is the equilibrium constant.

The value for $E_{0\mathrm{Hg}}$ has been determined by Lewis[6] and if the value for the equilibrium constant of the reaction shown is determined precisely, one can calculate the oxidation–reduction potential of the ferric--ferrous electrode.

Experimental Methods

(1) Attainment of equilibrium was accomplished by approaching the equilibrium of the reaction from both sides at a temperature of 25°. One set of runs was allowed to come to 25° in the water thermostat, approaching the equilibrium from the "cold side," so to speak. Another set of the same concentration was heated to 30–35° in an air thermostat, then brought to the equilibrium at 25° in the water-bath. This can be termed as approaching the equilibrium from the "hot side." These mixtures were continually rotated and shaken in a constant temperature bath at 25 ± 0.01". The solutions were analyzed for the ferrous iron and the mercurous mercury by withdrawing a weighed amount of the solution, approximately 100 g. being used for each analysis.

(2) The ease of reversibility of the reaction was determined by varying the mercury content, the temperature and the time of rotation (for both "hot" and "cold"). It was finally decided to use 40 cc. of mercury in about *500* cc. of solution and to rotate the mixtures for both "hot" and "cold" for at least forty-eight hours at 25° before any analyses were attempted. It had been determined previously that twenty-four hours of rotation at 30–35° was more than sufficient to shift the equilibrium and that twenty-four hours of rotation at 25° was more than sufficient to obtain the same equilibrium as that established from the "cold" side. Special

---

[6] **Lewis** and Randall, **Ref. 1**, p. **433.**

Pyrex bottles were made (holding about 500 cc.) which could be glass sealed. Ordinary glass-stoppered bottles, which were sealed with paraflin, failed to give reproducible and identical results for both "hot" and "cold" equilibrium mixtures at 25°. At the present time no explanation will be offered.

(3) Variation of Acid and Salt Concentrations.—In each of the five series the acid concentration was kept constant but the concentration of the ferric perchlorate (starting mixture) was varied down to 0.001 *C*. The acid concentration **was** varied from 0.02 to 0.002 C. The latter was found to be the lowest concentration at which no hydrolysis took place when 0.001 *C* iron solution was used. Lower concentration of ferric perchlorate than 0.001 C was not employed because the errors in the analyses would have been too great. In the 0.003 C perchloric acid series, 0.004 C iron was the upper limit. **A** starting solution containing 0.001 *C* of iron and 0.001 C of perchloric acid hydrolyzed.

Experimental Data and Calculations

Table II gives the experimental results obtained in 0.02, 0.01, 0.005, 0.003 and 0.002 *C* perchloric acid concentrations, respectively, with vary-

ing concentration of iron. $K'C_{Hg_2^{++}}$ represents the equilibrium constant calculated from total concentration by the equation

$$K'C_{Hg_2^{++}} = \frac{C_{Fe^{++}}^2 \times C_{Hg_2^{++}}}{C_{Fe^{+++}}^2}$$

It was discovered that if the equilibrium constants were calculated upon the assumption that mercurous ion were monovalent, interesting results were obtained. If mercurous ion were monovalent

$$K'C_{Hg^+} = \frac{C_{Fe^{++}} \times C_{Hg^+}}{C_{Fe^{+++}}}$$

No attempt is made to draw any conclusions from the values of $K'C_{Hg^+}$.

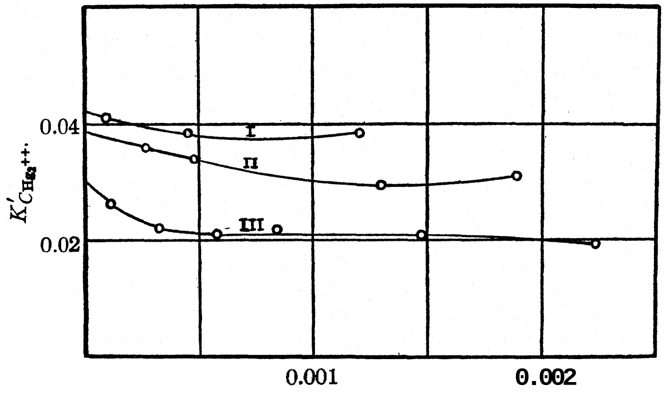

Fig. 1.—The apparent equilibrium constants from total concentration in varying acid and salt concentrations.

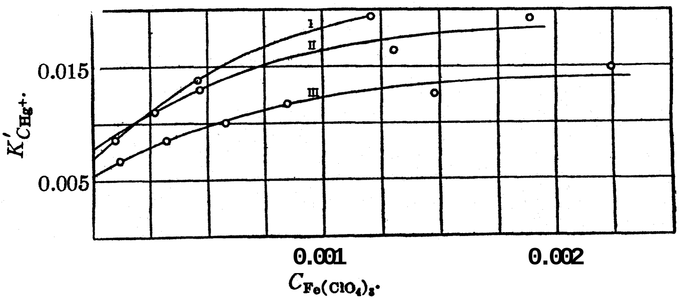

Fig. 1a.—The apparent equilibrium constants from total concentration in varying acid and salt concentrations.

In an analysis of a typical equilibrium mixture the percentage mean error was 0.1 for the determination of ferrous iron and 0.15 for mercurous mercury.

The Equilibrium Constant from Total Concentration.—The values of $K'C_{Hg_2^{++}}$ and $K'C_{Hg^+}$ in 0.02, 0.01, 0.005 (corresponding to I, II, III, respectively) C perchloric acid were plotted (Figs. 1 and 1a, respectively) against the C of the ferric perchlorate (at equilibrium) and the curves extrapolated to zero concentration of ferric perchlorate. The extrapolated values, Table III, were plotted (Figs. 2 and 2a, respectively) against the C of the perchloric acid and the curves again extrapolated to zero concentration of the acid.

Table III

Equilibrium Constant in Varying Acid Concentration

$C_{\mathrm{HClO_4}}$	$K''C_{\mathrm{Hg_2^{++}}}$	$K''C_{\mathrm{Hg^+}}$
0.020	0.0421	0.00706
.010	.0386	.00796
.005	.0310	.00556
.000	.0188	.00126

Due to the uncertainty of graphical extrapolation the data were extrapolated mathematically using the principle of moments and zero sum. A

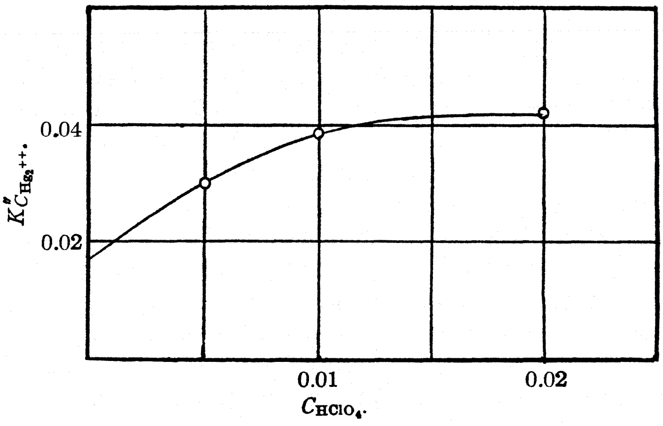

Fig. 2.—The equilibrium constants in varying acid against the acid concentration.

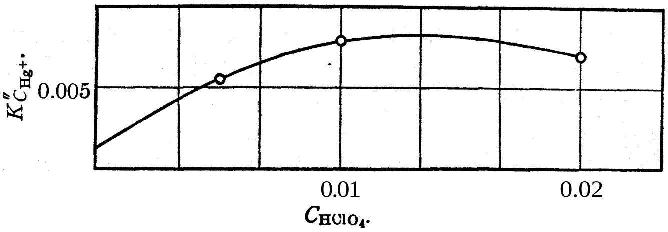

Fig. 2a.—The equilibrium constants in varying acid against the acid concentration.

value of 0.0188 was calculated for the true equilibrium constant ($K'C_{\mathrm{Hg_2^{++}}}$) and 0.00126 for the true equilibrium constant ($K'C_{\mathrm{Hg^+}}$) from total concentration.

The Equilibrium Constant from Ionic Strength.—It was possible in Series V, 0.002 *M* acid, 0.002 and 0.001 M ferric perchlorate, to calculate the activity coefficients in

$$K_f = \frac{C_{Fe^{++}}{}^2 \times f_{Fe^{++}}{}^2 \times C_{Hg_2^{++}} \times f_{Hg_2^{++}}}{C_{Fe^{+++}}{}^2 \times f_{Fe^{+++}}{}^2}$$

by the equation[6]

$$-\log f = 0.5z^2\sqrt{\mu}$$

The latter equation holds for most solutions whose ionic strengths are not greater than 0.01. Table IV gives the values obtained.

TABLE IV

THE EQUILIBRIUM CONSTANT FROM IONIC STRENGTH IN 0.002 M $HClO_4$

Total C_{Fe}	μ	f^{++}	f^{+++}	K_f
0.002	0.0117	0.608	0.326	0.01884
.001	.0068	.685	.427	.01751

Although the ionic strengths of the solutions containing 0.001 M ferric perchlorate (starting solution) and either 0.005 M or 0.003 M perchloric acid are 0.0097 and 0.0078, respectively, the equilibrium constants, using activity coefficients, calculate to be 0.0510 and 0.0274, respectively. It may be concluded that the equation used to calculate the activity coefficients does not hold for the foregoing solutions.

One may also calculate the equilibrium constants for all the solutions in Series III and IV, using activity coefficients, and then plot the values thus obtained against the square root of the ionic strength and extrapolate to zero ionic strength, assuming that the points lie on a straight line. The latter assumption, however, can hardly be justified, although the final extrapolated values agree closely among themselves and are not very far from 0.0184, the true equilibrium constant, since the equilibrium constant in each acid is different, although the ionic strengths of the solutions are the same and less than 0.01.

The true equilibrium constant may be taken as the average of the equilibrium constants obtained from total concentration and from (average) ionic strength in 0.002 M perchloric acid. The average value is 0.0184 or 0.018 ± 0.0005.

The Oxidation–Reduction Potential of the Ferric–Ferrous Electrode.—Using the equation

$$E_{0_{Fe}} = E_{0_{Hg}} - \frac{0.05915}{2}\log K$$

and Lewis's[5] value for E_{0Hg} (—0.7986 v.), the value for E_{0Fe} calculates to be −0.7473 v. Noyes and Brann[2] found from equilibrium data −0.7467 v., while Popoff and Kunz[3] report —0.7477 v. from e. m. f. measurements.

[6] Bronsted and La Mer, THIS JOURNAL. 46, 555 (1924).

Summary

1. The following reaction was studied chemically and found to be a truly and easily reversible reaction

$$2Fe^{+++} + 2Hg \rightleftharpoons 2Fe^{++} + Hg_2^{++}$$

2. The equilibrium constant of the reaction was calculated either from total concentration by suitable graphical and mathematical treatments or from ionic strength of dilute solutions, and was found to be 0.0180 ± 0.0005.

3. The principle of ionic strength may not be considered to hold even in solutions as low as 0.01 when there is too much acid present as compared with the other salts.

4. The oxidation-reduction potential of the ferric–ferrous electrode, calculated from the equation

$$E_{0_{Fe}} = E_{0_{Hg}} - \frac{0.05915}{2} \log K$$

was found to be −0.7473 v. This value agrees very closely with −0.7477 v. obtained from our former e. m. f. measurements.

METHODS OF CALCULATING AND AVERAGING RATE CONSTANTS[1]

BY W. E. ROSEVEARE

RECEIVED JANUARY 19, 1931 PUBLISHED MAY 6, 1931

Introduction

In order to obtain a more probable value of the rate of a chemical reaction, for temperature coefficients, etc., it has been customary to take the simple arithmetical average of individual calculated values. Due to the nature of the rate function, such an arithmetical average may possibly be as far from the true value as that calculated from the two least accurate measurements. This applies only to the average of rate constants which are calculated*from measurements made on a single sample of reacting material and not to the average of those found under identical conditions of time and concentration. Most rates of reaction have been calculated by the interval method or the method of integrating from the zero of time using the formulas: $k = \frac{1}{t_n - t_{n-1}} \ln\left(\frac{a - x_{n-1}}{a - x_n}\right)$ and $k = \frac{1}{t_n} \ln \frac{a}{a - x_n}$. The arithmetical averages of the rates calculated by these methods give quite different results and both are incorrect.

---

[1] This paper was presented in preliminary form by the author before the Mid-west Regional meeting of the American Chemical Society, May 9, 1930.

Present Incorrect Methods of Averaging

Error of the Interval Method Average.—It can be shown that the simple arithmetical average of the interval rate constants, when calculated for equal time intervals, is equal to the rate constant as calculated from the initial and final observed values of the concentration and is independent of all intermediate ones. If $k_{0,1}$, $k_{1,2}$, $k_{2,3}$ . . . k, $_{-1,n}$ are the interval rate constants for n intervals, then the arithmetical average will be: $(1/n)$ $(k_{0,1} +$ $k_{2,3}+\ldots$ k, $_{-1,n})$. For a unimolecular reaction $k_{0,1} = (1/At) \ln (C_0/C_1)$, where At is the time interval during'which the concentration changes from C_0 to C_1. If all the time intervals are the same and k_a is the arithmetical average, then

$$k_a = \frac{1}{n}\left[\frac{1}{\Delta t}\ln\frac{C_0}{C_1} + \frac{1}{\Delta t}\ln\frac{C_1}{C_2} + \ldots \frac{1}{\Delta t}\ln\frac{C_{n-1}}{C_n}\right]$$

$$k_a = \frac{1}{n\,\Delta t}\ln\left[\frac{C_0\,C_1\,C_2\,\ldots\,C_{n-1}}{C_1\,C_2\,C_3\,\ldots\,C_n}\right]$$

All the values of C cancel out except the first and the last and since $n\,At =$ $t,,$ then

$$k_a = \frac{1}{t_n}\ln\left(\frac{C_0}{C_n}\right)$$
$$k_a = k_{0,n}$$

Thus the arithmetical average is independent of all values except the first and last. This proof may be extended to a reaction of any order. It can be shown by very simple analytic geometry that, for points whose abscissas are equally spaced, the arithmetical average of the slopes of straight lines drawn through adjacent points is equal to the slope of the straight line drawn through the first and last points and is independent of the ordinates of the intermediate points. Wagner[2] showed this to be true in the case of a second order reaction.

Error of the Second Method.—When each value of k is calculated by integrating from the zero time, each value of $a - x$ is combined with a single value of the initial concentration which may rest on a single measurement. Guggenheim[a] pointed out that this gave undue weight to the initial concentration. Even though the initial concentrations were known with absolute accuracy, this method gives too much weight to the points near the zero of time.

Methods Applicable to Unimolecular Reactions

Rate measurements may be divided into two classes, depending on whether one analyzes for the concentration $(a - x)$ or the amount which has reacted, x.

When x is Measured Directly.—Guggenheim[3] developed a method

---

[2] C. Wagner, *Z. physik. Chem.*, *115*, 132 (1925).

[3] E. A. Guggenheim, *Phil. Mag.*, [7] *2*, 538 (1926).

which eliminates the use of the initial concentration. He plotted the common logarithm of the amounts reacting in a chosen interval of time against the time. The slope multiplied by **2.303** gave the rate constant.

The rate may also be determined analytically from three values of x, provided the time intervals between them are the same. If x_1, x_2 and x_3 are the amounts which have reacted at times t_1, t_2 and t_3, then

$$k(t_2 - t_1) = \ln \frac{(a - x_1)}{(a - x_2)} \qquad (1)$$

$$k(t_3 - t_2) = \ln \frac{(a - x_2)}{(a - x_3)} \qquad (2)$$

If we impose the condition that $(t_3 - t_2) = (t_2 - t_1)$, *i. e.*, the time intervals are the same, then

$$\frac{a - x_1}{a - x_2} = \frac{a - x_2}{a - \quad x\ a}$$

and

$$a = \frac{x_1x_3 - x_2^2}{x_1 - 2x_2 + x_3}$$

If t_1 was taken as the zero of time, then this equation would reduce to that obtained by Smith[4] for the initial concentration in terms of the concentrations at two times, one twice the other. Substituting a from Equation **3** in either Equation 1 or 2 we obtain

$$k = \frac{1}{\tau} \ln \frac{(x_2 - x_1)}{(x_3 - x_2)} \qquad (3)$$

where τ is the time interval between the x_1 and x_2 as well as between the x_2 and x_3. For a gaseous reaction followed by the change in volume at constant pressure or the pressure change at constant volume, the x's may be replaced, respectively, by the volume or pressure. This method and Guggenheim's are alike in that the initial concentrations are eliminated. Even though one finds a perfectly straight line using the former method or a constant value of k using the second method, it does not follow that the reaction obeys the simple unimolecular law. A straight line and a constant value of k will be obtained when and only if the rate is given by the equation $dx/dt = k(a - x) \pm k'(b - x)$, where k' and b may or may not be zero. This expresses the rate for a reversible reaction, a side reaction, a subsequent reaction and a reaction where the product combines with the reactant making it relatively inert, as well as for a simple unimolecular reaction. The reversibility can be determined from free energies and the other exceptions by chemical analyses and by trying the effect of adding some of the product to the reacting mixture. Thus one can obtain strong but not absolute evidence of unimolecularity when the original concentration cannot be measured.

In order to best show up a trend, the time intervals should be short, but

[4] **R. C. Smith,** ***Phil. Mag.,*** [7] 1,496 (1926).

to obtain the most probable value, the intervals should be longer. Since the value of $x_3 - x_2$ can never be greater than $x_2 - x_1$ and the probable error in x is a constant quantity independent of the time, the error in k will be due principally to the error in $x_3 - x_2$. Therefore, for the case when the error in determining the concentration has a greater effect on k than the error in measuring the time, the error may be considered as due to the error in $x_3 - x_2$ alone. In this case the accuracy will be greatest when $x_3 - x_2$ is greatest. If we let the concentration be a at t_1, then x_1 will be zero and Equation 3 becomes

$$k\tau = \ln \frac{x_2}{(x_3 - x_2)} \text{ or } x_3 - x_2 = x_2e^{-k\tau}$$

Setting the derivative with respect to τ of $x_3 - x_2$ equal to zero will make the latter a maximum and the error in k a minimum. Since $e^{-k\tau}$ does not equal zero, this gives

$$kx_2 - \mathrm{d}x_2/\mathrm{d}\tau = 0 \qquad (4)$$

By differentiating Equation 1 with respect to τ with $x_1 = 0$, one finds $\mathrm{d}x_2/\mathrm{d}\tau = k(a - x_2)$. Substituting this in Equation 4 gives $x_2 = a/2$, the condition for maximum accuracy in k. This means that if ln $(x_3 - x_2)$ is less accurately determined than τ, then the greatest accuracy is obtained when the concentration decreases 50% during the first interval and one-half that much during the second interval.

In order to best utilize data, when the error in measurement of time is negligible and one wishes to use this method as evidence for unimolecularity, it is best to take six measurements at equal time intervals near the beginning, six with the same time intervals when about 50% has reacted, and six more when about 75% has reacted, such that the time interval between the first and seventh equals that between the seventh and thirteenth, etc. Then one can calculate a rate constant from the first three, another from the second three, etc., giving two constants for the beginning, two for the middle and two nearer the end. This will show if there is a trend not represented by $\mathrm{d}x/\mathrm{d}t = k(a - x) \pm k'(b - x)$. To obtain the most probable value of the rate constant one should calculate it from the first, seventh and thirteenth; the second, eighth and fourteenth, etc. These constants will all have practically the same weight and will be independent and therefore may be averaged arithmetically.

When $(a - x)$ Is Measured Directly.—In this case one can calculate k from any two measurements of concentration and the time between them, but when there are more than two points, one is faced with the problem of deciding how to combine them. If the time is the least accurate measurement, then all points will have practically the same weight. On the other hand, if ln $(a - x)$ is least accurately determined, then each point will have a different weight since $a - x$ and not ln $(a - x)$ is directly measured. The probable error in $a - x$ in general is a constant quantity rather than a constant percentage error. In Fig. 1a the dotted lines show the limits of error due to a constant error in time and Fig. 1b shows the limits of error for a possible error in $(a - x)$ equal to one-tenth of the initial concentration. The weight changes in the same way regardless of the size of the error, the very large error being used merely to facilitate graphing. If r_c is the probable error in the concentration, then by expanding ln (C + r) in series and neglecting terms of second and higher powers, one has r_c/C as the probable error in ln C. Letting r_t be the probable error in measurement of the time, one can see from Fig. 2 that $r_t \tan \theta$ or kr_t is the probable error in ln C which would produce the same probable error in k as does r_t. Therefore, one may consider the time as entirely correct and that there are two probable errors in ln C, one due to error in measurement of C and the other due to error in measurement of t. The effective probable error of a point in terms of ln C will be $\sqrt{(kr_t)^2 + (r_c/C)^2}$. The weight p of any point will be inversely proportional to the square of its probable error, and therefore

$$p = \frac{1}{(kr_t)^2 + (r_c/C)^2} \qquad (5)$$

Thus one can calculate the weight of any point. It will be seen from formula (5) that if the error was due only to the error in measuring time, all points would have the same weight. On the other hand, if the error was due only to the error in determining concentration, the weight of each point would be proportional to C^2. The weight is important in the latter case, since if the weight at the start is taken as unity, the weight will be one-quarter when the reaction is 50% complete and one-hundredth when 90% complete,

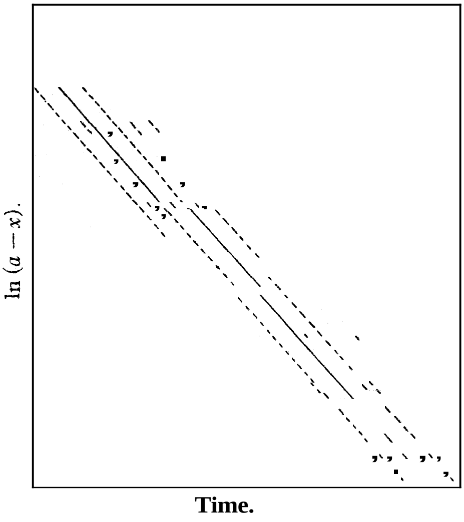

Fig. 1a.

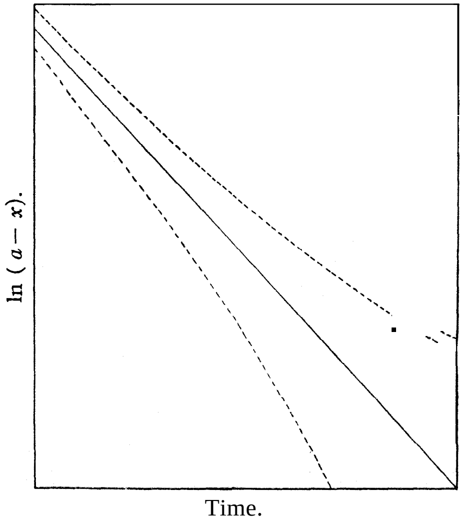

Fig. 1b.

1. Graphical Method.—This method of plotting ln $(a - x)$ against the time and drawing the best straight line through the points is well known. It has the advantage of showing trends and at present is certainly the best method for such cases. However, it has the disadvantage in that large graphs cannot be published and some data are more accurate than can be represented graphically.

2. Arithmetical Mean.—Where the weights of all points are nearly the same, a very convenient mean is obtained by dividing the points into two equal parts and taking a time weighted average of the slopes of pairs of points. If there are six points on the plot of ln C against t, one would take the slopes of the pairs of points 1-6, *2-5* and **3-4** and weight these according to the distance between the points. However, the distances between the points is very nearly proportional to their projection on either axis. Therefore, the weights may be taken as the difference in t for each pair of points. The slope from points 1 and 6 is $(\ln C_6 - \ln C_1)/(t_6 - t_1)$ and its weight will be $(t_6 - t_1)$. Then the weighted mean will be

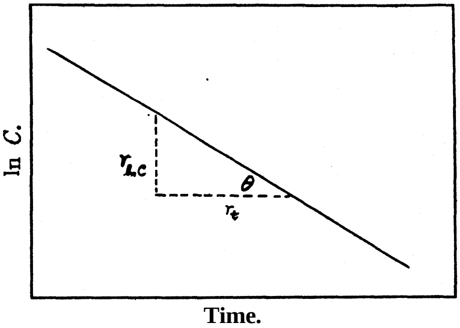

Fig. 2.

$$k_m = \frac{\frac{\ln C_6 - \ln C_1}{t_6 - t_1}(t_6 - t_1) + \frac{\ln C_5 - \ln C_2}{t_5 - t_2}(t_5 - t_2) + \frac{\ln C_4 - \ln C_3}{t_4 - t_3}(t_4 - t_1)}{(t_6 - t_1) + (t_5 - t_2) + (t_4 - t_5)}$$

Since the time differences in the numerator cancel out

$$k_m = \frac{(\ln C_6 + \ln C_5 + \ln C_4) - (\ln C_3 + \ln C_2 + \ln C_1)}{(t_6 + t_5 + t_4) - (t_3 + t_2 + t_1)}$$

and in general

$$k_m = 2.303\left[\frac{\sum\limits_{i=\frac{1}{2}n+1}^{i=..}\log C_i - \sum\limits_{i=1}^{i=\frac{1}{2}n}\log C_i}{\sum\limits_{i=\frac{1}{2}n+1}^{i=n} t_i - \sum\limits_{i=1}^{i=\frac{1}{2}n} t_i}\right]$$

A given error in time or log C produces the same magnitude of error in the above mean regardless of the time. Thus all points have equal weight. If there are an odd number of points, the middle one is not used, and therefore n is always even. This method should only be used for cases where the time is the least accurate measurement or for the rare case when the percentage error in analysis is a constant quantity.

3. Method of Least Squares.—This method of obtaining the slope of a straight line is well known, but it has rarely been used to calculate rate constants and when used **has** not been weighted. It has the disadvantage of requiring a great deal of arithmetical work, and weighting considerably increases the amount of work. The general formula for the slope of a straight line by the method of least squares is

$$s = \frac{\Sigma px\,\Sigma py - \Sigma p\,\Sigma pxy}{(\Sigma px)^2 - (\Sigma p)(\Sigma px^2)}$$

where p is the weight of a point whose coordinates are x and y. The rate constant of a unimolecular reaction will be

$$k = \frac{\Sigma pt\ 29\ \ln\,(a-x) - \Sigma p\,\Sigma pt\ln\,(a-x)}{(\Sigma pt)^2 - (\Sigma p)(\Sigma pt^2)}$$

The weight p of each point can be determined by the method previously given. This method has the advantage in that one can calculate the "probable error." The formula for calculating the probable error is given by Birge.[5] Professor Ingraham of the Mathematics Department of the University of Wisconsin pointed out to the author that the above method of least squares does not give the most probable value of the rate constant. Therefore the use of this method is questionable.

Concentration **Change** for Maximum Accuracy.—It is important to know how long to let a chemical reaction proceed in order to obtain the greatest probable accuracy in the rate constant, when the rate is calculated from the concentrations at two times. If r and r_0 are the probable errors in the concentrations C and C_0, then r/C and r_0/C_0 will be the corresponding errors in $\ln C$ and $\ln C_0$, providing the error is small. If one assumes that the error in k is due only to the error in concentration, then the probable error in k will be

$$r_k = \frac{1}{t}\sqrt{\left(\frac{r_0}{C_0}\right)^2 + \left(\frac{r}{C}\right)^2} \qquad (6)$$

If we let $y = C/C_0$, the fraction which has reacted at time t, then $kt = -\ln y$. Dividing Equation **6** by k, substituting $C = yC_0$, and $kt = -\ln y$, then the fractional error in k is

$$\frac{r_k}{k} = \frac{-1}{C_0 \ln y}\sqrt{(r_0)^2 + \left(\frac{r}{y}\right)^2} \qquad (7)$$

Taking the derivative of r_k/k with respect to y and setting it equal to zero, we have

$$(r_0/r)^2y^2 + 1 + \ln y = 0 \qquad (8)$$

which is the condition that the percentage error in k shall be a minimum. Since the probable error in the concentration, instead of being a constant percentage error, is almost always a constant quantity independent of the concentration, r_0 will be equal to r. Equation 8 then becomes: $-\ln y = y^2 + 1$ or $y =$ **0.33.** Thus, for the case when the error in time is negligible,

---

[5] *R. T.* Birge, *Phys. Rev. Suppl.*, *1*, **5** **(1929).**

the greatest probable accuracy in k is obtained by calculating it for the interval during which 67% of the material reacts.

In the case of fast reactions, the error in measuring the time may have a greater effect on the rate constant than the errors in measuring the concentration. One may calculate r'_0, the probable error in the initial concentration which would produce the same error in k as does the error in $(t_n - to)$. From Fig. 2 one can see that $\tan \theta = k$ and therefore for small values of r_{t_0}, $r'_{\ln C_0} = kr_{t_0}$. $r'_{\ln C_0}$ is the probable error in $\ln C_0$ which would produce the same probable departure from the line as does the actual probable error in t_0. The probable error r_t in reading the time is independent of time, and therefore the probable error in $(t, - t_0)$ will be $\sqrt{2}$. One may consider that t_n is entirely accurate and that all the error is in t_0 and equal to $r_t\sqrt{2}$. Since $r'_{\ln C_0} = r'_0/C_0$, and r_{t_0} is set equal to $r_t\sqrt{2}$, we have

$$r'_0 = kr_tC_0\sqrt{2} \tag{9}$$

Therefore one may consider the time as always correct and that there is a probable error in the initial concentration r_0 due to error in measurement of the concentration, and another probable error in the initial concentration r'_0 or $kr_tC_0\sqrt{2}$ due to errors in measurement of the time. Since the probable error in concentration r is independent of time, then r_0 may be replaced by r and the effective probable error expressed in terms of the initial concentration will be $\sqrt{r^2 + (kr_tC_0\sqrt{2})^2}$. Substituting this for r_0 in Equation 8, the general equation for optimum time will be

$$\left(\frac{kr_tC_0}{r}\right)^2 2y^2 + y^2 + 1 + \ln y = 0 \tag{10}$$

Table I gives for different ratios of $(kr_tC_0)/r$, the values of $1 - y$, the fraction which has reacted. Thus one can determine how far to let a

TABLE I

Y	$1 - y$ (fraction changed)	Ratio (kr_tC_0)
0.33	0.67	0.0
.3	.70	0.8
.2	.8	2.7
.1	.9	8.0
.05	.95	20.0

unimolecular reaction proceed in order to obtain the greatest probable accuracy in the rate constant, regardless of the probable errors in time and concentration. The probable errors in time and concentration must be estimated by the experimenter. When applying this formula it is only necessary to know an approximate value of the rate constant k, but it must be in terms of natural logarithms and the unit of time in which r_t is expressed. It should be remembered that these probable errors are probable departures from the correct values and not percentage errors.

Methods Applicable to Bimolecular Reactions

When x Is Measured Directly.—When the concentrations of the reacting substances are the same, one can calculate the rate constant from the amount reacting during two equal consecutive time intervals. For these intervals

$$k(t_2 - t_1) = \frac{1}{a - x_2} - \frac{1}{a - x_1} \tag{11}$$

$$k(t_3 - t_2) = \frac{1}{a - x_3} - \frac{1}{a - x_2} \tag{12}$$

If $t_2 - t_1 = t_3 - t_2$ then

$$\frac{1}{a - x_2} - \frac{1}{a - x_1} = \frac{1}{a - x_3} - \frac{1}{a - x_2} \tag{13}$$

and

$$a = \frac{2x_1x_3 - x_1x_2 - x_2x_3}{x_1 - 2x_2 + x_3} \tag{14}$$

Substituting this value of a in either equation (11) or (12), one obtains

$$k = \frac{1}{2\tau}\,\frac{[(x_2 - x_1) - (x_3 - x_2)]^2}{(x_3 - x_1)(x_2 - x_1)(x_3 - x_2)} \tag{15}$$

where τ is the time interval between x_1 and x_2 as well as between x_2 and x_3. If ΔC_1 and ΔC_2 are the changes in concentration during two equal and consecutive time intervals, Equation 15 may be written

$$k = \frac{1(\Delta C_1 - \Delta C_2)^2}{2\tau(\Delta C_1 + \Delta C_2)\Delta C_1 \Delta C_2} \tag{16}$$

Equation 15 may also be written

$$k = \frac{1}{2\tau(x_3 - x_1)}\left[\frac{x_2 - x_1}{x_3 - x_2} - 1\right]\left[1 - \frac{x_3 - x_2}{x_2 - x_1}\right] \tag{17}$$

Since $(x_3 - x_2)$ is always smaller than $(x_2 - x_1)$, which is smaller than $(x_3 - x_1)$, one can see from equation (17) that when τ is more accurately known than $(x_3 - x_2)$, the error in k will always be largely due to the error in $(x_3 - x_2)$. The probable accuracy in k will be very nearly a maximum when $(x_3 - x_2)$ is a maximum. Letting $t_1 = 0$, then $x_1 = 0$ and equation (13) becomes

$$\frac{2}{a - x_2} = \frac{1}{a} - \frac{1}{a - x_3} \tag{18}$$

or

$$(x_3 - x_2) = \frac{x_2(a - x_2)}{(a + x_2)} \tag{19}$$

In order that $x_3 - x_2$ shall be a maximum, its derivative is set equal to zero.

$$\frac{d(x_3 - x_2)}{dx_2} = \frac{-x_2}{a + x_2} - \frac{x_2(a - x_2)}{(a + x_2)^2} + \frac{a - x_2}{a + x_2} = 0 \tag{20}$$

This reduces to $x_2 = 0.414a$. Thus, when the rate is calculated from Formula 15 and the time interval is more accurately known than $x_3 - x_2$, the probable error in k will be smallest when about 41% reacts during the first time interval.

When *(a − x)* is Measured Directly.—The integrated equation for a bimolecular reaction, when the concentrations of the reactants are the same, may be written

$$k = \frac{1}{t}\left[\frac{1}{C} - \frac{1}{C_0}\right]$$

The probable error in concentration r is small compared to the concentration, and therefore one may use the series expansion $1/(c - r) = 1/C - r/C^2 + r^2/C^3 - \ldots$ and neglect all terms except the first two. The error in $1/C$ will then be r/C^2 and the probable error in k due to errors in concentration will be

$$r_k = \frac{1}{t}\sqrt{\left(\frac{r_0}{C_0^2}\right)^2 + \left(\frac{r}{C^2}\right)^2} \tag{21}$$

Letting $y = C/C_0$, dividing by k and letting $kt = 1/C - 1/C_0$, one obtains

$$\frac{r_k}{k} = \frac{\sqrt{r_0^2 + \frac{r^2}{y^4}}}{C_0(1/y - 1)} \tag{22}$$

The probable error will be a minimum when the derivative of r_k/k with respect to y is zero.

$$\frac{d(r_k/k)}{dy} = \frac{1}{C_0}\left[\left(\frac{1}{y} - 1\right)\left(\frac{-2r^2}{y^5}\right)\left(r_0^2 + \frac{r^2}{y^4}\right)^{-1/2} + \frac{1}{y^2}\left(r_0^2 + \frac{r^2}{y^4}\right)^{1/2}\right]\left[\frac{1}{y} - 1\right]^{-2} \tag{23}$$

Setting this equal to zero, we have

$$\left(\frac{r_0}{r}\right)^2 y^4 + 2y = 1 \tag{24}$$

One may calculate the probable error in the initial concentration r_0' that would produce the same probable error in k, as does the actual probable error in time r_t. By the same procedure that was used for the unimolecular reaction, one obtains $r_0' = kr_tC_0^2\sqrt{2}$, the effective probable error in the initial concentration will be $\sqrt{(kr_tC_0^2\sqrt{2})^2 + r^2}$ and the general equation for optimum accuracy will be

$$\left(\frac{kr_tC_0^2}{r}\right)^2 2y^4 + y^4 + 2y = 1 \tag{25}$$

Table II gives the values of $(1 - y)$ for different values of the ratio $kr_tC_0^2/r$. Thus for the case when the concentrations of the reactants are the same,

TABLE II

OPTIMUM CONCENTRATION CHANGE FOR BIMOLECULAR REACTION

Fraction changed $(1-y)$	0.53	0.6	0.7	0.8	0 9	0.95
Ratio $kr_tC_0^2/r$	.0	1.8	5	14	63	268

one may determine how much should react in order to obtain the maximum accuracy in k. In order to do this, one needs to know an approximate value of k and one has to estimate the probable error in measuring the time and concentration.

Summary and Conclusions

The rate constants of both unimolecular and bimolecular reactions can be calculated analytically when the initial concentration or time cannot be determined. This method, however, is not to be recommended when it is possible to determine the initial concentration accurately by direct means, since it has greater probable error.

The commonly used simple arithmetical average of rate constants is entirely incorrect and should never be used except for averaging rate constants calculated from entirely independent data, and then only when the probable errors are nearly alike. The method of least squares should be used with caution. The graphical method may be used in all cases where each point on the graph represents entirely independent data.

The author recommends that one should first determine whether the rate law holds within experimental error. Then, in case it does. one should take more data in such a manner that a number of values of k can be calculated from entirely independent data for approximately the optimum concentration change. These values of *k* may be averaged graphically or by taking the simple arithmetical average.

THE PHYSICAL IDENTITY OF ENANTIOMERS. THE CAMPHORIC ACIDS

BY ALAN NEWTON CAMPBELL

RECEIVED JANUARY 20, 1931 PUBLISHED MAY 6, 1931

In a recent paper[1] the author in collaboration with another was able to produce evidence that the d- and *l*-mandelic acids are not absolutely identical in their physical properties. Private criticism made at that time rested upon the contention that the d-form was not quite pure, despite the facts that the rotation of d-form was normal, and that the rotatory dispersions or rather differences in rotation for the two lines used, were the same, which would not be the case if one form were impure. Nevertheless, in view of this contention, it was thought advisable to prepare the next pair of enantiomers from independent optically active sources of opposite rotation. I am indebted to Dr. Kenyon for the suggestion that I should use the d- and I-camphors, or rather the camphoric acids obtainable from them. I have been exclusively occupied for the past fifteen months with this work, most of the time being spent on preparation and purification. As I surmise that criticism will, as usual, be directed rather to this question of purity than to ability to determine physical constants, I give a detailed statement of the methods of preparation and purification.

---

[1] Campbell and Garrow, *Trans. Faraday Soc*, 26, 560 (1930).

Preparation and Purification

Pure d-camphor was purchased from British Drug Houses (m. p. **176.3°** (uncorr.)): three hundred grams of d-camphor was heated with *2400* cc. of nitric acid (d **1.42)** and *1600* cc. water for sixty-five hours on the water-bath. The product was cooled and the crude d-camphoric acid filtered off.

The crude product was purified as follows. It was dissolved in 10% caustic soda and extracted with ether to remove unchanged camphor. The acid was reprecipitated with hydrochloric acid, dried and converted into its anhydride by refluxing with acetyl chloride. Excess acetyl chloride was removed by shaking with cold water. The anhydride was then dissolved in boiling alcohol and the solution allowed to crystallize. The purified anhydride was then hydrolyzed by boiling with potassium carbonate solution. d-Camphoric acid was precipitated from the alkaline solution by addition of hydrochloric acid. The precipitate was filtered and washed, and then recrystallized ten times from boiling water, the first crop of crystals being always rejected; *50* g. of *d*-camphoric acid was eventually obtained.

In order to decide whether this repeated recrystallization would constitute a purification from the opposite enantiomer, supposing it to be present, the solubility diagram for d-, *l*- and r-camphoric acids was determined, for 16°. The results were

	Solid phase		
	Dextro	Inactive	Inactive and dextro
Solubilities, g. per *100* g of water	0.679	0.12 *d* **0.121**	0.63 *d* *0.041*

When these figures are plotted Fig. 1 is obtained.

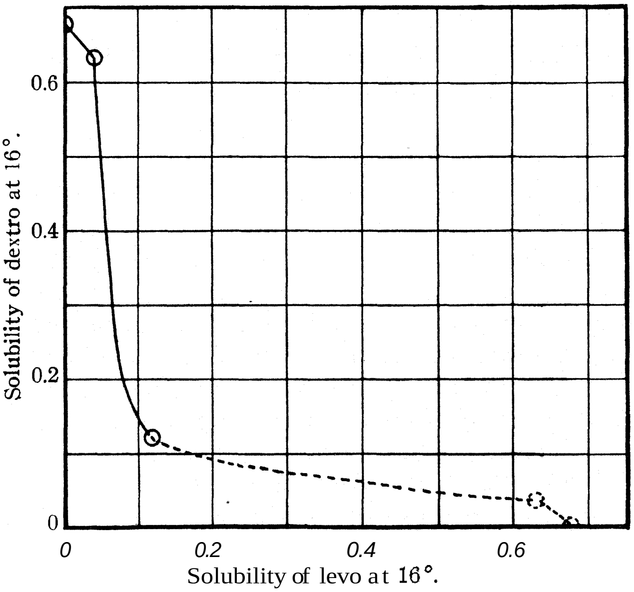

Fig. *1.*

The titration of the two acids eventually obtained, by standard baryta, gave equivalent weights of 99.90 (levo) and 100.00 (dextro); calcd., $^1/_2 \cdot 200.13$.

From the diagram it is apparent that the solid phase in contact with solution throughout the greater course of the curve is the racemic form. It therefore follows that if a solution of the d-form contains any appreciable quantity of the *l*-form, racemic form will separate from the solution (at room temperature) until the solution contains 0.63 g. of dextro and 0.04 g. of levo per 100 g. of water. Further evaporation will result in the deposition of *d*- and *l*- in the above proportions. Further than this, therefore, the purification of dextro cannot be carried. If, however, as has hitherto been stated, enantiomers are completely identical, then the complete solubility diagram will be perfectly symmetrical, and the recrystallization of the levo form will also result in a product which will be impure with opposite enantiomer, to precisely the same extent. Hence any objections urged against the differences in physical properties on the score of impurity fall to the ground.

Each recrystallization was allowed to stand overnight, in contact with the mother liquor, after separation and rejection of the crystals first appearing. Under these circumstances it is improbable that equilibrium was not attained, in view of the relatively large amount of active form separating from the solution.

The form of the solubility diagram bears out the contention of Ross and Summerville[2] that the racemate is a very stable one.

It was at first attempted to prepare *l*-camphoric acid from *l*-camphor, but it was found that commercial *l*-camphor was hopelessly impure. Recourse was therefore had to *l*-borneol as the starting material. *l*-Borneol was obtained from British Drug Houses, and it had the following physical constants: m. p. 203.5°; $[\alpha]_D^{16}$ −37.6 (in alcohol). The *l*-borneol was purified by the method of Haller.[3] The *l*-borneol acetate was distilled under reduced pressure, before freezing, to free it from non-volatile impurities. The purified *l*-borneol was then oxidized with nitric acid and purified in the above manner. The product eventually obtained had a chemical equivalent of 99.90, as against 100.00 for the d-form (calcd. 100.07).

In connection with the question of purity, the appearance of the preparations was well worth noting. They consisted entirely of large, clear, well-shaped crystals, of an average diameter of 5 mm. Apart from occasional twinning, they were well-shaped rhombohedra, having the hemihedral facets well developed. Admixture with the opposite enantiomer would have resulted in the formation of the racemic form, with a holohedral structure. After examining such a preparation carefully with a low-power lens, it is impossible to believe that it is not homogeneous.

Melting Points of the Camphoric Acids.—These were determined by the method described in the previous paper.[1] The precautions there described were repeated in the present instance. The following figures were obtained for the melting points of successive crops of crystals.

[2] Ross and Summerville, *J. Chem. Soc.*, 2778 (1926).

[3] Haller, Ann. *chim. phys.*, [6] 27,422 (1892).

TABLE I

MELTING POINTS

All these figures are uncorrected and therefore low, but the same thermometer was used for all determinations.

Dextro	187.5	188.0	186.0	186.0	186.0
Levo	183–189[a]	186.5[b]	186.5[b]	186.5[b]	186.5[b]

[a] Large but distorted crystals deposited slowly from aqueous solution of crude product [b] Successive recrystallizations of product.

Solubilities.—The solubilities were determined in water, since, though the solubility in acetone is conveniently large, camphoric acid forms a compound with acetone (private communication from Professor Smits). All solutions were filtered in the thermostat, by means of an apparatus previously described,[4] the saturated solution was weighed, and a weighed portion titrated with baryta. Solubilities are expressed, as usual, in grams per 100 g. of solvent.

TABLE II

SOLUBILITIES IN WATER

spectrometric attachment. Determinations with this instrument were therefore made with sodium light. Solutions were made up by weighing in the first place, but in order to be entirely independent of graduated apparatus, the densities of the solutions were determined in a pycnometer holding 11.660 cc. of water at 4°. A weighed portion of the solution was then titrated with baryta and calculated by the formula

$$[\alpha]^t_\lambda = \frac{\alpha \times 100}{l \times d \times p}$$

Specific Rotatory Power in Water.—A single determination of this was made, with the result $[\alpha]^{16}_{\lambda = 5960} + 46.3°$.

Specific Rotatory Power in Alcohol.—The alcohol used was the ordinary rectified alcohol, having d^{18}_4 0.80275. It therefore contained 96.99% of alcohol by weight. An 8-liter glass jar was filled with this alcohol, in order that identical solvent might be used throughout. In a few experiments carried out in Winnipeg I was of course obliged to use a different sample of alcohol, but it had an almost identical density and was used for both forms. The specific rotatory powers, at 18°, were as given in Table III.

TABLE III

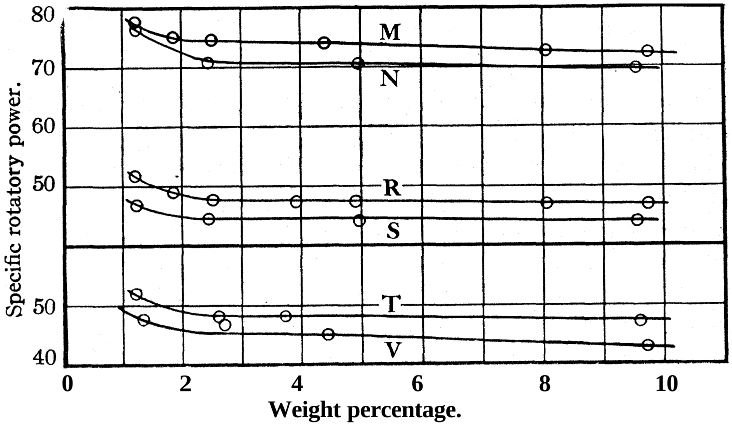
9.6	+47.3	
9.70		−43.0

When these figures are plotted the curves of Fig. 3 are obtained. The dispersions appear to be identical, while the rotations differ. Apart from the evidence of purity which this affords, it may have a theoretical significance. According to Hunter[5] dispersion is a more fundamentally constitutive property than rotation and, if this view is correct, it would seem to indicate that the difference between enantiomers is not constitutive, in the ordinary sense of that word, as indeed it could not be, but of a more superficial character.



M, Dextro, λ = 4610; N, levo, λ = 4610. R, Dextro, λ = 5960; S, levo, λ = 5960. T, Dextro, λ = 5986, 5890; V, levo, λ = 5896, 5890.

Fig. 3.

Conclusion.—The theoretical implications of these results have already been discussed in the previous paper.'

Summary of Results

1. Dextro and levo camphoric acids have been prepared in a state of purity.
2. The melting points, solubilities and specific rotatory powers of the two forms have been determined and compared.

THE SOLUBILITY OF CHLORINE IN AQUEOUS SOLUTIONS OF CHLORIDES AND THE FREE ENERGY OF TRICHLORIDE ION

BY M. S. SHERRILL AND E. F. IZARD

RECEIVED JANUARY 21, 1931 PUBLISHED MAY 6, 1931

Introduction

Previous investigations[1] show that the solubility of chlorine in water is decreased by small additions of hydrogen chloride, but is increased by larger additions. The initial decrease in solubility is readily explained by the depression of the hydrolysis of the dissolved chlorine by the added acid. At the higher concentrations of added acid, however, where the percentage hydrolysis is reduced to an extremely small value, a further decrease in solubility might be expected to arise from the salting-out effect of the hydrogen chloride. Actually an increase in solubility has been observed which indicates the formation of a complex ion, probably the trichloride ion, in sufficient amount to more than compensate the salting-out effect.

In contrast to hydrogen chloride, additions of sodium chloride to water continue to decrease the solubility of chlorine, even at the higher concentrations. This indicates that the salting-out effect predominates over the complex ion formation in determining the total solubility. This view is confirmed by the fact that the salting-out effect of the metallic chlorides is in general considerably greater than that of hydrochloric acid.[2]

In order to test these views more quantitatively, a systematic study was made of the solubility of chlorine at a pressure of one atmosphere and 25° in solutions of sulfuric acid, hydrogen chloride and a series of other chlorides. The results were compared with existing values of the solubility of oxygen in the presence of the same series of electrolytes. The solubility data relating to oxygen were taken from the compilation of Randall and Failey[2] and from an investigation by McArthur.[3] The theoretical considerations involved in the interpretation of the results of the solubility determinations are briefly as follows.

The dissolved chlorine exists in the saturated solutions partly in the form of free chlorine (Cl_2), partly in its hydrolyzed form (HClO), and the remainder in the form of the complex ion (Cl_3^-). In the case of the sulfuric acid solutions saturated with chlorine the complex-ion formation is inappreciable, and the small hydrolysis can be computed, so that the salting-out effect of the electrolyte on the chlorine as such can be estimated and compared with the corresponding effect on the dissolved oxygen in its

saturated solution. This is conveniently done by computing the ratio s_0/s of the saturation concentration of chlorine (Cl_2 as such) in pure water to its value in the presence of the electrolyte, and comparing it with the corresponding value for oxygen. This ratio represents the activity coefficient of the chlorine, or of the oxygen, in the presence of the different electrolytes.

Debye and McAuley[4] have shown, with the aid of the ion attraction theory, how the activity coefficient of a non-electrolyte in the presence of electrolyte varies, for a given solvent, with the nature and concentrations of the non-electrolyte and electrolyte. Though the derivation of this theoretical relation is complicated, the final result may be expressed for this special case of gas solubility by the relatively simple equation

$$\text{Log}\,\frac{s_0}{s} = \kappa\left(\frac{\partial D}{\partial s}\right)\frac{1}{r}\,\Sigma(C_i z_i)^2$$

In this equation κ is a constant characteristic of the solvent at a temperature T, the ratio $\partial D/\partial s$ is the rate of change of the dielectric constant of the solution (containing only non-electrolyte) with the concentration s of the non-electrolyte, r is a mean of the radii of the ions present, and c_i is the concentration and z_i the charge of any ion of kind i (hence $^1/_2\Sigma(c_i z_i)^2$ is the ionic strength). The ratio $\partial D/\partial s$ may be assumed to be independent of the concentration s, and therefore regarded as a constant characteristic of the non-electrolyte.

It follows from this theory that the saturation concentrations of chlorine and oxygen in different electrolytes of the same ionic strength must bear the definite relation to each other expressed by the equation

$$\frac{\text{Log}\,(s_0/s)_{Cl_2}}{\text{Log}\,(s_0/s)_{O_2}} = \text{Const.}$$

That is, the theory requires that at small concentrations this logarithmic ratio be independent of the particular ionic strength at which the solubilities of the two gases are compared, and also of the nature of the ions which make up that ionic strength.

Direct comparison of the solubility of chlorine with that of oxygen in solutions of sulfuric acid up to a concentration 1 formal (the concentration range covered by the compilation of Randall and Failey[2]) showed the activity coefficients of these two gases to be nearly the same, and correspondingly the logarithmic ratio to be approximately equal to unity. Thus, in 1.036 formal sulfuric acid the activity coefficients of the chlorine and oxygen in their saturated solutions were 1.170 and 1.185, respectively, and the corresponding logarithmic ratio was **0.925.**

In the interpretation of results this value for the logarithmic ratio was assumed to hold at all ionic strengths, and accordingly the concentration of free chlorine (Cl_2) in the various chlorine saturated solutions of chlorides

---

[4] Debye and McAuley, *Physik. Z.*, **26,** 22 (1925).

was computed from the known values of the solubility of oxygen in the same solutions with the aid of the equation

$$\text{Log } (s_0/s)_{Cl_2} = 0.925 \log (s_0/s)_{O_2} \qquad (1)$$

The hydrolyzed portion (HClO) of the dissolved chlorine was calculated, as indicated below, with the aid of the mass action law, and the remainder of the dissolved chlorine was assumed to be trichloride ion (Cl_3^-).

The equilibrium conditions of the reaction $Cl_2 + H_2O = H^+ + Cl^- +$ HClO, are represented by the equation

$$\frac{[H^+][Cl^-][HClO]}{[Cl_2][H_2O]} = \frac{\alpha^2(H^+)(Cl^-)(HClO)}{(Cl_2)(p/p_0)} = K \qquad (2)$$

in which the activities of the substances are indicated by brackets and the concentrations (expressed in moles per 1000 g. of water) by parentheses. The symbol a is the mean activity coefficient of the H^+ and Cl^- ions; and p/p_0 is the ratio of the vapor pressure of water in the solution to that of pure water. The value for the equilibrium constant K of the hydrolysis reaction was taken from Lewis and Randall[6] to be 4.84 X 10^{-4}. The mass action expression for the hydrolyzed part of the dissolved chlorine varies with the type of added electrolyte. The equations employed in computing the concentration of the hypochlorous acid (HClO) in c formal solution of the various substances were as follows

$$(HClO)^2 = K\,\frac{(p/p_0)[\Sigma(Cl_2) - (HClO)]}{2c\alpha^2} \quad \text{for } H_2SO_4 \qquad (3)$$

$$(HClO) = K\,\frac{(p/p_0)\,s}{c^2\alpha^2} \quad \text{for HCl} \qquad (4)$$

$$(HClO)^2 = K\,\frac{(p/p_0)\,s}{c\alpha^2} \quad \text{for NaCl or KCl} \qquad (5)$$

$$(HClO)^2 = K\,\frac{(p/p_0)\,s}{2c\alpha^2} \quad \text{for } BaCl_2 \qquad (6)$$

In applying Equation 3, the mean activity coefficient of the H^+ and Cl^- ions was placed equal to that found by Livingston[6] at the same ionic strength for H^+ and Br^- in mixtures of sulfuric acid and potassium bromide. The equation was derived under the assumption that H_2SO_4 is completely ionized into $2H^+$ and SO_4^-, since Livingston had made this assumption in evaluating the mean activity coefficients of hydrogen and bromide ions.

The values for the activity coefficient a substituted in Equation 4 were taken from Lewis and Randall;? in Equation 5 from Harned;[8] and in Equation 16 from Harned and Brumbaugh.[9]

Experimental Procedure

The solutions of the various electrolytes which were to be saturated with chlorine were prepared of known strength, and the conditions of saturation, described below, were so regulated that no change in concentration could result from the absorption of the chlorine. In consequence it was only necessary to analyze the saturated solutions for the total amount of dissolved chlorine. The solutions of sulfuric and hydrochloric acid were prepared by adding a weighed amount of distilled water to a weighed amount of a stock solution whose composition by weight had been carefully determined. The sodium, potassium and barium chloride solutions were prepared by adding weighed amounts of distilled water to weighed amounts of the carefully purified and dried salts.

The chlorine was prepared by the action of hydrochloric acid on chromic acid. and bubbled through the solution under investigation in an absorption train. As a precaution the absorption train was painted black to prevent the decomposition of chlorine by light. A brief description of the apparatus and method of saturating the solution with chlorine follows.

Two hundred cubic centimeters of 6.0 normal hydrochloric acid (the constant boiling mixture of hydrochloric acid and water) was added to a one-liter round-bottomed flask provided with a water-cooled return condenser. Into this flask were sealed two side tubes connecting with large funnels, and so arranged that concentrated hydrochloric acid could be delivered through one of these tubes beneath the surface of the liquid in the flask, and a saturated solution of chromic acid introduced through the other. The flask was heated by means of a ring burner, and the rate of influx of the two acids was regulated so as to keep the concentration of the hydrochloric acid in the flask nearly equal to that of the constant boiling mixture. The moist chlorine on leaving the condenser was bubbled through the solution under investigation in two washing bottles placed in series, and finally through a third portion of the solution in a bubble-tube, shown in the figure, which was especially designed to insure complete saturation and easy removal of a sample for analysis without loss of chlorine. The preliminary washing of the chlorine served to prevent loss by evaporation in this final absorption tube. When all air had been displaced from this train of apparatus and the solution approximately saturated at atmospheric pressure and room temperature with chlorine, the stopcock J was closed to supersaturate the solution by building up a somewhat larger pressure. After a few minutes stopcock H was closed, and the tube disconnected at the ground glass joint G. The tube was then placed in a rocking device in a thermostat at 25 ± 0.01°, and slowly rocked under these conditions for a short time. Finally stopcock J was opened and the agitation continued for three or four hours to ensure the solution being saturated with chlorine at the barometric pressure. In removing a sample for analysis the tube was placed in a vertical position in a rack in the thermostat. By applying pressure at J with both stopcocks open, the sample of solution was forced out through H directly into a weighiig bottle containing a solution of potassium iodide. The iodine liberated in this weighed sample was determined by titration with sodium thiosulfate using starch as an indicator.

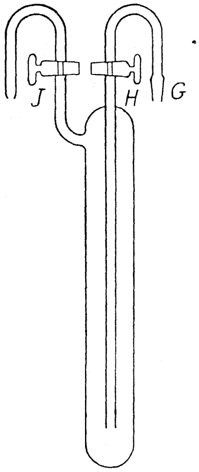

Fig. 1.

Tabulation and Discussion of Results

The results of the determination of the solubility of chlorine at 25° and one atmosphere in pure water, and in the presence of the various electrolytes are recorded in the following tables. In computing the solubilities from the experimental data the partial pressure of chlorine above the solution was found by deducting from the observed barometric pressure the vapor pressure of water in the respective solutions. Then the solubility corresponding to a saturation pressure of chlorine equal to one atmosphere was calculated by applying Henry's law, which is valid over the small range of pressure involved. The values for the vapor pressure of water, shown in the third column, were obtained for the solutions of sulfuric acid from Brönsted[10] and from Grollman and Frazer,[11] of hydrochloric acid from Dobson and Masson,[12] of sodium chloride from Negus,[13] of potassium chloride from Lovelace, Frazer and Sease[14] (calculated over from 20° to 25°), and of barium chloride, where no data were available, under the assumption that the vapor pressures of these solutions were equal to those of potassium chloride of the same formality.

The equilibrium concentrations recorded in the tables were calculated from the total solubility by the equations considered in the introduction. The value (0.0592 molal) given in Table I for the molality s_0 of Cl_2 in pure water saturated with chlorine at 25° and 1 atmosphere was obtained by extrapolation of the values for s, the molality of Cl_2 in the different sulfuric acid solutions saturated with chlorine, to zero concentration of sulfuric acid. This value for the solubility constant of chlorine in water was confirmed by making a similar extrapolation of the concentrations of the unhydrolyzed portion of the dissolved chlorine in solutions of hydrochloric acid saturated with chlorine. Since hydrochloric acid has a much larger effect in depressing the hydrolysis of chlorine than does sulfuric acid, and since the trichloride formation in the diluter solutions of hydrochloric acid is inappreciable, this latter method of extrapolation is attended with much less error.

A comparison of the values (in Table I) for the activity coefficient (s_0/s) of chlorine in the sulfuric acid solutions with the corresponding values for oxygen given by Randall and Failey[2] led to the adoption of equation (1) for the converse calculation of the values (in Table II) for the activity coefficient of chlorine in the chloride solutions. For these calculations reference was made to the solubility data for oxygen given by Randall and Failey,[2] and by McArthur.[3]

The equilibrium constant of the reaction $Cl_2(g) + Cl^- = Cl_3^-$ may be expressed in either of the following forms

$$K = \frac{\alpha_{Cl_3^-}\ (Cl_3^-)}{\alpha_{Cl^-}(Cl^-)\, p_{Cl_2}} \text{ or } K = \frac{\alpha_{Cl_3^-}\ (Cl_3^-)}{\alpha_{Cl^-}\, \alpha_{Cl_2}\, (Cl^-)(Cl_2)} \cdot s_0$$

dissolved chlorine. Each series of values thus computed should, on extrapolation to zero concentration of the added chloride, give the true value for the complex constant.

The best agreement of the complex constants among themselves was obtained in the case of the hydrogen chloride solutions. Furthermore, both expressions for computing the complex constant lead to substantially the same value, namely, nearly equal to 0.01.

This good agreement is accounted for by the fact that in the hydrogen chloride solutions an increase in solubility of chlorine due directly to the formation of the complex ion is the predominating effect, and hence the calculation of the concentration of the trichloride ion from the total solubility is attended with slight error. On the contrary, in the case of the other chloride solutions the increase in solubility due to complex ion formation becomes of minor influence, and is more than compensated by the very large decrease in solubility due to salting-out effect. The effect of hydrolysis also enters as a small but appreciable factor.

For example, in the 3.987 formal solution of hydrochloric acid the increase in solubility of chlorine (referred to 0.0592 m) due to hydrolysis is negligible, the decrease due to the salting-out effect is 15.3% whereas the increase due to complex-ion formation is 69.6%. In contrast, in the 3.989 formal solution of sodium chloride, the increase in solubility due to hydrolysis is 1.8%, the decrease due to the salting-out effect is 67.5%, and the increase due to complex-ion formation is 26.5%.

In the case of the solutions of sodium, potassium and barium chlorides the agreement of the values computed for the complex constants with each other, and with those obtained from the investigation of the hydrogen chloride, is very satisfactory when there is taken into consideration the fact that the large salting-out effect of these chlorides on chlorine was indirectly estimated by comparison with their salting-out effects on oxygen. Thus, for the sodium chloride and potassium chloride solutions, the complex constants recorded in the last column agree well among themselves, and yield an average value approximately equal to 0.01, the value found for solutions of hydrogen chloride. The values in the tenth column show greater variation among themselves and are all less than 0.01, but there appears to be a trend toward this value as the concentration of the added electrolyte approaches zero. The least satisfactory agreement was found in the case of the barium chloride solutions, due probably to the additional approximate assumptions involved in the calculations.

If 0.01 be adopted as the value for the complex constant of the trichloride ion, the free-energy decrease attending its formation out of chlorine gas and chloride ion may be computed by the familiar expression $-\Delta F = RT \ln K$. The result is shown by the free-energy equation

$$Cl_2(g) + Cl^- = Cl_3^- - 2730 \text{ calories}$$

According to Lewis and Randall at 25°

$$^1/_2H_2(g) + {}^1/_2Cl_2(g) = H^+ + Cl^- + 31{,}367 \text{ calories}$$

By addition of these two free-energy equations there results

$$^1/_2H_2(g) + {}^3/_2Cl_2(g) = H^+ + Cl_3^- + 28{,}637 \text{ calories}$$

That is, $\Delta F_{298} = -28{,}637$ calories for Cl_3^- (or for one formula weight of aqueous HCl_3).

Summary

The solubility of chlorine was determined at 25° and 1 atmosphere in solutions of sulfuric acid, of hydrogen chloride, of sodium chloride, of potassium chloride and of barium chloride, and compared with the corresponding solubilities of oxygen. By means of such a comparison the salting-out effect of these electrolytes on the dissolved chlorine was estimated, This made it possible to compute from the total solubility of chlorine the extent of trichloride formation in the chloride solutions, and the corresponding value for the equilibrium constant of the reaction $Cl_2(g) + Cl^- = Cl_3^-$. The value for this constant was found to be 0.01, the corresponding free energy of formation of trichloride ion, in the system of Lewis and Randall being $-28{,}637$ calories.

THE COMPARISON OF CERTAIN COMMERCIAL GETTERS

BY MARY R. ANDREWS AND JOHN S. BACON

RECEIVED JANUARY 26, 1931 PUBLISHED MAY 6, 1931

For many years certain materials have been used in lamps and vacuum tubes for the removal of traces of gases so as to improve the vacuum. These materials may be divided into two classes: (1) those acting as adsorbents by virtue of their finely divided condition or activation, that is, those having tremendous surfaces upon which gases can be strongly held by adsorption, and (2) those which possess high chemical activity. To the first class belong active charcoal, copper oxide powder, powdered thoria, etc. The second class includes the alkali metals, alkaline earth metals, and probably phosphorus—the material so much used in incandescent lamps. All of these materials are called "getters" in the technical slang of the day.

The work reported here is confined to a comparison of the efficacy of the common getters of class two. We have tested calcium, barium, magnesium, sodium and phosphorus for the degree of vacuum produced under given conditions and the speed with which this vacuum is reached. These getters are all used as thin coatings on the walls of bulbs or tubes. They are produced by evaporation and deposition of the element at much reduced pressures. This gives a film of large surface and presumably of material which has been freed of gas.

Kaye, in his book on high vacua (page 31), says that a pressure of 10^{-8} mm., or approximately 10^{-5} baryes, is probably the lowest *measured* pressure reached as yet. Working with Dr. Dushman, Mr. Bacon, in the Research Laboratory, recently attained a pressure of less than 5×10^{-9} mm. in a gage connected to a large tube of well degassed charcoal immersed in liquid air. This, then, is a degree of vacuum which it would be desirable to reach in production of vacua with getters. The best pressure we have attained in the experiments reported below is about 10^{-7} mm., but it is hoped that further work will so improve getter technique that this pressure may be materially reduced.

Method.—A 40-watt lamp-bulb containing the getter (see Fig. 1) was connected to an ionization gage of the type developed by Dushman and Found.[1] There was a short side arm at C by which the set was sealed to the exhaust system. The anode and leads of the gage were of molybdenum and the filaments of tungsten so that the whole could be thoroughly degassed by current, electron bombardment and high frequency induction heating. The bulb and gage were usually of soft glass.

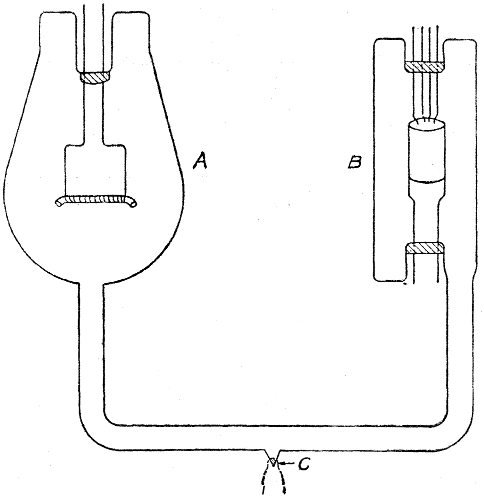

Fig. 1.—A, Bulb containing getter; B, ionization gage; *C*, point of exhaust and seal-off.

After exhaust and "bake-out" for an hour at 360°, the gage was thoroughly degassed and then enough getter vaporized and condensed on the walls of the lamp bulb to form a mirror over most of the inside surface. During the vaporization of the getter a considerable amount of gas which had been contained in it was evolved. This was reabsorbed in large part by the getter during its deposition, but an appreciable amount remained free. Therefore liquid air was applied to a trap below the set to catch any mercury vapor diffusing from the McLeod gage and traps and, after a short interval of pumping to remove gases that had not been absorbed by the getter during deposition, the set was sealed off. Pressures were usually read immediately after seal-off and at suitable intervals thereafter.

---

[1] Dushman and Found. *Phys. Rev.*, 17, 7 (1921); 23, 734 (1924).

The ideal method of laying down a getter of this type would be to vaporize and deposit it in a perfect vacuum so that immediately after deposition it is completely gas free. Gases appearing later in the bulb would then find a clean reagent in the best condition for reacting with or absorbing them. In practice there are several different methods of obtaining deposited getters. First is the chemical pellet, that is, a mixture of dry reagents which when heated to a high temperature will react to produce the desired metal, which is volatile at the temperature of the reaction. Thus sodium is produced from a mixture of NaCl + Ca. While this method has been much used, it has the objection that it is difficult, always, to remove the gas completely from any finely powdered material. It is bound to act like a getter of the first class mentioned at the beginning of the paper, retaining in considerable quantities adsorbed gas which will be freed when the mixture is heated. Moreover, if the reaction is exothermic, the temperature of the powdered mix rises suddenly once the reaction is started, and the metal is thrown out almost explosively. It would appear inevitable that in such a case a considerable quantity of dust from the mixture should be carried out with the metal vapor and be deposited on the walls of the bulb, where it might easily adsorb gas and later free it. The gas thrown out at the moment of reaction often gives a pressure of 25–50 baryes or more. It follows that the metal would deposit in the bulb in the presence of gas and possibly be contaminated with a considerable amount

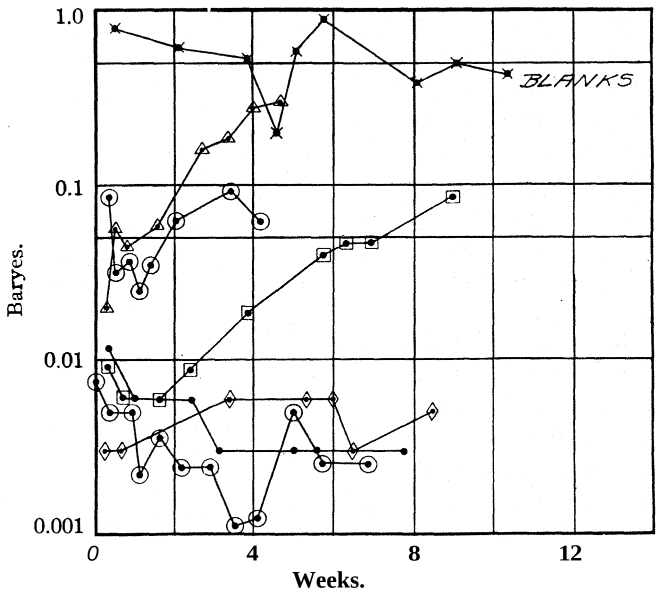

Fig. 2.—Magnesium: effect of increasingly thorough degassing.

of powdery solids. The reason for the widespread use of such pellets is, of course, the convenience of handling the mixture.; as compared with that of introducing the inflammable, low-melting metal as such.

A second method, used in depositing such metals as calcium and magnesium which can be produced in the form of large diameter wire, or rods, is to mount a short piece inside a spiral filament. When a current is passed through the filament, the metal inside is vaporized. The objection to this method is that the wire as manufactured at present always contains a large amount of gas and it appears to be impossible to preheat it evenly with the spiral so as to degas completely before vaporizing.

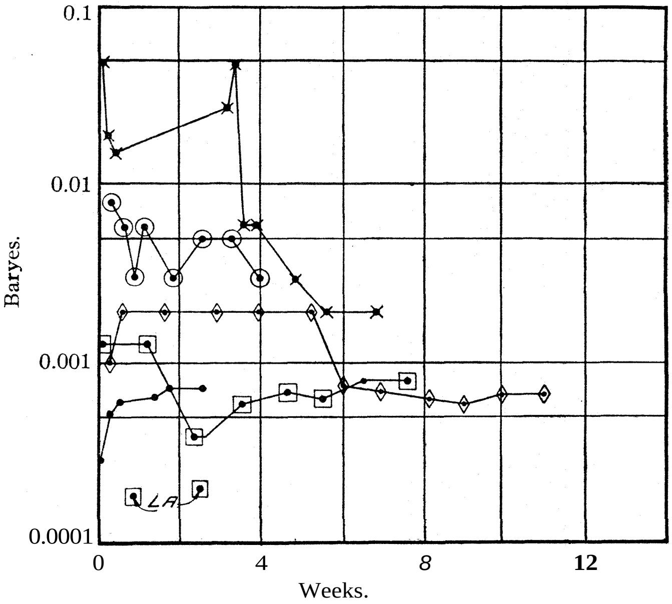

Fig. 3.— Calcium: effect of degassing.

A third method is to enclose the getter either pure or as an alloy in an envelope of a highly refractory metal such as molybdenum which will not give off any appreciable amount of gas and which can be heated by high frequency induction to a low temperature at first for degassing and later to a higher temperature for vaporizing the getter. This gives better results than the other two methods, as is shown in the curves.

Figure 2 shows the very marked effect of degassing magnesium in a spiral and in an envelope. The upper curve gives the average of two tubes run without getter, the two next lower curves are of magnesium flashed from spirals without a previous degassing, the next is of magnesium degassed by running the spiral at a bright red temperature for about fifteen minutes before the temperature was raised to vaporize the metal. The fifth and sixth curves are of magnesium degassed in molybdenum envelopes at a dull red for about fifteen minutes. The seventh curve is of magnesium in a molybdenum envelope, very well degassed and slowly vaporized in a system which pumped off the gas very rapidly.

Figure 3 shows the action of calcium. The two upper curves are of metal degassed for fifteen minutes in spirals, the three lower of metal much more carefully degassed. Two of these were calcium heated in spirals just to the evaporation point so that deposits were formed in two hours. The third was calcium which had been distilled twice in vacuum in a side tube before being distilled into the bulb. Barium gave very similar curves. It was used in the form of the barium–aluminum alloy (50–50) from which the barium metal was vaporized by high frequency induction heating.

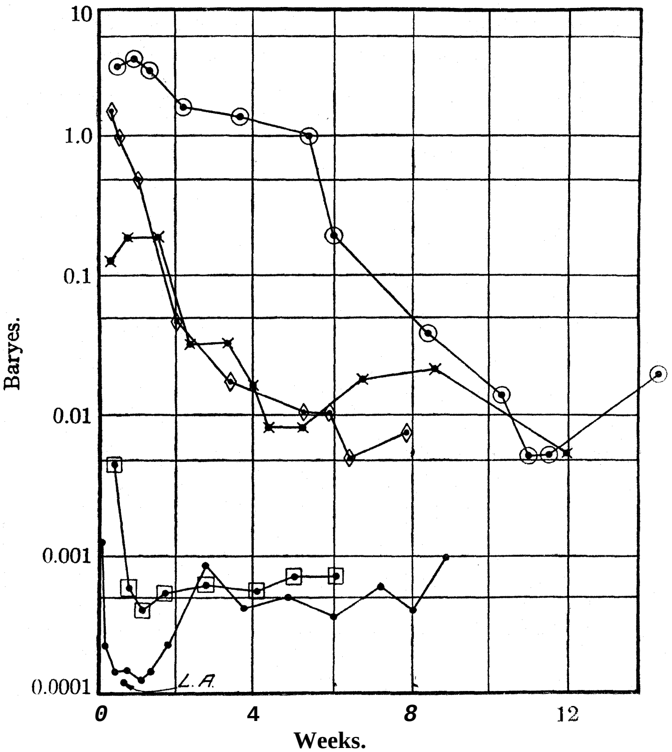

Fig. 4.—Sodium: effect of degassing. **Note slow rate of clean-up by gassy material.**

Sodium (Fig. 4) shows some interesting characteristics. For the three upper curves, chemical pellets were used. The clean-up was very slow and not very complete, though the pellets were always preheated to degas them as well as possible. But when sodium was deposited in the bulb by submerging the latter in a bath of molten sodium nitrate and passing sodium into the bulb by electrolysis, clean-up occured quickly and very much more completely, as is shown in the two lower curves.

Phosphorus (Fig. 5) was deposited by coating tungsten filaments with a suspension of red phosphorus and flashing them to a high temperature. This vaporizes the phosphorus very quickly, which seems to be essential to its effectiveness as a getter. There has been considerable work[2] done on the action of phosphorus as a getter, but our curves show this material to be only fair. Possibly larger amounts would yield better results. Our bulbs were tinged yellow by the deposit but were completely transparent.

We are unable to account with certainty for the irregularity of the curves shown. During our earlier tests we had some difficulty with readings obtained with the ionization gages when the pressures were low, in that they occasionally became negative. We found that when this occurred, the gage was generating oscillations of audible frequency so that a telephone inserted in the plate circuit emitted noises. We eliminated this by lowering the potential of the plate, but it appears possible that there might be higher frequency oscillations present at times, which would affect, somewhat, the pressure readings. We have not verified this. We thought temperature might have some influence, but tests on all the getters made after they had cleaned up most of the gas in the tube showed that the pressure was not affected by change of temperature from 0 to 90°. We are now testing other forms of ionization gages designed to operate without oscillating.

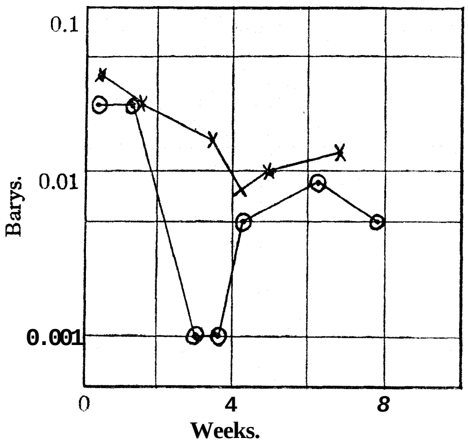

Fig. 5.—Phosphorus.

The above results point so conclusively to the fact that getters are good getters only when they are deposited quite gas-free that we are making experiments on vacuum fusion of them before they are used in vacuum tubes. The results will be reported later. That it is impossible to degas getters properly in a spiral and probably impossible without fusion, but that an effective getter can absorb considerable quantities of gas and eventually produce a fair vacuum, is shown by Fig. 6. This is the record of calcium held in a tungsten spiral which had been degassed for three

---

[2] N. R. Campbell, *Phil. Mag.*, 41, 685 (1921); 43, 914 (1922).

hours by running the spiral at red heat. Before the getter was deposited, the tube was sealed off. The bulb containing the getter was then immersed in liquid air (point L.A. Fig. 6) and the getter deposited by heating the spiral. It had been thought that by this procedure the depositing metal might carry down and hold all gases evolved from the hot calcium rod, but the gas pressure rose to some tenths of a barye during deposition (see point B). After complete deposition, the bulb was removed from the liquid air.

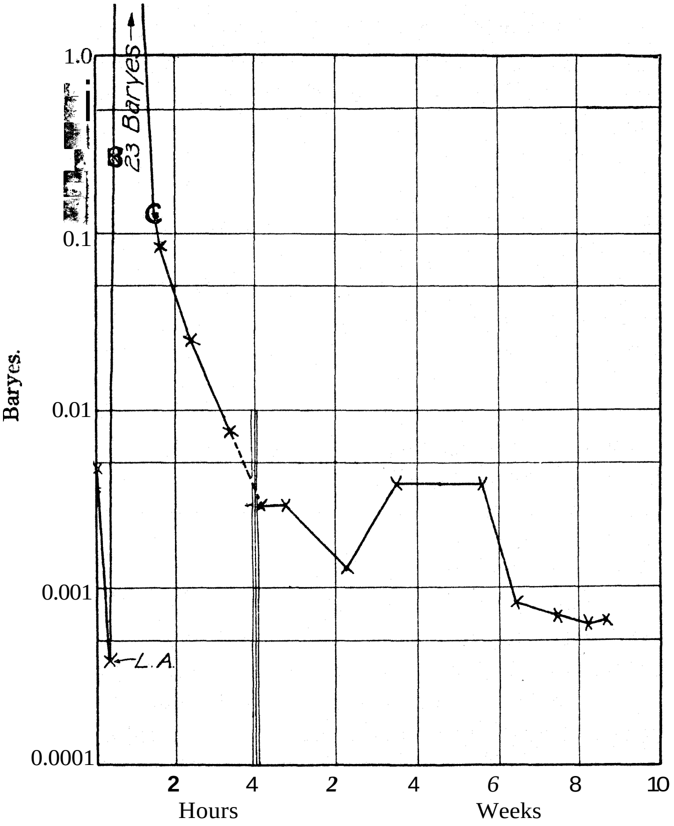

Fig. 6.—Calcium vaporized and deposited after seal-off.

The pressure promptly rose to twenty-three baryes. But the getter was active and absorbed this gas rapidly so that in half an hour the pressure had fallen to a small fraction of a barye (point C) and in the course of some weeks had gone below a thousandth of a bar, *i.* e., less than 10^{-6} mm.

It seems probable that some of these getters may have specific reactions with certain gases. The above experiments were all made with residual gas, that is, chiefly gas freed from the getter itself plus the possible traces escaping from the walls and metals of the getter bulb and gage. We have under way, however, a series of experiments in which getters are dosed with pure gases such as hydrogen, water vapor, etc. These will be reported later also.

The curves obtained from getters in vacuum suggest that the final clean-up of traces of gas in vacuum tubes is due to voltage discharge, *i. e.*, voltage clean-up. We are undertaking some experiments of this effect both without getters and in their presence.

Summary

Measurements made on a series of chemically active getters show that differences in the previous treatment of the getters to remove gas are of far greater importance than differences between the getters themselves in production of high vacuum. Poorly degassed getters absorb residual gas slowly and reach equilibrium at higher pressures than those attained by more gas-free material. These pressures do not depend on temperatures between 0 and 90°.

THE THERMAL DISSOCIATION OF CALCIUM HYDRIDE

BY CHARLES B. HURD AND KENNETH E. WALKER

RECEIVED JANUARY 29, 1931 PUBLISHED MAY 6, 1931

Introduction

The thermal dissociation of the hydrides of the alkali metals and of the alkaline earth metals has been the subject of considerable study. Various methods have been used, the general procedure being to heat the solid hydride to a definite temperature and measure the equilibrium pressure of the gaseous hydrogen.

In the earlier studies little or no attempt was made to shield the glass or quartz system from possible chemical action with the metal hydrides or their dissociation products. This action is serious at the high temperature at which calcium hydride undergoes appreciable dissociation. Recent investigators have attempted to shield the quartz tubing from chemical action. In the present paper, the writers describe an apparatus which is the result of experiments over a period of about four years. The apparatus is the only one which has been found to work satisfactorily with calcium hydride. It will, we believe, give satisfactory results in any of the higher temperature hydride investigations. Results are given here for the dissociation of calcium hydride. The dissociation of barium hydride is being studied and it is hoped that work on strontium hydride may be started soon

Historical

Calcium hydride is easily prepared by heating metallic calcium or certain alloys of calcium in hydrogen gas. The work of Guntz and Bassett,[1] of Moissan,[2] and of Brönsted,[3] is typical. Recently, Proskurnin and Kasarnowsky[4] have used the utmost care in preparing and handling the product. It is interesting to note, however, that the observations of the different investigators on the rate at which hydrogen is absorbed by the heated metallic calcium do not agree.

The results of the several studies on the thermal dissociation of calcium hydride appear to fall into two classes. The results of some investigators show a series of equilibrium pressures and temperatures which are reproducible and which fall upon a single curve. This curve is typical of a monovariant equilibrium consisting of a gas phase with one or more condensed phases. The results of Brönsted,[3] of Kraus and Hurd,[5] and of Remy-Cennetê,[6] show only one equilibrium curve.

Other investigators have found evidence that more than one equilibrium is possible, depending upon the relative proportions of calcium and hydrogen present. Moldenhauer and Roll-Hausen[7] believe that the dissociation takes place in two stages according to the equations

$$CaH_2 = CaH + {}^1/_2H_2$$
$$CaH = Ca + {}^1/_2H_2$$

Kassner and Stempel[8] have also found two equilibrium curves. The results of Ephraim and Michel,[9] and those of Hiittig and Brodkorb,[10] also show the apparent existence of more than one type of equilibrium, depending upon the relative amount of hydrogen which has been withdrawn from the original calcium hydride.

A source of error, common to the work which has been mentioned, is the possibility that calcium hydride or some solid product of the dissociation, may come into contact with the quartz container. Calcium hydride and quartz react at the elevated temperatures employed, setting free gaseous hydrogen. Hiittig and Brodkorb[10] found a steady increase in the pressure of hydrogen when the system was held at constant temperature. On the other hand, Kassner and Stempel[8] have shown by experiment that only a negligible loss of solid out of the equilibrium mixture occurred in their

experiments. In the work of Kraus and Hurd,[5] the calcium hydride was held in a vertical iron cylinder, with the lower end closed and the upper end open. The purpose of the iron cylinder was to protect the quartz tube. Some blackening of the quartz tube occurred, however, near the mouth of the iron cylinder.

Another possible source of error in these experiments is, obviously, that some of the solid products of decomposition may sublime to a cooler part of the quartz tube. Here they may reabsorb hydrogen, reducing the measured pressure and giving a false value for the equilibrium pressure at the temperature measured. The present study was made to eliminate these possible sources of error.

Apparatus

The logical improvement in the apparatus used for the determination of the dissociation pressure of calcium hydride would be to hold the calcium hydride inside the quartz tube in a closed container which would be permeable to hydrogen but not to calcium or calcium hydride. There are few such materials.

It was found that platinum or palladium could not be used, since small pieces of these metals alloyed with calcium. A long series of experiments was made, using closed cylinders of pure iron.[11]

This material was abandoned during 1929 when we found that consistent results could not be obtained. We note that Remy-Cennetté[6] has recently used the same method with one difference. He used an iron cylinder with a thin sheet of iron welded over one end.

We have found that nickel is the best material which we have tried. It is possible that cobalt might work successfully. The results with nickel over a period of a year have been so successful that we are prepared to recommend nickel.

The apparatus used is shown in Fig. 1 A clear quartz tube, A, 16-mm. in diameter and 102 cm. long was supported horizontally, in the electric furnace D. A chromel–alumel thermocouple B was so placed that its end touched the quartz tube even with the nickel cylinder C.

The nickel cylinder C was made of a 10 2 cm. length of pure nickel tubing. The wall thickness was 1.27 mm. and the outside diameter 9.6 mm. Two short tapered plugs of pure nickel were turned in a lathe. The short cylindrical tube and the plugs were carefully cleaned A plug was driven in one end of the short tube. Several pieces of freshly cleaned calcium were inserted in the cylinder and the other nickel plug inserted. These operations were carried out in a standard hydrogen bottle, the calcium having been cleaned in the bottle before being inserted in the cylinder. The calcium was a special pure calcium secured from the Research Laboratory of the General Electric Company. The plugs were pounded into the cylinder. Of six cylinders, made and filled in this way, two have leaked and four have been satisfactory at high temperatures.

---

[11] Unpublished thesis. Douglas Small, Union College, 1927; unpublished thesis, Dudley C. Smith, Union College, 1928

The outside of the nickel cylinder was cleaned and the cylinder was pushed to the end of the quartz tube A connection was made by means of a glass tube F to the glass measuring system The tube F must be slid over the quartz tube A and the de Khotinsky joint E must be built up outside the glass tube F. If a glass tube should be inserted into the end of the quartz tube and a de Khotinsky joint built over the end of the quartz tube, it will always soften and suck in when the inner end of the quartz tube is at temperatures of 800° or over, since the clear quartz transmits radiation very well from its hot end to the cement at the cool end. An ordinary vacuum manometer G and a connection H to a vacuum pump complete the apparatus. The mercury manometer ***G*** was read by a high grade cathetometer, reading to 0.01 cm.

The chromel–alumel thermocouple B was calibrated at several points. The cold end was kept in a mixture of cracked ice and distilled water in a vacuum bottle.

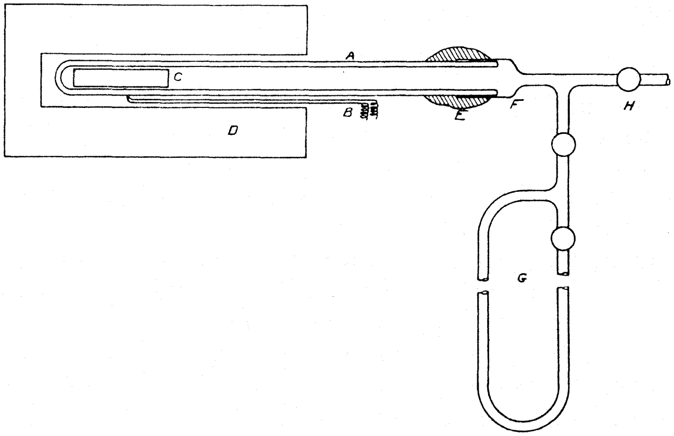

Fig. 1.—Apparatus employed in determining the dissociation pressures of calcium hydride.

Current through the electric furnace D was controlled, in spite of line voltage variations of as much as 10 volts by the use of UV-876 ballast tubes. One tube or two or three in parallel were used in series with the furnace on a 220 volt a. c. line. The single tube or the parallel two or three tube combinations gave constant currents of 1.7, **3.4** or 5.1 amps. A variable resistance shunted across the furnace allowed any fraction of the current to pass through the furnace. The necessary ammeters and voltmeters were included in the circuit.

A run was made as follows. **A** cylinder with a fresh charge of calcium, 1.0 to 1.4 g., was placed in tube A. The glass system was attached. The system was pumped out and the furnace raised to a temperature of 300°. The gases evolved were pumped out and the system tested for several days for leaks. The temperature was then slowly raised to 700° any gases evolved being pumped out. Enough specially purified hydrogen was then admitted to convert not over 90% of the calcium to hydride. After the calcium had had time enough to absorb 90 to 95% of the hydrogen (several days at this temperature), the gas remaining unabsorbed was quickly pumped out. All impurities which would not pass through the nickel were thus removed. The system was then held at a series of constant temperatures until a constant reading was obtained for the pressure of the hydrogen. Equilibrium pressures were approached from above and from below. To secure constancy of such pressures requires about a week at 800°. The securing of accurate results is, therefore, a very slow process.

A word of warning might not be out of place. The nickel cylinder works very well if not heated too high. At temperatures of 950–1000° the process of dissociation and diffusion takes place much more rapidly than at 800°, but the nickel cylinder undergoes a change, possibly forming an alloy with the calcium which then becomes nearly impermeable to hydrogen. No method was found of preventing this, and such cylinders were rendered useless.

Data

The results of three independent series of determinations are given in Table I. To obtain such data with the apparatus employed requires considerable time, several days being necessary to obtain a satisfactory equilibrium reading at the lower temperatures.

TABLE I

DISSOCIATION PRESSURES OF CALCIUM HYDRIDE AT DIFFERENT TEMPERATURES

T, °K	P, cm	$1/T \times 10^3$	$\log_{10} P$
Series 1 (Fig 2 circle)			
1090	3 93	0 917	0 594
1126	7.75	888	.889
1155	13 65	866	1.135
1177	20 25	850	1.306
1210	37 22	.826	1 571
Series 2 (Fig. 2 cross)			
1044	1.33	0.958	0.124
1065	2.04	.939	.310
991	0.42	1.009	−.377
1088	3.26	0.919	+.513
1109	5.21	.902	.717
1131	8.01	.884	.904
1082	2.84	,924	.453
Series 3 (Fig. 2 X)			
1011	0.45	0.989	−0.347
1041	1.13	.960	+ .053
1061	1.80	.942	.255
1091	3.53	.916	.548
1116	6.28	.896	.799

The results of these three runs are plotted on Fig. 2. The three sets of data agree reasonably well, giving a single curve. The greatest discrepancy occurs at the lowest temperature, where the pressures are lowest and are subject to the greatest error. In Fig. 3 we plot the results of several investigators in the field for comparison.

Discussion of Results

We are able to calculate the heat of reaction, ΔH, for the dissociation of calcium hydride from the relation

$$\frac{d \ln K_p}{d\ 1/T} = -\frac{\Delta H}{R}$$

where the symbols have their ordinary meaning and where $K_p = P_H$. We find from the slope of the curve, Fig. 2

$$\Delta H_{1100^\circ} = 51{,}100 \text{ calories}$$

If we use the equation

$$\Delta H = \Delta H_0 + 1.0\,T$$

we are able to estimate $\Delta H_0 = 50{,}000$ calories.

Values for the heat of reaction have been given by several investigators. Guntz and Bassett give 46,200 calories as the heat of formation of solid calcium hydride from its elements, calorimetrically determined, at ordinary temperatures. Bronsted gives a value of 45,100 while Kraus and Hurd with open cylinders found 48,400. Kassner and Stempel give 43,300 as the sum of the heats of reaction for their two stages. The data of Remy-Cenneté as shown by Fig. 3 would give about 50,000.

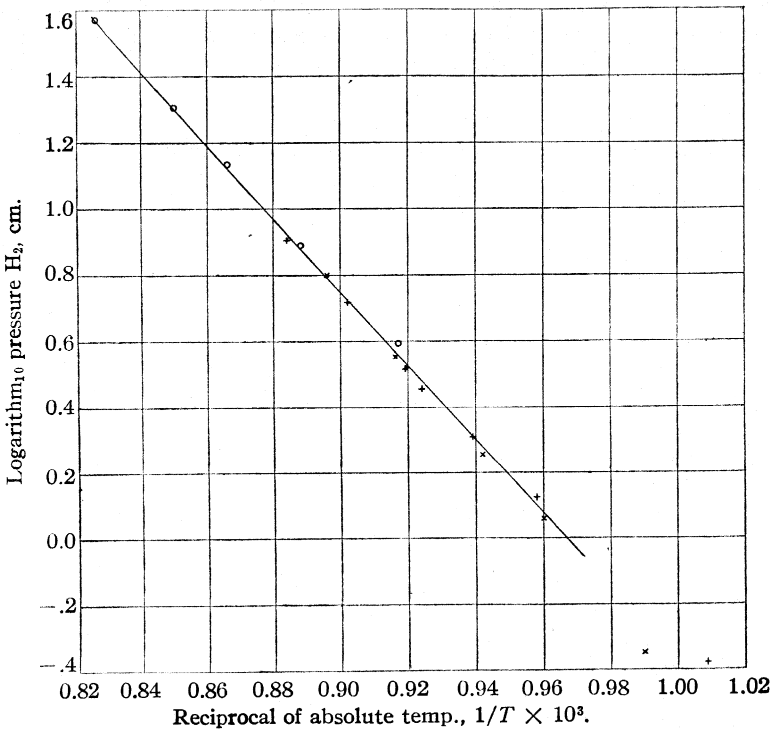

Fig. 2.

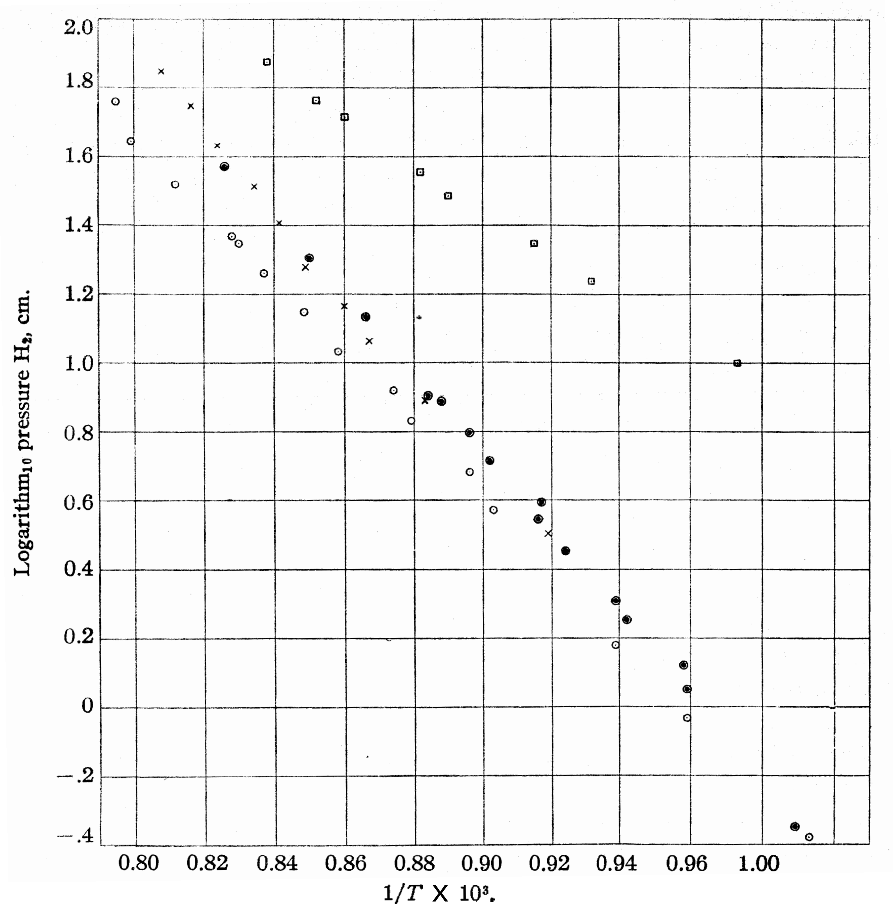
The value which we find for the heat of reaction, 51,100 calories, is seen to be considerably higher than former results, with the exception of the work of Remy-Cenneté. The agreement between our value and that of Remy-Cenneté is the more interesting, inasmuch as these two investigations utilize similar methods of confining the materials other than hydrogen which are present in the equilibrium mixtures.

The Mechanism of the Reaction

The opinions of various investigators in this field upon the course of the reaction for the dissociation of calcium hydride differ. All agree, apparently, that molecular hydrogen constitutes the gaseous product. The composition of the solid product or products is not definitely determined, as we have already mentioned in this paper. The results of Kassner and Stempel for what they believe to be the equilibrium



⊙, Kraus and Hurd; ◉, **Hurd and Walker**; ⊡, **Kassner and** Stempel; ×, Remy-Cenneté.

Fig, 3.—Comparison of results of several investigators on dissociation of calcium hydride.

$$CaH_2 \rightleftharpoons CaH + {}^1/_2H_2$$

are plotted in Fig. **3.**

We have been unable to detect any such equilibrium in our investigation.

We have admitted 90% of the hydrogen necessary to react with a weighed quantity of calcium to form CaH_2, and measured the equilibrium pressure at about 850°. Then at constant temperature we have withdrawn hydrogen by means of the pump in several steps until only about 20% of the hydrogen necessary to form CaH_2 was present. The equilibrium was allowed to establish itself after each withdrawal of hydrogen. The pressures measured agreed within the experimental error.

Experiments were also made where the equilibrium was approached by lowering the temperature from a higher temperature equilibrium. This, of course, caused an absorption of hydrogen and an increase of the combined hydrogen to calcium ratio. The same equilibrium pressure was found to establish itself as was found when the equilibrium was approached from a lower temperature, hydrogen having been removed.

We have not, in any case, added to the calcium more than 90% of the hydrogen, calculated as necessary to form CaH_2 with the weighed sample of calcium present in the nickel tube. Experiments are planned in which the calcium hydride will be formed by enclosing the calcium in the same type of closed nickel cylinder, placing this in a quartz tube, heating to 800° and passing a stream of pure hydrogen over it until the material has absorbed all the hydrogen possible. The tube will then be cooled to room temperature, still in hydrogen, removed, and placed in equilibrium apparatus shown in Fig. 1.

There is no apparent change in curvature of the log p against $1/T$ curve of Fig. 2 at the melting point of calcium, 810°, where $1/T \times 10^3 = 0.923$ Either these data are not sufficiently accurate to show this change of curvature or there is no calcium present.

Investigators who have worked with open containers have shown that calcium, if present, would have escaped from the containers at the higher temperatures, because of its appreciable vapor pressure. In the present investigation, only hydrogen could escape through the nickel cylinder, and we can, therefore, conclude nothing concerning the presence or absence of calcium.

Summary

An improved method for studying the thermal dissociation of calcium hydride has been described. The calcium hydride is contained in a closed nickel cylinder. This prevents action of the calcium or calcium hydride, on the quartz tube and removes a previous source of error in the determinations.

The method is recommended for any study where hydrogen is the only volatile constituent and where alloying does not occur with the nickel.

Three sets of data giving the equilibrium pressure of hydrogen as a function of temperature are given.

A graph, showing a comparison of results with those of other investigators, is given.

The value of the heat of reaction for the dissociation of calcium hydride is found to be 51,100 calories at 1100°K.

A brief discussion is given of the mechanism of the reaction.

THE OXIDATION OF FREE ALKYL GROUPS. PHOTO-OXIDATION OF GASEOUS METHYL IODIDE

BY JOHN REGINALD BATES AND ROBERT SPENCE

RECEIVED FEBRUARY 2, 1931 PUBLISHED MAY 6, 1931

One of the greatest difficulties facing most investigations connected with the oxidation of gaseous organic compounds such *as* the hydrocarbons, is the occurrence, at the relatively high temperatures which have previously been necessary, of numerous incomplete side reactions. These side reactions mask the fundamental processes, making complete elucidation of reaction mechanisms from kinetic studies almost impossible. However, it can be shown that the photochemical oxidation of alkyl halides, occurring at 0°, is essentially the oxidation of free alkyl groups and an investigation of the photo-oxidation of methyl iodide, the simplest member of the series, seemed to promise some information regarding the fundamental processes of hydrocarbon oxidation.

Previous workers studying the action of light on alkyl halides dealt with the liquids, and have, for the most part, come to conflicting conclusions. Donnan and Burke[1] and Stobbe and Schmidt[2] found that oxygen was necessary for decomposition of ethyl iodide as determined by the production of iodine. Job and Empschwiller[3] found that oxygen was not necessary for the decomposition of either ethyl or methyl iodides. In the former case they were able to obtain what was believed to be a photochemical "threshold" of reaction at 4100 Å., which was ascribed to the fact that the energy of this wave length coincided with the then accepted value for the C–I linkage. More recently, Iredale[4] has determined the quantum yield of ethyl iodide decomposition in the absence of oxygen. This he finds to be unity, as measured by the iodine liberated, and therefore concludes that the primary process is the separation of an ethyl group and an iodine atom. Work on gaseous methyl iodide has been confined to its absorption spectrum, first studied by Herzberg and Scheibe.[5] The absorption is con-

tinuous above 2000 Å., terminating in a short wave limit at 3000 Å. According to the band spectra theories of Franck and his co-workers[6] this indicates decomposition as the primary act of light absorption. Since the band in question is characteristic of the C–I linkage it may be safely assumed that the electronic excitation concerns **an** electron which goes to make this bond, and therefore that the decomposition is into a methyl group and an iodine atom. Mills and Iredale[7] have also studied the band and show that its long wave limit corresponds to the latest value for the C–I linkage, and come to the same conclusion. Absorption spectra taken by us before the publications of Herzberg and Scheibe are in agreement with these statements and indeed led to the present investigation.

Experimental

The reaction was followed by observing changes in pressure at constant volume as recorded on a mercury manometer. The cylindrical reaction vessel was of clear fused quartz, 50 mm. in diameter, 130 mm. long and having a volume of 240 cc., with two plane, circular, polished windows fused onto either end. This was fitted into a metal tank in such a way that one window was flush with the outer side of the tank, the latter being filled with ice and water to maintain a temperature of 0°. In this way the window was free from any condensation of iodine on the inside and the disturbing effects on the light intensity of ice or other foreign matter was eliminated. This would not have been possible had the vessel been totally immersed in ice water. Oxygen was taken directly from a tank, dried over calcium chloride and stored in a large bulb, from which samples could be admitted to the reaction vessel. Methyl iodide (Merck and Company) was distilled once, in *vacuo,* and kept under its own pressure, as a perfectly colorless liquid. The source of illumination was a mercury vapor lamp of the Kromayer type, so arranged that it could always be returned to exactly the same position after tilting to start the arc.

Experimental Results

The Action of Light on Methyl Iodide in the Absence of Oxygen.—Pure methyl iodide vapor undergoes a very slow decrease in pressure when illuminated for long periods and only small amounts of iodine are freed. For example, in Expt. 8, Table II, 80 mm. of methyl iodide was illuminated for six hours with a light intensity which, in the subsequent experiments with oxygen, gave a pressure decrease of 6 mm. per minute. The decrease in pressure after six hours was only 5.5 mm., iodine liberated being equivalent to 1.4 mm., and residual gas pressure when frozen out by carbon dioxide snow only about 10 mm. A series of experiments in which the change in pressure and the amount of permanent gas formed were

[7] Mills and Iredale, *Nature,* Oct. 1930, p. 604.

measured simultaneously showed an approximate parallelism between the decrease in total pressure and the increase in residual gas (Table I).

Budde Effect.—Immediately upon illumination, the pressure of the methyl iodide increased in a manner similar to the Budde effect in chlorine.[8] The increase is proportional to the total pressure up to about 100 mm., but appears to fall off somewhat above this pressure. Thus, we were able to obtain increases up to 2 mm. at 80–100 mm. of methyl iodide, while only 1.2 mm. was observed at 110–120 mm. This effect was also obtained in the presence of oxygen, especially when the latter was in high concentration, as can be seen from the curve in Fig. 1.

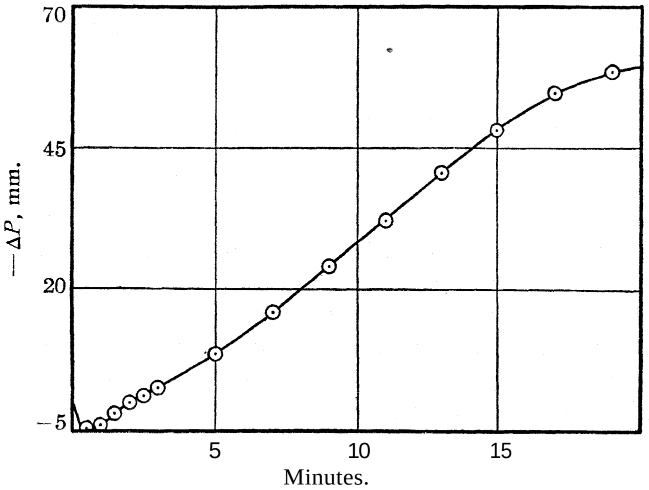

Fig. 1.—Typical experimental curve, ΔP plotted against time.

The Action of Light on Methyl Iodide in the Presence of Oxygen.—With oxygen present, the reaction velocity increases over a hundred-fold, thus becoming sufficiently rapid to permit of kinetic measurements. Iodine is liberated and upon reaching its vapor pressure of 0.03 mm. at 0°, condenses on the walls. This pressure of iodine does not absorb sufficient light to have any further photochemical influence upon the reaction. There is a variation in the total pressure decrease accompanying the re-

---

[8] Kistiakowsky, "Photochemical Processes," Chemical Catalog Co., 1928, p. 138.

action from a value slightly lower than the initial pressure, at low methyl iodide pressures, to about 20% greater at high methyl iodide pressures.[9] That iodine does not enter into the constitution of the final oxidation products was demonstrated by carrying a number of runs to completion and titrating the free iodine with $N/10$ thiosulfate. These values, together with the initial pressures of methyl iodide and oxygen, the total pressure decrease, and the value of the iodine titrations expressed in mm. of methyl iodide in the reaction vessel (1 mm. = 1.41×10^{-5} mole), are given in the first five columns of Table II. The values in the last column were calculated from the equation on page 1694.

[a] *AP* calcd. obtained from $-\Delta CH_3I$, since these runs were not carried to completion

The general course of the reaction is shown by the $-\Delta P/T$ curve (Fig. 1). After a small immediate expansion, the reaction proceeds rapidly for a few seconds, then slows up for several minutes before proceeding at an almost uniform rate, finally slowing down to zero when the reaction is complete. For high initial pressures of methyl iodide and oxygen, the period of uniform pressure decrease is of long duration but at low initial concentrations it practically disappears.

Identification and Analysis of Reaction Products. (a) **Noncondensable Gaseous Products.**—105.0 mm. of methyl iodide and **38** mm. of oxygen were illuminated until reaction was complete and the gaseous products slowly pumped off through a liquid air trap. No difference in pressure was observed when the liquid air was replaced by carbon dioxide–ether mixture and, when the trap was allowed to return to room temperature, the condensate exerted a pressure less by only 4 mm. than its pressure before evacuating. Hence, the hydrogen, carbon monoxide, ethane or methane formed in the reaction amounted to less than 4 mm.

---

[9] The highest pressure of methyl iodide studied was 110 mm., since its vapor pressure is 141 mm. at 0° and condensation of liquid in the capillary leads to the reaction vessel introduced errors between these pressures.

(b) Condensable Gaseous Products.—About 1 cc. of product condensable in liquid air was collected from about fifteen experiments in which 100 mm. of methyl iodide and 60 mm. of oxygen were allowed to react to completion. This liquid was carefully distilled, giving first a fraction boiling at 38–40°, slightly colored by iodine, then a colorless mobile liquid came over between 40 and 43°, identical in appearance, solubility and smell with a sample of pure methylal.[10] The vapor density, as measured by the Victor Meyer method, using 0.0185 g. of liquid, gave a value 52.5 for the molecular weight. Although the correct molecular weight of methylal is 76, pure methylal is partially hydrolyzed at 100° and 0.060 g. has an apparent molecular weight of 61.1. The condensate was soluble in water and did not smell of formaldehyde but gave the characteristic p-nitrophenylhydrazone of formaldehyde upon warming with an acid solution of p-nitrophenylhydrazine. The aqueous extract of the liquid from a flowing system, when treated with dilute resorcinol solution and poured over concentrated sulfuric acid, gave the reddish layer, tinged with purple and covered with a white, cloudy layer, characteristic of formaldehyde and methylal. Water was shown to be a constituent of the condensate by the fact that it turned anhydrous copper sulfate blue. Therefore, it was concluded that the condensable gaseous products of the reaction consist of methylal and water.

(c) Solid Products.—After having removed the gaseous and liquid products, the reaction vessel was washed out with ether to remove iodine. A white solid remained on the walls which was insoluble in water, alcohol or ether, but which reacted vigorously with concentrated nitric acid. Upon warming, the deposit evaporated, producing a powerful odor of formaldehyde.

(d) Determination of **Methylal,** Iodine **and Paraformaldehyde.**—Methylal was determined by collecting in a liquid air trap and titrating with thiosulfate after treating with a known excess of iodine. The iodine and paraformaldehyde formed were weighed in the vessel, the iodine determined by titration and paraformaldehyde obtained by difference.

Therefore, the total process may be represented as

$$4CH_3I + 2O_2 \longrightarrow (HCHO)_n + (CH_3O)_2CH_2 + H_2O + 2I_2$$

Polymerization of Formaldehyde and Synthesis of Methylal.—Formaldehyde was observed to polymerize both thermally and photochemically when introduced into the reaction vessel at 0°. The gas was produced by warming paraformaldehyde contained in a side tube. Figure 2 shows the general course of the reaction with formaldehyde alone, in the dark and in the light, and in the presence of methyl iodide or oxygen. A quantitative study of the polymerization was precluded owing to the varying rates at which the window became covered with polymer and to other undetermined factors such as the presence of small amounts of water vapor.[11] Thus, when the reaction vessel had been heated and evacuated for a long time, the velocity of polymerization of formaldehyde was lower, but when a small amount of methyl alcohol was introduced and allowed to react with formation of methylal and water, both the light and the dark polymerizations were greatly accelerated. According to the work of Bowen and Tietz,[12] acetaldehyde, in the presence of oxygen, partly reacts and partly polymerizes when illuminated with ultraviolet light, Formaldehyde should show similar properties, for Henri and Schou[13] find that below 2700 Å., predissociation bands and continuous absorption occur, while

above 2700, the bands show discontinuous, fine structure. Actually, the rate of polymerization is so great compared with the rate of oxidation that only polymerization is observed. However, Bredig and Goldberger[14] observed photochemical decomposition at 80°. Thus, 32.0 mm. (0.0135 g.) of formaldehyde and 104.0 mm. of oxygen gave 104.9 mm. of residual gas and 0.0150 g. of paraformaldehyde. The residual gas was slowly pumped off through a liquid-air trap but no condensate formed.

Formaldehyde and methyl alcohol condense together in the dark at 0°, giving methylal and water as the principal products. The reaction is so extremely rapid that only an approximate idea of the amounts of gas introduced could be obtained. The form of the $-\Delta p/T$ reaction curve appears in Fig. 3.

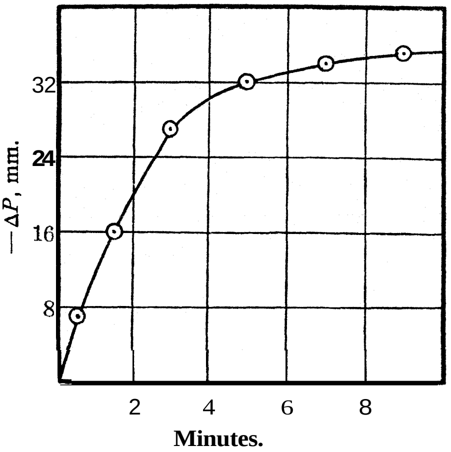

Fig. 3.—$\Delta P/T$ curve for condensation of formaldehyde and methyl alcohol.

Kinetic Studies

Variation of Rate of Oxidation of Methyl Iodide with Light Intensity.—The influence of varying light intensities was studied by measuring the rate after the induction period was over and a steady speed obtained. By interposing blackened copper gauze screens which had previously been calibrated on a visual photometer, it was possible to reduce the light intensity to known fractions. Table IV contains the results obtained in this manner and which point to a linear proportionality of reaction rate and light intensity to within 10%.

Table IV

Dependence on Light Intensity

% light intensity	$-\Delta P$ in mm. 2 min	5 min	7 min.	10 min.	$-dx/dt$	$-dx/dt/$ % intensity
100	0.6	2.1	3.3	5.1	5.60	5.60
50	0.7	1.4	1.9	2.6	2.50	5.00
35	0.5	0.9	1.4	2.2	1.83	6.23
29	0.3	0.8	1.2	2.1	1.70	5.86
100	1.0	2.9	4.1	5.3	5.60	5.60

Quantum Yield.—An attempt was made to determine an approximate quantum yield of the oxidation process. A normal solution of monochloroacetic acid, which Rudberg[15] has shown to have a quantum yield of unity in the region around 2500 Å., was placed in a cell of 1 cm. thickness,

---

[14] Bredig and Goldberger, *Z. physik. Chem.*, **110**, 521 (1924).

[15] Rudberg, *Z. Physik*, **24**, 247 (1924).

in front of the reaction vessel. The relative rates of reaction were obtained for the cell filled with this solution and with distilled water. After having done this, the reaction vessel itself was filled with chloroacetic acid of such a concentration as to absorb the same fraction of light as the 1 cm. cell, illuminated for a given time with the arc running as before, and the resulting hydrochloric acid titrated with standardized silver nitrate and ammonium thiocyanate. Using these observations, the quantum yield was calculated as follows

$$\frac{\text{Molecules}}{h\nu} = \frac{-\frac{\mathrm{d}p}{\mathrm{d}t} \times 1.41 \times 10^{-5} \times 6}{\frac{\text{Moles HCl}}{\text{hr.}} \times \frac{V_{\mathrm{H_2O}}}{V_{\mathrm{ClCH_2COOH}}}} - \frac{4.72 \times 1.41 \times 6 \times 10^{-5}}{1.0 \times 10^{-4} \times \frac{4.65}{2.70}} \equiv 2.3$$

where $-\mathrm{d}p/\mathrm{d}t$ is the maximum rate of methyl iodide consumption in mm./10 minutes obtained from Tables V and VI, 1.41×10^{-5} is the number of moles/mm. in the reaction vessel, $V_{\mathrm{H_2O}}$ and $V_{\mathrm{ClCH_2COOH}}$ rates with the small cell in front of the reaction vessel, filled with water and chloroacetic acid, respectively.

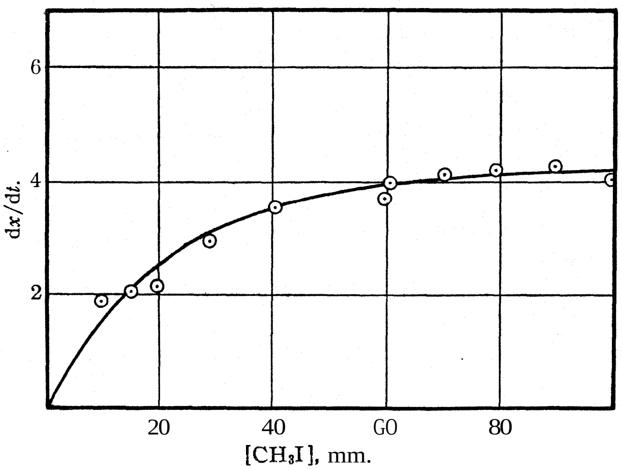

Fig. 4.—Variation of reaction rate with methyl iodide concentration, at constant oxygen concentration (100 mm.).

A value of 2 molecules/$h\nu$ for the oxidation process would give, according to the relative rates of the oxidation and decomposition of methyl iodide, a value of 0.02 for the quantum yield of the latter.

Variation with Methyl Iodide and Oxygen Concentrations.—In all the kinetic measurements, every effort was made to maintain uniform light intensity for each series of experiments, and constant conditions throughout the whole series. The uniformity of the light intensity during a series of experiments was checked by repeating one of the earlier experiments at the end, and if no change in rate occurred, then the light intensity was assumed to have remained constant. When an appreciable fall in intensity was detected, that series was discarded. Manometer readings were taken every minute for the first five minutes, then every five minutes and the results of each experiment plotted as $-\Delta P$ against time. The slope of the portion of these curves after the induction period was measured and expressed as mm. change/ten minutes. Table V contains the results obtained for varying concentrations of methyl iodide and constant oxygen concentration, while the relation between rate and methyl iodide concentration is illustrated graphically in Fig. 4. Taking the light intensity of this series as standard, the intensity of each subsequent series was compared with the standard intensity at 100 mm. of oxygen. Results for varying oxygen concentrations and constant methyl iodide concentrations appear in Table VI and Fig. 5.

Theoretical Discussion

Decomposition of Methyl Iodide.--Since the absorption spectrum of methyl iodide is continuous, we may assume that the primary process of light absorption is

$$CH_3I + h\nu \longrightarrow CH_3 + I' \qquad \text{(a)}$$

The rate of this reaction will be proportional to the number of quanta absorbed in unit time. From the absorption laws, then

$$-\frac{d[CH_3I]}{dt} = I_1(1 - e^{-[CH_3I]\alpha_1 d}) + I_2(1 - e^{-[CH_3I]\alpha_2 d}) + \dots$$

where I_1, I_2, etc., are the intensities of the various lines of the mercury arc, α_1, α_2, etc., are the absorption coefficients of methyl iodide for these lines, both expressed in appropriate units, and d is a constant, being the length of the vessel. Within the accuracy of our experiments, we are justified in taking as an approximation

$$-\frac{d[CH_3I]}{dt} = I(1 - e^{-[CH_3I]\alpha})$$

where I and a are over-all wave lengths, d being included in a, and $[CH_3I]$ is expressed in mm. of mercury.

In the absence of oxygen, the following reactions may take place

$$CH_3 + CH_3 + M \longrightarrow C_2H_6 + M' \qquad (b)$$
$$CH_3 + I + M \longrightarrow CH_3I + M' \qquad (c)$$
$$I + I + M \longrightarrow I_2 + M' \qquad (d)$$

The above processes involve collision either with a third molecule or with the wall (M). It must, however, be noted that any iodine atom colliding with the wall will probably be adsorbed or "cleaned up" as, for instance, is the case with hydrogen atoms, there to combine with other iodine atoms already absorbed. Bonhoeffer and Farkas[16] have found this to be the case in the photochemical decomposition of hydrogen iodide at low pressures. As soon as iodine molecules have been formed, the following two body process may occur

$$CH_3 + I_2 \longrightarrow CH_3I + I \qquad (e)$$

and the bimolecular reactions

$$CH_3 + I \longrightarrow CH_2 + HI^{17} \qquad (f)$$
$$CH_3 + CH_3I \longrightarrow C_2H_6 + I \qquad (g)$$
$$CH_3 + CH_3 \longrightarrow CH_4 + CH_2 \qquad (h)$$

are also possible. In addition, the presence of iodine on the walls will effectively reduce the probability of occurrence of the wall reaction (b) which can then only take place as a three-body process in the gas phase, for the probability of two methyl groups recombining on a surface of iodine will be much less than the probability of their combination with iodine itself. On the other hand, the reactions

$$I + CH_3I \longrightarrow CH_3 + I_2$$
$$I + CH_3I \longrightarrow CH_2I + HI$$
$$I + CH_3I \longrightarrow CH_2I_2 + H$$

are thermally impossible (H–I = 69 Cal.; C–H = 120 Cal.; I–I = 35 Cal.; C–I = 68 cal.).[17] The very low rate of formation of permanent gas and of free iodine when pure methyl iodide is illuminated indicates that the processes (b) and (g) must be of relatively infrequent occurrence. Therefore, methyl groups will, for the most part, reform methyl iodide by reason of reactions (c) and (e) and the remainder will form ethane according to (b) and (g) with (f) and (h) occurring as a subsidiary reaction. Also, the probability of (g) occurring must be extremely small; otherwise, owing to the relatively high concentration of methyl iodide as compared with iodine, there would be a rapid formation of ethane and consequently a high rate of pressure decrease.

From one point of view, methyl may be regarded as a pseudo halogen and reaction (g) could, therefore, be considered as an elementary replacement of I by CH_3. However, the fact that every "Elementar prozess" does not

---

[16] Bonhoeffer and Farkas, *Z. physik. Chem.*, 132, 235 (1928)

[17] The second hydrogen atom stripped from a carbon atom has a heat of linkage of only 30 k. cal., Mecke, *Z. Elektrochem.*, 36, 595 (1930).

occur on every collision, even when energetically possible, has become recognized during the past year. Kistiakowsky[18] has shown, for example, that oxygen atoms do not react with hydrogen molecules. The subject has been summarized by Franck and Rabinowitsch.[19]

In a paper which has just appeared, Hartel and Polanyi[20] have described a series of reactions of this type which, although exothermic, have an activation energy, and, therefore, do not go on every collision. Among those considered by them are the reaction of sodium atoms with alkyl halides, and methyl groups with hydrogen molecules. They find that the activation necessary for the exothermic reactions of sodium with methyl halides varies from 0 with methyl iodide to >25 Cal. with methyl fluoride, showing that it is a specific property of each reaction. In the case of methyl plus a hydrogen molecule, they give an activation energy of 8 Cal. In some experiments with methyl iodide and hydrogen in light, we found no effect on the rate of decomposition as measured by permanent gas formed, which would have been the case had the reaction

$$CH_3 + H_2 \longrightarrow CH_4 + H$$

been a probable one. An activation energy of 8 Cal. is equivalent to 10^6 collisions per reaction at 0°.

Methyl Iodide and Oxygen.—The photochemical oxidation of methyl iodide proceeds sufficiently rapidly to allow determinations of the rate of removal of methyl iodide to be made, and of the influence of such factors as light intensity, concentration of reactants, etc., upon this rate. Results obtained from a series of such measurements are set forth in the experimental part above. It is evident from Figs. 4 and 5, that the variation in the reaction rate follows fixed rules, which must have their origin in those fundamental chemical processes whose aggregate effect makes up the measured reaction. If, then, we can construct a mechanism of fundamental reactions, based on sound theoretical considerations, which will take account of all the observed phenomena and whose kinetic equation affords a complete description of the dependence of the reaction rate upon its physical parameters, then we can assume that mechanism to represent the true state of affairs, at least to the extent of our present knowledge.

For all practical purposes, the mechanism need only be concerned with reactions which make an appreciable contribution to the total rate of reaction. Now, all those reactions which we considered in the photochemical decomposition of methyl iodide, may be taken as occurring in the oxidation process also, but fortunately the greater part of them can be omitted from our kinetic considerations. Thus all reactions involving the formation of methane or other permanent gases (reactions b, f, g and h)

---

[18] Kistiakowsky, THIS JOURNAL, 52, 1868 (1930)

[19] Franck and Rabinowitsch, *Z. Elektrochem.*, 36, 794 (1930).

[20] Hartel and Polanyi, *Z. physik. Chem*, [B] **11**, 97 (1930).

can be neglected because experiment shows them to be over a hundred times slower than the oxidation process. Reaction (c) has been shown to be extremely improbable as a wall reaction and its extremely infrequent occurrence in the gas phase does not warrant its inclusion in our kinetic treatment, leaving only three of these processes which can materially affect the rate of oxidation.

$$\begin{aligned} CH_3I + h\nu &\longrightarrow CH_3 + I \\ CH_3 + I_2 &\longrightarrow CH_3I + I \\ I + M(I) &\longrightarrow I_2 \end{aligned}$$

In the presence of oxygen, methyl may react in the following way

$$CH_3 + O_2 \longrightarrow CH_2O + OH$$

Now, the possible three-body reaction of O_2 with CH_3 or I, can be neglected as being extremely infrequent, while reactions between OH and I_2 or O_2 are thermally improbable, leaving

$$OH + CH_3I \longrightarrow CH_3OH + I$$

to account for the removal of hydroxyl groups.

Since the rate of formation of iodine molecules from the atoms does not affect the rate of removal of methyl iodide, and, assuming that the formaldehyde and methyl alcohol formed will not play any part in these reactions, we have only to consider the following reactions to determine the rate of removal of methyl iodide

$$\begin{aligned} CH_3I + h\nu &\longrightarrow CH_3 + I & k_1 \\ CH_3 + I_2 &\longrightarrow CH_3I + I & k_2 \\ CH_3 + O_2 &\longrightarrow CH_2O + OH & k_3 \\ CH_3I + OH &\longrightarrow CH_3OH + I & k_4 \end{aligned}$$

Therefore

$$-\frac{d[CH_3I]}{dt} = k_1I_0\,(1 - e^{-\alpha[CH_3I]}) - [CH_3][I_2]k_2 + [CH_3I][OH]k_4$$

Assuming stationary concentrations of OH and CH_3, we can equate their respective rates of formation and removal as follows

$$\begin{aligned} OH\colon\quad [CH_3][O_2]k_3 &= [CH_3I][OH]k_4 & (1) \\ CH_3\colon\quad k_1A &= [CH_3][I_2]k_2 + [CH_3][O_2]k_3 & (2) \\ \text{where } A &= I_0\,(1 - e^{-\alpha[CH_3I]}) \end{aligned}$$

Therefore

$$[CH_3] = \frac{[CH_3I][OH]k_4}{[O_2]k_3}$$

whence

$$\frac{[CH_3I][OH]k_4}{[O_2]k_3} = \frac{A\,k_1}{[I_2]k_2 + [O_2]k_3}$$

But, from Equations 1 and 2

$$k_1A - [CH_3][I_2]k_2 = [CH_3I][OH]k_4$$

and consequently

$$\begin{aligned} -\frac{d[CH_3I]}{dt} &= 2[CH_3I][OH]k_4 \\ &= \frac{2\,A\,k_1[O_2]k_3}{[I_2]k_2 + [O_2]k_3} \end{aligned}$$

Now, it is evident from Table II that for the initial part of the reaction, that is, the portion considered in the kinetic measurements, $-\mathrm{d}[CH_3I]/\mathrm{d}t$ is approximately equal to $-\mathrm{d}P/\mathrm{d}t$ and

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{2I_0\,(1 - e^{-\alpha[CH_3I]})\,[O_2]}{\frac{k_2}{k_3}\,[I_2] + [O_2]}$$

assuming k_1 to be equal to unity.

It is to be noted that at high oxygen concentrations this mechanism gives a quantum yield of **2,** in terms of methyl iodide oxidation per quantum, which is the experimentally determined value.

Furthermore, even if we consider the total reaction, which will yield a slightly larger pressure decrease than corresponds to methyl iodide removed, as can be seen from the higher values in Table II, we can show that the kinetic equation remains essentially the same.

The formaldehyde and methyl alcohol react in the following ways

$$2CH_3OH + CH_2O \longrightarrow (CH_3O)_2CH_2 + H_2O \qquad k_5$$
$$nCH_2O \longrightarrow (CH_2O)n \qquad k_6$$
$$nCH_2O + h\nu \longrightarrow (CH_2O)n \qquad k_7$$

Assuming stationary concentrations of formaldehyde and methyl alcohol, we arrive at the equations

$$CH_3OH\text{:}\quad [CH_3I][OH]k_4 = [CH_3OH]^2[CH_2O]k_5 \tag{3}$$

$$CH_2O\text{:}\quad [CH_3][O_2]k_3 = \frac{[CH_3OH]^2[CH_2O]k_5}{2} + k_7A' + [CH_2O]^n\,k_6 \tag{4}$$

Equation 4 assumes the form it does if the rate of removal of formaldehyde by the methylal reaction is only half that of an equal volume of methyl alcohol, as we have shown to be true.

By a reasoning similar to that used above it may be shown from (1), (2), **(3)** and (4) that

$$\frac{\mathrm{d}(CH_2O)}{\mathrm{d}t} = \frac{\mathrm{d}(CH_3OH)}{\mathrm{d}t} = \frac{\mathrm{d}[(CH_3O)_2CH_2]}{\mathrm{d}t} = \frac{2\mathrm{d}(CH_2O)_n}{\mathrm{d}t} = \frac{k_1A\,[O_2]k_3}{[I_2]k_2 + [O_2]k_3} \tag{5}$$

Since the total pressure decrease must be proportional to the sum of these rates, we have again

$$-\frac{\mathrm{d}P}{\mathrm{d}t} = K\,\frac{k_1A\,[O_2]k_3}{[I_2]k_2 + [O_2]k_3}$$

and, therefore, the rate of pressure decrease is proportional to the rate of decrease of methyl iodide concentration. Approximate values for the constants α and k_2/k_3 were derived from the experimental results and, using these figures, the value of K was calculated and appears in the last column of Tables V and **VI.**

$$-\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{K\,(1 - e^{-0.047[CH_3I]})\,[O_2]}{12.3 + [O_2]} \tag{6}$$

Curves appearing in Figs. 4 and 5 were obtained theoretically from this equation and the experimental points plotted for purposes of comparison.

The constant **12.3** is equal to $k_2/k_3[I_2]$ and since $[I_2] = 0.03$ mm., $k_2/k_3 = 410$. Therefore, if methyl reacts with iodine on every collision, only one collision in about every four hundred between methyl and oxygen can be fruitful. Since this reaction is strongly exothermic, this is another elementary reaction which does not go on every collision, such as we have already discussed on page 1700. A more general discussion of the relative collision efficiencies of these reactions will be included in a forthcoming paper.

Besides the mechanism involving intermediate production of free hydroxyl groups, which is given above, another alternative mechanism is possible. The comparative inefficiency of the collisions between methyl and oxygen suggests the possible intervention of a third body and, indeed, the number of collisions of this type would be roughly of the same order as the number of efficient collisions between methyl and oxygen. The theory of intermediate peroxide formation, which has received considerable support in the case of hydrocarbon oxidation,[21] at once suggests itself and requires the following scheme of reaction: methyl iodide would be dissociated according to reaction (1) above and would be formed by reactions (2) above. Since the formation of a peroxide would necessitate a three-body process, we have

$$P + CH_3 + O_2 \longrightarrow CH_3O_2 + P' \qquad k_3'$$

where P represents the total pressure

$$CH_3I + CH_3O_2 \longrightarrow CH_2O + CH_3OH + I \qquad k_4'$$

while formaldehyde and methyl alcohol would be removed by reactions (5), (6) and (7) of the previous scheme, and by precisely the same reasoning that was used to derive Equation 6, we can obtain the equation

$$-\frac{dP}{dt} = \frac{K\,(1 - e^{-\alpha[CH_3I]})\,[O_2]}{\dfrac{k_2'[I_2]}{k_3'[P]} + [O_2]} \qquad (7)$$

According to this, increase in total pressure at low oxygen concentrations should increase the reaction velocity. Thus, comparing 50 mm. of methyl iodide and 10 mm. of oxygen, with 50 mm. of methyl iodide, 10 mm. of oxygen and 40 mm. of nitrogen, as predicted from Equation 7, the respective rates ought to be in the ratio of 1:2.35. Actually, we find by experiment that they are as 1:0.9. It would seem then, that the photochemical oxidation of methyl iodide is to be represented by the hydroxyl scheme and kinetic Equation 6, rather than by the peroxide scheme and Equation 7.

[21] **Lewis,** *J. Chem. Soc.,* 58 (1930); **Brunner and Rideal,** *ibid.,* 1162 (1928); **Thompson and Hinshelwood,** ***Proc. Roy. Soc.*** **(London), A125,** 277 (1929); **Callendar.** ***Engineering,*** 123, 147, 182, 210 (1927); **Fort and Hinshelwood,** ***Proc. Roy. Soc.*** **(London) A125,** 218 (1930).

Without wishing to lay too much stress upon this conclusion, the writers would point out that such a "hydroxyl" scheme is at least as probable a mechanism of hydrocarbon oxidation as a peroxide scheme, especially when it is considered that hydrocarbons generally do not react appreciably with oxygen until they reach temperatures at which dissociation begins to occur.

One of the authors (R. S.) wishes to express his indebtedness to the Commonwealth Fund for a Fellowship which enabled him to take part in the research.

Summary

1. Gaseous methyl iodide decomposes extremely slowly when illuminated with ultraviolet light, and exhibits a Budde effect similar to that obtained with chlorine.

2. The photo-oxidation of gaseous methyl iodide has been shown to be essentially an oxidation of free methyl groups.

3. Iodine, paraformaldehyde, methylal and water are practically the sole products of reaction.

4. The kinetics of the process have been investigated and found to agree with the theoretically derived mechanism.

THE OXIDATION OF IODIDE ION BY PERSULFATE ION. IV. KINETICS OF THE REACTION IN HIGHLY DILUTE AQUEOUS SOLUTION

BY CECIL V. KING AND MORRIS B. JACOBS

RECEIVED FEBRUARY 3, 1931 PUBLISHED MAY 6, 1931

Introduction

A combination of Bronsted's equation for the velocity of a bimolecular ionic reaction and the Debye–Hiickel limiting expression for the activity coefficient of an ion (in water at 25°) leads to the expression

$$\log k = \log k_0 + z_A z_B \sqrt{\mu} \qquad (1)$$

where k is the velocity constant observed and k_0 that at zero ionic strength. Introduction of the Debye–Hiickel expression necessitates velocity measurements at very low salt concentrations to test this expression; previously only three ionic reactions have been measured at concentrations below $\sqrt{\mu} = 0.14$ and two others below $\sqrt{\mu} = 0.25$. An excellent summary of this work has been given by Livingston[1] and we have reproduced his plot of ($\log k - \log k_0$) against $\sqrt{\mu}$ for the various reactions, including for comparison (in black circles, Fig. *1)* some of our measurements on the persulfate–iodide reaction.

[1] Livingston, *J. Chem. Ed.*, 7, 2887 (1930).

This reaction has been the subject of several previous investigations at higher ionic strengths than reported here. Price[2] found the reaction to be kinetically bimolecular, and noted the positive salt effect. He also observed the disturbing influence of the iodine formed in the course of the reaction on the velocity, a factor which has been clarified in this Laboratory (papers I and II of this series) and elsewhere.[3] Brönsted used the earlier measurements in verifying his theory of primary salt effect.[4]

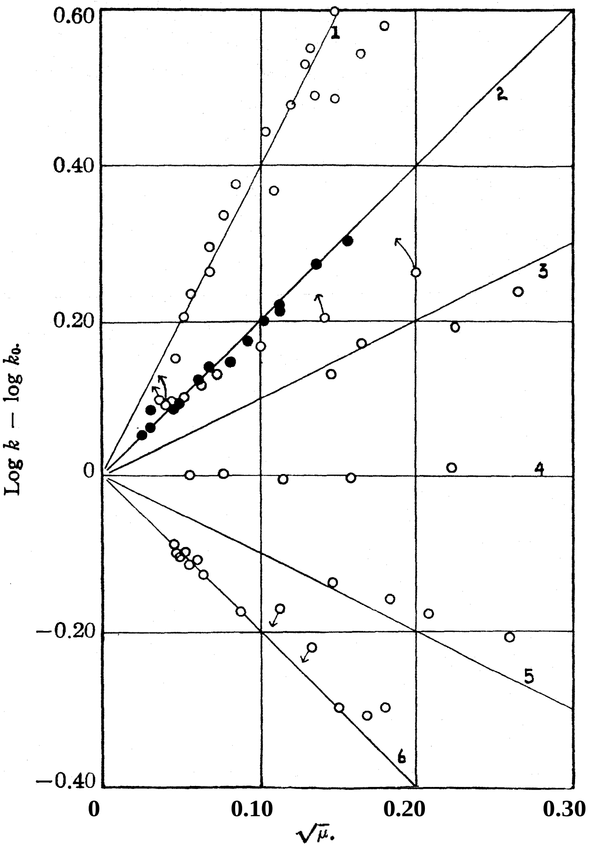

Fig. 1.—The effect of ionic strength on the velocity of ionic reactions.

The Experimental Method

The reaction has been followed in the past by titrating the iodine produced with standard thiosulfate. Such titrations become difficult in the

---

dilute solutions we wished to use, although the similar titration of thiosulfate with standard iodine has been carried out successfully in equally dilute solutions.[5] However, in addition to this difficulty we wished to avoid also the complicating factor of tri-iodide formation mentioned above, and therefore resorted to a scheme similar to that used in studying the Landolt reaction $(HIO_3 + H_2SO_3 \longrightarrow)$. To the solution of potassium persulfate and potassium iodide was added a small amount of sodium thiosulfate, which by its very rapid reaction with the iodine as it was liberated, kept the solution clear until it was all used up. The time of first appearance of iodine was determined with the aid of a balanced photo-cell circuit and sensitive galvanometer, with a long absorption cell; for accuracy the amount of thiosulfate was adjusted so that the iodine never appeared in less than approximately ten minutes. From this time and the known concentrations the velocity constant was calculated.

The velocity of other reactions has been measured in a similar manner, without using a photo-cell method and at much higher concentrations. The Landolt reaction has been mentioned above. Abel measured the velocity of the potassium iodide–hydrogen peroxide reaction by adding thiosulfate (which also reacts with the hydrogen peroxide, at a known, slow rate).[6] Abel and Fürth studied the oxidation of iodide by periodate by using arsenite to react with the liberated iodine and so prevent its appearance.[7]

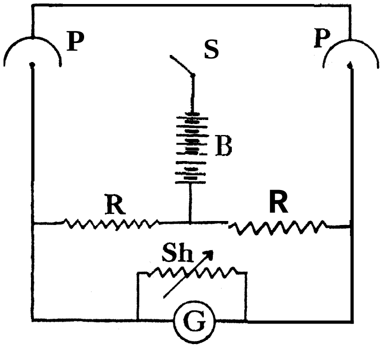

Fig. 2.—The photo-cell circuit: P, P, General Electric PJ14 photocells; S, switch; B, 90-volt battery; R, R, 100-000-ohm resistances: G, Leeds and Northrup wall galvanometer, resistance 1090 ohms, sensitivity 1133 megohms, period 13.1 seconds; Sh, shunt box.

Thiosulfate is oxidized very slowly by persulfate,[8] especially in dilute solutions of persulfate and at low ionic strength, so that this factor was negligible except when the persulfate concentration was much higher than the iodide concentration, as will be noted later.

The photo-cell circuit used is shown diagrammatically in Fig. 2. Vacuum type cells were used, since the circuit was too unstable with gas-filled cells. The source of light was a 400-watt projection bulb operated on 110 volts d. c. The lamp was inclosed in a metal housing, cooled by a small fan. Two beams of light were first passed through glass filters—a combina-

tion of Corning "Didymium" and "Theater Blue^{M}—to filter out most of the light not absorbed by iodine solutions. The light then passed, on one side through the reaction cell—a 5 × 20 cm. glass tube with plane glass ends and side tube for filling—thermostaled at 25 ± 0.02°, and on the other side through a similar cell containing distilled water. The beams then passed through iris diaphragms to the two photo-cells. Sufficient light was obtained without the use of a lens system.

This balanced circuit automatically compensates for most of the fluctuations in the source of light, in battery voltage, etc. Since it is difficult to find two photo-cells with exactly similar characteristics, two 100,000 ohm resistances exactly alike, etc., this compensation is not perfect. Sometimes the galvanometer reading was quite constant over a long period of time: sometimes there were small variations or a slow drift. To fix the time of appearance of iodine more exactly, galvanometer readings were plotted against time and by extrapolating as shown in Fig. 3, the time was determined to ±0.1 minute in most cases.

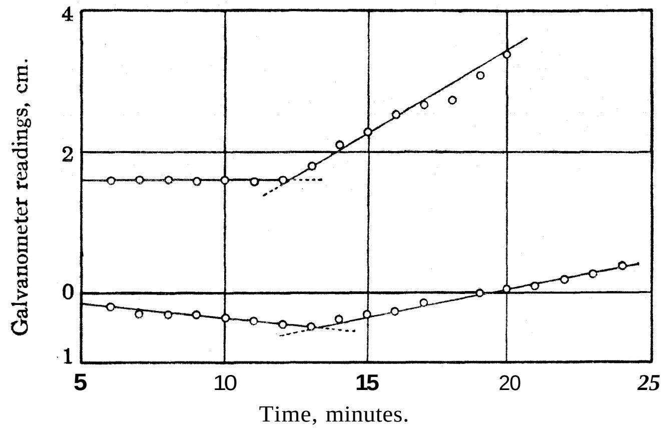

Fig. 3.—The method of obtaining the time of appearance of iodine.

The galvanometer shunt was used only while balancing the circuit and not when measurements were being made. It was found that the appearance of $3 \times 10^{-}$[illegible] moles per liter of iodine gave a galvanometer deflection of approximately 2 cm. The absorption of light increases somewhat more than linearly with the concentration of iodine, but the iodine appears more slowly as the time progresses, hence the approximate linearity of the curves in Fig. 3 over the first few minutes of iodine liberation.

This method gave a much more sensitive test for iodine than the visual test with starch. The latter is, according to Kolthoff,[9] sensitive to about

---

[9] Kolthoff, "Volumetric Analysis," John Wiley and Sons, Inc., New York, 1929, Vol. 11. p. 350.

1×10^{-5} mole of iodine per liter (if 4×10^{-5} M I^- is present). This may under certain conditions be increased to 5×10^{-6} mole of iodine per liter.

Partington[10] states that one part per million of iodine (approximately 2.5×10^{-5} mole per liter) can be detected with starch. He also states that basic lanthanum and praseodymium acetates can be used to detect traces of iodine. Experiments in this Laboratory showed the first of these to be slightly more sensitive than starch. However, the photo-cell method was far better for our purpose.

Materials and Method

All the water used was redistilled from dilute alkaline permanganate and condensed in a block tin condenser. All salts were recrystallized at least twice from this water. Especial pains were taken to free the potassium iodide from traces of iodine since this would react immediately with some of the thiosulfate added. Measurements made with different lots of several of the salts agreed well. Measurements at the highest ionic strengths used checked previous measurements within 2%. King and Steinbach[8] found the velocity of this reaction to be some 25% less in the presence of 0.02 M thiosulfate than in the presence of 0.02 M potassium sulfate. However, in the presence of $10^{-7} - 10^{-5}$ M thiosulfate, as used in this investigation, the agreement with previous measurements indicates that the reaction is perfectly normal.

Standard solutions of all the salts except the thiosulfate were made by weighing the salt and dissolving in the required volume of water. Sodium thiosulfate was standardized by titrating the iodine liberated from potassium iodide by a known amount of persulfate.[11] Aliquot parts of the standard solution were diluted to the required concentrations.

All solutions were brought to 25° before mixing, the time of mixing noted, and galvanometer readings started as soon as the absorption cell was filled and in the bath.

The velocity constants were calculated from the differential equation

$$\frac{-\mathrm{d}C_{S_2O_8^-}}{dt} = kC_{S_2O_8^-}\, C_{I^-}$$

The interval from the time of mixing until the first appearance of iodine was used as dt, $-\mathrm{d}C_{S_2O_3^-}$ was calculated from the known concentration of thiosulfate, and $C_{S_2O_8^-}$, C_{I^-} were the initial concentrations. Since the concentration of thiosulfate was seldom more than 2% of that of the persulfate or iodide, this procedure gives sufficiently accurate values of k.

Experimental

In the first series of experiments the potassium persulfate concentration

was varied from 0.000125 to 0.0048 *M*, and the potassium iodide from one to three times the persulfate concentration. The values of $\sqrt{\mu}$ and log *k* are given in Table I; to save space, the concentrations are omitted. In Fig. 4, log k is plotted against $\sqrt{\mu}$. The straight line is drawn with the slope +2 in such a way that it best fits the points at the lowest values of $\sqrt{\mu}$; it is evident that the experimental values agree with the theoretical up to $\sqrt{\mu}$ = 0.06, but that above this value there is an increasing negative

deviation. Since the best straight line extrapolates to log $k_0 = \bar{2}.94$ or -1.06, Equation 6 becomes

$$\log k = -1.06 + 2\sqrt{\mu}$$

The figure -1.06 is not, however, the value we shall accept as best for log k_0 (see discussion at end of paper).

Since we should expect to find a reaction in solutions containing only univalent ions to follow the theoretical expressions to much higher ionic strengths than if bivalent ions are present, it appears that the above method of using mixtures containing uni- and bivalent ions is a poor choice. It would be preferable to keep the concentration of persulfate as low as possible and increase the iodide concentration, or keep both low and add an inert salt to raise the ionic strength. This was accordingly done in the succeeding experiments.

In the second series the potassium persulfate concentration was kept at 0.00015 M and the potassium iodide concentration at 0.0005 *M* (except for the four lowest points), while potassium chloride was added to raise the ionic strength. In a parallel series the persulfate concentration was kept at the same value while increasing concentrations of iodide were used to raise the ionic strength. The results are given in Tables II and III and plotted in Fig. 5, the experiments with added potassium chloride as open circles, those with potassium iodide as black circles. Here the best straight line with the slope +2 through the lowest points extrapolates to the value log $k_0 = \bar{2}.925$ or -1.075, which is only 1.6% different from the value found

before and probably within the experimental error of such velocity measurements. It will be seen that these experiments follow the theoretical slope quite well to $\sqrt{\mu} = 0.16$, the highest value used. The theoretical equation becomes

$$\log k = -1.076 + 2\sqrt{\mu}$$

In the fourth series an attempt was made to keep the potassium iodide concentration low (0.0005 M) and raise the ionic strength by adding larger amounts of potassium persulfate. These results are plotted in Fig. 6 (open circles). It will be seen that the results are not in accord with the theory in that the value of k rises far above the theoretical and at higher ionic strengths actually decreases again. The explanation lies in the fact that in most of these experiments the ratio of persulfate to thiosulfate concentrations was such that an appreciable percentage of the thiosulfate is oxidized directly instead of through the intermediate iodine. It was found before[8] that the rate of the persulfate–thiosulfate reaction is much more dependent on the persulfate concentration than on the thiosulfate concentration. In these experiments, with **0.00015** M persulfate **and 5** $\times 10^{-7}$ M thiosulfate, not over 1% of the thiosulfate is oxidized directly; while with 0.004 M persulfate and $1 \times 10^{-5} M$ thiosulfate the percentage is much larger. The iodide concentration was low; if this were raised to twice the

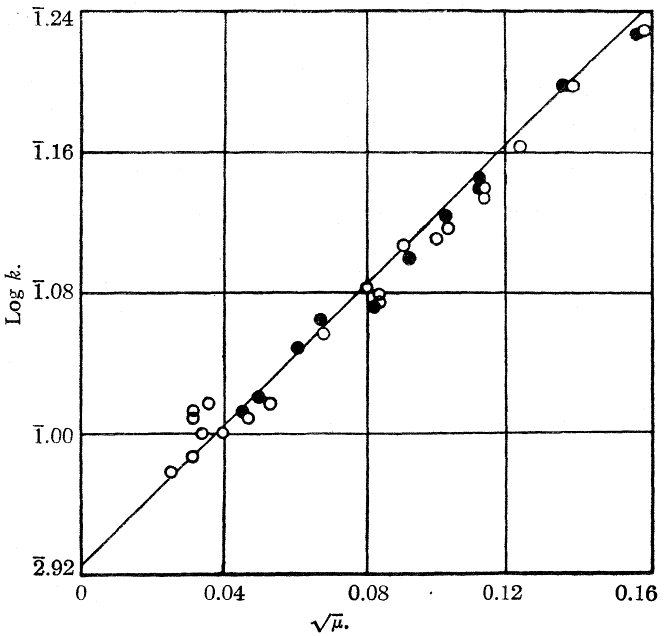

Fig. 5.—Persulfate concentration low; ionic strength raised by adding KCl (O)and KI (O).

persulfate concentration, as in the first series, the velocity of the main reaction would be increased 10–20 times and again not over 1% of the thiosulfate would be oxidized directly.

When the persulfate concentration was increased to the highest value used, 0.012 M, the thiosulfate concentration had to be increased to 4 X 10^{-5} *M*, almost 10% of the iodide concentration; the velocity of the main reaction was such that the percentage of thiosulfate oxidized directly was again low; while the fact that the differential equation was used to calculate k introduces an error of a few per cent.

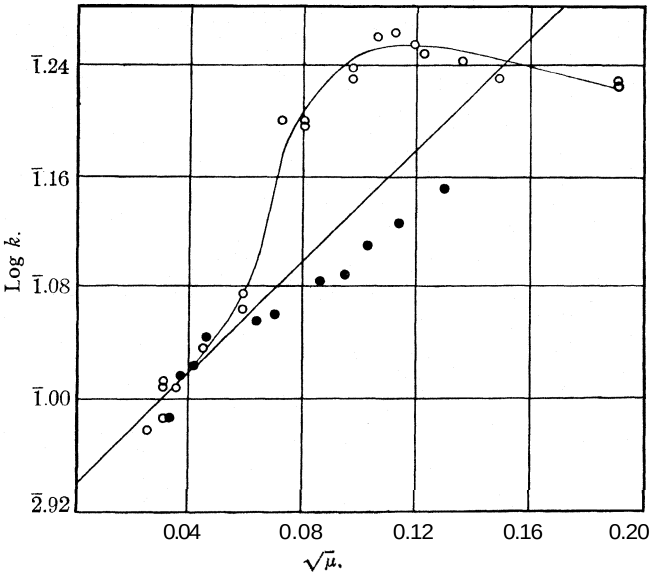

Fig. 6.—Iodide concentration low; ionic strength raised by adding $K_2S_2O_8$ (O) and $MgSO_4$ (@).

Calculation shows that if we assume a value of 2.5 × 10^{-5} as an average for the unimolecular constant of the persulfate–thiosulfate reaction over this range of ionic strengths, and correct the curve shown in Fig. 6 accordingly, reasonable values are obtained for the persulfate–iodide velocity. Unfortunately, no direct measurements of the persulfate–thiosulfate reaction at such low ionic strengths are available, but this value is not improbable.

To obtain better values for the effect of bivalent ions on this reaction, in the last series both the persulfate and iodide concentrations were kept low (0.00015 and 0,0005 *M*, respectively) and magnesium sulfate was used to raise the ionic strength. The results are given in Table IV and plotted in Fig. 6 (black circles). Here we see that the results are normal, the theorectical slope is followed to $\sqrt{\mu} = 0.05$ or 0.06, and the deviations at higher ionic strengths are in the expected direction, For the two sets of experi-

ments plotted in Fig, 6, the straight line which fits best extrapolates again to log $k_0 = -1.06$.

Discussion

It seems rather surprising that when the ionic strength is made up largely of univalent ions, the best straight line should extrapolate to log $k_0 = -1.075$, while with a large proportion of bivalent ions present the best straight line should extrapolate to log $k_0 = -1.06$. The difference is just at the limit of experimental error, but seems too consistent to be of no significance. The explanation may lie in the inaccuracy of the Debye–Hückel equation for bivalent and trivalent ions, even in very dilute solutions. This inaccuracy was noticed by Bronsted, La Mer[12] and their collaborators and finally explained by Gronwall, La Mer and Sandved,[13] who showed that an extension of the mathematical treatment of Debye and Hückel leads to a modified equation for the activity coefficient of ions of higher valence more in accord with experiment than the limiting expression. We cannot apply the Gronwall–La Mer–Sandved extension quantitatively for lack of sufficiently accurate data, but its qualitative significance can be shown. In the region $\sqrt{\mu} = 0.04$ to 0.08 (approximately) the activity coefficient of the bivalent persulfate ion (f_A) will be somewhat smaller than $\log^{-1}(-0.5\, z_2 \sqrt{\mu})$, and that of the iodide ion (f_B) will be practically equal to $\log^{-1}(-0.5\, z^2 \sqrt{\mu})$. But the activity coefficient of AB, a trivalent ion, will have a negative deviation from $\log^{-1}(-0.5\, z^2\sqrt{\mu})$ still greater than that of the persulfate ion, and the value of $\log f_A f_B/f_{AB}$ will therefore be greater than calculated and used in deriving equation (1). At higher concentrations the logarithmic value will again be equal to and finally less than $z_A z_B \sqrt{\mu}$.

For this reason we prefer to take the limiting equation found with added uni-univalent salts, namely

$$\log k = -1075 + 2\sqrt{\mu}$$

as extrapolating to the best value of k_0, the velocity constant at zero ionic strength. This gives the value

$$k_0 = 0.0841$$

---

[12] Bronsted, La Mer and others, THIS JOURNAL, 43, 2265 (1921); 46, 555 (1924); 49, 363, 410 (1927).

[13] Gronwall, La Mer and Sandved, *Physik. Z.*, 29,358 (1928).

In view of the uncertainty regarding the quantitative application of the Gronwall–La Mer–Sandved equation, it is useless to attempt to apply a more or less empirically extended activity coefficient equation in explanation of the curves in Figs. 4 and 6.

Summary

The velocity of the persulfate–iodide ion reaction has been measured, in aqueous solution at 25°, between values of $\mu = 0.000625$ and $\mu = 0.025$, with an accuracy of about ±1.5%.

The velocity was measured by adding small known amounts of thiosulfate to the reacting solution and noting the time of first appearance of iodine with the aid of a photo-cell circuit far more sensitive to traces of iodine than the visual starch test. The velocity constants, in solutions containing as few ions of valence higher than unity as possible, follow accurately the linear equation

$$\log k = -1.075 + 2\sqrt{\mu}$$

to at least as high a concentration as $\mu = 0.025$.

The small difference in the extrapolation of the plot of log k against $\sqrt{\mu}$ for univalent and bivalent ions may be qualitatively explained by the difference between the original Debye–Hückel limiting equation for the activity coefficient of an ion and the Gronwall–La Mer–Sandved extension for ions of higher valence than unity.

[COMMUNICATION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF ROCHESTER]

THE SOLUBILITY OF GOLD IN MERCURY. III

BY ARTHUR A. SUNIER AND LAW G. WEINER

RECEIVED FEBRUARY 12, 1931 PUBLISHED MAY 6, 1931

In earlier papers[1] the results of a study of the solubility of gold in mercury in the temperature interval 0 to 200° were presented. The present paper will deal with a similar study in the range 200 to 300°. The need of such a study will be apparent to all who critically examine the published data[2] in this range of temperature. Although the precision of measurement is not as great as that obtained in earlier papers, it is felt that the method and results are of sufficient interest to warrant publication at this time.

Materials

The mercury was carefully purified and tested as described in earlier papers. In one run (B) mercury was used which was obtained by evapora-

tion from some earlier runs. Gold in the form of foil, said to contain less than 0.01% impurity, was used in about half of the determinations; in the other half (F to J) gold residues from earlier runs were used. No difference in solubility could be traced to this procedure.

Apparatus

Two types of solubility tubes were used. The first type will not be pictured as it differed only slightly from tubes used earlier The second type is pictured in Figs. 1 and 2 in the tube holders which will be described later. Instead of having a vacuum in these tubes, they were filled with hydrogen at a pressure a little below that of the atmosphere. At elevated temperatures a pressure greater than atmospheric was produced; consequently when the capillary A was broken, hydrogen issued from the capillary and the amalgam filtered through the fine capillary connecting the tubes R and H. It will be noted that the size of these tubes is somewhat smaller than those used earlier; this was necessary because of the increased solubility of gold at these higher temperatures.

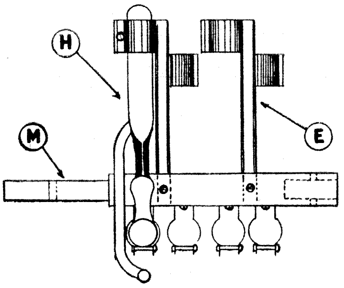

Fig. 1.

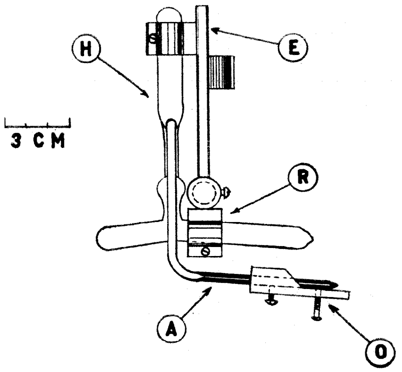

.Fig. 2.

The tubes were shaken in an air-bath, shown diagrammatically in its final form in Pig. 3, of about one cubic foot capacity. One five-hundred watt heater made of nichrome ribbon was placed in each corner (H) of the bath as indicated. Suitable combinations of heaters could be made, to enable a more even distribution of heat, and one heater was placed in circuit with a suitable rheostat to give the fine adjustments of heat required. A four bladed fan (F) rotated for the most part at 600 r. p. m. was placed at one end of the bath. Through the other end of the bath was placed the brass shafting, having a diameter of 16 mm., holding the eight solubility tubes. This shaft was made in three parts, A, B, C The first part was the longest and was held in place by suitable self-aligning bearings (not shown) and was connected with a double eccentric mechanism (which need not be described in detail) in such a way that the shaft oscillated back and forth through an angle of about ninety degrees about eleven times per minute. Parts B and C were of about equal length and were so constructed that they could be removed from or fastened to part A with little difficulty. Figures 1 and 2 give front and side views of part B, to scale. Four pairs of clamps were provided on each of these sections. In Figs. 1 and 2 only one solubility tube is shown in place so as not to complicate the figures.

The thermometer was placed in a small metal cup (N) containing about 50 g. of bismuth solder. As some of the thermometer emerged from the bath, a glass chimney was provided in later runs. This chimney could be electrically heated to very nearly the temperature of the bath, thus eliminating large stem corrections. Temperature measurements were made with a nitrogen-filled mercury thermometer standardized against a similar thermometer recently standardized by the Physical Laboratory of the Taylor Instrument Company. It is believed that most of the recorded temperatures are accurate to ±0.2°. In the runs up to 275° a Beckmann thermometer was inserted in another metal cup (not shown) in the opposite end of the bath; this thermometer rarely showed changes of 0.1° when the apparatus was working smoothly.

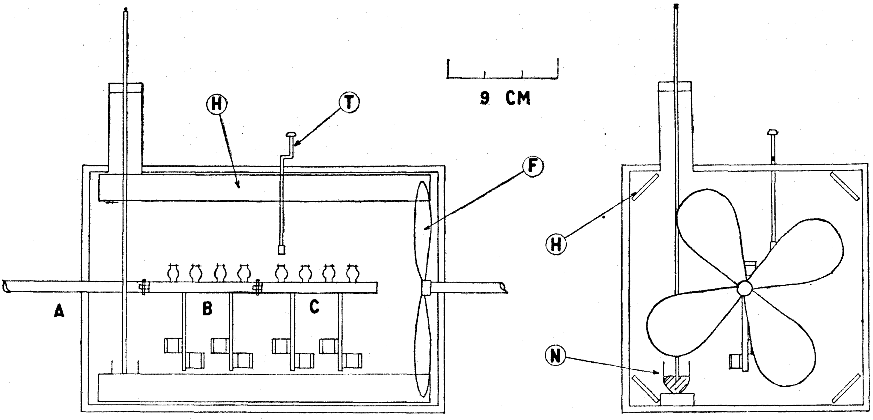

Fig. 3.

The air-bath was very heavily lagged with transite and magnesia board. It was provided with a mica window, kept covered except when it was desired to inspect the tubes. The top of the bath was provided with removable sections to allow inserting the brackets with care and also breaking the capillaries.

Experimental Procedure

The tubes of the first type were filled in the same way as described in earlier papers Tubes of the second type were supplied with mercury and for the most part about 100% excess gold, using Britton and McBain's data as a guide. These elements were placed in part R of the tube (Fig. *2)* and the tube R was sealed as indicated. The capillary was connected to a Hy-vac pump and the tube was thoroughly evacuated, then it was filled with hydrogen and re-evacuated, this flushing process being repeated three or four times. Then, when the pressure of hydrogen was a little less than that of the atmosphere, the capillary was sealed off as indicated. A slight indentation was made on the capillary A, to keep the breaker block in position; the capillary was also file marked a little below the point where the screw O touches the capillary. The tube was next placed in the clamps and the breaker block fastened on in the proper place by means of the screw (not lettered), and also by means of some small asbestos blocks (not shown).

In every run but one, equilibrium was attained from both the high and low sides Eight tubes were made up, four being placed in bracket B and four in bracket C. When bracket B was fastened to the shaft A (by means of a screw) the oscillating mechanism was set in motion and the temperature of the bath was raised to five or ten degrees above the solubility temperature and held there for three or four hours. Then the temperature was lowered to about one degree above the solubility temperature, when a section of the top of the bath was removed and bracket C was quickly inserted and fastened to the end of bracket B. The temperature was then quickly brought to the desired point and held there manually for another three-hour period.

When it was time to sample, the shaking mechanism was stopped and the shaft **ABC** was rotated **180** degrees; the tubes thus were brought to the sampling position (in Fig. **2** the tubes are shown in the shaking position). **A** very narrow **(1** X **7** cm.) section of the top was next removed and the special breaking tool (T Fig. **3)** placed over the head of the breaking screw O, Fig. **2.** **A** slight turn of the tool sufficed to break the capillary in the proper place, thus allowing the amalgam to filter properly. The capillaries of the eight tubes were broken one by one, this operation taking about five minutes. After filtration the bath was allowed to cool somewhat, then the tubes were removed from the bath. The sampling tubes H were cut off when cool; their contents were **then** carefully transferred to weighed crucibles.

The amalgams were analyzed by the method described in the first paper of this series. For the purpose of developing technique and checking the method of analysis, the various preliminary experiments described in the first paper were repeated; the results were essentially the same as those presented earlier and need not be repeated. It may be said that when the weight of the gold residue approximated **1 g.,** the last traces of mercury were removed with difficulty; in fact on the average the analysis yielded results about 0.5% high.

Experimental Results

In Table I will be found data for the second run made at 239.2°. In Table II will be found a summary of the results obtained in all of the runs. It will be noted that some of the numbers in column two are placed in

parentheses; these indicate those tubes omitted from the computation of the average because the results were more than four times the deviation from the mean. The letters in column 1 indicate the order in which the runs were made. It will be noted that determinations H and I are missing. Eight tubes were made up for each of these determinations and the run conducted in the usual way, but at the end of the experiment it was evident that all of the gold had gone into solution, since no residue remained. This absence of excess gold was the first indication that the data of Britton and McBain were in error at the higher temperatures. Determination J was then made, four of the tubes containing a little less than 14 atomic % of gold, which is **50%** more than the value of the solubility at **300** recorded by Britton and McBain; the other four tubes contained **100%** excess of gold. These eight tubes were run for six hours, attaining equilibrium only from the low side. At the conclusion of the run the tubes containing the lesser quantity of gold had no residue, but the analyses showed that these tubes were apparently only slightly below the saturation point, hence the results are averaged in with those containing the larger amounts of gold.

All of the solubilities are expressed in atomic per cent. of gold. **A** table giving the solubility at rounded temperatures will, it is hoped, be presented in another paper.

Discussion of Results

In Fig. 4 the results are plotted as atomic per cent. of gold *versus* temperature. **A** log N *vs.* $1/T$ plot was constructed but there was a marked departure from a straight line, pointing most certainly to the fact that pure gold is not the solid phase but rather some compound of gold and mercury whose formula is not known at present.

The researches of both Parravano and Plaskin were carried out employing cooling curves. Britton and McBain analyzed the liquid phase in equilibrium with the solid phase, but no blank runs were recorded so it is difficult to estimate the probable accuracy of their results. It is hardly possible that the maximum reported by them is due to analytical errors; it would seem rather to be due to an error in sampling, but even this is not wholly satisfactory since below 225° their results are essentially in agreement with the present results. This marked discrepancy in the results at 300° led to the execution of some supplementary experiments which will be discussed under "Supplementary Experiments."

It may be well to discuss briefly, at this point, several possible sources of error in the present experiments. On the analytical side it is believed that 1% would be a very liberal estimate of the maximum error, and this error was occasioned by the large residues of gold obtained in several of the experiments—residues of **2** to 4 g. being obtained in runs D and E. In later runs a definite effort was made to keep the residues below one **gram.**

Occasionally it would be found that in several tubes of a given run the gold strips were not transferred from one end of the tube R to the other end, hence the attainment of equilibrium was hindered to some extent. Then, further, spattering tended to result especially with the larger weights of gold. If the tiny droplets of mercury or amalgam produced on the walls of the tube were not gotten into the main body of the amalgam in subsequent oscillations of the tube, a slight dilution effect (in the low side tubes) would be produced at the time of sampling when these droplets coalesced with the main portion of the amalgam. This is believed to be one of the greatest sources of error in the present experiments where such small amounts of amalgam are involved. It may be that this source of error can be eliminated by making the tube R straight and of smaller bore, and making a little larger the bulb and tube connecting the tubes H and R.

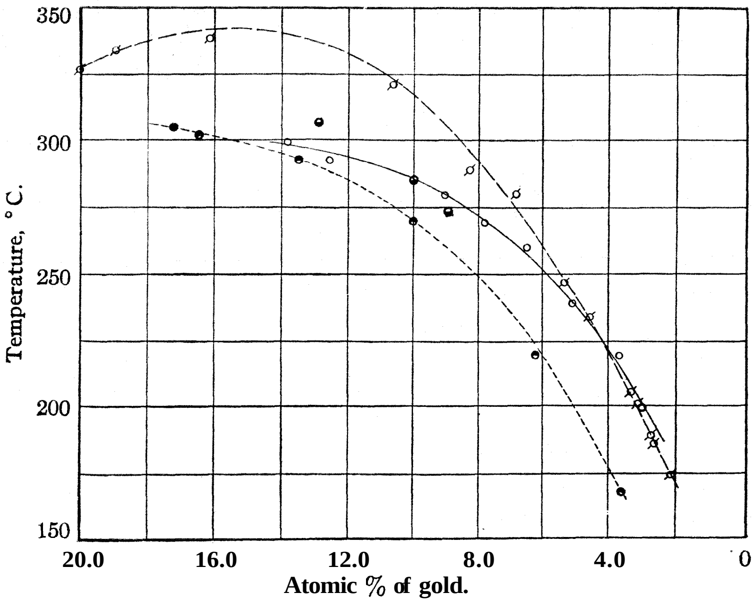

Fig. 4.—Solubility of gold in mercury: - -●- -, Parravano; —ø—, Britton and McBain; 8, Plaskin; —O—, Authors.

In the two earlier papers mention was made of a slight error which may have arisen from the capillary used in admitting air when filtering the amalgams. Such an error was eliminated in the present experiments by the new design of the solubility tube.

Temperature constancy and uniformity in an air-bath is rather difficult to obtain and this is believed to be largely responsible for the rather poorer precision of measurement in the present experiments.

Supplementary Experiments

Britton and McBain performed two supplementary experiments concerning which the following is said: "A satisfactory indication of the correctness of the above data has been obtained in the following manner. Two tubes having a narrow constriction in the middle, like an hour glass, and containing known mixtures of gold and mercury were sealed, and then heated in a small electric furnace provided with windows, and observations were made on the disappearance and reformation of the solid phase by complete inversion of the tube and furnace. Tube I contained a mixture of **30%** gold and **70%** of mercury; some solid was still present at 348° but none at 355°; the temperature of complete liquefaction determined from the curve was **352'.** Tube II contained 50% of gold and 50% of mercury; some solid was still present at 398° but none at **406';** the temperature of complete liquefaction was 392°."

Unfortunately no mention is made of further runs in the concentration range **8** to **18%** To supply this needed information several runs were made by the present authors with the special object of determining whether or not a maximum in the solubility curve was to be found at about 14.3%, this being the value given by Britton and McBain.

The tubes used in the present supplementary experiments were similar to those used in runs **A** to J; the capillary connecting the tubes H and R (Fig. 2) had a larger bore and the capillary A was affixed to the bottom of the sampling tube H. Weighed quantities of gold and mercury, as indicated in Table III, were introduced into the tubes, which were then evacuated to **0.3** mm. The tubes were now placed in the brackets, rocked back and forth and observations of the disappearance and reappearance of the solid phase on complete inversion of the tubes were made through the mica window. Considerable care was exercised in determining the solubility temperature. In another research involving non-metallic solutions it has been shown[3] that a rate of heating of **0.1'** per minute gave a result accurate

TABLE III

to about one-half of one degree. It is difficult to estimate what the corresponding error would be in metallic systems such as the one under consideration, but from preliminary observations in this Laboratory it would appear that the error would be no greater than that just mentioned. The solubility temperature was determined at a number of different rates of heating, 1, 0.25, 0.1° per minute. In Table III the results are for a rate of 0.1" per minute.

From an inspection of Table III it is apparent that these supplementary runs corroborate the data presented in Table II, and thus no maximum in the curve is found for a temperature of 300°. Considerable confidence is placed in these runs using the synthetic method; indeed it appears such a promising method that it is being used in another research in this system in the temperature range 300 to 400°.

Summary

About fifty determinations of the solubility of gold in mercury have been made, in the temperature interval 200 to 300°, with a modified solubility tube and an air-bath. No maximum in the solubility curve is found, the results being confirmed by six supplementary runs using the synthetic method.

BUREAU OR CHEMISTRY AND SOILS]

THE COMPRESSIBILITY ISOTHERMS OF HELIUM AT TEMPERATURES FROM –70 TO 200° AND AT PRESSURES TO 1000 ATMOSPHERES

BY R. WIEBE, V. L. GADDY AND CONRAD HEINS, JR.

RECEIVED FEBRUARY 12, 1931 PUBLISHED MAY 6, 1931

This is the eighth report of a series from this Laboratory concerning the physical properties at high pressures of gases and their mixtures that are of interest in the commercial synthesis of ammonia.[1] It was thought desirable to include helium in this program since its properties would assist in the solution of several problems of importance. The knowledge of the compressibility of a gas which is chemically inactive and only slightly adsorbed by most catalysts will aid greatly in the determination of the adsorption of various gases on catalysts at high pressures. It will also be of value in the theoretical study of gases under high pressures.

The gas was obtained from the Amarillo Helium Plant of the U. S.

Bureau of Mines and was 97.8% pure when delivered, the impurities being nitrogen and traces of methane. The crude helium was expanded into a gas-holder through a copper trap filled with charcoal cooled by liquid air. After this operation the analysis indicated an average purity of about 99.5%. The partly purified gas was compressed to about 125 atmospheres, passed under pressure through copper alloy traps containing charcoal kept at liquid air temperature, and finally stored in "200-foot" cylinders until ready for use. The compressibility of the final product did not change when a charcoal trap was put in the line at a point just before the gas entered the high pressure pipet. Kefractometric analysis by the Bureau of Standards[2] indicated a purity of 100% with an experimental accuracy of 0.05%. Altogether, nine cubic meters of gas were purified during the course of the experiment.

Method and Apparatus

The general procedure and the type of apparatus have been described by Bartlett and others.[1b,1d,e,3] The high pressure measurements were made in the following pipets

Pipet	Volume
Chrome vanadium steel pipet[4]	23.081
Chrome vanadium steel pipet	4.095
Copper alloy pipet	3.998

The copper alloy pipet was used principally at the lower temperatures. With the help of Bartlett's values,[1d] the pipets were calibrated at 0° with hydrogen at 100, 200, 500 and 1000 atmospheres. The compressibility factor for helium at 0° and 100 atmospheres based on this calibration was found to be 1.0523 when expressed in Amagat units. (Amagat unit is defined as the ratio of PV/P_0V_0 where P and V are the pressure and volume, respectively, at some particular temperature and P_0 and V_0 the corresponding values at 0° and one atmosphere.) The value, 1.0523, was used for checking the volumes of the pipet at frequent intervals. Temperature measurements were made by means of two thermocouples, a five-junction copper-constantan couple for the low-temperature range and a three-junction chromel–X–copel for temperatures above zero degrees centigrade. Both had been calibrated and checked at the Bureau of Standards. The e. m. f. was read on a Leeds and Northrup Type K potentiometer which, including the standard cell, had also been calibrated previously by the Bureau of Standards.

---

[2] Courtesy of S. F. Pickering, Bureau of Standards.

[3] For a more detailed description of the apparatus see Dilley and Edwards, Dept. of Agriculture, Circular No. 61, 1929.

[4] Composition of chrome vanadium steel: Cr, 1.3%; V, 0.2%; C, 0.2–0.3%. Composition of copper alloy: Cu, 65.00%; Fe, 2.60%; Mn, 6.03%; Zn, 21.69%; Al, 5.72%; Pb, trace.

The old piston and cylinder of the 1000 atmosphere gage[1d] were replaced by new ones. The new piston diameter was 0.48824 cm. and that of the cylinder 0.48870 cm. at the point of equilibrium.

The newly equipped 1000 atmosphere gage was checked against the 200 atmosphere gage[1d] at 200 atmospheres and it was found that the calculated and experimental values checked better than 2 parts in 10,000 at 200 atmospheres. Temperatures were kept constant within 0.05". The accuracy of calibration of the high pressure pipets is estimated to be 0.03 of 1 . On the average at least three separate runs were made to determine each point. In the majority of cases the maximum deviation between the values obtained in each run was less than 0.05 of 1% ; but with the exception of three points at 200° (at 400, 600 and 800 atmospheres), where it was as high as 0.2, the maximum deviation did not exceed 0.1 of 1%. When plotting $\Delta \equiv V\left(\frac{PV}{RT} - 1\right)$[5] against temperature it was found that the above three points did not fall on a smooth curve, the first and third were about 0.2 of 1% too low while the second was the same amount too high. With the exceptions mentioned the general accuracy is estimated to be better than 0.1 of 1%. It is hoped at some later date to extend the measurements and determine the three points more accurately.

The experimental results of this investigation are presented in Table I and are expressed in Amagat units. Column 3 gives the direct experimental values; in Column 4 we have calculated the corresponding values from Equations 1–6 which were obtained from the experimental data by the method of least squares, throwing all the adjustment onto the measured volumes.[6] Finally in Columns 5 and 6 the values of Holborn and Otto[7] and Gibby, Tanner and Masson[8] are presented for comparison. The only other work at higher pressures was done by Bridgman,[9] who measured the compressibility of a known weight of 95.8% helium from 3000 to 15,000 kg./sq. cm. The absolute volume at 3000 kg./sq. cm. was unknown and the results given are relative to this unknown volume. He corrected his values for the impurity, assuming it to be nitrogen.

In conclusion the authors take pleasure in acknowledging the friendly cooperation of the staff of the Fixed Nitrogen Research Laboratory; especially we are indebted to Dr. R. T. Milner, who assisted us in the purification of helium.

THE SYSTEM LITHIUM BROMATE-WATER

BY JOHN P. SIMMONS AND WILLIAM F. WALDECK

RECEIVED FEBRUARY 14, 1931 PUBLISHED MAY 6, 1931

According to A. Potilitzin,[1] crystallization of lithium bromate from aqueous solution results in the formation of a mixture of anhydrous and monohydrate crystals. On the other hand, P. Mylius and R. Funk[2] are of the opinion that the salt exists only in the anhydrous form. This conflict of opinion seemed to justify further investigation concerning the composition of solid phases which are capable of existence when lithium bromate and water are allowed to come to equilibrium at different temperatures.

Experimental

Preparation of Lithium Bromate.—Lithium bromate was made by bringing together solutions of lithium sulfate and barium bromate, titrating one against the other until a drop of either gave no precipitate. The filtrate from the barium sulfate was concentrated and upon cooling lithium bromate crystallized out. Analysis of the dried salt iodimetrically gave in duplicate analyses 99.50 and 100.0% lithium bromate.

Procedure

All solubility measurements were made by agitating lithium bromate with water in small Pyrex glass-stoppered tubes. Samples of from 0.5 to 1.5 cc. were drawn off by means of pipets into 15-cc. weighing bottles. The solutions were evaporated to dryness and the residues heated to constant weight at 110°.

Two sources of error occur in this method of analysis. The salt may suffer some decomposition during drying and there may be a loss of water by evaporation during the transfer of the solution from the solubility tube to the weighing bottle. These errors were shown to be negligible by the following experiments.

(1) 0.5909 g. of lithium bromate was placed in a weighing bottle, water added, then evaporated and the residue heated at 110° to constant weight. At the end of this treatment the weight of the residue was 0.5912 g.

(2) Water at 75° was transferred to a weighing bottle and allowed to stand exposed to the atmosphere for thirty seconds, during which time

---

[1] Potilitzin, J. Russ. *Phys.-Chem. Soc.*, 22, i, 391 (1891).

[2] Mylius and Punk, *Ber.*, 30,1718 (1897).

there was a loss of 1.6 mg. Since ten seconds is the average time for transfer of a sample of solution, it is reasonable to assume that the loss in the case of pure water for this latter interval would be about 0.5 mg. Moreover, the solutions contained about one-third molar quantities of the salt, so that due to this fact evaporation ought to be reduced a further one-third or to about 0.2 mg. It is obvious then that errors due to the above sources may be considered negligible.

In the solubility measurements from 5 to 53° inclusive, automatically controlled water thermostats were used. At the higher temperatures a saturated solution of calcium chloride, covered with a layer of oil, was placed in a 3-liter beaker. The latter was placed in an oven heated by gas and controlled by hand, served as a thermostat. The calcium chloride solution and the system being studied were stirred by wind turbines until equilibrium was attained. The lower temperatures were maintained constant within 0.02° and the higher within 0.10°. Equilibrium appeared to be reached quickly, usually in about three hours. The metastable point shown on the curve at 30° was obtained by allowing a solution saturated at 100° to cool to 30° over a period of eight hours. This solution was kept at 30° for four hours without stirring and then analyzed. The point so obtained fell so well on a continuation of the anhydrous curve that it is reasonably certain that it is very close to the true value.

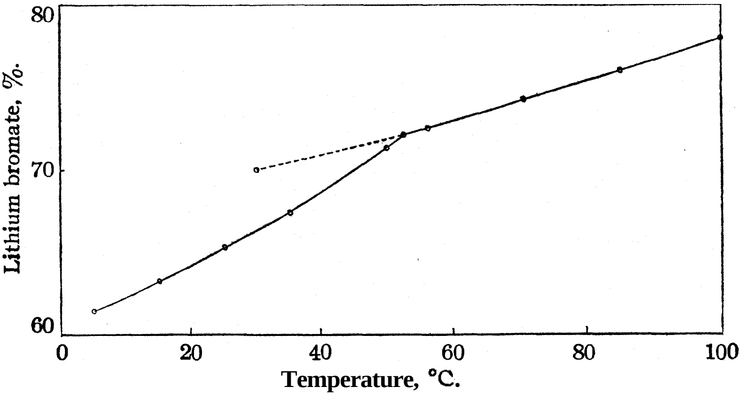

Fig. 1.—Solubility of lithium bromate in water.

The results of these measurements are given in the table and when plotted the curve of Fig. 1 is obtained.

Temp., °C.	% $LiBrO_3$	Temp., °C.	% $LiBrO_3$
5	61.6	53	72.4
15	63.3	56	72.6
25	65.4	70.5	74.3
35	67.5	85	76.2
50	71.5	100	78.0

An inspection of the curve in Fig. I shows a distinct break at about 52° and proves the existence of at least two solid phases. These results were obtained from the nndersaturated side only as the salt showed a great tendency to form supersaturated solutions.

To determine the composition of the solid phases, moist crystals which had come out of solution at room temperature were placed in a desiccator with anhydrous lithium bromate until no further loss was observed. Analysis of this material showed 0.995 and 1.008 molecules of water to one molecule of lithium bromate, in other words, the monohydrate. Crystals grown at 55° were small brilliant pyramids and upon analysis proved to be anhydrous lithium bromate. It is therefore evident that the two solid phases involved in this system are lithium brornate monohydrate, which is stable below 52°, and anhydrous lithium bromate stable above this temperature.

The determination of the transition point of lithium bromate–lithium bromate monohydrate was also made by cooling a solution saturated at 80° and, although supersaturation gave some difficulty, a number of results were obtained which gave an average figure of 50.8°. The agreement between this value and the one obtained by the solubility method may be considered good in view of the great viscosity of the solutions, the slight increase in solubility of the anhydrous lithium bromate with increase in temperature, and the marked tendency to form supersaturated solutions.

Attempts to determine the melting point of anhydrous lithium bromate by direct measurement gave an average of 248'. This, however, is low as some decomposition was observed. Extrapolation of the solubility curve indicated a melting point of 260'.

Summary

1. The solubility of lithium bromate in water has been determined over the range of temperature 5–100°.
2. Lithium bromate may exist in contact with its aqueous solutions as the monohydrate or as anhydrous salt.
3. The transition temperature lies between 50.8 and 52°.
4. The melting point of anhydrous lithium brornate lies between 248 and approximately 260°.

THE ABSORPTION SPECTRUM AND PHOTOCHEMICAL DECOMPOSITION OF HYDRIODIC ACID

BY G. K. ROLLEFSON AND J. E. BOOHER

RECEIVED FEBRUARY 16, 1931 PUBLISHED MAY 6, 1931

The photochemical decomposition of hydriodic acid has been the subject of investigation from time to time for fifty years. The first mention of the reaction was by Lemoine[1] but the first detailed investigation was carried out by Bodenstein.[2,3,4] The quantum yield was determined by Warburg[5] for the wave lengths 2070, 2530 and 2820 Å. and found to be approximately two. This value was found to hold for wave lengths slightly greater than 3000 Å. by Bodenstein and Lieneweg. Coehn and Stuckardt[6] have investigated the reaction in quartz, uviol and Jena glass vessels using a quartz mercury arc as a source of light and found that the reaction occurred in all the vessels but was markedly slower in those of glass than in the quartz or uviol.

The absorption spectrum has been studied by several investigators,[6,7,8] who report essentially the same results, namely, a continuous absorption extending from 3340 Å. toward shorter wave lengths. Bodenstein and Lieneweg report slight absorption as far as 3600 Å.

These results have led to the decomposition being ascribed to the dissociation of an hydriodic acid molecule into a normal hydrogen atom and an iodine atom in the $^2P_1$ state followed by the reaction of the hydrogen atom with a second molecule of hydriodic acid. The iodine atoms produced combine to form molecules either by triple collision in the gas phase or at the walls. This explanation seems adequate for those wave lengths transmitted by quartz or uviol glass but in the case of decomposition in ordinary glass vessels we must assume either another mechanism, since the reported absorption is beyond the transmission limit of ordinary glass, or else the absorption must extend considerably beyond the limit given above. The observation of Salant and Sandow in their work on the Raman effect for hydriodic acid gas[9] that the 4047 Å. line of the mercury arc caused decomposition emphasizes this fact. The experiments described in this paper were designed to clarify the situation concerning this reaction in the long wave length region.

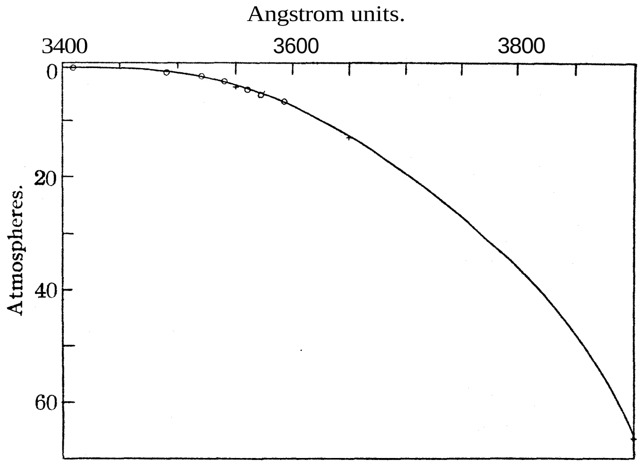
[9] Salant and Sandow, *Phys. Rev.*, 6, 1591 (1930).

The hydriodic acid used in the experiments we have performed was prepared by dropping a concentrated solution of the gas onto phosphorus pentoxide. The gas evolved was purified by passing it through a tube filled with phosphorus pentoxide and condensed with liquid air. It was distilled from the solid state, condensed in a tube the walls of which were covered with a film of mercury and this process was repeated several times. The final product was distilled into the reaction vessels or absorption tubes as needed. A water white product was obtained.

The first tests were to determine whether the decomposition could be sensitized by iodine. For this purpose several tubes of Pyrex glass were filled with the gas to one atmosphere pressure and various amounts of iodine added. These were illuminated by a bank of tungsten filament lamps for two days at a temperature of approximately 175° and the amount of decomposition determined by absorbing the iodine and hydriodic acid and measuring the residual hydrogen. The results showed no sign of any sensitization by the iodine, which is in agreement with the observation made by Bodenstein and Lieneweg at one pressure of iodine.



○, Gaseous hydriodic acid; +, liquid hydriodic acid.

Fig. 1.

In order to determine whether any decomposition was caused by visible light, three tubes were filled with pure hydriodic acid gas. One of these tubes was left in the dark and the other two were exposed to sunlight for about two weeks. One was surrounded by water and the other by a solution of quinine sulfate, which absorbed all light of wave length less than 4050 Å. On opening the tubes it was found that there had been no reaction in the tube left in the dark or in the one surrounded by the quinine sulfate solution, but the third one showed about 25% decomposition. This indicated that the decomposition must be attributed to absorption of light of wave length less than 4050 Å.; therefore we turned our attention to an investigation of the absorption in this region.

As we were primarily interested in determining whether the absorption extended to longer wave lengths than 3300 Å., it was possible to carry out the observations using vessels of Pyrex glass. The absorption spectrum of the gas was determined using a tube 175 cm. long with an internal diameter of 1.5 cm., and the pressure of the gas was varied from 1 to 8.5 atmospheres. The source of light was a 6-volt, 108-watt tungsten filament lamp which gives a continuous spectrum extending to approximately 2700 Å. The absorption tube, however, did not transmit wave lengths shorter than 3200 Å. The spectra were photographed with a Hilger quartz spectrograph. The absorption was perfectly continuous and at the highest pressure the edge of the blackening on the plate appeared at approximately 3550 Å. The variation in the absorption with pressure is shown in Fig. 1 by plotting the limit of the blackening on the photographic plate against the pressure. It is apparent that the absorption extends considerably beyond the limit of 3340 Å. given in the literature. Furthermore, it is obvious from the trend of the points that the limit of the absorption has not been reached even at the highest pressures used. The absorption for greater concentrations of hydriodic acid was carried out using the liquid. That such measurements could be used to extend the measurements on the gas was shown by comparing the absorption of a one-centimeter thick layer of liquid with the absorption of a layer of gas having the same value for the concentration times the thickness, *i.* e., a column 175 cm. long at a pressure of 4.4 atmospheres.

The absorption appeared to be identical for both conditions so the measurements were extended using the liquid up to a layer fifteen centimeters deep. The results were calculated to equivalent gas pressures in the long tube and plotted with the data on the gas in Fig. 1. The points plotted are for exposures of twenty seconds. From the curve we see that the absorption extends at least as far as 3900 Å. With shorter exposures a limit between 3950 and 4000 Å. was reached.

From the results which have just been given it is apparent that the absorption limit of 3340 Å. given in the earlier work is not a true limit characteristic of the gas. Such being the case, the interpretation of the absorption limit as corresponding to the energy of dissociation of the HI molecule into a normal hydrogen and an excited iodine atom becomes invalid. By this we do not mean that there is no absorption corresponding to such a process but rather that the observed absorption is due to a combination of this process with a dissociation into normal atoms. The value for the heat of dissociation of HI into normal atoms as calculated from thermal data is 69,000 cal. or 3 volts. The energy necessary to raise an iodine atom to the first stage of excitation is 0.95 volt. From these data it is readily calculated that the longest wave length which should dissociate the molecule into a normal hydrogen atom and an excited iodine atom is 3120 Å., whereas the value for both atoms in the normal state is 4120 Å. On this basis we should interpret the continuous absorption found between 3120 and 4000 Å. as causing a dissociation of the molecules into normal atoms, the excess energy going into kinetic energy of the atoms. The absorption at wave lengths less than 3120 Å. may be due partly to this process and partly to dissociation plus activation of the iodine, with the excess energy going into translational energy of the atoms.

The occurrence of two absorption processes of this type differing only in the excitation of the iodine atom is similar to the behavior of sodium iodide[10] except that in the latter case the intensity distribution was such that two well-defined maxima were readily distinguished. In the present case the

---

[10] Franck, Kuhn and Rollefson, *Z. Physik,* 43, **155 (1927)**.

intensity distribution may be explained by assuming that the potential energy curves[11] for the normal and two excited states are as shown in Fig. 2. The curve A represents the normal state with a strong chemical binding, which is to be correlated with the relatively large value for the magnitude of the fundamental vibration quantum, ν (cm.$^{-1}$) = *2233,* found by Salant and Sandow[9] in the Raman spectrum of the gas. The upper states B and C represent much weaker bindings with the minima of the potential curves lying at a much greater separation of the nuclei than for A. Due to the magnitude of the vibration quantum in state A the absorption will be almost entirely from the zero or first vibrational states. On our diagram this is represented by the region between the vertical lines *ab* and *cd.* The portions of the curves B and C lying between these lines represent energies greater than the heats of dissociation of the respective states and therefore when absorption occurs we find it to the short wave length side of the minimum energy necessary for dissociation.

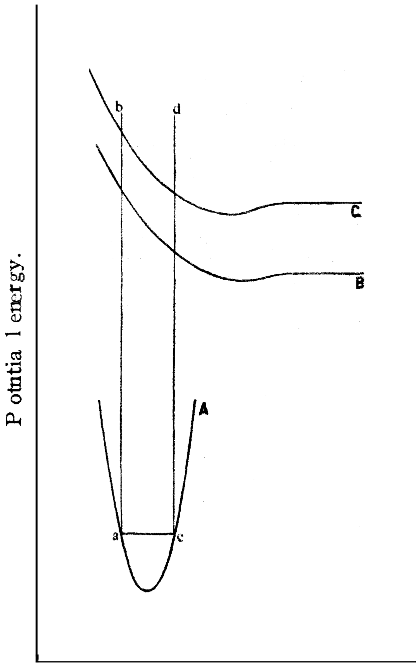


Fig. 2.

The dissociation products for curve B are normal atoms and for C a normal hydrogen atom and excited iodine atom. No dissociation products have been indicated for the lowest state, A, as the available evidence does not allow a definite decision. From the fact that HI shows an infra-red rotation and rotation–vibration spectrum in absorption, we may conclude that the binding is fairly polar in character. It is quite likely that in the zero and first vibrational levels the molecule may be considered as an example of ionic binding.

The mechanism of the photochemical decomposition is essentially the same for all effective wave lengths. The first step is

$$HI + h\nu = H + I \text{ or } I^*$$

followed by

$$H + HI = H_2 + HI$$

and the recombination of the iodine atoms. Since the iodine atoms do not enter into any reaction affecting decomposition, it makes no difference whether the iodine atom formed in the initial step is activated or not.

---

[11] Franck, *Trans. Faraday Soc.*, 21,536 (1926).

The slowness of the reaction in glass vessels is to be attributed to the small absorption coefficient for wave lengths transmitted by glass.

Summary

It has been shown that the continuous absorption of hydriodic acid extends up to a wave length of 4000 Å. instead of terminating at 3340 Å. as reported by others. The absorption on the long wave length side of 3120 Å. has been interpreted as due to the dissociation of the molecule into normal atoms and that on the shorter wave length side as due to a dissociation with the iodine atom excited. The intensity distribution of the absorption has been discussed with reference to the potential energy curves for the normal and excited states of the molecule. The photochemical decomposition of hydriodic acid has been shown to be due to this absorption and the mechanism of the reaction has been discussed.

THE ELECTROMETRIC AND CATALYTIC DETERMINATION OF HYDROGEN-ION CONCENTRATION. THE MEAN ACTIVITY COEFFICIENTS OF THE IONS OF BENZOIC ACID IN POTASSIUM CHLORIDE SOLUTIONS[1]

BY MARTIN KILPATRICK, JR., AND ELWYN F. CHASE[1a]

RECEIVED FEBRUARY 17, 1931 PUBLISHED MAY 6, 1931

In connection with some work on the dissociation constants of indicators in aqueous salt solutions it became necessary to have buffer solutions of known hydrogen-ion concentration. Most buffer systems are standardized in terms of hydrogen-ion activity, the determination being based on certain non-thermodynamic assumptions regarding diffusion potentials. Where the classical dissociation constant is known in a given salt solution, the hydrogen-ion concentration can be calculated. However, accurate values of the dissociation constants are known for few acids except in very dilute solutions. The purpose of the present work is to determine the hydrogen-ion concentration of a series of benzoate–benzoic acid buffers in aqueous solutions of potassium chloride by two different methods. At the same time the mean activity coefficient $\sqrt{f_{H^+} f_{B^-}}$ will be obtained. The method of determining $f_{H^+} f_{B^-}$ the product of the activity coefficients, is as follows. The thermodynamic dissociation constant is equal to

---

[1] Paper Presented at the Indianapolis Meeting of the American Chemical Society, April, 1931.

[1a] Abstracted in part from the thesis of Elwyn F. Chase to be presented to the Faculty of the Graduate School of the University of Pennsylvania in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

$$Ka = \frac{a_{\mathrm{H}^+}\,a_{\mathrm{B}^-}}{a_{\mathrm{HB}}} = \frac{C_{\mathrm{H}^+}\,C_{\mathrm{B}^-}}{a_{\mathrm{HB}}}\,f_{\mathrm{H}^+}\,f_{\mathrm{B}^-}$$

If at constant temperature the solutions are always saturated in respect to benzoic acid, the activity of the molecular benzoic acid is constant in all solutions and its value can be obtained from the solubility in pure water taking into account only that part of the benzoic acid which is present as molecules. At 25° the ionic strength of the saturated benzoic acid solution is approximately 0.001 and the activity of the molecular benzoic acid can be set equal to its concentration within the limits of the error of measurement. The hydrogen-ion concentration is determined by the electrometric and catalytic methods, and the benzoate concentration is calculated from the stoichiometric composition of the buffer. The dissociation constant at zero electrolyte concentration can be determined from conductivity measurements. From these data we calculate the product $f_{\mathrm{H}^+}\,f_{\mathrm{B}^-}$.

The Electrometric Method

The method employed is the same as that used by Güntelberg and Schiodt[2] and is based on the principle of Bronsted[3] which has been so useful in kinetic problems: "If a salt solution acts as a solvent for other salts, present in concentrations small compared with that of the solvent salt, the variation in the solute system keeping the medium or solvent salt unchanged will not, as in the case of pure water solutions, invalidate the ordinary gas laws and make the mass action law inapplicable." In other words, the activity coefficients of the substances present in small amount are independent of the small quantities of these substances and are determined solely by the salt present in large amount. Thus if we have a set of solutions of low hydrogen-ion concentration in potassium chloride solutions of relatively high concentration, we can assume that the activity coefficient of the hydrogen ion in these solutions of high constant potassium chloride concentration is constant. The assumption of practically complete ionization of the hydrochloric acid gives us a set of standards of known hydrogen-ion concentration. If the hydrogen-ion concentration in the above solutions is 0.01 molar, we do not have to take into account the possible alkalinity of the potassium chloride, which can be kept under 1 X 10^{-4} M. These standards at various potassium chloride concentrations from 0.01 to 3.0 M were compared with the benzoate–benzoic acid buffers by means of the quinhydrone electrode. The activity coefficient of the hydrogen ion was kept the same in both the standard and the unknown by keeping the ionic strength the same in each, where potassium chloride contributed from 90 to 99% of the ionic strength in practically all cases. The cell measured was

$$\mathrm{Pt}\,\Big|\,Q\quad \begin{matrix} c\ \mathrm{HCl\ and} \\ (m-c)\ \mathrm{KCl} \end{matrix}\,\Big|\,\begin{matrix}\mathrm{Satd.}\\ \mathrm{KCl}\end{matrix}\,\Big|\,\begin{matrix} (m-b)\ \mathrm{KCl\ and} \\ b\ \mathrm{NaOOCC_6H_5\ ratd.\ with\ C_6H_5COOH} \end{matrix}\quad Q\,\Big|\,\mathrm{Pt}$$

[2] Giintelberg and Schiodt, *Z. physik. Chem.*, 135,393 (1928).

[3] Brönsted, *Trans. Faraday Soc.*, **23,430 (1927).**

Under the conditions of the experiment the diffusion potential would be small.

Experimental Part

The buffers were prepared by adding potassium chloride and carbonate-free sodium hydroxide solutions to pure benzoic acid in glass bottles and rotating the mixture in a thermostat at 25.15 ± 0.01° until saturated with benzoic acid. It was found that Kahlbaum benzoic acid could be used without further purification. The acid was rotated in the bath for twenty-four hours, a sample of the saturated solution was removed and the acid concentration determined by titration with sodium hydroxide in an atmosphere free from carbon dioxide, using phenol red as indicator. The residue of benzoic acid was then rotated with more water and the solubility redetermined. This was repeated several times and in all cases the determinations agreed within 0.5%. To be certain that twenty-four hours of rotation was sufficient, determinations were made on samples rotated for varying lengths of time up to two hundred hours, without an appreciable change in solubility. Table I summarizes the results of these determinations and Table II gives the values obtained by other workers.

The potassium chloride was Kahlbaum "with certificate of guarantee" and the small quantities of alkali present could be neglected in the well-buffered solutions. The standard hydrochloric acid solutions were prepared from weighed amounts of potassium chloride and constant boiling hydrochloric acid made according to Hulett.

The cell as shown in Fig. 1 consisted of two cylindrical electrode vessels A and A' of Pyrex glass connected through stopcocks B and B' to the reservoir C for the saturated potassium chloride solution. The electrodes D and D′ were pieces of bright platinum foil which were cleaned and heated to redness just before using. Constrictions at E and E′ served to hold cotton plugs on which the quinhydrone was placed. Through the inlets F and F′ nitrogen was passed into the solution to remove dissolved oxygen and to keep the solutions stirred, while the tubes G and G' served for adjusting the junctions H and H′ and for emptying the vessels. The apparatus was set in a thermostat at **25.15** ± 0.05°.

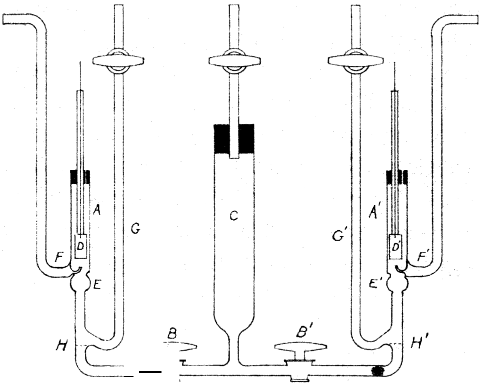

Fig. 1 –The *quinhydrone* **cell.**

The method of carrying out a determination was as follows. The standard hydrochloric acid solution in potassium chloride and the buffer solution were placed in **A** and A', respectively, and carbon dioxide-free nitrogen was bubbled through the solutions. By gentle suction at G and G′ the junctions were made at H and H'. Quinhydrone was added from a spatula and the electrodes were set in place. The potential difference was measured by means of a Type K Leeds and Northrup potentiometer and a suitable galvanometer. The readings were usually constant to 0.0001 volt for the first fifteen minutes. Over the range studied **0.0001** volt represents approximately **0.3%** in hydrogen-ion concentration. In general the results were reproducible to 1% in hydrogen-ion concentration.

The cell reaction is

$$\textit{Quinhydrone} + 2\mathrm{H}^+ + 2e \longrightarrow \textit{Hydroquinone}$$

and the potential is given by

$$E = E_0 + \frac{RT}{2F}\ln\frac{a_{\mathrm{Hy}}}{a_{\mathrm{Q}}|a_{\mathrm{H}}^2} = E - \frac{RT}{F}\ln a_{\mathrm{H}} + \frac{RT}{2}\ln\frac{f_{\mathrm{Hy}}}{f_{\mathrm{Q}}}$$

since $C_{\mathrm{Hy}} = C_{\mathrm{Q}}$. The last term is the salt error which cancels out in our experiments because the activity coefficients in both solutions are equal. Since at constant potassium chloride concentration we may replace the ratio of the activities of the hydrogen ion by the ratio of the concentrations and

$$AE = \frac{RT}{F} \ln \frac{C'_{H^+}}{C_{H^+}} = 0.05914 \log \frac{C'_{H^+}}{C_{H^+}}$$

and

$$\log C'_{H} = \frac{AE}{0.05914} + \log C_{H^+}$$

where C_{H^+} is the known concentration of the hydrogen ion in the standard solution of hydrochloric acid in potassium chloride and C'_{H^+} is the hydrogen-ion concentration of the buffer solution.

Table III gives the results of these determinations. The concentration of potassium chloride in each standard solution can be obtained by subtracting the hydrogen-ion concentration as given in Column **2** from the total electrolyte concentration as given in Column 1. Similarly the difference between Column 1 and the concentration of the sodium ion in Column 5 gives the concentration of potassium chloride for the buffer solutions.

The Catalytic Method

The catalytic method has been used for the determination of hydrogen-ion concentration in a number of cases but as in the case of the electrometric and colorimetric methods a proper consideration of the electrolyte effect is necessary for accurate determinations. In addition, in choosing a suitable reaction we have to consider, as well as the effect of the hydrogen ion, possible catalytic effects of acids other than the hydrogen ion. Both

NOTE.—Table IV gives some measurements carried out by Mr. W. H. Berry at 20° which are given for comparison with the results of Guntelberg and Schiodt and to complete the values over the whole concentration range. They are not to be considered as accurate as the measurements of Giintelberg and Schiodt.

of these factors have been discussed in the recent paper of Bronsted and Grove.[4]

Bronsted and Wynne-Jones[6] used the rate of hydrolysis of diethyl acetal to determine the hydrogen-ion concentration of formic acid buffer solutions *at* ionic strengths up to 0.05. They showed that this reaction was not catalyzed by acids weaker than the hydrogen ion (H_3O^+) and Bronsted has calculated that in all cases the effect of acids stronger than the hydrogen ion (H_3O^+), such as hydrochloric acid, will hardly be detectable in aqueous solution.[6] In order to know the proportionality between the rate of reaction and the hydrogen-ion concentration for a given medium, Bronsted and Wynne-Jones determined the rate of reaction in a solution of hydrochloric acid in potassium nitrate and assumed that the same proportionality factor could be used for formic acid-sodium formate buffer solutions. A similar assumption has been used by previous workers.' However, as further studies of primary salt effect have been made for these zero type reactions (a reaction between an ion and a non-electrolyte), it has been

[7] See Kilpatrick, THIS JOURNAL, 48, 2091 (1926)

realized that although the effect is linear in conformity with the theory the magnitude of the effect between $\mu = 0.01$ and $\mu = 0.10$ for uni-univalent electrolytes is in many cases much greater than the 2 to 4% stated for the reactions studied previous to 1922.[8] For the decomposition of nitrosotriacetonamine catalyzed by hydroxyl ion, the effect between $\mu = 0.01$ and $\mu = 0.10$ is 7% when sodium chloride is the solvent salt.[7] For the hydration of ethylene oxide catalyzed by hydrogen ion it is 9% for the solvent salt sodium perchlorate over the same range of concentration.[9] In the hydrolysis of diazoacetic ester catalyzed by hydrogen ion it is 14% for the same solvent salt and for the hydrolysis of diethyl acetal it is 11% for potassium chloride and approximately 13% for sodium chloride and potassium nitrate. The last two values are from Bronsted and Wynne-Jones[5] and are doubtful in that the concentration of strong acid used was only 0.0008 M. Bronsted and Grove[4] extended these studies to other acetals studied originally by Skrabal[10] and found that the primary salt effect is large and varies with the individual salt to such an extent that one is confined to the determination of the hydrogen-ion concentrations of unbuffered solutions of weak acids where the electrolyte concentration is below $\mu = 0.01$.[11]

Our problem was to determine the hydrogen-ion concentration of the benzoate buffers up to 3.0 molar concentration of potassium chloride. A search of the literature failed to reveal a suitable reaction with a small electrolyte effect, so the hydrolysis of diethyl acetal was used. As already pointed out, the primary salt effect cannot be studied at 25° because we must deal with such low concentrations of strong acids that the results are uncertain. Our method consisted of determining the electrolyte (salt) effect at 0° where the reaction is slow enough to permit the use of 0.01 to 0.005 molar hydrochloric acid. By determining accurately the temperature coefficient, which from previous experience would be expected to be independent of electrolyte concentration,[12,7] the proportionality of the rate to the hydrogen-ion concentration for the various concentrations of solvent salt at 25.15° was calculated. Then by determining the rate of reaction with the benzoate–benzoic acid buffer solutions we obtained the hydrogen-ion concentration.

Experimental Method

The experiments at 0° were carried out in a dilatometer previously used for the determination of the rate of hydration of acetic anhydride.[13] It was

found very convenient to have the whole apparatus in a refrigerator room which was kept a few degrees above the freezing point of water. Two samples of acetal were used and gave the same results. Preparation A boiled between 102 and 103° (760 mm.), while preparation B was very carefully fractionated and boiled at 103° (759 mm.). Preparation B was completely free from acidic impurities. Table V gives the results of the experiments in various concentrations of potassium chloride at 0°.

TABLE V

2.0	.00395	2.00	.0445	11.25

[a] = acetal sample B

The salt effect from 0.01 to 0.10 molar is 10% and over the range studied changes from 2.48 to 11.25, a four-fold increase. Experiments at higher concentrations of potassium chloride show an even greater effect between 2 and 3 molar but these results are more uncertain than the others, due to the lower hydrochloric acid concentrations, and are not given here. In Fig. 2 $k_{H_3O^+}$ is plotted against the electrolyte concentration. The electrolyte

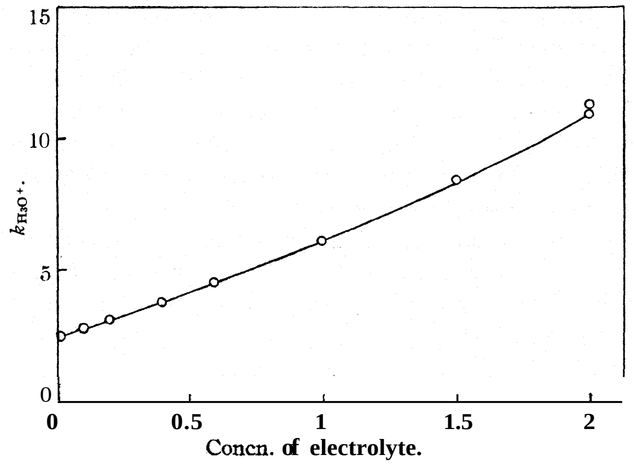

Fig. 2.—The electrolyte effect on $k_{H_3O^+}$.

effect is linear and for dilute solutions the experimental results can be expressed by the equation

$$k = 2.40 + 3.40\,c$$

where c represents the total equivalent electrolyte concentration. To emphasize again the dependence of the effect upon the individual nature of the salt, $k_{H_3O^+}$ for a solution 0.75 M in potassium nitrate is 4.34 as against 5.04 for the corresponding potassium chloride solution.

The temperature coefficient was determined by the two-thermostat method.[14] The reaction was followed dilatometrically, the reacting solutions being confined in two dilatometers similar in design to that used in the study of the hydration of ethylene oxide.[15] The dilatometers were placed in thermostats regulated to ±0.003° and at temperatures exactly five degrees apart as determined by a calibrated resistance thermometer. Portions of a solution of suitable acid concentration were placed in the mixing chambers of the dilatometers and after thermal equilibrium was established with the baths, acetal was added. The velocity constants were determined in the usual way. Although the hydrogen-ion concentrations were too small to be known accurately they were the same in both cases and the temperature coefficient was obtained directly from the velocity constants. The results are given in Table VI, which also contains the heat of activation E calculated from the Arrhenius equation.

TABLE VI

THE TEMPERATURE COEFFICIENT

KCl, moles per liter	0	0	0	0	1.0	2.0
$k_{25.00}/k_{20.00}$	1.870	1.893	1.887	1.894	1.923	1.944
E, cal. per degree	21,720	22,150	22,000	22,160	22,690	23,070

The temperature coefficient seems to increase slightly with increasing salt concentration but this may be due to experimental error and we have given E an average value of 22,300 calories from which we calculated $k_{25.15}/k_0 = 32.19$. An error of 1% in k_{25}/k_{20} means about the same percentage error in E, which would mean a possible error of 3% in $k_{25.15}/k_0$. The velocity constant $k_{H_3O^+}$ for 25.15' is determined by multiplying $k_{H_3O^+}$ for 0° for each electrolyte concentration by 32.19.

Table VII gives the results of the determinations of hydrogen-ion concentration in the buffer solutions. In Column 6 are given the hydrogen-ion concentrations as determined by the electrometric method.

The agreement between the two methods is fairly good, the catalytic method giving slightly lower values above 1 molar concentration of electrolyte. At higher electrolyte concentrations the deviations obtained are greater, apparently exceeding the experimental error. These differences

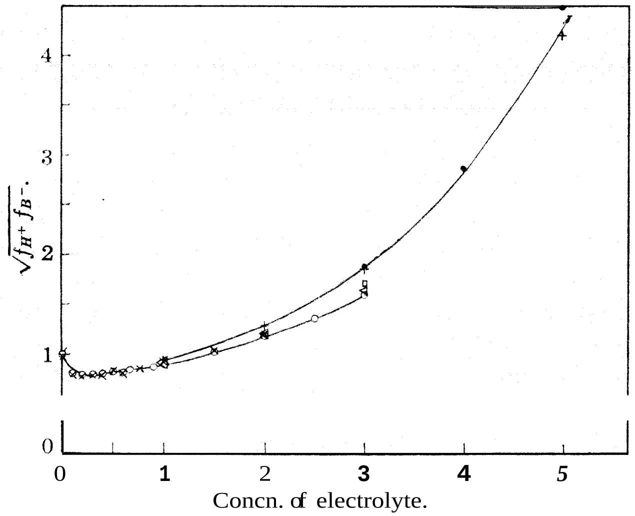
2.0			1.29	
3.0			1.85	1.89
4.0			2.85	2.86
5.0			4.19	4.48

The values of the mean activity coefficients of the ions of benzoic acid can be calculated from the following equation

$$\sqrt{f_{H^+} f_{B^-}} = \sqrt{\frac{Ka\, a_{HB}}{C_{H^+}\, C_{B^-}}}$$

the product $C_{H^+} C_{B^-}$ being given in Tables III and VII. Ka is set equal to 6.31 × 10^{-5}.[16] The value for the activity of the molecular benzoic acid is obtained from the solubility of benzoic acid in water by subtracting the small part present as ions, a_{HB} being set equal to 0.0265. Table VIII gives the values of $\sqrt{f_{H^+} f_{B^-}}$ from the electrometric and catalytic methods at the various concentrations of electrolyte (potassium chloride and benzoate). For comparison we have included the values of Berry and those of Güntelberg and Schiodt in sodium chloride solutions.



⊙, E. m. f., 25°; X, catalytic, 25°; ◁, Berry, 20°; □, G. + S., 20° (in KCl); +, Berry, 20°; ●, G. + S., 20° (in NaCl); ♂, Simons.

Fig. 3.—Mean activity coefficients of the ions of benzoic acid in KCl and NaCl solutions.

From Table VIII and Fig. 3 it is to be noted that the mean activity coefficient is higher in solutions of sodium chloride than in the corresponding solutions of potassium chloride in all cases. Güntelberg and Schiodt[2] interpret this as being due to the predominance of the "salting out" effect over that of interaction.

In another communication will be given the activity coefficients of the molecular acid determined from solubility measurements and K_c, the

---

[16] This value has been determined by J. K. Simons by conductance measurements and will be the subject of another communication.

classical dissociation constant. At that time a comparison will be made of the activity coefficients of benzoic acid and those of other acids.

Summary

The hydrogen-ion concentrations of benzoic acid–benzoate buffers saturated with benzoic acid in potassium chloride solutions have been determined by two independent methods.

The results obtained by the catalytic method are in agreement with those determined by the quinhydrone electrode.

In both cases "electrolyte effects" have been considered.

The mean activity coefficients of the ions of benzoic acid have been determined in potassium and sodium chloride solutions.

THE SOLUBILITIES OF CERTAIN SLIGHTLY SOLUBLE ORGANIC COMPOUNDS IN WATER[1]

BY PAUL M. GROSS AND JOHN H. SAYLOR

RECEIVED FEBRUARY 18, 1931 PUBLISHED MAY 6, 1931

As part of a general investigation of solubility in relation to polar character, the solubilities of a number of slightly soluble organic compounds in water have been determined. Since the final interpretation of the data from this standpoint must await the completion of certain supplementary measurements now under way, it seemed advisable to publish the solubility data at this time since no reliable values for the solubilities of these substances are available in the literature.

Experimental

Method.—The saturated solutions of the substances were prepared by shaking in a thermostat and were analyzed by means of an interferometer. The instrument used was a combination liquid and gas interferometer made by Zeiss.

The procedure was a modification of that of Adams[2] and of Gross.[3] The standard or reference solutions were made by dissolving weighed amounts of the substance under investigation in approximately 1000 g. of water. In the case of liquids, a vial containing a weighed amount of the substance was dropped into the weighed sample of water contained in a glass stoppered bottle. During the weighing, the vial was closed with a cork stopper and care was taken that the liquid did not come in contact with the stopper. The stopper of the vial was removed, the vial quickly

---

[1] Based upon a thesis submitted by John H. Saylor in partial fulfilment of the requirements for the Ph.D. degree at Duke University.

[2] Adams, THIS JOURNAL, 37, 1181 (1915).

[3] Gross, *ibid.*, 51, 2362 (1929).

dropped into the water and the bottle immediately stoppered. Solids were weighed out on a watch glass and quantitatively transferred to the bottle containing the water. The free space above the solutions was kept small enough to render negligible the error due to vapor losses. In most cases, this space was not more than 10 cc. per 1000 g. of solution. In the case of the less volatile liquids and solids, the vapor space was made somewhat larger in order to shorten the time of shaking necessary for complete solution. The bottles were placed in a shaker and shaken until all of the substance was dissolved. Inspection showed whether all of the drops of a liquid or particles of a solid had disappeared. The method, by which the proper concentrations to use for the standards were chosen, will be described below.

Three standard solutions, A, B and C were used whose concentrations were so chosen that the reading of the weakest against the strongest was not more than two hundred drum divisions. The concentrations of the standard solutions were usually about 0.25 or 0.3 that of the saturated solution. $\Delta C/\Delta R$, the value of a drum division in grams per 1000 g. of solution, was calculated from the difference between the concentrations of A and B and from the interferometer reading of A against B. $\Delta C/\Delta R$ obtained in the same fashion from A and C served as a check on the value obtained. In some cases B was also read against C. This gave not only an additional check on the value of $\Delta C/\Delta R$ but also checked the accuracy with which the solutions were prepared. An average value of $\Delta C/\Delta R$ was then used in the solubility measurements. Dry pipets were used for sampling the solutions. The interferometer chamber was dried after every determination by a stream of warm air.

The concentration difference between A and C was so chosen as to give a reading of not more than two hundred scale divisions, because for larger differences the drum reading is not a linear function of the concentration except in special cases.[4] In the present work the linearity of drum reading against concentration over the range of two hundred divisions was checked directly by plotting the readings of A against B and A against C against the corresponding concentrations. Within the limits of accuracy necessary, a straight line was obtained in all cases. Concordant values of $\Delta C/\Delta R$ also gave a direct test of the linear relationship.

The saturated solutions of a substance under investigation were prepared by shaking an excess of the liquid or solid with about 500 g. of water in thin-walled cylindrical flasks in a large water thermostat. The thermostat was regulated at 30 ± 0.01° and at 15 ± 0.02°. In all cases the flasks were shaken for at least twelve hours, and in most instances they were shaken for a longer period of time. Samples were then withdrawn from two or three different saturation flasks and read against water in the interferom-

---

[4] Adams, This Journal, 37, 1181 (1915); Gans and Bose, *Z. Instrumentenk.*, 36, 137 (1916).

eter. Equilibrium was usually reached in less than twelve hours, as shown by the constancy of the readings of the saturated solutions at different time intervals. It was possible in most cases to reproduce the readings of the saturated solutions within two or three scale divisions of the interferometer drum. The values of $\Delta C/\Delta R$ were of the same order of magnitude for all aliphatic compounds. Also the values of $\Delta C/AR$ were of the same order of magnitude for all aromatic compounds.

The value of $\Delta C/AR$ in the case of a given aromatic compound could be employed to calculate approximately the amounts of substances necessary to make up the standard solutions of all other aromatic compounds. Likewise, the value of $\Delta C/\Delta R$ in the case of a given aliphatic compound could be used to calculate the amounts of substances needed to make up the standard solutions of all aliphatic compounds. The only other quantities needed were the readings of the saturated solutions of the substances in question. These readings when multiplied by $\Delta C/\Delta R$ would give the approximate concentrations of the saturated solutions. Then the amounts of substances which would give standard solutions of the desired concentrations could be calculated.

From the reading of the saturated solution and the average value of $\Delta C/\Delta R$, it was possible to calculate the extent to which the saturated solution would have to be diluted in order to give a reading of less than two hundred divisions when read against one of the standard solutions as a reference. Usually this difference was made about one hundred rather than two hundred divisions. The weight of water necessary for the dilution was put in a 500-cc. glass-stoppered volumetric flask. A two-holed rubber stopper carrying a glass siphon fitted with a stopcock was then placed in the saturating flask in the thermostat. The siphon was started by gently blowing into the flask. Enough of the saturated solution was allowed to siphon over and discarded to insure thorough rinsing of the siphon. Then a sample large enough to fill the volumetric flask to the mark was run into it. The sample was run in beneath the surface of the water in the volumetric flask in order to prevent loss by evaporation. The volumetric flask was immediately stoppered and weighed, thus giving the weight of the saturated solution added. The dilution of the saturated solution could then be calculated. A sample of this diluted solution was read in the interferometer against a sample of the standard solution. The standard solution chosen was usually the one whose concentration was between the standard with the lowest and the standard with the highest concentration, as the bottle containing this intermediate standard had had fewer samples removed from it. The concentration of the saturated solution was calculated from the reading of the dilution against the standard, the concentration of the standard, the value of $AC/$ AR and the dilution of the saturated solution.

In the case of some substances whose saturated solutions did not give a reading of over five or six hundred scale divisions against water, the values of $\Delta C/\Delta R$ were obtained by reading the standards directly against water. The saturated solutions were then diluted so as to give a reading of less than two hundred when read against water.

In all cases, duplicate determinations were run on samples from at least two different saturated solutions of the same substance. The 80-mm. chamber of the interferometer was used throughout except for the saturated solutions of some of the more soluble substances. In those cases, the 40-mm. chamber was employed.

The method used has several advantages. As mentioned above, it is not necessary to correct for the non-linearity of drum reading as a function of concentration since no reading exceeds two hundred divisions. Also, errors in dilution, reading of the interferometer, etc., will have a small effect on the precision of the final result since the reading is a difference measurement between the dilution and the reference solution. The reference solution can be prepared with a high degree of precision.

The method as used has the further advantage that it affords a check on the purity of the organic substances. Since varying amounts of the same substance were used in preparing different saturated solutions of the substance, if any soluble impurities were present, the interferometer readings for these saturated solutions would not agree with each other.

Materials

The chloroform, carbon tetrachloride and toluene were Baker's c. P. analyzed grade. All of the other organic substances were Eastman Kodak Co. best grade. The substances were purified by fractional distillation unless otherwise stated. For this purpose, two all-glass stills of the type described by Gross and Wright[5] were so designed that the thermometers were totally immersed in the vapor, eliminating exposed thread corrections. The large still had a capacity of one liter and had a fractionating column a meter long. The small still had a capacity of 250 cc. and had a column 0.5 meter long. Pressures were read on an accurate barometer. Temperatures below 105° were read on thermometers calibrated by the Bureau of Standards. For higher temperatures, a set of Anschiitz thermometers of good quality were used. Boiling points were corrected to 760 mm. by means of Craft's rule when dT/dP was not given in the literature. Unless otherwise stated, melting points were taken in open tubes on 5- or 10-g. samples.

Chloroform.—Two kilos were shaken for one hour with sodium hydroxide solution, washed twice with distilled water, shaken three times with concd. sulfuric acid, twice with distilled water, once with mercury and finally washed with distilled water and dried over calcium chloride as recommended by Harris.[6] The dried product was fractionated in the large still. A fraction of about 700 g. which boiled from 61.07-61.09" was used. Timmermans[7] gives a boiling point of 61.09–61.21'.

Carbon Tetrachloride.—This was purified according to the method of Williams and

Krchma.[8] One kilo was refluxed for eight hours over mercury, shaken twice with coned. sulfuric acid, shaken with dilute sodium hydroxide, washed with distilled water and dried over calcium chloride. It was then fractionated in the large still. A fraction of about 800 g. boiling at 76.74 ± 0 02" was used. Timmermans[7] gives a boiling point of 76.74–76.76°.

Benzene.—This material was a sample of benzene purified for another purpose according to the method of Richards and Shipley.[9] Baker's C. P. crystallizable benzene was shaken successively with sulfuric acid, water, sodium hydroxide solution, water and mercury; dried over calcium chloride and then over sodium, distilled through a long all-glass column and a fraction of about one liter boiling between 80.05–80.07° collected. This was then recrystallized three times by freezing, resulting in a sample of about 700 cc. with m. p. 5.40". This was dried over sodium in a glass-stoppered distilling flask for two years and was distilled directly from this flask into carefully dried bottles whose necks were sealed off after distillii the benzene into them.

Toluene.—The material was purified according to the method of Beal and Souther.[10] A fraction of 600 g. all of which came over at 110.74 ± 0.02" was used. Timmermans[11] gives a boiling point of 110.7°. "International Critical Tables" gives a boiling point of 110.5°.

Monochlorobenzene.—A fraction of approximately 700 g. all of which came over at 131.83 ± 0.02' was used. Timmermans[7] gives a boiling point of 131.99–132.01°.

Monobromobenzene.—A fraction of 700 g. boiling from 155.88 to 155.93° was used. Timmermans[7] gives a boiling point of 156.14–156.16".

Nitrobenzene.—A sample containing 700 g. of this material was distilled under reduced pressure using cork stoppers as recommended by Roberts and Bury.[12] The first and last portions were discarded. The distillate was fractionally frozen twice. A fraction of 400 g. melting at 5.7" was used. "International Critical Tables" gives a melting point of 5.7°.

Ethylene Bromide.—Two different samples were purified. The first sample, containing 250 g., was fractionally frozen five times according to the method of Biron.[13] A fraction of 125 g. melting at 9.7" was used. The second sample had a slightly yellow color before it was purified. Four hundred grams of it was fractionated. A sample containing 250 g. boiling from 131.19–131.29° was used. "International Critical Tables" gives a boiling point of 131.7". This fraction melted at 9.7°. Biron[13] gives a melting point of 10.012°.

Methylene Bromide.—Two samples were used. The first containing 100 g. was fractionated through a Hempel column. Nearly all distilled over at 97.2°. The second sample containing 300 g. was distilled in the small glass still. A fraction of 200 g. boiling from 97.13 to 97.23° was used. "International Critical Tables" gives a boiling point of 97.8°. Timmermans[14] gives a boiling point of 96.5°.

Normal **Butyl** Bromide.—Two hundred grams of this material was fractionated three times through a Hempel column. A fraction containing about 75 g. boiling from 101.52 to 101.72° was used. "International Critical Tables" gives a boiling point of 101.6°.

***p*-Dichlorobenzene.**—A sample melting at 52.7' was recrystallized twice from ethyl

alcohol. The product melted at 52.84°. "International Critical Tables" gives a melting point of 52.9'.

Bromoform.—A sample containing 500 g. was partially frozen once as recommended by Cauwood and Turner.[15] A fraction of about 350 g. melting at 7.7° was used. "International Critical Tables" gives a melting point of 7.7°.

Ethylene Chloride.—This was a portion of material previously purified.'

Ethyl Iodide.—The fraction used, which contained 125 g., boiled at 72 42°. Timmermans[16] gives a boiling point of 72.30°.

Normal Propyl Bromide.—A fraction of about 300 g. boiling from 70.97–71.08° was used. Timmermans[17] gives a boiling point of 71.0'.

Methylene Iodide.—A sample containing 300 g. of this material was shaken with sodium thiosulfate solution in order to decolorize it. It was then washed with distilled water, dried over potassium carbonate and fractionally frozen twice. A fraction of about 200 g. melting at 5.85' was used. "International Critical Tables" gives melting points of 5.2 and 5.7°.

Normal Propyl Iodide.—The sample of 200 g. was highly colored with iodine. It was decolorized by shaking with sodium thiosulfate solution. It was then washed twice with distilled water and dried for ten days over aluminum oxide. The dried substance was fractionated. A fraction of 100 g. boiling from 102.28 to 102.58° was used. Timmermans[11] gives a boiling point of 102.4°.

Carbon Tetrabromide.—This material was recrystallized once from ethyl alcohol and once from petroleum ether. It was found impossible to obtain a sharp melting point. Melting point determinations were carried out in an open tube using a 10-g. sample; in a capillary tube and in a sealed bulb. "International Critical Tables" gives a melting point of 91.1°. However, according to Biltz and Meinecke,[18] it is impossible to obtain a sharp melting point in an open tube due to partial decomposition of the carbon tetrabromide. In a capillary tube, the above authors found that the melting point was 92.5'. Our experience in the present work indicates a slight decomposition at the melting point.

***m*-Dinitrobenzene.**—This material was recrystallized three times from ethyl alcohol. The product used melted at 89.5'. "International Critical Tables" gives a melting point of 89.7".

***p*-Nitroaniline.**—This was recrystallized successively from ethyl alcohol, methyl alcohol, a mixture of ethyl and methyl alcohols, ethyl alcohol and finally from water. It was found to be impossible to obtain a sharp melting point. Melting points were taken in an open tube, a capillary tube and in a sealed bulb. In the capillary tube, all of the solid had disappeared at 147' but the sample did not melt sharply. The indications point to decomposition at the melting point. "International Critical Tables" gives 148° for the melting point. The value quoted in Beilstein and found in most of the literature is 147°.

Water.—Distilled water of good quality was obtained from the laboratory supply.

Results

The following substances were also purified with the intention of measuring their solubility: methyl iodide, trichloroethylene, ethylidene bromide, benzyl benzoate, isopropyl bromide, nitromethane and ethyl bromide. However, all of these substances were found to hydrolyze. The following

materials were available as Eastman Kodak Co. best grade: isopropyl iodide, tetrachloroethane, and tetrachloroethylene. These were found to hydrolyze. They were not further purified as from their nature and from the extent of hydrolysis it seemed likely that the existence of this hydrolysis was attributable not to impurities but to the substances themselves.

Hydrolysis was readily detected by the fact that constant interferometer readings of the saturated solutions could not be obtained, the readings continuing to increase over a period of time. Hydrolysis was confirmed in the case of the halogen compounds by appropriate tests for acid and halogen in the aqueous solutions. Nitromethane solutions showed increasing interferometer readings over a period of time. This was probably due to the formation of the pseudo acid as postulated by Hantzsch.[19]

[19] Hantzsch and Schultze, *Ber.*, 29,699,2251 (1896).

The solubilities of all the substances measured and the estimated errors of all determinations are given in Tables I and II. The error was estimated from values of duplicate determinations.

Rex[20] gives values for the solubilities of several of the substances measured in this investigation. Most of his values are higher than those obtained in the present work. As previously suggested by one of us,[3] this may be due to the possible loss of liquid in Rex's measurements. Also several of the compounds which he measured have been shown to hydrolyze in the present work, thus making the validity of his results doubtful in these cases. However, hydrolysis may not have introduced *a* significant error in his work if the determinations were completed in a sufficiently short interval of time.

Discussion

Attention may be drawn to a number of points of interest in connection with these data. The magnitude of some of the solubility values is surprisingly large for substances such as chloroform and ethylene chloride which are commonly thought of as "insolublc" in water. In view of this it would seem that water should at least be thought of when considering solvent media in which to carry out reactions involving such substances.

The existence of appreciable hydrolysis in the cases of a number of the compounds mentioned above, whose solubility we wished to determine, is of interest in connection with the statements found in the standard organic references that such hydrolysis does not occur. This indicates that the criteria commonly used to detect such hydrolysis are inadequate.

Lastly, this method of analysis or some modification of it would seem to have considerable promise as a method for studying reaction rates. We plan to investigate some of these hydrolyses from this point of view.

Summary

1. A modification of the existing methods for using the interferometer in the determination of the solubility of difficultly soluble liquids and solids in water and aqueous solutions is described.

2. The solubilities of a number of organic compounds in water at 30 and 15° are given.

EQUILIBRIUM IN SYSTEMS COMPOSED OF SULFUR DIOXIDE AND AMMONIUM OR AN ALKALI IODIDE[1]

BY H. W. FOOTE AND JOSEPH FLEISCHER

RECEIVED FEBRUARY 27, 1931 PUBLISHED MAY 6, 1931

Systems composed of sulfur dioxide and an alkali iodide have been investigated chiefly by Walden and Centnerzwer,[2] Ephraim and Kornblum,[3] and De Forcrand and Tabouris.[4] All the investigators mentioned have obtained solid addition products of the two components, but there is much disagreement as to their composition, due partly to the fact that the existing equilibrium conditions have not been sufficiently studied. The pressure–temperature data in the various systems are also incomplete and many results which are comparable do not agree closely.

We have determined the composition of the solid phases and the vapor pressure relations in the two component systems consisting of sulfur dioxide with sodium, potassium, rubidium, cesium and ammonium iodides between the maximum limits of −25 and +25°. The invariant points within this temperature range have also been determined. At room temperature, a slow reaction takes place between the components which results in the liberation of iodine. The reaction only becomes noticeable after several days, and it is not sufficiently rapid to offer difficulty in determining vapor pressures.

Method, Apparatus and Procedure

In two component systems like those under consideration, composed of a volatile and a non-volatile component, the equilibria involved, as well as the composition of existing compounds, can be readily studied through the medium of the vapor pressure relations, which are entirely analogous in principle to those in a system composed of a salt and water. A complete vapor pressure-composition isotherm of a system formed of sulfur dioxide and a salt with which it forms an addition product exhibits a sharp change in pressure at the composition of the pure compound, while constant vapor pressures are exhibited by the univariant systems on either side of the pure compound regardless of the relative amounts of the phases present. The determination of the vapor pressures of these univariant systems as a function of temperature fixes the limits of pressure and temperature between which the compounds formed are stable. The intersection of the

vapor pressure curves fixes the invariant points existing in the temperature range studied. If no addition products form, the vapor pressure relations are correspondingly simplified.

The measurements were carried out with an apparatus, the essential features of which are illustrated in Fig. 1 (not drawn to scale). The volume of the bulb was 29.3 cc. Tubes A, B, and C were each provided with a well-ground, mercury sealed stopcock. Tube A was attached to a manometer through a fused joint. The manometer was of the open type and was therefore used in conjunction with a calibrated barometer. The final pressures were rounded off to the nearest millimeter after the usual corrections. Tube B was connected with a two-liter suction flask which served as a vacuum reservoir. By means of a three-way stopcock, the reservoir could be connected with a pump, shut off, or opened to the air. Tube C connected with the supply of sulfur dioxide, which was dried by means of concentrated sulfuric acid.

A silvered Dewar flask of two liters' capacity served as a thermostat. Temperatures somewhat below 0° were obtained by mixtures of ice and sodium chloride. The lowest temperatures were produced by the additional use of ammonium chloride. The variation in temperature could be kept within about 0.1° for the time necessary for the systems to reach equilibrium. The thermometer used had been calibrated with considerable care.

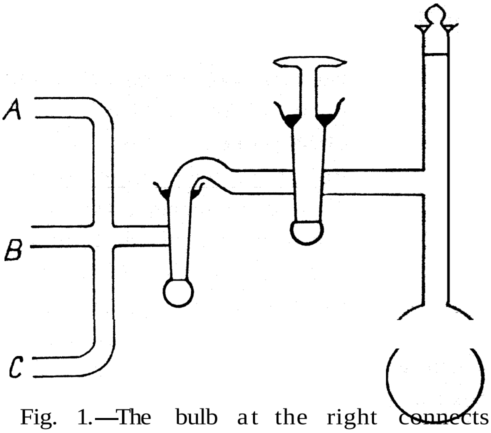

Fig. 1.—The bulb at the right connects through mercury-sealed stopcock and detachable ground-glass joint with the tubes A, B and C.

The salts were dried at 100° either in a vacuum or in a stream of dry air free from carbon dioxide. When necessary, the salts were purified by customary methods and in every case the purity was checked by analysis.

The experimental procedure was, in general, as follows. A weighed quantity of salt was introduced into the bulb, the stopper sealed in and the bulb and contents weighed. The bulb was then attached to the apparatus, the joint being sealed with mercury. The entire apparatus was then alternately evacuated and filled with sulfur dioxide to remove air. Twenty to thirty grams of sulfur dioxide was then allowed to condense in the bulb at a temperature of about −20°.

Before making any measurements, it was essential to insure the complete conversion of the original salt into its highest addition product. With salts rather insoluble in liquid sulfur dioxide, this was accomplished by allowing the finely ground iodide to stand for twelve hours or more in the presence of an excess of liquid. In all cases where the solubility allowed, the solid was brought completely into solution by removing the bulb from the bath and warming. The addition product was then crystallized from the solution by cooling and, if necessary, by evaporating a portion of the solvent. A vapor pressure–composition isotherm was usually carried out on this material at a temperature approximating −20° with the object of determining the univariant systems of three phases and the composition of any addition products. A temperature constant within several tenths of a degree was sufficient for this purpose. After the vapor pressure of

the saturated solution was determined, sulfur dioxide was allowed to evaporate at a pressure of some thirty or forty millimeters below this value until the material in the bulb was in equilibrium with this pressure, as indicated by the absence of any trend in the meniscus of the manometer when the system was closed. This procedure left a homogeneous solid in the bulb which was of necessity the highest addition product which could form at the temperature of the isotherm or at a higher temperature, and its composition could be calculated after weighing the bulb and making the proper small correction for the weight of sulfur dioxide present as vapor in the bulb at known temperature and pressure. If a second addition product existed, its composition was next determined in a similar manner.

The behavior of a compound as it warmed to room temperature in the bulb gave helpful information concerning the relations existing in the system. Decomposition into a liquid and a solid indicated the existence of a transition temperature between the temperature of the bath and that of the room; melting to a clear liquid indicated a congruent melting point; while the absence of any change showed that no invariant point existed in this temperature range.

In determining the vapor pressure curves of the three-phase univariant systems, the pressure reached the equilibrium value rapidly whenever a liquid phase were present if the bulb were shaken thoroughly. In such a case, the presence of the solid phase could be confirmed both visually and by checking for constant vapor pressure after withdrawing a portion of the sulfur dioxide. Such mixtures were allowed to stand for at least a half hour at constant temperature before the pressure was measured. In cases where two solids were present, instead of solid and liquid, equilibrium pressures were established rather slowly, more so when approached from higher pressures than from lower. The determinations were therefore made by averaging the value obtained from an initially lower pressure on standing for several hours with that reached from an initially higher value, a procedure which, on duplicating, proved to give satisfactory results.

When the vapor pressure curves had been determined for a system, it was frequently possible to determine the composition of a compound in the following simple manner which was applicable whenever the temperature could be adjusted to a value such that atmospheric pressure was intermediate between the vapor pressures of the saturated solution of the compound and that of the next lower univariant system. The bulb containing the saturated solution was immersed in a bath at such a temperature, and sulfur dioxide allowed to evaporate until the contents of the bulb were in equilibrium with a pressure of one atmosphere of sulfur dioxide; this could occur only when the liquid had disappeared. The evaporation was conveniently carried out by bubbling the gas through a thin layer of mercury serving as a trap, contained in a small vessel open to the air. By means of this contrivance, only the sulfur dioxide exerting a pressure greater than one atmosphere could escape and the point where evaporation was complete was indicated by cessation of bubbling. The composition of the compound could then be determined by weighing the bulb, Similarly, the composition of a lower addition product could be determined by repeating the same process at a higher temperature, where atmospheric pressure was intermediate between the pressure of the two univariant systems which limit the formation of the lower compound.

The vapor pressure data, with a few exceptions, were found to satisfy equations of the form

$$\log p = \frac{A}{T} + B$$

The exceptions all consisted of the saturated solutions of the compounds the solubility of which increased with temperature sufficiently to cause a divergence from the usual curve of vapor pressure. The heat of vaporization per mole of sulfur dioxide was calculated for the normal cases by the relation $\Delta H = 2.303$ AR, where R is the gas constant in calories, and A is the constant in the equation above.

Sodium Iodide and Sulfur Dioxide.—This system was first studied by Ephraim and Kornblum[3] and later by De Forcrand and Tabouris.[4] The former described two compounds, one yellow and the other red, to which they assigned the formulas $NaI \cdot 4SO_2$ and $NaI \cdot 2SO_2$, respectively. The latter found but one compound to which they gave the formula $NaI \cdot 3SO_2$.

In the present investigation it was found that on standing in contact with liquid sulfur dioxide below 0°, sodium iodide is converted to a bright yellow solid, $NaI \cdot 4SO_2$. The compound is rather insoluble in the liquid, to which it imparts, however, a pale red color. On evaporating the solvent, the compound crystallizes in the form of transparent pale yellow cubes. If heated in a closed system above a transition temperature of 1.4°, the compound melts incongruently and forms a bright red compound, whose composition as shown below corresponds to the rather unusual formula $3NaI \cdot 8SO_2$. The reverse change takes place readily on cooling below the transition point.

The composition of both compounds was determined as previously described, by evaporating sulfur dioxide at atmospheric pressure from the saturated solutions at temperatures where the vapor pressure data given below showed that only the pure compounds were stable. The temperature adopted for the higher compound was −8°, and for the lower, +8°.

The following results were obtained:

$NaI \cdot 4SO_2$			$3NaI \cdot 8SO_2$		
NaI, g.	SO_2, g.	Ratio $NaI:SO_2$	NaI, g.	SO_2, g.	Ratio $NaI:SO_2$
3.698	6.377	1:4.04	3.698	4.268	3:8.10
6.933	11.759	1:3.97	4.898	5.638	3:8.07
4.989	8.616	1:4.04	8.725	9.907	3:7.98
			9.778	11.248	3:8.07
			4.989	5.704	3:7.94

The compound to which we have assigned the unusual formula $3NaI\cdot8SO_2$ is undoubtedly the red compound to which the formula $NaI\cdot3SO_2$ was assigned by De Forcrand and Tabouris, and $NaI\cdot2SO_2$ by Ephraim and Kornblum. The former investigators prepared the compound by starting with a saturated solution at a low temperature and allowing the excess sulfur dioxide to evaporate at 0° and atmospheric pressure. While this method should, in principle, yield the lower compound ultimately in pure condition, it involves the primary formation of the higher 1:4 compound, followed by its subsequent decomposition, and the latter process is slow. The writers repeated this experiment of De Forcrand and Tabouris at 0° and after two hours the escape of sulfur dioxide nearly ceased and the empirical composition of the residue corresponded to $NaI\cdot2.96SO_2$. On raising the temperature to +3°, which is just above the transition point (1.4°), the excess of sulfur dioxide was converted to liquid and escaped in a few minutes, leaving a residue corresponding closely to the 3:8 ratio. Ephraim and Kornblum obtained the same red compound by passing sulfur dioxide over the iodide at 0° and atmospheric pressure, a procedure which should yield the pure compound. The experimental data reported by them (5.86 g. of sulfur dioxide absorbed by 5.15 g. of sodium iodide) yield the formula $3NaI\cdot7.98SO_2$, almost exactly the 3:8 ratio, and indicate that the pure compound was obtained, but that the results were misinterpreted, as the formula $NaI\cdot2SO_2$ was assigned.

The following vapor pressure data were obtained on the three univariant systems. Here and in all subsequent cases pressure is given in centimeters of mercury. Whenever applicable, the equation for calculating the vapor pressures is given, as well as AH.

I. $NaI\cdot4SO_2$–Solution–Vapor

The vapor pressure curves of systems I and II above intersect at +1.4°, a transition point where the four phases in equilibrium are the two addition products, solution and vapor. This temperature was also determined directly by immersing a bulb containing the compound $NaI\cdot4SO_2$ with its saturated solution in a bath of slowly rising temperature contained in a transparent Dewar flask and observing the temperature at which the red 3:8 compound first appeared. This temperature was found to be +1.5°, in close agreement with the result obtained from the vapor pressure curves.

Above the transition point, another univariant system exists, but the pressures were too high to be determined with safety in our apparatus. It consists of the phases $3NaI{\cdot}8SO_2$–solution–vapor.

The vapor pressure curves of the three systems are shown in Fig. 2.

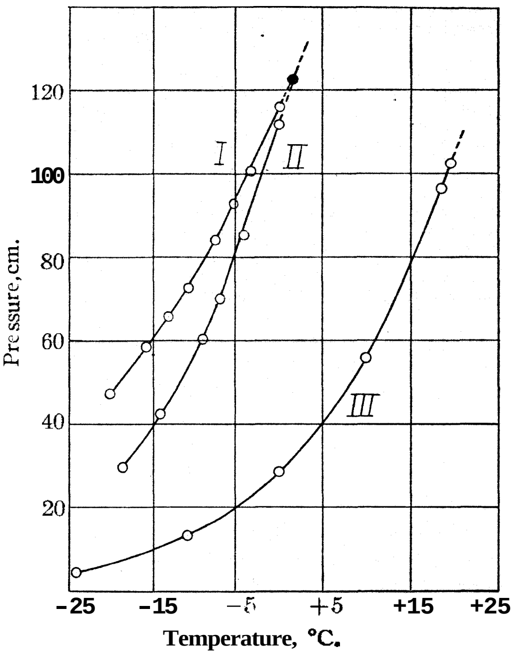

Fig. 2.—NaI–SO_2. Curves I. II and III represent, respectively, the systems $NaI{\cdot}4SO_2$–solution–vapor; $NaI{\cdot}4SO_2$–$3NaI{\cdot}8SO_2$–vapor; and $3NaI{\cdot}8SO_2$–NaI–vapor. The black dot represents the invariant system of four phases.

Potassium Iodide and Sulfur Dioxide.—Walden and Centnerzwer[2] have investigated the freezing point diagram of this system over a wide range of temperature and have described the compounds $KI{\cdot}4SO_2$ and $KI{\cdot}14SO_2$. The latter compound only exists at very low temperatures, below the range we have investigated. Pechard[5] and Fox[6] claim the existence of the compound $KI{\cdot}SO_2$, and Kistiakowsky,[7] the compound $2KI{\cdot}SO_2$. We have found no evidence that either of these compounds exists.

Isothermal evaporation of unsaturated solutions at pressures slightly below those of the saturated solutions between —20 and —5° left residues corresponding to the formula $KI{\cdot}4SO_2$, thus confirming Walden and Centnerzwer's formula. The following results were obtained

KI, g.	SO_2, g.	Ratio KI:SO_2	Temp., °C.
5.491	8.419	1:3.98	-18.3
5.159	7.951	1:3.99	-15.0
7.113	11.003	1:4.01	-12.0
6.680	10.352	1:4.02	- 7.6

---

[5] Pechard, *Compt. rend.*, 130, 1188 (1900).

[6] Fox, *Z. physik. Chem.*, 41, 458 (1902).

[7] Kistiakowsky, *J. Russ. Phys.-Chem. Soc.*, 34, 24 (1902).

The compound has a pale red color and crystallizes in cubes. The saturated solution has a pale yellow color at −20°, but due to the rapidly increasing solubility, the color deepens and the viscosity increases as the temperature rises. Withdrawal of sulfur dioxide from the compound at 0° results in the appearance of white potassium iodide, the pressure remaining constant until the sulfur dioxide is almost completely removed, thus showing the non-existence of compounds containing less sulfur dioxide. The vapor pressure curves of the three univariant systems are given in the following table and are plotted in the diagram (Fig. 3).

The three curves intersect at about +0.2°, which is the invariant point where the two solid phases, liquid and vapor, coexist. Walden and Centnerzwer[2] also determined this temperature (+0.26°) and considered it a transition point rather

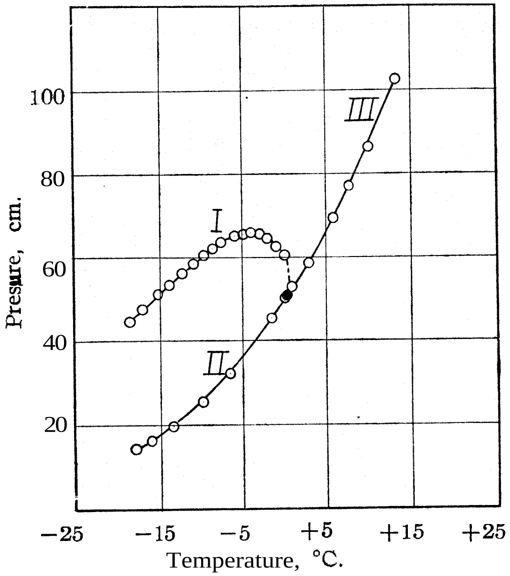

Fig. 3.—KI-SO_2. Curves I, II and III represent, respectively, the systems KI·$4SO_2$–solution–vapor, KI·$4SO_2$–KI–vapor, and KI–solution–vapor. The black dot represents the invariant system of four phases.

I. KI·$4SO_2$-Solution–Vapor

$$\text{Log } p = 8.345 - \frac{1814.3}{T}$$

$$\Delta H = 8300$$

than a eutectic, so that the melting point was incongruent. We found the pure compound, however, melted congruently to a clear liquid and the form of the vapor pressure curve (Fig. 3, I) also indicates that the pure compound melts slightly above the invariant point, which is therefore a eutectic rather than a transition point. In either case, the composition of the liquid at the invariant point is very close indeed to that of the compound $KI{\cdot}4SO_2$.

Rubidium Iodide and Sulfur Dioxide.—Rubidium iodide dissolves readily in liquid sulfur dioxide to give an orange-red solution. On evaporating this solution at 0° and atmospheric pressure, using the mercury bubbler, a solid residue of transparent yellow needles remained, the composition of which corresponded to the formula $RbI{\cdot}3SO_2$.

RbI, g	SO_2 g.	Ratio RbI:SO_2
4.376	4.045	1:3.06
4.971	4.577	1:3.05
4.608	4.217	1:3.03
5.125	4.719	1:3.05

Removal of sulfur dioxide from the solid compound caused the appearance of white rubidium iodide, and the pressure remained constant until the sulfur dioxide was almost completely removed; therefore, no lower compound exists. At room temperature the compound decomposed to a very viscous orange-brown liquid and solid rubidium iodide, indicating the existence of a transition temperature.

The vapor pressures of the univariant systems are shown in the following tables and Fig. 4. The vapor pressure curve of the saturated solution of the compound in liquid sulfur dioxide could not be determined over the entire range, as, at the higher temperatures, the pressures became too high for the apparatus, but the curve must display a maximum as indicated. The intersection of

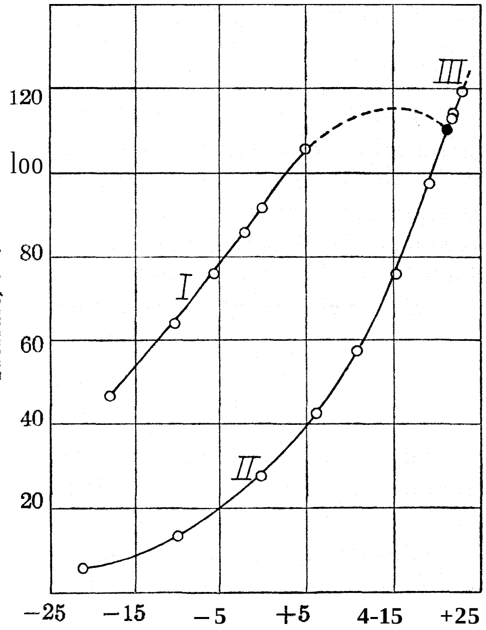

Fig. 4.—RbI–SO_2. Curves I. II and III represent, respectively, the systems $RbI{\cdot}3SO_2$–solution –vapor; $RbI{:}3SO_2$–RbI–vapor and RbI–solution –vapor. The black dot represents the in-variant system of four phases.

Curves II and III places the transition temperature at +21.3°; Curve I must meet the other curves at this point.

I. $RbI \cdot 3SO_2$–Solution–Vapor

19.20	97.4

$$\text{Log } p = 9\,836 - \frac{2294.0}{T}$$

$$\Delta H = 10{,}500$$

III. RbI–Solution–Vapor

T, °C.	p, cm.
+21.75	113.0
22.0	114.1
23.0	119.4

De Forcrand and Tabouris[4] found the same composition for the compound that we have found. Their result for the vapor pressure of the saturated solution at 0° is 82 cm., a value almost 10 cm. below ours, which was repeatedly checked on different samples of salt. Ephraim and Kornblum[3] state that rubidium iodide absorbed 4.4 moles of sulfur dioxide per mole of salt at 0°—an inexplicable result—and therefore assigned the formula $RbI \cdot 4SO_2$ to the compound.

Cesium Iodide and Sulfur Dioxide.—Cesium iodide dissolves readily in liquid sulfur dioxide, giving a pale red solution. Evaporation of the latter at 0° and atmospheric pressure left a residue of pale yellow needles of composition corresponding to the formula $CsI \cdot 3SO_2$, confirming the formula of De Forcrand and Tabouris.[4] Ephraim and Kornblum[3] assigned the formula $CsI \cdot 4SO_2$ to this compound.

The following results were obtained

CsI, g.	SO_2, g.	Ratio $CsI:SO_2$
5.144	3.946	1:3.05
4.844	3.693	1:3.03

Removal of sulfur dioxide from the compound resulted in the appearance of white cesium iodide and the pressure remained constant until the sulfur dioxide was nearly all removed, showing the absence of lower compounds.

The increasing solubility of the compound in liquid sulfur dioxide with rising temperature causes the vapor pressure curve of the saturated solution to diverge considerably from that of pure sulfur dioxide, although its form can be expressed by an equation of the usual type over the temperature range studied. At somewhat higher temperatures, the curvature probably reverses and the curves of the two univariant systems intersect. Following are the results of the vapor pressure determinations. The results are plotted in Fig. 5.

I. $CsI\cdot3SO_2$–Solution–Vapor

12.40	60.3
17.10	80.8
20.25	98.2

$$\text{Log } p = 9.629 - \frac{2240.6}{T}$$

$$\Delta H = 10,250$$

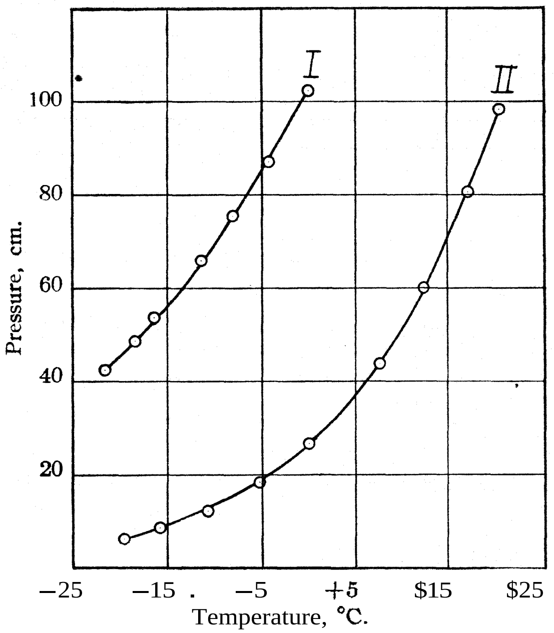

Fig. 5.—CsI–SO_2. Curves I and II represent, respectively, the systems $CsI\cdot3SO_2$–solution–vapor and $CsI\cdot3SO_2$–CsI–vapor

Ammonium Iodide and Sulfur Dioxide.—There appear to be no data in the literature on this system. Ammonium iodide dissolves readily in liquid sulfur dioxide forming a red solution. Evaporation of sulfur dioxide from unsaturated solutions to a pressure somewhat below that of the

NH_4I, g.	SO_2, g.	Ratio $NH_4I:SO_2$	Temp., °C.
4.883	6.647	1:3.08	−22
3.383	4.636	1:3.10	−19
5.980	8.160	1:3.09	−20

saturated solution, at three temperatures, left in each case a residue of yellow needles having the composition corresponding to $NH_4I \cdot 3SO_2$.

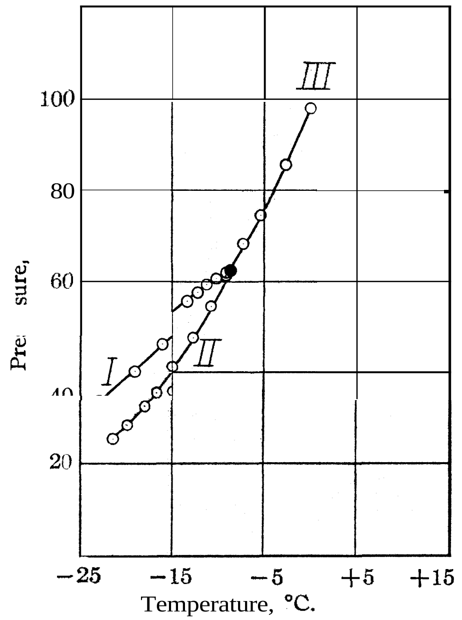

Fig. 6.—NH_4I–SO_2. Curves I, II and III represent, respectively, the systems $NH_4I \cdot 3SO_2$–solution–vapor; $NH_4I \cdot 3SO_2$–NH_4I–vapor; and NH_4I–solution–vapor. To avoid confusion, the results in the metastable region of curve III are omitted. The black dot represents the invariant system of four phases.

The existence of lower compounds was disproved by the fact that withdrawal of sulfur dioxide from the compound caused the appearance of white ammonium iodide and the pressure remained constant until sulfur dioxide was almost completely removed.

The existence of a transition temperature was indicated by the fact that on removal from the freezing bath, the compound $NH_4I \cdot 3SO_2$ decomposed to yield a liquid and a solid. The intersection of the vapor pressure curves of the three univariant systems placed the transition temperature at −8.8°. At this temperature, the phases in equilibrium are $NH_4I \cdot 3SO_2$–NH_4I–solution–vapor.

The vapor pressure data are given below and plotted in Fig. 6. It was possible to obtain some measurements on the system NH_4I–solution–vapor at temperatures below the transition point, a region in which the system is

metastable. As in the case of all the simple alkali iodides (as distinct from the addition products) the solubility of ammonium iodide in sulfur dioxide decreases with rising temperature.

Summary

The composition of the solid addition products and the vapor pressure curves limiting the stability of these compounds have been determined between the maximum limits of -25 and $+25°$ for the 2-component systems of sulfur dioxide with sodium, potassium, rubidium, cesium and ammonium iodides.

THE KINETICS OF THE DECOMPOSITION OF AMMONIA ON COPPER

BY J. K. DIXON[1]

RECEIVED FEBRUARY 27, 1931 PUBLISHED MAY 6, 1931

The decomposition of ammonia on the surfaces of certain metals has been studied by Hinshelwood and Burk, Schwab and Kunsman.[2] In each case the metal in the form of a hot filament has been used to decompose the ammonia. In order to obtain a true conception of a heterogeneous reaction a knowledge of the following is necessary: (1) the heats of adsorption of the gases involved in the reaction; (2) the amount of each gas adsorbed, as a function of its pressure; (3) the rates of adsorption of the gases; and (4) the law expressing the relation between the velocity of reaction and the pressures of the gases above the surfaces.[3] Except at low pressures, the use of a filament as a surface precludes any attempts to make measurements on the first three quantities. The object of the present work has been to study the kinetics of the decomposition of ammonia on copper, using enough of the metal to make later measurements on the first three factors possible.

Elod and Banholzer[4] have studied the decomposition of ammonia on copper and iron by a dynamic method. Their results on copper agree with those given here and can now be interpreted in a quantitative way.

Experimental

About fifty experiments on the decomposition of ammonia on forty grams of granular copper (see below) were performed in a static system.

The experiments were reproducible, but it was not possible to obtain an equation which would explain the rate of decomposition correctly. As only the general conclusions and a possible explanation of these experiments will be reported here, the details of the experiments will be omitted.

Experiments were then carried out in a dynamic system, from which it has been possible to set up an equation which expresses the rate of decomposition correctly.

Materials.—Ammonia from a tank was passed over fused potassium hydroxide and then through two tubes of anhydrous barium oxide. The latter removes water efficiently and does not react with ammonia. The gas obtained was completely absorbed by dilute sulfuric acid. Tank nitrogen (99.9%) was passed over copper turnings at 450°, then over solid potassium hydroxide and finally through phosphorus pentoxide. Tank hydrogen was passed over copper turnings at 350°, over potassium hydroxide and over phosphorus pentoxide.

Copper oxide, Kahlbaum's "pea-size," was sieved to 10–16 mesh and reduced in oxygen-free hydrogen. Since the temperature range studied in the catalytic reaction was 500–625°, the final twelve hours of reduction was made at 700°. The copper was strongly sintered, characterized by a true copper color.[5]

Apparatus and Experimental Procedure.—Ammonia passed from its purification train through a flowmeter and then over the copper catalyst. Hydrogen, nitrogen, or both, were added to the ammonia stream, as desired, before the latter entered the catalyst chamber. The amounts of added nitrogen and hydrogen were determined by suitable flowmeters. The amount of ammonia escaping decomposition in a definite length of time was found by absorbing it in dilute sulfuric acid of known concentration and titrating the excess acid with sodium hydroxide. The quantity of ammonia entering the catalyst chamber was known from the calibration of the ammonia flowmeter; hence, the percentage decomposition was easily calculated. It was possible to divert the "off" gases to a gas analysis apparatus by means of a three-way stopcock. The entire apparatus was constructed of Pyrex glass, the only rubber connection being used to lead the exit gases to the absorbing bottle.

Fig. 1.

The type of capillary used in the flowmeters is shown in Fig. 1. It is recommended because it is easily made, does not become clogged, gives a gas flow proportional to the pressure head and can be made to give small flow rates when the pressure head (mercury) is appreciable. For each of the gases, the pressure head on the flowmeter was kept constant by means of an overflow in the gas purification train. The hydrogen and nitrogen flowmeters were standardized by "displacing" water and, in the case of small flow rates, by using mercury in place of water. The accuracy was ±1.0%. The ammonia flowmeter was standardized by titration, the accuracy being ±0.3%. Since the ammonia flow rate decreased as the room temperature increased, the flowmeter was calibrated three or four times a day and hence it was unnecessary to calculate the corrections to be applied on account of these temperature variations.

Thirty-five grams of the copper catalyst, with an apparent volume of 15 cc., was held in an unfused quartz vessel, whose volume was 25 cc. and to which were attached inlet and outlet tubes. Connection with the rest of the apparatus was made by means of graded quartz to Pyrex seals. The inlet gases passed down through the furnace

---

[5] When the oxide is reduced at 180–200°, it has a purple appearance.

and then entered at the bottom of the catalyst chamber. A furnace, wrapped with nichrome wire and electrically heated, was drawn up about the catalyst tube and the free space in the furnace filled with iron rods in order to equalize the temperature. A chromel–alumel thermocouple was fixed against the catalyst tube at the mid-point of the catalyst and the temperature determined in this way has been taken as that of the catalyst. The furnace was well insulated with asbestos; consequently the maximum temperature variation during an experiment was ±1°.

The experimental procedure was, first, to pass a suitable gas mixture over the catalyst for ten to fifteen minutes at the temperature of the experiment in order to assure constant conditions above the surface. Then the ammonia in the "off" gases was absorbed in approximately 50 cc. of standard sulfuric acid for a suitable length of time and the excess acid determined by titrating back with sodium hydroxide, using methyl orange as indicator. A small correction was determined and made for the amount of ammonia escaping absorption in the acid. This correction proved to be negligible except for high rates of flow of nitrogen or hydrogen. Three or four runs were performed for each gas mixture and the mean of these results has been used in subsequent calculations. In any experiment the values of the percentage decomposition vary among themselves by not over 1%. When the mean is compared with that for the same experiment performed at a different date, the variation is not over ±5%.

Results and Interpretation

The rate of decomposition has been studied at 495.5, 542.5, 581.5 and 619.5°. In Table I are given the results of the experiments at 542.5 and 581.5°; the results at 495.5 and 619.5° are analogous. The flow rates throughout are expressed in cc. per minute reduced to 25° and 760 mm. pressure. In the first column is given the experiment number, in the second the temperature in degrees centigrade, and in the third the volume of ammonia entering the catalyst tube per minute. The fourth column gives the percentage of ammonia decomposed, the fifth the hydrogen inlet flow rate and the sixth the inlet flow rate of nitrogen.

If we consider any small element of length of the catalyst tube containing an amount of surface, dA, then the rate of disappearance of ammonia per minute is proportional to this surface area. The composition of the gas above this surface is assumed to be constant. If we let V be the total flow rate of gas over dA, v the flow rate of ammonia, v_{H} the flow rate of hydrogen and v_{N} that for nitrogen, each in cc. per minute, then

$$V = v'_{\mathrm{H}} + v'_{\mathrm{N}} + 2v' - v \tag{1}$$

The primed quantities refer to the flow rates of the inlet gases. The pressures of ammonia, hydrogen and nitrogen are

$$p = \frac{v}{V}P \qquad p_{\mathrm{H}} = \frac{v_{\mathrm{H}}}{V}P \qquad p_{\mathrm{N}} = \frac{v_{\mathrm{N}}}{V}P \tag{2}$$

where P is the total pressure, which is the barometric pressure in this case. The experiments indicate that the rate of decomposition of the ammonia is proportional to p and inversely proportional to p_{H}. If dv is the amount of ammonia decomposed per minute on the surface dA, then

$$-\mathrm{d}v = k\,\mathrm{d}A\,\frac{p}{p_{\mathrm{H}}} = k\,\mathrm{d}A\,\frac{v}{v_{\mathrm{H}}} \quad \text{or} \quad -\frac{v_{\mathrm{H}}\mathrm{d}v}{v} = k\,\mathrm{d}A$$

TABLE I

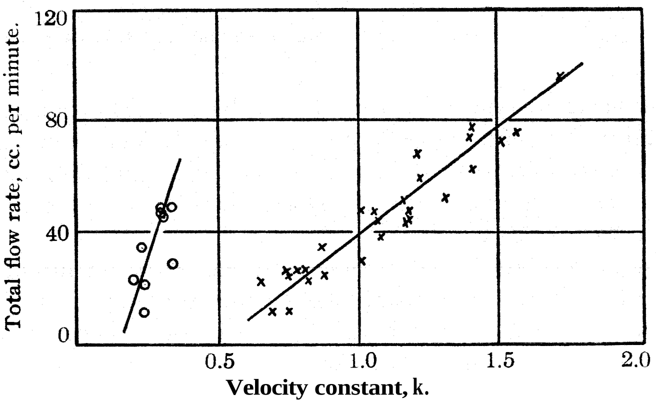
k representing the number of cc. of ammonia decomposed per minute on unit surface when $p = p_H = 1$ atmosphere. When $A = 0$, $v = v'$, $v_H = v'_H$ and $v_N = v'_N$; when $A = A_1$, the total area of the catalyst, then $v = v_f$, which is calculated from the percentage decomposition. Therefore

$$-\int_{v'}^{v_f} \frac{v_H dv}{v} = -\int_{v'}^{v_f} \frac{(2/3\, v'_H + v' - v)\, dv}{v} = 2/3\, kA_1, \text{ or} \qquad (3)$$

$$(2/3\, v'_H + v') \ln \frac{v'}{v_f} - v' + v_f = 2/3\, kA_1 = k_1$$

The barometric pressure is given in the seventh column of Table I and the calculated values of k_1 in the eighth column. The latter are not quite constant, but increase with the flow rate, as illustrated in Fig. 2. If the velocity of decomposition is assumed to be proportional to $p/(1 + k_2p)$ instead of p, it is possible to account for the increase of k_1 as we add nitrogen, that is, increase the total flow rate. Since the activity of the catalyst increased slightly with time and the experimental accuracy of the determination of the percentage decomposition was about ±5%, the introduction of a second constant, k_2, is not warranted. If, for example, in Expt. 10, Table I, we assume that the percentage decomposition is 23.6, then k_1 becomes 1.06. That is, an error of 10% in the percentage decomposition makes an error of 20 to 25% in k_1. In Expt. 37, where the amount of added hydrogen is large and the percentage decomposition small, the experimental error may be greater than 5%, hence the agreement of the constant with those from other experiments is satisfactory.



⊙, 542.5"; X, 581.5 °.

Fig 2.—The dependence of the velocity constant on the total flow rate.

In Expts. 11, 37 and 42 the average ammonia pressures are 62, 22 and 10 and the average hydrogen pressures 10, 53 and 3.7, respectively, in centimeters of mercury. The pressure range for ammonia is from 10 to 60 cm. and the range of hydrogen pressures 4 to 50 cm.

The results of the experiments in the static system agree in some respects with those of the dynamic method. Nitrogen had no effect on the rate of decomposition of the ammonia. A number of experiments were made with the same initial pressure of ammonia, but varying initial pressures of added hydrogen. The results are given in Table II, in which the first column gives the initial pressure of ammonia, the second the *initial* pressure of hydrogen, and the third the initial slope of the pressure–time curve.

The reaction velocity is seen to be very nearly inversely proportional to the hydrogen pressure. The velocity constants, k, calculated from the results of the static experiments by means of the equation

$$-\frac{d\,p_{NH_3}}{dt} = \frac{k\,(p_{NH_3})^n}{(p_{H_2})^m} \qquad (4)$$

with $n = m = 1$, drop off as the reaction proceeds. It would be necessary to assume that $n > 2$ and $m > 1$, and neither a whole number, in order to obtain a true constant. Such a procedure has been adopted by Schwab and

Schmidt in order to explain their results on the decomposition of ammonia on a platinum filament, above 25 mm. pressure.[2c] They were the first to point out the complexity of the reaction mechanism and their experiments showed the same rapid decrease in velocity with time which we have observed in a static system.

It seems more plausible to assume a simpler reaction mechanism and that the falling off in rate is partly due to a covering of the surface by an unstable nitride or other compound. In the case of copper it is known that copper oxide and ammonia react to form a nitride,[6] and Beilby and Henderson[7] report the formation of copper nitride by the action of ammonia on copper at high temperatures. The question of a nitride formation was investigated in the dynamic system. An analysis of the "off gas from the catalyst was carried out at various times during the kinetic studies. Table III shows that the ratio of the hydrogen formed to the sum of hydrogen and nitrogen is that which we would expect if none of the nitrogen were disappearing to form a nitride.

Since the amount of nitrogen held by the copper might have been very small compared with the total set free by decomposition or since the nitride might have formed and remained in a nearly constant amount,[8] a different procedure was adopted to detect a possible nitride formation under the conditions of the kinetic studies. A sample of Kahlbaum's

copper oxide, 17.7756 g., was reduced completely in pure hydrogen at 300°. The weight of copper expected was 14.201 g. and the value found was 14.229 g. Pure ammonia was then passed over this heated catalyst, decomposition beginning at 410°. The temperature was raised to 500–550°, where the rate of decomposition of the ammonia was high. The copper with its containing tube was cooled from time to time and weighed, but there was no increase in weight. Finally, the ammonia was passed over the copper continuously for three days and the weight was again determined and found to be the same. During the course of the treatment with ammonia the weight of the copper decreased 0,002 g.

The negative results of these experiments do not disprove that a trace of some compound might be formed on the surface which would inhibit the reaction considerably. Experiments of the type described by Mittasch and Frankenburger[9] might yield information with regard to compound formation.

The Temperature Coefficient.—The heat of activation, E, of the decomposition on copper has been determined from the reaction velocity constants at 495.5, 542.5, 581.5 and 619.5°. E in calories per mole has been calculated by means of the equation

$$E = 2.303 \left(\log_{10} \frac{k_2}{k_1}\right) \left(\frac{T_1 \times T_2}{T_2 - T_1}\right) \qquad (5)$$

R is the gas constant expressed in calories per mole per degree; k_2 and k_1 are the velocity constants at the absolute temperatures, T_2 and T_1, respectively. The values of $\log_{10} k$ corresponding to a certain total flow rate of gas have been plotted against $1/T$, the resulting curve being a straight line. The slope of the curve was used to calculate E. In Table IV the first column gives the temperature in degrees centigrade, the second the total gas flow rate, the third the velocity constant and the fourth column the energy of activation, E.

Table IV

The Energy or Activation for the Decomposition of Ammonia on Copper

t, °C.	V, cc./min.	k	E, cal./mole
542.5	12	0.20	42,000
581.5	12	.65	
495.5	25	.041	
542.5	25	.24	46,500
581.5	25	.82	
619.5	25	2.80	
495.5	50	0.041	
542.5	50	.32	47,500
581.5	50	1.15	
619.5	50	3.90	

The most probable value of E is 46,000 ± 2000 calories per mole.

The Results of Elöd and Banholzer

Eldd and Banholzer[10] have made measurements on the decomposition of ammonia on copper by a dynamic method which was essentially the same as we have used here. Their results may now be explained by assuming the same reaction mechanism, that is, by using equation (3) to calculate velocity constants. A few typical calculations of their results are given in Table V. The first column gives the table number and the second column the experiment number from their paper. The notation in the other columns is consistent with that used in our Table I, except that the flow rates are in terms of cc. per hour, hence k_1 is expressed in these units.

TABLE V

THE DECOMPOSITION OF AMMONIA ON COPPER ACCORDING TO ELÖD AND BANHOLZER

$t = 700°$[a]

Table	Expt.	v'	v'_H	v'_N	k_1	Table	Expt.	v'	v'_H	v'_N	k
2	1	180	0.0	0.0	28	3	1	1191	0.0	0	26
2	4	2260	.0	.0	33	3	3	1292	.0	1000	35
2	7	5340	.0	.0	37	3	4	1292	.0	5000	31
2	8	7700	.0	.0	23	3	5	1353	.0	10000	35
2	9	11400	.0	.0	35	3	6	1212	.0	16000	31[b]

[a] The temperature is not given, but a comparison with their Table VIII shows that it is probably 700°.

[b] Experiments 7–10 give values of $k_1 = 15$–20, but the value for the percentage decomposition in Erpt. 9, with $v'_N = v'_H = 0$, does not agree with Expt. 7 of Table II.

The heat of activation calculated from the values of k_1 at 600 and 700" is 63,000 calories per mole (Ref. 4, Expts. 5 and 6, Table VIII). The percentage decomposition measured at 600° was 3.7, too small to be accurate, and this may account for the high value of the heat of activation.

In Table VI are given some of the values of k_1, according to Equation 3, calculated from the experiments of Elöd and Banholzer for the decomposition of ammonia on an iron catalyst in a flowing system.

TABLE VI

THE DECOMPOSITION OF AMMONIA ON IRON ACCORDING TO ELÖD AND BANHOLZER

$t = 700°$

Table	Expt.	v'	v'_H	k_1[a]	Table	Expt.	v'	v'_H	k_1
1	2	554	0.0	826	6	7 and 8	1135	10000	1495
1	4	2438	.0	1055	7	2	2229	2000	1070
1	6	4480	.0	1365	7	5 and 4	3504	3500	1005
1	9	10015	.0	1805	7	6 and 7	5513	5500	1275
6	2	1063	1000	1150	7	8	8333	8000	1320
6	5 and 6	1129	5000	1305					

[a] Nitrogen has no effect.

The heat of activation calculated from the values of k_1 at 600 and 700° is 37,900 calories per mole. It should be noted that k_1 increases as the flow rate increases in the same general way as we have found for copper.

The Poisoning Effects of Carbon Monoxide

It is known that carbon monoxide has a higher heat of adsorption an copper than hydrogen and ammonia[11] and, therefore, in small traces, should have a pronounced inhibiting effect on the decomposition of ammonia. Carbon monoxide from formic acid and sulfuric acid was purified and dried carefully and then added to the ammonia stream before the latter reached the copper catalyst. The percentage decomposition of the ammonia was determined in the usual way. Carbon monoxide reacts with ammonia to form hydrogen cyanide and water. The "effect" of carbon monoxide which has been measured is due to the sum of the effects of carbon monoxide, water and hydrogen cyanide. The results of the experiments are given in Table VII and are interesting because the first trace of carbon monoxide produced an appreciable lowering of the rate of decomposition; but subsequent increase in the amount had little added effect.

TABLE VII

THE EFFECT OF CARBON MONOXIDE ON THE DECOMPOSITION OF AMMONIA ON COPPER

$t = 581.5°$

NH_3 per minute, cc	CO per minute, cc	% NH_3 decomposed	Expt.
32.3	0.00	21.60	1
32.3	.30	18.00	2
32.3	.79	18.20	3
32.3	1.34	18.00	4
43.8	0.00	18.40	5, 9, 10, 12
43.8	.35	15.65	8, 11
43.8	.70	15.40	7
43.8	1.20	14.86	13
43.8	1.35	14.85	6

The copper used had been sintered at 700° (see Materials) and consequently possessed a nearly uniform surface. A very small partial pressure of carbon monoxide was sufficient to cover the few active patches remaining on the catalyst; but further increase in its pressure required that the carbon monoxide compete for a portion of the uniform surface and its effect was then necessarily very similar to that of adding hydrogen. The discussion which follows throws some doubt on this explanation, but it is presented nevertheless.

Discussion

Since the rate of decomposition of ammonia has been found to be proportional to the ammonia pressure and inversely proportional to the hydrogen pressure, we can say that the surface of the copper is almost completely covered with hydrogen and that the amount of surface available for ammonia adsorption is small. The fraction of this available surface which is covered with ammonia is proportional to the ammonia pressure.

[11] Taylor, *Z. Elektrochem.*, 35, 542 (1929).

It is surprising that this simple explanation fits the facts over wide ranges of pressures. The observed heat of activation of 46,000 calories per mole is probably the true value since Beebe and Taylor,[12] and Dew and Taylor,[13] have found nearly the same values for the heats of adsorption of hydrogen and ammonia on copper, 9600 and 9200 calories per mole, respectively. The results of the experiments with carbon monoxide, which show a small fraction of the surface is abnormally active, will not alter this conclusion materially.

The use of heats of adsorption to predict catalytic activity meets with serious objections in the light of recent experimental work. When pure ammonia was passed over copper at 581.5°, the average ammonia pressure above the metal was about 60 cm. and the average hydrogen pressure about 10 cm. In the ratio of 6:1, the hydrogen nearly completely covers the surface of the metal. Hence, if the accommodation coefficients of the two gases are the same, the rate of evaporation of hydrogen from the surface must be very much smaller than that of ammonia. To consider this particular case more closely, let k_2 and k_2' be the rates of evaporation of ammonia and hydrogen, respectively, at 581.5°, each for unit area of covered surface. It is easily shown that k_2'/k_2 has the values 1/54, 1/114, 1/594 when the ratio of the fraction of the total surface covered by hydrogen to that covered by ammonia has the values 9:1, 19:1 and 99:1, respectively.[14] The pressure of hydrogen has been taken as one-sixth that of the ammonia. Hinshelwood[15] assumes that

$$k_2 = b_2e^{-\lambda/RT} \quad \text{and} \quad k_2' = b_2'e^{-\lambda'/RT} \tag{6}$$

where λ and λ′ are the heats of desorption and the b's are constants. Using the ratios of k_2'/k_2 as given above and letting $b_2 = b_2'$, it is found that $\lambda' = \lambda + 2200$, $\lambda + 8100$ and $\lambda + 10{,}900$, respectively. The constant b_2 must be 10^3 to 10^4 times as large as b_2' in order for λ′ to equal λ. Although measurements cannot be made at high temperatures, it does not seem probable that the heats of adsorption differ by such values at high pressures. For practical purposes at least the use of equation (6) is doubtless incorrect.

Further evidence that these equations are not correct has been discussed by Taylor.[16] In some cases a gas with a higher heat of adsorption can be pumped off a metal much more easily than a gas with a lower heat of adsorption. Unless the constant b varies enormously from gas to gas, the rate of evaporation is influenced by some other factors besides the heat of adsorption. Recently Benton and White[17] have reached the conclusion that when

hydrogen is adsorbed by nickel above −100° the adsorbed gas is activated, possibly existing as atomic hydrogen. In this ease the rate of evaporation would not be determined solely by the heat of desorption. The same conclusion is probably true for copper.

From three different viewpoints we are led to the conclusion that the equations (6) are not correct and, therefore, it is not correct to assume that the true heat of activation of a heterogeneous reaction is equal to the observed heat of activation, minus the heats of adsorption of the reactants, plus the heats of adsorption of the products which retard. Experiments on the rate of adsorption of gases by copper are in progress, from which we should be able to draw more definite conclusions with regard to various points in the foregoing discussion.

I wish to thank Professor Hugh S. Taylor for suggesting this problem and for his constant advice and criticism.

Summary

The kinetics of the decomposition of ammonia on copper have been studied by a dynamic method. The experiments were made on a large amount of catalyst between 495 and 620° with ammonia and hydrogen partial pressures between 4 and 50, and 10 and 60 centimeters of mercury, respectively. The rate of decomposition was proportional to the ammonia pressure and inversely proportional to the hydrogen pressure. Experiments in a static system confirmed the facts that the rate was inversely proportional to the hydrogen pressure and independent of the nitrogen pressure. There was no appreciable formation of copper nitride under the conditions of the experiments. The heat of activation of the reaction was 46,000 ± 2000 calories per mole. Carbon monoxide in small amounts poisoned the surface of the copper; the first amount had the greatest inhibiting effect.

Some objections to the use of heats of adsorption in calculating true heats of activation of heterogeneous reactions have been pointed out. Measurements on rates of adsorption of gases by copper are in progress.

THE USE OF BUFFERED AMMONIA IN THE IODIMETRIC THIOCYANATE DETERMINATION

BY H. ARMIN PAGEL AND HERMAN J. KOCH

RECEIVED FEBRUARY 27, 1931 PUBLISHED MAY 6, 1931

The suitability of borax as a non-volatile alkaline buffer to accelerate the oxidation of thiocyanate with iodine was shown by Pagel and Ames.[1] **A.** Schwicker[2] used a solution of ammonium borate as buffer (synthetically prepared by adding approximately the equivalent amount of boric acid to ammonia). Both methods give accurate results.

In case, however, it is desired to determine borate in the same sample, both of the above methods would be undesirable. Schwicker suggests that dilute ammonia accelerates the oxidation, but that there is danger of the formation of insoluble iodides of nitrogen unless the ammonia is added with extreme care; hence he discourages its use.

We have found, however, that the proper amount of dilute ammonia containing about an equivalent amount of ammonium salt does not react irreversibly with iodine, even with a large excess of iodine on long standing. Furthermore, a fixed volume of this solution gives accurate results independent of a wide range of volume and of thiocyanate (Table III). From the oxidation reaction in alkaline medium

$$NCS^- + 4I_2 + 8OH^- \longrightarrow SO_4^{=} + 7I^- + 4H_2O + ICN \qquad (A)$$

it is apparent that equivalent amounts of hydroxyl and iodine are required, Upon acidification the iodocyanogen again reacts with iodide, liberating free iodine; hence the net reaction used as a basis of computation is

$$NCS^- + 3I_2 + 4H_2O \longrightarrow SO_4^{=} + CN^- + 8H^+ + 6I^- \qquad (B)$$

With this in view an amount of ammonia was chosen which should contain sufficient reserve hydroxyl to provide for the oxidation of a large amount of thiocyanate, and still not be too alkaline in case only small amounts of thiocyanate were present. Thus, for instance, 20 cc. of 1 N ammonia should provide for 150 cc. of titration with 0.1 N iodine and still leave in excess 5 cc. of 1 N ammonia to insure complete oxidation. It should also be noted that large amounts of additional ammonium salts do not interfere with either the accuracy or the time required for complete oxidation.

Materials and Apparatus.—The preparation of solutions and type of apparatus used in this work was in general identically as described in a previous publication.[1] The additional reagents used were all "Highest Purity;" nevertheless blanks were run in all cases to detect traces of thiocyanate or other interfering impurities.

---

[1] Pagel and Ames, THIS JOURNAL, 52,2698, 3093 (1930).

[2] A. Schwicker, Z. *anal. Chem.*, 77,278 (1929).

Experimental

Various amounts of ammonium sulfate (ranging from 1 to 6 g.) were dissolved in 20 cc. of 1 N ammonia and the resulting solution diluted with water to 150 cc. Then 35 cc. of 0.1 *N* iodine was added and the mixture allowed to stand from five to fifteen minutes in a dark cupboard. After acidifying with 5 cc. of 6 *N* hydrochloric acid, the iodine was immediately titrated slowly with thiosulfate, using starch indicator after the iodine color had been almost completely discharged. The equivalent amounts of iodine were also prepared from pipetted portions of standard iodate and 3 g. of potassium iodide, treated with a slight excess over the calculated amount of hydrochloric acid. The buffered ammonia solution was then added to the liberated iodine and the procedure completed as above. In both cases the thiosulfate titrations agreed identically with values obtained in the iodine–thiosulfate ratios determined in the usual manner. Ammonium chloride and nitrate substituted for the sulfate likewise gave perfect results. The analyses of known amounts of thiocyanate (tabulated in Tables I, II and III) were carried out according to the method given in the procedure below.

Procedure

The solution containing the thiocyanate in a volume of 150 to 300 cc. should be practically neutral to litmus. Any excess of strong acid or base should be neutralized. Slight acidity or alkalinity due to hydrolysis of salts may be ignored. If heavy metals which produce insoluble hydroxides are present, ammonia is added until faintly alkaline to litmus. The buffer solution containing 1 g. of ammonium salt (sulfate, chloride or nitrate) dissolved in 20 cc. of 1 N ammonia is then added and the mixture treated with standard iodine with a minimum excess of 5 cc. This excess is determined with sufficient accuracy by comparing colors with 5 cc. of iodine in a similar volume of water. (This reference solution should be prepared before starting the titration.) A larger excess of iodine does no harm. After standing for four to five minutes the solution is acidified with an excess of about 5 cc. of 6 *N* hydrochloric acid and the excess iodine immediately titrated with standard thiosulfate.

In case standard iodate is used as a source of iodine, certain modifications may be necessary. If the salts of heavy metals or of weak acids are absent, the iodate and potassium iodide may be added directly to the neutral solution of thiocyanate. A small excess of hydrochloric acid (1 or 2 cc. of 1 *N*) in addition to the calculated amount is then added. (A large excess of acid must be avoided since this would unnecessarily neutralize large amounts of the ammonia buffer.) The ammonia buffer solution is then added, the mixture allowed to stand for four to five minutes and the determination completed as stated above.

In case heavy metals or salts of weak acids are present, the iodine must be liberated in a separate flask, and the faintly alkaline mixture containing the thiocyanate is added to the liberated iodine. The ammonia buffer may be added either to the liberated iodine or the faintly alkaline thiocyanate mixture.

Table I shows the results obtained using standard iodine, with 20 cc. of 1 N ammonia and 6 g. of the given ammonium salt as buffer. The volume during oxidation was approximately 150 cc. Five minutes was allowed for complete oxidation. Identical results were obtained in fifteen minutes. The excess iodine to that required for reaction (A) ranged from approximately *5.3* to 6.5 cc. (namely, the difference between "iodine added" and $^4/_3$ times "calcd. iodine").

As previously stated, Table III shows that 20 cc. of 1 N ammonia even in the presence of large amounts of ammonium salt provides for large amounts of thiocyanate. Borax does not interfere; furthermore, large amounts of precipitated hydroxides have no effect on the completeness of oxidation. In a series of comparable determinations (not shown), it was found that the oxidation was apparently complete in two minutes, but four to five minutes is recommended in all cases.

In Table III, 20 cc. 1 N ammonia containing 1 g. of ammonium sulfate was used as buffer. The additional salts added are listed.

Nickel, cobalt and manganese, even in relatively small amounts, produced very erratic results.

Summary

It has been shown that the proper amount of ammonia treated with ammonium salts gives the proper alkalinity for the rapid iodimetric determination of thiocyanate, over a wide range of conditions.

Data, and the details of procedure, and also a citation of some interfering metallic radicals, have been included.

EQUILIBRIA IN THE IRON–NITROGEN SYSTEM

BY STEPHEN BRUNAUER, M. E. JEFFERSON, P. H. EMMETT AND S. B. HENDRICKS

RECEIVED FEBRUARY 28, 1931 PUBLISHED MAY 6, 1931

In a previous paper[1] the values of the equilibrium constants for the reaction

$$2Fe_4N + 3H_2 = 8Fe + 2NH_3 \quad K_1 = (P_{NH_3})^2/(P_{H_2})^3 \tag{1}$$

were reported at various temperatures and with their help the dissociation pressures of Fe_4N were calculated. While these experiments were being extended to iron nitrides of higher nitrogen content, Lehrer,[2] Eisenhut and Kaupp[3] and Lehrer[4] published exhaustive studies of both the iron–NH_3–iron nitride–H_2 and the iron–nitrogen system by magnetometric and x-ray methods. The investigations in the present paper have been restricted to (1) the extension of our equilibrium data on the above reaction to 400 and 575°; (2) a determination of the equilibrium constants for the conversion of Fe_4N into the higher nitrides by NH_3–H_2 mixtures at 400, 444 and 500°; and (3) a study of the equilibria at 400 and 444° within the solid solutions formed by the higher nitrides. Some additional information has also been obtained relative to the purity of the Fe and Fe_4N phases involved in reaction (1). In the designation of the solid phases we have adopted the nomenclature of Hägg.[5] Iron containing only as much nitrogen as may dissolve in it below the P_{NH_3}–P_{H_2} ratio necessary for its conversion into Fe_4N constitutes the a-phase. The nitride approximating Fe_4N in composition over the temperature range studied is the γ'-phase. The ϵ-phase is the series of solid solutions ranging in composition from approximately that of Fe_3N to that of Fe_2N in our experiments.

Apparatus and Experimental Procedure

A dynamic system similar to that described in our previous paper was used. Hydrogen–ammonia mixtures of definite compositions were passed over a sample of iron at a fixed temperature. The gases were obtained and purified in the manner previously described.[1] Calibrated water-jacketed flowmeters permitted mixing the two gases accurately in any desired proportion immediately before passing them over the sample. All readings were corrected to the temperature and pressure at which the flowmeters were originally calibrated.

The iron used was obtained by the reduction in hydrogen of C. P. ferric

oxalate. Iron reduced from ferric oxide has also been tried, but it cracked ammonia appreciably at 444°.

The glass reaction vessel was similar to that described in the previous paper. An attached side tube which was kept outside the furnace had three arms: one for taking samples for x-ray powder photographs, one for samples for chemical analysis, and one for mixing x-ray samples with reference substances. The reaction tube was heated by a nichrome wound furnace controlled by hand adjusted rheostats. An aluminum block was used inside the furnace as a temperature equalizer. The variation in temperature was not more than ±1.5° during a run. In the experiments carried out at 444° the furnace was replaced by a sulfur bath; the temperature in these runs was constant within ±0.5°. All temperatures were determined with chromel–alumel thermocouples in conjunction with a Leeds and Northrup Type K potentiometer. The thermocouples were calibrated against a platinum–platinum–rhodium thermocouple, calibrated by the U. S. Bureau of Standards.

In a typical experiment a charge of about 20 g. of ferric oxalate was completely reduced in the reaction tube in a stream of hydrogen at about 450°. Various mixtures of ammonia–hydrogen were then passed over the iron for definite periods of time at a fixed temperature. The composition of the gaseous mixture was checked by titration before and after it passed over the iron. At a flow of approximately 100 cc. of gas per minute no cracking occurred at 400 and 444°; slight cracking took place, however, with high P_{NH_3}–P_{H_2} ratios from 500 to 575°. Equilibrium was usually reached in ten to twenty hours at 400°, in five to ten hours at 444° and in five hours or less at 500° and higher temperatures.

At the end of each experiment pure nitrogen was run over the hot sample for a few seconds to flush out the NH_3–H_2 mixtures; the reaction tube was then removed from the furnace and the sample cooled quickly with the stream of nitrogen still passing over it. When the tube was cool an x-ray sample was taken and three samples were sealed off for analysis. These samples were then dissolved without exposure to air by breaking their containers under sulfuric acid. The nitrogen and iron contents of the samples were then determined by the Kjeldahl and the Jones reductor methods, respectively.

The x-ray data were obtained from powder diffraction photographs taken with iron K radiation in a camera of about 3.46 cm. radius. For determining the lattice dimensions the nitride samples were mixed with sodium chloride. In each case measurements were made on at least three photographs.

Results and Discussion

A. Equilibrium Runs.—The equilibrium runs for the Fe–Fe_4N system at 400 and 575° are given in Table I. From them it can be concluded that at 1 atmosphere pressure an NH_3–H_2 mixture need not contain more than 37% NH_3 to convert Fe into Fe_4N at 400, and 14.5% at 575°.

TABLE I

SUMMARY OF EQUILIBRIUM RUNS IN THE SYSTEM $Fe–NH_3–Fe_4N–H_2$ AT 400 AND 575°

Run	Temp.. °C.	NH_3 in NH_3–H_2 gas mixture, %	N_2 by weight in samples (average), %	X-ray diffraction pattern
M1	400	35	0.09	No photograph
M2		37	.14	No photograph
M3		39	.17	No Fe_4N, only Fe
M4		41	.48	Fe_4N present
P1		37	.09	Presence of Fe_4N doubtful
P2		37	.10	Very faint Fe_4N
P3		37	.11	Very faint Fe_4N
A3	575	11.5–13	.13	Only Fe
A4		12–14	.13	Only Fe
A5		14–15	.31	Very faint Fe_4N
A6		14.6–16	2.46	Strong Fe_4N

The results of the equilibrium runs in the system γ'–NH_3–ϵ–H_2 are given in Table II. The equilibrium constants were determined at 400, 444 and 500°. At temperatures of 550° and higher the cracking of ammonia made the determination of the constants impracticable.

TABLE II

SUMMARY OF EQUILIBRIUM RUNS IN THE SYSTEM γ'–NH_3–ϵ–H_2

Run	Temp., °C.	Starting material	NH_3 in NH_3–H_2 gas mixture, %	N_2 by weight in samples (average), %	X-ray diffraction pattern
P6	400	γ'	75	5.91	Only Fe_4N
P8		γ'	77	5.93	Only Fe_4N
P11		γ'	79	6.15	Presence of ϵ besides Fe_4N
F1		ϵ	79	8.78	No photograph
F2		ϵ	77	8.47	Only ϵ
F3		ϵ	75	8.22	Only ϵ
F4		ϵ	75	8.07	Presence of Fe_4N besides ϵ
III 4	444	γ'	75	6.83	Presence of ϵ and γ'
III 5		$\epsilon + \gamma'$	70	5.99	Presence of ϵ and γ'
III 12		γ'	70	6.03	Only Fe_4N
III 13		γ'	72	5.85	Only Fe_4N
III 14		γ'	72	6.14	Faint lines of ϵ besides Fe_4N
IV 2		γ'	70	6.05	Very faint lines of ϵ
IV 3		γ' (trace ϵ)	70	6.13	Very faint lines of ϵ
IV 4		γ' (trace ϵ)	72	6.20	ϵ lines stronger
B2	500	ϵ	59	7.89	Only ϵ
B3		ϵ	58	7.89	Only ϵ
B4		ϵ	56	7.63	Distinct Fe_4N lines
B5		ϵ (some γ')	54	7.30	No photograph
B6		$\epsilon + \gamma'$	58	7.45	No photograph

The errors in these experiments consist of those involved **(1)** in obtaining a constant and definite NH_3–H_2 mixture, (2) in measuring the temperature of the reacting material, and **(3)** in determining the composition and amounts of the solid phases at the end of each run. Errors **(1)** and (2) are considerably less than in the previous paper because of **(1)** the correction for variation of pressure and temperature of the flowmeter capillaries from the temperature and pressure at which they were calibrated, and **(2)** better temperature regulation. The ammonia percentages given are accurate to ± 0.5; we accordingly estimate that the percentage of ammonia in an NH_3–H_2 mixture at 1 atm. necessary to convert Fe to Fe_4N is 37 ± 2 at 400, and 14.5 ± 1 at 575°. The equilibrium percentage of ammonia for the conversion of Fe_4N into the a-phase is 77 ± **2** at 400, 70 ± 2 at 444, and 57 ± 1.5 at 500°.

It should be pointed out that the "equilibrium" values deduced from Table I above, as well as those presented in Table I of the previous publication from this Laboratory, for the Fe–Fe_4N system in reality represent only the upper limit of the true equilibrium values for two reasons. In the first place, because of the sluggishness with which NH_3–H_2 mixtures slightly below equilibrium reduced the nitride, experiments approaching equilibrium from the high nitride side were impracticable. Furthermore, any thermal decomposition of the Fe_4N formed in these experiments would tend to increase the apparent percentage ammonia necessary to convert Fe into Fe_4N. The thermal decomposition rate of the nitride samples used **was** very low. No satisfactory method of correctly estimating the influence of this factor on the equilibrium constant has as yet been devised. The slowness of the thermal decomposition compared to the rate of nitride formation makes it highly probable, however, that this influence is small.

The equilibrium measurements on the γ'–ϵ system were approached from both the high and low nitride sides. These values, however, are still susceptible to any influence that the thermal decomposition of the a-phase may have on them, and must in a strict sense also be regarded as upper limits of the true equilibrium values.

In Fig. 1 curve **A** is a plot of log K_1, the equilibrium constant for reaction (1), against $1/T$. Of the six points in the plot, four were reported in the previous paper, two were determined in the present experiments. The dotted line shows the curve obtained by Lehrer[2,4] in this region by the magnetometric method. The agreement between the two sets of experiments seems well within the combined experimental errors.

The equilibrium constant for the conversion of Fe_4N into a nitride of the solid solution region ϵ may be calculated from the equation

$$8Fe_xN + 3(4 - x)H_2 = 2xFe_4N + 2(4 - x)NH_3 \quad K_2 = (P_{NH_3})^{2(4-x)}/(P_{H_2})^{3(4-x)} \qquad (2)$$

In the temperature region studied the composition of the nitride of lowest nitrogen content of the a-phase is such as to make the value of x approximately equal to **3.** Consequently as a convenient means of comparing our results with those of Lehrer we have plotted in Fig. 1, curve B, $1/T$ against log K_3 corresponding to the reaction

$$8Fe_3N + 3He = 6Fe_4N + 2NH_3 \quad K_3 = (P_{NH_3})^2/(P_{H_2})^3 \qquad (3)$$

The dissociation pressure of Fe_4N into Fe and nitrogen is as previously pointed out approximately 5000 atmospheres at about 450°. Similar calculations from data of Table II indicate that the dissociation pressure of the ϵ-phase containing about **7.9%** nitrogen into Fe_4N and nitrogen is of the order of 3×10^5 atmospheres at 450°.

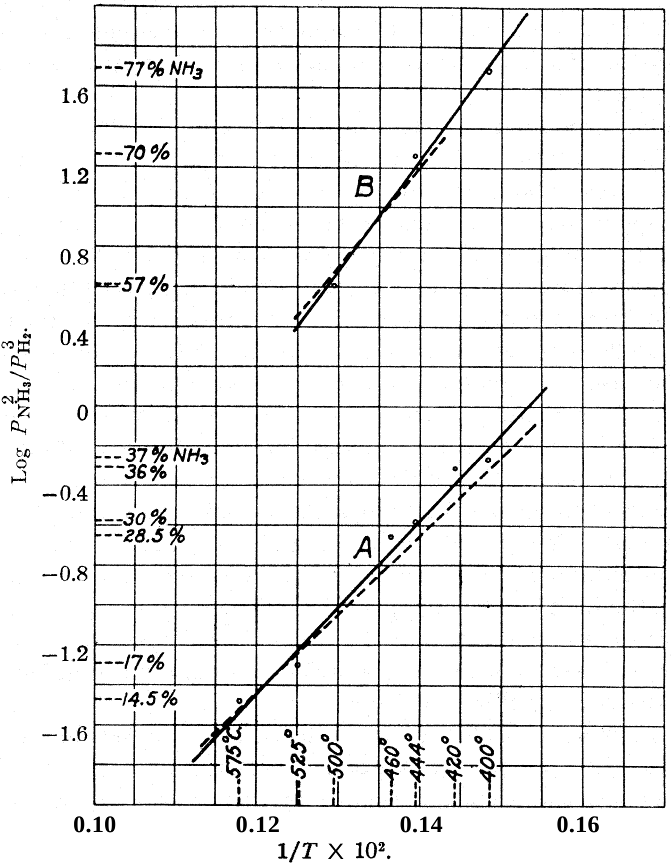

Fig. 1.—Variation of log K_1 and log K_3 with $1/T$.

B. Composition of **the** Phases

The a-Phase.—An exhaustive investigation of the amount of nitrogen taken up by iron when exposed to NH_3–H_2 mixtures containing less ammonia than corresponds to the Fe–Fe_4N equilibrium has not been included in the present experiments. However, in twelve experiments at temperatures between **400** and **575"** and at ammonia concentrations only a few per cent. below equilibrium, no more than 0.2% nitrogen could be put into the iron samples in five to ten hours' exposure. The probable error in the analytical determination was ± **0.02%** nitrogen. X-Ray diffraction patterns obtained did not show a change in the lattice constant of α-iron taking up 0.2% nitrogen.

The γ'-Phase.—In agreement with the results of Eisenhut and Kaupp our experiments indicate a variation in the composition of the γ'-phase from about **5.65** to 5.95% nitrogen. The probable analytical error in this region was ±0.05% nitrogen. The magnitude of the error in this narrow solid solution region made it impracticable to determine accurately the variation of composition of the γ'-phase as a function of the P_{NH_3}/P_{H_2} ratio used in its formation. X-Ray diffraction patterns did not show a variation in the lattice constarit of the γ'-phase with increasing nitrogen content.

The ϵ-Phase.—The variation in the composition of the ϵ-phase with increasing P_{NH_3}/P_{H_2} ratios was investigated at **400** and 444°. The summary of these experiments is given in Table III. At temperatures of 500° and higher an appreciable decomposition of the nitride prevented us from making similar investigations.

TABLE III

COMPOSITION OP THE ϵ-PHASE IN EQUILIBRIUM WITH VARIOUS NH_3–H_2 MIXTURES

	Composition of the t-phase. % N_2 by weight in nitride					
	400°			444°		
NH_3 in NH_3–H_2 gas mixtures. %	High nitride side	Low nitride side	Best average value	High nitride side	Low nitride side	Best average value
72	..	..	..	7.9	..	7.9
75	..	..	..	8.1	..	8 1
80	8.4	..	8 4	8.8	..	8.8
85	..	..	..	9.2	..	9 2
90	9 45	9.25	9 4	9.7	9.7	9.7
95	10.15	10.15	1015	1025	10.4	10.35
98	..	..	..	10.95	10.85	10.9
100	11.05	..	11.05	11.2	..	11.2

The probable analytical error varied between ±0.06% nitrogen for the lower limit of the e-phase to ±0.10% nitrogen for the upper limit. As the table shows, equilibrium was approached from both high and low nitride sides whenever the reaction rate permitted it. This was possible only with gas mixtures containing over **85%** of ammonia. Below this value equilibrium could be conveniently approached from the high nitride side only.

Figure 2 represents the variation in the composition of the various iron nitrides with increasing P_{NH_3}/P_{H_2} ratios at **400** and **444".** The slopes of the curves representing the variation in the composition of the phases α and y' are uncertain; for this reason they were drawn with dotted lines.

Errors in the determination of the lattice dimensions of the ϵ-phase by means of x-ray powder photographs might arise from systematic errors inherent in the method and from accidental errors of measurements. The technique ordinarily used consists in mounting a small sample coaxial with a cylindrical film. If the sample is too thick, the diffraction cones will not have apexes on the same line. If the sample is not accurately centered, each line on the film will be at a different distance from it. Divergence of the x-ray beams also introduces an error into the measurements. For a cubic substance these errors can partially be corrected for by extrapolating to $\Theta = 90°$ a curve obtained by plotting the values of A_K, the measured values of a_0, against the corresponding values of Θ.[6] The determination by this method of two parameters defining the dimensions of a hexagonal lattice must depend upon a relationship between them. In either case considerable error can be introduced by the extrapolation, particularly so if values of A_K are not determined for large values of Θ. This method was used by Eisenhut and Kaupp[3] in the determination of a and c for various samples of the ϵ-phase.

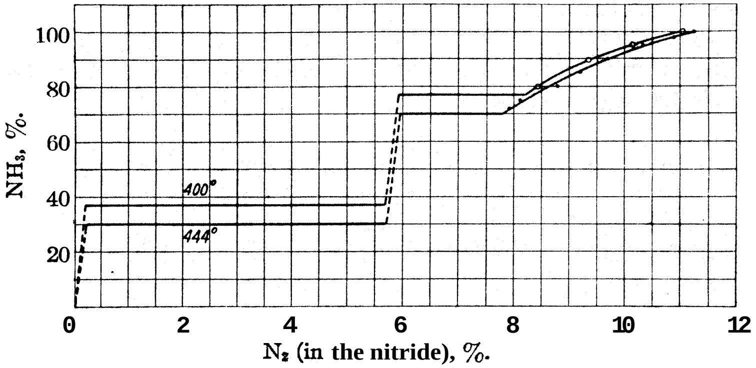

Fig. 2.—Equilibrium diagram showing the variation of the percentage nitrogen in the iron nitrides with the percentage ammonia in the ammonia–hydrogen mixtures.

In our work we effectively eliminated these sources of error by reducing the sample to very small cross sectional area, approximately the half value thickness, and by using only those films that had constant radii, determined from the sodium chloride reference lines. This method approximates the ideal case given by Kettmann.[6] The probable limits of error for the a values given in Table IV are ±0.002 Å., for the c values ±0.003 Å.

The x-ray data obtained from the ϵ-phase are summarized in Table IV. The values of a and c corresponding to various compositions of the solid phase are listed in this table and are shown in Fig. 3 in comparison with the values of Eisenhut and Kaupp and Hägg.[7] The three sets of results, although closely similar, show variations that we believe to be greater than

our experimental error. Eisenhut and Kaupp indicated that both a and *c* of the e-phase are linear functions of the nitrogen concentration expressed

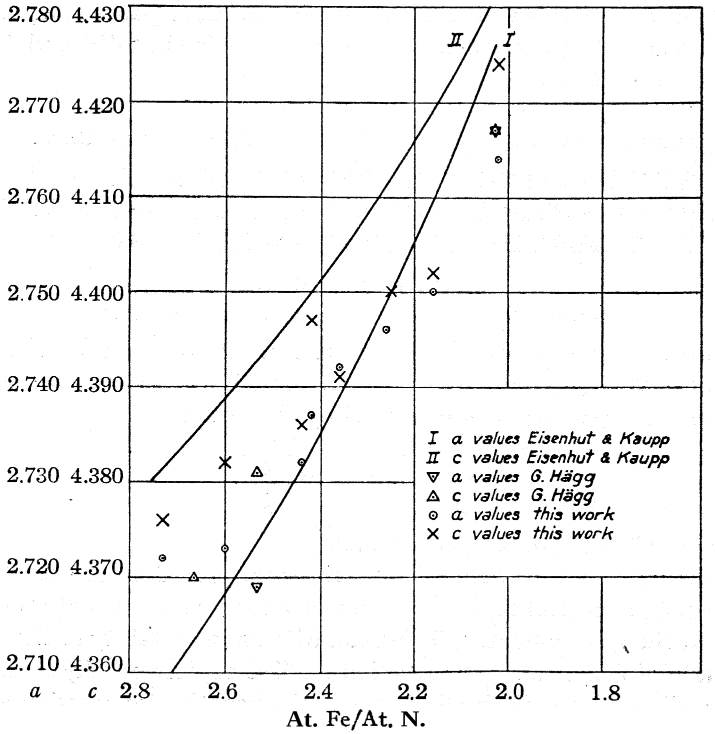

Fig. 3.—Variation in the lattice constants a and *c* of the e-phase with increasing atomic ratios Fe:N.

as per cent. by weight. Within the limits of our experimental error it is possible for a to be a linear function either of the nitrogen concentration expressed as per cent. by weight, or of the ratio of the number of iron to nitrogen atoms. The values of c, however, are not linear functions of either of these variables. We do not believe that any of the results thus far obtained are sufficiently accurate to warrant the deduction of empirical equations expressing either *a* or *c* as functions of the nitrogen concentration.

We wish to acknowledge the excellent cooperation of Miss Ellen Z. Kibbe, who analyzed all the nitride samples, and Mr. Leonardo Testa, glass blower.

Summary

1. The equilibrium data for the reaction $2Fe_4N + 3H_2 = 8Fe + 2NH_3$ have been extended to 400 and 575'; they indicate that the percentage of NH_3 in an NH_3–H_2 mixture at 1 atmosphere necessary to convert Fe to Fe_4N is 37 ± 2 at 400, and 14.5 ± 1 at 575'.

2. The percentages of ammonia in an NH_3–H_2 mixture in equilibrium with the solid phases γ' and ϵ were found to be 77 ± 2 at 400, 70 ± 2 at 444 and 57 ± 1.5 at 500°.

3. The composition and lattice dimensions of the e-phase in equilibrium with various NH_3–H_2 mixtures have been determined at 400 and 444'.

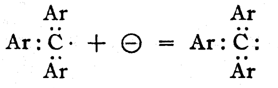
THE ELECTRON AFFINITY OF FREE RADICALS. II. DIPHENYL-ALPHA-NAPHTHYLMETHYL DIPHENYLBIPHENYL AND PHENYLBIPHENYL-ALPHA-NAPHTHYLMETHYL

BY HENRY E. BENT

RECEIVED MARCH 2, 1931 PUBLISHED MAY 6, 1931

The work to be described in this paper is a continuation of the study of the effect of various groups on the electron affinity of organic free radicals.[1] The type reaction may be represented by the equation



$$\mathrm{Ar}:\overset{\mathrm{Ar}}{\underset{\mathrm{Ar}}{\ddot{\underset{\cdot\cdot}{C}}}}\cdot + \ominus = \mathrm{Ar}:\overset{\mathrm{Ar}}{\underset{\mathrm{Ar}}{\ddot{\underset{\cdot\cdot}{C}}}}: \quad (1)$$

Ar, in general, being an aromatic group.

The details of the method and experimental procedure are described in the first paper on triphenylmethyl, in which it was shown that its electron affinity in the gaseous state is 59 kg. cal. with an uncertainty of the order of magnitude of 5 kg. cal. The reaction studied experimentally is the addition of sodium to the free radical to give the negative ion in ether solution

$$Na + R = Na^+ + R^- \quad (2)$$

---

[1] H. E. Bent, THIS JOURNAL, 52, 1498 (1930).

in which R is the free radical. It is possible to determine the free energy change for this reaction by shaking a solution of the sodium salt with mercury. This partially reverses the reaction and from the equilibrium data the free energy change for Reaction 2 is obtained. By combining appropriate equations an estimate is then obtained for Reaction 1 in the gaseous phase.

This paper describes the work on three more free radicals which were chosen because of the large dissociation of the corresponding ethanes and because of their increasing complexity. The large dissociation of the ethane makes it possible to assume in the dilute solutions used that all of the material is in the form of the free radical.

Procedure

The experimental technique has been improved in two or three respects. The final crystallization of the chloride, which is sensitive to moisture, is carried out in an atmosphere of carbon dioxide. A convenient apparatus is made by cutting the bottom from a ten-liter bottle, inverting, and supporting a glass shelf at the beginning of the constriction of the neck. This shelf is put in place by fastening corks to the inside of the bottle with sealing wax melted onto the glass with a soldering iron. Dry carbon dioxide is then passed steadily into the neck of the bottle during recrystallization. Analysis of the gas shows that objects may be moved in and out of the bottle without introducing as much as 1% of air. The purified chloride is transferred to a small bottle without coming in contact with air. This small bottle, Fig. 1, may be evacuated for removal of the last traces of solvent and permits removal of a sample without introducing air a steady stream of carbon dioxide preventing downward diffusion while the sample is removed with the aid of a long silver spatula.

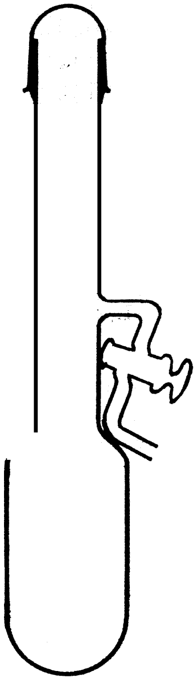


Fig. 1.—Sample bottle.

The alundum disks used for filtering the solutions have been replaced by sintered Pyrex disks, which give tighter seals to Pyrex and less adsorption of water or other reactive compounds.[2]

Materials

α-**Naphthyldiphenylchloromethane.**—This compound was prepared from the corresponding carbinol, obtained from the Eastman Kodak Co., by treating with hydrogen chloride. The chloride so formed melted at 169–171° and the analysis for chlorine by the Carius method gave 10.65 and 10.89; calcd., 10.79.

---

[2] W. F. Bruce and H. E. Bent, THIS JOURNAL, 53, 990 (1931).

Diphenylbiphenylchloromethane.—Dr. R. B. Whitney very kindly furnished this compound. The preparation of benzophenone[3] was carried as far as the chloride stage as the first step. This was then isolated[4] and the final Friedel and Crafts reaction carried out according to the directions of Schlenk.[5] After recrystallization, analysis for chlorine gave 9.75; calcd., 10.0.

Phenylbiphenyl-α-naphthylchloromethane.—Phenylbiphenyl ketone was prepared[6] and converted into the carbinol by means of α-naphthylmagnesium bromide.[7] The chloride was then treated with hydrogen chloride gas as usual and after recrystallization analysis for chlorine gave 8.45 and 8.47; calcd., 8.76.

Experimental Results

The experimental data are given in Table I, the last column giving the mean value of log K for Reaction 2. In the sixth column the calculation is made assuming the salt to be completely ionized, an assumption which,

of course, is not correct. The data of this column are given for the purpose of showing to what extent the assumed ionization constant influences the final results. In the seventh column the value of K_3, the ionization constant of the sodium salt, is taken as 10^{-4}. This is the same value that was used in the first paper and gives the most concordant results for K_2. One would hardly expect a variation of more than a power of ten among such similar compounds and anything smaller than this is not significant for these calculations. Although the assumption that the mass law may be applied to the ionization of these electrolytes in ether solution, using concentration for activities, is certainly not accurate,[8] it probably introduced no significant error which would alter the conclusions. Only if these compounds deviated widely in their behavior, not only from the simple mass law but also from each other, would the conclusions drawn from these experiments be in error.

Discussion of Results

The equilibrium constants corresponding to the addition of sodium to four different free radicals have been determined experimentally. For sodium the standard state is taken as the metal at 25°. For the radical and the two ions the activity is taken as equal to the mole fraction. The total reaction may be considered to be the sum of two reactions: first, sodium metal giving sodium ion and an electron; second, free radical plus an electron giving the methide ion.

$$\begin{array}{llll} \mathrm{Na} & & = \mathrm{Na}^+ & + \ominus \\ \ominus & + \mathrm{R} & = \mathrm{R}^- & \\ \hline \mathrm{Na} & + \mathrm{R} & = \mathrm{Na}^+ & + \mathrm{R}^- \\ \textbf{solid} & \textbf{ether} & \textbf{ether} & \textbf{ether} \end{array} \qquad (2)$$

The equilibrium constants given in Table I are for this total reaction. In discussing the results it is perhaps more convenient to express them as free energies with the aid of the equation $AF = -RT \ln K$. Table II gives the values in kilogram calories for AF of Reaction 2.

TABLE II

THE FREE ENERGY OF ADDITION OF SODIUM TO FREE RADICALS IN ETHER SOLUTION

Triphenylmethyl	Diphenyl-α-naphthylmethyl	Diphenylbiphenylmethyl	Phenyl-α-naphthylbiphenylmethyl
			AF, −17.9	AF, −18.6	ΔF, −19.1	AF, −19.5

Ziegler and Wollschitt, Ann., 479, 123 (1930).

The free energy data given in Table II are, therefore, the sums of the free energy changes for the two parts which go to make up reaction (2). Since, in every case, sodium ion is being formed in ether solution, the energy change corresponding to this part of the reaction will be a constant and any changes in ΔF in Table II must be due to the changing electron affinity of the free radical. In the first paper of this series an estimate of 59 kg. cal. was obtained for the electron affinity of triphenylmethyl in the gaseous state. As far as possible comparisons should be made in the gaseous state in order to eliminate the effect of the solvent. When this is done the variation of 1.6 kg. cal. in the electron affinities of the free radicals studied becomes a little less than **3%** of the energy change in the gaseous state. One may say, then, that to a rather rough first approximation the electron affinity of the four free radicals studied is the same.

Further examination of the data leads to the conclusion that within this 3% variation in the electron affinity there are regularities which are significant. An increase in the size of the molecule causes an increased electron affinity. Thus, substitution of an α-naphthyl group for the phenyl group produces a change in ΔF of **0.7** kg. cal., while a substitution of biphenyl for phenyl produces a change of 1.2 kg, cal. The two groups substituted in the same molecule produce an effect which, within the accuracy of the experiments, is the sum of their effects individually, namely, 1.6 kg. cal. The experimental error is about 0.2 kg. cal.

The fact just noted, that the larger molecules have the greater electron affinity, is very surprising when considered in conjunction with the data on the dissociation of the corresponding ethanes. If the energy change accompanying the process of joining two carbon atoms is determined by the behavior of the electrons entering into the bond, then a larger electron affinity might be expected to give rise to a greater strength of chemical bond. For polar compounds this may readily be demonstrated by breaking up the whole process of compound formation into several steps, as has been done by Born, one of which is the addition of an electron to the negative element. It becomes evident in this case that a greater electron affinity, other factors remaining constant, causes the resulting compound to be more stable. The same fact may be observed when considering a series of compounds such as the halogen derivatives of a number of metals. The fluorides are most stable, then the chlorides, bromides and iodides. This is the same order found in measuring the electron affinities of the halogens, fluorine having the greatest and iodine the least electron affinity. The oxides and sulfides show a similar connection. In fact, the phenomenon that the greater electron affinity is associated with the more stable compound seems to be quite general. When we turn to non-polar compounds we find that it is not quite so easy to break up the process of compound formation into a number of steps which are known experimentally. However, here also stability seems to be associated with a large electron affinity. The best illustration is probably to be found in the stability of the halogen molecules, iodine, which dissociates readily, having a small electron affinity and fluorine, which has a large heat of dissociation, having a high electron affinity.

It would appear, therefore, that the electron affinity of an atom or molecule is a measure of the energy change accompanying a process which is very intimately related to chemical valence and the stability of chemical compounds. The two processes, of course, have much in common. In the case of the electron affinity the process involved is the bringing of an electron to a carbon atom which has seven electrons around it, six of which are shared In the case of the formation of a carbon-carbon bond an electron is brought to the same carbon but, in this case, is not a free electron but is an odd electron of another carbon atom. From the standpoint of these relations one would expect the larger free radicals to be the least dissociated, judging by their electron affinities, which are the greatest. What one finds is that these are the free radicals which are most dissociated. Walden[9] has summarized the various data which all lead to the conclusion that the larger free radicals studied in this work are those which are most dissociated.

The way out of this difficulty seems to be with the aid of the concept of steric hindrance. If we assume that the strength of the bond is determined not alone by the behavior of the electrons forming the valence pair but also by the rest of the molecule, then it is possible to understand the above facts. In Fig. 2, a schematic curve, we may indicate very roughly the potential energy of a system of a free radical and an electron as a function of the distance, r, between them. We may also assume that a free electron approaches to about the same distance from the central carbon atom regardless of the bulk or exact position of other groups attached to it, the depth of the valley in this potential energy curve being the 59 kg. cal. determined in this investigation. If, however, the electron were attached to a bulky group of atoms we might not be surprised to find that it could approach only to a distance corresponding to the position (A) on the curve, and the decrease in the energy of the system would be correspondingly less. The fact that the

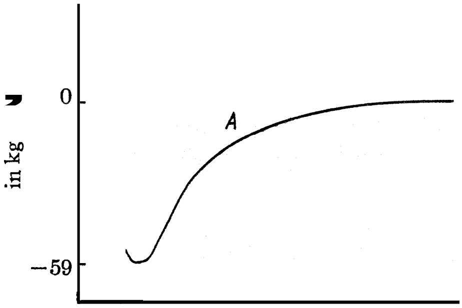

Fig. 2.—The electron affinity as a function of the distance of the electron from the equilibrium position in the molecule.

---

[9] P. Walden, "Chemie der freien Radikale," Verlag von S. Hirzel, Leipzig, 1924.

larger free radicals have somewhat deeper potential energy curves, therefore, has little effect on the firmness of a weak bond, this being determined primarily by the closeness of approach of the two atoms. Thus, the biphenyl and α-naphthyl groups prevent the central carbon atoms coming as close together as they do when phenyl groups are involved, and the bond is correspondingly weaker.

This idea also explains the fact that the heat of dissociation of the normal aliphatic carbon–carbon bond is about 73 kg. cal.,[10] while the heat of dissociation of the bond in hexaphenylethane is about 11 kg. cal.[11] These figures indicate that the steric effect prevents the two carbon atoms approaching closer than the distance which corresponds to about one-seventh of the way down the potential energy curve for two aliphatic carbon atoms. The fact that the heat of dissociation of ethane is about the same as the value calculated for a single bond in diamond[10] indicates that the hydrogen atoms in ethane introduce, as might be expected, no steric effect.

Two questions remain to be considered: first, the significance of the solvent in these equilibria, and, second, the use of free energy data in discussing the potential energy curve in Fig. 2. Although the conclusions discussed above are found not to be altered by either of these considerations, they can hardly be dismissed without careful attention.

The solvent undoubtedly has a very great effect on the equilibrium studied experimentally. In the paper on triphenylmethyl it was shown that the solvent affected the free energy change of the reaction to the extent of about 77 kg. cal. Since most of this 77 kg. cal. comes in the solvation of the sodium ion, the effect of the ether on the electron affinity of the free radical is very much less. The significant problem, however, is to determine to what extent the effect of the solvent will vary from one compound to another. Considering the reaction

$$R + \ominus = R^-$$

it is necessary to discover in what way the activities will change in passing from the standard state for the solution to the standard state for the gas reaction, and in particular how this change will vary with radicals of varying size. The effect of the solvent may be divided into three parts: first, the change in activity in passing from the standard state in solution to the standard state in the gas resulting from the van der Waals' forces; second, a similar effect resulting from more specific valence forces centering around the unsaturation in the free radical; third, the effect of the solvent resulting from the charge on the ion. The first of these factors, that of van der Waals' forces, does not have to be considered inasmuch as it will be the same for the ion as for the free radical and will, therefore, cancel out.

---

[10] Taylor, "Treatise on Physical Chemistry," D. Van Nostrand Co., Inc., New York, 1931, p. 328.

[11] Ziegler and Ewald, Ann., 473, 163 (1929).

The second, the effect of valence forces, probably is not significant, inasmuch as Ziegler and Ewald[11] have shown that the change in the dissociation constant and the heat of dissociation of hexaphenylethane, in passing through a series of eight widely varying solvents, varies less than 2 kg. cal. In considering the third factor, the effect of the solvent resulting from the charge on the ion, we find that there is an increase in the free energy in passing from the ion in solution to the ion in the gaseous state. The amount may be calculated by Born's equation

$$AF = \frac{e^4}{2r}(1 - 1/D)$$

which gives 27 kg. cal. for an ion of radius 4.6 Å. An increase of 33% in the volume of the ion would cause a decrease of about 2.7 kg. cal. in this free energy change. This would also result in $-AF$ for the electron affinity of a large free radical in the gaseous state being larger than for a small one as compared with the values in ether solution. Therefore, we are led to the conclusion that the solvent affects the comparison of free energies to a small extent, 3–5 kg. cal., and that the observation that the larger molecule has the greater electron affinity would be still more marked in the gaseous state.[12]

The second question to be considered is the relation between the free energy change of the gas reaction and the heat of the reaction. Since the free radical and its ion are of the same mass, by the Sackur–Tetrode equation they will have the same entropy. The change in entropy for the reaction will be just the entropy of the electron gas which is of the order of three entropy units. Therefore, for this reaction AF equals ΔH to within 1 kg. cal., making use of the equation $AF = AH - TAS$. Hence for practical purposes we can interchange free energy and heat of reaction in discussing these reactions.

In conclusion, the writer takes pleasure in acknowledging the work of Mr. M. E. Dorfman in making measurements on one of the compounds and the assistance of Dr. R. B. Whitney in preparing another.

[12] A somewhat different way of treating the same problem of the effect of the solvent on the equilibrium is to consider the changes in heat content and entropy of the reactants and products in passing from the solution to the gaseous state. The changes in entropy of the ion were calculated by the method used by Latimer and Kasper[13] for water solutions taking the experimental data of Bridgeman for the coefficient of thermal expansion of ether and integrating graphically. The change in entropy of the free radical was estimated from Hildebrand's modification of Trouton's rule and from his definition of regular solutions as being those for which there is no entropy change on mixing, The heat change for the ion was calculated by the equation of Born given above, which is for either heat or free energy change. The heat of solution of the free radical would be practically the same for both and was estimated from Hildebrand's modification of Trouton's rule and the specific heats. The result was approximately the same as from the more direct procedure and offers confirmation of that result.

[13] Latimer and Kasper, THIS JOURNAL, 51, 2293 (1929)

Summary

1. As a first approximation the electron affinity in the gaseous state of the four free radicals studied is 60 kilogram calories.

2. The substitution of larger groups for phenyl slightly increases the electron affinity. The effect of substituting two groups is approximately the sum of the effects of the groups individually.

3. The fact that the larger free radicals have the greater electron affinity and the smaller tendency to form ethanes suggests that due to steric hindrance the carbon atoms cannot approach each other as closely and, therefore, the energy liberated is smaller.

4. The effect of the solvent on the equilibrium is considered and found to be essentially the same for the four free radicals studied.

THERMODYNAMIC PROPERTIES OF FUSED SOLUTIONS OF SODIUM BROMIDE IN SILVER BROMIDE

BY EDWARD J. SALSTROM

RECEIVED MARCH 2, 1931 PUBLISHED MAY 6, 1931

The following investigation represents a contribution to the general program begun by Hildebrand and Ruhle[1] of gathering data upon the free energy of dilution of fused salt solutions. The system selected, solutions of sodium bromide in silver bromide, is a continuation of the more recent study by Salstrom and Hildebrand[2] of investigating the influence of the size of the cation of the diluting salt upon the activity of the solvent. The freezing point–composition diagram obtained for this system by Sandonnini and Scarpa[3] shows no evidence of complex salt formations which might add complexity to any interpretation of the results.

Experimental Part

The sodium bromide was from commercial sources of high purity The remaining materials, apparatus and procedure involved in this investigation were essentially the same as those described for the previous study of lithium bromide in silver bromide.[2,4] In short, the method consists of removing hydrolysis and oxidation products from the cell by bubbling a stream of dry hydrogen bromide gas through the fused salts for at least two hours. Bromine gas generated by electrolysis of fused lead bromide

was then bubbled through the melt over a graphite rod dipping into the solution. Equilibrium was attained in about two hours. Readings were then taken at certain temperature intervals over the whole permitted temperature range several times. Ascending and descending series were in complete agreement.

The results of the e. m. f. measurements of the cell, Ag(s)/AgBr(l), NaBr(l)/Br_2(g), are given in Table I and plotted in Fig. 1. The values for pure silver bromide are those obtained in the silver bromide–lithium bromide investigation.[2] Because of the high melting point of solutions rich in sodium bromide, measurements on cells beyond a half mole fraction of this salt could not be obtained with the Pyrex containers used. The study of cells containing increasing fractions of sodium bromide was also increasingly limited as to temperature range. The extreme deviations of the observed values from the straight lines drawn through them in Fig. 1 is 0.4 millivolt, and the average deviation is less than 0.15 millivolt.

Since the theoretical treatment of the results will ultimately require a knowledge of the interionic distances, it was considered desirable to measure the density of a solution containing a half mole fraction of each salt. The method consisted in weighing a tungsten-weighted quartz bulb in air, in water and then at various temperatures in the fused salt solution, correcting[5] each time for the expansion of quartz. The bulb was sharply tapped before each reading to remove any adhering bubbles of gas. The densities observed are given in Table II.

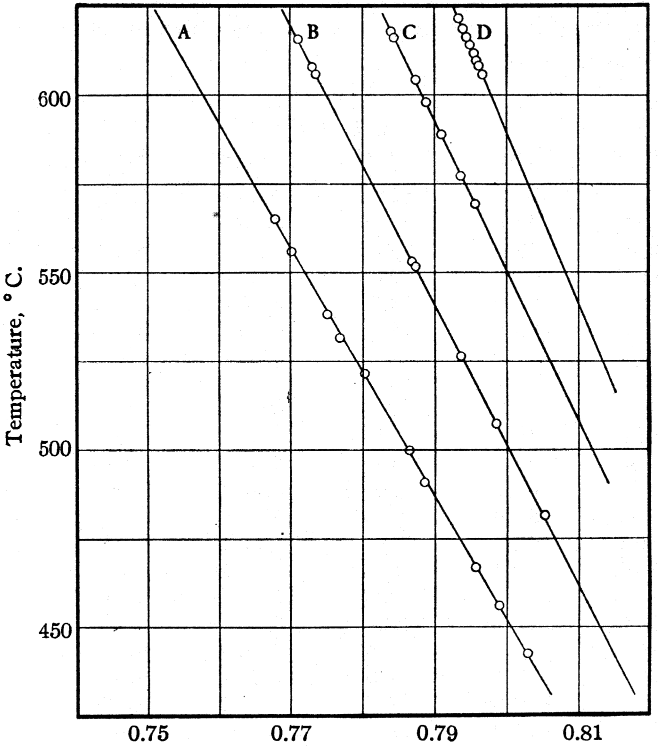

Fig. 1.—Temperature, e. m. f. and composition relations of the cells **Ag/AgBr, NaBr/Br₂.** Mole fraction of silver bromide in A is 1.000, B is 0.7485, C is 0.6045 and D is 0.5130.

TABLE II

DENSITIES OF 0.5 MOLE FRACTION OF NaBr IN AgBr

Temp., °C.	619.3	616.0	615.0	613.2	612.0	609.5	607.4
Density	3.754	3.757	3.758	3.759	3.760	3.762	3.764

The observed values yield the equation for the density of 0.5 mole fraction of sodium bromide in silver bromide, $d^t = 4.311 - 0.0009\ t$. Using the density values for silver bromide obtained by **Lorenz** and **Höchberg**[6]

---

[5] Data are not available for calculating the effect of surface tension of the fused solution upon the suspending wire but, because of the fineness of the platinum wire employed, it is believed that such corrections would prove negligible.

[6] **Lorenz** and **Höchberg,** *Z. anorg. allgem. Chem.*, 94, 288 (1916).

and for sodium bromide obtained by Jaeger,[7] we have calculated the molal volumes of silver bromide and sodium bromide at 600° as 34.74 cc. and 42.01 cc., respectively. A 50 mole per cent. solution at this temperature has a molal volume of 38.53 cc., which is 0.15 cc. more than additive.

Discussion of Results

Since our main interest lies in the relation of free energy to composition at constant temperature, we obtained from Fig. 1 plotted on a large scale the values of the e. m. f., E, determined for each solution at the temperatures 550 and 600°, together with their values of dE/dt. These temperature coefficients fall off almost linearly with the mole fraction of silver bromide, N_1. From these values we have obtained by the aid of the usual formulas, values of the entropy, ΔS_1, and partial molal entropy, $\bar{S}_1$, the free energy of formation, ΔF_1, and the partial molal free energy or free energy of dilution, $\bar{F}_1$, the molal heat of formation, ΔH_1, and the heat of dilution, $\bar{H}_1$, the activity, a_1, and the activity coefficient, a_1/N_1.

TABLE III

ENERGY RELATIONS OF SILVER BROMIDE WHEN DILUTED WITH SODIUM BROMIDE

550°, $\bar{F}_1$ (cal.)	0	−370	−650	−850
550°, ΔH_1 (cal.)	−23320	−23040	−22980	−22800
550°, $\bar{H}_1$ (cal.)	0	280	340	520
550". a_1	1.0000	0.8014	0.6719	0.5952
550°, a_1/N_1	1.000	1.071	1.112	1.160
600°, E (volt)	0.7577	0.7749	0.7883	0.7979
600°, ΔF_1 (cal.)	−17480	−17880	−18190	−18410
600°, $\bar{F}_1$ (cal.)	0	−400	−710	−930
600°, a_1	1.000	0.7956	0.6658	0.5861
600°, a_1/N_1	1.000	1.063	1.101	1.142

These values are given in Table III and Fig. 2; Curve A shows $-\bar{F}_1$ plotted against log $(1/N_1)$ where N_1 is the mole fraction of silver bromide. If we attempt to calculate $-\bar{F}_1$ by assuming the activity to be equal to the mole fraction we find that the simple assumption of complete ionization of both salts or of no ionization yield the same result, namely $a_1 = N_1$. This is evident when it is considered that dilution with sodium bromide would, if both salts were completely ionized, make no change in the proportion of bromide ion, but merely substitute sodium ion for silver ion, thus reducing the activity of the latter and hence of silver bromide in proportion to N_1, the

[7] Jaeger, *Z. anorg. allgem. Chem.*, 101, 16 (1917).

same as for the case of no ionization. Such calculations are represented by curve B, Fig. 2, slightly higher than the observed. There is therefore a positive deviation of the activity from Raoult's law since a_1/N_1 is greater than unity. However, the deviation is not nearly so marked as that found for solutions of lithium bromide and silver bromide.[2]

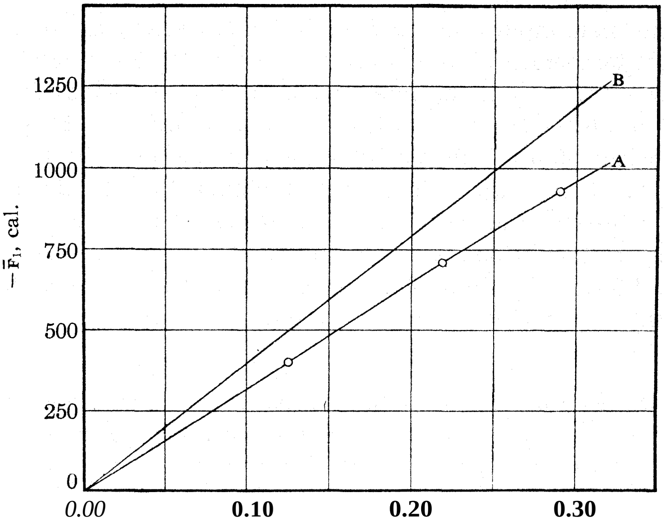

Fig. 2.—Change in free energy of silver bromide at 600° upon dilution with sodium bromide: A, observed; B, calculated.

It is of interest to note that dilution of silver bromide by lithium bromide,[2] which on the basis of complete ionization assumption simply means a substitution of the small lithium ion for the silver ion of more than double its size, lowers the activity of silver bromide far less than a similar dilution by sodium bromide where the substituted silver ion is only about four-thirds the size of the substituting ion. It therefore seems evident that the change in interionic forces due to the substitution of ions of varying size should be considered. This phase of the investigation is being carried further by studying the change in activity of silver bromide upon dilution with potassium bromide and rubidium bromide where the substituting cations are even larger. When data for these systems are at hand we expect to make a more comprehensive study of the whole subject.

Summary

1. E. m. f. measurements have been made of the cell, Ag(s)/AgBr(l), NaBr(l)/Br_2(g) at mole fractions of silver bromide varying from **1.00** to **0.513** between the temperatures **450** and 620°.

2. Calculations have been made of the free energy of dilution, the heat

of dilution, entropy, activity and activity coefficients of these solutions at the temperatures of 550 and 600°.

3. Density determinations of 0.5 mole fraction sodium bromide in silver bromide were made between 600 and 620° and may be expressed by the equation, $d^t = \mathbf{4.311} - 0.0009\,t$.

4. It is pointed out that the positive deviation of the results from Raoult's law seem to indicate that changes in interionic forces upon dilution should be considered.

DEFORMATION OF ELECTRON SHELLS. III. THE MAGNETIC SUSCEPTIBILITY OF NEODYMIUM NITRATE

BY P. W. SELWOOD[1]

RECEIVED MARCH 4, 1931 PUBLISHED MAY 6, 1931

The object of this work, as pointed out in previous papers,[2] was to investigate the relations existing between the absorption spectra and other properties of certain rare earth salts. It has already been shown that in the case of aqueous solutions of neodymium salts a shift toward the red of the absorption bands with increasing concentration is attended with an increase in the ionic refraction of the neodymium. The purpose of the work here reported was to see whether the magnetic susceptibility of neodymium nitrate suffered a perceptible change as the changes in absorption and refraction were taking place.

Experimental

The magnetic apparatus used resembled the Bauer and Piccard[3] modification of Quinckes' capillary rise method. As shown in Fig. 1 the capillary tube C, which was **1** mm. in internal diameter, was placed between the truncated poles of a Weiss electromagnet. The interspace between the poles was **3** mm. During the course of readings the meniscus was always returned to the same position both while the field was applied and while it was off. It was, therefore, not necessary that the field should be uniform, although an investigation showed that it was uniform over a considerable region. The meniscus was observed by means of the telescope A. The magnet was operated with a current of 5.2 amperes, which was sufficient nearly to saturate the iron pole-pieces as is shown in Fig. 2. This procedure is essential if error is not to be introduced from the hysteresis characteristics of the iron.4 It also reduces the proportionate error from slight deviations in the current through the magnet.

[3] **Bauer and Piccard, J.** *Phys.,* **1,** 97 **(1920).**

[4] Sève, ***Ann. chim. phys.,*** *27,425* **(1912).**

As the susceptibility of most paramagnetic substances is inversely proportional to the absolute temperature, it was necessary to control the temperature of the solution contained in the magnetic field. This was done by circulating water from a thermostat constant to 0.1° through a brass collar made to fit snugly between the pole-pieces. Windows were provided for illumination and observation of the meniscus,

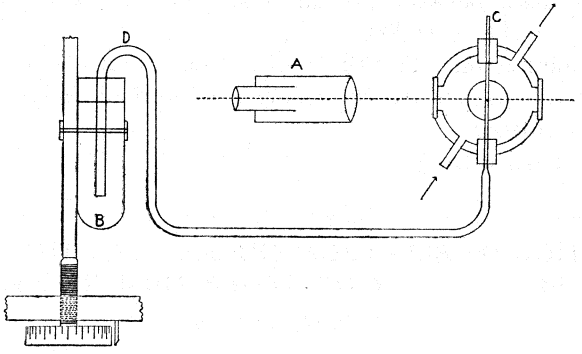

Fig. 1.—Apparatus for measuring magnetic susceptibilities.

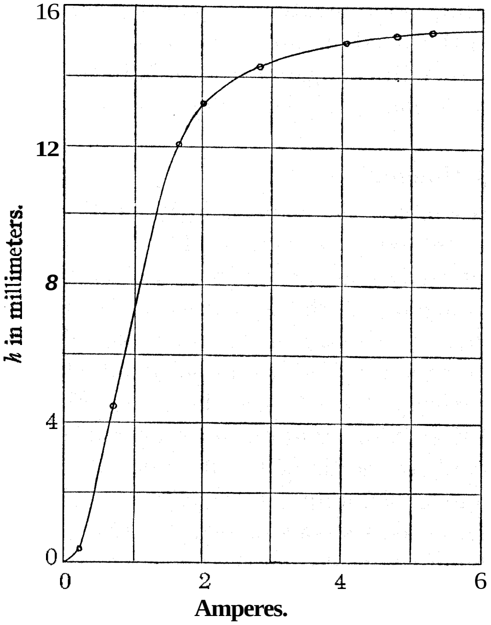

Fig. 2.—Variation of rise of liquid in magnetic field with current through magnet.

The height of the meniscus was controlled by the reservoir B which **was** mounted on the moving frame of a cathetometer. It was possible by this means to duplicate the setting of the meniscus in the absence of the field to **0.01** mm. As the amount of each solution available was not large, it was necessary to reduce the size of the reservoir until the cross section of the tube D was an appreciable fraction of that of the reservoir. This introduced a slight correction to the change in height of the reservoir, owing to immersion of the tube D. The latter had an internal diameter of 2 mm. In the case of the most concentrated solutions *h* was about **30** mm.

As great absolute accuracy for the measurements was not essential, the apparatus was calibrated with redistilled water whose mass susceptibility at 20° was taken as -0.720×10^{-6}.[5] This indicated a field strength of 26,600 gausses with a current of 5.2 amperes. The mass susceptibility of the solutions was then calculated from the relation

$$X_s = \frac{\frac{2hdg}{H^2} + K_0}{d}$$

where h is the true rise of the solution in the reservoir, d is the density of the solution at 20°, g is the gravitational constant, H is the field strength, and K_0 is the volume susceptibility of air, which is given by Brant as 0.0288×10^{-6} at 20°. For diamagnetic substances the above equation is modified to

$$X_s = \frac{\frac{2hd_1g}{H^2} + K_0}{d}$$

where d_1 is the density of the liquid in the reservoir B, which, however, did not differ from d by more than a fraction of 1%.

The apparent susceptibility of the solute was then calculated from the relation

$$X = \frac{X_s + 0.72(1 - p)10^{-6}}{p}$$

where p is the weight fraction of solute present.

The densities and compositions of the solutions were determined as described in previous communications.

The preparation of pure, neutral solutions of rare earth nitrates is a problem which has heretofore given some difficulty. One of the methods used by the author, which consisted of treating the pure oxide with insufficient acid to effect complete solution, has the disadvantage that the resulting excess hydrated oxide is difficult to remove. The other method, which is the prolonged fractional crystallization of the slightly acid salt from distilled water has the disadvantage that it is difficult to remove the last trace of the acid. This is no doubt due to the high solubility of the rare earth nitrates in water.

The method devised for the present work apparently overcomes both these disadvantages. The neodymium oxide, the preparation of which was described elsewhere, was again treated with hydrogen sulfide, and was precipitated repeatedly as oxalate in order to remove all common elements. The oxide was dissolved in a slight excess of redistilled nitric acid and was then heated for half an hour at 250° under reduced pressure (a few mm. of mercury). This resulted not only in the elimination of all excess nitric acid, but in the complete dehydration of the salt, as determined by analysis. The anhydrous salt was very hygroscopic and gave a clear solution in both water and ethyl alcohol, which is not the case with neodymium nitrate which has been heated until decomposition commences at 280–290°. It

---

[5] **Brant,** *Phys. Rev,* **17, 678 (1921)**

was found that in the presence of a reducing agent such as alcohol, decomposition of the nitrate took place below 100°. It is believed that this is the first time that anhydrous neodymium nitrate has been prepared. In view of the good solubility of the nitrate in ethyl alcohol, opportunity was taken to measure its magnetic susceptibility in that solvent. The aqueous solutions prepared from the anhydrous salt may be concentrated by slow evaporation without hydrolysis taking place, but if the solution is boiled, a white basic nitrate appears. The solutions so prepared appear to be identical in physical properties with the solutions most carefully prepared by other methods.

Results

The magnetic susceptibilities of the solutions investigated, together with the apparent susceptibility of the anhydrous salt and of the neodymium ion, are given in Table I. The apparent susceptibility of the neodymium suffers a decrease of over 2% in the concentration range 0.3 to 3 molar.

TABLE I

THE MAGNETIC SUSCEPTIBILITY OF NEODYMIUM NITRATE AT 20°

% $Nd(NO_3)_3$ by weight	Moles per liter	$\chi_s \times 10^6$	$\chi_{Nd(NO_3)_3} \times 10^6$	$\chi_{Nd^{+++}} \times 10^6$ per g ion
9.33	0.304	0.764	15.2	4980
18.56	.6574	2.223	15.13	4960
26.63	1.016	3.518	15.19	4980
33.57	1.367	4.587	15.09	4950
39.51	1.709	5.499	15.02	4930
45.05	2.068	6.395	15.08	4940
50.36	2.458	7.163	14.93	4900
51.30	2.524	7.303	14.90	4890
53.99	2.738	7.725	14.92	4890
58.04	3.089	8.267	14.76	4880

The susceptibility of the neodymium ion calculated from the molecular susceptibility in the more dilute solutions agrees with the value 4970 × 10^{-6} found by Decker,[6] who worked with dilute solutions of the nitrate. Zernike and James,[7] who worked with the crystalline sulfate octahydrate, obtained a value of 5109 × 10^{-6}.

In order to find the susceptibility of neodymium nitrate in alcohol solution, it was necessary to measure the susceptibility of ethyl alcohol. The mass susceptibility at 20° was found to be -0.76×10^{-6}. Landolt–Bornstein gives -0.73 for 99% C_2H_5OH to -0.81 for absolute C_2H_5OH.

The susceptibility of a nearly saturated solution of neodymium nitrate in ethyl alcohol, containing 22.57% by weight or 0.6732 mole of $Nd(NO_3)_3$ per liter, was found to be 2.748 × 10^{-6}. This gave an apparent value for the neodymium nitrate of 14.9 × 10^{-6}. In view of the fairly large maxi-

---

[6] Decker, Ann. *Physik,* 79,324 (1926).

[7] Zernike and James, THIS JOURNAL, 48,2827 (1926).

mum probable error in determining the susceptibility of the alcohol, this value for the nitrate cannot be said to differ from the value obtained in aqueous solution.

Discussion of Results

The various measurements made by the author have shown that a relation, as predicted by Foex,[8] exists between the absorption spectrum, the refraction and the magnetic susceptibility of the neodymium ion. A concentration shift of the absorption bands toward the red is attended with an increase in refraction and a decrease in magnetic susceptibility. In view of the poor development of magnetochemical theory, and the fact that practically no work has been done on the theoretical investigation of rare earth absorption spectra, it scarcely seems possible to present an interpretation of the author's results in terms of atomic structure. It may not, however, be out of place to offer a few general remarks on the subject.

In general, the effective part of a magnetic ion is capable of independent change of orientation so far as its neighbors can influence it. That is, the magnetic susceptibility is not related to the closeness of association of the positive and negative ions as is, for instance, the dielectric constant. It is reasonable to suppose, however, that the combined influence of neighboring ions in concentrated solutions and especially in crystals would produce a field which would in some way affect the mean susceptibility of the active ion.

Owing to the difficulty of preparing the pure rare earths, it is important that comparisons of the susceptibility of different compounds of the same element should be made by the same investigator using the same materials. Unfortunately, few such measurements are available. St. Meyer,[9] who examined several salts of neodymium, does not give the individual results; but in the table given by Zernike and James[7] it is evident that the susceptibility of neodymium in the oxide has consistently been found to be lower than in the sulfate. That is a result which might be expected if the closeness of atomic binding has anything to do with the magnetic susceptibility.

The theories of Weiss, Kunz and others,[10] in an effort to account for deviations from Curie's law, consider the mutual action of the molecules or ions. These theories yield an expression $X = c/(T - \Theta)$ for the variation of susceptibility with temperature, where Θ is interpreted as a measure of the molecular field, which may be either positive or negative.

Williams'[11] work on neodymium oxide shows that the temperature variation may be expressed by $X = c/(T - \Theta)$ where $\Theta = -44°$. The

[11] Williams, *ibid.*, **12, 158 (1918).**

variation in the susceptibility of neodymium nitrate found here could be accounted for by an increase of ten units (degrees C.) in 8, the molecular field being considered negative. Over the limited temperature range available it would scarcely be possible to detect such a change in 8 directly, with the experimental apparatus described.

In the case of gadolinium sulfate, as is well known, Θ is practically zero, and it might be argued by analogy that, in view of the close chemical relationship between gadolinium and neodymium, the introduction of the molecular field in the case of the latter is artificial; but the author found almost no absorption spectra shift in the case of gadolinium solutions. The explanation is, perhaps, not that the gadolinium sulfate has no molecular field, but that its more stable electron structure is less sensitive to external influence.

The nature of the molecular field remains much in doubt. As stated by Stoner[12] "...the conclusion which may be drawn is that the molecular field cannot be interpreted as being simply either magnetic or electrostatic." However, "...that there are strong forces of some kind, whose effects are similar to those of magnetic fields, is undoubted."

While the work on nitrogen–oxygen mixtures tends to show that the molecular field is a function of the concentration of the magnetic molecule, the situation in such mixtures must be very different from that in the solution of an electrolyte.

Certain small temperature shifts in the absorption spectrum of gadolinium chloride are interpreted by Freed and Spedding[13] as being due to a decrease in difference between the two energy levels involved, under the influence of the electric field of the neighboring negative ions. The same argument applies to the absorption shifts of neodymium previously reported by the author.

Now Fajans[14] interprets an increase of refraction with concentration as resulting from the deformation of the cation owing to the approach of the negative field of the anion. While there is, of course, the possibility that the observed absorption and refraction changes take place by an entirely different mechanism than the magnetic change, still it is natural to try to relate them.

It has already been suggested by Cabrera and Duperier[15] that the molecular field in the case of crystalline paramagnetic substances may be identified with the "deformation" of Fajans. They say, "It is evident that, in general, we can attribute the constant 8 to a deformation of the outer electron layer of the paramagnetic atom, under the action of the

other atoms combined chemically with it." There seems no reason, then, why the shift of absorption bands should not be produced by the same mechanism. Some information as to the nature of the molecular field could be gained by measurements on the susceptibility of neodymium salts diluted with the isomorphic **salts** of the diamagnetic rare earth lanthanum.

The author wishes to thank Dr. Charles P. Smyth for his interest and advice in this work. He is also indebted to Dr. B. S. Hopkins, of the University of Illinois, for the use of several hundred grams of pure neodymium oxide.

Summary

The magnetic susceptibility of neodymium nitrate in aqueous solution has been found to decrease with increasing concentration. This behavior is discussed in connection with changes in absorption spectrum and refraction previously reported by the author, and with reference to Fajans' theory of the deformation of electron shells.

OBSERVATIONS ON THE RARE EARTHS. XXXVII. ELECTROLYTIC PREPARATION OF RARE EARTH AMALGAMS. 1. PREPARATION OF AMALGAMS OF LANTHANUM AND NEODYMIUM[1]

BY L. F. AUDRIETH, E. E. JUKKOLA AND R. E. MEINTS, WITH B. S. HOPKINS

RECEIVED MARCH 19, 1931 PUBLISHED MAY 6, 1931

In line with a series of investigations[2] which are being carried out in this Laboratory involving the use of non-aqueous solvents for the electrodeposition of metals, preliminary experiments have been performed in an effort to plate the metals of the rare earth family from solutions of their salts in various organic and inorganic solvents, but with no marked success. That such a suggestion is not new is evident from the researches of Matignon,[3] who prepared anhydrous salts of many of the rare earth elements and investigated their solubilities in various non-aqueous solvents. In connection with these studies he says, "If a solvent could be found in which salts (of the rare earth metals) ionized it would be easy to isolate the metals by simple electrolysis after the manner of Kahlenberg." Matignon had

---

[1] This paper was presented before the Division of Physical and Inorganic Chemistry the Indianapolis meeting of the American Chemical Society, April, 1931.

[2] For earlier papers of this series see Yntema and Audrieth, THIS JOURNAL, 52, 2693 (1930); Audrieth and Yntema, J. *Phys. Chem.*, 34, 1903 (1930); Audrieth and Nelson, *Chem. Rev.*, 8,335 *(1931).*

[3] Matignon, Ann. *chim. phys.*, VIII, 8, 267 (1906).

evidently been much impressed by the researches of Kahlenberg,[4] who succeeded in depositing lithium from solutions of the chloride in pyridine. The preparation of the rare earth metals presents a problem of extraordinary scientific interest, in view of the fact that only six of the sixteen elements of this group have ever been obtained in the free form (Yt, Ce, La, Nd, Sm, Eu) and only two in a high state of purity (Ce, La).

Amalgams of many active metals have been prepared by the electrolysis of concentrated aqueous salt solutions using a mercury cathode. In several instances it has been found that amalgams of higher concentration can be prepared very much more readily and with less attendant decomposition by the use of non-aqueous ionizing media. Thus, Hevesy[5] prepared a 30% barium amalgam by the electrolysis of a concentrated solution of the iodide in pyridine using a mercury cathode. Laszczynski[6] prepared concentrated amalgams of potassium and sodium by electrolysis of the corresponding thiocyanates in acetone under similar conditions. Kettenbeil[7] also studied the preparation of amalgams of various elements, but was not able to prepare those "of the rare earth metals by electrolysis of their salt solutions at a mercury cathode." He reported negative results in his attempts to prepare amalgams of cerium, yttrium, didymium, zirconium and thorium electrolytically, using water, pyridine and alcohol as solvents.

However, amalgams of yttrium, cerium and lanthanum have been prepared by thermal methods and their properties studied. The decomposition of cerium amalgam has been suggested as a method for the purification of the metal.[8] In view of these facts a study of the electrolytic preparation of rare earth amalgams was undertaken in the hope that these would lead indirectly to the isolation of metals of the rare earth family which have not, as yet, been obtained in the free state.

The experimental results outlined below prove conclusively that it is possible to prepare rare earth amalgams electrolytically, not only from aqueous solution, but more conveniently by the use of absolute alcoholic solutions. The present paper concerns itself with the amalgams of lanthanum and neodymium,[9] two of the commoner members of the rare earth family. Subsequent papers will deal with the preparation of other amalgams and their decomposition for the preparation of the free metals.

Experimental

Preparation of Materials.—Anhydrous neodymium chloride was prepared by the dehydration of the hexahydrate in an atmosphere of dry hydrogen chloride in the apparatus designed by Kremers.[10]

Anhydrous lanthanum nitrate can be prepared most advantageously by application of the method employed by Booth[11] in the preparation of anhydrous beryllium nitrate, involving the use of fused ammonium nitrate. In a typical run 20 g. of lanthanum oxide was dissolved slowly in 40 g. of fused ammonium nitrate at a temperature of 170° to yield a clear solution. The temperature was then raised slowly during the course of several hours until most of the ammonium nitrate had been decomposed and the melt had solidified. The material was then ground to a powder and heated for ten hours at a bath temperature of 300° to volatilize completely the remainder of the ammonium nitrate. The resulting product was ignited to the oxide for analysis.

Anal. Subs., 0.3666, 0.3995: La_2O_3, 0.1832, 0.1998. Calcd. for $La(NO_3)_3$: La, 42.77. Found: La, 42.61, 42.65.

The anhydrous nitrate is a white, powdery substance which is extremely hygroscopic. The resulting product is very soluble in water, liquid ammonia, acetone, pyridine and acetonitrile.

Several efforts were made to prepare anhydrous neodymium nitrate by the same method. However, a product was always obtained which contained ammonia and which analyzed for the compound $Nd(NO_3)_3 \cdot NH_4NO_3$. Any attempt to remove the excess of ammonium nitrate by raising the bath temperature above 290" resulted in the formation of the insoluble basic nitrate.

The mono-hydrated halides employed in these experiments were prepared by long continued dehydration of the more highly hydrated salts in *vacuo* at 100°. Their composition was checked by analysis. Dehydration at higher temperatures usually led to the formation of insoluble basic compounds.

Apparatus.—Various types of electrolytic cells were used. The test-tube type (noted as T. T. in the tables) consisted of a large Pyrex test-tube, 200 × 38 mm., to which was sealed a glass-stoppered delivery tube with a small side arm to permit contact with the mercury cathode by means of a platinum wire. A platinum flag was used as the anode and the apparatus fitted with a stirring device. To handle larger quantities of mercury and solution Erlenmeyer flasks of various sizes were used in place of the Pyrex test-tube.

Where aqueous solutions were employed an H-shaped cell was used in order to prevent in so far as possible reaction of the anodic products with

---

[10] Kremers, *Ind.* Eng. Chem., 17, 298 (1925).

[11] Booth, THIS JOURNAL, 52, 2581 (1930).

the amalgams. In all cases the electrolytic cells were immersed in running water to keep the solutions at approximately room temperature.

Manipulation.—All solutions were electrolyzed for varying periods of time using a 110 d. c. current. Upon completion of the runs the cathodic materials were separated from the supernatant solutions, washed with either distilled water or absolute alcohol, and then allowed to decompose by contact with air. It was found that hydrochloric acid would not react completely with the amalgams; consequently analyses were carried out by permitting samples to decompose by exposure to the air over a period of ten days, followed by titration with standard acid to determine their rare earth metal content.

Preparation of Neodymium Amalgams.—The results for a number of typical runs are given in Table I. In all experiments involving the use of aqueous solutions an insoluble precipitate of the basic salt was obtained which would settle upon the cathode and render difficult the production of more concentrated amalgams. This did not occur when the anhydrous chloride or the mono-hydrated halides were electrolyzed in alcoholic solution.

Amalgam formation was not observed when the double neodymium ammonium nitrate, $Nd(NO_3)_3 \cdot NH_4NO_3$, was used as the solute. Reduction of the nitrate to the nitrite ion was found to have taken place.

In several experiments a pasty amalgam was obtained, indicating the formation of a Nd–Hg compound only slightly soluble in mercury. This problem is under investigation at the present time.

Neodymium amalgams are readily attacked and decomposed by air with formation of the basic carbonate. Such amalgams also undergo slow reaction with alcohol, acetone and water. They are best preserved in a vacuum or under a saturated alcoholic solution of the electrolyte.

TABLE I
PREPARATION OF NEODYMIUM AMALGAMS

Run	Type of cell	Concn. of soln.	Solvent	Time, hours	Curr. density, amp./sq. cm	Amalgam, per cent. by weight of N

---

[12] Aqueous chloride solutions prepared by dissolving the oxide in hydrochloric acid.

Much of the mercury may be removed by distillation in *vacuo,* but not completely even at the temperature at which Pyrex glass begins to melt. The product obtained under these conditions is an extremely pyrophoric, black powder which takes fire in air. This material has been decomposed, with the elimination of the remainder of the mercury to give neodymium metal, in a high vacuum furnace using a tungsten boat, which served as the heating element. This same apparatus has even been used for volatilization of the neodymium metal with the deposition of an extremely reactive film of the element.

Lanthanum Amalgams.—Table II gives some of the experimental data covering the preparation of amalgams of lanthanum. These resemble very closely in reactions and properties the corresponding neodymium amalgams. (Table **11.)**

TABLE II

PREPARATION OF LANTHANUM AMALGAMS

Expt.	Type of cell	Composition and concn. of soln	Length of run, hours	Current density, amp./sq. cm.	Atom per cent. of La in amalgam
9a[a]	H	25 g. La_2O_3[12] to give 35 cc. of aqueous chloride soln.	6	0.2–0.1	1.6

1[d]	T. T.	10 g. La_2O_3[12] to give 25 cc. of aqueous chloride soln.	0.5	.6	Slight
3b[e]	T. T.	9 g. $LaBr_3 \cdot H_2O$ in 20 cc. C_2H_5OH	20	.35	3.1

[a] Formation of much basic salt causing current to decrease gradually, fair amalgam. [b] Reduction of nitrate to nitrite, no amalgam formed. [c] Basic chloride, LaOCl, precipitated; no amalgam. [d] Basic chloride formed, Hg^{++} ions present in electrolyte. [e] Pasty amalgam formed; solution remained clear; no basic salt precipitated.

Summary

Amalgams of neodymium and lanthanum may be prepared by electrolysis of aqueous and alcoholic solutions of various of their salts using a mercury cathode. Electrolysis of the anhydrous halides, or the monohydrated halides, in alcoholic solution gives better results than the use of water as a solvent. These amalgams are extremely reactive and undergo ready decomposition. The free metals may be obtained from them by heating the amalgams in *vacuo.*

URBANA, ILLINOIS

NOTES

Intensive Drying.—One or two papers published in America record failures to obtain results which their authors expected from the drying of liquids.[1]

The explanation appears to be that while expending a great deal of trouble in obtaining the liquids in the pure state, the glass of the apparatus was not sufficiently dried.

As far as can be made out from the published papers, the phosphorus pentoxide was entirely submerged in the liquid. The glass therefore obtained very little drying effect after the apparatus was sealed up. In my original experiments as described[2] a side tube or bulb containing phosphorus pentoxide was always introduced for the sole purpose of drying the glass while the separate drying of the liquid by phosphorus pentoxide was taking place. I have recently pointed out[3] that the deep-seated moisture in glass is very difficult to remove and, in my experience, this removal to the degree necessary for these experiments is only possible by very long exposure to an atmosphere dried by phosphorus pentoxide. It is obvious that the dryness of a system is only the dryness of its wettest part.

RECEIVED DECEMBER 10, 1930
PUBLISHED MAY 6, 1931

Note on the Reaction between Hydrogen Sulfide and Mercury.— In a recent communication [THIS JOURNAL, 52, 885 (1930)], Lilienfeld and White reported the results of a study of the reaction between hydrogen sulfide and silver, and showed that the metal is attacked by hydrogen sulfide at room temperature only in the presence of oxygen and moisture; the reaction commonly supposed to occur with the production of hydrogen, *viz.*

$$2Ag + H_2S = Ag_2S + H_2$$

was found to be endothermal and not to take place at ordinary temperatures. The following observations, which show qualitatively that the reaction between hydrogen sulfide and mercury is analogous to that of the gas and silver, were noted during the preparation and purification of hydrogen sulfide in an apparatus containing several H_2S/Hg interfaces. Work to be carried out involved the measurement of pressure with a manometer, the mercury of which would be in continuous contact with pure hydrogen sulfide, hence it was necessary to determine whether any reaction took place.

Hydrogen sulfide, prepared by the action of dilute hydrochloric acid upon "Analytical Reagent" ferrous sulfide *in vacuo*, was passed over powdered ferrous sulfide, dried over phosphorus pentoxide, condensed in liquid air and subjected to fractional distillation. Rejected fractions were discharged at open mercury surfaces, which soon became coated with sulfide. A sample of the pure gas finally obtained was sealed up in contact with pure mercury for three months. No trace of blackening of the surface could be seen, but at the end of this period the introduction of a trace of moist air into the tube caused the mercury surface to be covered with a black film in a few hours.

Ample confirmation of the immunity of mercury from attack by hydrogen sulfide free from air and moisture was evident as the work progressed; the gas could be safely stored in tubes over mercury, and pressure measurements could be carried out without risk of contamination of the meniscus.

In their paper Lilienfeld and White mentioned that phosphorus pentoxide could not be used to dry hydrogen sulfide as it oxidized the gas to sulfur dioxide. To investigate this point the tests employed by these authors were used in an examination of the gas prepared as described. Analyses of samples of the gas showed sulfur dioxide to be absent, while no sulfur residue was left by the evaporation of a carbon disulfide extract of the contents of a phosphorus pentoxide tube through which about 25 liters of gas had passed.

It is probable that the phosphorus pentoxide used by the American workers contained lower oxides of phosphorus, which were responsible for the oxidation of the hydrogen sulfide. The drying agent used in this work was tested according to the method described by Whitaker [J. *Chem. Soc.*, 127, 2219 (1925)], and was found to be free from lower oxides.

The Construction of a Flexible Glass Diaphragm for a Clicker Gage.—The utility of the glass clicker gage for measuring pressure changes in gas reactions has been emphasized by several investigators, in particular D. F. Smith and W. W. Taylor.[1] The essential part of this gage is the glass diaphragm. It must be strong enough to withstand a considerable pressure difference on the two sides, thin enough to have high sensitivity, and must click audibly at a definite pressure difference. As Smith and Taylor point out, the construction of a good diaphragm is very tedious. The following method is simpler and requires fewer trials to make a satisfactory diaphragm.

[1] Smith and Taylor, THIS JOURNAL, 46, 1393 (1924).

A thin glass bulb is blown at the end of a 3-mm. tube in the usual manner, but just before it becomes rigid it is squeezed lightly by a U-shaped piece of spring brass. This operation forms a banjo-shaped bulb. The flattened sides possess concentric corrugations which give superior clicking characteristics to the diaphragm. Usually only one side clicks well. However, in case there is confusion because both sides click near the same pressure difference, one of them can be heated until the corrugations are destroyed.

THE MOLECULAR WEIGHT OF CASEIN. III[1]

BY D. C. CARPENTER

RECEIVED SEPTEMBER 16, 1930 PUBLISHED MAY 6, 1931

In the two previous papers of this series, Svedberg, Carpenter and Carpenter[2] have described their experiments dealing with the determination of the molecular weight of casein by use of the ultracentrifuge. Casein prepared either by the method of Hammarsten[3] or the method of Van Slyke and Baker[4] was shown to consist of a mixture of protein molecules of different molecular weights. Furthermore, different specimens prepared by the latter method were shown to consist of different mixtures.

By extracting Hammarsten casein with warm acidified alcohol we have separated a protein which behaved as a monomolecular substance and which had a molecular weight of 375,000. This was found to constitute about 30% of the crude Hammarsten casein. The other chief constituent of crude casein was studied in several samples of Van Slyke and Baker casein and it was shown that the molecular weight of this constituent lay between 75,000 and 100,000.

That the protein of molecular weight between 75,000 and 100,000, the one of 188,000 and the acid-alcohol soluble one of molecular weight 375,000 are separate and distinct species has been shown by the serological studies of Carpenter and Hucker.[5]

This paper deals with the estimation of the molecular weight of the

simplest of these proteins, the one which is the chief constituent of crude casein prepared by either of the foregoing methods and which may be fractionated by potassium oxalate. We propose to find the molecular weight of this protein through calculations based upon the sulfur, phosphorus and various amino acid contents of the protein, This idea is not particularly new, as it has been used by Cohn and his co-workers[6] in attempts to calculate the probable molecular weight of several proteins. The method of attack, however, presupposes (a) a monomolecular protein and (b) accurate analytical procedure for the estimation of the desired constituent. The former requisite is most easily fulfilled when we are dealing with a crystallizable protein and is most difficult of fulfilment when we are concerned with the amorphous proteins. The second requirement, of methods which yield the correct amino acid content after hydrolysis of the protein, must take into account the amount of any given amino acid which is destroyed by the hydrolytic process or lost in other ways. Losses by the Fischer ester method have been examined on known mixtures of amino acids by Osborne and Jones[7] and found to range from 20 to 80% for various amino acids.

In determining the molecular weight of a protein from the amino acids which it contains, it is obvious that the larger the individual molecular weight of a given amino acid and the smaller the number of times it occurs in the parent protein, the greater will be the accuracy of the molecular weight estimation. From the older analyses of casein[8] which were based on what we now know to have been a mixture of material, it seems probable that the determination of cystine, tryptophane and histidine will be of most service to us in selecting the molecular weight. Methods for estimating these amino acids have been worked out for use on relatively small quantities of protein and have been reported as satisfactory. As tyrosine can be estimated in the same hydrolysate after removal of the tryptophane, we propose to carry out this determination also, but will bear in mind at the outset that as there is considerable tyrosine in casein, the molecular weight of the parent protein based on the tyrosine content can scarcely have the same degree of certainty as the results of the cystine, tryptophane and histidine analyses.

Part I. Analysis of the Protein

Sulfur.—The various methods proposed for the estimation of sulfur in proteins have been critically examined by Redfield and Huckle.[9] Of these methods the Liebig and Koch, and the Liebig methods gave the maximum recovery of sulfur from a sample of peptone. In brief the Liebig

[9] Redfield and Huckle, THIS JOURNAL, 37, 607 (1915).

and Koch method[10] consists of a preliminary digestion of the protein with nitric acid followed by a fusion with potassium hydroxide and potassium nitrate, while the Liebig method is the same except that it omits the preliminary digestion with nitric acid.[11]

Determination of Sulfur.—For the estimation of sulfur in casein we have employed the Liebig and Koch method of oxidation. About one gram of casein was digested in a Kjeldahl flask with *25* cc. of concentrated nitric acid at a brisk boil for two hours. The solution was cooled in running water and ***20*** cc. of a 40% potassium hydroxide solution added slowly to the contents of the flask, which turned deep brown in color. The solution was transferred to a nickel crucible containing 0.5 g. of potassium nitrate and evaporated over an alcohol lamp, the flask being rinsed several times and the rinsings added to the contents of the crucible as the solution volume in the latter was reduced by evaporation. The contents of the crucible were then brought to gentle fusion over an alcohol lamp to complete oxidation of the protein. After cooling, the contents of the crucible were dissolved in water, made acid with hydrochloric acid, evaporated twice to dryness with hydrochloric acid to expel nitric acid, baked to dehydrate silica, dissolved in dilute hydrochloric acid, filtered and the sulfate in the filtrate precipitated in the usual way with barium chloride, filtered, washed, ignited and weighed as barium sulfate. The results of the sulfur analysis are reported in Table I and show that the protein under examination contains 0.785% of sulfur.

Phosphorus.—Hillebrand and Lundell[12] have shown that no volatilization of phosphates occurs when heated with excess sulfuric acid below 150°. Prolonged heating at higher temperatures, however, caused conversion of H_3PO_4 to HPO_2 and $H_4P_2O_7$, which resulted in large phosphorus losses.

Baumann[13] and Martland and Robison[14] appear to be the first workers to recognize the above findings and the significance they had in the phosphorus estimation in phosphorus-containing organic compounds. Both of these workers decomposed organic materials in the presence of concentrated sulfuric acid and emphasized that phosphorus losses occurred when the temperature rose sufficiently for white sulfur trioxide fumes to appear. The former used small amounts of 30% hydrogen peroxide and the latter used nitric acid in the presence of sulfuric acid to carry out the oxidation. Both finally estimated the phosphorus by colorimetric methods.

Determination of Phosphorus.—In our own experiments we have oxidized the protein with sulfuric acid and hydrogen peroxide as recommended by Baumann,[13] adding hydrogen peroxide and heating until no further charring occurred, being careful to so restrict the heating that no sulfur trioxide fumes were lost. The solution was then diluted with water made neutral with ammonia, then acidified with nitric acid and the phosphorus precipitated as phosphomolybdate under the conditions recommended by McCandless and Burton.[15] The yellow precipitate was filtered off, washed with 5%

ammonium nitrate until free from molybdenum, dissolved in ammonia and the solution filtered. The solution was then neutralized to litmus paper by dropwise addition of 1:1 hydrochloric acid, stirring continuotisly, and the phosphorus precipitated in the cold with magnesia mixture, followed after fifteen minutes by the addition of 12 cc. of concentrated ammonia per 100 cc. of solution volume. After standing overnight the precipitate was filtered off, washed with 2.5% ammonia, and finally with a little ammonium nitrate solution to assist in burning the filter paper. The precipitate was dried and heated carefully over a low flame and then ignited to constant weight with strong ignition and weighed as $Mg_2P_2O_7$. Blanks were run on the reagents used in both the sulfur and phosphorus estimations and the results corrected therefor. The results of the phosphorus determinations are given in Table I and show that the protein contains 0.856% of phosphorus

Recovery of Cystine.—Hoffman and Gortner[16] have followed the effect of boiling cystine with 20% hydrochloric acid for different lengths of time by the bromate titration of Okuda[17] and found that after boiling periods of twenty-four and forty-eight hours the titratable cystine recovered was 93.99 and 92.52%, respectively, of the initial amount. These authors also record the fact that the recovered cystine was optically inactive and its phosphotungstate was more soluble than that of the original plate cystine used in the experiment, and concluded that an isomeric form of cystine had been produced. Plimmer and Lowndes[18] record that cystine loses 7% of its nitrogen by boiling with acids and that only 40% of the resultant material is precipitated by phosphotungstic acid, whereas about 97% of the original cystine is precipitated by this reagent.

For the purposes of this paper we are not concerned with what products are formed from cystine under the acid treatment but only with the matter of how much cystine escapes this change for a definite period. We have accordingly followed the change during the boiling process by the iodate method of Okuda.[19] This method is applicable for the determination of cystine and cysteine in the presence of all protein cleavage products.

In short the method consists of reducing cystine to cysteine with zinc dust and acid, and oxidizing the cysteine back to cystine with potassium iodate. The reactions involved are

Okuda recommends a $M/300$ potassium iodate solution for the titration, *1* cc. of which theoretically equals *0.0024* g. of cystine. At *17.5'* Okuda found that 1 cc. corresponded to *0.00215* g. of cystine and the writer has found *0.00226* g. at *18.5'*. Acid concentration and particularly the temperature must be fairly well controlled if concordant results **are** to be obtained. Starch indicator was used to mark the end-point of the titration more clearly.

Experimental

Three hundred and fifty milligrams of cystine four times recrystallized by the method of Folin[20] and dried in *vacuo* at 61°, was weighed out, dissolved in 2% hydrochloric acid and made up to 100 cc.; 10-cc. portions of this standard solution were then placed in Kjeldahl flasks and the calculated amount of concd. hydrochloric acid and distilled water added to make 100 cc. of 20% hydrochloric acid. Test-tube condensers closely fitting the necks of the Kjeldahl flasks were inserted and the entire set of flasks (with the exception of No. 1) were heated by an air-bath to the boiling temperature. At intervals of twenty-four hours one of the series of flasks was removed from the bath, the condensers washed off with a little water, the contents of the flask transferred to a distilling flask and the bulk of the hydrochloric acid removed by distilling in *vacua*. The contents of the flask was then transferred to a 50-cc. volumetric flask and diluted to volume. For determining the acidity of this solution, 1 cc. was removed and titrated with standard sodium hydroxide and the calculated hydrochloric acid or sodium hydroxide required to bring the remainder of the cystine solution to a concentration of 2% hydrochloric acid was added. The cystine was now reduced to cysteine by the addition of 0.5 g. of zinc dust, reacting overnight at room temperature. The solution was filtered and the zinc and filter paper washed with 50 cc. of 2% hydrochloric acid and to the filtrate 5 cc. of 5% potassium iodide solution and an equal volume of 4% hydrochloric acid were added, the temperature adjusted to 18.5° and the titration carried out at once with $M/300$ potassium iodate, using starch as indicator.

The results of these experiments are recorded in Table II. It is to be noted that the recovery of cystine is quantitative in solutions which have not been heated strongly, but that in solutions which have been boiled even for twenty-four hours, considerable

[20] Folin, J. *Bwl. Chem.*, 8, 9 (1910).

cystine has been lost. The rate of loss appears to be greatest during the first twenty-four hours but additional boiling produces additional losses. These results parallel those obtained by Hoffman and Gortner[16] but the losses in cystine are somewhat greater in magnitude than they record.

That cystine analyses on proteins must be corrected for the losses incurred during the period of boiling with 20% hydrochloric acid is evident. That the same amount of destruction of cystine would occur in the hydrolysis of a protein or in a solution where other amino acids are present, from the foregoing data we are unable to say. This matter will be taken up later in this paper.

Recovery of Cystine.—It is entirely possible that what has often been reported in the literature as cystine in proteins, existed in the protein not as cystine, but in the reduced form as cysteine. It is almost useless to try to distinguish between cystine and cysteine quantitatively when both occur together, without the presence of an invert gaseous phase during the entire period of hydrolysis of the protein. Cysteine is very easily oxidized to cystine by oxygen of the air, particularly if the solution is warm, and strong reducing agents are required to carry out the reduction of cystine to cysteine.[21]

Experimental Part

A solution of purified cystine in hydrochloric acid was reduced overnight with tin,[21] treated with hydrogen sulfide to remove tin, filtered in an atmosphere of hydrogen, and hydrogen sulfide removed from the filtrate by the rapid passage of hydrogen gas through the solution; 10-cc. samples of this solution (39.00 mg. of cysteine) were pipetted into Kjeldahl flasks and the calculated amounts of concd. hydrochloric acid and water were added to make 100 cc. of 20% hydrochloric acid. Test-tube condensers were lowered into the necks of the flasks and the flasks heated in an air-bath at the boiling temperature in the same way as the cystine experiments just described. Number 1 was made up to volume in a 100-cc. volumetric flask with 2% hydrochloric acid and was not boiled or distilled in *vacuo*. Numbers 2, 3, 4 and 5 were boiled for various intervals, transferred to distilling flasks and the bulk of the hydrochloric acid distilled off in *vacuo*, the residue transferred to 50-cc. volumetric flasks and made up to volume; 1-cc. samples of these were titrated with standard sodium hydroxide and the calculated amount of hydrochloric acid or sodium hydroxide added to the remainder of the solution to bring the hydrochloric

acid concentration to *2%*. Each of these solutions was then reduced with *0.5* g. of powdered zinc overnight at room temperature, the solutions filtered and the zinc residue and paper washed with 50 cc. of *2%* hydrochloric acid; then 5 cc. each of 5% potassium iodide and *4%* hydrochloric acid solutions were added and the solutions titrated with $M/300$ potassium iodate without delay in the presence of starch indicator. The results of these experiments are given in Table III, and show that considerable cysteine is lost even by a short period of boiling with 20% hydrochloric acid. No further loss seems to occur after twenty-four hours.

Recovery of Cystine and Cysteine in Protein Hydrolysis.—While the foregoing data show that considerable cystine or cysteine is lost during a heating with 20% hydrochloric acid, they do not necessarily represent the losses encountered in the presence of other amino acids, especially in the presence of the quantities of the latter present in the native protein under investigation. We have, therefore, determined the recovery of known amounts of cystine and cysteine when added to gelatin and also to casein when hydrolyzed with 20% hydrochloric acid for seventy-two hours, following the same procedure for handling the hydrolysate and estimating cystine and cysteine as outlined before. These data are given in Tables IV and V and show that in both gelatin and casein there is considerably less cystine or cysteine recovered when the boiling with 20% hydrochloric acid is done under conditions approximating those of the actual protein hydrolysis. There is, therefore, no "sparing action" on the decomposition of the cystine or cysteine through the presence of other amino acids. The

[a] By actual standardization 1 cc. of KIO_3 soln. = *0.226* mg. of cystine

above data show that of added amounts of cystine only about 63% is reclaimed under the conditions of hydrolysis stated, with either protein. In the case of cysteine about 70% is recovered when gelatin is hydrolyzed. That account must be taken of these losses before an accurate estimation of the cystine or cysteine in a protein can be made is entirely obvious.

Cystine Content of Casein.—In Table VI are recorded data of four separate casein hydrolyses in which the cystine has been determined as outlined before. In calculating the actual cystine content of the protein we have assumed that the added amino acid behaves the same in the hydrolysis process as the original amino acid contained in the protein and for cystine we have used the recovery factor as obtained from Tables IV and V. These data show that the cystine content of casein is close to 0.488%. Calculated as cysteine this is 0.44%, but as will be shown later in this paper, it is probable that there is no cysteine in casein, it being there in the oxidized form as cystine.

TABLE VI

CYSTINE CONTENT OF CASEIN

Expt.	Casein hydrolyzed, g	Vol KIO_3 soln reqd, cc (a)	Cystine, mg.	Corr cystine, mg (b)	Cystine. %

Calculated as cysteine					440

(a) 1 Cc. of KIO_3 soln. equals 0.226 mg. of cystine at 18.5°. (b) Using recovery factor of 63.5% for cystine and 70.5% for cysteine.

Tryptophane and Tyrosine.—In the hydrolysis of protein to be used for tryptophane analyses we are limited to alkaline reagents and to splitting by enzymes. Even with these, appreciable amounts of the tryptophane are converted into indole.[22] The majority of methods for the estimation of tryptophane are colorimetric and in practically all of these the presence of indole or its derivatives so alters the color of the solution to be compared that anything but a rough match is impossible. For instance the method of Folin and Ciocalteu[23] gives excellent results on pure tryptophane solutions but is of little use on hydrolysates, due to the red color developed by indole derivatives on the phenol reagent. Kraus[24] finds that the indole products may be removed quantitatively by shaking out with toluene and meets with considerable success in using the vanillin–hydrochloric reaction in estimating tryptophane after an enzymatic hydrolysis of the protein.

Homer[25] hydrolyzes the protein with barium hydroxide and after the customary separating by mercuric sulfate, brominates the tryptophane with nascent bromine and titrates the excess bromine as iodine with sodium thiosulfate.

Experimental

The method which we have adopted and used in this work is essentially the hydrolysis method of Folin and Ciocalteu[23] using sodium hydroxide, followed by Homer's method of bromination[25] at a low temperature.

One gram of protein was introduced into a new clean 250-cc. Kjeldahl flask, 2 cc. of butyl alcohol added to prevent foaming, and also a short spiral of silver wire and 4 g. of sodium hydroxide (as a 20% soln.). A test-tube condenser was placed in the neck of the flask, the flask mounted over a hot air-bath and boiled for twenty-four hours. At the end of the boiling period the condenser was removed, washed off with 10 cc. of water, and the boiling continued for ten minutes to remove the alcohol; the flask was then removed from the bath and while still hot 10 cc. of 14 N sulfuric acid added dropwise from a pipet, shaking well to precipitate silica; 5 cc. more of 14 N sulfuric acid was added, the flask cooled, the contents rinsed into a 100-cc. volumetric flask and diluted to 100 cc. The flask was well shaken and the solution filtered through a dry filter. The filtration is slow and the funnel should be covered with a watch glass to prevent evaporation.

To ascertain whether tryptophane was removed from a solution containing freshly precipitated silica we have conducted the experiments given in Table VII, adding various amounts of sodium silicate to change the amount of silica present. After silica removal these solutions were compared by the colorimetric method of Folin and Ciocalteu using

(a) Color standard contained 5.00 mg. of tyrosine per 100 cc.; height compared, 25 mm.

---

[25] Homer, J. *Biol.* Chem., 22, 369 (1915).

carefully prepared tyrosine as the color standard. As there was no indole in these solutions the color comparison was entirely satisfactory. Approximately 97% of the total tryptophane content appeared in the filtrate no matter how much silica was present as adsorbent. This seems to indicate that whatever loss of tryptophane occurs is due to adsorption by the filter paper rather than by silica. About the same recovery is shown for tyrosine in the experiments reported in Table VIII. In subsequent experiments the first 10 cc. of filtrate from the removal of silica was discarded, the remainder of the filtrate reserved for analysis and stored in the dark at 0°.

For the analysis of the hydrolysate, 8 cc. of hydrolysate was transferred to a 15-cc. centrifuge tube and 4 cc. of 15% mercuric sulfate in 6 N sulfuric acid added. The mixture was allowed to stand overnight in the ice box and then centrifuged for five minutes. The liquid was decanted into a 100-cc. volumetric flask, draining well and rinsing the tube edge with 0.1 N sulfuric acid. The sediment in the centrifuge tube was washed with 10 cc. of 1.5% mercuric sulfate in $2N$ sulfuric acid, stirring with a fine glass rod. The tube was centrifuged again and the liquid decanted as before into the 100-cc. flask, draining arid washing again as before. The sediment in the centrifuge tube was reserved for the tryptophane determination.

Tyrosine.—Tyrosine in the mother liquid was determined as recommended by Folin and Ciocalteu, except that we have found that diluting the red-orange solution after development of the color was best done with N sulfuric acid instead of with water. If the dilution to standard volume is made with water, an opacity develops within a few moments that renders color comparisons inaccurate. No trouble has been experienced when N sulfuric acid has been used as the diluent.

Tryptophane.—The sediment in the centrifuge tube was suspended in 10 cc. of N hydrochloric acid, warmed on the steam-bath, decomposed with hydrogen sulfide and centrifuged. The solution containing the tryptophane was then decanted into a beaker and the precipitated mercuric sulfide washed twice with 0.1 N hydrochloric acid, which after centrifuging was added to the main tryptophane solution. The solution was heated over the steam-bath until freed from hydrogen sulfide and treated with phosphotungstic acid solution to remove polypeptides, avoiding an excess. The solution was placed in the ice box overnight and the slight precipitate of polypeptides filtered off. The excess phosphotungstic acid was removed by barium hydroxide and the excess barium removed by sulfuric acid, avoiding an excess of the latter. The solution was filtered into a stoppered Erlenmeyer flask and cooled to 0°.

For the bromination of the tryptophane, 0.5 cc. of concd. hydrochloric acid, 5 cc. of 10% potassium bromide and 10 cc. of 0.01 N potassium bromate were added to the solution and the flask placed at 0° overnight (eighteen hours) for the reaction to complete itself. The excess bromine in the reaction flask was estimated by adding 5 cc. of 10% potassium iodide and titrating the liberated iodine with 0.01 N sodium thiosulfate solution, adding 1 cc. of starch solution as indicator.

The potassium bromate and sodium thiosulfate solutions are, of course, standardized against each other and the potassium bromate in turn against purified tryptophane in known amounts. Conducting the bromination under the conditions we have used, 1 cc. of 0.01 N potassium bromate will brominate 0.2296 mg. of tryptophane. This is practically identical with the value 0.2304 mg. found by Homer[25] for the bromination at 17" after six to eight hours, each tryptophane molecule requiring 8.86 moles of nascent bromine.

Recovery of Tryptophane and Tyrosine from Casein Hydrolysates and the Tryptophane and Tyrosine Contents of Casein.—In Tables IX and X are recorded our results on the tryptophane and tyrosine content of

casein and the percentage recovered of known amounts of each amino acid added before hydrolysis of the protein. The data show that 81.3% of the added tryptophane and 99.4% of the added tyrosine were reclaimed quantitatively under the conditions of hydrolysis. The correct contents of tryptophane and tyrosine in the simplest casein are therefore 1.237 and 5.55%, respectively.

TABLE IX

TRYPTOPHANE CONTENT OF CASEIN

Expt.	Casein, g.	Added tryptophane, mg.	Added tyrosine, mg.	$N/100$ $KBrO_3$ soln. reqd., cc.[a]	Tryptophane found, mg.	Tryptophane recov., %	Tryptophane in casein %

Mean								5.55

[a] Standard for Expts. 1 and 2 contained 6.00 mg. of tyrosine per 100 cc. Standard for Expt. 3 contained 12.00 mg. of tyrosine per 100 cc.

Homer[25] has shown that the bromination of indoleacetic and indolepropionic acid takes very nearly the same amount of bromine as required by tryptophane and hence the presence of these substances would not interfere materially in the above determination, as each of them no doubt originally occurred in the protein as tryptophane. Indole and skatole, however, require only about two-thirds as much bromine as tryptophane in the bromination reaction. Homer believes that as the solubility of both of these substances is very low, very little error will be introduced into the final titration by their presence. At any rate the tendency would be to give a calculated tryptophane content slightly too low and a calculated molecular weight of the protein too high on this account.

Our data show that the presence of added tryptophane and tyrosine has no influence on the recovery of each other from the hydrolysate.

Histidine.—For the determination of the basic amino acids in proteins, Vickery and Leavenworth[26] have worked out a reliable method. The

---

[26] Vickery and Leavenworth, *J. Biol. Chem.*, 76, 707 (1928).

method is, however, only applicable to large quantities of protein. As we have not had sufficient material for carrying out their method, we have used the method described by Hanke[27] and Koessler and Hanke[28] in our work, as the latter is a colorimetric method in which only small amounts of protein are required. The method in brief after separation of histidine and arginine from the hydrolysate consists in coupling histidine with *p*-diazobenzenesulfonic acid in the presence of sodium carbonate to form a reddish-orange color. The principal drawback to the determination is the fleeting character of the color developed, which usually makes more than one reading on a given trial impossible. Hanke states that no other substances likely to be present except histamine and tyramine affect the color to be compared, and that these would not be expected to be present except in putrescent decomposition. The reader is referred to Hanke's paper[27] for details of the method. We have used Hanke's method throughout with no changes, except that we have hydrolyzed the casein with sodium hydroxide in the same way as in the foregoing tryptophane determinations. In fact we have used the identical hydrolysate solutions which were prepared for the tryptophane and tyrosine determinations.

Through lack of a larger supply of the pure casein species under examination, we have been unable as yet to carry out experiments to ascertain the recovery of known added amounts of histidine from casein digests under the conditions of the alkaline hydrolysis used, and we will report the histidine content as we have found it, without reference to any possible corrections for histidine destroyed during the hydrolysis.

Histidine Content of Casein.—In Table XI are recorded data of three separate casein hydrolyses, in which the histidine has been determined as

TABLE XI

[27] Hanke, *J. Biol. Chem.*, 66, 475 (1925).

[28] Koessler and Hanke, *ibid.*, 66, 505 (1925).

given above. Assuming that no histidine has been lost during the hydrolysis, the histidine content appears to be 1.776%. As the same amount of histidine was recovered from hydrolyzing casein to which known amounts of tryptophane and tyrosine had been purposely added, it appears that either these amino acids interfere to a like degree or else not at all, in the recovery and determination of histidine.

Part II. Estimation of the Molecular Weight.—It is obvious that provided we have a pure protein and have made no mistakes in the analyses for the various constituents, each constituent will occur in the molecular weight of the protein a whole number of times its own molecular (or atomic) weight. In the instance at hand we may also be guided by the centrifuging results of Svedberg, Carpenter and Carpenter,[2] who showed that the molecular species in question had a molecular weight between 75,000 and 100,000.

Calculated from the Sulfur and Phosphorus Content.—On the basis of 0.7855% sulfur in the protein we calculate that the minimal molecular weight possible for the protein is 4081.4 and from the value 0.8559% for phosphorus, that the corresponding value is 3626.5. The smallest number which will contain each of these numbers a whole number of times (least common multiple) is obviously

Sulfur.............................. 4081.4 × 8 = 32,651.2
Phosphorus......................... 3626.5 × 9 = 32,598.5

with a mean value for the least common multiple (S_8P_9) of 32,624.8. The actual molecular weight of the protein is some whole multiple of this last number. The values possible are

1×	2×	3×	4×
32,625	65,250	97,875	130,500

Out of these values the only one which satisfies the centrifuging results is the number 97,875, which shows that the least common multiple number is multiplied by 3 and that S_{24} and P_{27} represent the respective proportions of these elements in the protein. Calculating the molecular weight directly from the content of each of these elements separately, we obtain

From sulfur determination (S_{24}), molecular weight = 97,954
From phosphorous determination (P_{27}), molecular weight = 97,796

Calculated from Cystine Content.—From the cystine value 0.488% we calculate that the minimum molecular weight of the protein is 49,234. The molecular weight is some whole multiple of this number

1×	2×	3×
49,234	98,468	147,702

from which 98,468 is selected as the *only* value possible to reconcile with the centrifuging results. This result agrees well with that calculated from the sulfur and phosphorus analyses.

Assuming that the cystine occurs as cysteine in the amount 0.44%, we calculate that the minimum molecular weight must be 27,536 and the possible molecular weight

1×	2×	3×	4×
27,536	55,072	82,608	110,144

The value 82,608 is the only possibility from this series and this is impossible to reconcile with the values obtained from the sulfur and phosphorus analyses. In other words the assumption that cysteine occurs in the protein instead of cystine does not appear to be in accord with the facts.

Calculated from Tryptophane Content.—From the tryptophane content of 1.23% we calculate the minimum molecular weight of the protein to be 16,498. The molecular weight is, of course, a whole number multiple of this minimum number

1×	2×	3×	4×	5×	6×
16,498	32,996	49,494	65,992	82,490	98,988

Of this series the values 82,490 and 98,988 both satisfy the centrifuging results, but only the latter, 98,988, is in harmony with the sulfur and phosphorus results. It is concluded, therefore, that the latter is the only possible choice.

Calculated from Tyrosine Content.—As there is so large a quantity of tyrosine present in casein, 5.55%, we cannot estimate the molecular weight of the protein with any certainty, for the minimal molecular weight is calculated to be 3266. Thirty times this value, however, gives a possible molecular weight of 97,980, which is in harmony with all the results we have obtained thus far with this protein.

Calculated from Histidine Content.—Assuming that the histidine figure, 1.776%, requires no correction, we calculate that the minimal molecular weight is 8953. The only possible multiples of this value that are in harmony with the centrifuging results are the multiples 9, 10 and 11, giving molecular weight values, respectively, of 80,577, 89,530 and 98,480. As the latter value 98,480 is in harmony with our results with other constituents, it is considered to be the best choice of the three values.

Table XII

Summary of Results and Calculation of Molecular Weight

	Found, %	Minimum mol. wt.	Multiple	Probable mol. wt. of casein
Sulfur	0.7855	4,081	24	97,954
Phosphorus	0.8559	3,626	27	97,796
Cystine	0.488	49,234	2	98,468
Tryptophane	1.237	16,498	6	98,988
Tyrosine	5.55	3,266	30	97,980
Histidine	1.776	8,953	11	98,480
			Mean	98,279

Results and Conclusions

We have summarized our analytical results and calculations of the molecular weight of the simplest casein species in Table XII and conclude that the value 98,000 for the molecular weight agrees best with all our different analyses and also with our previous results with the ultracentrifuge.

Summary

1. The protein contained in crude casein, which has been shown to have a molecular weight between 75,000 and 100,000 by the ultracentrifuge, has been subjected to analysis.
2. The sulfur, phosphorus, cystine, tryptophane, tyrosine and histidine contents have been found to be 0.785, 0.856, 0.488, 1.237, 5.55 and 1.776%, respectively.
3. The most probable value for the molecular weight of this protein, consistent between the above analyses and the results obtained with the ultracentrifuge, was shown to be 98,000.

THE ABSORPTION SPECTRA OF ORTHO-CHLOROPHENOL INDOPHENOL AND OF ORTHO-CRESOL INDOPHENOL

BY MATILDA MOLDENHAUER BROOKS

RECEIVED OCTOBER 29, 1930 PUBLISHED MAY 6, 1931

Spectrophotometric determinations of the absorption spectra of *o*-chlorophenol indophenol and of o-cresol indophenol[1] between wave lengths of 480 and 680 mμ are presented in this paper. Two samples of each dye were used: a very pure sample[2] obtained from Dr. W. Mansfield Clark, to whom the writer is indebted for its presentation, and a commercial sample from the LaMotte Chemical Products Co.

The dyes were dissolved in various buffer solutions in concentrations of 0.00005, 0.0001 and 0.0002 M. These concentration values were based upon the assumption that the samples used consisted of the designated dyestuffs exclusively. Since in the case of one sample, this was apparently not true, the actual concentrations in this case were probably lower than

---

[1] Cohen, Gibbs and Clark, *Public Health Rpts.*, **39,** 381 (1924).

[2] Dr. Clark writes: "Each of the dyes was sufficiently free from components of an oxidation–reduction system other than the dye system to permit fairly accurate characterizations of the oxidation–reduction potential of the true dye system, but no claim is made that the material consists of dye alone. Indeed, it was found preferable to salt-out the sodium salts of the indophenols rather than to attempt methods of purification which were found to produce appreciable decomposition of the dye with the introduction of other oxidation–reduction systems. In consequence, many of the preparations in this group of dyes contain large quantities of sodium chloride."

those given. At ***PH*** 8.0, Sorensen's phosphate buffers were used; at PH's 8.6 and 9.6, Clark's boric acid buffers in the concentrations indicated. These buffers differ in salt concentration but neither adding sodium chloride nor changing the concentration of the buffer produced any change in the absorption curve.

The analyses were made with a 1928 model Bausch and Lomb spectrophotometer.

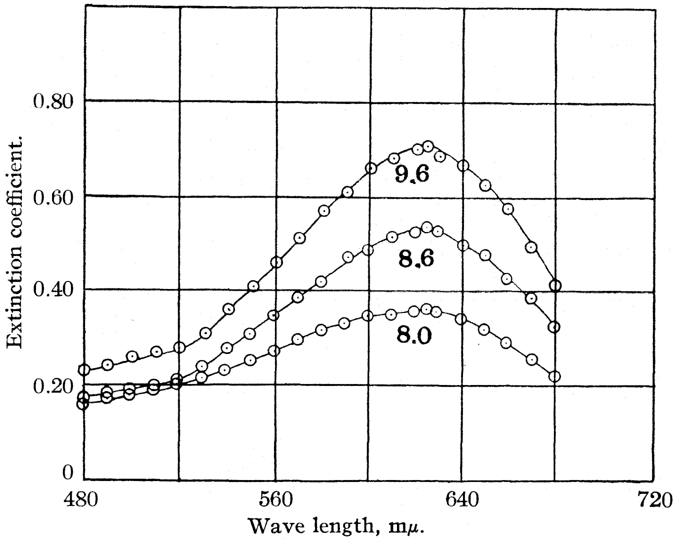

Fig. 1.—*o*-Chlorophenol indophenol: 0.0001 *M;* Clark's sample.

Figures 1 and 2 represent the absorption curves of Clark's sample and of the commercial sample of o-chlorophenol indophenol, respectively. The letters on the curves refer to ***P**H* of the solution. In both cases the absorption maximum is at 625 mμ. Since the two samples give extinction coefficients that are almost identical, they would appear to have essentially the same purity with respect to dye content. Since this dye is almost completely dissociated at PH 9.6 (*pK*, 7.0) the absorption curve at that PH is that of the blue ion. The curves at PH 8.0 and 8.6, which represent predominantly also the blue ion, differ from that *at* PH 9.6 only in the height of the peak, decreasing as the PH decreases. In Fig. 2 9.6 (2) represents a concentration of 0.0002 M or twice that of the remaining curves of both figures. The height of the maximum in this case is about twice that of the corresponding curve at half the concentration, as demanded by the Lambert–Beers Law.

Figures *3* and 4 are absorption curves of *o*-cresol indophenol, based upon Clark's and the commercial sample, respectively. Since the *pK* in this case is at 8.4, the dye at 9.6 is about 95% dissociated, and the absorption maximum of the blue ion is at 610 mp. As the *P*H and the concentration of the dye decrease, there is a decrease in the height of the peak. In these curves the symbol (1) represents a M concentration of 0.00005; (2), 0.0001 M and (3), 0.0002 M.

At *P*H 8.0 the red acid dye predominates and the absorption maximum shifts to 500 mμ with a slight secondary maximum at 610, indicating the presence of some of the blue ion (28%).

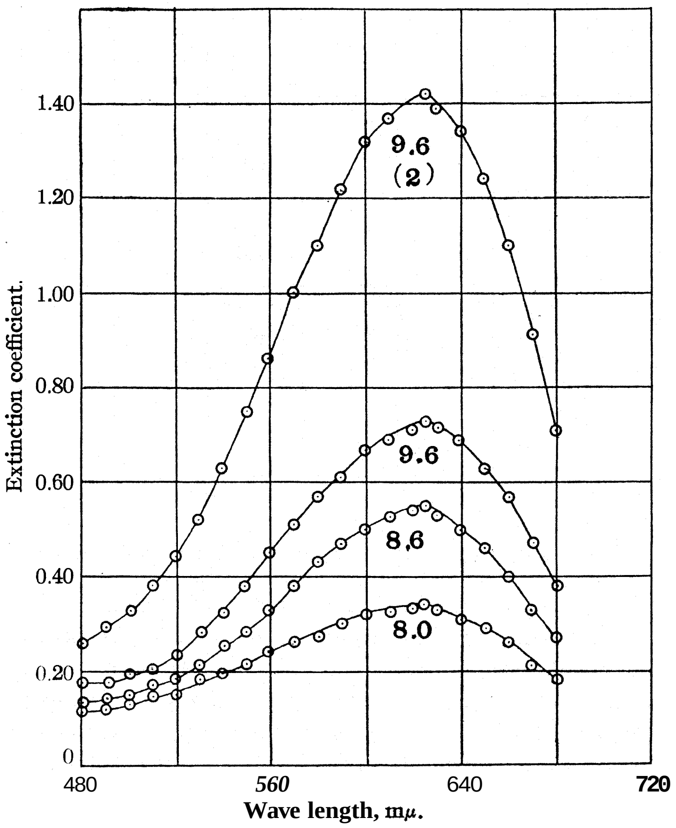

Fig. 2.—*o*-Chlorophenol indophenol: 0.0001 M; 0.0002 M; commercial sample.

These curves show the rise in the absorption maximum with increase in *P*H and in concentration of the dye solution. Alkalinities higher than *P*H 9.6 have no further effect.

Corresponding to rather rough colorimetric studies indicating that the color of the commercial sample was about 50% of that of Clark's sample, it will be seen that the extinction coefficients of the commercial sample at the wave length of maximum absorption at all *P*H values are between 51 and

54% of those for Clark's sample. It therefore appears that uncolored impurities are present in the commercial sample of o-cresol indophenol to the extent of about 47.5% by weight.

When the depth of the absorbing layer was increased to 2 or 3 cm. (as compared with 1 cm. used in the figures), the absorption curves coincided with those observed when a 1 cm. layer of dye solution of twice or three times the concentration was used. Lambert and Beer's Law is therefore valid over this range of concentrations.

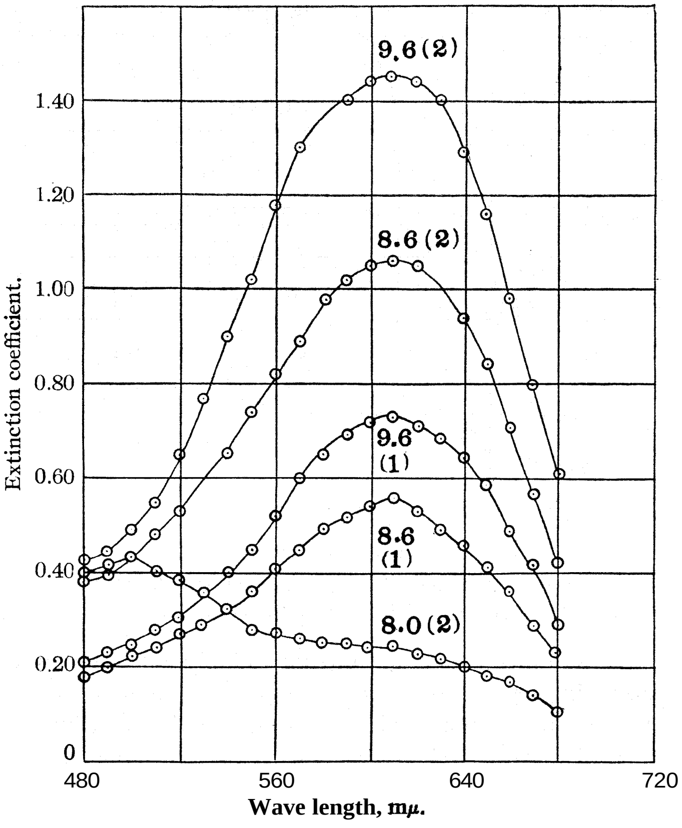

Fig. 3.—o-Cresol indophenol: (1), 0.00005 *M;* (2), 0.0011 M; Clark's sample.

The writer wishes to thank the Board of Research of the University of California for purchasing the spectrophotometer with which these readings were made.

Summary

1. Spectrophotometric studies of o-chlorophenol indophenol and of o-cresol indophenol have been made using two samples of each dye; one a

commercial sample and the other a very pure one obtained from Dr. W. Mansfield Clark.

2. The absorption maximum of o-chlorophenol indophenol at *P*H's 8.0 to 9.6 is at 625 mp. At these PH values the blue ion predominates. The absorption maximum of the dissociated form of o-cresol indophenol is at **610** mμ and that of the red acid form is at **500** mp.

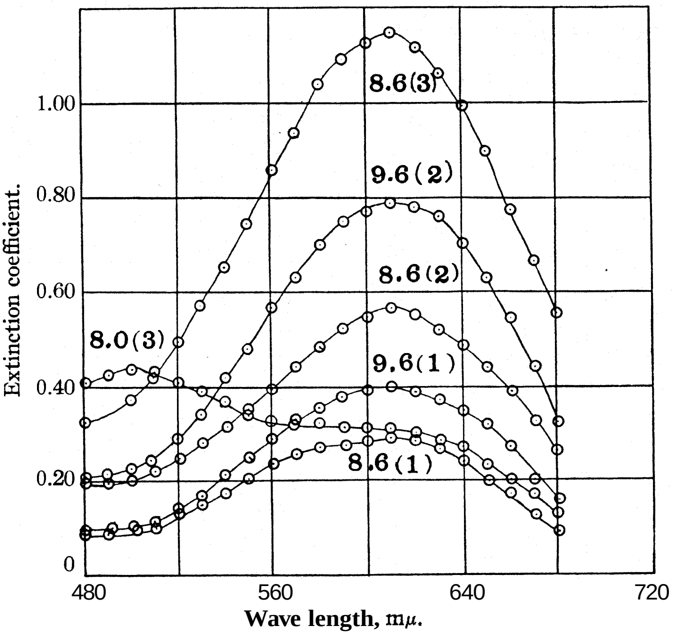

Fig. 4.—o-Cresol indophenol: (1). 0.00005 *M;* (2). 0.0001 M; (3), 0.0002 *M;* **commercial sample.**

3. The two samples of o-chlorophenol indophenol are about of equal purity, whereas in the case of o-cresol indophenol the commercial sample appears to be only between 51 and 54% as pure as that of Clark.

4. The height of the maxima varies with PH and concentration of the dye.

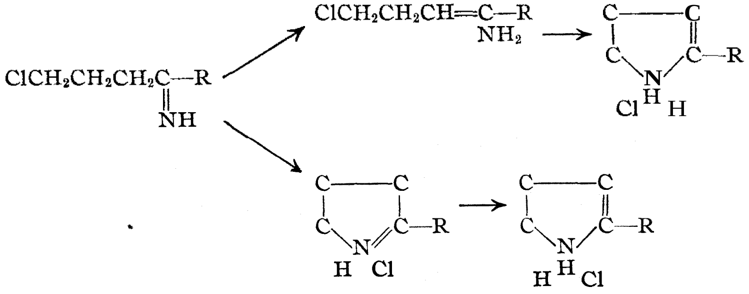
A GENERAL METHOD OF SYNTHESIS FOR ALPHA-SUBSTITUTED PYRROLINES AND PYRROLIDINES

BY LYMAN C. CRAIG, HELEN BULBROOK AND R. M. HIXON

RECEIVED DECEMBER 1, 1930 PUBLISHED MAY 6, 1931

In extending the series of pyrrole and pyrrolidine compounds for the contemplated study of insecticidal action and physical properties[1] several α-substituted pyrrolidine derivatives were desired. The methods of synthesis reported in the literature[2] are, in general, difficult and inadequate for the preparation of larger amounts of these compounds. Cloke[3] described a rearrangement of y-chloropropylketimines to pyrroline derivatives and proposed this as a convenient synthesis of a-substituted pyrrolines. His work was devoted chiefly to a study of the mechanism of the reaction, the yields of pyrroline compounds formed being particularly disappointing for the preparation of the aliphatic substituted pyrrolines. If satisfactory yields of a-substituted pyrroline derivatives could be obtained by this reaction, reduction would offer a convenient method of synthesis for α-substituted pyrrolidine derivatives. The reaction has been studied for this particular purpose.

If we accept the mechanism given by Cloke for the formation of the a-substituted pyrrolines as indicated by either one or both of the equations



then it would seem possible that ring closure could be effected by raising the temperature of the reaction mixture containing the addition product of the y-chlorobutyronitrile without going through the steps of forming the ketimine itself. The reaction would then go according to either or both of the equations

---

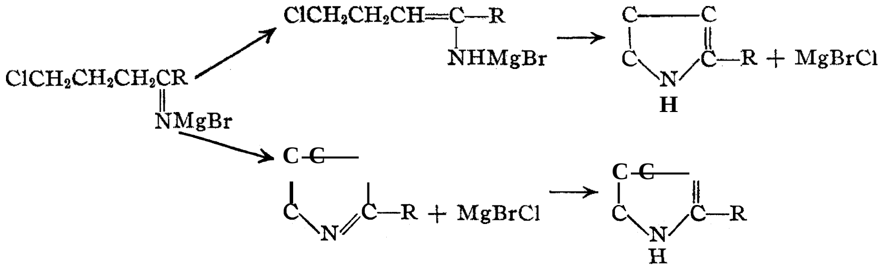
[3] **Cloke,** THIS JOURNAL, 51,1174 (1929).



Accordingly an experiment was performed in which the ether was removed from the phenylmagnesium bromide–nitrile addition product and dry xylene added, keeping the volume constant. When the temperature approached that of boiling xylene, the mixture suddenly reacted to give a viscous semi-crystalline material which was probably a mixture of MgClBr and a-phenylpyrroline-N-magnesium bromide, the latter compound being formed by reaction of the a-substituted pyrroline with the excess phenylmagnesium bromide. This method of ring closure gives much better yields than are obtained by passing through the ketimines since there is partial hydrolysis of the ketimine to the corresponding ketone. The procedure is also shorter as the pyrroline can easily be recovered from the mixture by either steam distillation or extraction with ether, according to solubility in water. The yields of a-phenyl, a-ethyl and a-benzylpyrroline are, respectively, 55, 46 and 13% of the theoretical. The order of reactivity of the Grignard compounds from which they are derived is the reverse of this.

Since the yield of the pyrroline compound as obtained by the ketimine reaction is reduced through unavoidable hydrolysis to the ketone, it seemed probable that this loss could be eliminated by reducing the ketimine acetate of the substituted γ-chloropropylketimine to the corresponding amine. These compounds on heating split out hydrochloric acid to give a-substituted pyrrolidines. a-Phenylpyrrolidine was prepared by this method but the yield was not as high as that obtained by passing through α-phenylpyrroline as an intermediate. No attempt was made to extend the method of synthesis to the a-alkylpyrrolidines.

Aliphatic a-substituted pyrrolidines can be obtained easily by catalytic reduction[4] of a-substituted pyrrolines. With aromatic a-substituted pyrrolines, reduction of the benzene ring also takes place. Catalytic reduction of a-phenylpyrroline gave a mixture of reduction products that could not be separated. The literature is conflicting regarding chemical reduction of a-phenylpyrroline. Gabriel and Colman[2] obtained a quantitative reduction to a-phenylpyrrolidine using tin and concentrated hydrochloric acid, while LaForge[6] was not able to reduce a-phenylpyrroline. In this Laboratory the results of Gabriel and Colman were confirmed.

[5] LaForge, This Journal, 50, 2471 (1928).

Experimental

α-Phenylpyrroline.—A solution of phenylmagnesium bromide was prepared using 150 cc. of anhydrous ether, 8.6 g. of magnesium and 56 g. of bromobenzene. To this 15 g. of γ-chlorobutyronitrile in an equal volume of ether was added. The Grignard addition product precipitated when most of the nitrile had been added. The mixture was refluxed for two hours; the reflux condenser was then reversed and the ether allowed to distil off, keeping the volume constant by addition of xylene dried over sodium. When the ether had practically all distilled over, the mixture suddenly reacted to give a solid semi-crystalline mass. The mixture was then treated with a solution of ammonium chloride and the xylene layer removed. The aqueous layer was extracted once with ether and the ether extract added to the xylene solution. The a-phenylpyrrolidine was extracted from the organic solvents with a small volume of hydrochloric acid, the hydrochloric acid layer washed once with ether to remove xylene and heated to remove the ether. It was then treated with excess strong caustic solution, the oily layer dried over solid potassium hydroxide and distilled, 11 g. coming over at 120–130° under 18 mm. The yield was 55% of the theoretical. Several grams of a high-boiling residue was left. The picrate melted at 198° as reported by Gabriel and Colman.[2] The identity of this compound was further proved by reduction to a-pheaylpyrrolidine.

Reduction of α-Phenylpyrroline.—α-Phenylpyrroline was reduced with tin and hydrochloric acid according to the method of Gabriel and Colman.[2] The reduction product showed a constant boiling point of 120" under 20 mm. and gave a picratc that melted at 148° as previously reported. Catalytic reduction using absolute alcohol acidified with hydrochloric acid as a solvent did not go quantitatively but gave an indefinite mixture from which a picrate melting at 148° was isolated.

α-Phenyl-N-methylpyrrolidine.—In attempting to prepare the a-phenyl-N-methyipyrrolidine by methylation of a-phenylpyrrolidine according to the directions of LaForge,[5] it was found that large quantities of the quaternary derivative were formed and purification by the Hinsburg secondary–tertiary amine separation gave a few drops only of a tertiary amine when 5 g. of starting material was used. A picrate prepared from the tertiary amine melted at 196°. This tertiary amine in ether solution reacted with benzoyl chloride, which indicated ring rupture in analogy to nicotine. Purification of a-phenyl-N-methylpyrrolidine is for this reason difficult and analysis is not sufficiently sensitive to show the absence of large amounts of a-phenylpyrrolidine in the a-phenyl-N-methylpyrrolidine fraction.

Reduction of Phenyl-γ-chloropropyl Ketimine.—The phenylmagnesium bromide addition product of γ-chlorobutyronitrile was prepared as in the synthesis of α-phenylpyrroline using the same quantities throughout. Glacial acetic acid was then slowly added until all the Grignard reagent was destroyed, the ether decanted and the residue dissolved in as little glacial acetic acid as possible. After adding 0.3 g. of platinum oxide–platinum black catalyst the solution was shaken in an atmosphere of hydrogen. In two hours reduction was complete and the catalyst was filtered off. Most of the acetic acid was removed by distillation using a water-bath and reduced pressure. The residue was then made strongly alkaline and steam distilled. Recovery of the base by making the distillate strongly acid with hydrochloric acid, evaporating to a small volume, treating with excess of strong caustic and drying over solid potassium hydroxide gave 5 g. of base boiling at 120" under 20 mm. pressure. A picrate melted at 148° as reported by Gabriel and Colman[2] for a-phenylpyrrolidine and a mixed melting point confirmed its identity. It is interesting to note that in this case the benzene ring was not reduced.

α-Ethylpyrroline.—A Grignard reagent was prepared using 8.6 g. of magnesium. 38 g. of ethyl bromide and 150 cc. of anhydrous ether. To this was added 15 g. of γ-chlorobutyronitrile in an equal volume of ether. The mixture was refluxed for two hours, then the ether removed by distillation, replacing it as a solvent with anhydrous xylene. After the mixture had reacted it was treated with **50** cc. of water and the xylene decanted. The residue was treated with caustic solution and steam distilled. After adding **15** cc. of concentrated hydrochloric acid to the distillate it was shaken in a separatory funnel with the xylene layer. The acid layer was washed once with ether and concentrated to a volume of approximately **50** cc. It was then treated with strong caustic, the oily layer drawn off and dried over solid potassium hydroxide. The oil, amounting to 11 cc., was distilled, **6.5** g. of distillate coming over under a temperature of 140". The yield was 46% of the theoretical. It gave a picrate melting at 87° when crystallized from absolute alcohol. The gold chloride could be crystallized from water strongly acidified with hydrochloric acid and melted at **122".** A sample for analysis was dried in a vacuum desiccator at room temperature. a-Ethylpyrroline was first prepared by Dennstedt[6] but the only derivative reported was the chloroplatinate.

Anal. Calcd. for $C_6H_{11}NHAuCl_4$: Au, **45.20.** Found: Au, **45.25, 45.30.**

As a further confirmation of the identity of this compound it was reduced catalytically with Adams and Shriner platinum oxide platinum black catalyst to a-ethyl' pyrrolidine. The reduction was quantitative. A picrate of a-ethylpyrrolidine melted at 85° as reported by Muller and Wacks.[2] A sample of the free oil with a constant boiling point was obtained by recrystallizing the picrate and regenerating; **12** g. of distillate and **28** g. of picric acid were added to **300** cc. of absolute alcohol. The alcohol was heated to effect solution and slowly cooled to the temperature of ice water; **24** g. of crystalline picrate, **melting at 85–86°,** was filtered off. The whole was treated with **50** cc. of water containing **15** cc. of concentrated hydrochloric acid, heated to boiling, cooled, then filtered and the picric acid washed with a small volume of water. The filtrate was then treated with strong caustic, the oil separating dried over solid potassium hydroxide and distilled. It distilled entirely at 125–126° and weighed **5.5** g. It was a colorless oil with a foul musty odor and did not color on standing. It is interesting to note that Hielscher[2] reports that he was not able to distil pure a-methylpyrroline or α-methyl-N-methylpyrroline without decomposition. There was no sign of decomposition during the distillation of pure a-ethylpyrroline.

In the literature" it is reported that a-methylpyrroline and compounds of like structure exist in water solution in a state of equilibrium, a molecule of a-substituted pyrroline reacting with one of water to form y-aminopropyl substituted ketones. Pure a-ethylpyrroline dissolved in a small volume of water did not react with either phenylhydrazine or phenylsemicarbazide in the cold. However, upon warming in a small volume of water for one hour on the water-bath equivalent quantities of α-ethylpyrroline and phenylsemicarbazide hydrochloride, a white solid insoluble in water and alcohol and melting at 244° was formed.

α-Benzylpyrroline.—A Grignard reagent was prepared using **8.6** g. of magnesium, **45** g. of benzyl chloride and **220 cc.** of anhydrous ether; **15** g. of y-chlorobutyronitrile was slowly added and the mixture refluxed for two hours. The ether was then removed by distillation, replacing it as solvent by xylene. As was the case with the other two derivatives prepared there was no sudden separation of solid material. When all of the ether had volatilized, the mixture was heated for one-half hour and the α-benzylpyrroline recovered in the same manner as was a-phenylpyrroline; **3** g. of distillate boiling at 126–128° under 15 mm. pressure was obtained. The yield was 13% of the theoretical. It was a colorless oil which rapidly colored in air, and was soluble in all organic

solvents and insoluble in water. A picrate crystallized from alcohol melted at 89°. A gold chloride crystallized from an alcohol–water mixture, strongly acidified with hydrochloric acid, melted with decomposition at 125°. A sample was dried in a vacuum desiccator at room temperature and immediately analyzed as it showed some signs of decomposition. The following analyses were run on the gold chloride and free base, respectively.

A reference to this compound could not be found in the literature.

Summary

A study has been made of the synthesis reported by Cloke for the preparation of α-substituted pyrrolines from y-chlorobutyronitrile. The yields have been increased and the procedure shortened by elimination of magnesium chlorobromide from the addition product of the Grignard reagent with y-chlorobutyronitrile, closing the ring without passing through the intermediate ketimine.

α-Ethylpyrroline has been obtained pure for the first time and its boiling point reported.

The work of Gabriel and Colman on the reduction of a-phenylpyrroline with tin and hydrochloric acid has been confirmed. The catalytic reduction of this compound yields an indefinite mixture.

γ-Chloropropylphenyl ketimine acetate has been reduced catalytically to 1-phenyl-1-amino-4-chlorobutane although the latter compound was not isolated due to the ease with which it splits out hydrochloric acid to form α-phenylpyrrolidine.

α-Benzylpyrroline has been synthesized for the first time and suitable derivatives of it are reported.

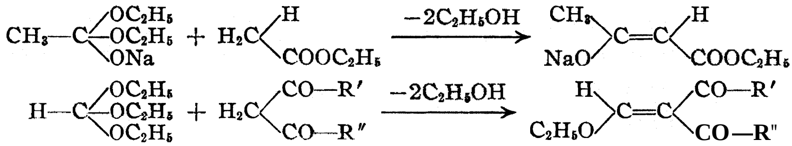
CONDENSATION OF ORTHO ESTERS WITH ACETOACETIC ESTER AND MALONIC ESTER[1]

BY PETER P. T. SAH

RECEIVED DECEMBER 19, 1930 PUBLISHED MAY 6, 1931

The condensation of ortho-formic ester with compounds containing a reactive methylene group between two carbonyl groups, such as acetoacetic ester, malonic ester, acetylacetone, etc., was a classical piece of work of Claisen,[2] who compared the analogy of this type of condensation to the formation of acetoacetic ester



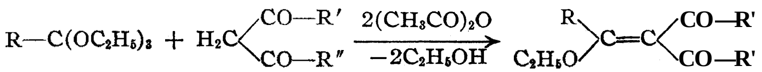
$$\mathrm{CH_3{-}C(OC_2H_5)_2(ONa) + H_2C(H)(COOC_2H_5) \xrightarrow{-2C_2H_5OH} (CH_3)(NaO)C{=}C(H)(COOC_2H_5)}$$

$$\mathrm{H{-}C(OC_2H_5)_3 + H_2C(CO{-}R')(CO{-}R'') \xrightarrow{-2C_2H_5OH} (H)(C_2H_5O)C{=}C(CO{-}R')(CO{-}R'')}$$

where R′ and R" are alkyl, aryl or alkoxy groups.

The condensation products, esters of hydroxymethylene acids, formed very stable inorganic salts. The unstable acids were also isolated by Claisen and found to be exceedingly strong acids. They may be considered as derivatives of formic acid in which the carbonyl oxygen is replaced by a carbon atom attached to two negative groups.

By using triethyl ortho-acetate[3] and triethyl orthobenzoate[4] in place of triethyl ortho-formate in the above condensation, we have been able to isolate the methyl and the phenyl derivatives of ethoxymethylene esters and identify them through their copper salts. The condensation is, therefore, a general reaction for the class of ortho esters. The mechanism of the reaction may be expressed according to the following general equation, where R represents an alkyl or an aryl group



$$\mathrm{R{-}C(OC_2H_5)_3 + H_2C(CO{-}R')(CO{-}R'') \xrightarrow[-2C_2H_5OH]{2(CH_3CO)_2O} (R)(C_2H_5O)C{=}C(CO{-}R')(CO{-}R')}$$

Experimental

General Procedure for the Condensation.[5]—All the reagents used were freshly distilled and the apparatus kept absolutely anhydrous. One

mole of ortho ester, one mole of acetoacetic ester or malonic ester and two moles of acetic anhydride (freshly distilled over sodium, b. p. 137°) were mixed and refluxed vigorously for four hours on an oil-bath with or without the addition of fused zinc chloride to catalyze the condensation. The resulting ethyl acetate and acetic acid were removed by distillation at atmospheric pressure till the thermometer, which was immersed in the solution, registered 120°. The mixture was then again refluxed for an hour and some more ethyl acetate was distilled out.[6] The residue was then fractionated under a reduced pressure of 3 mm. produced by an oil pump. A small amount of acetic acid and acetic anhydride distilled over first, then the unreacted esters and finally the condensation product. The yield of the ethoxymethylene esters thus obtained varied exceedingly, depending upon the following factors: (1) purity of the reagents used, (2) time of reaction, (3) stability of the ortho ester used, (4) stability of the condensation product and (5) the presence of catalysts. With this procedure, Claisen's experiments could be easily repeated with a yield of 50–60% under the best condition.

Description of the Condensation Products

Ethyl **methyl-ethoxymethylene-acetoacetate**, from triethyl ortho-acetate (b. p. 144–146°) and ethyl acetoacetate, was a yellowish-white glycol-thick liquid, boiling unsteadily between 108 to 123° at 3 mm. The low yield of the product, the color, and the unsteadiness of its boiling point were undoubtedly due to partial decomposition during distillation. On standing, the compound deepened in color; yield, about 8 g. from 162 g. of triethyl ortho-acetate used. The addition of fused zinc chloride during the condensation produced no favorable effect upon the yield.

Diethyl **methyl-ethoxymethylene-malonate,** from triethyl ortho-acetate and diethyl malonate, was a glycol-thick liquid distilling unsteadily from 123 to 128° at 3 mm. The reddish-brown color due to partial decomposition could not be removed by redistillation; yield, about 5 g. from 162 g. of triethyl ortho-acetate used. The greater part of the ortho ester was decomposed by acetic anhydride to 3 moles of ethyl acetate.[6] Addition of fused zinc chloride produced no favorable effect upon the yield.

Ethyl **phenyl-ethoxymethylene-acetoacetate**, from triethyl ortho-benzoate[7] and ethyl acetoacetate, was a glycol-thick liquid, boiling very steadily at 185–186° at 3 mm. without any decomposition; d_4^{25} 1.0949; n_D^{25} 1.5512. Freshly distilled, the liquid was practically colorless. It may be kept in a well-stoppered bottle for months without any noticeable change; yield, over 40 g. from 124 g. of triethyl orthobenzoate used. Addition of fused zinc chloride increased the yield slightly.

Diethyl **phenyl-ethoxymethylene-malonate,** from triethyl ortho-benzoate and diethyl malonate, was a stable, colorless, glycol-thick liquid, boiling very constantly at 188–190° at 3 mm. without any decomposition; d_4^{25} 1.0738; n_D^{25} 1.4928; yield, over

---

[6] The enormous amount of ethyl acetate formed during the condensation was undoubtedly due to the side reaction between acetic anhydride and ortho ester as mentioned by Sawitsch, *Jahrsb. über die Fortschritte der Chemie,* 391 (1860).

[7] This was prepared by adding an alcoholic solution of sodium ethoxide to benzotrichloride: b. p. 240° at atm. pressure; 128–130° at 3 mm.; n_D^{25}, 1.4938; d_4^{25}, 1.0325. Compare with Röse, Ann., 205, 250 (1880).

25 g. from 75 g. of triethyl ortho-benzoate used. Addition of fused zinc chloride increased the yield considerably.

All these condensation products were insoluble in water, but very soluble in ether, ethyl alcohol, ethyl acetate, glacial acetic acid, acetone, benzene, chloroform and carbon tetrachloride. Warm water decomposed them to their corresponding constituents. the double bond being very sensitive to hydrolysis.[2]

Copper Salts of the Condensation Products.—These were easily obtained by shaking the ester with a cold saturated solution of copper acetate. They were quite stable and served to characterize these new condensation products. The copper salts of the methyl homologs had the same solubility as those of the hydroxymethylene acids described by Claisen.2 They were insoluble in cold concentrated copper acetate solution, soluble in ethyl alcohol, isoamyl alcohol, acetone and hot benzene, from which they reprecipitated on cooling. With pyridine they formed a beautiful violet solution, which distinguished them from copper acetoacetate and copper malonate. Warm water hydrolyzed them to copper oxide. Both are greenish-blue in color.

The copper salts of the phenyl analogs, light blue in color, were very insoluble in the ordinary solvents. Warm water hydrolyzed them to copper oxide and their corresponding constituents, the odor of which, especially ethyl benzoate, could be easily identified. They gave no violet color with pyridine.

[8] Abderhalden and Schnitzler, Z. *physiol. Chem.*, 163, 95 (1926).

Summary

1. Triethyl ortho-acetate condensed only with difficulty with either ethyl acetoacetate or diethyl malonate in the presence of acetic anhydride, forming the methyl homologs of ethoxymethylene esters. They were unstable liquids, decomposing partially on distillation. They formed, however, characteristic copper salts which could be purified and identified.

2. Triethyl ortho-benzoate condensed easily with either ethyl acetoacetate or diethyl malonate, forming very stable phenyl analogs of ethoxymethylene esters with definite physical properties. Their copper salts were also made and analyzed.

STUDIES IN THE 3-NITROPHTHALIC ACID SERIES

BY H. W. UNDERWOOD, JR., AND R. L. WAKEMAN[1]

RECEIVED DECEMBER 29, 1930 PUBLISHED MAY 6, 1931

I. Phenol-3-nitrophthalein and Resorcinol-3-nitrophthalein.—This paper gives an account of the preparation of phenol-3-nitrophthalein and resorcinol-3-nitrophthalein and a comparison of the properties of these compounds with those of phenolphthalein and fluorescein. In previous contributions[2] dealing with derivatives of phthalic and diphenic acids, it was pointed out that the groups in diphenic anhydride give the sodium salt of phenoldiphenein a light yellow instead of a red color and that an alkaline solution of resorcinoldiphenein does not show fluorescence.

Discussion of Experiments

All of the temperatures given are uncorrected.

Phenol-3-nitrophthalein.—Fifteen grams of 3-nitrophthalic anhydride, 16.1 g. of phenol (calcd. amt. × 1.1) and 3 g. of concd. sulfuric acid (*d* 1.84) were placed in a loosely stoppered Erlenmeyer flask and heated in an oil-bath which was rapidly raised to 170°, maintained at this temperature for about two and one-half hours and then at 215–220" for three hours longer. After the reaction product had cooled, it was powdered and added to about 600 cc. of water in a beaker. The mixture was boiled for four hours to remove the excess of phenol; the water lost by evaporation was replaced from time to time. The insoluble solid was collected on a filter, transferred to a beaker and stirred with three 60-cc. portions of 3.5% sodium hydroxide solution. Acidification of the combined, filtered alkaline liquids yielded a dark colored precipitate. This material was collected on a filter, dried for forty-eight hours at room temperature and then ground with six 100-cc. portions of ether in a mortar. The ether

---

[1] Some of the experimental results described in this paper are taken from a thesis submitted to the Faculty of the Massachusetts Institute of Technology by R. L. Wakeman in partial fulfilment of the requirements for the degree of Bachelor of Science.

[2] Underwood and Kochmann, THIS JOURNAL, 45,3071 (1923); 46,2069 (1924).

extract was filtered, and the solvent was removed by distillation on a water-bath. Phenol-3-nitrophthalein was obtained in the form of long yellow needles, m. p. 20P 205°, by crystallization from acetone, with the use of decolorizing carbon. The crystals weighed 0.6 g. (2.1% yield). The compound dissolves in sodium hydroxide solution with the development of a violet color. A very dilute solution of the sodium salt of phenol-3-nitrophthalein becomes practically colorless upon the addition of a large excess of concd. sodium hydroxide solution. Apparently the nitro group in 3-nitrophthalic anhydride gives a violet instead of a red color to the sodium salt of the phenol condensation product.

Anal. Calcd. for $C_{20}H_{13}O_6N$: C, 66.10; H, 3.61; N, 3.86. Found: C, 65.91, 65.73; H, 3.80, 3.85; N, 4.01, 4.12.

Resorcinol-3-nitrophthalein.—An intimate mixture of 5 g. of 3-nitrophthalic anhydride and 6.3 g. of resorcinol (calcd. amt. X 1.1) was placed in a large test-tube, and heated at 195–200° for one and one-fourth hours. After the melt had cooled, it was powdered and boiled with 150 cc. of water for half an hour. The solid reaction product was collected on a filter, and then stirred with two 60-cc. portions of 2% sodium hydroxide solution. The filtered alkaline solution was acidified with 6 N sulfuric acid and shaken with three 80-cc. portions and one 40-cc. portion of ether. The ether extract was filtered, and the solvent was removed by distillation on a water-bath. The solid residue was extracted with 40 cc. of boiling alcohol, and water was added to the hot filtered solution, with stirring, until it became turbid. The mixture was heated to its boiling point and then allowed to cool slowly to room temperature. The precipitated resorcinol-3-nitrophthalein was collected on a filter, dried in the air and for a short time at 105°. Another lot of resorcinol-3-nitrophthalein was obtained by concentrating the filtrate to approximately one-half its volume. The product was dissolved in a small amount of boiling alcohol, precipitated by the addition of water, collected on a filter and dried at 105°. The yield of resorcinol-3-nitrophthalein, m. p. 260°, was 1.7 g. (17.4%). The product formed red crystalline granules, which dissolved in sodium hydroxide solution with the development of a brownish-yellow color. A dilute alkaline solution of resorcinol-3-nitrophthalein exhibited a green fluorescence, but not nearly to the same extent as a solution of fluorescein.

Anal. Calcd. for $C_{20}H_{11}O_7N$: C, 63.65; H, 2.94; N, 3.71. Found: C, 63.54, 63.30; H, 3.20, 3.11; N, 3.95, 3.88.

II. Reactions of Derivatives of 3-Nitrophthalic Acid with Acetic Anhydride.—Investigations dealing with the removal of alcohol, water and ammonia from derivatives of phthalic and diphenic acids have been previously described. It was noted that monomethyl diphenate and mono-ethyl diphenate, as well as the dimethyl and diethyl esters of diphenic and phthalic acids, remain unchanged when heated with acetic anhydride, but monomethyl and mono-ethyl phthalates yield phthalic anhydride. Under similar conditions diphenamic acid is dehydrated in two different ways, giving diphenimide and 2-cyanobiphenyl-2'-carboxylic acid; the diamide of diphenic acid is transformed into 2,2'-dicyanobiphenyl, through the loss of two molecules of water. Phthalamic acid is converted into phthalimide and phthalic anhydride by treatment with acetic anhydride, and phthalamide gives *o*-cyanobenzamide and phthalimide.[3]

---

[3] Underwood and Clough, THIS JOURNAL, 51, 583 (1929); Underwood and Barker, *ibid.*, 52, 4082 (1930).

Discussion of Experiments

The methyl esters and the amides of 3-nitrophthalic acid have been previously prepared. We used dry hydrogen chloride instead of concd. sulfuric acid as a catalyst in the synthesis of dimethyl 3-nitrophthalate. The procedures given in the literature for the preparation of 3-nitrophthalimide and 3-nitrophthalic acid monoamide (1) involve the dehydration of mono-ammonium 3-nitrophthalate by heat alone and the treatment of 3-nitrophthalimide with barium hydroxide solution, respectively.[4] We found that it was advantageous to employ a mixture of the mono-ammonium salt and anhydrous zinc chloride and to use sodium hydroxide instead of barium hydroxide; typical experiments are described below.

Monomethyl 3-Nitrophthalates.—Five grams of each ester was heated with 5 g. of glacial acetic acid and 8 g. of acetic anhydride for six hours at 145°. Practically all of the liquid was then removed by distillation, and the residue was cooled in ice. The product was crystallized from a small amount of glacial acetic acid. 3-Nitrophthalic acid methyl ester (1) was recovered unchanged. Two grams of 3-nitrophthalic anhydride was obtained from the 3-nitrophthalic acid methyl ester (2).

Dimethyl 3-Nitrophthalate.—After a mixture of 5 g. of dimethyl 3-nitrophthalate, 5 g. of glacial acetic acid and 8 g. of acetic anhydride had been refluxed for six hours at 145°, the liquid was removed by distillation, and the residue was cooled in ice. Practically all of the ester was recovered unchanged.

3-Nitrophthalimide.—A solution of the mono-ammonium salt of 3-nitrophthalic acid, prepared by the addition of the acid to the calculated amount of concd. ammonium hydroxide, was evaporated practically to dryness. The product was collected on a filter and dried. An intimate mixture of 15 g. of powdered mono-ammonium 3-nitrophthalate and 5 g. of powdered anhydrous zinc chloride was placed in a large test-tube and heated at 225–230° for four and one-half hours. The melt was allowed to cool, transferred to a mortar, reduced to a powder and extracted with four 15-cc. portions of boiling acetone. The filtered acetone solution was refluxed with 0.3 g. of decolorizing carbon for several minutes and filtered; this treatment was repeated. About two-thirds of the solvent was removed by distillation on a water-bath, and the residue was cooled in ice. The 3-nitrophthalimide was collected on a filter and dried for half an hour at 100°. The yield of 3-nitrophthalimide, m. p. 214–215°, was 5.05 g. (40%).

3-Nitrophthalamic Acids.—Five grams of 3-nitrophthalic acid monoamide (2) was refluxed with 5 g. of glacial acetic acid and 8 g. of acetic anhydride for six hours at 145°. The crystals deposited when the solution was cooled in ice were collected on a filter and recrystallized from alcohol. Two and one-tenth grams of 3-nitrophthalimide was obtained.

When 10 g. of 3-nitrophthalimide was heated with 25 cc. of 10% sodium hydroxide solution (calcd. amt. × 1.34) and 35 cc. of water for an hour at 80–85°, most of the solid gradually dissolved. 3-Nitrophthalic acid monoamide (1) was precipitated by acidification of the hot filtered solution with concd. hydrochloric acid. After the reaction mixture had been cooled in ice, the solid was collected on a filter, washed with 20 cc. of water and dried in a vacuum desiccator over anhydrous calcium chloride. The yield of 3-nitrophthalic acid monoamide (1) was 7.5 g. (68.6%). The product softened at 144–146°, solidified as the temperature was raised and remelted at 214–215°.

A solution of 5 g. of the monoamide in 5 g. of glacial acetic acid and 8 g. of acetic anhydride was refluxed for six hours at 145°, and then allowed to stand for twelve hours. The solid which formed was collected on a filter. The filtrate was diluted

---

[4] Bogert and Boroschek, THIS JOURNAL, 23, 740 (1901).

with 40 cc. of ether and filtered again. The reaction product, which weighed 2.9 g. after crystallization from a small amount of a mixture of equal volumes of alcohol and acetone, was identified as 3-nitrophthalimide.

3-Nitrophthalamide.—By use of the procedure described above, we obtained 2.1 g. of 3-nitrophthalimide by heating 5 g. of 3-nitrophthalamide with 5 g. of glacial acetic acid and 8 g. of acetic anhydride for six hours at 145°. A small amount of impure acetamide was secured by fractionation of the distillate.

Summary

Phenol-3-nitrophthalein and resorcinol-3-nitrophthalein are formed by the condensation of 3-nitrophthalic anhydride with phenol and resorcinol respectively. Phenol-3-nitrophthalein dissolves in sodium hydroxide solution with the development of a violet color. A dilute alkaline solution of resorcinol-3-nitrophthalein exhibits a green fluorescence, but not nearly to the same extent as a solution of fluorescein.

When 3-nitrophthalic acid monomethyl ester (1) and dimethyl 3-nitrophthalate are heated with acetic anhydride, each ester remains unchanged. Under similar conditions 3-nitrophthalic acid monomethyl ester (2) yields 3-nitrophthalic anhydride. The isomeric 3-nitrophthalamic acids and 3-nitrophthalamide are converted into 3-nitrophthalimide by treatment with acetic anhydride.

A NEW MODIFICATION OF THE REFORMATSKY REACTION

BY J. A. NIEUWLAND AND S. FLORENTINE DALY

RECEIVED JANUARY 19, 1931 PUBLISHED MAY 6, 1931

Reformatsky published a new method for making β-hydroxy acids from ketones or aldehydes by condensing them with α-iodo esters in the presence of zinc.[1] Later, he and his associates and others[2] published records of reactions in which bromo acid esters had been substituted for iodo esters. Reformatsky also made the statement that chloro esters react with ketones in a manner analogous to bromo and iodo esters but do not react with aldehydes.[3]

Although β-hydroxy acids have been made from chloro esters by the use of sodamide,[4] with an aldehyde or ketone, there is no record in the literature to show that it has been done with zinc as a condensing agent.

We have found that chloro esters do not condense with ketones or aldehydes in the presence of zinc alone, but that the reaction can be effected

---

by the addition of copper powder to the reaction mixture. The following is typical of the procedure used and is a modification of the method of Lindenbaum and others.[2,5]

A mixture of *35* g. of acetophenone, 38 g. of chloroacetic ester and *35* g. of benzene with 18 g. of zinc and 3 g. of copper is refluxed and heated with a small flame until the most vigorous reaction subsides. When the reaction mixture is shaken frequently the unused zinc does not cake.

After cooling, the mixture is decomposed with 20% solution of ice-cold sulfuric acid, which is added slowly until all the solid matter in the reaction mixture has dissolved. The oily layer is separated and the water layer extracted several times with ether. The ether extract and oil are combined and allowed to remain overnight on anhydrous sodium sulfate. The liquid is decanted and after the ether and benzene have been removed on a water-bath it is fractionated under diminished pressure.

The ester is saponified with 25% alcoholic sodium hydroxide, and refluxed for two hours. The alcohol is then distilled off on a water-bath, the solid salt dissolved in a small quantity of water and the acid precipitated with concentrated hydrochloric acid. In most cases an oil as well as a white precipitate of acid forms in the water solution. When the oil does not disappear on standing or by reprecipitating the acid from sodium carbonate solution, it is removed by drying the crystals of the acid between filter papers or on a porous plate.

Among the condensations accomplished in this way are those of the esters of chloroacetic acid, phenylchloroacetic acid and chlorobutyric acid, respectively, with benzaldehyde, benzophenone, propiophenone, *p*-methoxyacetophenone, *p*-tolyl methyl ketone, acetophenone, ethyl acetoacetate and acetone. These reactions were carried out under varied conditions. The results are indicated in the following table.

Percentage yield is calculated from the original quantity of aldehyde or ketone used

	Product formed	In benzene	In xylene	**Without** solvent
1[a]	Cinnamic acid	35% acid	10% acid	22% acid
2"	2,2-Diphenylhydracrylic acid	30% acid	47% acid	52% acid
3	2-Ethylcinnamic acid		33% acid	
4"	p-Methoxy-2-methylcinnamic acid	52% ester	48% ester	
5	*p*-Tolyl-2-methylacrylic acid	13% ester		No ester
6	2-Methylcinnamic acid	40% ester	10 5% ester	No ester
7	2-Hydroxy-2-methylglutaric acid	27% ester		
8	1-Ethyl-2-methyl-2-hydroxymethylbutyrate	33% ester		No ester
9	I-Phenylcinnamic acid	18% ester		No ester
10"	1-Phenyl-2,2-hydroxy-*p*-methoxyphenylbutyric acid	27% ester		No ester

[a] Some of the original ketone may be recovered.

---

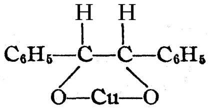
[5] Rupe and Busolt, *Ber.,* 40, 4537 (1907).

The acids and esters synthesized were identified by their physical constants recorded in the literature, with the exception of 1-phenyl-2,2-hydroxy-*p*-methoxy-phenylbutyric acid. This compound is not described in the literature. From analysis and the Zeisel reaction its formula is CH_3-$C(OH)C_6H_4OCH_3CHC_6H_4COOH$.

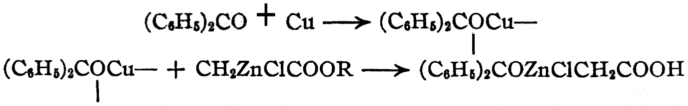
The methyl ester is a colorless liquid, boiling at 113–115° at 20 mm. A yield of about 64% is obtained when calculation is based on the amount of unused ketone recovered. Although the methyl ester has a constant boiling point, the saponification product from it is a mixture of white crystalline solid and oil. This oil is probably one or more of the possible isomers of the acid, since on standing it solidifies to a white crystalline solid. The crystals, white leaflets, dried on filter paper to remove traces of oil, melt at 75°. They dissolve readily in alcohol, ether, benzene and hot water and to some extent in cold water.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71; H, 6.71; O, 21.23. Found: C, 72.8; H, 6.8; O, 20.4. Zeisel reaction for methyl group in methyl ester: Calcd.: OMe, 20.6; equivalent. 300.016. Found: 19.82.

The effect produced by copper powder in β-hydroxy acid synthesis is probably due to the formation of *a* copper–ketone compound such as has been described by Bernoulli and Schaaf.[6] Two moles of benzaldehyde is combined with copper. The formula assigned by them to the compound is



Since such compounds as this, once formed, do not, as a rule, break up readily, it seems more reasonable to attribute the accelerating effect to some copper-containing radical in solution. In that case a reaction such as the following might be offered as a plausible explanation



$$(C_6H_5)_2CO + Cu \longrightarrow (C_6H_5)_2COCu\text{—}$$

$$(C_6H_5)_2COCu\text{—} + CH_2ZnClCOOR \longrightarrow (C_6H_5)_2COZnClCH_2COOH$$

According to Bernoulli and Schaaf,[6] the copper–aldehyde compounds do not form with pure aldehyde or ketone, but only in the presence of a solvent. The rate of formation is dependent on the fluidity of the solvent and the temperature of the solution. These compounds form most readily in benzene as a solvent. Their presence is detected by the green, green-blue or green-yellow color of refluxed solutions of copper powder and an aldehyde or ketone dissolved in benzene or in a chloro ester. These solutions, freed from all unused copper powder, effect β-hydroxy syntheses. A synthesis is also accomplished when dry copper oxide is substituted for copper powder,

---

[6] Bernoulli and Schaaf, *Helv. Chim. Acta,* 5, 721–731 (1922); Fritz Schaaf, *Z. anorg. allgem. Chem.,* 126, 237–253 (1923).

but no synthesis takes place with anhydrous copper sulfate as a catalyst. Zinc bronze also fails to promote synthesis.

All efforts to form and use the zinc–chloro ester compound, CH_2ZnCl-COOH, assumed by Reformatsky,[2] instead of zinc metal and a chloro ester, were unsuccessful.

Cadmium powder alone, as well as cadmium powder with copper powder as condensing agents, fails to promote a β-hydroxy acid synthesis.

In general, then, the reaction is most satisfactory in a medium of benzene (Table). This is not because the copper–aldehyde or copper–ketone compound forms most readily in benzene; the same reaction occurs in some cases (Table) with no solvent other than a chloro ester added to the ketone or aldehyde. The fact leads to the conclusion that the primary function of the additional solvent is the regulation of the temperature of the reaction mixture.

The importance of benzene as a temperature regulator can be seen in its use with phenylchloroacetic ester. If the temperature in these reactions be high, diphenylsuccinic ester is formed. High temperature also destroys some ketones, as methoxyacetophenone, so that a low boiling point solvent must be present to prevent decomposition. In small quantities of benzene (equivalent molar quantities of ketone and solvent), *p*-methoxyacetophenone condenses with chloroacetic ester to a β-hydroxy acid ester, but decomposes with an equivalent quantity of benzene with phenylchloroacetic ester. If, however, enough benzene is used to keep the boiling point of the mixture between 98 and 100°, synthesis takes place.

The length of time for the reaction has a notable effect on the yield of β-hydroxy acid ester. When the calculation is based on the amount of zinc dissolved, the theoretical yield of β-hydroxy acid ester is never obtained. If the percentage yield be calculated from the amount of aldehyde or ketone used, which is found by deducting the amount of unused aldehyde or ketone recovered, fairly high percentage yields are obtained. If the reaction runs long enough to use the theoretical amount of zinc, a viscous residue with high boiling point results, no ketone can be recovered, and the percentage yield of β-hydroxy acid ester is low.

The effects of temperature and reaction time on these reactions are illustrated by the results obtained from successive runs of acetophenone with chloroacetic ester, in various solvents and during periods of time extending from thirty minutes to eight hours. With benzene as a solvent, a one-hour run gave 42% ester and an eight hour gave 38% ester; with xylene as a solvent the yield for a one-hour run was 28% ester and for an eight-hour run, 10.5% ester; without a solvent, the corresponding yields were, respectively, 14% ester and no ester.

High temperature as well as prolonged heating tends to increase the quantity of viscous material formed. For example, when xylene is used as a solvent, the reaction product forms a char-cake with zinc in the bottom of the flask. With benzene as a solvent, even on prolonged heating, the reaction products continue to dissolve in the solvent.

There is evidence then of reactions subsequent to the formation of P-hydroxy esters and runs of brief periods and minimum reaction temperatures are the most satisfactory. So that, in general, the most satisfactory yields are obtained when the reaction time is limited to the period of most vigorous reaction and when an optimum reaction temperature is secured. Benzene is the best solvent, since it brings the temperature into the necessary range; it also keeps free metal surface available since the reaction products are soluble in it; it obviates the formation of char-cake.

Summary

1. A β-hydroxy synthesis is obtained from a-chloro esters and aldehydes or ketones and zinc, through the action of copper metal or cupric oxide.
2. The catalytic action of copper is accounted for by the formation of an intermediate between copper and the aldehyde or ketone present, which then reacts with the zinc–chloro ester compound of the chloro esters and accelerates the synthesis.
3. Benzene is the best solvent, since it brings the temperature into the necessary range. It also keeps free metal surface available since the products are soluble in it.

Limited reaction time increases yields.

CYCLIC AMMONO KETONES[1] AND ACID CHLORIDES OF THE QUINOXALINE SERIES

BY R. A. OGG, JR., AND F. W. BERGSTROM

RECEIVED JANUARY 30, 1931 PUBLISHED MAY 6, 1931

In a previous communication[1a] quinoxaline was shown to be formally an ammono glyoxal, and experimental evidence was presented in confirmation of this view. In the present article it is desired to consider a number of derivatives of quinoxaline from the standpoint of the ammonia system, and to give the results of the experimental work supporting the analogies advanced.

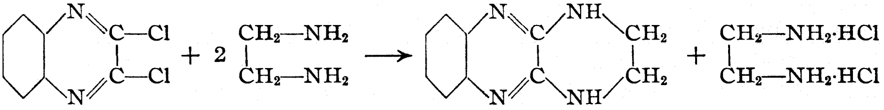
2,3-Dichloroquinoxaline.—From its structural formula, 
---

[1] The strict ammonia analogues of the aquo ketones are unknown. Because of the third valence of the nitrogen, all ammono ketones are acetals at the same time. Strain, THIS JOURNAL, 49, 1559 (1927).

[1a] Ogg and Bergstrom, *ibid.*, 53,245 (1931).

this compound is seen to be a substituted ammono oxalyl chloride,[2] and hence should show properties analogous to those of acid chlorides. The method of preparation is in accord with this view. 2,3-Dichloroquinoxaline is prepared[3] by the action of phosphorus pentachloride on 2,3-dihydroxyquinoxaline, which was shown in the previous communication to be an ester of a mixed aquoammono oxalic acid. This reaction is analogous to the formation of oxalyl chloride from oxalic acid and phosphorus pentachloride.

As an acid chloride, 2,3-dichloroquinoxaline should react with primary and secondary amines, *i. e.*, ammono alcohols, eliminating hydrogen chloride and producing ammono esters. This is actually the case, Hinsberg and Schwantes[4] having carried out such reactions with various aromatic diamines and with ethylamine. In the present work, a similar reaction has been obtained with ethylenediamine, resulting in a new cyclic ammono ester, o-phenylene ethylene oxamidine. It should be mentioned that the reactivity of 2,3-dichloroquinoxaline is much less than that of aquo acid chlorides.



2,3-Dichloroquinoxaline.—2,3-Dihydroxyquinoxaline was prepared by the method of Meyer and Seelinger,[5] and converted into 2,3-dichloroquinoxaline by heating with two equivalents of phosphorus pentachloride at 180°, according to the procedure of Hinsberg and Pollak.[3]

o-Phenylene Ethylene **Oxamidine.**—Two grams of 2,3-dichloroquinoxaline and 2 *g.* (three equivalents) of ethylenediamine were sealed in a tube and heated for two hours at 150°. The tube was then opened and the contents were washed with water. The residue was treated with dilute hydrochloric acid, and the solution, after filtration, was rendered alkaline with ammonia. The white precipitate was recrystallized from alcohol in the form of colorless leaves, sparingly soluble in alcohol, insoluble in water, but soluble in acids. Alcoholic solutions showed a faint fluorescence. The melting point was above 350°. The compound was halogen free.

Anal. Subs., 0.0977: 0.09537 *N* HCl (Kjeldahl), 21.90 cc. Calcd. for $C_{10}H_{10}N_4$: N, 30.09. Found: N, 29.94.

The reaction of an acyl chloride with a Grignard reagent gives as the first product a ketone and magnesium halide. 2,3-Dichloroquinoxaline, as an ammono di-acid chloride (-ester), has been found to react with two equivalents of alkyl magnesium halide, yielding the corresponding ammono diketone (-diacetal), *i.* e., 2,3-dialkylquinoxaline.

---

[2] It is an o-phenylene ester and acid chloride of ammono oxalic acid,

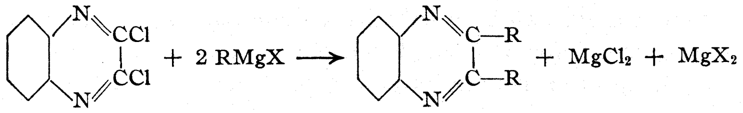
[3] Hinsberg and Pollak, *Ber.*, 29, 784 (1896).

[4] Hinsberg and Schwantes, *ibid.*, 36, 4048 (1903).

[5] Meyer and Seelinger, *ibid.*, 29,2641 (1896).



This reaction constitutes a new method of synthesis of such compounds, and was used to prepare 2,3-dimethylquinoxaline and the hitherto unknown 2,3-di-*n*-propylquinoxaline. The latter substance was found to be identical with that prepared by another method (*vide infra*).

The reaction of a considerable excess over two equivalents of methylmagnesium iodide with 2,3-dichloroquinoxaline yielded only a small quantity of 2,3-dimethylquinoxaline and a considerable amount of a red tarry substance, possibly a reduction product of the 2,3-dimethylquinoxaline. It was hoped that 2,2,3,3-tetramethyl-1,2,3,4-tetrahydroquinoxaline might be formed in this reaction.

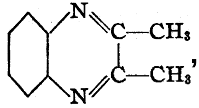
One remarkable fact noted was that 2,3-dichloroquinoxaline did not react at all with phenylmagnesium bromide, even on prolonged refluxing of the ether solution.

2,3-Dimethylquinoxaline.—Three grams of solid 2.3-dichloroquinoxaline was added to an ethereal solution of methylmagnesium iodide (2.1 equivalents). A very vigorous reaction ensued, the 2,3-dichloroquinoxaline dissolving to give a brilliant red solution. After an hour of refluxing, the mixture was decomposed by addition of liquid ammonia, which was then evaporated. The residue was extracted with ether. The red ether solution was steam distilled, the ether first coming over, then a small quantity of unidentified solid, and finally the main product, an oil which readily solidified as fine white needles. This was purified by repeated steam distillation. The substance possessed the peppermint-like odor and the same melting point (106° corr.) as pure 2,3-dimethylquinoxaline, prepared by the method of Gabriel and Sonn.[6] A mixture of equal quantities of the two melted sharply at 106° (corr.), proving their identity; yield of 2,3-dimethylquinoxaline, 60%.

2,3-Di-*n*-propylquinoxaline.—Five grams of 2,3-dichloroquinoxaline was added to an ethereal solution of *n*-propylmagnesium iodide (2.1 equivalents). A vigorous reaction took place, the solution turning deep brown in color. After two hours, the mixture was treated with ammonia as above, and then extracted with ether. Evaporation of the ether left a dark, mushy residue which was extracted with dilute hydrochloric acid. The acid solution was decolorized with charcoal and then made alkaline with ammonia, whereupon an oil separated. The solution was heated to boiling and filtered with suction, the oil passing through the paper and leaving a slight solid residue. After cooling, the solidified oil was filtered off and pressed on a porous plate. It was dissolved in acetone and reprecipitated by careful addition of water, appearing as white cubical crystals, melting at 42.9° (corr.); yield of 2,3-di-*n*-propylquinoxaline, 30% of the theoretical.

Anal. Subs., 0.0547: 0,09537 N HCl (Kjeldahl), 5.40 cc. Calcd. for $C_{14}H_{18}N_2$: N, 13.08. Found: N, 13.19.

2,3-Dimethylquinoxaline.—It is readily seen from the structure of this compound,



, that it contains two ammono carbonyl groups,

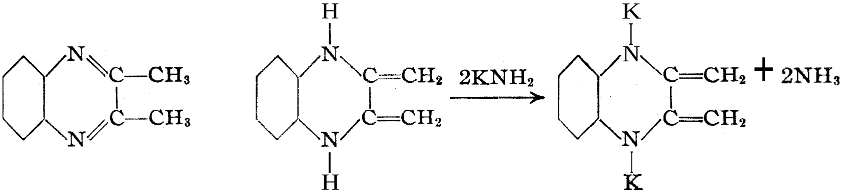
---

[6] Gabriel and Sonn, *Ber.*, 40, 4850 (1907).

>C=N—, and is to be regarded as a substituted ammono 1,2-diketone, a substituted ammono diacetyl.' The methods of synthesis are in agreement with the analogy. 2,3-Dimethylquinoxaline was prepared by Gabriel and Sonn[6] by the action of o-phenylenediamine on diacetyl, a reaction which is to be interpreted as the ammonolysis of diacetyl by a substituted ammonia. In this investigation, 2,3-dimethylquinoxaline was synthesized by the action of methylmagnesium iodide on 2,3-dichloroquinoxaline, just as, hypothetically, oxalyl chloride and methylmagnesium iodide should yield diacetyl.[8] Furthermore, 2,3-dimethylquinoxaline behaves as an ammono diketone on reduction, yielding the corresponding ammono di secondary alcohol, *i. e.*, I, 2,3,4-tetrahydro-2,3-dimethylquinoxaline.[9] In addition, 2,3-dimethylquinoxaline yields with benzaldehyde a dibenzal derivative, a type of reaction characteristic of ketones[10] that contain an acetyl group.

Since diacetyl readily adds Grignard reagents[1'''] and hydrocyanic acid,[11b] similar reactions were attempted with 2,3-dimethylquinoxaline, but without result. Hydrogen cyanide had no effect, while ethereal methylmagnesium iodide caused slow conversion to a red tar not further investigated.

A typical property of ketones having a hydrogen atom on the a-carbon atom is the formation of salts of the enol form through the agency of alkali metals, alcoholates or alkali metal amides. Furthermore, such salts react with alkyl halides, yielding usually metal halide and an a-alkyl derivative of the ketone.[12] In the present investigation, it has been found that the ammono diketone, 2,3-dimethylquinoxaline, behaves in an analogous fashion. Thus it has been found to react with potassium amide in liquid ammonia, giving a well-crystallized dipotassium salt of the ammono dienol modification.



Mills and Smith, J. *Chem. Soc.*, *121*, 2724 (1922), have suggested the strong resemblance between the CH_3—C=N— group of heterocyclic bases and the carbonyl group of the aquo ketones containing a methyl group.

[8] Actually, oxalyl chloride decomposes so readily into phosgene and carbon monoxide that it does not give this reaction.

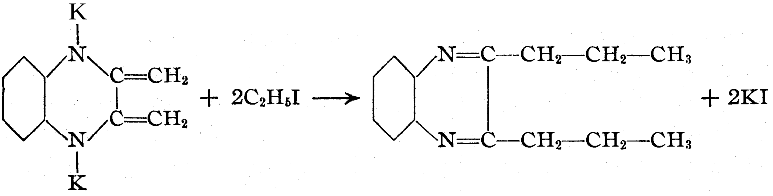
[9] Gibson, *J. Chem. Soc.*, 342 (1927).

[10] Bennet and Willis, *ibid.*, 1960 (1928).

[11] (a) Zelinsky, *Ber.*, **35**, 2138 (1902); (b) Fittig, Daimler and Keller, *Ann.*, 249, 208 (1888).

[12] Haller, *Bull. soc. chim.*, *31*, 1073 (1922), and other articles.

This salt on hydrolysis yielded unchanged 2,3-dimethylquinoxaline and potassium hydroxide. Furthermore, the salt reacted readily with two equivalents of ethyl iodide, producing potassium iodide and 2,3-di-*n*-propylquinoxaline, found to be identical with that described earlier in this paper. This reaction is seen to be analogous to that undergone by the salts of aquo ketones.[13]



It should be noted that the structure of this new compound has been definitely proved from its synthesis by two entirely different methods.

The above reaction should proceed equally well with other alkyl halides and constitutes a new method for the synthesis of 2,3-dialkylquinoxalines. It is also apparently the first synthesis of this type to be carried out with an ammono diketone.

2,3-Dimethylquinoxaline.—This was prepared by the method of Gabriel and Sonn[6,14] from o-phenylenediamine and diacetyl monoxime, and was purified by steam distillation. The white crystals of the hydrate readily effloresced, and when anhydrous melted at 106° (corr.).

Dipotassium Salt of 2,3-Dimethylquinoxaline.—This was prepared in an ammonia tube, using the technique described by Franklin.[15] One gram of anhydrous 2,3-dimethylquinoxaline was treated with two equivalents of potassium amide in liquid ammonia. The 2.3-dimethylquinoxaline (which was only slightly soluble in pure ammonia) dissolved rapidly to give a clear deep red solution. On cooling in a bath of liquid ammonia, an abundant precipitate of long greenish-yellow crystals formed. These were washed by decantation and recrystallized four times. The final washings were of the same red color as the initial, showing this to be the color of the dissolved salt. The leg containing the salt was evacuated for analysis at 60°. The sample was dissolved in dilute hydrochloric acid and one quarter of the solution was used for each analysis; weight of salt, 1.0280 g.

Anal. Subs., 0.2570: 0.09537 N HCl (Kjeldahl), 23.30 cc. Subs., 0.2570: K_2SO_4, 0.1914. Calcd. for $C_{10}H_8N_2K_2$: N, 11.95; K, 33.37. Found: N, 12.12; K, 33.42.

Qualitative investigation of the products of hydrolysis showed them to be potassium hydroxide and 2,3-dimethylquinoxaline.

2,3-Di-*n*-propylquinoxaline.—One gram of 2,3-dimethylquinoxaline was converted

---

[13] The alkylation of quinaldine, which is to be regarded as a substituted ammono ketone, has likewise been carried out by the action of alkyl halides on alkali salts of the ammono-enol modification of quinaldine. Bergstrom, Science, 72, 402 (1930); Ziegler and Zeiser, *Ann.*, 485, 178 (1931). As to a possible mechanism of alkylations of this type, see Decker, Helv. *Chim. Acta*, 13, 666 (1930).

[14] Henderson, J. Chem. *Soc.*, 466 (1929).

[15] Franklin, THIS JOURNAL, 27, 831 (1905); 29, 1694 (1907); 35, 1460 (1913); *J. Phys.* Chem., 15, 510 (1911); 16, 694 (1912).

into the dipotassium salt by treatment (in an ammonia tube) with two equivalents of potassium amide in liquid ammonia. After evaporation of the ammonia, the tube was evacuated at 50°. A slight excess over two equivalents of ethyl iodide (2 g.) in 10 cc. of absolute ether was sucked into the evacuated tube. A very vigorous reaction ensued, the greenish-yellow crystals being replaced by a fine white precipitate of potassium iodide The tube was finally warmed for a few minutes at 100°, and then cooled and opened. The contents were washed out with water. The ether layer was separated and evaporated, leaving a brown partially crystalline mass. By suction on a filter some dark oil was removed, leaving cubical crystals. These were pressed on a porous plate, and then dissolved in dilute hydrochloric acid. The solution was decolorized with charcoal and neutralized with ammonia. The precipitate was filtered off (after cooling), again pressed on a plate, and finally precipitated from acetone solution by addition of water. So obtained, the product consisted of colorless cubical crystals, m. p. 42.9° (corr.), very soluble in organic solvents, insoluble in water, soluble in dilute acids. It was slightly volatile with steam.

Anal. Subs., 0.1449, 0.1508; CO_2, 0.4166, 0.4329; H_2O, 0.1125, 0.1149. Subs., 0.1023, 0.1020; 0.09537 N HCl, 9.99 cc., 9.92 cc. (Kjeldahl). Calcd. for $C_{14}H_{18}N_2$: C, 78.47; H, 8.46; N, 13.07. Found: C, 78.39, 78.30; H, 8.69, 8.53; N, 13 05, 12.99.

The above substance was identical in all respects with the 2,3-di-*n*-propylquinoxaline prepared (*vide supra*) from 2,3-dichloroquinoxaline and n-propylmagnesium iodide. A mixture of the two gave exactly the same melting point as either constituent: yield by the above reaction, 70% of the theoretical.

The small amount of oily by-product mentioned above decolorized a carbon tetrachloride solution of bromine (a reaction not given by 2,3-di-*n*-propylquinoxaline). It is suggested that this substance may have been the di-N-ethyl derivative of the ammono dienol of 2,3-dimethylquinoxaline.

2,3-Diphenylquinoxaline.—In accord with previous analogies, 2,3-diphenylquinoxaline is to be regarded as a substituted ammono aromatic diketone, a substituted ammono benzil. In agreement with this view, it is synthesized[r6] by the action of o-phenylenediamine on benzil, an ammonolysis of the type before described. Just as benzil on partial reduction yields benzoin, which can be reoxidized to benzil, so 2,3-diphenylquinoxaline gives on gentle reduction 1,2-dihydro-2,3-diphenylquinoxaline,[16] an ammono benzoin, which may also be prepared from benzoin and *o*-phenylenediamine.[17] Upon oxidation, the compound yields 2,3-diphenylquinoxaline.

On strong reduction benzil gives the optically isomeric di-secondary alcohols hydrobenzoin and isohydrobenzoin, while 2,3-diphenylquinoxaline yields the corresponding ammono di-secondary alcohols, racemic and internally compensated 1,2,3,4-tetrahydro-2,3-diphenylquinoxalines.[18]

Since benzil adds hydrocyanic acid and Grignard reagents, similar reactions were attempted with 2,3-diphenylquinoxaline, but as in the case of 2,3-dimethylquinoxaline, unsuccessfully.

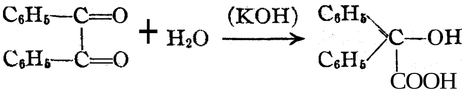
The most remarkable of the reactions of benzil is the well-known rearrangement in the presence of a base to a salt of benzilic acid.

---

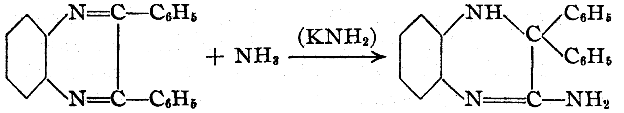
[16] Hinsberg and Konig, Ber., 27, 2181 (1894).

[17] O. Fischer, *ibid.*, 24, 719 (1891).

[18] Bennett and Gibson, *J. Chem. Soc.*, 123,1570 (1923).



It has been found that 2,3-diphenylquinoxaline probably undergoes an analogous rearrangement in the presence of the ammono base potassium amide in liquid ammonia, producing what appears to be the hitherto unknown 1,2-dihydro-2,2-diphenyl-3-aminoquinoxaline, which is to be regarded as a substituted ammono benzilic acid.



Although we were unable to prove this structure by direct synthesis, it is the most probable. If this is the structure, the reaction is the first example of the benzilic acid rearrangement in the ammonia system.

2,3-Diphenylquinoxaline.—This was prepared by the method of Hinsberg and König[18] from benzil and o-phenylenediamine.

1,2-Dihydro-2,2-diphenyl-3-aminoquinoxaline.—When 2,3-diphenylquinoxaline, which was practically insoluble in liquid ammonia, was treated with two equivalents of potassium amide in that solvent it dissolved, giving a deep violet solution, but underwent no further change, or at best only a very slow one. (It is worth noting that benzil dissolves in cold alcoholic potassium hydroxide to give a deep violet solution.) Heating was therefore employed to accelerate the reaction: 1.2 g. of potassium was converted catalytically into amide in a straight tube containing liquid ammonia; 2.2 g. of diphenylquinoxaline was then added and the tube sealed off, enclosing about 20 cc. of liquid ammonia. The sealed tube was heated in the steel bomb described by Blair[19] for ten hours at 130–140°. The solution was then still colored but contained a precipitate. After evaporation of the ammonia, the residue was treated with water, and the resulting brown solid was washed and dried. It was extracted twice with hot benzene (to remove 2.3-diphenylquinoxaline). The residue was dissolved in alcohol and decolorized with charcoal. By concentrating and cooling the solution, the product was obtained as colorless rhombohedra, fairly soluble in alcohol, insoluble in water and benzene. The substance melted without decomposition at 287° (corr.) and could be sublimed in beautiful colorless flakes. It was basic, giving a crystalline hydrochloride with alcoholic or aqueous hydrochloric acid. It dissolved in concentrated sulfuric acid without color.

Anal. Subs., 0.1417, 0.1491: CO_2, 0.4178, 0.4389; H_2O, 0.0686, 0.0733. Subs., 0.0706, 0.1032: 0.09537 N HCl (Kjeldahl), 7.48, 10.90 cc. Calcd. for $C_{20}H_{17}N_3$: C, 80.24; H, 5.72; N, 14.04. Found: C, 80.41, 80.28: H, 5.42, 5.50; N, 14.16, 14.11.

Thus the substance is seen to have the correct composition for the expected 1,2-dihydro-2,2-diphenyl-3-aminoquinoxaline. This is the most probable structure for the new compound, in view of its stability and high melting point. Oddly enough, the substance did not react with nitrous acid. Also, it was unaffected by heating with alcoholic hydrochloric acid at 150°. It is realized that in view of these facts some doubt may be cast upon the structure assigned, and attempts will be made to prove this structure by direct syntheses. The yield was 30% but much of the diphenylquinoxaline was recovered unchanged.

---

[19] Blair, THIS JOURNAL, 48, 87 (1926).

Summary

2,3-Dichloroquinoxaline, 2,3-dimethylquinoxaline and 2,3-diphenylquinoxaline have been shown to be substitution products, respectively, of an ammono oxalyl chloride, an ammono diacetyl and an ammono benzil, and experimental evidence confirming this view has been presented.

Two new methods for the synthesis of 2,3-dialkylquinoxalines have been developed.

The alkylation of an ammono diketone by converting it into a salt of the ammono dienol modification and treating this with an alkyl halide has been carried out for the first time.

Evidence of a benzilic acid rearrangement of an ammono benzil has been found.

The following new compounds have been prepared: o-phenylene ethylene oxamidine, 2,3-di-*n*-propylquinoxaline, the &potassium salt of 2,3-dimethylquinoxaline dienol, 1,2-dihydro-2,2-diphenyl-3-aminoquinoxaline (structure not definitely proven).

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

SOME RELATIONSHIPS OF THE RATIO OF REACTANTS TO THE EXTENT OF CONVERSION OF BENZALDEHYDE AND FURFURALDEHYDE TO THEIR ACETALS

BY HOMER ADKINS, JOSEPH SEMB AND LESTER M. BOLANDER

RECEIVED FEBRUARY 2, 1931 PUBLISHED MAY 6, 1931

Most of the measurements which have been made in this Laboratory upon the relationship of the structure of aldehydes and alcohols to the extent of the acetal reaction have been made upon mixtures resulting from the reaction of approximately eleven moles of alcohol with one mole of aldehyde.[1] This ratio of reactants was originally selected in order to preserve the homogeneity of the reaction mixtures, and has been used in other cases in order to obtain a direct comparison of the extent of conversion of various pairs of reactants. More recently it has seemed desirable to ascertain to what extent, if at all, the calculated equilibrium constants for this reaction are dependent upon the ratio of reactants. Such a study has now been made for certain of the acetals of benzaldehyde and furfuraldehyde.

The Reaction of **Benzaldehyde with** Alcohols.—Test-tubes (1 X 15 cm.) so marked as to make it easy to measure into them approximately the desired volume of alcohol and benzaldehyde, were drawn out preparatory to

---

[1] Adkins, Adams, Hartung, Street and Broderick, THIS JOURNAL, 47, 1358 (1925); 49,2517 (1927); 50,162 (1928); 50,178 (1928).

sealing, placed in an oven at 115° overnight, cooled in a desiccator and weighed. Approximately the desired quantity of ethanol and 0.00045 g. of hydrogen chloride in ethanol were added and the tube again weighed. Approximately the desired amount of benzaldehyde was added and the tube sealed off and weighed. The tube was then placed in a thermostat and held at 25° for approximately four days. The tubes were opened and samples varying from 0.9 to 5.0 ml., depending upon the concentration of the benzaldehyde, were removed by means of a pipet for analysis.

The Determination of **Benzaldehyde.**—The sulfite method[2] is not satisfactory in the analyses for benzaldehyde because of the indefiniteness of the end-point. The hydrogen peroxide method was found to be much more satisfactory if the method of Adams[3] was modified as in the following procedure. Thirty ml. of 3% hydrogen peroxide, prepared by diluting "superoxol," was added to 20 ml. of 0.34 N sodium hydroxide previously heated in a 250-ml. Erlenmeyer flask to 40°. The sample to be analyzed, and which contained approximately 0.35 g. of benzaldehyde, was added and followed by 5 ml. of ethanol. The reaction mixture was kept with occasional shaking in a thermostat at 40° for thirty-five minutes, after which 10 ml. more of the hydrogen peroxide solution was added and the flask again placed in the thermostat. After a total of fifty minutes in the thermostat the reaction mixture was titrated with standard acid. Blanks containing all the reagents noted above except the sample from the acetal reaction mixture were subjected to the same treatment as in the analyses and a correction made for the acidity so developed. The effect of varying the size of the sample, the quality of the hydrogen peroxide, and the temperature and time for oxidation were investigated and the above procedure was found to be quite accurate and the most satisfactory, The reliability of the method is indicated by the fact that in five successive analyses a sample of benzaldehyde showed a purity of 98.6, 99.2, 97.6, 97.4 and 99.0%.

The Reaction of **Furfural with** Alcohols.—The desired amounts of furfural and ethanol containing hydrogen chloride were weighed into a flask so that they were in the desired ratio and the total volume was 25 ml. The reaction mixture contained 0.0001 g. of hydrogen chloride. The reaction of furfural and ethanol is complete within a few hours but in these experiments the mixtures were allowed to stand for at least twenty-four hours before an analysis was made.

The Determination of **Furfural.**—The sulfite method was used for the analysis and the procedure was essentially the same as that previously described.[4] The equation on which this analysis is based is

$$C_5H_4O_2 + Na_2SO_3 + H_2O = C_5H_4O_2NaHSO_3 + NaOH$$

---

[2] Seyewetz and Bardin, J. *Soc. Chem. Ind.*, 25,202 (1906).

[3] Adams and Adkins, THIS JOURNAL, 47,362 (1925).

[4] Adkins and Broderick, *ibid.*, 50,184 (1928).

In the case of certain aldehydes the amount of aldehyde may be calculated on the basis of a titration with a solution of an acid which has been standardized by one of the methods commonly used in acidimetry. However, this is not a justifiable procedure for all aldehydes at various concentrations and it is far more accurate to standardize the acid against the aldehyde, under the conditions in which the acid is to be used in analysis. In this case samples containing from 0.10 to 0.25 g. of furfural with and without the addition of alcohol and furfural acetal were added to 40 ml. of a 10% sodium sulfite solution and the solution titrated with acid having a normality of 0.215 N as standardized against a solution of sodium hydroxide. In seven determinations 1 ml. of the acid was equivalent to 0.0231 * 1 g. of furfural. The normality of the acid against furfural was thus 0.241. This relationship between the normality of an acid against alkali and against furfural is not fixed but varies somewhat with the operator, because the end-point in the furfural titration is rather indefinite and is determined by a color comparison. This makes it necessary for each operator to standardize his acid solution against furfural.

Preparation of **Furfural Acetal.**—This acetal has been prepared by the reaction of the aldehyde with orthoformic ester as described by Claisen.[5] The preparation of the acetal by the less costly method involving the reaction of furfural with alcohol has apparently hitherto not been successful because of the sensitivity of the aldehyde toward hydrogen chloride, and because of its low equilibrium point in the acetal reaction. A practical method for carrying out this preparation has been developed after a rather extended study. A reaction mixture containing 96 g. (1 mole) of furfural, 276 g. (6 moles) of dry ethanol and 0.0012 g. of anhydrous hydrogen chloride was allowed to stand for one day. Ten ml. of water containing 1 g. of sodium carbonate was then added and the mixture subjected to fractionation through a Widmer column 30 cm. in length. The fractionation was carried out slowly so that the distillate was not more than 2 ml. per minute. After removal of the alcohol the liquid was filtered, transferred to a 250-ml. flask and fractionated through the Widmer column under a pressure of 16 to 19 mm. A yield of 24% of the theoretical amount, *i.* e., 41 g. of acetal of b. p. 77–79' (16 mm.) and 184–185° (740 mm.) was obtained on the average. Claisen reported the boiling point of the acetal as 189–191°, while Scheibler, Sotschek and Friese[6] reported 180–184°. If the amount of alcohol in proportion to the furfural was much less than that recommended above or if the concentration of catalyst was much greater the yields of acetal were materially reduced. The acetal may also be obtained from the reaction mixture by pouring it into a liter of water containing 1 g. of sodium carbonate. The water-insoluble layer was

---

[5] Claisen, Ber., 40, 3907 (1907).

[6] Scheibler, Sotschek and Friese, *ibid.*, 57B, 1444 (1924).

then placed over anhydrous sodium sulfate, while another liter of water was added to the aqueous layer in order to throw out more of the acetal. The combined water-insoluble layers after drying were then fractionated. The yield of acetal so obtained was usually about 2 g. less than by the first process in which the alcohol was removed by distillation.

Ratio of Reactants and Extent of Acetal Reaction.—There are recorded in Table I the percentage conversions of benzaldehyde and furfuraldehyde to their acetals in their reaction with various alcohols at various concentrations. The average deviation from the mean in these determinations is indicated in column two of the table after the sign for plus or minus. The number of reaction mixtures which were analyzed is indicated by the figures in parentheses in column two of the table. The value for the equilibrium constant given in column three of the table was calculated on the basis of the concentrations at equilibrium expressed as mole fractions.

TABLE I

RATIO OP REACTANTS AND EXTENT OF ACETAL REACTION

Moles of alcohol per mole of aldehyde	Conversion of aldehyde to acetal, %	*K*
	Ethanol and Benzaldehyde	
2.08	25.1±1.1 (8)	0.091
3.90	34.110.8 (6)	.079
5.87	41.9±2.0 (6)	.089
7.80	48.6±1.8 (7)	.082
9.96	53.0±1.1 (8)	.081
	n-Butanol and Benzaldehyde	
2.02	24.8±1.5 (7)	.091
4.17	36.0±1.9 (6)	.082
6.13	44.0±2.2 (6)	.084
8.01	48.9±1.3 (7)	.080
9.90	52.7±0.7 (6)	.080
	Propanol-2 and Benzaldehyde	
1.85	6.7±1.1 (5)	.0045
5.86	11.1±0.8 (3)	.0030
10.41	18.7±0.5 (2)	.0047
	Ethanol and Furfuraldehyde	
2.02	17.1±0.5 (2)	.036
6.06	32.6±0.5 (2)	.036
6.21	32.9±0.3 (2)	.035
9.80	39.8±0.7 (2)	.034
11.08	43.7±0.6 (2)	.039
	Methanol and Furfuraldehyde	
4.40	39.5±0.5 (2)	.098

In addition to these determinations upon the synthesis of acetals a reaction mixture was made containing 0.3 mole of furfural acetal, 0.181 mole of water, **3.335** moles of ethanol and **0.0001** g. of hydrogen chloride. After equilibrium had been established the concentrations of the reactants were **0.193** mole of acetal, **3.549** moles of ethanol, **0.074** mole of water and 0.107 mole of furfuraldehyde. The equilibrium constant is thus **0.041.** The analysis of another equilibrium mixture resulting from the hydrolysis of furfuraldehyde acetal indicated the value of K to be **0.039.**

The percentage conversion of benzaldehyde to the acetals in its reaction with ethanol and propanol-2, and for the reaction of furfuraldehyde with ethanol and methanol, have been determined previously for reaction mixtures which contained **1** mole of aldehyde to **11** moles of the alcohol.[7] The values for the equilibrium constants calculated from Adams' data on the basis of the concentrations at equilibrium expressed as mole fractions are as follows: benzaldehyde with ethanol, 0.024, with propanol-2, **0.0030;** furfuraldehyde with methanol, **0.113,** with ethanol, **0.029.** It may be seen from a comparison of these values with those given in Table I that there is a fair agreement between the values of K now reported and those calculated from Adams' data except for the reaction of benzaldehyde and ethanol. It is believed that this discrepancy is due to his procedure for the oxidation of benzaldehyde, which has been proved in this investigation to give inaccurate results.

The values for the equilibrium constant recorded in Table I indicate that there is very little if any change in the constant when the moles of alcohol per mole of aldehyde is increased from **2** to **10.** It is possible that there is a small decrease in the value of the constant with increasing concentrations of alcohol. Such a change in the calculated equilibrium constant is not surprising if it is considered that the acetal reaction is not the only reaction which may modify the concentration of the components of the system under study.

$$\mathrm{RCHO + R'OH = RCH(OH)OR'} \qquad \text{(I)}$$

$$\mathrm{RCH(OH)OR' + R'OH = RCH(OR')_2 + H_2O} \qquad \text{(II)}$$

$$\mathrm{RCHO + H_2O = RCH(OH)_2} \qquad \text{(III)}$$

It was previously shown[8] that the formation of acetals probably proceeds through Reactions I and II. Some of the water formed according to Equation II would add to the aldehyde as in Equation III. Thus as the extent of the acetal reaction increased with increase in the ratio of alcohol to aldehyde, there would also occur an increase in Reaction III which would decrease the actual concentration of aldehyde (or hemiacetal) and thus the increase in the conversion of aldehyde to acetal would not be as great as would be calculated. On the basis of this argument such an effect would become even more marked with those aldehydes which show much higher percentage conversion. It is hoped that the effect of the ratio of reactants

---

[7] Adkins and Adams, This journal, 47, 1370 (1925).

[8] Adkins and Broderick, *ibid.*, 50, 499 (1928).

upon the equilibrium constant may be extended to the study of aldehydes which show much higher percentage conversion than do those referred to in this paper.

Summary

For the first time a method for the preparation of furfural acetal from the aldehyde and ethanol has been described.

The effect of the ratio of reactants upon the extent of the reaction of benzaldehyde with ethanol, butanol and propanol-2 and of furfural with ethanol has been determined when the ratio of aldehyde to alcohol is varied from 1 to 2 to 1 to 10. The equilibrium constant for the first two of these reactions was found to be identical for the two alcohols but to decrease slightly with increase in ratio of alcohol to aldehyde.[9] The equilibrium constant for the reaction of benzaldehyde with propanol-2 and of furfuraldehyde with ethanol appeared to be independent of the concentration of reactants. The equilibrium constant for the reaction of furfuraldehyde and methanol has been redetermined.

RESIN STUDIES. I. THE PREPARATION AND AUTOXIDATION OF PRECIPITATED LEAD ROSINATE

BY W. A. LA LANDE, JR.

RECEIVED FEBRUARY 3, 1931 PUBLISHED MAY 6. 1931

I. Preparation of Precipitated Lead Rosinate

Introduction.—In attempting to study quantitatively the absorption of oxygen by lead rosinate it was obviously important to begin with a material of known and reproducible composition, preferably a normal salt, which had not been exposed to oxidation. Lead rosinate was made by several of the methods proposed in the literature for the preparation of rosinates and abietates[1] and was found objectionable for two reasons. (1) The rosinate responded positively to the starch–iodide test for peroxides immediately after the preparation was completed. (2) The composition (usually complex) of the precipitates obtained according to the

---

[9] The equilibrium constants for the reactions of butanol and ethanol with benzaldehyde are the same only when they are calculated upon the basis of concentrations expressed as mole fractions. They are not identical if the calculation is made upon the basis of concentrations expressed as moles per liter as was done in previous papers in this series.

[1] Pardeller, *Seifensieder-Ztg.*, 1256 (1909); Ellingson, THIS JOURNAL, 36, 325 (1914); Bontoux, *Rev. chim. ind.*, *28*, 157 (1919); Steele, THIS JOURNAL, 44, 1332 (1922); Dupont, Desalbres and Bernette, Bull. *soc. chim.*, 39, 488 (1926); Uzac, *ibid.*, 37, 1194 (1925); Uzac, *Chimie* et *industrie*, *14*, 186 (1925).

given directions was not reproducible within a reasonable range. All of the products contained an appreciable quantity of alkali.

In order to provide a suitable material, a study was made of the factors governing the composition of the precipitate formed on adding a solution of a lead salt to a sodium rosinate solution.

Discussion.—From preliminary experiments it was evident that with the ordinary methods of preparation, oxidation of the rosinate began in the early stages of the procedure. Oxidation and absorption of carbon dioxide progressed during the saponification of the rosin and the precipitate was exposed to air during washing, filtration and drying. As a result, in spite of ordinary precautions and reasonably rapid manipulation, the precipitate always responded positively to tests for oxidation. In order to obtain a product uncontaminated by oxidation it was necessary to carry out all steps in the preparation of lead rosinate in the absence of oxygen. Accordingly, the apparatus illustrated in Fig. 1 was devised.

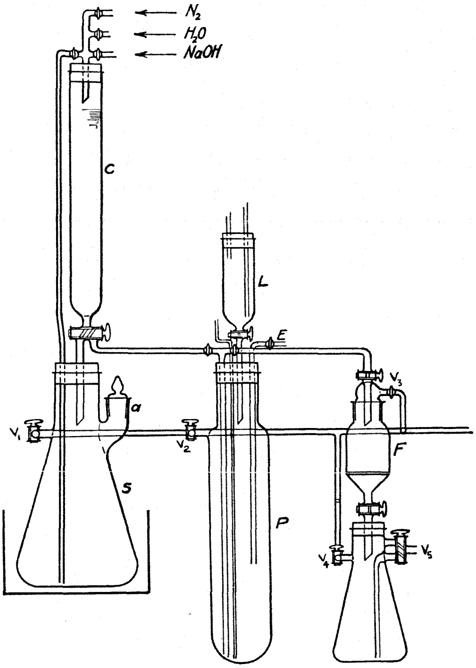

Fig. 1.

The problem presented by the second objection mentioned above was met by investigating several hitherto apparently neglected factors in the preparation of lead rosinate. It was possible to obtain precipitates of reproducible and nearly theoretical composition only by using very dilute solutions of lead acetate and sodium rosinate. Two per cent. solutions of the reactants were found most practical for the precipitation. With more concentrated solutions the precipitate formed was lumpy, bulky and heterogeneous, difficult to wash and purify, and altogether unsuitable for the purpose for which it was intended. The composition of the precipitate was also found to vary with the rate of addition of the lead acetate solution to the sodium rosinate, and with the time and rate of agitation of the reaction mixture. When lead acetate is added dropwise to sodium rosinate solution, several reactions can take place simultaneously. As the solutions mix, an insoluble rosinate tends to be precipitated. Due to its gelatinous, bulky structure the precipitate immediately occludes some of the rosinate solution and some of the lead acetate solution. This precipitate is of indefinite composition and is further reacted upon by the excess rosinate solution. The composite precipitate at first contains an excess of abietic acid. By agitation with a large excess of lead salt the abietic acid content of the precipitate is transposed to lead abietate. This transposition is a slow one and accounts for the results obtained by varying the time of agitation, i. e., the lead content of the precipitate is increased to a maximum, corresponding to lead abietate, by agitating the acid salt with the excess lead solution. If the lead solution is added slowly the composite precipitate is subsequently very much more slowly (never completely) transposed to the normal salt. In one experiment where the lead solution was added over a period of forty minutes, the precipitate contained only 22% of lead. The best results were obtained by adding the lead solution over a period of four to five minutes. Vigorous and prolonged agitation was absolutely essential during all stages of the preparation. Room temperature was most satisfactory for the preparation of the rosinate. Both lead nitrate and lead acetate were used as precipitants. Previous investigators have usually employed the acetate. No difference in composition of the rosinate dependent on the use of nitrate or acetate was observed.

Experimental

Materials.—Hercules "I" wood rosin of recent manufacture was used in all the experiments: Sap. no., 172.1; acid no., 161.1. Samples in the form of rather large lumps were taken from the interior of a large piece of the rosin and quickly weighed and transferred to the apparatus.

The water used for the preparation of solutions and for the washing of the precipitate was purified by redistilling ordinary distilled water from an alkaline suspension of manganous hydroxide.

Carbonate-free sodium hydroxide was made according to the directions of Küster.[2] The solution was stored in a ceresine lined bottle fitted with the lines and stopcocks necessary for transferring the solution to the various parts of the apparatus, $N = 0.5670$.

Tank nitrogen was bubbled through alkaline pyrogallol solution to remove the gross amounts of oxygen. The remaining traces of oxygen were removed by passing the gas over glowing copper. Tank oxygen was dried by passing the gas through concentrated sulfuric acid, ascarite and calcium chloride.

The organic solvents were dried over sodium and redistilled. The other reagents used in the work were "Baker's Analyzed" brand.

All parts of the apparatus were thoroughly purged with nitrogen before being used.

Seventy-five grams of rosin was charged into the saponifying flask F through "a" (Fig. 1). The equivalent amount of sodium hydroxide and enough water to make a 5% solution were then added through C Four hundred cc. of this solution was displaced into P, the precipitating vessel, by nitrogen pressure. After diluting the solution until it contained 1.64% of rosin, 1.37 times the equivalent of lead acetate (17.26 g.) in 800 cc. of water was added through L. The reaction mixture was vigorously agitated

---

[2] Küster, *Z. anorg. Chem.*, 13, 134 (1897).

for one hour after the addition of the lead solution, and for five minutes after each subsequent addition of wash water. The washing was considered complete when the decantate failed to give a coloration with sodium sulfide solution. The precipitate was displaced onto the filter F[3] by nitrogen pressure on V_1 and suction on V_5. It was possible to obtain in this way a thick, firm cake of the precipitate. The stopcocks on the filter were then closed and the product kept thus until needed. The precipitate was dried by shaking a portion of it onto a clock glass and quickly transferring it to a phosphorus pentoxide desiccator which was immediately evacuated. The total time of exposure to the air at this point did not exceed twenty seconds. A one-gram sample of the rosinate did not oxidize a starch–iodide solution. After exposing another sample to the air for a few minutes the product liberated iodine from the iodide. Solutions of the rosinate in various organic solvents were perfectly clear—an indication of the absence of any free inorganic compound. After 200 days in an evacuated tube the rosinate had become slightly darker in color. On heating a sample of the rosinate in a capillary tube in a sulfuric acid bath, no visible change occurred until the temperature rose to 70°, then a progressive darkening and shrinking began. There was no definite melting point, but the sample shrunk to small, clear, dark amber globules (140–150°) and then spread around the wall of the tube in a viscous film This film became almost black and quite opaque at 160–170°, due in part to a separation of metallic lead, and in part to decomposition of the acid.

Analysis of Lead Rosinate.—The metal content of a rosinate or abietate is a reliable index of its purity. In this investigation the ordinary methods of determination were abandoned in favor of the following procedure.

A weighed sample of the rosinate (0.5 g.) was dissolved in 20 cc. of hot 50% alcoholic 2 *N* sodium hydroxide. Twice the calculated amount of 50% alcoholic 2 *N* sodium sulfide was added and after boiling gently for ten minutes the mixture was filtered. The precipitate was first washed with dilute alcoholic sodium hydroxide solution, then with hot water saturated with hydrogen sulfide, and finally dissolved in boilig 1:3 nitric acid. The lead was precipitated electrolytically as lead dioxide. The deposit was dried at 220–230°.

Anal. Subs., 0.4502, 0.5648: PbO_2, 0.1252, 0.1575. Calcd. for this rosinate: Pb, 24.13.[4] Found: Pb, 24.18, 24.02.

These results were checked against those obtained by decomposing samples with concentrated sulfuric acid and a little nitric acid in a Kjeldahl flask. The lead was weighed as sulfate or chromate.

Anal. Subs., (1) 0.9650, (2) 0.7940, (3) 0.6475, (4) 0.6952: $PbSO_4$: (1) 0.3389, (2) 0.2791; $PbCrO_4$: (3) 0.2444, (4) 0.2492. Found: Pb, 24.00, 24.03, 24.20, 24.25.

---

[3] This piece of apparatus was made from a Jena glass, tall form Büchner funnel with a sealed-in fritted glass filter plate. The glassblower worked the open end into a bottle neck and fitted it with a ground-in stopper bearing the two stopcocks. Precipitates can be dried very conveniently in inert atmospheres in this type of filter by closing the stopcocks, transferring the apparatus to the oven and connecting the stem of the funnel to the source of the gas.

[4] Calculated from the saponification no., the rosin used contained 92.90% of abietic acid, or 1 g. of rosin = 0.929 g. of abietic acid. This is equivalent to 0.318 g. of Pb. Since the unsaponifiables are co-precipitated, the precipitate will contain 0.318 g. of Pb + 0.929 g. of abietic acid + 0.071 g. of unsaponifiable, or 1.318 g. for each 1 g. of rosin originally present, provided the normal salt forms. The calculated lead content is therefore 24.13%. By the same reasoning the precipitate of rosinate contains 94.7% of normal lead abietate.

The alkali content of the rosinate was determined by Steele's method.[5] One drop of 0.05 N hydrochloric acid discharged the faint pink color produced in the aqueous extract of the ash by phenolphthalein. The amount of alkali in the sample was therefore negligible.

2. The Autoxidation of Precipitated Lead Rosinate

Introduction.—Maly was probably the first to notice that rosin and abietic acid increase in weight on exposure to the air.[6] Subsequently identified as a process of autoxidation, this phenomenon has been the subject of considerable study, both in the solid acid and in solutions of the acid.[7] On the other hand, little work has been done on the obviously related subject of the autoxidation of metallic rosinates and abietates. To supply some necessary data for an investigation still in progress, the course and extent of the reaction

$$\underset{\substack{\text{solid}\\\text{(as rosinate)}}}{Pb(C_{20}H_{29}O_2)_2} + O_2 \longrightarrow$$

was studied. A solution of the rosinate offers the best means of obtaining rapid and complete absorption of oxygen, but the method does not permit of the obtaining or manipulation of indisputably unchanged intermediate products. Another objection arises from the fact that the degree of absorption is somewhat affected by the solvent used. In the type of system studied in this paper, the reaction proceeds at a conveniently slow rate and the reversibility of the reaction can be directly and easily studied by submitting the reaction mixture to various changes of temperature and pressure. Lead rosinate rather than pure lead abietate was used because results obtained with it had the same significance as those obtained by using pure lead abietate. It was, therefore, unnecessary to execute the much more laborious preparation of the latter compound.

Several methods were tried for following the course of the progressive absorption of oxygen by lead rosinate. Manometric technique was found to be unsatisfactory; the results obtained were not reproducible and the final values were misleading. Frequent shaking of the sample did not improve the results. Since some of the products of the autoxidation of the rosinate liberate iodine from potassium iodide, it appeared possible to follow the course of the oxidation by an iodimetrie method. This procedure required too much material and was abandoned. The gravimetric method outlined below was finally adopted as the most practical from the standpoints of convenience, accuracy and economy.

Experimental.—The lead rosinate used in all the experiments was prepared by the method outlined in the first part of this paper. All of the samples were taken at the same time from the same batch of material.

Samples of the rosinate of equal weight (0.4840 g.), in the form of fine powder, were weighed into glass-stoppered weighing bottles. 40 mm. in diameter and 50 mm. in height. The average thickness of the layer of rosinate was 2 mm. Each of the samples thus prepared was used immediately. The stopper of the weighing bottle was removed and the bottle was placed in the vessel shown in Fig. 2. The piece of apparatus was then transferred to the oven or thermostat, and dry preheated oxygen or nitrogen (as the experiment required) passed through at the rate of 300 cc. per hour. This rate provided a slowly but constantly changing atmosphere of the gas, without danger of loss through agitation of the powder. No attempt was made to obtain a fine temperature control, but all of the given temperatures were the same throughout a given run with a maximum variation of ±1°. Each sample was heated for a timed interval, then allowed to cool in oxygen or nitrogen, and finally weighed after six hours in the desiccator. Before each subsequent exposure to the gas the powder was mixed by rotating the stoppered weighing bottle. In the experiment carried out under pressure the weighing bottle was placed in an Emerson bomb, the pressure raised to the required amount, and the bomb then transferred to the oven.

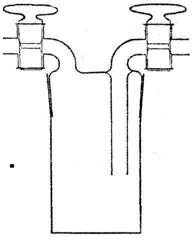

Fig. 2.

Experimental Results.—All the results recorded are average values obtained from at least two experiments conducted under precisely the same conditions.

In Table I showing the increase in weight of lead rosinate in pure dry oxygen at various temperatures, the final value in each sub-table represents the time and percentage increase in weight at which the system came to equilibrium. All runs were continued for at least one hundred hours after this point was reached in order to eliminate the possibility of a false or transient equilibrium. In each sub-table (except 125°) the data between the last result and the one immediately above it have been omitted

for space reasons. These omitted values when plotted all fall on a curve gently sloping to the maximum or final value. The calculation of the percentage increase in weight is based on the original weight of the sample. The results are plotted in Fig. 3 for the first two hundred hours.

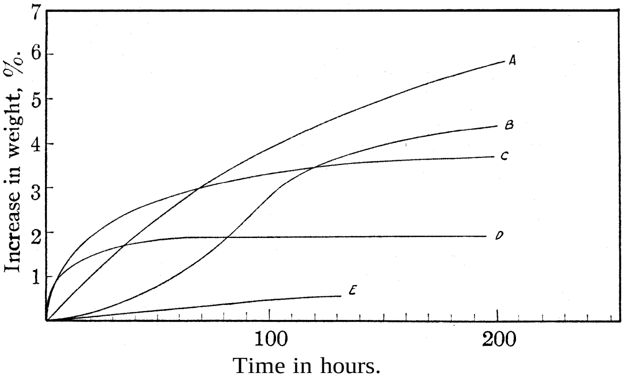

Fig. 3.—Course of the increase in weight of lead rosinate in oxygen at various temperatures and at 28° and 60 atmospheres: A, 28° at 60 atm.; B, 28°; C, 65°; D, 100"; E, 125°.

In Table II the results obtained for maximum absorption at the various temperatures are summarized. For comparison and correction, the results obtained by heating the rosinate in nitrogen at the various temperatures are included (Col. 2). These values represent a loss in weight, *i.* e., the rosinate is appreciably volatile at 100 and 125°. The values for the apparent oxygen absorption at 100 and 125° (Col. 3) have been corrected, in'order to take into account the loss in weight of the rosinate when heated to these temperatures in an inert atmosphere. The corrected values are shown in the fourth column and represent the actual oxygen absorption. The molar equivalent of oxygen absorbed is calculated from the weight of oxygen absorbable by a rosinate containing 94.70% of normal lead abietate.

TABLE II

ABSORPTION DATA

T, °C.	Change in weight, % a, in N_2	 b, in O_2	a + b Oxygen absorbed, %	Molar equiv. of O_2 absorbed
28 (60 atm.)	−0.00	7.63	7.63	2.04
28	− .00	6.33	6.33	1.59
65	− .00	4.03	4.05	1.08
100	− .31	1.89	2.20	0.55
125	−1.52	0.53	2.05	.51

The relation of the apparent oxygen absorption (Table II, Col. 3) to the actual oxygen absorption (Table II, Col. 4) is shown graphically in Fig. 4.

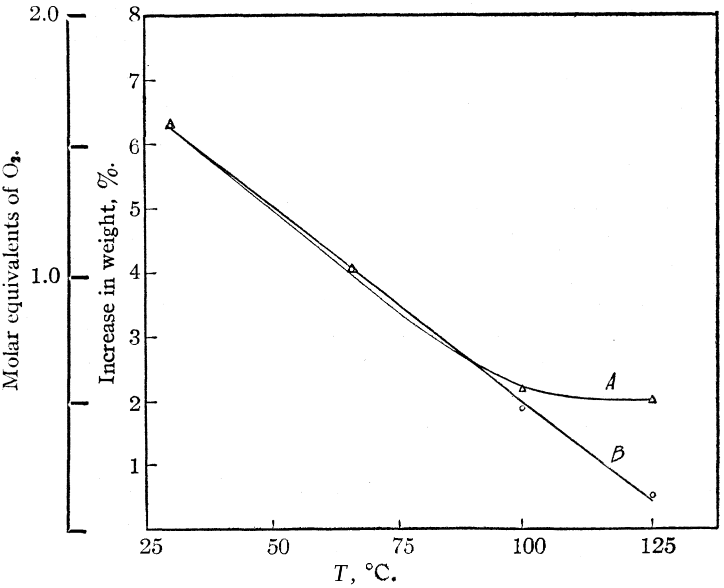

Fig. 4.—Maximum oxygen absorbed at various temperatures by lead rosinate: A, *actual* O_2 absorbed; B, apparent O_2 absorbed.

The results obtained after heating several of the oxidized samples in nitrogen to constant weight are reproduced in Table III. All the values determined for 100° are corrected for the slight volatility of the rosinate itself at that temperature (see Table II, Col. 2).

TABLE III

EXPERIMENTAL DATA

Loss on heating in N_2 to constant weight at	100°	65°	100°	100°
As % O_2 (of total absorbed)	57.0	17.6	48.7	47.0
As molar equivalent of Or	1.14	0.28	0.77	0.51
Molar equivalent of O_2 remaining	0.86	1.31	.82	.57

Discussion of Results.—The results recorded in Tables I and II show that the rate and degree of oxygen absorption by lead rosinate depend, for a given pressure, on the temperature. Dupont and Lévy[8] worked at only one temperature (60°) and it must, therefore, be assumed that this temperature was designedly or fortuitously selected since their final results indicated a sharp end-point when one mole of oxygen had been absorbed. The curve B (Fig. 3) is the familiar S-shaped curve characteristic of autocatalytic processes. The amount of oxygen absorbed at equilibrium corresponded to three atoms of oxygen. This does not necessarily indicate the formation of a compound $Pb(Ab)_2 \cdot 3O$. It is a great deal more probable that the reaction mixture at this point was a combination of all the possible reaction products, with the final product present in largest amount. The mixture slowly liberated iodine from aqueous iodide, quickly from acidified iodide. The product obtained when the experiment was repeated at the same temperature but under sixty atmospheres' pressure also liberated iodine from aqueous and acidified iodide. The results in this experiment are in good agreement with those obtained by Dupont and Lévy for abietic acid, *i. e.*, each abietate group absorbed one mole of oxygen at equilibrium.

In curves C, D and E there is again an indication that the amount of oxygen absorbed corresponded to one or two atomic equivalents of oxygen. It is more possible however, that the reaction product was a mixture. All of these oxidation products liberated iodine from aqueous iodide (very slowly) and from acidified iodide (more rapidly).

If the degree of oxygen absorption at constant pressure decreases with rising temperature, a reversibility of the initial reaction is indicated. The dissociation of the end-product (or equilibrium product) in the autoxidation of the rosinate evidently proceeds progressively as the temperature is raised. There is an indication that this dissociation is never complete, and that a maximum dissociation is reached when one atomic equivalent of oxygen remains fixed by the rosinate (Fig. 4). The amount of oxygen absorbed in each case is thus an index of the stability (and the concentration) of the end-product at a given temperature, for a constant pressure. This reasoning was applied in an experiment, the results of which are recorded in Table III. If the end-product in the autoxidation of the rosinate at *a* given temperature and pressure was placed in an atmosphere

---

[8] Dupont and Lévy, *Compt. rend.*, 189, 763 (1929).

of lower oxygen pressure, it slowly lost weight. If, however, the temperature was raised at the lower pressure, the loss in weight occurred quickly. In the experiment, in order to increase the effect, the temperature was raised about 30° and the partial pressure of the oxygen was decreased to zero (100% nitrogen). All the oxidized samples which were treated thus still liberated iodine from iodide although the reaction was much slower compared with the action of the rosinate on the iodide before this treatment. The gas evolved from the oxidized samples was passed over anhydrous copper sulfate and bubbled through barium hydroxide and palladous chloride solutions. There was no indication of the color or turbidity which water, carbon dioxide and carbon monoxide would have produced with these reagents. The gas evolved from two half-gram samples of the oxidized rosinate was passed through the heated, packed tube of a combustion furnace. The effluent gas was received in barium hydroxide solution. No turbidity was observed. The author thus feels justified in assuming that the gas evolved from the oxidized rosinate was pure oxygen. The rosinates again absorbed oxygen when exposed to the gas, but very slowly, an effect undoubtedly due to the change in surface produced by a slight sintering of the powder at the higher temperatures. It was believed before the experiment was tried that the relative amount of oxygen lost and the actual amount remaining fixed would be the same in each case. This would have proved decisively that a stable oxygen compound was formed during the autoxidation. The data obtained (Table III) were not in sufficiently good agreement to be interpreted as substantiating this belief. It is possible that such a compound was formed, but in an amount depending on the conditions of the particular experiment. Hence the amount of oxygen remaining fixed would vary. Another explanation of the apparent non-existence of a relationship among the values obtained for the amount of oxygen remaining fixed at zero oxygen pressure is the possibility of an immeasurably slow but positive dissociation of the more stable oxygen compounds formed during the autoxidation. In other words, these values would approach each other if the conditions were maintained for a sufficiently long time.

According to Dupont and Lévy the autoxidation of abietic acid is accomplished through the agency of an intermediate oxide HAbO, and a peroxide $HAbO \cdot O_2$, the final product being $HAbO_2$. Unfortunately, the action of this final product on an iodide solution was not investigated. If the autoxidation of lead rosinate proceeds by a similar mechanism, two moles of oxygen should be absorbed by one mole of lead abietate. Actually, this result was obtained in only one instance (Table 11), *i. e.*, under the most extreme conditions tried, and the product readily oxidized iodide. This would indicate that the end-product itself is capable of acting as an oxidizer, or that the product obtained under the most extreme conditions

(28°, 60 atm.) was still an equilibrium mixture of end-product and intermediate peroxides. The most obvious interpretation of the data obtained in this investigation would favor the latter conclusion.

The writer takes this opportunity to thank Professor H. S. Lukens for help and suggestions obtained from him during the course of this work. Thanks are also due Mr. J. G. Butz for helpful suggestions.

Summary

A study has been made of some of the factors which influence the composition of the precipitate formed by adding the solution of a lead salt to sodium rosinate solution.

An apparatus has been devised in which all the steps in the preparation of the rosinate may be carried out in an inert atmosphere.

A method for the analysis of the metal content of rosinates has been proposed.

The course, extent and reversibility of the autoxidation of lead rosinate has been studied, using a carefully prepared rosinate of known composition.

The results have been discussed from the viewpoint of the theory suggested by Dupont and Lévy for the autoxidation of abietic acid.

COMPETITIVE HYDROGENATIONS. II

BY F. F. DIWOKY AND HOMER ADKINS

RECEIVED FEBRUARY 4, 1931 PUBLISHED MAY 6, 1931

Recently it was shown that there was no apparent relationship between the relative rates of the hydrogenation over platinum of pure compounds taken separately and their relative rates of hydrogenation in mixtures.[1] For example, *d*-α-pinene was much more rapidly hydrogenated than was cinnamic acid and yet in a mixture of pinene and cinnamic acid the latter was completely hydrogenated before the former took up any hydrogen. It was also ascertained that a reducible substance not undergoing hydrogenation may greatly accelerate the hydrogenation of another compound. For example, pure pinene, which was much more rapidly hydrogenated than was pure allyl alcohol, increased the rate of hydrogenation of allyl alcohol almost seven-fold without itself being hydrogenated to any considerable extent. The results given in this paper are concerned with an extension of this study to the use of nickel catalysts in the hydrogenation of mixtures of reducible compounds.

Originally it was intended to determine *(a)* the time required for hy-

---

[1] Adkins, Diwoky and Broderick, THIS JOURNAL, 51,3418 (1929).

drogenation of certain representative compounds over a nickel catalyst; (*b*) the time required for the absorption of one-half the quantity of hydrogen necessary for the complete hydrogenation of the components of equimolecular mixtures of two compounds; (*c*) the distribution of hydrogen between the components of the mixture; (*d*) the time required for the absorption of all the hydrogen necessary for the complete hydrogenation of the components of the mixtures of compounds. However, the last of these objectives was reached in the case of only four mixtures (benzene with toluene, with diphenylamine and with phenol and of pyridine with phenol) because the hydrogenations could not be made complete under conditions which were comparable with those used for the pure compounds and the half hydrogenation of mixtures.

There are recorded in Table I the time required and the proportion of products in the hydrogenation of ten compounds and of thirty-two mixtures of these compounds with each other. The amount of each compound used in each experiment was 0.5 mole except for the mixtures containing acetanilide, for which the quantities were cut in half. A temperature of 175° was used for the hydrogenations involving aniline, acetanilide and diphenyl, and for the mixture of pyridine and toluene. A temperature of 132° was used for pure benzyl alcohol and 125° for the mixture of benzyl alcohol and benzene; while 150° was used for all the other hydrogenations. Two grams of catalyst was used for diphenylamine and the mixture of it with toluene. One gram of catalyst was used in all other experiments. The initial pressure (at 20°) in all experiments was 136 atmospheres: the hydrogenations took place at pressures from 125 to 200 atmospheres.

TABLE I

HYDROGENATION OF PURE COMPOUNDS AND MIXTURES

Hydrogen acceptors	% H_2	Time, min.	Product(s) and % yields
Benzene	100	0	Cyclohexane

Aniline + quinoline	98	5	Cyclohexylamine (0); tetrahydroquinoline (100)
Aniline + diphenylamine	25	1000	Cyclohexylamine (24); dicyclohexylamine (3)
Benzyl alcohol + quinoline	103	0	Tetrahydroquinoline (100)
Benzyl alcohol + diphenylamine	62	170	Toluene (66); cyclohexylcarbinol (16); dicyclohexylamine (17)
Benzyl alcohol + acetanilide	100	60	Toluene (58); cyclohexylcarbinol (42); N-acetylcyclohexylamine (20)

In the case of the mixtures the reaction was allowed to proceed (when possible) until the amount of hydrogen absorbed was approximately equal to the amount of hydrogen required for the complete hydrogenation of one of the components. The bomb was then allowed to cool to room temperature and the amount of hydrogen actually absorbed determined. The amount of hydrogen actually absorbed is given in the second column of the table. One hundred per cent. hydrogen adsorption is that required for the complete hydrogenation of one of the two components of a mixture. In the case of mixtures this in general means 1.5 moles of hydrogen. For mixtures containing quinoline or acetanilide the amount is 1.0 and 0.75 mole of hydrogen, respectively. Benzyl alcohol presents a unique case since there are two reactions, one of which requires 3 moles and the other 1 mole of hydrogen for 1 mole of the alcohol. In the case of mixtures containing benzyl alcohol 100% absorption means 3 moles of hydrogen per mole of alcohol. The time (in minutes) given in column 3 of the table is that elapsing between the time at which the designated temperature was reached and the time at which the hydrogenation was stopped. The hydrogenation was stopped either because the desired amount of hydrogen had been taken up or because the catalyst had become inactive. A zero in this column means that hydrogenation was complete at the time that the designated temperature was reached. Eighty minutes were required to heat the bomb from 20 to 150° and fifteen minutes from 150 to 175°. There are given in column 4 of the table the name and yield of the various products of hydrogenation.

The rate of hydrogenation of phenol and quinoline at 2 to 3 atmospheres' pressure was determined for the sake of comparison with those at 125 to 200 atmospheres. Two grams of catalyst with 0.2 mole of each compound was used at 135°. Phenol was completely reduced in about two hundred and fifty minutes while quinoline was completely converted into tetrahydroquinoline in two hundred minutes

If the nine compounds which were hydrogenated are listed in the order of decreasing rate of hydrogenation, the order is (1) quinoline, (2) benzene, (3) toluene, (4) phenol, (5) benzyl alcohol, (6) pyridine, (7) diphenylamine, (8) acetanilide and (9) aniline. (This order is not independent of the pressure of hydrogen at which reaction occurs because phenol for example reduces readily at 2 or 3 atmospheres while some of the other compounds are not hydrogenated at all over the nickel catalyst at the lower pressures.) The relative rates of hydrogenation of these compounds in a mixture are in many cases very different from that which would be expected from the relative rates of hydrogenation of the single compounds. If the compounds are listed in the order of preferential hydrogenation in mixtures the sequence is (and using the numbers assigned to each compound above) (1) quinoline, (6) pyridine, (9) aniline, (5) benzyl alcohol, (4) phenol, (7) diphenylamine, (2) benzene, (8) acetanilide, (3) toluene. That is, if a mixture of any two compounds in the above list is partially hydrogenated under the experimental conditions used in this investigation, the compound which is higher in the list just given will receive the greater proportion of the hydrogen.

In the case of mixtures of some compounds having the same functional groups, the relative rates of hydrogenation of the components of a mixture are qualitatively what would be expected from a knowledge of the rates of hydrogenation of the single compounds. This is true for the mixture of benzene and toluene and for the one of quinoline and pyridine. The increased proportion of cyclohexanol from phenol in toluene as compared with the results in benzene is in agreement with the relative rates of hydrogenation of toluene and benzene. However, the relative rates of hydrogenation of benzene and phenol in a mixture are not at all what would be anticipated from a knowledge of the rates of hydrogenation of the compounds taken singly.

It appears that a compound such as aniline which is very slowly and never completely hydrogenated and which shows every sign of poisoning the catalyst for its own hydrogenation, may yet be almost without effect upon the hydrogenation of another compound. Quinoline for example hydrogenated practically as rapidly in the presence as in the absence of aniline. In a similar way aniline was almost without effect upon the hydrogenation of pyridine. In contrast with this is the effect of aniline, quinoline or pyridine in inhibiting completely the hydrogenation of the easily reduced benzene or toluene.

The time for the hydrogenation of a mixture of quinoline and pyridine was more than twice the sum of the times for the hydrogenation of the components, that is to say, each compound was inhibiting the hydrogenation of the other.

The hydrogenation of diphenylamine over nickel was accelerated by benzene and toluene although not so markedly as was the hydrogenation of allyl alcohol by pinene over platinum. The hydrogenation of aniline was also accelerated by the presence of phenol. Phenol and benzene in these experiments were also hydrogenated to the extent of 24% but toluene was almost completely resistant to hydrogenation just as was pinene in the mixture with allyl alcohol.

Benzyl alcohol is hydrogenated to both toluene and cyclohexylcarbinol, so that with this compound there is a competitive hydrogenation even with a single compound. For the catalyst and conditions used in this investigation for the hydrogenation of benzyl alcohol the ratio of the products was about 5 moles of toluene to 1 of the cyclohexylcarbinol. The ratio of alcohol to toluene was increased by the presence of phenol and diphenylamine and especially by benzene and acetanilide, which were themselves only reduced to the extent of 10 to 20%. This is all the more remarkable since at the temperature used for the hydrogenation of the mixtures (175°) pure benzyl alcohol is quantitatively reduced to toluene.

It is generally accepted that the combination of the catalyst and at least one if not both of the reactants is an essential step in such reactions as are here under consideration. Preferential adsorption would thus serve to account for many of the discrepancies in rate between the hydrogenation of single compounds alone and in mixture with other compounds. Upon this basis pyridine is preferentially hydrogenated in a mixture with the more easily hydrogenated benzene because it is adsorbed almost to the exclusion of benzene. It is noteworthy that the order of compounds quinoline, pyridine, aniline, benzyl alcohol, phenol, diphenylamine, benzene, acetanilide, toluene, which is the order of preferential hydrogenation in mixtures, is one which in general might reasonably be expected to hold for a tendency to form addition compounds.

Experimental Part

The apparatus and the general method of procedure were the same as those previously described.[2] The compounds submitted to hydrogenation were of the best grade sold by the Eastman Kodak Company and the Mallinckrodt Chemical Company and were in general not submitted to any purification other than a careful fractionation. The benzene and toluene were thiophene free. The catalysts were made as previously described. The values given for the hydrogen absorption are accurate to within plus or minus 4%. The accuracy of the values for the ratio of products varies a good deal in different analyses and in extreme cases may be as much as ±7%.

Analysis of Reaction Products.—The products of reaction were separated whenever possible by fractionations through a Widmer column at a suitable pressure. Whenever fractionation did not give a satisfactory separation of the components of a reaction mixture, advantage was taken of chemical as well as of physical differences between the components. The separation of cyclohexane from benzene, and methylcyclohexane from toluene was made with sulfuric acid containing 30% of sulfur trioxide. The separation of aniline, pyridine and piperidine from hydrocarbons was made by extracting a weighed portion of the product with a slight excess of hydrochloric acid, the extract made alkaline with solid sodium hydroxide, saturated with salt, extracted twice with 100 ml. of ether and the ethereal extract dried and fractionated. The absence of pyridine (except in one experiment) was shown by the test of Fiilnegg and Riesenfeld.[3] Piperidine was identified by its benzene sulfone piperidine, m. p. 92–93°. When necessary pyridine and piperidine were separated as by Arndt and Nachway.[4] The products from the hydrogenation of phenol and aniline were separated as follows. A weighed sample was put into solution with ether, treated with an excess over the calculated amount of dilute sodium hydroxide solution to remove phenol, the ether

---

[2] Adkins and Cramer, THIS JOURNAL, 52, 4349 (1930).

[4] Arndt and Nachway, *Ber.*, 59B, 448 (1926).

layer separated, dried over solid potassium hydroxide, separated again from the watery layer, the ether distilled off, product weighed and phenol calculated by loss in weight. This product consisted of cyclohexanol, cyclohexylamine, aniline and dicyclohexylamine. This weighed sample was extracted with dilute hydrochloric acid, extracted with two 75-ml. portions of ether and the layers separated. By the usual method cyclohexanol was obtained from the ether extract, the amines recovered from the hydrochloric acid extract and separated by fractional distillation. Cyclohexanol was separated from phenol by extracting a weighed amount with dilute sodium hydroxide, washing and drying the insoluble portion prior to distillation. Phenol was determined by difference. Mixtures of acetanilide and N-acetylcyclohexylamine were hydrolyzed as by Davis[5] and the amines separated by fractional distillation. Phenylcyclohexylamine and dicyclohexylamine were separated as by Fouque.[6] The former had a boiling point of 160–164° (22 mm.) and its picrate had a melting point of 163–164°.

Summary

The rates of hydrogenation of quinoline, benzene, toluene, phenol, benzyl alcohol, pyridine, diphenylamine, acetanilide and aniline have been determined over a nickel catalyst at 125–175° and under pressures of hydrogen from 125–200 atmospheres. The compounds have been listed in the order of decreasing rate of hydrogenation. Thirty-two mixtures of these compounds, each mixture containing two components, were subjected to the action of hydrogen over a nickel catalyst and the mixture allowed to take up as much hydrogen as would have been sufficient to completely hydrogenate one of the components of the mixture. The rate of absorption of the hydrogen and its distribution between the components of the mixture were determined by analysis of the reaction mixture. It was found that if the compounds were listed in the series, quinoline, pyridine, aniline, benzyl alcohol, phenol, diphenylamine, benzene, acetanilide and aniline, in any mixture containing two of them, the one higher in the series would receive the greater proportions of the hydrogen. Pyridine and quinoline in mixtures with other compounds took all, or practically all of the hydrogen. Apparently there is no relationship between the relative rates of hydrogenation of these compounds singly and in mixtures. The relative rates of hydrogenation of the components of a mixture are at least in part presumably dependent upon selective adsorption by the catalyst through two possible acceptors of hydrogen.

The hydrogenation of diphenylamine was accelerated by toluene and benzene, and the hydrogenation of aniline by the presence of phenol in the reaction mixture.

[5] Davis, *J. Chem. Soc.*, 95, 1397 (1909).

[6] Fouque, *Ann. chim.*, **15**, 291–32 (1921).

The ratio of cyclohexylcarbinol to toluene produced in the hydrogenation of benzyl alcohol, was increased by the presence of phenol or diphenylamine and especially of benzene or acetanilide in the reaction mixture.

AMINO ALCOHOLS. VI. THE PREPARATION AND PHARMACODYNAMIC ACTIVITY OF FOUR ISOMERIC PHENYLPROPYLAMINES

BY WALTER H. HARTUNG AND JAMES C. MUNCH

RECEIVED FEBRUARY 7, 1931 PUBLISHED MAY 6, 1931

The commoner hypertensive amines are derivatives of β-phenylethylamine, that is, compounds containing the aromatic nucleus separated from the amino group by two carbons of an aliphatic side chain; e. g., tyramine $HOC_6H_4CH_2CH_2NH_2$, epinephrine, $(HO)_2C_6H_3CHOHCH_2NHCH_3$, and ephedrine, $C_6H_5CHOHCH(NHCH_3)CH_3$, all have this common structure.

Recorded pharmacological studies with compounds in which the relative position of these two functional groups is modified are rare.

Barger and Dale,[1] in their classical study on the relationship between chemical structure and sympathomimetic action, included a series of compounds in which the relative position of the amino portion with respect to the phenyl group varied. They found that aniline has no specific action; benzylamine gives a trace of the desired activity, a-phenylethylamine is feebly active, β-phenylethylamine highly active and most active of the series, while y-phenylpropylamine, $C_6H_5CH_2CH_2CH_2NH_2$, is again much less effective. While no allowance was made for any influence on the physiological activity that might be produced by the successive lengthening of the side chain, they nevertheless advanced the conclusion that "the optimum constitution of a fatty–aromatic amine for the production of sympathomimetic action is, therefore, that which is found in adrenaline itself, *viz.*, a benzene ring with a side chain of two carbon atoms, of which the second bears the amino group."

Concerning the value of the two-carbon side chain these conclusions must, in the light of recent findings, be amended, for it has been amply demonstrated that amino alcohols of the ephedrine type, that is, compounds with three carbons in the side chain, are not only very active pharmacologically but may even possess physiological and therapeutic virtues not resident in the corresponding compounds with but two carbons.[2]

---

[1] Barger and Dale, J. *Physiol.*, 41, 19 (1910). Cf. Pyman, J. *Chem. Soc.*, 111, 1103 (1917).

(a) Chen, Wu and Henriksen, *J. Pharmacol.*, 36, 363 (1929); (b) Hartung and Munch, THIS JOURNAL, 51, 2262 (1929); (c) Hartung, Munch, Deckert and Crossley, *ibid.*, 52, 3317 (1930); (d) Piness, Miller and Alles, J. *Am. Med. Assn.*, 94, 790 (1930).

Aside from this work of Barger and Dale, comparatively little has been done to substantiate the other part of their conclusion, namely, the necessity for having the aryl and amino groups on adjacent carbons of an aliphatic side chain. Baehr and Pick[3] observed that if in hordenine, p-$HOC_6H_4CH_2CH_2N(CH_3)_2$, the dimethylamino group is removed from the aromatic portion by three or four carbons,[4] the pressor potency becomes correspondingly less. Hasama, in comparing the isomeric phenylethanolamines, $C_6H_5CH(NH_2)CH_2OH$ and $C_6H_5CHOHCH_2NH_2$, found the former to have no influence on the blood pressure,[5] whereas the activity of the latter is well established.

Matsuo and Mizuno[6] report that α-phenylethylamine, $C_6H_5CH(NH_2)CH_3$, increased the contraction amplitude of the frog heart and the blood pressure of a rabbit, while the β-compound, $C_6H_5CH_2CH_2NH_2$, showed the opposite effect.

The present investigation was undertaken to determine, if possible, whether in the series of amino alcohols being studied in these Laboratories maximum activity is obtained when the aryl and amino groups are separated by two aliphatic carbon atoms. And in order to confine as nearly as possible any modification in physiological behavior to a corresponding change in the relative positions of these two functional groups, four isomeric phenylpropylamines were prepared and their behavior observed. These four compounds are given in Table I along with a summary of their pharmacological and toxicological behavior. β-Phenylethylamine and phenylpropanolamine are included for comparison.

TABLE I

DATA ON COMPOUNDS

	Base	M. L. D. of hydrochloride, mg./kg. Rats, subcutaneous	M. L. D. of hydrochloride, mg./kg. Rabbits, intravenous	Pressor activity of hydrochloride (Intravenous to dogs)
I	$C_6H_5CH_2CH_2NH_2$	..	60	1 Mg./kg. gave good rise that persisted about 20 min.
II	$C_6H_5CH(NH_2)CH_2CH_3$	1000	50	1 Mg./kg., very slight rise
III	$C_6H_5CH_2CH(NH_2)CH_3$	25	25	1 Mg./kg. gave rise equal to that of I. Effect persisted longer. Orally active[Zd]
IV	$C_6H_5CH_2CH_2CH_2NH_2$	100	50	1 Mg./kg. gave medium transitory rise
V	$C_6H_5CH(CH_3)CH_2NH_2$	500	50	Good pressor; also active after oral administration.
VI	$C_6H_5CHOHCH(NH_2)CH_3$	.	75–90	Equals ephedrine

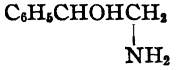
The data on comparative pressor potencies are not yet satisfactorily quantitative, but the information thus far obtained is very illuminating. For instance, it is readily seen that Barger and Dale are substantially correct in ascribing the optimum constitution for producing a rise in blood pressure to compounds containing at least a β-phenylethylamine skeleton. If any deviation is made from this elementary structure either by moving the amino closer to the phenyl (II) or by removing it farther away (IV), the degree of physiological response is very greatly diminished. But if this minimum skeleton is left unchanged (III, V and VI), substitutions in the other portions of the molecule may modify the nature of the pharmacodynamic behavior, but the ability to produce a rise in blood pressure is not diminished.

Chen, Wu and Henriksen[2a] attribute the oral efficacy of ephedrine to the presence of the third carbon in the side chain; thus, for instance, phenylpropanolamine (VI) is active when taken by mouth whereas phenylethanolamine, $C_6H_5CHOHCH_2NH_2$, is not.

Piness, Miller and Alles,[2d] who are interested clinically in phenylethanolamine, were desirous of determining what it lacked structurally to make it active when administered orally. Since phenylethanolamine differs from ephedrine by two methyl groups, one in the side chain and the other on the amino group, they investigated two methyl substituted derivatives of β-phenylethylamine, one in which the methyl was substituted on the nitrogen and the other in the side chain. They found the former ineffective when given by mouth and the latter, with three carbons in the side chain, very active when so administered. Hence, they also conclude that it is the three-carbon side chain that makes for oral activity.

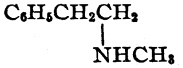


$$C_6H_5CHOH\underset{\substack{|\\ NH_2}}{CH_2}$$

Phenylethanolamine

$$C_6H_5CHOH\underset{\substack{|\\ NHCH_3}}{CH}CH_3$$

Ephedrine



$$C_6H_5CH_2\underset{\substack{|\\ NHCH_3}}{CH_2}$$

$$C_6H_5CH_2\underset{\substack{|\\ NH_2}}{CH}CH_3$$

Our results show that in extending the side chain of β-phenylethylamine, the entering methyl may be substituted on either of the two aliphatic carbons and in either case (III and V) oral activity is conferred. While quantitative values for pressor activity of these two isomers have not yet been determined, the wide differences in toxicity are very well defined and very striking indeed.

Phenylpropanolamine (VI) is included in the table in order to emphasize the importance of the alcoholic hydroxyl. Its elimination, which gives III, increases the intravenous toxicity to rabbits by 300% or more, a very significant extent.

Procedure

All the amines were prepared by the catalytic hydrogenation of an appropriate intermediate by the process already described.[7]

Experimental

Phenyl-1-amino-1-propane.—Propiophenone oxime[8] was dissolved in absolute alcohol containing three equivalents of hydrogen chloride and smoothly reduced to the corresponding amine, isolated as the hydrochloride The salt melted at 189.5° (corr.) and the base distilled at 100–105° at 35 mm.; a benzoyl derivative melted at 115–116° (corr.).[9]

Phenyl-I-amino-2-propane was obtained by reducing phenyl-1-chloro-1-amino-2-propane. Sixteen grams of phenylpropanolamine was heated in a bomb tube with 130 ml. of concentrated hydrochloric acid at 110–115° for four hours. No pressure developed. The solution was then chilled in an ice–salt bath and the hydrochloride of phenyl-1-chloro-1-amino-2-propane which settled out was filtered off, dried and recrystallized from absolute alcohol. The crystals melted at 201° (corr.); 8.5 g., a yield of 48%. Calcd. for $C_9H_{12}NClHCl$: Cl, 34.4. Found: Cl, 33.3. The organic chlorine seems to be very labile and further recrystallization gives a product with even less chlorine.

By shaking the chloro compound, dissolved in absolute alcohol, with palladium catalyst in an atmosphere of hydrogen, the chlorine was completely replaced by hydrogen; the resulting amine was isolated as hydrochloride, the salt melting at 144–147° and the base distilling at 200-201° (uncorr.).[10]

Phenyl-1-amino-3-propane.—An impure cinnamaldoxime[11] was reduced in an absolute alcoholic solution containing three equivalents of hydrogen chloride. Reduction ceased when 90% of the hydrogen calculated as required by the pure oxime had been taken up. The catalyst was removed and the filtrate evaporated to dryness on a steam-bath; the residue was taken up in water and an insoluble dark oily impurity removed by extraction with ether. The aqueous solution was treated with excess alkali, the liberated base extracted with ether, dried over sodium sulfate and distilled, boiling at 216–220° (uncorr.). For $C_6H_5CH_2CH_2CH_2NH_2$ the following boiling points are recorded 215°[12] 215–216°,[13] 221.5°.[14] The hydrochloride was precipitated from an ethereal solution of the base by addition of an absolute alcoholic solution of hydrogen chloride. The salt melted at 218" (corr.) From 11.6 g. of cinnamaldoxime 8.1 g. of the salt was obtained, a yield of 60%.

Phenyl-2-amino-1-propane was obtained from a-phenylpropionitrile. This intermediate nitrile was prepared from the sodium derivative of phenylacetonitrile and methyl iodide according to the directions of Victor Meyer[15] and Freund and König[16]

[16] Freund and Konig, Ber., 26, 2874 (1893).

However, the good yields they report, as high as 79%, have not been duplicated; our yields were 10–14%

The reduction of α-phenylpropionitrile dissolved in absolute alcohol containing three equivalents of hydrogen chloride proceeded smoothly and completely, although about a third as rapidly as for the oximes, and the product was isolated as its hydrochloride salt, melting at 123–124° (corr.). Freund and König, by reducing the nitrile with sodium and absolute alcohol, obtained the base $C_6H_5CH(CH_3)CH_2NH_2$, whose hydrochloride melted at 124°.

Summary

Four isomeric phenylpropylamines were prepared by catalytic hydrogenation of an appropriate intermediate. A preliminary pharmacological examination of these compounds indicates that:

(1) The optimum skeleton for pressor compounds is β-phenylethylamine.

(2) A shift in the relative positions of the phenyl and amino groups very greatly decreases pressor potency.

(3) Substitution of a methyl on either of the two carbons in the side chain of this skeleton confers oral activity.

(4) The presence of the secondary alcoholic hydroxyl in phenylpropanolamine serves to decrease the toxicity to a degree that becomes significant therapeutically.

THE PREPARATION OF ALIPHATIC AMIDES

BY JAMES A. MITCHELL AND E. EMMET REID

RECEIVED FEBRUARY 9, 1931 PUBLISHED MAY 6, 1931

The most satisfactory methods of preparing amides have involved dehydration of the ammonium salt of the corresponding acid. Hofmann[1] prepared various amides by heating ammonium salts of aliphatic acids for five or six hours at 230° under pressure. Kundig[2] prepared acetamide by the rapid distillation of ammonium acetate and by heating an alcoholic solution of acetic acid and ammonia in a sealed tube for a long time at 100°. He also obtained a yield of amide greater than 25% by passing dry ammonia through acetic acid and then heating to boiling. Grant and James[3] have prepared amides by saturating the acid with dry ammonia and boiling. Dunlap,[4] Keller[5] and Verley[6] have modified the procedure by heating sodium acetate and ammonium chloride at 240°.

[4] Dunlap, *ibid.*, 24, 762 (1902).

[5] Keller, *J. prakt. Chem.*, [2] 31, 364 (1885).

[6] Verley, *Bull. soc. chim.*, [3] 9, 691 (1893).

Acetamide is best prepared according to Coleman and Alvarado[7] by heating a mixture of ammonium acetate and acetic acid under a reflux condenser in such a manner that the excess acetic acid and the water formed in the reaction are slowly distilled off.[8] Noyes and Goebel have also shown that acetic acid catalyzes the reaction.

This method is very satisfactory for preparing acetamide, but is not economical for the higher aliphatic acids on account of the cost of the large excess of acid required. This suggested using an excess of the other reactant, ammonia, which is cheap.

Instances in which dimethyl amides were prepared in a similar manner are rare. Franchimont and Klobbie[9] prepared dimethyl heptoamide by heating the acid with dimethylamine at 230° in a sealed tube. Verley[6] prepared dimethyl formamide and acetamide by distilling a mixture of an alkali salt of the acid and dimethylamine hydrochloride.

Results

We have found that by passing ammonia gas through aliphatic acids kept at a suitable temperature in such a way that the water formed is continually removed, the equilibrium point of the reaction may be displaced far to the amide side and very high yields of amides obtained. The results with the aliphatic amides are indicated in Table I.

The temperature at which the acid is heated is sufficient to dehydrate a small proportion of the higher amides to form the nitriles. This reaction becomes appreciable with butyric and the higher amides.

The reaction velocity is appreciably slower with the higher acids. Heptoic acid reacts much more slowly than caproic and caprylic more slowly than heptoic. Lauric acid was heated at 185° for sixteen hours. Only a small fraction was converted to the amide. No amide was obtained from palmitic or stearic acid upon heating either at 125 or 190° for considerable intervals of time. The ammonium salts of these acids are probably unstable under the conditions of the experiments.

Similar experiments were performed in which anhydrous zinc chloride was added to acetic, propionic and caproic acids. No difference in rate of formation of the amide was observed when compared with parallel experiments with no zinc chloride.

Zinc chloride is a catalyst, however, for dehydration of the amide to the nitrile. At a temperature higher than that used in the preparation of the amide *a* considerable proportion of caproic acid is converted to the nitrile.

Although small amounts of nitrile are formed in distilling acetamide and

ble in ether as the molecular weight increases. This furnishes a satisfactory recrystallization medium for all but acetamide. The amides are more effectively recrystallized from hot benzene. The crystals, however, tenaciously absorb the solvent and it is advisable to centrifuge.

Dimethyl amides were prepared in the same manner, the ammonia being replaced by dimethylamine. The results are given in Table II. The dimethyl amides obtained were all liquids at ordinary temperatures and were purified by distillation.

Experimental

The apparatus employed consisted of a flask with a jacketed reflux condenser. The condenser was connected top and bottom with a side tube of the same length, which upon being filled with water could be kept at any desired temperature up to 90° by means of a Bunsen burner placed at the lower end of the side-tube. The flask containing the acid was heated to any desired temperature by an oil-bath. Temperatures were read from a thermometer which was placed inside the flask and extended into the condenser. The ammonia delivery tube entered at the top of the condenser and extended to the bottom of the flask.

For the preparation of the amides a stream of ammonia, taken directly from a cylinder, was passed through the delivery tube and bubbled through the acid the entire duration of the experiment. The water formed in the reaction was swept out through a tube just at the top of the condenser jacket into a bulb.

Samples of amides were carefully purified. After the preliminary vacuum distillation the amides were further purified by crystallization from pure benzene and absolute ether, frequently centrifuging and drying over sulfuric acid in a vacuum desiccator until accurate melting points were obtained, checking for several recrystallizations. The melting points were taken with a calibrated Anschiitz thermometer. Every precaution was taken to prevent overheating of the melting point bath and its temperature was kept uniform by efficient stirring. Melting points quoted in Table I are the corrected ones.

Acetamide was purified by recrystallizing four times from methyl alcohol and ether, centrifuging twice. Propionamide was crystallized once from methyl alcohol and ether, followed by centrifuging, and then recrystallized twice from ether. Butyramide" was crystallized from benzene, centrifuged and recrystallized three times from ether, followed by centrifuging. Butyramide[b] was crystallized three times from ether, and centrifuged. Valeramide was crystallized three times from ether and centrifuged. Caproamide[c] was crystallized three times from ether and centrifuged twice. Caproamide,[d] heptoamide and caprylamide were crystallized from benzene, centrifuged, and recrystallized twice from ether.

For the preparation of the dimethyl amides, the apparatus was attached to a water pump at the exit side and a current of air mixed with dimethylamine, prepared by dropping an aqueous solution of the amine[11] on solid potassium carbonate, was drawn through the acid during the course of the experiment. The gas was dried by passing it over solid potassium hydroxide. Certain experiments indicated, however, that drying was not essential. The reaction proceeds much faster with dimethylamine than with ammonia.

A study of the physical properties of dimethyl amides, together with methods of preparation and purification, is being continued in this Laboratory by other workers.

Summary

A satisfactory and economical method has been described for the preparation of amides and dimethyl arnides from the normal acids of the aliphatic series up to caprylic.

Accurate melting points of the amides from acetic to caprylic have been determined.

THE POLARIMETRIC REDUCING SUGAR RELATIONSHIPS OF STARCH HYDROLYTIC PRODUCTS RESULTING FROM DIASTATIC ACTION

BY D. T. ENGLIS, G. T. PFEIFER AND J. L. GABBY

RECEIVED FEBRUARY 12, 1931 PUBLISHED MAY 6, 1931

The relationship between the specific rotation and copper reducing values of starch hydrolytic products as formed under the influence of diastatic action has been the subject of considerable study. In the early work of Brown and Heron[1] a close relationship was not observed but later work by Brown and associates[2] showed that the hydrolytic products first formed were in a condition of lower optical value and if equilibrium condition of the mutarotating mixture was reached, the rotation assumed the calculated value. Rolfe and Defren[3] claim the same close relationship when the hydrolysis of starch is brought about by acids. Using amylodextrin as the substrate in place of starch, Ford and Guthrie[4] have applied the principle to the estimation of the diastatic power of malt. By determining the change in rotation and multiplying by an appropriate factor

---

[11] Kindly furnished by the du Pont Co.

[1] Brown and Heron, J. Chem. *Soc.*, **35**, 596 (1879).

[2] Brown, Morris and Millar, *ibid.*, **71**, 115 (1897).

they arrive at a Lintner value for the preparation. More recently Gore[5] has employed a very similar procedure with Lintner's soluble starch as the substrate and proposes the method for the quantitative determination of diastatic activity of flour and various other products. In view of the probable complexity and the differences in character of the diastases which are obtained from different sources, as well as the changes in characteristics of the enzyme prepared by different methods of treatment of the same source materials, it is remarkable that the relationship between opticity and reducing power has been as close as it apparently has been. It may be due to the fact that most of the work in this connection has been done with malt diastase. While many investigators have assumed that the enzyme, maltase, is generally absent from malt preparations, the work of Daish[6] has shown that it is of wide occurrence in plant materials. That its presence is very significant has been emphasized by Davis.[7] It is with the consideration of the presence of a glucose-forming enzyme and its effect upon the polarimetric method for the determination of diastase activity that this paper is primarily concerned.

The hydrolysis of starch is usually represented as going through the following steps

Starch → dextrins → maltose → glucose

Since the reducing value and optical value of the products between starch and maltose are still matters of much uncertainty, these may be omitted from consideration for the moment and attention directed to the theoretical changes in the polarization and reducing values of the other products. The weight relations are as follows

1 g. of starch → 1.05 g. of maltose (or 1.10 g. of maltose hydrate) → 1.1 g. of glucose

If the specific rotations of the above substances are 199, 138 and 52.5, respectively, then the rotation for 1 g. of soluble starch and its hydrolytic products maltose and glucose if present in 100 cc. and polarized in a 4-dm. tube, Ventzke scale, would be

Starch		Maltose		Glucose
22.9°	→	16.8°	→	6.66°

and the drop in rotation assuming complete conversion to maltose or glucose would be 6.1 or 16.24° Ventzke, respectively. The reducing changes for 1 g. of starch expressed as apparent maltose hydrate would be

Starch		Maltose hydrate		Glucose
0	→	1.10	→	$\frac{1.10}{0.61\text{[8]}} = 1.8$

---

[5] Gore, J. *Assoc. Official Agr. Chem.*, 364 (1923).

[6] Daish, *Biochem. J.*, 10, 49 (1916).

[7] Davis, *ibid.*, 10, 30 (1916).

[8] Average value of the reducing ratio of maltose to glucose from Munson–Walker table.

Hence if 1 g. of starch was completely converted to maltose the Polarization–Reduction ratio (P/R), expressed as Ventzke° 4-dm. tube/Apparent maltose hydrate would be 6.1/1.1 or 5.54 and if converted to glucose would be 16.24/1.8 or 9.04.

A calculation of this ratio from the data of Gore gives the following results

Interval of sample removal	1/2	1	1 1/2	2	2 1/2	3
Ratio for 1/2 hr. interval	5.58	6.00	4.73	6.44	...	4.62
Ratio for total interval	5.58	5.66	5.37	5.71	...	5.65

It is of interest that these values are reasonably close to 5.54, the theoretical value to be obtained assuming complete conversion to maltose.

The object of the experimental work was to determine the polarization–reduction ratio for different amylases and make certain of the general applicability of the method. It was believed that the study might also throw some light on the mechanism of the hydrolysis of starch.

Taka diastase is known to be capable of forming a large proportion of glucose from starch and methods have been devised for the estimation of starch,[9,10,11] assuming formation of maltose and glucose. On account of its glucose forming ability it was chosen as a representative amylase of somewhat different character than that of malt.

Experimental

The method of procedure followed was essentially that outlined by Gore[5] in all instances where the diastase was added in the form of a solution or an extract. In two instances where the diastase yielding material was added in the form of a flour the method of Rumsey[12] was followed. For this method several flasks containing identical quantities of reacting materials were prepared; then after different digestion periods flasks were removed, the solutions clarified and prepared for analysis for apparent maltose. In an article supplementary to one previously cited, Gore[13] recommends buffering the starch substrate so that the PH is 4.5–5.5. Using as he suggested the equivalent of 10 cc. of both normal acetic acid and sodium acetate per liter of substrate, a PH value of 4.6 was found. The reaction mixture was buffered in this way in most of the experiments.

Some of the digestion operations were made at room temperature, which was near to 21° at the time. In others the starch solution was brought to a slightly higher temperature, 25 or 39° before the diastase was added. It was then kept at the definite temperature in a thermostat throughout the reaction period. Duplicate determinations of the amount of copper reduced were made by the Munson and Walker method for each interval in all digestion operations and the average values taken. The polarimetric values were the average of six or more readings taken after mutarotation had reached equilibrium.

[13] Gore, THIS JOURNAL, 47, 281 (1925).

As substrate material, Lintner's soluble starch supplied by Merck was used in the majority of the experiments. In a few of the later ones a special type of starch prepared as described recently by Gore[14] was employed. However, the concentration was still maintained near 2% instead of 4% as he suggests.

The materials which served as sources of the enzymes were different samples of Taka diastase from Parke, Davis and Company, several commercial malt diastase samples, samples of barley, flour and alfalfa meal.

Partial details of the results of two experiments are given in Table I. These and a number of others are summarized briefly in Table II.

TABLE I

OPTICAL ACTIVITY–REDUCING SUGAR RELATIONSHIPS DURING STARCH HYDROLYSIS UNDER THE INFLUENCE OF ENZYMES

2.5	26.78	1.051	6.12	5.11
3	26.60	1.090	4.61	5.09

Discussion

In the first observations no particular attention was given to maintenance of a constant temperature during digestion, since it was assumed that both polarization and reduction changes would be similarly affected. More careful consideration made it apparent that if the amylase system is composed of several components each with its own particular optimum, the polarization–reduction ratio might vary with the temperature and other factors.

[a] No buffer. [b] Special starch.

Considerable difficulty was experienced at times in making the polarimetric observations. The solutions often became quite turbid and the end-point was uncertain. Even the special form of soluble starch prepared according to Gore's directions did not eliminate this trouble. Sometimes the results of duplicate experiments would show almost identical reducing sugar values but markedly different polarimetric changes and vice *versa.* On the whole the results were far from satisfactory and in many respects discouraging. Experiments 15 and 16 using barley flour according to Rumsey's[12] method gave results analogous to the samples of malt diastase. In these experiments the major portion of the change took place during the first half hour interval. If endocellular amylases were present they had very little effect on the P/R ratio.

In conclusion it may be said that although there seem to be differences in the hydrolytic characteristics of malt and Taka diastase materials the effect upon the polarization reduction ratio is such that the variation is probably no greater than other experimental errors in such determinations.

To be of value in throwing light on the mechanism of the hydrolysis of starch the method will have to be improved or give more consistent results for other investigators than it has been possible to attain in this study. It is evident that further attention in this connection must be given to the properties of the hydrolytic products intermediate between starch and maltose.

As can be noted in the data of Gore and those of Table I, the ratio P/R for each successive one-half hour unit interval fluctuates considerably, probably due to error in polarimetric readings, but these differences are smoothed out when the change is calculated from the initial point and some compensation of errors takes place.

In contrast to anticipated results, Taka diastase gave on the whole somewhat lower P/R ratios than malt diastase in the initial stages. This seemed to be more or less independent of the extent of hydrolysis (the latter being represented by the magnitude of the change in rotation given in the last column of Table II). This fact would tend to indicate the formation of reducing substances with relatively little change in optical activity from that of the original starch. It is probable that some glucose is formed from a saccharide unit other than maltose and that it may precede maltose or be formed simultaneously with it, thus giving the lower P/R ratio. Experiments 7 and 12 are out of harmony with others of the Taka diastase group in this respect and had other anomalous features in addition. They are included to indicate experimental variations which sometimes occur without apparent cause. From the results of the experiments completed, temperature, concentration of enzyme and buffering of the solution cannot be said to show any significant effect on the ratio.

Experiment 6 with an extract of alfalfa meal gave a rapid polarimetric change with very little saccharification and hence abnormally high P/R ratios.

Summary

Theoretical consideration of the properties of the final products of hydrolysis of starch resulting from diastatic conversion seemed to indicate that the assumed constant relationship between the polarimetric and reducing sugar values would not hold if glucose as well as maltose resulted from the action of the amylase system. It was further believed that the ratios found might furnish information on the mechanism of the hydrolysis of starch.

Determinations of the ratio have been carried out using Taka diastase as a glucose forming amylase system. The ratios found were different from those anticipated and indicate that the changes in the early stages of hydrolysis are probably unlike those of malt diastase.

While the ratios found were not constant, determinations of diastatic activity based upon the assumption of a constant value will probably not

involve an error more serious than those from other sources in such procedures.

Improvements in the procedure will be necessary to give definite information as to the course of hydrolysis of starch.

CELLULOSE FUROATE[1,2]

BY KENNETH A. KOBE WITH RALPH E. MONTONNA

RECEIVED FEBRUARY 18, 1931 PUBLISHED MAY 6, 1931

The increasing industrial importance of cellulose esters presents an attractive field of investigation for new derivatives with desirable properties. One ester which has many desirable properties but which has not been used to any extent because of its excessive cost is cellulose benzoate. The great similarity of furoic acid[3] to benzoic acid made it desirable to prepare cellulose furoate with the hope that it would exhibit the same desirable properties as the benzoate. The recent extensive commercial development of furfural from which the acid can be readily obtained seemed to offer possibilities of obtaining this ester more cheaply than the corresponding benzoate derivative. This ester would be an "all cellulose" ester since furfural can be produced by distilling oxycellulose with dilute hydrochloric acid.

Discussion of Results

The preparation of furoic acid esters of cellulose was accomplished by means of a modified Schotten–Baumann reaction such as had been employed in the preparation of cellulose benzoate.[4] Tetrachloroethane was used as the diluent. Two types of products seemed to be formed as in the case of cellulose acetate, fibrous esters amounting to 65% of the theoretical and analyzing from 2.5 to 3 furoate residues per C_6 unit, and soluble, black, furoylated degradation products analyzing more than three furoate residues. This investigation was restricted mainly to the former product. The fibrous ester was always colored, varying in shade from light yellow to dark brown, and was insoluble in all the usual solvents for cellulose esters.

The saponification values were obtained by the method of Cross and Bevan as modified by Woodbridge.[5] Analyses show that one acid residue is much more firmly bound than are the other two. This is in accord with the present accepted structure[6] of the hexose residues in cellulose, which show one primary and two secondary alcoholic hydroxyl groups. When the fibers stood for twenty-four hours with standard sodium alcoholate solution, only two furoate groups were removed, while on standing for seven days or refluxing for four hours all groups were removed. It was necessary to make a correction for increase of acid value due to decomposition of the furoic acid.

Experimental

Materials.—The cellulose was standard cellulose. The pyridine was of C. P. quality and was used without further purification. The furoyl chloride, tetrachloroethane and butyl acetate were technical grades and were redistilled before use.

Method.—Two grams of cellulose was covered with 100 cc. of diluent, usually tetrachloroethane, and the pyridine and furoyl chloride then added. The flask was attached to a reflux condenser and placed in a paraffin-bath which was heated so that the solvent just boiled. It was usually allowed to heat for three hours and then cooled The contents of the flask were poured onto a Büchner funnel and the fibers were sucked dry, then washed with chloroform and with alcohol. The fibers were boiled in several portions of water to remove any traces of solvent or reagents. They were sucked dry and all water removed in an oven at 100°. The material in solution was precipitated with petroleum ether, boiled with water and dried.

The maximum yield of fibers (3.6 g. = 65.7%) was secured with 15 cc. each of pyridine and furoyl chloride (2.6 times the theoretical), using 100 cc. of tetrachloroethane as the diluent and heating for three hours. Excess pyridine causes the fibers to lose tensile strength and become dark brown in color; excess furoyl chloride causes a lowered yield. When butyl acetate was used as a solvent, a horn-like mass having a very low saponification value was obtained. Heating for longer periods of time causes a decreased yield of fibers and an increased yield of soluble material of which 1.3 g was obtained by heating for twenty-four hours while but 0.2 to 0.3 g. forms in the three-hour period.

Analysis of Product.—The fibers were rubbed through a 10-mesh screen and mixed to give a uniform sample. A 0.3-g. sample was covered with 50 cc. of an alcohol solution of sodium alcoholate and allowed to stand for twenty-four hours, seven days or refluxed for four hours. The excess alkali was titrated using thymol blue as the indicator. When furoic acid was heated with sodium alcoholate solution for four hours, the acid value increased from 90.1 to 105.3% so that a correction was made in all samples treated in this manner.

Expt.	Stand 24 hrs., %	Reflux 4 hrs., %	Reflux corrected, %	Acid groups per C_6 unit
16	57.6	70.1	66.0	2.2
17	62.4	71.1	67.0	2.3
18	59.3	69.2	65.1	2.1
19	65.2	74.4	74.4	2.9
20	59.5	70.5	70.5	2.5

---

[5] Woodbridge, THIS JOURNAL, 31, 1067 (1909).

[6] Hibbert, *J. Ind. Eng. Chem.*, 13,256,334 (1921).

The 1.3 g. of soluble material gave 82.2% furoic acid on standing for twenty-four hours with the sodium alcoholate solution (values from other experiments were 83.5 and 81.6%).

Calculated saponification values: trifuroate, $C_6H_7O_2(OOCC_4H_3O)_3$ = 75.75% of C_4H_3OCOOH; difuroate, $C_6H_8O_3(OOCC_4H_3O)_2$ = 64.0%.

Summary

1. Cellulose di- and trifuroates have been prepared by treating standard cellulose with furoyl chloride in the presence of pyridine. The esters were fibrous, dark colored and insoluble in the usual solvents for cellulose esters.
2. A considerable degradation of cellulose takes place during the reaction with the production of furoylated degradation products of cellulose which are black amorphous substances.
3. The analysis of cellulose trifuroate by saponification shows very clearly the fundamental difference of two of the alcoholic hydroxyl groups in the hexose residue from the third or primary hydroxyl and thus confirms the present accepted structure of the hexose residue.

SOME HETEROCYCLIC DERIVATIVES OF DIPHENYL

BY J. M. F. LEAPER

RECEIVED FEBRUARY 19, 1931 PUBLISHED MAY 6, 1931

The production on a large scale of diphenyl in order to supply the demand for this very useful heat-transfer medium has already resulted in the price of this material being brought down to a figure comparable with that of any of the polynuclear hydrocarbons, except naphthalene.

Its applications in the chemical industry for synthetic purposes are in consequence destined to become of increasing importance, especially as it appears likely that the price can be further reduced.

The recent work by Jenkins, McCullough and Booth[1] has indicated for instance that the simple mono-chloro, nitro and amino derivatives can be produced readily on a commercial basis, and the work of C. H. Penning[2] has extended the knowledge of the polychlorinated derivatives.

The present paper covers some new heterocyclic compounds derived from 4-amidodiphenyl, the derivatives chosen for study being such as might be expected to be of possible commercial application in the rubber industry, in froth flotation of ores, as inhibitors in steel pickling or in dyestuff manufacture.

Use has been made in this work of the method described by R. Herz[3] for introducing sulfur into the ring by the action of sulfur chloride on the

---

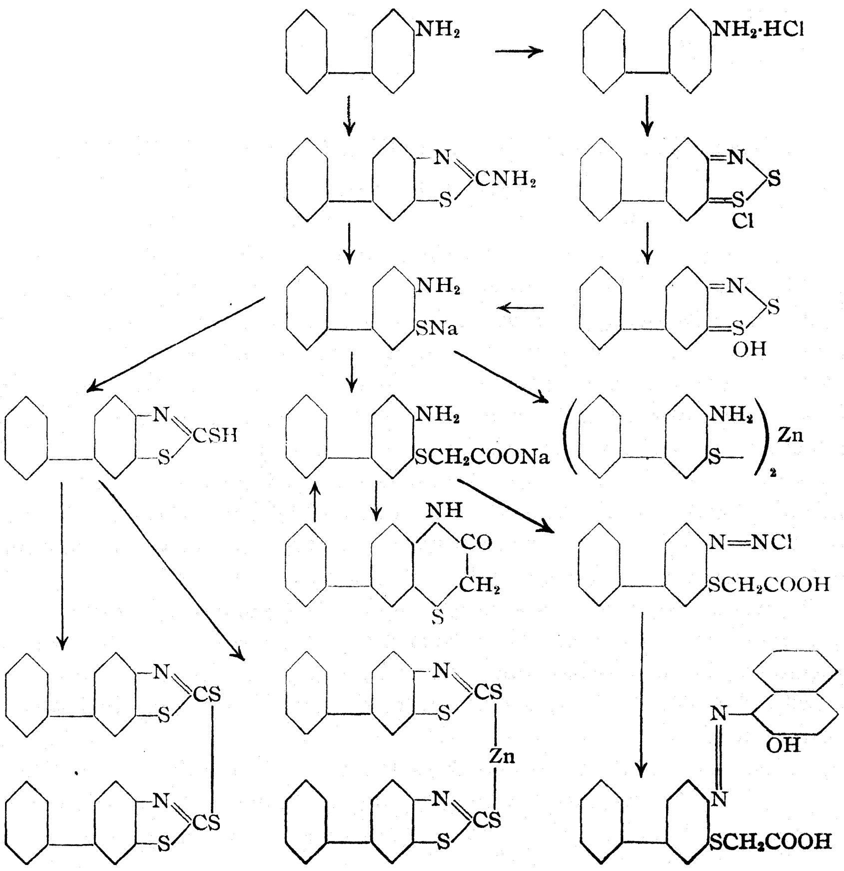
[3] Herz, German Patent 360,690.

hydrochlorides of amino compounds having a free ortho position. This reaction is the keystone of many important industrial syntheses, for example, in the Hydron Pink and Orange series of thioindigoids (Truttwin, "Enzyklopaedie der Kuepenfarbstoffe"), as also in the excellent method of A. H. Ney[4] for the manufacture of substituted mercaptothiazoles

Besides the characteristic ring grouping formed by the Herz reaction, chlorination of the amino compound also usually occurs if a free para position is present or if certain groups are in this position, and it appeared to the writer possible that in the case of diphenyl the tendency for chlorine substitution might extend through to the 4'-position. This, however, proved not to be the case since all derivatives obtained were unsubstituted in this part of the nucleus.

The course of the reactions described is graphically shown in the Flow Sheet.

FLOW SHEET



---

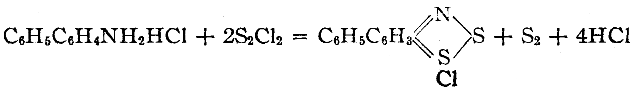
[4] Ney, U. S. Patent 1,788,585

Experimental Part

The diphenyl used for the work was the ordinary commercial product marketed by the Federal Phosphorus Company. Its setting point was 68" and it was considered unnecessary to subject it to recrystallization.

At the inception of this work the 4-aminodiphenyl used was prepared by the method of Bell, Kenyon and Robinson;[5] later the methods of Jenkins, McCullough and Booth[1] became available and were found somewhat more convenient for preparing the finely divided hydrochlorides necessary for the Herz reaction. The 4-nitro compound used for the reduction was crystallized once from methanol, when it had a melting point of 113°. The 4-amino hydrochloride was obtained from the benzene solution of the base by first drying the latter over calcium chloride and then passing in dry hydrochloric acid gas with rapid agitation. The benzene was filtered on a Biichner funnel and air drawn through the hydrochloride until dry. The product was then ready for the Herz reaction

Phenylphenylene Thiazthionium Chloride.—Seven hundred grams of sulfur monochloride was placed in a three-necked flask provided with an efficient agitator; 100 g. of thoroughly dry 4-aminodiphenyl hydrochloride was slowly added at 20° and agitation continued at this temperature overnight The next morning 400 cc. of benzene was added and the temperature then raised to 75–80" and kept at this point with good agitation under a reflux condenser for four and one-half hours Hydrogen chloride gas is evolved during this period and the color of the reaction mass changes from yellow to a reddish-brown. The reaction mixture was now allowed to cool to room temperature and filtered on a dry Biichner funnel. It was washed with enough benzene to remove yellow mother liquor and allowed to dry at room temperature, yield, 140 g. (calcd. 129 g.) The main impurity present is free sulfur formed in the reaction.



$$\mathrm{C_6H_5C_6H_4NH_2HCl + 2S_2Cl_2 = C_6H_5C_6H_3{<}\overset{N}{\underset{\underset{Cl}{S}}{}}{>}S + S_2 + 4HCl}$$

The excess sulfur chloride and benzene can be recovered readily from the filtrate by distillation. The product is a finely crystalline brownish-red powder, slightly soluble in ring hydrocarbons and in acetic acid. It may be purified by dissolving in cold acetic acid, filtering and adding to the filtrate sufficient dry ether to slowly precipitate the thiazonium chloride.

Anal. Calcd. for $C_{12}H_8NS_2Cl$: N, 5.28; S, 24.15; Cl, 13.37. Found: N, 5.20; S, 24.72; Cl, 13.13.

On attempting to obtain a melting point, the product charred at about 130°.

Phenylphenylene Thiazthionium Hydrate.—The chloride is stirred at room temperature with water overnight. The chloride appears to go partly into solution at first with a yellow color, quickly precipitating out again as a purplish powder, the solution meanwhile becoming strongly acid (HCl). On further stirring the precipitate becomes lighter colored until after about sixteen hours it is almost white when the reaction is complete. It is filtered off, washed with water until free from acid and dried. The weight obtained is the theoretical. A sample of the hydrate prepared from the purified chloride by the above method gave a negative test for chlorine, proving that the only chlorine in the chloride was that attached to the labile thiazonium sulfur.

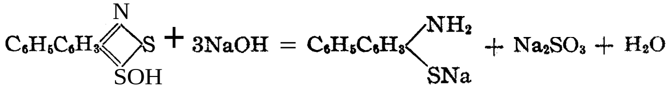
Anal Calcd. for $C_{12}H_9ONS_2$: N, 5.67; S, 25.91. Found: N, 5.59; S, 26.24

The "hydrate" is soluble in alcohol, from which it may be precipitated in fine needles by careful addition of water and allowing to stand It melts at about 135° with charring and decomposition.

---

[5] Bell, Kenyon and Robinson, *J. Chem. Soc*, 1239 (1926).

4-Amido-3-mercaptodiphenyl (**Zinc** Salt).—The reaction is as follows



$$C_6H_5C_6H_3(N)(S)(SOH) + 3NaOH = C_6H_5C_6H_3(NH_2)(SNa) + Na_2SO_3 + H_2O$$

the sodium salt being then precipitated as the zinc salt.

Forty grams of the hydrate, figured on the dry basis, preferably the still wet filtrate from the conversion of the chloride, are slurried with enough water to make about **400** cc. A little ice is added and **64** cc. of 35° BC. sodium hydroxide with stirring. The hydrate goes into solution immediately with the exception of a small portion of insoluble impurity. The solution should now color Clayton yellow paper pink, indicating excess of sodium hydroxide over the sodium salt of the thiophenol. The solution is filtered and zinc chloride solution added until no further precipitate is obtained. The precipitate is redissolved in a mixture of dilute hydrochloric acid and alcohol Excess of sodium acetate solution is added to precipitate zinc mercaptide.

Anal. Calcd. for $(C_{12}H_{10}NS)_2Zn$: Zn, **14.05.** Found: Zn, **13.55.**

The pure zinc mercaptide may be used for any of the condensation reactions, but the crude solution of sodium mercaptide obtained by dissolving the hydrate in sodium hydroxide is quite suitable for all purposes and is much more convenient. The sodium salt may also be precipitated out with excess of sodium hydroxide if desired.

Air passed into the sodium hydroxide solution of the thiophenol precipitates the disulfide as a somewhat resinous mass, which is difficult to purify. No analysis was made of this.

2-Mercapto-6-phenylbenzothiazole.—Forty grams of crude phenylphenylene thiazthionium chloride is converted to the hydrate as described above, the latter filtered off, washed well and re-slurried with enough water to make about **180** cc. and **40** cc. of 35" Bé. sodium hydroxide is added. The mixture is agitated for ten minutes and transferred to a flask; **10** cc. of carbon disulfide is added and the whole heated to refluxing temperature under a condenser. After about five minutes a crystalline magma appears in the reaction mass. With further heating the deep yellow color of trithiocarbonate changes to a light brownish color and at the end of about forty minutes the crystalline precipitate all goes into solution. The reaction of the solution is now alkaline to Brilliant yellow paper but not to Clayton yellow. The solution is diluted to 800 cc., cooled to room temperature and dilute hydrochloric acid added with agitation until neutral to Brilliant yellow. The thiazole comes out as an almost white precipitate. It is filtered, washed and dried; yield, **29.5** g. **(87%** of calcd. figured on the 4-aminodiphenyl), m. p. **220".** Recrystallized twice from benzene containing 10% "Cellosolve." the melting point remained constant at **230.5°**.

Anal. Calcd, for $C_{13}H_9NS_2$: N, 5.76; S, **26.33.** Found: N, **5.68;** S, **26.16.**

The product is soluble in sodium and potassium hydroxides but practically insoluble in ammonia (distinction from 2-mercaptobenzothiazole, which is soluble in ammonia), very slightly soluble in alcohol, somewhat more so in benzene and in glycol mono-ethyl ether ("Cellosolve").

Bis-6-phenyl-2-benzothiazole Disulfide.—Four and nine-tenths grams of phenylmercaptobenzothiazole is dissolved in **2.2** cc of **35" Bé.** sodium hydroxide **and 100** cc. of water; **2.5** g. of iodine dissolved in *75* cc. of water containing potassium iodide are added to the thiazole solution. The creamy white precipitate of disulfide is filtered off, washed well and dried; yield, **4** g. The product is insoluble in alcohol, soluble in benzene, and very soluble in chloroform. Crystallized once from a mixture of alcohol and benzene and once from benzene, the product melts at **163°**.

Anal. Calcd. for $C_{26}H_{16}N_2S_4$: N, **5.78;** S, 26.45. Pound: N, **5.71;** **S, 26.72.**

Zinc and Lead Salts of 2-Mercapto-6-phenylbenzothiazole.—The thiazole dissolved in alcohol is precipitated by the calculated amount of zinc sulfate in aqueous solution, the precipitated zinc salt washed and dried; it is a white powder.

Anal. Calcd. for $C_{26}H_{16}N_2S_4Zn$: Zn, 11.90. Found: Zn, 11.41.

The lead salt was made similarly using diethylene glycol monoethyl ether ("Carbitol") for dissolving the thiazole and an aqueous solution of lead acetate, and is a yellow crystalline powder.

Anal. Calcd. for $C_{26}H_{16}N_2S_4Pb$: Pb, 29.97. Found: Pb, 30.55

It was thought desirable to prepare the 2-mercapto-6-phenylbenzothiazole by the method suggested by Herz and Schubert[6] from 4-amidodiphenyl by treating with sodium thiocyanate and bromine in acetic acid solution giving 2-amido-6-phenylbenzothiazole, the latter then being heated with a considerable excess of potassium hydroxide, splitting the thiazole ring and giving the amidothiophenol. The alkaline solution of the latter is then treated with carbon disulfide as in the previous method.

2-Amido-6-phenylbenzothiazole.—8.3 g. of 4-amidodiphenyl and 3.2 g. of sodium thiocyanate are agitated with 120 cc. of glacial acetic acid at 50°; 2 cc. of bromine is added drop by drop and agitation continued for one hour. The mixture is then cooled, diluted and sodium hydroxide added until slightly alkaline. The amidothiazole precipitated as a creamy white powder. It was filtered, washed and dried; yield, 8.8 g. The product is soluble in hot dilute hydrochloric acid and is purified by filtering this hot solution and allowing the hydrochloride to crystallize out. This is washed a little and basified by treatment with sodium hydroxide, then washed, dried and recrystallized from hot benzene, separating in creamy white plates of m. p. 227–228°.

Anal. Calcd. for $C_{13}H_{10}N_2S$: N, 12.38; S, 14.16. Found: N, 12.46; S, 14.15.

This product was treated for four to five hours with strong potassium hydroxide in considerable excess, when ammonia was evolved and the heterocyclic ring split back to the amidothiophenol. The resulting solution was divided into two parts One portion was treated with carbon disulfide as above, precipitated with hydrochloric acid and the separated yellow precipitate dried and recrystallized once from benzene. The product obtained melted at 229° and when mixed with 2-mercapto-6-phenylbenzothiazole previously obtained, there was no diminution in melting point. The second portion of the thiophenol solution was heated with sodium chloroacetate, the solution precipitated with hydrochloric acid and heated to form the thioglycolic anhydride. This was filtered off. dried and crystallized once from benzene. The product melted at 210° and when mixed with the anhydride obtained from the thiazthionium chloride described below, melted at 211°.

2-Amido-5-phenylthioglycolic Acid.—Forty grams of the thionium chloride was converted to the hydrate as above described, the latter filtered off, washed, mixed with water to make 400 cc., 65 cc. of 35° Bé. sodium hydroxide added, agitated for five minutes, filtered, 21 g. of chloroacetic acid previously neutralized with dilute sodium hydroxide added and the mixture heated for a half hour to 60° with agitation. The condensation is now complete and hydrochloric acid is added, precipitating the crude amidophenylthioglycolic acid. On heating the acidiied mixture the precipitate, which is at first somewhat resinous, becomes crystalline, indicating a change to the inner anhydride. This is filtered off, washed and dried; yield, 31 g. (about 94% figured on amidodiphenyl). Recrystallized twice from hot benzene it gives white leaflets of m. p. 212–212.5°.

Anal. Calcd. for $C_{14}H_{11}ONS_3$: N, 5.81; S, 13.28. Found: N, 5.73: S, 13.41.

---

[6] Herz and Schubert, U. S. Patent. 1,788,297.

On heating with concd. sodium hydroxide the anhydride is converted back to the sodium salt of amidothioglycolic acid.

Diazotization of Amidothioglycolic Acid.—A solution of the crude sodium salt obtained by addition of sodium hydroxide to the hydrate as described above was mixed with an equimolecular amount of sodium nitrite solution, and the mixture added slowly at 10° with good agitation to dilute hydrochloric acid, keeping the solution acid to Congo paper. Agitation is continued for one hour. The diazo solution was filtered and added to an alkaline β-naphthol solution as usual. The dye precipitates at once Some acetic acid was added and the dye filtered off, washed, dried and crystallized from acetic acid, giving reddish needles with a metallic appearance.

Anal. Calcd. for $C_{24}H_{18}O_3N_2S$: N, 6.76; S, 7.73. Found: N, 6.73; S, 7.79.

A similar coupling was made also using o-phenylphenol (Dow) instead of β-naphthol. This gave a dyestuff having an orange color in acetic acid solution, the β-naphthol dye giving a bluish-red solution.

Preliminary Experiments Made on the Preparation of the Substituted Thioindigoid Dyestuff According to the Methods of Herz.[7]—Starting from the diazotized *o*-amidothioglycolic acid, it was converted to the nitrite by the Sandmeyer reaction and then to the substituted thionaphthene by saponification, the latter then being oxidized to the thioindigo, gave a dyestuff which dyed cotton bluish-red shades from a hydrosulfite vat. Further investigation of this dyestuff is reserved for later publication.

In connection with the sodium salt of the amidothioglycolic acid, an interesting fact was noted. It was at first intended to salt out this sodium salt from the crude solution obtained by heating the amidothiophenol with excess of sodium chloroacetate in order to obtain a purer product for diazotization, etc. It was found, however, that the sodium amidothioglycolate thus obtained was almost insoluble in cold water after salting out, whereas in the presence of the usual impurities, *i. e.*, sodium sulfide, sodium sulfite, sodium chloroacetate, etc., a quite concentrated cold solution could be obtained, which was more convenient for diazotization.

Summary

1. The course of the Herz reaction as applied to 4-amidodiphenyl was established.
2. Some new heterocyclic derivatives related to 3-mercapto-4-aminodiphenyl have been prepared and described.
3. 6-Phenyl-2-mercaptobenzothiazole was made by two methods.
4. A new azo dye was prepared.

A STUDY OF THE TOXICITY OF TOXICAROL, DEGUELIN AND TEPHROSIN USING THE GOLDFISH AS THE TEST ANIMAL

BY W. A. GERSDORFF

RECEIVED FEBRUARY 24, 1931 PUBLISHED MAY 6, 1931

The goldfish (*Carassius auratus*), having proved to be a good test animal in the study of toxicity, has been used in the toxicological examination of various substances that is now in progress in this Laboratory. The substances tested have been constituents of fish-poisoning plants and their derivatives. The method used by the author has been described in a previous paper,[1] and a study by that method of the toxicity of rotenone and two of its derivatives, isorotenone and dihydrorotenone, has also been published.[2] This paper presents the results of a similar examination of toxicarol, deguelin and tephrosin, toxic constituents of two fish poisoning plants of the genus Cracca (*Tephrosia*).

Toxicarol (m. p. 219°) and deguelin[3] (m. p. 171°) were isolated from the roots of C. *toxicaria* by *E. P.* Clark of this Laboratory.[4] It was shown by him that both substances are found also in the roots of *Deguelia (Derris) elliptica*, and in addition deguelin occurs in the roots of *Lonchocarpus nicou* ("cubé") and the leaves of C. *vogelii*.

Tephrosin (m. p. 198°) was isolated from the leaves of *C. vogelii*.[5] It may also be obtained, however, from derris and cubé roots.

The chemical structure of these three substances is not yet fully known. Toxicarol is an optically inactive compound of the molecular formula $C_{23}H_{22}O_7$, possessing two hydroxyl and two methoxyl groups. Deguelin is an optically inactive dimethoxy lactone having the molecular formula $C_{23}H_{22}O_6$. Tephrosin is a dimethoxy lactone with the molecular formula $C_{23}H_{22}O_7$. It is suggested by Clark that tephrosin is an hydroxydeguelin. It is to be noted that the molecular formulas for toxicarol and tephrosin differ from that of rotenone by having one more atom of oxygen, whereas the formula for deguelin is identical with that of rotenone.

On account of the slight solubility of the compounds in water, acetone was used as the solvent. It was found necessary early in these toxicological studies with rotenone and some of its derivatives to work with freshly prepared stock solutions of the compounds in acetone, since such solutions when allowed to stand underwent appreciable chemical change, as evidenced by a change in the color of the solution, with a concomitant loss in

toxicity. The loss of toxicity of solutions of rotenone has also been noted by Jones and Davidson, who used insects as the test animals.[6] That the solutions change on standing was observed in the present study especially with toxicarol and deguelin. Acetone solutions of toxicarol suffer a rapid loss in toxicity to goldfish; acetone solutions of deguelin, however, undergo an appreciable increase in toxicity. Acetone solutions of tephrosin either do not undergo a change in toxicity or the change is slow as compared to that of the other two compounds.

The data are given in Tables I to III. The survival time curves and the velocity of fatality curves which were plotted from these data are given in Figs. 1 and 2. In the former curves the ordinates are survival times in minutes; in the latter, they are the reciprocals of the survival times multi-

plied by 100. In both types of curves the abscissas are concentrations in milligrams per liter.

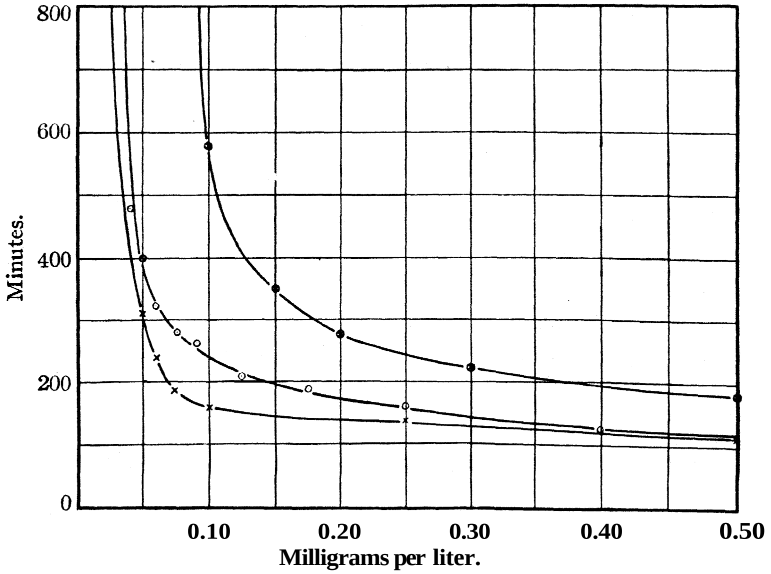

Fig. 1.—Survival time curves: X, toxicarol; ⊙, deguelin; ⊗, tephrosin.

Until an equation better expressing the course of toxic action is found acceptable, the formula used in the preceding papers, that is, Powers' formula, toxicity = $\sqrt{\tan \theta / a}$, will again be used as a measure of the relative toxicities of the three substances studied here. In this formula data obtained from the velocity of fatality curve are used. A portion of this curve approximates a straight line since its corresponding portion of the survival time curve approximates an equilateral hyperbola. This straight line, representing the theoretical velocity of fatality, is prolonged to cut the x-axis at a point designated a; tan Θ is the slope of this line. In this way values are obtained for the theoretical threshold of toxicity, that is, the concentration below which the substance does not cause death, and the rate of increase of the theoretical velocity of fatality with increase in concentration. The formula expresses the opposite effect of these two variables.

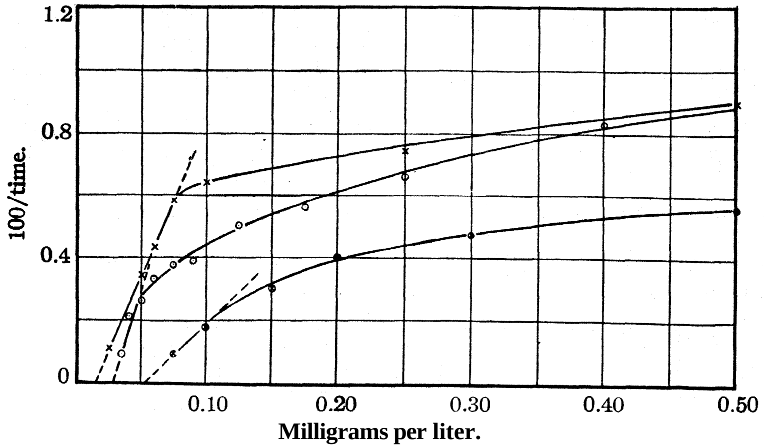

Fig. 2.—Velocity of fatality curves: X, toxicarol; ⊙, deguelin; ⊗, tephrosin.

The comparative toxicities of the substances under consideration derived according to this equation are shown in Table IV. The values given for a and tan Θ are based on the expression of concentration in milligrams per liter and time in minutes. The values for the toxicities are compared to that for rotenone since rotenone was the first as well as the most toxic of the compounds studied.

TABLE IV

COMPARATIVE TOXICITY AT 27°C. OF TOXICAROL, DEGUELIN, AND TEPHROSIN TO GOLDFISH

Substance	a, mg. per liter	Tan Θ		Relative toxicity with respect to rotenone
Toxicarol	0.015	0.097	2.5	0.65
Deguelin	.030	.150	2.2	.56
Tephrosin	.055	.043	0.88	.23

Conclusions

Of the three compounds studied, toxicarol has the lowest threshold of toxicity, 0.015 mg. per liter. That of deguelin is twice as great and that of tephrosin nearly four times as great. The threshold of toxicity of rotenone is slightly lower than that of toxicarol. The velocity of fatality of deguelin increases with increase in concentration at a higher rate than that of toxicarol (half again as high), but this rate is lower for tephrosin (less than half that of toxicarol). The rate of increase for rotenone is double that of toxicarol. At higher concentrations, when the rate of increase decreases, toxicarol is slightly more toxic than deguelin and tephrosin is considerably less toxic; for example, at a concentration of 0.20 mg. per liter the survival times are, respectively, 139, 175 and 274 minutes. Rotenone at higher concentrations is considerably more toxic than toxicarol; at a concentration of 0.20 mg. per liter the survival time is sixty-five minutes. According to Powers' formula, which is an expression of relative toxicity considering the first two factors only, the three substances studied have the following decreasing order of toxicity: toxicarol, deguelin and tephrosin. Their toxicities are 65, 56 and 23%, respectively, of that of rotenone.

CATALYTIC REDUCTION OF MIXTURES OF PARA-NITRO- AND NITROSOPHENOLS WITH ALDEHYDES AND KETONES

BY RANDOLPH T. MAJOR

RECEIVED FEBRUARY 24, 1931 PUBLISHED MAY 6, 1931

In connection with an attempt to prepare certain O-arylhydroxylamines it was noted that when the product that was formed by the catalytic reduction of 2,4-dinitrophenol in solution in acetone was benzoylated by the usual method of Schotten–Baumann, the compound expected, (2,4-bis-benzaminophenyl) benzoate, m. p. 233°,[1] was not obtained. Analyses indicated that the new compound contained one C_3H_6 group more than does (2,4-bis-benzaminophenyl) benzoate. When, however, the solvent that was used was either dioxane or isopropyl alcohol instead of acetone the expected (2,4-bis-benzamino-phenyl) benzoate was formed.

These facts pointed to the probability of a condensation taking place between acetone and the phenol during the reduction.

A solution of 2,4-dinitrophenetole[2] was then catalytically reduced and benzoylated. The compound that was obtained was found to be the expected new compound (2,4-bis-benzamino)-phenetole.

Thinking that the phenol group might have something to do with the peculiar course of the reduction in the first case mentioned, ortho, meta and para nitrophenols were catalytically reduced in solution in acetone.

When *p*-nitrophenol was catalytically reduced in the presence of acetone

---

[1] Post and Stuckenberg, *Ann.*, 205, 69 (1880).

[2] Willgerodt, *Ber.*, 12,764 (1879).

some p-aminophenol was formed, but there was also obtained another product which was soluble in alkalies and acids and which could be separated from p-aminophenol by shaking a solution of the two in acids with benzaldehyde, which combined with and precipitated the *p*-aminophenol.[3] This other product was shown to be the same compound that was formed by the catalytic reduction of 4-(isopropylidene-amino)-phenol, $(CH_3)_2C=NC_6H_4OH$,[4] and corresponded in every way to 4-(isopropyl-amino-phenol which had previously been prepared by the action of isopropyl chloride on *p*-aminophenol.[5] Various derivatives were made, including the hydrochloride, dibenzoyl derivative, the nitroso derivative and the phenyl isocyanate addition product.

When, however, o-nitrophenol was catalytically reduced in the presence of acetone no (2-isopropylamino)-phenol was formed but when the reduction product was benzoylated (2-benzamino-phenyl) benzoate[e] was obtained. Also when m-nitrophenol was reduced in the presence of acetone, no m-isopropylaminophenol could be detected.

Obviously, therefore, the compound that was formed by the benzoylation of the reduction product of the mixture of 2,4-dinitrophenol and acetone was (2-benzamino-4-benzoyl-(isopropyl)-amino)-phenylbenzoate, $2,4\text{-}(C_6H_5CONH)(C_6H_5CONCH(CH_3)_2)C_6H_4\text{–}OCOC_6H_5$.

The course of the reaction was not simply a condensation between the p-aminophenol formed during the reduction and the acetone which was present, followed by further reduction. This was shown by catalytically reducing a mixture of p-aminophenol and of acetone. No 4-(isopropylamino)-phenol was obtained.

By a similar process (4-*sec.*-butylamino)-phenol was formed by the reduction of a mixture of *p*-nitrophenol and methyl ethyl ketone, and 4 (amyl-3-amino)-phenol hydrochloride, $p\text{-}(C_2H_5)_2CHNHC_6H_4OH\cdot HCl$, was formed from the reduction products of a mixture of *p*-nitrophenol and diethyl ketone.

However, when *p*-nitrophenol was reduced in the presence of acetophenone or menthone, only p-aminophenol was obtained.

Also, when nitrobenzene was catalytically reduced in the presence of acetone, no n-isopropylaniline was formed.

On the other hand, good yields of 4-(isopropylamino)-phenol were obtained by the reduction of p-nitrosophenol in the presence of acetone.

Attention was next directed to the possibility of condensation between 4-nitrophenols and aldehydes during reduction. No definite, crystalline

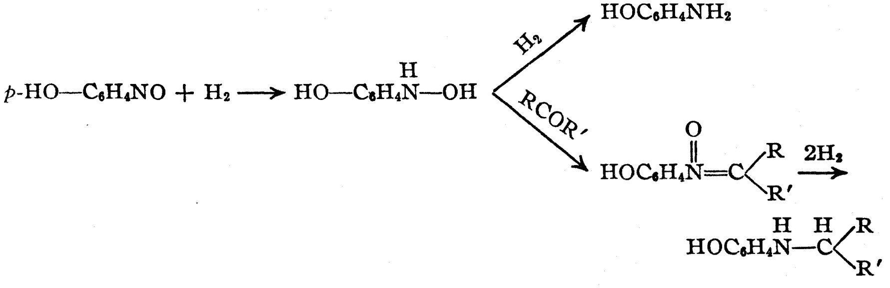
condensation products were isolated when p-nitrophenol was catalytically reduced in the presence of either formaldehyde or acetaldehyde. However, when a mixture of p-nitrophenol, benzaldehyde and an inert solvent such as methanol was catalytically reduced, a considerable yield of 4-(dibenzylamino)-phenol[7] was obtained.

It was also found that reduction of a mixture of *p*-aminophenol and benzaldehyde gave a good yield of 4-(dibenzylamino)-phenol.

A complete explanation of the rather peculiar reactions that have been recorded is not at present clear. However, in the case of the reduction of mixtures of ketones and p-nitro- and nitrosophenols it seems clear that some intermediate product formed during reduction of the substituted phenols condensed with the ketone and the condensation product was, in turn, reduced. The most likely intermediate products that could behave in this way are the corresponding hydroxylamines. It has been shown by Hoffmann and Victor Meyer that hydroxylamines are formed as intermediate products in the reduction of many nitro compounds.[8] According to this conception the reaction must proceed in the following manner



Apparently a hydroxy group in the para position to the nitrogen atom must increase the chemical activity of the hydroxylamine group which is formed during the reduction. That this is probably true is indicated by the fact that while zinc dust and water reduce nitrobenzene and most of its derivatives to phenyl hydroxylamines,[9] the same agents reduce *p*-nitrophenols to *p*-aminophenols.[10]

In the case of the reduction of a mixture of *p*-nitrophenol and benzaldehyde, the same sort of reaction probably occurred at first and then due to the greater activity of aldehydes as compared with ketones condensation took place between the aldehyde and the secondary amine which had been formed. Finally, there was reduction of the new condensation product. The reaction may be represented as follows

Experimental Part

General Method of Reduction.—All of the reductions described in this paper were carried out in a Burgess–Parr Reduction Apparatus." The hydrogenation catalyst was in every case platinum oxide.[12]

Reduction Followed by Direct Benzoylation of the Reduction Product.—The appropriate mixtures shown in Table I were reduced. The reduction products were diluted with water and benzoylated with a mixture of benzoyl chloride and sodium hydroxide.

TABLE I

REDUCTION EXPERIMENTS

Mixture reduced		Solid product obtained			Nitrogen, %	
Solid	Solvent	M. p., °C.	Crystallized from	Formula	Calcd.	Found
2,4-Dinitrophenol	Acetone	171	Alc.	$C_{30}H_{26}O_4N_2$	5.86	6.11
2,4-Dinitrophenol	Isopropyl alc.	233[b]	..[c]	....	..	..
2,4-Dinitrophenetole	Acetone[a]	189	Alc.	$C_{22}H_{20}O_3N_2$	7.78	7.80 7.57[d]

[a] The same compound was obtained when other solvents such as 1,4-dioxane, methanol and glacial acetic acid were used in place of acetone. [b] Post and Stuckenberg, Ref. 1, give 231–233° as them. p. of 2,4-(bis-benzamino)-phenyl benzoate and state that the compound is insoluble in alcohol. [c] Insoluble in alcohol. [d] Mol. wt. Calcd. for $C_{22}H_{20}O_3N_2$: 360. Found: 362,365 (Menzies–Wright method).[13]

Hydrolysis of 2,4-(Bis-benzamino)-phenetole.—A solution of 2.5 g. of 2,4-(bis-benzamino)-phenetole in concentrated hydrochloric acid was heated in a sealed tube at 155–160° for four hours. After the tube had been cooled long needle-like crystals were found in the solution. These were filtered and the filtrate extracted with ether. The solid which was left after the ether had been evaporated and the above-mentioned solid precipitate were identified as benzoic acid by their solubility in organic solvents and alkalies, relatively slight solubility in water and the melting point of 121–122°,[14] yield 71%.

The acid filtrate described above was evaporated to dryness in *vacuo.* One gram of solid remained. To 0.3 g. of this was added a dilute aqueous solution of picric acid.

A pale yellow precipitate formed which was recrystallized from dilute alcohol; decomposition point 120°.[15]

Another portion of the solid left after excess of hydrochloric acid had been evaporated was dissolved in water and benzoylated with benzoyl chloride and sodium hydroxide. A

[12] Adams and Shriner, THIS JOURNAL, 45, 2171 (1923).

[13] Menzies and Wright, Jr., *ibid.*, 43, 2314 (1921).

[14] Reissert, *Ber.*, 23, 2244 (1890), gives 121.25° as them. p. of benzoic acid.

[15] Lumière and Seyewetz, *Bull. soc. chim.*, *[111]9*, 597 (1893), give 120° as the decomposition point of 2,4-diaminophenol picrate.

solid was obtained which was relatively insoluble in alcohol; m. p. 233°. A mixture with 2,4-(bis-benzamino)-phenyl benzoate also melted at 233°.

Reduction of a Mixture of *p*-Nitrophenol and Acetone.—A solution of 0.18 mole of *p*-nitrophenol in one mole of acetone was reduced. When the reduction was complete the solution was evaporated to dryness. The residue was then extracted with hot benzene. The portion which did not dissolve was soluble in hot acetone, m. p. 184° with decomposition.[16]

When the above-mentioned solution in hot benzene was cooled, a solid precipitated which melted with decomposition at 143°. The filtrate from this was evaporated to dryness. An oil remained, most of which was insoluble in dilute acids. It was accordingly washed with dilute hydrochloric acid and extracted with ether. Evaporation of the ether left a solid which was recrystallized from benzene; m. p. 115°. A mixture of p-nitrophenol with this compound also melted at 115°. It was soluble in dilute alkalies.

The above-mentioned solid, m. p. 143°, was dissolved in dilute acetic acid and the solution shaken with an excess of benzaldehyde for ten minutes. The excess benzaldehyde and any condensation product with it was extracted with ether. The acid layer was neutralized with sodium carbonate. A cream colored precipitate formed which was recrystallized from benzene; m. p. 155–156° with some decomposition; yield, 45%. It occurred in the form of fine white needles.

Anal. Calcd. for $C_9H_{13}ON$: C, 71.47; H, 8.67; N, 9.27; mol. wt., 151.11. Found: C, 71.4, 71.72; H, 8.95, 8.77; N, 9.64; mol. wt. (Menzies–Wright method),[13] 150.

4-(Isopropyl-(nitroso)-amino)-phenol, *p*-$C_3H_7N(NO)C_6H_4OH$.—A cold solution of 0.5 g. of 4-(isopropylamino)-phenol in dilute hydrochloric acid was treated with an aqueous solution of 0.25 g. of sodium nitrite in water. After standing for a short while, salt solution was added and the solution was extracted with ether. When the ether was evaporated a yellow solid was left which was soluble in dilute alkalies but insoluble in acids. It gave the Liebermann nitroso reaction.[17] It was recrystallized from benzene; m. p. 112–113°.

Anal. Calcd. for $C_9H_{12}N_2O_2$: N. 15.54. Found: N, 15.05.

4-(Phenylcarbamino-(isopropyl)-amino)-phenol.—A solution of 0.4 g. of *p*-isopropylamino-phenol and 0.6 g. of phenyl isocyanate in dry benzene was heated to boiling. A white precipitate formed. The solution was cooled and the solid was filtered off. It was insoluble in dilute acids but soluble in dilute alkali. It was recrystallized from benzene; m. p. 214–215° with some decomposition.

Anal. Calcd. for $C_{16}H_{18}O_2N_2$: N, 10.38. Found: N, 10.80. 10.79.

4-Isopropylamino-phenol.—A solution of 2.5 g. of 4-(isopropylidene-amino)-phenol in alcohol was reduced. After completion of the reduction the alcohol was evaporated A solid remained which was recrystallized from benzene; m. p. 155–156°. A mixture of this solid with the compound, m. p. 155–156°, obtained by the catalytic reduction of a mixture of p-nitrophenol and acetone also melted at 155–156°.

Reduction of a Mixture of a Nitrophenol and a Ketone Followed by Treatment of the Reduction Product with Nitrous Acid.—A solution of the nitrophenol in the ketone, and methanol, also when the ketone was diethyl ketone, was reduced. The volatile material was then evaporated in *vacuo* at room temperature. The residue was dissolved in cold dilute hydrochloric acid. A cold aqueous solution of sodium nitrite was then added. The nitroso derivative of the *sec.*-alkylaminophenol precipitated.

---

[16] Lossen, *Ann.*, 175, 296 (1875), gives 184° as the decomposition point of *p*-aminophenol.

Para	Diethyl	60	89–90[b]	$C_{11}H_{16}O_2N_2$	13.44	13.21 13.57

[a] A portion of the residue left after acetone had been evaporated was benzoylated with a mixture of benzoyl chloride and dilute sodium hydroxide. A solid formed which was recrystallized from alcohol; m. p. 182°.[18] [b] Purified by dissolving in alcohol. treating with decolorizing carbon, filtering and reprecipitating with water. It was then twice recrystallized from a one to one mixture of benzene and petroleum ether and finally dissolved in glacial acetic acid and reprecipitated with water.

Separation of the **Alkyl Aminophenols** by Treatment of the Reduction Products with **Benzaldehyde.**—After the reduction was complete the volatile solvents were evaporated in *vacuo.* The residue was dissolved in dilute acetic acid. The solution was shaken with a slight excess of benzaldehyde and then extracted with ether. The aqueous solution was then made neutral with sodium carbonate. Any alkylaminophenol which had been formed during the reduction precipitated. These phenols darkened when they were exposed to air and light. All were soluble in acids and alkalies.

TABLE III

EXPERIMENTAL DATA

Mixture reduced Solid	Ketone	Product obtained Yield, %	M. p., °C.	Formula	Nitrogen, % Calcd.	Found
m-Nitrophenol	Acetone	Negl.	.....	......	..	....
p-Aminophenol	Acetone	No	.....	......	..	....
p-Nitrophenol	Methyl ethyl[a]	34	118–119[c]	$C_{10}H_{15}ON$	8.50	8.80 8.68
p-Nitrophenol	Menthone[a]	No	.....	......	..	....
Nitrobenzene	Acetone	No[b]	.....	......	..	....
p-Nitrosophenol	Acetone	54	155–156[d]	$C_9H_{13}ON$	9.27	9.12 9.22

[a] The mixture to be reduced was diluted with methyl alcohol.

[b] No oil precipitated when the acid solution was treated with sodium carbonate, nor could any be extracted with ether. Another portion of the oily residue from the reduction was treated with benzoyl chloride and sodium hydroxide. The solid which formed was recrystallized from alcohol. White platelets were obtained; m. p. 161°. A mixture of this compound with pure benzanilide also melted at 161°. The last portion of the oily residue was distilled. After a small amount of acetone and other low-boiling material had distilled over, the rest all distilled at about 184°,[19] and the temperature of the distilling liquids never rose to the boiling point of N-isopropylaniline.[20]

[c] Recrystallized three times from toluene.

[d] Recrystallized from benzene.

Reduction of a Mixture of p-Nitrophenol and Acetophenone.—A solution of 0.05 mole of *p*-nitrophenol, and 0.05 mole of acetophenone in alcohol was reduced. A precipitate formed. It was filtered off; m. p. 184° with decomposition;[16] yield, 4 g. Water

---

[18] Hinsberg and Udranszky, Ref. 6b, give 182° as the m. p. of 2-(benzamino)-phenyl benzoate.

[19] Thorpe, J. Chem. *Soc.*, 37, 221 (1880), gives 184° as the b. p. of aniline.

[20] Pictet and Crepieux, *Ber.*, 21, 1109 (1888), give 209–210° as the b. p. of N-isopropylaniline.

was added to the filtrate and the mixture benzoylated with benzoyl chloride and sodium hydroxide. The solid which formed was recrystallized from alcohol; m. p. 233°.[21]

4-(Isopropylamino)-phenol Hydrochloride.—Dry hydrogen chloride was passed into a solution of 4-(isopropylamino)-phenol in a mixture of chloroform and dry ether. The solid which formed was dissolved in absolute alcohol and reprecipitated with dry ether. The 4-(isopropylamino)-phenol from the reduction of 4-(isopropylidene-amino)-phenol and that formed by the reduction of a mixture of *p*-nitrophenol and acetone both gave hydrochlorides which melted at 189°; a mixture of the two also melted at 189°.

Hydrochloride of the **4-(Isopropylamino)-phenol** Obtained by the Reduction of a Mixture of ***p*-Nitrophenol** and Acetone.—Anal. Calcd. for $C_9H_{14}ONCl$: Cl, 18.91. Found: Cl, 19.31, 19.18.

Hydrochloride of the **4-(Isopropylamino)-phenol** Obtained by the Reduction of **4-(Isopropylidene-amino)-phenol.**—*Anal.* Calcd. for $C_9H_{14}ONCl$: Cl, 18.91. Found: Cl, 18.88.

4-(*Sec*.-alkylamino)-phenol Hydrochloride.—A solution of **4-(*sec*.-alkylamino)**-phenol or its nitroso derivative in concentrated hydrochloric acid was evaporated to dryness *in vacuo* at room temperature. Of course, oxides of nitrogen were evolved when acid was added to the nitroso derivative. The solid residue was dissolved in absolute alcohol and reprecipitated with dry ether. These hydrochlorides had no definite melting point but decomposed when heated.

TABLE IV

EXPERIMENTAL DATA

		Nitrogen. % of chloride	
Substituted phenol dissolved	**Formula**	**Calcd.**	**Found**
4-(*Sec*.-butylamino)-phenol	$C_{10}H_{16}ONCl$	6.96	6.93 6.96
4-(Amyl-3-(nitroso)-amino)-phenol	$C_{11}H_{18}ONCl$	6.51	6.39 6.23

Reduction of a Mixture of ***p*-Nitrophenol** and **Benzaldehyde.—A** solution of 0.1 mole of *p*-nitrophenol and **0.3** mole of benzaldehyde in methanol was catalytically reduced in the usual manner. The reduced solution was then evaporated in *vacuo* to remove methanol. Ether was added to the residue. White crystals remained which decomposed at 184°,[16] were insoluble in water but soluble in acids and alkalies and were darkened by standing in the air in the light. The ethereal filtrate from these crystals was washed with sodium bisulfite and then sodium carbonate in order to remove benzaldehyde and acids. The ether solution was then extracted with dilute hydrochloric acid. During this extraction a solid precipitated. It was treated with dilute sodium carbonate solution and this solution was extracted with ether. Evaporation of the ether left a solid which was recrystallized from 75% alcohol; m. p. 127–128°. The same solid was obtained by addition of sodium carbonate to the extract in hydrochloric acid described above. In that case an oil precipitated which was extracted with ether. This solution was evaporated and the residue was recrystallized from 75% alcohol; m. p. 127–128°.[22]

Anal. Calcd. for $C_{20}H_{19}ON$: N, 4.85. Found: N, 5.05.

Benzoylation of Substituted ***p*-Aminophenols.—A** solution of the substituted *p*-aminophenol in sodium hydroxide was shaken for several minutes with benzoyl chloride. **A** solid benzoate was formed.

Reduction of a Mixture of ***p*-Aminophenol and Benzaldehyde.—A** solution of 0.05 mole of *p*-aminophenol and 0.15 mole of benzaldehyde in 20 cc. of methanol and 50

---

[21] Hinsberg and Udranszky, Ref. 6b, give 231" as the m. p. of 4-(benzamino)-phenyl benzoate.

[22] Bakunin, *Gazz. chim.* ital., **II**, 36, 211 (1906); Chem. *Centr.*, **II**, 1413 (1906), gives 127" as the m. p. of 4-(dibenzylamino)-phenol.

TABLE V

EXPERIMENTAL DATA

Substance	M. p., °C.	Recrystallized from	Nitrogen, % Calcd.	Found
4-(Benzoyl-(isopropyl)-amino)-phenyl benzoate, $C_6H_5CON(C_3H_7)C_6H_4OCOC_6H_5$	174–175[a]	EtOH	3.90	3.97
4-(Dibenzylamino-phenyl) benzoate	143–144	Iso-PrOH	3.56	3.84 3.63

[a] Occurred in the form of white needles.

cc. of 1,4-dioxane was reduced. When reduction was complete the solution was evaporated to dryness. An oil remained which was dissolved in ether. The ethereal solution was shaken for some time with an aqueous solution of sodium bisulfite. The ethereal layer was then washed with a solution of sodium carbonate. The ether was then evaporated. An oil remained which solidified. The solid was twice recrystallized from 75% ethyl alcohol. Needle-like almost colorless crystals were obtained, m. p. 127°; yield 73%. A mixture of these crystals with 4-dibenzylaminophenol also melted at 127°.

Anal. Calcd. for $C_{20}H_{19}ON$: N, 4.85. Found: N, 5.07, 5.08.

A study of the condensation which takes place between ketones and aldehydes with *p*-nitroaniline and *p*-phenylenediamine during reduction has also been made and will shortly be submitted for publication.

The author wishes to express his appreciation to Mr. Douglass F. Hayman for many of the analyses which are recorded in this paper.

Summary

1. Catalytic reduction of a mixture of *p*-nitrophenol or *p*-nitrosophenol and an aliphatic ketone led to the formation of 4-(*sec.*-alkyl-amino)-phenols.

2. Various derivatives of 4-(*sec.*-alkyl-amino)-phenols have been prepared.

3. Catalytic reduction of 2,4-dinitrophenol and acetone led to the formation of 2-amino-4-isopropylamino-phenol.

4. There is no appreciable condensation between ketones and any of the following nitro compounds during catalytic reduction: nitrobenzene, #-nitrophenetole, o-nitrophenol, and m-nitrophenol.

5. There was no appreciable condensation between p-nitrophenol and either acetophenone or menthone during catalytic reduction.

6. 4-(Dibenzylamino)-phenol was prepared by the catalytic reduction of a mixture of benzaldehyde and p-nitrophenol, and also of a mixture of benzaldehyde and *p*-aminophenol.

THE ORGANIC ACIDS OF SPINACH, BROCCOLI AND LETTUCE[1]

BY E. K. NELSON AND H. H. MOTTERN

RECEIVED FEBRUARY 25, 1931 PUBLISHED MAY 6, 1931

The value of acids in food metabolism depends upon whether the acid is easily metabolized, as are citric and malic, or difficultly metabolized, as oxalic or benzoic, since by the oxidation of the organic acid radical the alkaline mineral is left in the system and helps to maintain a proper alkaline reserve.

Much work has been done to determine the organic acids of fruits, but little seems to be on record as to their presence in the common vegetables, no doubt for the reason that the acids in fruits are free or partly free, whereas in vegetables they are, for the most part, present as salts.

The examination of certain green vegetables for oxalic acid prompted an extension of the work to include identification of other organic acids present.

Arbenz[2] and Esbach[3] have reported the presence of considerable amounts of oxalic acid in spinach. Arbenz found 0.29% and Esbach 0.32% of oxalic acid in the fresh material.

A more recent investigation by Alice E. Ryder[4] appeared while the present investigation was in progress. In three samples of spinach Ryder found 0.486, 0.652 and 0.692% of oxalic acid.

Examination of Spinach

The spinach used for the present investigation was purchased on the Washington market early in February, 1930.

Oxalic acid was determined by the method of Arbenz.[2] Twenty grams of dry spinach was extracted with 150 cc. of 15% boiling hydrochloric acid, the mixture was filtered, and the filtrate was evaporated to dryness, dissolved in 20 cc. of water and extracted with ether in a perforation ouffit to complete extraction. The residue from the ether was dissolved in water, and ammonia was added until the solution was alkaline. It was then reacidified with acetic acid and precipitated hot with calcium chloride solution. The precipitate was redissolved in hydrochloric acid and reprecipitated as above until the crystals were pure calcium oxalate as determined by the microscope. The precipitate was ignited over the blast lamp and weighed as calcium oxide. By this method the dried spinach was found to contain 3.72% of anhydrous oxalic acid, equivalent to 0.31% on the basis of the fresh material (the spinach contained 8.3% dry matter).

For the separation of the other non-volatile acids of spinach, 500 g. of the dried spinach was extracted with boiling water, and the acids were precipitated from the extract with lead subacetate. The acids recovered from the lead precipitate were allowed to crystallize and filtered from the greater part of the oxalic acid. When esterified the sirupy filtrate afforded 6 g. of crude esters.

[1] Food Research Division Contribution No. 92.

[2] Arbenz, *Mitt. Lebensm. Hyg.*, **8,** 98 (1917).

[3] Esbach, *Bull. Gen. Ther. Med. Chir.,* 114,385 (1883).

[4] Ryder, *J. Home Econ.,* 22,309 (1930).

Two fractionations at 10 mm. yielded 0.7 g. boiling at 120°, 0.7 g. boiling at 120–140°, and 2.0 g. boiling at 140–160°. The lower fraction, on treatment with hydrazine hydrate, afforded an abundant precipitate of needles of oxalic acid hydrazide, melting at 235°. The intermediate fraction yielded l-malic hydrazide melting at 178–179°. The higher boiling fraction gave two hydrazides, one evidently l-malic hydrazide, crystallizing in nodules, and another crystallizing in clear rosets of prisms which melted at 107°, showing that it was citric hydrazide. It was further identified as citric hydrazide by optical crystallographic examination.[5]

Examination of Broccoli

The broccoli used, described as *Brassica Oleraceae,* var. Botrytis, or sprouting variety, was purchased on the Washington market. As no complete analysis of broccoli has been published, a thorough examination was made.

The buds, leaves and stems were examined separately. The methods of analysis used were those prescribed in "Methods of Analysis" of the A.O.A.C.

An investigation was also made of the organic acids of broccoli according to the ester distillation method.

The results of the analysis of broccoli are given in Table I.

TABLE I

ANALYSIS OF BROCCOLI, *Brassica Oleraceae*

	Buds		Leaves		Stems	
	Fresh, %	Dry, %	Fresh, %	Dry, %	Fresh, %	Dry %
Moisture	88.1		88.3		90.9	
Ether extract	0.74	6.19	0.84	7.17		
Crude fiber	1.42	11.91	1.11	9.45		
Protein	4.39	36.93	4.04	34.41		
Invert sugar		Trace				
Sucrose		None				
Starch	1.30	10.88				
Pentosans	0.91	7.61				
Ash	1.69	14.23	2.41	20.55		
Acid insol. ash	0.028	0.24	0.061	0.52		
P_2O_5	.17	1.39	.12	1.03		
CaO	.30	2.56	.38	3.27		
Ferric and aluminum oxides	.012	0.10	.026	0.22		
Mn_3O_4	.006	.051	.005	0.041		
MgO	.021	.18	.16	1.33		
K_2O	.30	2.51	.34	2.90		
Alkalinity of ash, cc. $N/10$ per 100 g.	93.4	785	144	1485		
Nitrates as KNO_3	0.09	0.76	0.12	1.05	0.25	2.74
Oxalic acid	0.02	0.16	0.02	0.15	0.01	0.11

Oxalic acid was determined by the method of Arbenz.[2]

For the investigation of the non-volatile acids twenty and one-half kilograms of broccoli was extracted with boiling water and the extract concentrated to two liters. After dilution with an equal volume of alcohol, the acids were precipitated with lead subacetate, and after being washed the lead salts were decomposed with sulfuric acid. After removal of the excess of sulfuric acid, the solution of organic acids was concentrated

---

[5] Optical examinations were made by G. L. Keenan of the Food, Drug and Insecticide Administration.

to small volume and thoroughly extracted with ether. The residue from the ether was partly crystalline and weighed slightly less than one gram. The crystalline acid, after recrystallization, did not have a sharp melting point, but succinic and oxalic acids were identified in it by optical crystallographic methods.

The acids unextracted by ether were esterified in the usual manner and afforded 26.5 g. of the ethyl esters of organic acids.

The mixed esters were fractionated three times at 10 mm. The following fractions were obtained

1	90–125°	0.9 g.	
2	125–135°	5.1 g.	α_D −10.5°
3	135–145°	0.4 g.	
4	145–155"	1.0 g.	
5	155–165°	1.6 g.	
6	165–170°	10.8 g.	

Residue and loss, 6.7 g.

The hydrazides of the acids were prepared from these fractions and purified. Fractions 1, 2, 3 and 4 yielded *l*-malic hydrazide, melting at 178–179°; fraction 5 was a mixture of ethyl malate and ethyl citrate; fraction 6 yielded citric hydrazide in its hydrated form melting at 104–106°.

The non-volatile acids of broccoli are therefore *l*-malic and citric acids with small amounts of oxalic and succinic acids.

Examination of Lettuce

Thirty-nine and seven-tenths kilos of lettuce, purchased on the Washington market, was dried. yielding 2630 g. of the dried vegetable.

Twenty grams examined by the Arbenz[2] method for oxalic acid yielded 0.164% of oxalic acid, equivalent to 0.01% on the basis of the undried lettuce.

Two and one-half kilos of the dried vegetable was extracted with boiling water and the extract was concentrated and mixed with an equal volume of alcohol. The lead salts were precipitated with lead subacetate, and the acids recovered from the lead precipitate were converted into the ethyl esters; 73.5 g. of crude ethyl esters was obtained. The ester mixture was fractionated three times at 10 mm. Fractions were obtained as follows

1	100–110°	1.0 g.	
2	127–135°	32.5 g.	α_D −10.6°
3	135–145°	0.9 g.	
4	145–155°	1.0 g.	
5	155–165°	1.3 g.	
6	165–170°	24.5 g.	

Residue 5.0 g.

The hydrazides were prepared from these fractions. Fraction 1 yielded *l*-malic hydrazide and a little levulinic hydrazide. Fraction 2 afforded *l*-malic hydrazide, melting at 178–179°, as did also fractions 3 and 4. Fraction 5 was a mixture. Fraction 6 yielded citric hydrazide, hydrated form, melting at 104–106° and identified by optical crystallographic examination.

The proper ester fractions, calculated to *l*-malic and citric acids, show that fresh lettuce contains approximately 0.065% of *l*-malic acid and 0.048% of citric acid.

Summary

Fresh spinach was found to contain 0.31% of oxalic acid. Citric acid and a small quantity of malic acid were separated by the ester distillation method.

Analysis of broccoli shows that the leaves and buds have materially the same composition and nutritive value. Both buds and leaves contain proteins somewhat in excess of that reported in spinach.[6]

The predominating organic acid in broccoli is citric acid. It also contains *l*-malic acid and small amounts of oxalic and succinic acids. The proportion of citric and malic acids is 3:2.

The organic acids of lettuce were found to be oxalic acid, 0.011%, *l*-malic acid, about 0.065%, and citric acid, about 0.048%.

MIXED BENZOINS. IV. DETERMINATION OF THE STRUCTURE OF MIXED BENZOINS BY THE BECKMANN REACTION[1]

BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED FEBRUARY 28, 1931 PUBLISHED MAY 6, 1931

The rigid determination of the structure of a number of mixed (unsymmetrically substituted) benzoins would allow important generalizations to be made as to the reactivity of various aromatic aldehydes, and would also contribute to the wider use of benzoins in synthetic work. Up to the present time a few mixed benzoins have been assigned structures, largely on the basis of their production (or the production of the isomer) by the Grignard reaction. Benzanisoin,[2a] benzfuroin[2b] and p-dimethylaminobenzoin[3] have been so determined. In addition, the structure of benzfuroin has been deduced by a Beckmann reaction,[4] that of p-dimethylaminobenzoin by an indirect method,[5] and that of benzanisoin by synthesis from the desoxy compound.[6] The structures of the three foregoing benzoins may therefore be taken as definitely settled, and the authors have taken these compounds as standards in this paper.

For determining the structure of mixed benzoins, the Grignard reaction, although probably trustworthy, is anything but convenient. Indirect

---

[1] Since submitting this paper, a note has appeared by Tiffeneau and Lévy, *Compt. rend.* 192, 287 (1931), in which the structures of some mixed benzoins are determined by fission with potassium hydroxide. The results with benzfuroin, benzpiperoin and benzanisoin agree with those of the present authors. Horbye, Ref. 11, has determined the structures of benzpiperoin and benzanisoin by an oxidation method.

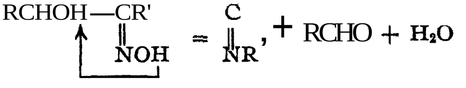
methods are of limited application. The authors therefore decided to examine further the reaction of Werner and Detscheff[4] in order to work out a more facile and general method, and found that, with some modifications in technique, the reaction leaves little to be desired from a practical point of view. Seven mixed benzoins (the same as were used in Part III)[7] were investigated, and structures assigned to them and to their oximes.

The Beckmann reaction, using benzenesulfone chloride, does not generally give an amide with benzoin oximes, but a mixture of an aldehyde and a nitrile or isonitrile. This is known as a Beckmann reaction of the second type and is formulated by Werner and Detscheff[4] as follows

$$\begin{array}{l} \mathrm{RCHOH{-}CR'} \\ \ \uparrow \qquad \| \\ \mathrm{HO{-}N} \end{array} = \mathrm{RCHO} + \begin{array}{c} \mathrm{CR'} \\ ||| \\ \mathrm{N} \end{array} + \mathrm{H_2O}$$

(1)



$$\begin{array}{l} \mathrm{RCHOH{-}CR'} \\ \ \uparrow \quad \| \\ \ \ \mathrm{NOH} \end{array} = \begin{array}{c} \mathrm{C} \\ \| \\ \mathrm{NR'} \end{array} + \mathrm{RCHO} + \mathrm{H_2O}$$

(2)

involving in the first case the elimination of water between the two adjacent hydroxyl groups and in the second case the wandering of a hydroxyl group and a radical, with the elimination of a molecule of water. The authors prefer to regard the reaction as taking place by the usual vicinal transposition of the first type, followed by the fission of the enol form of the amide. Oxime (1) would give the amide, RCHOHN=C(OH)R'(RCHOHNHCOR'), which, after the manner of the von Braun fission,[8] would (spontaneously) give RCHO and R'CN, as before. The alternative (improbable) fission between the N and C(OH) groups would give RCN and R'CHO, corresponding, on Werner and Detscheff's views, to the isomeric benzoin. If *trans* groups were concerned, then RCHO and R'N=C would be expected.

In the case of oxime (2) the normal product would be the amide RCHOH-C(OH)=NR' (RCHOHCONHR'), which might lose water between the two hydroxyl groups, giving RCHO and R'N=C.[9] If *trans* groups were involved, RCHO and R'CN (corresponding to oxime (1)) would be formed. Fission between the C(OH) and N groups would give products never observed in this type of reaction.

The conception of the Beckmann reaction involving the transposition of vicinal groups has been attacked by several workers, notably by Meisen-

---

[7] Buck and Ide, THIS JOURNAL, 53, 1536 (1931).

[8] Von Braun and Müller, *Ber.*, 39, 2018 (1906), where, for example, benzylbenzamide, with phosphorus pentabromide gives benzyl bromide and benzonitrile.

[9] In this connection the authors have found that mandelic anilide with phosphorus pentachloride gives phenylisonitrile. Werner and Piguet, *Ber.*, 37, 4309 (1904), have obtained mandelic anilide from β-benzoin oxime (*syn*-phenyl) by using benzenesulfone chloride with pyridine. The same oxime, using alkali in place of pyridine, gives benzaldehyde and phenylisonitrile.

heimer (who, however, worked chiefly on benzil oximes). The matter cannot be regarded as settled, and the present authors prefer to interpret their results on the basis of vicinal transposition, or on Werner and Detscheff's theory, both giving the same structure. The reason for so doing is the complete agreement of the structures so deduced with those found by other methods in the three cases cited above.

It will be seen that the aldehyde formed determines the structure of the parent benzoin, while the formation of a nitrile or of an isonitrile discriminates between the two oximes, the *syn*-phenyl oxime giving the isonitrile and the *anti*-phenyl oxime the nitrile. For practical purposes only the aldehyde need be isolated to determine the position of the carbonyl group in the benzoin. Either oxime, or indeed a mixture of the two, could be used for this purpose.

The benzoins examined in the present paper, together with the desoxy compounds derived from them (as main product) by reduction, are listed below (letters as in Part III, Ref. 7).

$ClC_6H_4CHOHCOC_6H_3(OMe)_2$	A	$ClC_6H_4CH_2COC_6H_3(OMe)_2$
$ClC_6H_4CHOHCOC_6H_4OMe$	B	$ClC_6H_4CH_2COC_6H_4OMe$
$ClC_6H_4CHOHCOC_6H_4NMe_2$	C	$ClC_6H_4CH_2COC_6H_4NMe_2$
$ClC_6H_4CHOHCOC_6H_3O_2CH_2$	D	$ClC_6H_4CH_2COC_6H_3O_2CH_2$
$C_6H_5CHOHCOC_6H_4OMe$	E	$C_6H_5COCH_2C_6H_4OMe$
$C_6H_5CHOHCOC_6H_3O_2CH_2$	G	$C_6H_5CH_2COC_6H_3O_2CH_2$
$C_6H_5CHOHCOC_6H_4NMe_2$	H	$C_6H_5CH_2COC_6H_4NMe_2$

In the majority of cases the desoxy compound is formed by the replacement of the CHOH group by CH_2. The case of benzoin E shows that the reduction is not simple and that the hydrobenzoin or the isohydrobenzoin is involved[10] and that it is not permissible to infer the structure of the benzoin from that of the desoxy compound produced by reduction.

It will be seen that, so far as they go, the results obtained support Hörbye's[11] view that the CHOH group takes the position adjacent to the unsubstituted phenyl group. To this group may now be added the o-chlorophenyl group. The results are at variance with some of Staudinger's[12] views but support the contentions of Jenkins.[3,5]

Experimental

Oximes.—Three general methods were used to prepare the oximes of the mixed benzoins. (1) The benzoin was allowed to stand in alcoholic solution at room temperature with hydroxylamine acetate and the product precipitated by gradual addition of water. (2) The benzoin was warmed on the bath with hydroxylamine and excess of sodium hydroxide, all in alcoholic solution, usually for three hours. The oxime was precipi-

---

[10] Orékhoff and Tiffeneau, *Bull soc. chim.*, [4] 37, 1410 (1925).

[12] Staudinger, *Ber.*, 46, 3530, 3535 (1913).

tated by carbon dioxide. This method is useful when the benzoin is sparingly soluble in alcohol. (3) The benzoin, in pyridine solution, was warmed on the bath for three hours with hydroxylamine hydrochloride and the reaction mixture then gradually diluted with water.

The method was selected by trial, yield being the consideration. In no case was more than one oxime isolated, although the isomer was carefully sought for. When the yield was mediocre, the remainder of the material was recovered as a thick gum, probably containing unchanged starting material and decomposition products as well as the isomeric oxime. It is quite possible that the isomer could be obtained by other methods. All of the oximes obtained were of the a-(anti-phenyl) form, except that from p-dimethylaminobenzoin, which was the β-isomer. The oximes were recrystallized from alcohol, in which they are moderately soluble, until pure. As a rule, they are sparingly soluble in other solvents, except pyridine. The compounds are tabulated below.

TABLE I

OXIMES

Benzoin	No. in Pt. III	Form	No. of prep.	Yield. %	M. p., °C.	Appearance	Formula	Nitrogen analyses Calcd.	Nitrogen analyses Found	Structure of benzoin (*v. s.*)	No. of oxime

[a] Form obscure.

Beckmann Reaction.—The Beckmann reaction was carried out in alkaline (sodium hydroxide) solution, using benzenesulfone chloride as the transforming agent. The chloride was added in portions to the alkali–oxime mixture, the whole being shaken vigorously and care being taken that the mixture remained alkaline. The temperature was not allowed to rise more than a few degrees. The reaction mixture was shaken until the chloride had disappeared, then cooled and the oily layer exhaustively extracted with ether, the extract dried over sodium sulfate and the ether driven off. The oil remaining was fractionated under low pressure, using a fine capillary. When benzaldehyde was present, this was removed at 10-mm. pressure, and the pressure then lowered to 0.5–1.0 mm. and the second product distilled off. This usually solidified in the receiver. In other cases (*o*-chlorobenzaldehyde) the oil was all fractionated at 0.5–1.0 mm. The fractions, which, however, were usually sharply separated, were redistilled if necessary under reduced pressure. Benzaldehyde was identified by its properties and by its conversion into benzoin (mixed melting point determinations). o-Chlorobenzaldehyde, after purification via the bisulfite compound, was identified by its properties and by mixed melting point determinations of its oxime with 2-chlorobenz-anti-aldoxime. The nitriles were identified by mixed melting point determinations with the authentic nitrile when this was available, but they were always hydrolyzed, by the Radziscewski[13] method, to the amide and identified by properties and by mixed melting point determinations with the authentic amide.

It is doubtful whether an isonitrile odor (cf. Ref. 4) is of much significance. Its presence in the case of oximes D and E must be ascribed to a side reaction or (unlikely) to a trace of the other oxime. In the case of oxime H the odor was intense, but it was not possible to isolate the isonitrile. Werner and Detscheff[4] encountered the same difficulty. The absence of any nitrile (obtained without difficulty from oxime C) is evidence for the-formation of the isonitrile. This observation also answers the possible objection that the nitriles might be formed from the isonitriles by distillation, although this is unlikely at the temperatures to which

[13] Technique of Rupe and Majewski, Ber., 33,3401 (1900), using somewhat stronger peroxide.

they were exposed (the nitriles distil at about 120° below 1.0 mm.). In the case of oximes A, D and H much black, amorphous matter was formed in the reaction. Some of this was separated from the ether extract; the rest appeared as residue in the distilling vessel. The residue is not formed by decomposition during distillation, as can be seen by the small residues from oximes B and G. The results are given in tabular form.

Summary

The structures of seven mixed benzoins, obtained by the usual potassium cyanide condensation, have been determined by means of a second-type Beckmann reaction. The results, interpreted according to Werner's views of the Beckmann rearrangement, give structures in agreement with those determined by independent methods.

CROTYL ETHERS OF PHENOL

BY CHARLES D. HURD AND FRANK L. COHEN

RECEIVED FEBRUARY 28, 1931 PUBLISHED MAY 6, 1931

When allyl aryl ethers are heated, rearrangement into o-allylphenols usually occurs with ease. The same has been shown to be true in some cases when substituted allyl aryl ethers undergo pyrolysis. Only the following groups seem to have received study in this connection: (1) crotyl, $CH_3CH=CHCH_2-$, with phenol,[1,2] β-naphthol,[2] and hydroxynaphthoquinone;[3] *(2)* cinnamyl, $C_6H_5CH=CHCH_2-$, with phenol;[4] **(3)** a-methylcrotyl, $CH_3CH=CH-CH(CH_3)-$, with phenol;[5] (4) γ-methylcrotyl, $(CH_3)_2C=CHCH_2-$, with phenol;[6] (5) α,α-dimethylallyl, $CH_2=CH-C(CH_3)_2-$, with phenol;[7] (6) geranyl, $CH_2=C(CH_3)-(CH_2)_3-C(CH_3)=CHCH_2-$, with catechol.[8]

The first four groups undergo rearrangement of the type exemplified in the equation

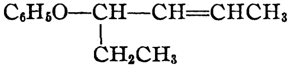
With $C_6H_5—O—C(CH_3)_2CH{=}CH_2$, however, the pyrolysis leads to isoprene and phenol.

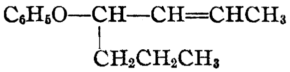
In the case of a-methylcrotyl phenyl ether, we corroborated the results of Claisen[4] in all essential details. To extend this study, the following substituted allyl ethers of phenol were investigated

a-Ethylcrotyl phenyl ether



$$C_6H_5O—\underset{\displaystyle CH_2CH_3}{\underset{|}{C}H}—CH{=}CHCH_3$$

α-*n*-Propylcrotyl phenyl ether



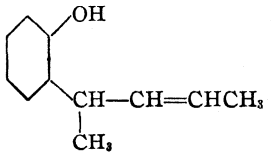
$$C_6H_5O—\underset{\displaystyle CH_2CH_2CH_3}{\underset{|}{C}H}—CH{=}CHCH_3$$

α,α,γ-Trimethylcrotyl phenyl ether, $C_6H_5O—C(CH_3)_2CH{=}C(CH_3)_2$

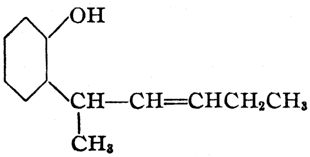
a-n-Propylallyl phenyl ether, $C_6H_5O—CH(C_3H_7(n))—CH{=}CH_2$, was also synthesized and studied. This will be reported in a later paper.

Synthesis of these ethers was effected by refluxing phenol, potassium carbonate and the corresponding crotyl chloride in an ether–acetone solution for several hours. The a-ethyl- and a-propylcrotyl ethers could be purified by vacuum distillation but the trimethylcrotyl ether underwent pyrolysis with such treatment. All of these ethers were liquids.

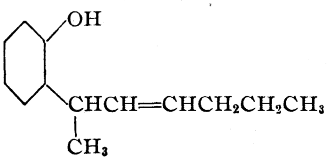
Pyrolysis.—Normal rearrangements of a-methyl-, a-ethyl- and α-*n*-propylcrotyl phenyl ethers occurred when they were heated. A temperature of 200° sufficed for the first two, and with the third an exothermic reaction was noticed at 228°. The products formed in the three cases, respectively, were o-a-methylcrotylphenol (I), *o*-α,δ-dimethylcrotylphenol (11), and o-a-methyl-6-ethylcrotylphenol (III). The yields in the three cases were **83,** 75 and **52%.** All of these phenols were very viscous oils and were alkali-soluble.



I



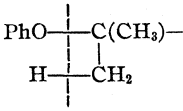
II



III

For a similar type of rearrangement, trimethylcrotyl phenyl ether should have given rise to *o*-α,α,γ-trimethylcrotylphenol,  but none was found. Instead, the reaction followed an entirely different course, yielding phenol, 2,4-dimethylpentadiene-1,3 and tar. The yield of the diene was about 33%.

The course of pyrolysis of these crotyl ethers is sufficiently analogous to the course of pyrolysis of similar allyl and propargyl ethers which have already been studied that two generalizations may be made. (1) Rearrangement into an ortho or para substituted phenol is the chief effect in the heating of allyl or crotyl aryl ethers, and the same holds if the allyl or crotyl groups contain one alpha substituent. Thus, compounds of the types $Ar—O—CH_2CH{=}CH_2$, $Ar—O—CH_2CH{=}CHR$, $Ar—O—CHRCH{=}CH_2$ and $Ar—O—CHRCH{=}CHR$ may be expected to rearrange if there is an available o- or *p*-position in the aromatic nucleus. (2) When α,α-disubstituted allyl, crotyl or propargyl aryl ethers are heated, they undergo scission into a phenol and a hydrocarbon. These ethers of phenol have been studied: α,α-dimethylallyl,[7] trimethylcrotyl (this paper), and trimethylpropargyl.[9] All of these contain the grouping $Ph—O—C(CH_3)_2—z$ and all pyrolyze into $PhOH + CH_2{=}C(CH_3)—z$. It might be argued that the reason for hydrocarbon formation in these cases is the presence of the hydrogens on the a-methyl substituent, thereby making it easy for the phenol to be detached, thus



$$\begin{array}{l} PhO\,\vdots\,C(CH_3)—z \\ \quad\ \ \vdots\quad | \\ H\,\vdots\,CH_2 \end{array}$$

However, the alpha monosubstituted allyl and crotyl ethers with a similar structure fail to give this scission into phenol and hydrocarbon. Furthermore, triphenylpropargyl phenyl ether,[9] with no structure of the  $\begin{array}{l} PhO—C{=} \\ \quad\ \ | \\ H—C{=} \end{array}$ type, also yields phenol and a hydrocarbon on pyrolysis.

The rearrangement of aryl crotyl ethers is a special case of the "three-carbon system": $xCH_2—CH{=}CHR \longrightarrow CH_2{=}CH—CHxR$. Undoubtedly the mechanisms of both[10] are similar. In turn, the three-carbon system is but a special case of the general formulation: $xE—E{=}E' \longrightarrow E{=}E—E'x$, wherein E represents any element such as C, N, O or S. The union between E and x is a loose one. Applied to the phenyl crotyl ethers, the products of the reaction seem to be most readily explained by assuming an initial scission at the position of weakness, $PhO\,\vdots\,\text{crotyl}$, into radicals which immediately readjust themselves. With a primary or secondary crotyl radical, the PhO— radical rearranges to  before attaching

---

[9] Hurd and Cohen, THIS JOURNAL, 53, 1068 (1931).

[10] For a survey of the three-carbon system, see "Annual Reports on the Progress of Chemistry," 25, 119–130 (1929).

itself to the y-crotyl carbon. If the crotyl group is tertiary, the PhO- radical selects a hydrogen from the crotyl radical, giving phenol and a hydrocarbon.

The triphenylmethyl alkyl ethers[11] resemble the crotyl (or allyl) aryl ethers in being far less stable than most other ethers. With them, heat induces a rupture of the carbon-to-oxygen bond on the side of the radical with low electron attraction, namely, the triphenylmethyl radical. Evidence for this is the isolation of triphenylmethane and an aldehyde (or ketone) as pyrolytic products. Undoubtedly, the initial effect of heat with both series of ethers (Ar—O—crotyl and R—O—CPh_3) is very similar, if not identical.

Experimental Part

The β-unsaturated alcohols were synthesized by literature methods. Pentene-3-ol-2,[12] hexene-2-ol-4[13] and heptene-2-ol-4 were prepared by the interaction of crotonaldehyde in the cold with a Grignard reagent (Me-, Et- and n-Pr-MgBr, respectively). The yields of the three alcohols were 47, 60 and 68%. 2,4-Dimethylpentene-3-ol-2 was prepared in 30% yield[14] from mesityl oxide and methylmagnesium iodide. Simultaneously, a 57% yield of 2,4-dimethylpentadiene-1,3 was realized.

Chlorides from the Alcohols.—2-Chloropentene-3 was synthesized[15] by interaction of the alcohol (in absolute ether) with phosphorus trichloride. The reaction was left for three days at room temperature, whereupon a 37% yield was realized. In the preparation[13,16] of 4-chlorohexene-2 and 4-chloroheptene-2, phosphorus pentachloride was used instead of the trichloride. The yields were 54 and 73%, respectively.

Trimethylcrotyl chloride (2,4-dimethyl-2-chloropentene-3) was too unstable for purification by distillation. It was prepared in solution as follows. To 5.0 g. of 2,4-dimethylbutene-3-ol-2 dissolved in 25 cc. of dry ether was added 2.0 g. of phosphorus trichloride. The reaction mixture was kept at ice temperature for an hour and then it was left for two days at room temperature. The ether solution was decanted from the phosphorus acid layer, after which it was washed with water and dried over sodium sulfate. This solution of trimethylcrotyl chloride was used in subsequent reactions with no further purification, since all attempts to distil it gave almost quantitative yields of 2,4-dimethylpentadiene-1,3.

Synthesis of the Phenyl Ethers

a-Methylcrotyl phenyl ether was prepared by Claisen's method.[5] Our yield of the ether from 2-chloropentene-3 was only 30% instead of 40%, and our boiling point at 12 mm. was 103–104° instead of 96–98°. A weight of tarry material was formed which was equal to the weight of the desired ether.

a-Ethylcrotyl Phenyl Ether.—To a solution of 10 g. of 4-chlorohexene-2 (0.08 mole) in 100 cc. of dry ether was added 10 g. of anhydrous potassium carbonate, 40 cc. of pure

[16] Reif, Ref. 15. p. 2742.

acetone and 7.6 g. of phenol (0.09 mole). The reaction mixture was refluxed vigorously for eleven hours. Water was then added to dissolve the salts and to remove some of the acetone and excess phenol. The ether solution was washed with dilute alkali until it was free from phenol. After drying over calcium chloride, the solution was distilled at reduced pressure. Four grams of the unreacted chloride, b. p. 50–53° at 15 mm., 4.2 g. of a-ethylcrotyl phenyl ether, b. p. 116–118° at 15 mm., and 1.8 g. of *o*-α,δ-dimethylcrotylphenol, b. p. 140–143° at 15 mm., were obtained. The 4.2 g. yield of the ether is a 30% yield.

Anal. Subs., 0.1512, 0.1413: CO_2, 0.4525, 0.4216; H_2O, 0.1240, 0.1157. Calcd. for $C_{12}H_{16}O$: C, 81.75; H, 9.15. Found: C, 81.4, 81.5; H, 9.11, 9.10.

a-n-Propylcrotyl Phenyl Ether.—A mixture of 20 g. of 4-chloroheptene-2 (0.14 mole), 40 cc. of pure acetone, 26 g. of potassium carbonate (0.2 mole), 100 cc. of dry ether and 16.8 g. of phenol (0.2 mole) was placed in a liter round-bottomed flask and refluxed vigorously for six hours. Water was then added, the ether layer separated and washed with small portions of normal alkali, dried over calcium chloride and fractionated. Propylcrotyl phenyl ether, b. p. 153–154° at 23 mm., was obtained as a colorless viscid oil, which almost immediately turned to a dark red on cooling. The tarry residue decomposed on further heating. The yield was 17.4 g., or 65%.

Anal. Subs.. 0.1408: CO_2, 0.4219; H_2O, 0.1197. Calcd. for $C_{13}H_{18}O$: C, 82.04; H, 9.54. Found: C, 81.8; H, 9.44.

α,α,γ-Trimethylcrotyl Phenyl Ether.—To the ether solution which contained the trimethylcrotyl chloride (see above) was added 25 cc. of acetone, 5.0 g. of potassium carbonate and 3.7 g. of phenol. This was refluxed for several hours and 50 cc. of ether was added. The ether solution was then washed with dilute sodium hydroxide and water, dried over sodium sulfate and carefully distilled. After removing the ether and the 2,4-dimethylpentadiene-1,3 which was formed simultaneously, an almost colorless but quite viscous oil remained. Its index of refraction n_D^{20} was 1.3047. The oil did not distil at 150" and 1.5 mm., whereas above 150" decomposition ensued.

Mol. wt. Subs., 0.2114; benzene, 21.96 g.; freezing point lowering, 0.240°. Calcd. for $C_{13}H_{18}O$: mol. wt., 190.1. Found: 189.0.

Pyrolysis of the Ethers

From 2 to 10 g. of the ether specimens was placed in a side-arm test-tube or in a small distilling flask which was connected with a small condenser. In turn, this was attached to a receiver which was immersed in an ice–salt bath. A thermometer was extended into the ether, and the reaction tube was heated by immersion in an oil-bath.

With a-methylcrotyl phenyl ether, a temperature of 200° was maintained for one hour. The pyrolytic mixture was then cooled, dissolved in ether and the alkali-soluble material washed out with 5% sodium hydroxide. The alkali-soluble material was then obtained fairly pure by acidifying the alkaline solution. The yellowish oil which resulted was ether-extracted, dried and distilled. o-a-Methylcrotylphenol was a colorless, viscous oil with a strong phenolic odor. The boiling point of 120–121" at 11 mm. corresponded to that given by Claisen.[5] The yield from 4 g. was 3.3 g., which is 83% of the theoretical.

α-Ethylcrotyl Phenyl Ether.—Four grams of this ether was heated slowly until the temperature was 200–205°. At this point the ether darkened appreciably and seemed to reflux slightly. No volatile material was evolved. The temperature was maintained for thirty minutes without any further apparent change. After cooling, the reaction product was dissolved in 50 cc. of ether and washed with dilute alkali. The alkaline solution was acidified and a red oil separated. The reaction product was then ex-

tracted with more alkali until no more alkali-soluble material remained. Four extractions with **10-cc.** portions of normal sodium hydroxide solution were **sufficient.** The alkali-soluble material, which was obtained as an oil when acid was added, was extracted with ether, dried, and the solution distilled.

o-α,δ-Dimethylcrotylphenol was obtained as a red oil. At **15 mm.** it boiled at **143–145°.** The **yield** was **3.1** g., or 75%.

Anal. Subs., **0.1030, 0.1650: CO_2, 0.3090, 0.4958; H_2O, 0.0843, 0.1343. Calcd.** for $C_{12}H_{16}O$: C, **81.75;** H, **9.10.** Found: C, 81.9, 81.8; H, 9.10, 8.98.

α-*n*-Propylcrotyl Phenyl Ether.—A **9.5-g.** sample of this ether was pyrolyzed. At **228–230°** rearrangement occurred exothermically. No volatile distillate was observed. After continued heating for one-half hour, the pyrolyzed mixture was fractionally distilled and 5.2 g. of alkali-soluble material, b. p. 154–155° at 14 mm., was obtained. Also, **2.1** g. of unchanged ether, b. p. 143–145° at **14** mm., was recovered. The pyrolyzed material, α-methyl-δ-ethylcrotylphenol, $HO—C_6H_4—CH(CH_3)—CH{=}CHCH_2CH_2CH_3$ was completely alkali-soluble. It was light yellow in color and very viscous. The yield was 54% of the theoretical value.

Anal. Subs., **0.1614, 0.1531: CO_2, 0.4853, 0.4595; H_2O, 0.1375, 0.1309.** Calcd. for $C_{13}H_{18}O$: C, **82.04;** H, **9.54.** Found: C, 82.0, 81.9; H, **9.46, 9.49.**

α,α,γ-Trimethylcrotyl Phenyl Ether.—Two grams of **α,α,γ-trimethylcrotyl** phenyl ether was heated at such a rate that the difference in temperature between the bath and the ether did not exceed 5°. At 150° the ether showed an appreciable darkening. At **160–170°** there was an evolution of vapor which was condensed and collected in a small receiving flask. The material in the test-tube reaction flask rapidly became darker. The temperature of **160–170°** was maintained for half an hour until evolution of the volatile material ceased. The residual material in the reaction tube was a thick black tar after it had cooled.

The volatile distillate was shown to be 2,4-dimethylpentadiene-1,3.[17] Its boiling point was **92–93'.** The yield of this material was **0.3 g.,** or **33%** of the theoretical. The tarry residue was extracted with small portions of normal alkali, the **alkaline** extract acidified and treated with bromine water until no more bromine was absorbed. Half a gram of **tribromophenol** was obtained, which corresponded to **0.2** g. of phenol. No other alkali-soluble material was isolated.

Summary

The following ethers of phenol have been synthesized and studied: **α-methylcrotyl,** a-ethylcrotyl, a-n-propylcrotyl and a,a,y-trimethylcrotyl. The first three of these ethers rearranged into phenolic isomers on heating, namely, into o-a-methylcrotylphenol, *o*-α,δ-dimethylcrotylphenol, and o-ar-methyl-6-ethylcrotylphenol. The trimethylcrotyl ether was less stable than the others and it pyrolyzed into phenol and 2,4-dimethylpentadiene-1,3.

It was pointed out that the substituted **allyl aryl** ethers with the grouping $Ar—O—CH_2—C{=}C$ or $Ar—O—CHR—C{=}C$ may be expected to rearrange on heating, whereas with a grouping such as $Ar—O—CR_2—C{=}C$ pyrolysis leads to phenol (ArOH) and a hydrocarbon.

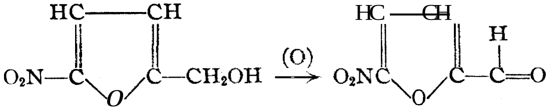
NITROFURFURYL ALCOHOL

BY HENRY GILMAN AND GEORGE F. WRIGHT

RECEIVED MARCH 2, 1931 PUBLISHED MAY 6, 1931

Introduction

In continuation of studies on direct substitutions of the furan nucleus, a first nitrofurfuryl alcohol has been prepared. The synthesis has been effected by the nitration of furfuryl acetate, followed by hydrolysis of the nitro ester to the nitro alcohol. The nitrofurfuryl alcohol can be oxidized to the recently prepared nitrofurfural.[1]



The nitro group in nitrofurfural has been placed provisionally[2] in the 5 position. It is highly significant that the aldehydic group and the alcoholic (acetate) group orient to the same position. Very probably the mode of substitution in both cases is that described earlier, namely, a 1,4-addition to a conjugated system.[3] Again,' the nitro group has a marked stabilizing effect on the furan nucleus.

Experimental Part

Nitration of **Furfuryl** Acetate.—To 286 g. of acetic anhydride, kept at a temperature below −5" is added dropwise 87.4 g. (1.38 moles) of fuming nitric acid (sp. gr. 1.61). Then 70 g. (0.5 mole) of furfuryl acetate[4] dissolved in 102 g. of acetic anhydride is added, with stirring and at −20°, to the nitrating mixture.[5] When addition is complete the reaction is stirred for one hour at −20°, and then poured upon cracked ice. Sodium hydroxide solution, together with ice to maintain the low temperature, is added with vigorous stirring until the solution is exactly neutral. The oil which separates is drawn off and the solution extracted once with about 700 cc. of ether. The combined oil and ether extract is treated with about 200 cc. of pyridine; after a few hours the ether is evaporated, and the residue diluted with water and chilled. Thereupon, the oil which separates becomes solid, and gives 55 g., a 59.5% yield, of nitrofurfuryl acetate melting at 40°. Crystallization from an alcohol–water solution gives pure white crystals melting at 47°.

[2] The definite position of this and other substituents is being determined by a miscellany of methods including an absolute method of orientation, concerning which reference might be made to a recent study by Gilman and Wright, ***Iowa State College J. of Sci.***, 5, 85 (1931).

[3] Gilman and Wright, THIS JOURNAL, 52,3349 (1930).

[4] Prepared in accordance with the procedure described in "Organic Syntheses," 1927, Vol. VII, p. 44.

[5] The temperature was maintained by chilling with a solid carbon dioxide–furfural mixture.

The direct nitration of the so-called water-insoluble form of furfuryl alcohol proceeds smoothly, but decomposition sets in on subsequent treatment with pyridine.[1] Apparently nitrofurfuryl nitrate is among the products which are being investigated.

Hydrolysis of Nitrofurfuryl Acetate.—Eighteen and one-half g. (0.1 mole) of nitrofurfuryl acetate is refluxed for twenty minutes with 200 cc. of 5% sulfuric acid. The solution is chilled and filtered by suction to remove 0.2 g. of an as yet unidentified compound[6] melting at 73°. The filtrate is extracted thrice with 50-cc. portions of ether and the combined ether extracts are dried over sodium sulfate. The residue, after removal of the ether, is distilled under reduced pressure (157°, 8 mm.), to give a yellow oil which solidified overnight to the nitrofurfuryl alcohol melting at 32°. The yield is 9–10 g. or 49–55%.

Anal. Calcd. for $C_5H_5O_4N$: C, 41.95; H, 3.52. Found: C, 41.96; H, 3.76.

Oxidation of Nitrofurfuryl Alcohol.—The nitrofurfuryl alcohol was oxidized by heating for two days at 40–50° with a mixture of manganese dioxide and 50% sulfuric acid. The ether extract from this oxidation gave nitrofurfural melting at 36°. This showed no depression in a mixed melting point determination with an authentic specimen.'

The authors are grateful to R. R. Burtner for assistance in this study. He has shown that furfuryl chloride and furfuryl methyl ether also undergo ready substitution, the chloromethyl and alkoxymethyl groups orienting like the acetate group.

Summary

The first nitrofurfuryl alcohol has been prepared by the hydrolysis of nitrofurfuryl acetate, which was obtained by the direct nitration of furfuryl acetate. The nitro group markedly stabilizes the furan nucleus.

THE IDENTIFICATION OF PHENOLS AS THE ESTERS OF 3,5-DINITROBENZOIC ACID

BY MAX PHILLIPS AND GEORGE L. KEENAN

RECEIVED MARCH 4, 1931 PUBLISHED MAY 6, 1931

In connection with an investigation on the chemistry of lignin which one of the authors has been conducting, an occasion arose requiring the identification of the phenols produced when lignin is subjected to destructive distillation or is distilled with zinc dust in an atmosphere of hydrogen. Attempts were made to prepare the usual derivatives of phenols such as the benzoyl derivatives, the phenyl, diphenyl and α-naphthyl urethans, and the *p*-nitrobenzyl ethers, but all these were found to be liquid at room temperature and therefore unsuitable for the purpose of identification. It was found, however, that 3,5-dinitrobenzoyl chloride condensed with the phenols under investigation and yielded products which could be

---

[6] The same compound has been isolated in small quantities from the direct nitration of water-insoluble furfuryl alcohol in acetic anhydride.

readily purified by crystallization. The 3,5-dinitrobenzoyl chloride was first used as a reagent for the identification of alcohols[1] and has been applied by Brown and Kremers[2] to the identification of phenols. The method prescribed by these investigators is; however, difficult to carry out, particularly when only a small quantity of a phenolic substance is available.

In this paper a new and simple method for the preparation of the 3,5-dinitrobenzoyl derivatives of phenols is described. Some of the more important physical properties of these derivatives, including the data on the optical properties of the crystals, are recorded.

Experimental

Materials Used.—The 3,5-dinitrobenzoyl chloride used in all our experiments was obtained from the Eastman Kodak Company.

Phenols.—All the phenols except those listed below were obtained from the Eastman Kodak Company.

Phenol.—This was the regular U. S. P. product

5-Hydroxy-1,3-dimethylbenzene.—This was prepared through the diazo reaction from 5-amino-1,3-dimethylbenzene.

Thymol.—This was the U S. P. product.

Isoeugenol.—This was a Kahlbaum product.

Creosol (**1-Methyl-3-methoxy-4-hydroxybenzene**).—The creosol was synthesized from vanillin by the application of the Clemensen[3] reduction method. The procedure was briefly as follows. To 20 g. of vanillin and 400 cc. of hydrochloric acid (200 cc. of hydrochloric acid *d* 1.19 and 200 cc. of water), 100 grams of amalgamated zinc was added, and the mixture was boiled under a reflux condenser for eight hours. The reaction product was allowed to cool to room temperature, and extracted with ether. The ether solution was extracted with a solution of sodium bisulfite, dried over anhydrous sodium sulfate, and the ether distilled off. The residue was fractionally distilled, and the fraction which distilled over at 219–221° was retained; yield, 5 g. (27.6%). A methoxyl determination gave the following results.

Anal. Subs., 0.1254: AgI, 0.2111. Calcd. for $C_8H_{10}O_2$: CH_3O, 22.46. Found: CH_3O, 22.23.

1-*n*-Propyl-3-methoxy-4-hydroxybenzene.—This was prepared by the catalytic reduction of eugenol. The procedure was as follows. One-tenth of a mole of eugenol (16.4 g.) was dissolved in 150 cc. of 95% ethanol, 0.2 g. of platinum catalyst was added (prepared according to the directions given by Adams, Voorhees and Shriner)[4] and the mixture was shaken in a shaking machine in an atmosphere of hydrogen until the calculated amount of hydrogen was absorbed. The platinum was filtered off and the filtrate distilled. At first alcohol came over, then the temperature rose rapidly and an oil distilled over at 250–255°. This was redistilled, and the main portion came over at 251–253° (corrected for stem exposure) (765.8 mm.); yield, 12 g. (72.2%).

Anal. Subs., 0.1552: AgI, 0.2170. Calcd. for $C_{10}H_{14}O_2$: CH_3O, 18.67. Found: CH_3O, 18.47.

Preparation of the 3,5-Dinitrobenzoyl Esters of the Phenols.--4.01 mole of the phenol and 2.3 g. (0.01 mole) of 3,5-dinitrobenzoyl chloride were added to 20 cc. of c. p. pyridine, and the mixture was heated over a free flame under the reflux condenser for one hour. The reaction product was cooled and poured into about 400 cc. of cold 5% sulfuric acid. If the crude reaction product separated as a solid, it was filtered off and washed with water until the wash water was acid free. The product was added to 200 cc. of 2% sodium hydroxide solution, the mixture was well stirred, filtered, washed with water, and then crystallized. When the reaction product separated out as an oil or as a gummy mass, it was dissolved in ether and the ether solution washed successively with water, 2% sodium hydroxide, and finally with water. The ether was distilled off and the residue crystallized. In all cases except one the reaction products were crystallized from 95% ethanol. The 3,5-dinitrobenzoyl derivative of isoeugenol was crystallized from n-butyl alcohol.

Melting Point Determinations.—The melting points were determined in a Roth[5] type of apparatus with Anschiitz thermometers which had been standardized by the Bureau of Standards.

Nitrogen Determinations.—The nitrogen was determined by the Kjeldahl method, modified for the determination of nitrogen in nitro compounds. The modified Pamas–Wagner micro Kjeldahl apparatus[6] was used. Approximately twenty milligrams of substance were taken for each determination.

The results of the melting point and nitrogen determinations are given in Table I.

Optical Properties of the Crystals.—The optical properties of the crystals were determined by the immersion method[7] which has been used successfully by one of the authors in the identification of several types of organic compounds.[8] The 3,5-dinitrobenzoyl derivatives of the phenols were most satisfactorily studied in solutions of potassium mercuric iodide in glycerol and water, although for rapid determinative work, oily liquids consisting of mixtures of mineral oils, monochloronaphthalene and methylene iodide can be used.

The results obtained are given in Table II. Because of the peculiar cleavage properties of the 3,5-dinitrobenzoyl derivatives of eugenol and isoeugenol the optical properties of the crystals could not be determined with any degree of accuracy and therefore are not included in the table.

Summary

1. A method for the preparation of the 3,5-dinitrobenzoyl derivatives of phenols is described. This method can be conveniently used for the identification of phenols.
2. The melting points and the optical properties of the crystals of the 3,5-dinitrobenzoyl derivatives of several phenols were determined.
3. Methods for the preparation of creosol and of 1-n-propyl-3-methoxy-4-hydroxybenzene are given.

THE REARRANGEMENT OF SATURATED ALKYL PHENYL ETHERS. SYNTHESIS OF ISOPROPYL PHENOL AND CRESOLS[1]

BY JOSEPH B. NIEDERL AND SAMUEL NATELSON

RECEIVED MARCH 5, 1931 PUBLISHED MAY 6, 1931

Theoretical Part

In an earlier publication[2] a report was given on the condensation of olefins with phenols under the influence of concentrated sulfuric acid in the cold. The results obtained differed from those already reported in the literature, ethers being obtained and not the corresponding substituted phenols. It was suggested that the condensation process used by the other authors brought about rearrangement of the ethers first formed.

[1] Constructed from the second half of the thesis presented by Samuel Natelson to the Faculty of the Graduate School of New York University in candidacy for the degree of Doctor of Philosophy, 1931. Presented at the Indianapolis meeting of the American Chemical Society, April 3, 1931.

[2] Niederl and Natelson, THIS JOURNAL, **53,** 272 (1931).

Koenigs,[3] and Schrauth and Quasebarth[4] used a mixture of sulfuric and acetic acids as condensing agents and obtained the corresponding substituted phenols on warming. This condensation process is close to the one employed by the authors, concentrated sulfuric acid in the cold, yet the results were different.

For the conclusive proof of the reaction mechanism offered in such condensations, it was necessary that it be shown that saturated alkyl phenyl ethers would rearrange under the conditions used by Koenig. In all the ethers obtained (*sec.*-amyl phenyl and cresyl ethers; di-isobutyl phenyl and cresyl ethers) the oxygen is at a secondary or tertiary carbon atom. Since no data on the rearrangement of such types of compounds could be found in the literature, the simplest case, the various isopropyl phenyl and cresyl ethers, was then chosen for study.

There have been numerous cases of rearrangement already reported.[5] Where the alkyl group is a negative one, mere heat is necessary.[6] As the alkyl group becomes less and less negative, various reagents, such as zinc chloride and hydrogen chloride, have to be used to effect rearrangement.[5b,e]

A mixture of concentrated sulfuric and glacial acetic acid should then be an excellent means for rearranging alkyl phenyl ethers. This reagent has the advantage of bringing the whole reaction mixture into homogeneous solution, while at the same time the concentration of the active rearranging agent, sulfuric acid can be reduced to any desired quantity. The ease with which the resultant product may be isolated is apparent, it only being necessary to add water to separate the rearranged product.

From the reactions studied there appears to be very little side reaction, the only product obtained other than the rearranged ether being the original ether itself, which can be again subjected to rearrangement.

The mechanism for this type of rearrangement as offered by Van Alphen involves oxonium formation. Kursanov suggests hydrolysis of the ether to the phenol and the alkyl halide and then recombination with the formation of a substituted phenol. Neither of these authors explains the rearrangement of alkyl ethers in the absence of a rearranging agent. Claisen's mechanism is a special one and requires the presence of the unsaturation in the alkyl residue. From Latimer's considerations,[7] the

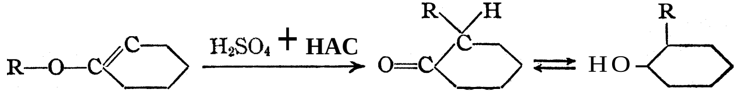
substituted phenol structure is a more stable configuration than that of the ether and therefore when placed in a suitable medium or under suitable conditions, readjustment to the more stable configuration should be expected.

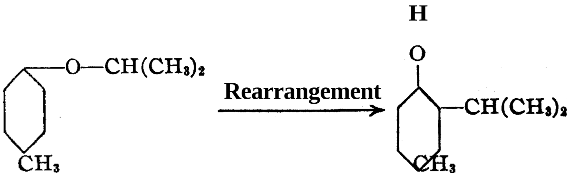
Drawing an analogy from keto–enol tautomerism and rearrangement of vinyl alkyl ethers to the corresponding aldehydes, the series of reactions may be represented as



As mentioned before, the ethers chosen for study were the isopropyl phenyl and cresyl ethers. Some of these ethers and the corresponding phenols obtained after rearrangement had not been previously prepared and had to be characterized.

The complete identification of the substituted phenols formed would involve determination of the position of the alkyl groups introduced. This would permit us to draw conclusions and generalizations which would be of great value in the identification and structure proof of a number of new longer chain phenols obtained by a similar process and to be described later.

The rearrangement of isopropyl *p*-cresyl ether was first studied. The reaction went smoothly and the rearranged phenol was isolated.



The isopropyl group could migrate to the ortho position only, the para position being occupied and meta rearrangement being rare.

The rearrangement of isopropyl phenyl ether gave rise to a product the main portion of which distilled in the neighborhood of the boiling point of o-isopropyl phenol as reported in the literature.[8]

The product obtained on treating this product with bromoacetic acid was identical with that reported in the literature for *o*-isopropylphenoxyacetic acid.[9]

The product therefore appears to be identical with o-isopropylphenol and the alkyl group in the ether has apparently migrated ortho to the hydroxyl group

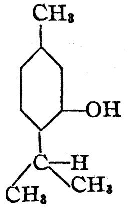
---

[8] Spica, *Gazz. chim. ital.*, *9*, 442 (1879); *Jahresb.*, 663 (1880).

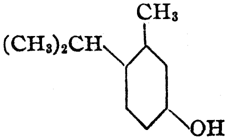
[9] Fileti, *Gazz. chim. ital.*, *16*, 129 (1886).

It was expected that by the rearrangement of the isopropyl *m*-cresyl ether, thymol would be obtained. Actually a strong odor of thymol was observed, the total product boiling between 230-240°. From the fraction boiling between 231-235° a derivative with bromoacetic acid was made which melted 4° lower than that of thymol. According to Crum-Brown's rule there are three isomeric products possible upon the introduction of an isopropyl group into m-cresol.

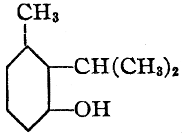
I



II



III

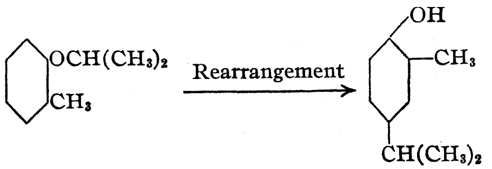


Thymol **3-Methyl-4-isopropylphenol** **2-Isopropyl-3-methylphenol**

Of these only I (thymol) has been identified conclusively. A condensation product furnished by Read[10] was studied and was found to be different from thymol and the rearranged isopropyl m-cresyl ether.

Usually upon treatment of an alcohol with phenol in the presence of a condensing agent the alkyl radical enters in a position para to the hydroxyl group.[11] Structural Formula II may then be assigned to these types of products. The only possible structure for the substituted phenol obtained from isopropyl m-cresyl ether by the rearrangement process mentioned before, would then be Formula I or III, which would be in harmony with the fact observed that whenever the ortho positions are free migration to this place is preferred. Formula III would involve readjustment to a position which should be particularly non-reactive due to such phenomena as steric hindrance. A definite stand as to the position occupied is not being taken until the behavior of this compound is studied further.

The rearrangement of the o-cresyl isopropyl ether gave rise to a product which was identified by its physical and chemical properties and by its bromine derivative as *p*-isopropyl-*o*-methylphenol. The compound appears to be identical with that obtained by Kelbe and Spica,[12] the structure of which is given as



---

[10] (a) Read, Sharp and Dohme, private communication; (b) Mazzara, *Gazz. chim. ital.*, 12,505 (1882).

[11] Senkowski, *Ber.*, 24,2974 (1891); Anschütz and Beckerhoff, *ibid.*, 28,407 (1895).

[12] Kelbe, Ann., 210, 40 (1881); Spica, *Gazz. chim. ital.*, 12,552 (1882).

With a methyl group occupying an ortho position, migration para to the hydroxyl group appears to be favored.

Experimental Part

Preparation of Isopropylphenyl and Cresyl Ethers.--One molecular weight of the phenol or cresol was placed in a three-necked flask fitted with a reflux condenser. Fifty-eight grams (excess) of finely powdered potassium hydroxide was added and the whole heated with a low flame, when a homogeneous viscous mass is formed; 125 g. (excess) of isopropyl bromide was then slowly added through a dropping funnel extending below the level of the liquid. Constant warming was necessary to keep the whole mass from solidifying. After all the halide had been added refluxing was continued for two hours more. The mass was allowed to cool and then 500 cc. of water was added to dissolve the separated sodium bromide. A light oil appeared at the top of the liquid. This was removed in a separatory funnel and washed successively with 10% alkali and then twice with water. The separated light yellow oil was dried over calcium chloride and then distilled. One fractionation was sufficient to give a colorless constant boiling oil.

Rearrangement of Isopropylphenyl and Cresyl Ethers.—The rearrangement mixture consists of a solution of 150 cc. of concentrated sulfuric acid in sufficient glacial acetic acid to make up to a liter: 80 cc. of the ether prepared as above was placed in a flask fitted with a reflux condenser and a calcium chloride addition tube; 200 cc. of the rearrangement mixture was added and the whole shaken. Two layers are formed at first, but the mixture becomes homogeneous on warming. The solution was then refluxed gently for five hours. The temperature of the solution on refluxing is constant between 125–130°. The reaction mixture was then allowed to stand overnight. It assumed a deep red color. The whole was transferred to a 500-cc. separatory funnel and 200 cc. of water added. Sufficient solid hydrated sodium carbonate was added to neutralize the sulfuric acid (180 g.). The separatory funnel was then filled with a saturated salt solution. On standing, a heavy viscous oil separated to form the upper layer. The lower layer was allowed to drain off and discarded and the upper layer extracted with 10% potassium hydroxide solution. The alkali-insoluble portion was redistilled to reclaim unchanged ether. The alkali extract was neutralized with cold concentrated hydrochloric acid, ice being thrown in to keep the reaction mixture cool, when a deeply colored oil separated. The mixture was extracted with ether, the ether distilled off and the residue fractionated.

From 72 g. of ether. 39 g. of rearranged alkali-soluble product was obtained. and 16 g. of unchanged ether in the case of *m*-cresyl isopropyl ether. This corresponds to a 54% yield on the basis of the total ether at the outset, or a 70% yield taking into consideration the ether recovered.

Preparation of Isopropylphenoxy- and Cresoxyacetic Acids.—About one gram of the substituted phenol was weighed out carefully on an analytical balance. The exact quantity of 1 N potassium hydroxide was added and the whole gently warmed. A slight excess of bromoacetic acid was weighed into a separate flask and carefully neutralized with 1 *N* potassium hydroxide. The two solutions were mixed and then gently boiled for five minutes. Decolorizing charcoal was added and the whole filtered while hot. While still warm the calculated quantity of concentrated hydrochloric acid was added and the mixture allowed to stand. The separated crystalline product was filtered off and recrystallized from hot water.

Summary

Saturated alkyl phenyl ethers (isopropylphenyl and cresyl ethers) were rearranged to the corresponding substituted phenols by means of a mixture of concentrated sulfuric and glacial acetic acid. Proofs for the probable structure of the products obtained were advanced and a general rule as to the way of migration of the alkyl groups was given.

As the possibility of rearranging even short chain, saturated phenyl ethers has now been demonstrated, a series of related problems such as the rearrangement of some of the more important phenyl ethers of mono and poly functional alkanes are now being investigated.

The physiological properties of the substituted phenols mentioned before are being studied.

[COMMUNICATION NO. 460 FROM THE KODAK RESEARCH LABORATORIES]

EFFECT OF NEUTRAL SALTS ON THE RATE OF HYDROLYSIS OF CELLULOSE ACETATE IN ACETIC ACID SOLUTIONS[1]

BY J. T. FUESS AND C. J. STAUD

RECEIVED MARCH 7, 1931 PUBLISHED MAY 6, 1931

Introduction

The effect of the presence of neutral salts of the alkali metals **on** the rate of chemical reactions has been the subject of the investigation of several workers in recent years. The published results appear to have been concerned mostly with crystalloids. L. E. Bowe[2] has investigated the effect of sodium chloride and sodium bromide on the rate of saponification of ethyl acetate by hydrochloric acid. Grube and Schmid[3] studied the hydrolysis of cyanamide to urea by nitric acid in the presence of nitrates, and the saponification of ethyl acetate by hydrochloric acid in the presence of alkali and alkaline earth chlorides. Hawkins[4] worked on the

hydrolysis of ethyl acetate in dilute aqueous solutions; Kautz and Robinson[5] gave results of an investigation of the hydrolysis of sucrose by hydrochloric acid in the presence of alkali and alkaline earth chlorides. Sherman, Caldwell and Cleaveland[6] ascertained the effect of neutral salts on the rate of inversion of starch by amylase, and Roberts and Terry[7] investigated the velocity of saponification of ethyl formate by ammonium hydroxide in the presence of ammonium salts. In general, it has been observed that neutral salts increase the reaction velocity in rather widely different types of reactions.

As far as has been learned, however, no publication has been made of the effect of neutral salts on the rate of hydrolysis of cellulose esters. Since these compounds present a different aspect of the general problem in that their dispersions are colloidal in character, an investigation of the results obtained by the addition of neutral salts appeared of interest.

Experimental

Cellulose acetate was prepared by the esterification of cellulose in the form of cotton linters, through the action of a mixture consisting of acetic anhydride, acetic acid and a catalyst. A calculated amount of water more than sufficient to convert the excess acetic anhydride to acetic acid was added. In this way the difficulty of redissolving cellulose triacetate in acetic acid with possible lack of uniformity of the solution was overcome. The concentration of the various components of the solutions used in the hydrolysis experiments was as follows: cellulose triacetate, 89 g., acetyl content 43.5 to 44.2% (theoretical 44.8%); acetic acid, 563.5 g.; water, 22.9 g.; sulfuric acid, 0.9 g.; phosphoric acid, 2.7 g., and sodium bisulfate, 2.0 g.

Four groups of experiments were carried out. In each series fresh preparations of cellulose triacetate were made in sufficient quantity for all of the experiments in that group. The procedure employed in acetylation was the same in all cases.

Three 550-g. portions of cellulose triacetate solutions of the composition given above were taken for the first series of experiments. One contained in addition 17 g. of sodium nitrate, the second 20 g. of potassium nitrate, while the third contained no neutral salt, this portion serving as a control. The hydrolyses were carried out in glass-stoppered bottles, maintained at 53 ± 1° in a constant-temperature air-bath. After various intervals throughout the saponification approximately 100-g. samples were removed and these, after dilution with an equal volume of acetone to assist in obtaining fluffy precipitates which could be easily washed, were precipitated by pouring slowly into warm water (approximately 60°) with vigorous stirring. The precipitated cellulose acetates were then washed with water until the residual acid had been removed, as indicated by testing the precipitates with brom thymol blue. They were then air-dried.

The acetyl content of each sample was determined using a modification of the Knoevenagel method as given below.

Approximately one-half gram of the material after air-drying is placed in a small glass weighing bottle and further dried at 105° for sixteen to eighteen hours. After cooling in a desiccator over anhydrous calcium chloride, the bottle and contents are weighed. The cellulose acetate is transferred to a 250-cc. Erlenmeyer flask, the bottle again weighed and the weight of sample obtained by difference.

[7] E. N. Roberts and E. M. Terry, *ibid.*, 52, 2604 (1930).

Twenty cubic centimeters of 75% ethyl alcohol (by weight) are added and, after covering the flask, maintained at 56° in an air-bath for thirty minutes. At the end of this time 20 cc. of 0.5 N sodium hydroxide is pipetted into the flask. The flask is then stoppered and after heating at 56° for fifteen minutes it is permitted to stand at room temperature for approximately twenty-four hours. The excess alkali is back-titrated using 0.5 *N* hydrochloric acid. The acetyl content is calculated using the formula

$$\% \ \mathrm{CH_3CO} = \frac{(\text{Cc. of NaOH taken} \times N - \text{cc. HCl used} \times N) \times 0.043)}{\text{Weight of sample}} \times 100$$

The results obtained in the first series are given in Table I and graphically in Fig. 1.

The sample from the hydrolysis in the presence of potassium nitrate after forty hours appears to have met with an accident during analysis.

A second series of experiments was carried out using solutions of the same composition as employed in the first group of experiments, but adding 10 *g.* of sodium nitrate to one of three samples, maintaining two as controls. This was done to confirm the results previously obtained. The hydrolysis procedure and method of determination of acetyl content were the same as those previously described. The results are given in Table II and graphically in Fig. 2.

Fig. 2.

Since Hawkins found that the alkali sulfates exerted an effect on the saponification of ethyl acetate of approximate numerical equality but opposite in sign from that of the nitrates, it appeared of interest to ascertain the results of sodium and potassium sulfates in place of the corresponding nitrates in the hydrolysis of cellulose acetate.

The procedures employed were the same as those previously described. The amounts of sodium and potassium sulfates added were approximately molecular equivalents of the corresponding nitrates used in the first series of experiments, that is, 15 g. of potassium sulfate and 14 g. of sodium sulfate, both being in the anhydrous form.

The results of the third series of experiments are given in Table III and graphically in Fig. 3.

In the fourth series of experiments, the run was made using sodium chloride for comparison with the results obtained using sodium nitrate and sodium sulfate. Two experiments were made to determine whether the addition of the neutral salts after partial hydrolysis would exhibit the same effect as when added at the start of the reaction.

Five portions of cellulose triacetate solution were taken; to one was

Discussion

From an examination of the data there appear several points of interest to be considered. It is seen that in all cases the presence of the neutral salts of the alkali metals tried, resulted in a retardation of the rate of saponification. The factors influencing this saponification in colloidal solution and in media in which activity coefficients do not appear to have been accurately determined, make this reaction too complex and the data too meager to permit of calculation of the reaction constants. It is thought, however, that the qualitative results of this problem are of sufficient interest to warrant brief discussion.

From the first series of experiments (Table I, Fig. 1) in which sodium nitrate and potassium nitrate were present at the beginning of the saponification in approximately molecular equivalents, it appears that the retarding effect is not influenced by the difference in atomic weight between sodium and potassium, but that the controlling influence is dependent upon the presence of the nitrate radical. When sodium or potassium nitrate is used, the decrease in acetyl content in forty-two hours is approximately 1%, whereas the saponification in the absence of salt had resulted in a reduction of the acetyl content of 5%. This corresponds to the removal of 2.2% of the available acetyl in the case of saponification in the presence of sodium and potassium nitrate and 11.2% in the absence of neutral salts. The data given in Table II and Fig. 2 confirm the results of the first group of experiments as regards the effect of sodium nitrate and indicate the degree of reproducibility of such saponification.

When sodium and potassium sulfates were employed in approximately molecular equivalents of the corresponding nitrates, retardation was again observed (Table III, Fig. 3). In this case the neutral salts permitted saponification of but 2.3% of the available acetyl as compared to 9.9% for the control. It therefore appears that the effect of the sulfate radical is approximately equal to that of the nitrates previously mentioned. The effect noted in these experiments is different from that observed by Hawkins in the saponification of ethyl acetate in which it was found that the sulfates and nitrates had opposite effects upon the saponification rate.

In the fourth series of experiments (Table IV, Fig. 4) a comparison of the first two experiments, in which sodium nitrate and sodium chloride were used, indicates that during forty-two hours of saponification the effect of the former is almost double that of the latter, the percentage of available acetyl removed in the case of sodium nitrate being 2.7% and for sodium chloride 5.3%. During the same period the control decreased 7.0%. All of the hydrolyses to which no salts were added during the first forty-two hours show the same acetyl content, within experimental error, being 40.3, 40.2 and 40.6%. A comparison of the results when sodium nitrate and sodium chloride were added after forty-two hours of saponification shows the following at the end of forty-eight hours' subsequent hydrolysis. The experiment in which sodium nitrate was used showed a decrease of 2.5% of the remaining available acetyl content, the sodium chloride experiment 7.4%, while the control to which no salt had been added decreased 8.7%. The curves indicate that the effect of the addition of neutral salts after saponification has proceeded for some time is not instantaneous.

In general, it is noted that the effect of the presence of neutral salts of the alkali metals in a reaction involving the saponification of cellulose acetate in colloidal dispersion in acetic acid, is opposite to that recorded by investigators of similar reactions involving crystalloids.

The subject matter of this paper is covered by a pending patent application of Eastman Kodak Company and the publication of this paper is not to be taken in any way as suggesting or permitting the commercial use of this development.

Summary

The effect of the presence of the nitrates, sulfates and chlorides of sodium and potassium on the rate of saponification of cellulose acetate dispersed in acetic acid has been studied.

It has been found that all of these salts appear to exert a retarding influence on the reaction rate. A greater effect was observed when nitrates and sulfates were used than when chloride was employed.

Addition of neutral salts after the reaction had proceeded for forty-two hours showed an effect similar to that noted when they were present at the beginning of the saponification.

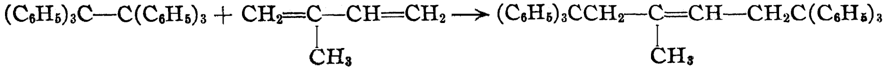
THE ADDITION OF FREE RADICALS TO UNSATURATED COMPOUNDS (PRELIMINARY PAPER)

BY J. B. CONANT AND H. W. SCHERP

RECEIVED MARCH 10, 1931 PUBLISHED MAY 6, 1931

Free radicals containing trivalent carbon such as triphenylmethyl are known to combine with quinones (forming a di-ether) and with free radicals containing divalent nitrogen. Aside from these reactions there seems to be no published account of the addition of a free radical to an unsaturated organic compound. We have now found that triphenylmethyl (hexaphenylethane) combines with isoprene and dimethylbutadiene; the addition takes place in the 1,4 position.



$$(C_6H_5)_3C—C(C_6H_5)_3 + CH_2{=}\underset{\substack{|\\ CH_3}}{C}—CH{=}CH_2 \longrightarrow (C_6H_5)_3CCH_2—\underset{\substack{|\\ CH_3}}{C}{=}CH—CH_2C(C_6H_5)_3$$

The structure of the product obtained from isoprene was established by ozonization. Triphenylpropionic acid and 1,1,1-triphenylbutanone-3 were obtained from the ozonide by decomposition and oxidation with silver oxide. The identity of these compounds was proved by mixed melting point determinations with synthetic material. The ketone is new and was synthesized from triphenylpropionic acid by converting the latter into the acid chloride and treating with methyl zinc chloride in ether.

The nature of the product obtained with dimethylbutadiene was shown by the fact that on ozonization the same triphenylbutanone was obtained. The two new hydrocarbons obtained from isoprene and dimethylbutadiene, respectively, melted at 166 and 240°, respectively. Both combined with bromine in chloroform solution but considerable substitution takes place as evidenced by the copious evolution of hydrogen bromide.

It is a matter of considerable interest to see how far the type of addition reaction we have discovered can be extended. There seems no reason to believe that it is limited to dienes or to ethanes as highly dissociated as hexaphenylethane. Such reactive linkages as those in maleic anhydride or acrolein might well be expected to combine with free carbon radicals. Indeed, we have evidence that a reaction does take place between each of these compounds and triphenylmethyl but the nature of the product has not been as yet determined. We have been unable to bring about the addition of hexaphenylethane to 1,4-diphenylbutadiene, cinnamalacetophenone, or cinnamalmalonic acid, A study of the application of this reaction to the polyenes (including the carotinoid pigments) is now in progress.

Experimental Part

Reaction of Hexaphenylethane with Isoprene.—Three grams of hexaphenylethane (prepared from triphenylmethyl chloride and molecular silver) was treated with 40 cc. of isoprene in an atmosphere of nitrogen. After standing for two days, all the solid had dissolved and the orange-red color of the solution had changed to pale yellow. The excess isoprene was removed by distillation, the sirupy residue finally being heated on the steam-bath. On treatment with a mixture of ether and petroleum ether, 1.3 g. of slightly yellowish crystals was obtained which melted at 160–161°. On recrystallization from ether 0.6 g. of product melting at 164–165° was obtained. A more convenient method of obtaining crude hexaphenylethane in quantity is by the reduction of triphenylmethyl chloride. This crude material can be used directly in the addition reactions; an example of this procedure is as follows. The chloride (10 g.) was dissolved in 200 cc. of acetone in a 2-liter flask and 15 cc. of concentrated hydrochloric acid was added. A strong current of carbon dioxide was passed into the flask and 100 cc. of approximately 1 *N* vanadous chloride was run into the solution. On adding a liter of water, the product precipitated in granular form. It was filtered off, thoroughly washed with water and transferred without drying to a 200-cc. flask fitted with a two-holed stopper carrying a dropping funnel and connection to a nitrogen–vacuum pump apparatus. The flask was swept out three times with nitrogen, about 40 cc. of isoprene run in and finally the flask was left under a pressure of 1–2 cm. of mercury for three days with occasional shaking. The excess isoprene was then distilled off and the residue taken up in about 300 cc. of ether. The solution was filtered, evaporated to a small volume and on standing overnight at 0°, 6.3 g. of large glassy crystals formed, which melted at 162–163°. On recrystallization from ether, 4.5 g. melting at 164–164.5° was obtained; yield, 45% of the theoretical calculated from the triphenylmethyl chloride.

Another equally convenient procedure for preparing the addition product of isoprene and hexaphenylethane is to employ benzene as a solvent and form the free radical from the chloride and metallic mercury in the presence of the unsaturated compound. The following is a typical procedure: **15** g. of triphenylmethyl chloride, **3.6** g. of isoprene, **50** cc. of thiophene-free benzene and **50** g. of mercury were sealed in a nitrogen filled capsule and shaken for seventeen hours. After ten days' standing, the reaction mixture was worked up in the same fashion as the previous preparation; yield, after one recrystallization from benzene and ether, **10.8** g. or **72%;** melting point, 163–164°.

1,4-(Triphenylmethyl)-2-methylbutene-2.—A portion of this substance was carefully crystallized from ether for analysis; melting point, 166°.

Anal. Calcd. for $C_{43}H_{38}$: C, 93.1; H, 6.9. Found: C, 92.7, 92.8, 92.6, 92.6, 93.0; H, 7.07, 7.04, 6.91, 6.98, 7.0.

Molecular weight (neglecting the first increment) in benzene, cryoscopic. Benzene, 25.47, 25.47 g.; substance, 0.1799, 0.1928 g.; At, 0.076, 0.079°. Molecular weight, 475,490. Calcd. for $C_{43}H_{38}$: 554.

Ozonization.—Two grams of the hydrocarbon was dissolved in about 200 cc. of carbon tetrachloride and ozonized oxygen prepared by means of an electric discharge apparatus was bubbled through for three hours, when the solution was very turbid. The solution was cooled with ice during the reaction. On shaking with water and zinc dust, and filtering, a clear solution was obtained. The carbon tetrachloride was evaporated off under reduced pressure and the yellow gummy residue was taken up in ether. This solution was shaken for one-half hour with saturated sodium bisulfite solution, and the aqueous layer was acidified with hydrochloric acid. A small amount of oily material separated, but not enough to indicate that any appreciable extraction had occurred.

The ether was then boiled off and the residue dissolved in methyl alcohol. About one gram of sodium hydroxide and the freshly precipitated silver oxide from 3 g. of silver nitrate were added. After three hours' boiling, during which a characteristic "silver mirror" appeared, the hot solution was filtered, acidified with hydrochloric acid and evaporated to a small volume under reduced pressure. There was no precipitate of silver chloride. The mixture was dissolved in ether and extracted with sodium carbonate solution. The aqueous layer was acidified with hydrochloric acid, extracted with ether, and the acid removed once more with sodium carbonate solution. The acid was then reprecipitated by hydrochloric acid, extracted with ether, and crystallized from ether and petroleum ether; yield, 0.6 g. melting at 177.5–178.5°. Calculated as β-triphenylpropionic acid, the yield was 55%.

A duplicate experiment was carried out, but no sodium hydroxide was used in the silver oxide oxidation. At the end of the oxidation, 10 cc. of concentrated hydrochloric acid was added and boiling continued for one-half hour to liberate the acid from the silver salt; yield, 0.4 g. (37%) melting at 179°. The combined acids were recrystallized from 50% alcohol, the product being in the form of fine needles and melting at 180.5°. A mixed melting point with synthetic β-triphenylpropionic acid showed no depression.[1]

The non-acid fractions from the ozonizations were concentrated and treated with petroleum ether to the point of cloudiness. On standing overnight at 0°, a total of 0.85 g. of crystalline material melting at 135–137° was obtained; yield calculated as 1,1,1-triphenylbutanone-3, 39%. After two recrystallizations from ether, the substance melted at 140.5–141°. A mixed melting point with the synthetic material (see below) gave no depression.

1,1,1-Triphenylbutanone-3 was prepared by the reaction of β-triphenylpropionyl chloride and zinc methyl chloride.[2] Methylmagnesium iodide was prepared in the usual

---

[1] Fosse, *Compt. rend.*, 145, 197 (1907); Kellerman, THIS JOURNAL, 49, 1737 (1927).

[2] This method was developed by W. D. Peterson in this Laboratory.

fashion from 0.45 g. of magnesium turnings, 2.7 g. of methyl iodide and 40 cc. of absolute ether. Four grams of stick zinc chloride was fused under reduced pressure until bubbling ceased. It was then taken up in 25 cc. of absolute ether and added to the Grignard reagent, cooling the latter meanwhile with an ice-salt mixture. The solution was then warmed to room temperature and stirred for fifteen minutes. β-Triphenylpropionyl chloride was prepared by treating β-triphenylpropionic acid with three times the calculated amount of thionyl chloride. The excess thionyl chloride was boiled off and the product heated under reduced pressure until odorless. A solution of 4 g. of this material in absolute ether was added to the zinc methyl chloride. After one hour's stirring with gentle boiling, the mixture was allowed to stand overnight. It was then decomposed with water and hydrochloric acid. The ether solution was washed with sodium hydroxide to remove any β-triphenylpropionic acid, dried with calcium chloride and evaporated to a small volume. On standing for some time, a crystalline product formed, which had a low indefinite melting point and was obviously impure. A portion was recrystallized twice from ether, and 0.33 g. of material melting sharply at 140.5–141° was obtained. In addition, 1.0 g. of another substance melting at 120–124° was obtained. (This was not further investigated.) The substance yielded iodoform on treatment with iodine and sodium hydroxide in methyl alcohol solution.

Anal. Calcd. for $C_{22}H_{20}O$: C, 88.0; H, 6.7. Found: C, 88.2, 88.0; H, 6.9, 6.7.

Reaction of Hexaphenylethane with Dimethylbutadiene.—2,3-Dimethylbutadiene was prepared by the catalytic dehydration of pinacol with iodine, following the directions of Hibbert.[3] Five grams of triphenylmethyl chloride, 1.5 g. of dimethylbutadiene, 10 cc. of thiophene-free benzene and 15 g. of mercury were sealed in a nitrogen filled capsule and shaken on a machine for twelve hours. After one week's standing the contents of the capsule were shaken for some time with air to oxidize any hexaphenylethane, filtered, and concentrated. A slightly yellow crystalline material was precipitated by petroleum ether. This was recrystallized from benzene and petroleum ether, 1 g. melting at 227–231° being obtained. This was recrystallized twice from benzene and ether for analysis. It then melted at 240° under nitrogen with some decomposition.

Anal.[4] Calcd. for $C_{44}H_{40}$: C, 92.9; H, 7.1. Found: C, 92.6, 92.6; H, 7.36, 7.38.

Ozonization.—Ozonized oxygen was bubbled for five hours through a solution of 0.8 g. of the hydrocarbon in 50 cc. of carbon tetrachloride chilled with ice. After shaking with water and zinc dust and filtering, the solution was evaporated to dryness under reduced pressure. The gummy residue was dissolved in 5 cc. of ether, and a sandy precipitate formed weighing about 0.025 g. and melting above 150". The mother liquor was allowed to evaporate slowly at room temperature and the crystals which formed were washed with ether and recrystallized from the same solvent. The yield was 0.16 g. or 19%. The melting point was 140.5–141°. A mixed melting point with synthetic $(C_6H_5)_3CCH_2COCH_3$ showed no depression.

Summary

Triphenylmethyl combines with isoprene and dimethylbutadiene, addition taking place in the 1,4-position.

CYCLOHEXYLMAGNESIUM CHLORIDE AND BROMIDE

By Henry Gilman and E. A. Zoellner

Received March 10, 1931 Published May 6, 1931

Introduction

Grignard reagents are alike in the sense that they can be represented by the general formula RMgX. Strictly speaking, the resemblance ends here because of differences in rate of formation,[1] differences in yields,[2] differences in conditions for obtaining optimal yields,[3] differences in rates of reaction[4] and yields and kind of products with other reactants,[5] and differences in the degree of dissociation[6] and the extent of the equilibrium with $R_2Mg + MgX_2$ compounds.[6,7]

There are essential differences in the optimal conditions for the preparation of various RMgX compounds. Fortunately, these are not of a kind to warrant special procedures for every possible Grignard reagent. Actually it is possible to arrange roughly the methods for the preparation of RMgX compounds after the relative reactivities of the halogen in definite groups of RX compounds like R_3CX, RCH=CHX, RCH=CH-CH_2X, etc.

Cyclohexyl halides have properties which serve to set them apart from other RX compounds. This is reflected in some of the results reported in the present study. The relatively low and erratic yields and the troublesome by-products of cyclohexylmagnesium chloride and bromide, as reported very recently by different investigators,[8] can be avoided. It is possible to prepare cyclohexylmagnesium bromide in yields of about 92%, and cyclohexylmagnesium chloride in yields of about 96.5%.

The decrease in yield when cyclohexyl bromide is added very rapidly to magnesium in ether is one of the largest so far observed for RMgX

compounds, and is the largest decrease now known for a secondary bromide. On the other hand, the corresponding chloride shows but a small decrease in yield when the RCl compound is added rapidly. Very generally, a significant drop in yield of RMgX compound with a rapid addition of halide can be correlated with low and erratic results unless special conditions are observed. Partly for this reason it is recommended that cyclohexylmagnesium chloride instead of the bromide be used whenever possible. Not only does the chloride give higher yields of RMgX compound, but it gives higher yields with an astonishing abuse or lack of care in addition. Furthermore, RMgCl compounds enjoy other advantages over RMgBr and RMgI compounds: (1) they frequently undergo more ready reaction with another compound; (2) they generally give higher yields of products with a given reactant, and on the basis of an equal content of RMgX compound; and (3) there is probably a general lesser opportunity for side reactions because the binary system ($MgCl_2$ + Mg) is less active[g] than the corresponding systems with magnesium bromide and magnesium iodide. Over and against these general advantages, they are formed with slightly greater difficulty than the corresponding bromides or iodides; but the difference in time of starting, when a catalyst like iodine or the activated magnesium-copper alloy is used, is very small.

Experimental Part

The apparatus and general procedure were those used in related studies.[10] The quantity of RX compound was 0.05 mole, and the yields so obtained were duplicated in larger runs (0.2 and 0.5 mole). Additional confirmation of the essential correctness of the results obtained by titration was had in the very high yield of cyclohexanecarboxylic acid isolated subsequent to carbonation.

TABLE I

YIELDS OF CYCLOHEXYLMAGNESIUM CHLORIDE AND BROMIDE IN 0.05 MOLE EXPERIMENTS

RMgX (0.05 mole)	Magnesium (atom) Turnings	80-80 mesh	Av. % yield of RMgX
$C_6H_{11}MgCl$	0.055	..	91.1[a]
$C_6H_{11}MgCl$	...	0.055	94.4[b]
$C_6H_{11}MgCl$	...	.15	96.6[c]
$C_6H_{11}MgBr$	.055	..	80.1[d]
$C_6H_{11}MgBr$	...	.055	84.0[b]
$C_6H_{11}MgBr$	...	.15	92.0[e]

[a] About a 10% solution of chlorocyclohexane in ether was used to start the reaction with magnesium. In all experiments a small crystal of iodine was used. When all of the chloride had been added, the apparent reaction (as indicated by gentle refluxing, with no application of external heat) was five to ten minutes. When this spontaneous reaction had ceased, the mixture was stirred and refluxed for ten to fifteen minutes be-

---

[e] Gomberg and Bachmann, THIS JOURNAL, 49, 2584 (1927); Gilman and Brown, *ibid.*, 52, 1128 (1930).

[10] Gilman, Zoellner and Dickey, *ibid.*, 51, 1576, 1583 (1929).

fore removing aliquots for analysis. In an experiment where the chloride in ether was added at one time (instead of dropwise over a period of thirty minutes), the yield was 90%, and the spontaneous reaction continued for thirty-five minutes after all the halide had been added. This yield was decreased 5% when undistilled chloride was used.

[b] Reaction sets in immediately with the fine magnesium (30–80 mesh). These runs were made under the same conditions as those with commercial turnings, with the exception that 8 equivalents of ether were used. The time of addition of the halide in ether was thirty minutes.

[c] The time of addition in these experiments was one hour, and 0.425 mole of ether was used. A larger ratio of ether is used with fine magnesium in order to reduce the spattering of magnesium on the walls of the flask.

[d] The bromide reacts more readily than the chloride, and an initial concentration of **6–7%** in ether is sufficient to start the reaction. Spontaneous reaction continued for five minutes after adding all of the bromide over a period of thirty minutes, and the mixture was then stirred and refluxed for ten minutes before removing samples for analysis. When all of the bromide in ether is added at once (after starting the reaction with a part of the bromide), the spontaneous reaction continues for twelve minutes and the yield drops to 54%. The time during which the spontaneous reaction occurs subsequent to addition of all of the halide is apparently a qualitative measure of the relative reactivity of the halide toward magnesium. Undistilled bromide decreases the yield **3%.**

The halides were freshly distilled, and as such gave higher yields and started to react with magnesium more readily than undistilled material. The time, and with some RX compounds the yield, is influenced by the nature of commercially available magnesium turnings. It is not an easy matter to describe the physical condition of the turnings, but those which gave the best results in the present study were about 0.48 mm. in thickness, 4 mm. in breadth and 10–50 mm. in length, when the coils were unwound.

Recommended Procedure for Laboratory Preparation.—The magnesium turnings (1.1 atom equivalents) are barely covered with ether and sufficient pure halide is added to give an optimal initial concentration (6–7% with bromide and 15% or greater with the chloride). After adding a crystal of iodine heat is applied, without stirring, and these conditions are maintained for five to ten minutes after the iodine color has disappeared. Reaction having set in, sufficient ether is added to cover the magnesium while it is stirred, and then the remainder of the halide in ether[11] is added. The rate of addition varies with the halide. With the chloride, there is no appreciable harm in rapid addition. However, the bromide must be added more slowly, and generally at a rate that causes gentle refluxing.

When all of the halide has been added, stirring and refluxing are continued for fifteen to twenty minutes with the chloride, and for ten minutes with the bromide.

The yield of cyclohexylmagnesium chloride in 0.2 and 0.5 mole runs under the above conditions is 92–95%.

In carbonating the Grignard reagent prepared as above, it is recommended that provision be made to admit an inert gas like nitrogen during

[11] In all about 6 mole equivalents of ether are used. One-half of this ether can be added to the mixture after the reaction has started, and the remainder is used to dilute the halide.

the cooling which is preliminary to carbonation. By so doing, the yield is improved because otherwise oxygen from the atmosphere would be pulled in and react with the Grignard reagent. In a 0.2 mole run the yield of cyclohexanecarboxylic acid based on an 80% yield of cyclohexylmagnesium bromide was 83%; and the yield of acid based on a 92% yield of cyclohexylmagnesium chloride was **93%.** It is recommended that the solution be diluted with ether (300–500 cc. in a 0.2 mole run) prior to carbonation, because of the sparingly soluble salt (RCOOMgBr) which is formed.

Summary

Cyclohexylmagnesium chloride and bromide can be prepared in excellent yields. In its reaction with magnesium, bromocyclohexane differs significantly from other secondary bromides. General recommendations are given for the use of RCl in preference to RBr and RI compounds for the preparation of Grignard reagents.

PHYSICAL PROPERTIES OF THE NORMAL PARAFFIN HYDROCARBONS, PENTANE TO DODECANE

BY A. F. SHEPARD, A. L. HENNE AND T. MIDGLEY, JR.

RECEIVED MARCH 11, 1931 PUBLISHED MAY 6, 1931

This paper presents some physical constants of the normal paraffin hydrocarbons, from pentane to dodecane, inclusive. These compounds have been prepared from a common source, and have all been purified by the same method and to the same extent. Consequently, physical measurements obtained with such samples are more comparable among themselves than are the isolated results obtained by various workers who have used different methods of synthesis, purification and measurement.

Preparation of the Samples.—The starting material was a special gasoline with a normal paraffin hydrocarbon content of about 70%. It was obtained from The Standard Oil Company of Indiana through the courtesy of R. E. Wilson. It was roughly separated into its constituents by distillation. Each cut was then treated with chlorosulfonic acid until a one-week treatment no longer altered the density. The details of this treatment have been reported previously.[1] Further purification was accomplished by careful fractionation through a flat spiral fractionating column, equipped with an efficient dephlegmator. The progress of the purification was measured by the density variations of the distillates. The purification was regarded as having reached its practical limit when the over-all density differences of several successive distillate fractions did

not exceed a few units of the fifth decimal. Table I summarizes the experimental results.

TABLE I

PREPARATIVE DATA

[a] Chlorosulfonic acid treatment of pentane is unnecessary; *cf.* S. Young. J. Chem. *Soc.*, 71, 440 (1897); 75, 172 (1899).

Repeated fractional crystallizations of these compounds gave no further separation; the freezing ranges were smaller than 0.1°.

Purity Tests.—Two criteria have been relied upon to indicate the degree of purity obtained, namely, the total boiling range (distillation curve) and the total freezing range (freezing curve). Details of the measurements are as follows.

Boiling ranges were determined on large samples of the hydrocarbons, usually 250 cc. The specimens were slowly distilled from a tube of the dimensions specified for the determination of the boiling point of sulfur.[2] The tube was provided with a side arm 17 mm. in diameter and was heated directly only on a small area at the bottom. Temperature readings were made as in an Engler distillation and the barometer was read at the same time. Superheating occurred when the last 5–10% of the sample was being taken off. To minimize this, the

[2] Mueller and Burgess, This Journal, 41, 745 (1919).

thermometer was covered with 0.5 g. of cotton,[3] which prevented superheating fairly effectively without changing the other distillation points or holding back much material. Where the substances boiled above 100°, a radiation shield of the type recommended by Mueller and Burgess[2] was used.[4] The boiling points were duplicated within ±0.01°.

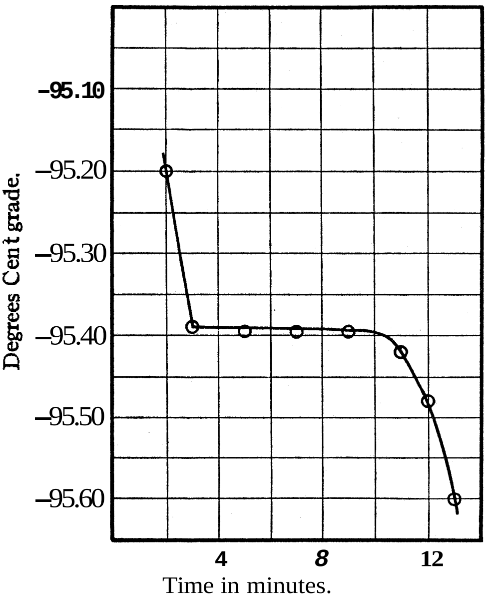

Fig. 2.—n-Hexane.

Since the accuracy of the absolute temperature measurements may have been less certain, the method of measuring is described. A platinum resistance thermometer (Leeds and Northrup No. 8162) was used. The Wheatstone bridge employed in the resistance measurements was of the Mueller type; the coils were checked among themselves and against primary standards, and corrections were made for temperature changes. A D'Arsonval galvanometer was used to determine the bridge balance; it was sufficiently sensitive to permit the measurements of less than 0.00001 ohm with the measuring current of 0.01 ampere which was used.

Calibration of the thermometer was made in the standard way at the ice, steam and sulfur points, taking the boiling point of sulfur as 444.60°.[5] The constants of the thermometer were as follows: R_0, 2.5079 ohms; R_{100}, 3.4882 ohms; $R_{443.22°}$, 6.62855 ohms. The fundamental coefficient calculated from these data is 0.003909 and A is 1.504, which constants indicate the platinum to be of the requisite purity. Checks on the calibration were obtained at the transition point of sodium sulfate decahydrate, and at several other temperatures between 0 and 100" against an instrument newly calibrated by the Bureau of Standards. All the instruments were frequently rechecked and agreement to ±0.01° was obtained in all cases.

A Fortin barometer was used in all the work; it was checked against the

---

[3] An equivalent volume of glass wool was used when undecane and dodecane were distilled.

[4] The use of this shield made no change in the observed boiling points of water and of octane.

local Weather Bureau instruments and the necessary corrections were made for temperature, elevation, latitude and capillarity. Boiling points were determined at several pressures near 760 mm. and were corrected to standard conditions with the aid of the dt/dp noted in Table II. The values thus obtained agreed in general to ±0.01°.

Dry	36.05	68.73	98.40	125.61	150.74	174.10	195.92	216.42

NOTE.—Undecane and dodecane did not appear to be absolutely stable to distillation at atmospheric pressure. The distilled specimens gave a slight brown color to concd. sulfuric acid on shaking with it, and the acid on dilution had the odor of a higher alcohol. The pure materials gave no color on shaking with this acid, and no odor on dilution.

Freezing points were determined on 120-cc. samples. The resistance thermometer used had been calibrated for low temperature work by the Bureau of Standards. The constants of the thermometer were as follows: R_0, 25.575 ohm; R_{100}, 35.532; and A and β in the modified Callendar equation for use at low temperatures were 1.48 and 0.115. respectively. The freezing curves are given in Figs. 1–8.

Physical Properties.—The following properties have been measured.

Boiling Points and Freezing Points.—The experimental details are reported in the preceding paragraphs. For typographical reasons, only every fourth experimental point is reproduced on the freezing curves.

TABLE III

ROILING POINTS, MELTING POINTS AND DENSITIES

n-Paraffin	B. p , °C.	M. p., °C.	d_4^{20}	d_4^{25}
Pentane	36 00	−129.93	0 62632	
Hexane	68.71	− 95.39	.65945	0.65502
Heptane	98.38	− 90.65	.68378	.67963
Octane	125.59	− 56.90	.70279	,69882
Nonane	150.71	− 53.68	.71780	.71398
Decane	174.06	− 29.76	.73014	.72643
Undecane	195.84	− 25 65	.74025	.73667
Dodecane	216 23	− 9.73		.74542

Densities.—Densities have been taken at 20 and 25°. They were measured in 40-cc. pycnometers of the Sprengel type. The necessary temperature control was obtained with a thermostat held constant to ±0.01°, and the absolute accuracy of the temperature was checked against three Bureau of Standards thermometers. Weighings were made with standardized weights. All densities were reduced to vacuum and are accurate to *0.00003.

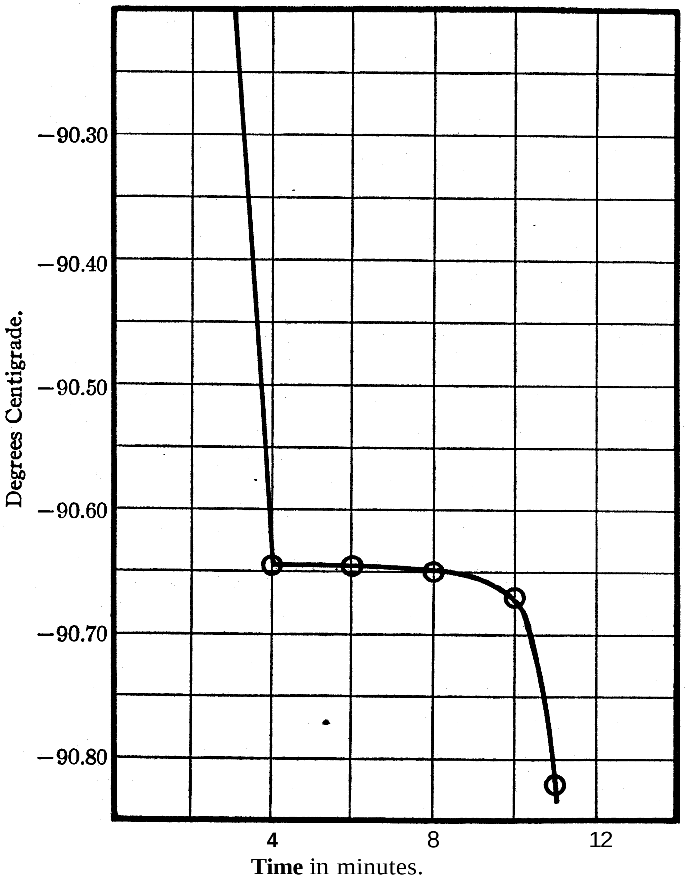

Fig. **3.—n-Heptane.**

Refractive Indices **and** Molecular Refractions.—Refractive indices relative to air were measured with a Pulfrich refractometer for the α, β and D lines. The refractometer was calibrated with pure water and the temperature desired was maintained by a current of water from a thermostat regulated to ±0.01°, the temperature of which had been checked with two Bureau of Standards thermometers. The refractometer prism was at the temperature indicated. Determinations were made at 20, 25 and 45.3° and are given in Table IV. Table V gives the molecular refractions and dispersions at 25°, calculated by the Lorentz–Lorenz formula, and by the more exact empirical formula of Eykman.[6]

[a] From data at 20°.

Critical Temperature of Solution.—The critical temperature of solution of each hydrocarbon was measured in freshly distilled dry aniline having a boiling range <0.1°. Known amounts of aniline and the hydrocarbons were sealed in tubes and placed in a holder which was immersed in a large insulated water-bath. The bath was provided with an efficient stirrer and the tubes were continuously shaken while observations were being made. The Critical Temperature of Solution was observed on raising and lowering the temperature of the bath, and the rate of heating and cooling was such that the values obtained on heating and cooling checked to 0.1°. Temperatures were measured with a Beckmann thermometer which was frequently checked against two standard instruments. The results are believed to be reproducible to only ±0.1° because of the

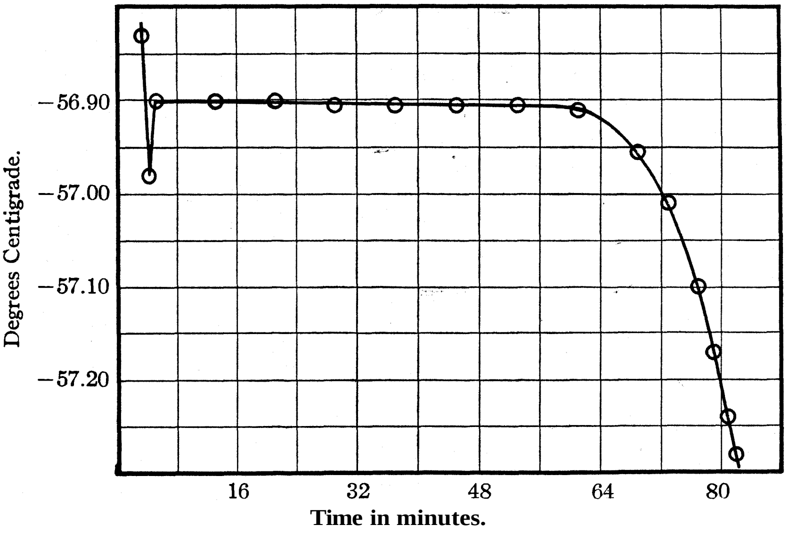

Fig. 4.----Octane.

personal factor involved in judging the exact temperature of complete solution. Fig. 9 shows the results obtained.

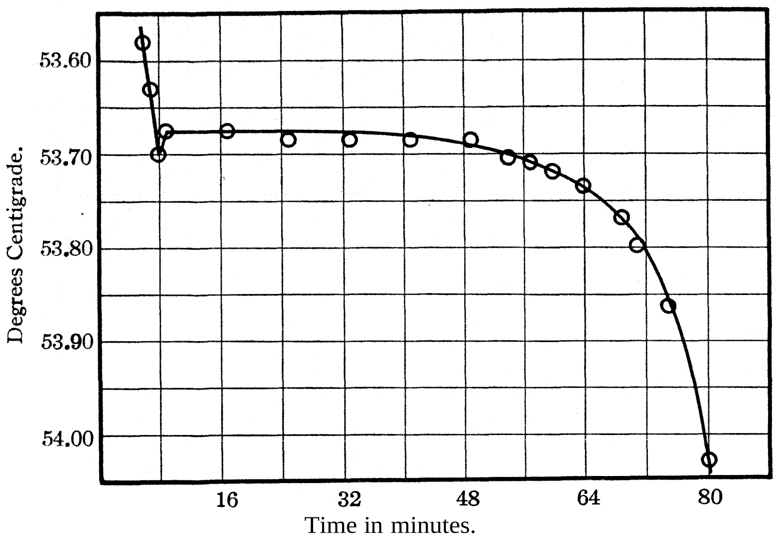

Fig. 5.—n-Nonane.

Viscosities.—Viscosities were measured in a pyrex viscometer of the type recommended by Washburn and Williams.[7] In view of the element of uncertainty attendant to the use of a kinetic energy correction,[8] the dimensions of the instrument were so adjusted that the kinetic energy correction amounted to less than 0.5% of the viscosity value in the case of n-pentane. The correction was neglected in computing the viscosities. The temperature was controlled to ±0.02° during the measurements; the values obtained are accurate to 0.5%.

Other Properties.—Several other properties have been

Empirical Relation Involving the Boiling Points, Molecular Weight, Refractive Indices and Densities.—Nekrasov[11] has proposed the relation $T\frac{\sqrt{MR}}{M-MR} = \text{constant}$, where T is the boiling point in °K., M is the molecular weight, and MR is the molecular refraction calculated by means of the Lorentz–Lorenz formula. He computed the constants of the normal paraffins by using data from the Landolt–Börnstein tables. They are reported in the second column of Table VII. They seem to exhibit a

Summary

The normal paraffin hydrocarbons, from pentane to dodecane inclusive, have been prepared from a common source, by a single method, and in a comparable state of purity. Their boiling points, freezing points, densities, refractive indices, viscosities and critical temperature of solution in aniline have been determined. Evidence is presented to support the degree of accuracy claimed for the measurements. The boiling points and molecular refractions have been correlated by means of the Nekrasov equation.

THE THERMAL DECOMPOSITION OF ORGANIC COMPOUNDS FROM THE STANDPOINT OF FREE RADICALS. I. SATURATED HYDROCARBONS

BY F. O. RICE

RECEIVED MARCH 12, 1931 PUBLISHED MAY 6, 1931

When an organic compound decomposes, we may assume that it is broken up into two or more radicals depending on the number of bonds in the molecule. These radicals fly apart and the probability that they meet again and react is so small that we can neglect it. A radical produced in this way may do one of three things: first, it may react with one of the surrounding molecules; second, it may decompose into a compound and a smaller radical; or, third, it may diffuse to the wall and be absorbed there. In order to simplify our problem we will consider only a small fractional decomposition (a maximum of 5 to 10%) of the organic compound. Under these conditions the radicals produced can react only with the original substance and our problem is much less complicated. On the other hand, if we allow the organic compound to decompose to a considerable extent, the radicals react not only with the original compound but also with the products of the reaction, and the whole problem becomes hopelessly involved.

We can proceed with some confidence to examine the mechanism of the decomposition of organic compounds from this point of view because the actual existence of the simple alkyl radicals has now been demonstrated. Paneth and Hofeditz[1] heated lead tetramethyl in a rapid current of hydrogen and showed that the methyl groups were carried along the tube and could be made to react as far as 40 cm. from their point of origin. A later report by Paneth and Lautsch[2] stated that by means of similar experiments they had been successful in preparing the free ethyl radical. Less direct, although equally convincing, experiments have been made by Taylor and Jones,[3] in which they initiated the polymerization of ethylene by ethyl groups formed in the decomposition of lead or mercury alkyls.

The necessity for the use of free radicals in explaining the mechanism of organic decompositions becomes very evident even in the decompositions of fairly simple organic compounds. Propane decomposes into propylene and hydrogen, and it is conceivable that this occurs by the separation of a hydrogen molecule formed by two hydrogen atoms from adjacent carbon atoms; but it also breaks up into methane and ethylene, and for this to occur a hydrogen atom must jump from a 1 position to a 3 position, a

behavior which to say the least would be very remarkable.[4] Even more improbable mechanisms must be used to represent the decomposition of more complicated compounds.

When a paraffin hydrocarbon decomposes, we may assume that a C–C bond or a C–H bond breaks, and that this occurs in different ways depending on the complexity of the molecule. In order to determine the nature of the different fragments it is necessary to obtain an estimate of the strength of the different bonds present. From thermochemical measurements,[5] the heat of formation of methane from gaseous carbon and gaseous hydrogen atoms is

$$C_g + 4H_g \longrightarrow CH_{4g} + 373.2 \text{ kg. cal.}$$

which gives for the strength of the C–H bond in methane the value **93.3** kg. cal. A similar calculation for ethane gives

$$2C_g + 6H_g \longrightarrow C_2H_{6g} + 630.8 \text{ kg. cal.}$$

The strength of the C–H bonds in ethane will probably be slightly less than that of the C–H bonds in methane, but for the purpose of calculating the strength of the C–C bond we may assume that the C–H bond in methane and ethane has the same strength; there are six C–H bonds in ethane so that the strength of the C–C bond in ethane is $630.8-(6 \times 93.3)=71.0$ kg. cal.[6] It is obvious therefore that any breaking of a C–H bond is wholly negligible compared with that of a C–C bond. Paraffin hydrocarbons therefore decompose only through rupture of a C–C bond, thus producing two free radicals which fly apart and whose fate we will now consider.

A methyl group formed in this way probably undergoes only one reaction, namely, it takes a hydrogen atom from a molecule of the surrounding hydrocarbon to form methane and leave a free radical containing the same number of carbon atoms as the original hydrocarbon. It is true that this reaction will require some energy of activation, but even if it requires as much as 50,000 cal. it will go a great deal faster than the decomposition of the original hydrocarbon which requires a minimum activation energy of 71,000 cal. Furthermore, this process can occur even if the C–H bonds in methane and in the hydrocarbon have the same strength and it is

---

[4] It is possible, of course, that one of the methyl groups might take one of the adjacent hydrogen atoms and the ethylidene radical then rearrange to ethylene; this mechanism, however, is not much better and could not occur in the reaction $CH_3COCH_3 \longrightarrow CH_4 + CH_2{=}CO$.

[5] The necessary data were taken from the "International Critical Tables," Volume V. Similar calculations have been made by Fajans, *Ber.*, 53, 643 (1920); 55, 2826 (1922); see also Weinberg, *ibid.*, 53, 1347, 1353, 1519 (1920); Hückel, *ibid.*, 55, 2839 (1922); Thiel, *ibid.*, 55, 2844 (1922).

[6] These figures will be used in the discussion and calculations but they are by no means certain, and will be discussed in greater detail in a separate communication: See Ellis, Phys. Rev., 33, 27 (1929); Mecke, *Nature*, 125, 527 (1930); Iredale and Mills, *ibid.*, 126, 604 (1930); Mecke, *Z.* physik. *Chem.*, [B] 7, 108 (1930); Hogness, paper presented at Indianapolis Meeting, American Chemical Society, April, 1930.

greatly favored by the condition which we have imposed, namely, a small percentage decomposition of the original hydrocarbon and therefore a small percentage of methane present. The methyl radical has a high chance of colliding with the hydrocarbon molecule and combining with one of its hydrogen atoms, but the hydrocarbon radical produced collides mainly with hydrocarbon molecules and only rarely with a methane molecule; furthermore, the process of methane formation from the free methyl group is also favored by the fact that the C–H bonds in methane are stronger than those in any other hydrocarbon. However, since heats of combustion are approximately additive, this difference is not great and can at most amount to 3 or 4 kg. cal. If we assume, for example, a difference of 2 kg. cal. in the C–H bonds of methane and the hydrocarbon under consideration, we can calculate the relative probability of loss of a hydrogen atom by a methane molecule or by a hydrocarbon molecule, when the two substances are present in equal concentrations. At 600° the process, CH_3 + hydrocarbon = CH_4 + hydrocarbon-radical, is $e^{2000/2 \times 873} = 3.2$ times more probable than the reverse reaction.

It is obvious that in the decomposition of hydrocarbons, radicals higher than methyl will be produced and we shall now discuss their possible behavior. Unlike the methyl group they can undergo two kinds of reactions; first, they may take a hydrogen atom from the surrounding hydrocarbon molecules and form a saturated hydrocarbon containing the same number of carbon atoms in the molecule; or, second, they may decompose either by giving off a hydrogen atom and forming a compound containing the same number of carbon atoms as the original hydrocarbon or they may break into a compound and a smaller free radical. This behavior may be best discussed with reference to a special example.

From the preceding discussion it will be seen that propane can decompose in one way only, namely, into a free methyl group and a free ethyl group. The resulting methyl group can undergo only one reaction, forming methane, but there are two possibilities for the ethyl group; it can take a hydrogen atom from one of the surrounding propane molecules to form ethane or it can decompose into ethylene and a hydrogen atom. It is now necessary to examine whether this last reaction can occur to an appreciable extent. The heat of formation of ethylene from gaseous carbon and gaseous hydrogen atoms is

$$2C_g + 4H \longrightarrow C_2H_{4g} + 497.0 \text{ kg. cal.}$$

The hydrogen atoms in ethylene are probably more strongly bound than those in methane, but as a first approximation we may assume that they are identical and we can thus calculate[5] the strength of the C=C bond to be $497.0 - (4 \times 93.3) = 123.8$ kg. cal. Therefore when a hydrogen atom flies off from the ethyl radical, a single bond becomes a double bond and thus $123.8 - 71.0 = 52.8$ kg. cal. becomes available. The energy necessary to break a C–H bond is 93.3 kg. cal., so that at least 93.3−52.8=40.5 kg. cal. of activation energy must be provided. Since the propane decomposition requires a heat of activation of at least 71.0 kg. cal., a rough estimate of the ratio of its decomposition to that of the decomposition of the ethyl radical into ethylene and hydrogen atoms is given by $e^{71000-40500/RT}$; for 600° and equal concentrations of propane and ethyl groups this ratio is $1:10^{7.5}$.

It is possible therefore, through a process of internal compensation, for a free radical to decompose into a hydrogen atom and a compound containing a double bond; the formation of the double bond contributes to the activation energy necessary to decompose the radical and thus permits the separation of a free hydrogen atom. An ethyl radical might also decompose into a methyl radical and the methylene radical, but this reaction would require a minimum activation energy of 71 kg. cal., and is therefore much less probable than the decomposition into ethylene and a hydrogen atom, which requires only 40.5 kg. cal.

It does not seem possible to calculate the relative probabilities of the two reactions

$$CH_3CH_2 + CH_3CH_2CH_3 \longrightarrow C_2H_6 + \text{propyl or isopropyl radical, and}$$
$$CH_3CH_2 \longrightarrow CH_2{=}CH_2 + H$$

but we can predict that dilution with an inert gas will diminish the bimolecular formation of ethane and leave the unimolecular decomposition unaffected; raising the temperature should also favor the ethylene reaction, since ethylene becomes relatively more stable than ethane at high temperatures.

When a hydrogen atom is removed from propane by a methyl or an ethyl group, either a free n-propyl or free isopropyl group results. The n-propyl radical can break up in a variety of ways, such as $CH_3CH_2CH_2 \longrightarrow CH_2{=}CH_2 + CH_3$, or $CH_3CH_2CH_2 \longrightarrow CH_3CH{=}CH_2 + H$, or $CH_3CH_2CH_2 \longrightarrow CH_3CH_2 + CH_2$. The first reaction is the most probable one since its minimum activation energy is only 18.2 kg. cal., as compared with 40.5 kg. cal. for the second and 71 kg. cal. for the third reaction. The isopropyl radical can also decompose in a variety of ways, but here again we find that the reaction

$$CH_3CHCH_3 \longrightarrow CH_2{=}CHCH_3 + H$$

is very much more probable than any other since it requires a minimum activation energy of 40.5 kg. cal. With hydrocarbons higher than propane we obtain the corresponding higher radicals and these can decompose in a great variety of ways; in every case, however, we can make calculations similar to those made for the propyl and isopropyl radicals and we find almost without exception that one decomposition is very much more probable than any other.

We see, therefore, that if any free radical R (except methyl) is introduced into a hydrocarbon it can decompose either into a hydrogen atom and a compound containing a double bond or into a smaller free radical and a compound containing a double bond. If a hydrogen atom is produced it will combine with one of the hydrogen atoms of the surrounding hydrocarbon to give a hydrogen molecule and the free radical R' corresponding to the hydrocarbon. This free radical, R', is also formed if the original free radical R combines with one of the hydrogen atoms of the hydrocarbon. The radical R' can only dissociate and will give a compound containing a double bond and either a smaller free radical or a hydrogen atom. Whichever is produced will then start a new cycle of reactions in which it is regenerated and this process presumably may go on for a great number of times.

Organic decompositions are therefore regarded as chain reactions in which certain atoms or radicals start a cycle of reactions at the end of which they are regenerated and start a new cycle. It follows, therefore, that the composition of the products is practically independent of the primary decomposition of the hydrocarbon and is determined almost exclusively by the chain cycle; this of course is only true if the chains are fairly long, *i. e.*, if they consist of 100 or more cycles. The atoms or groups which are regenerated are called carriers,[7] in order to distinguish them from other radicals which do not carry on the chain; the carriers are different for different reactions and are sometimes not produced in the primary decomposition but only at the end of the first chain cycle; since in the succeeding cycle the carrier is converted into a paraffin hydrocarbon, the carriers determine the saturated part of the products of the decomposition. The carriers may be destroyed in various ways, although combination through ternary collisions is probably the most important; recombination may also occur to some extent on the walls of the vessel but this effect cannot be very great because an increase of the surface to volume ratio does not appreciably affect the rate of decomposition.

Up to the present we have assumed that the C–H bond in all hydrocarbons and radicals is the same, and this is undoubtedly true in most cases to within 1 or 2%. However, before considering in detail the decomposition of the various hydrocarbons, it seems desirable to try to make an estimate of this small correction for the different C–H bonds. If we consider, for example, a free methyl group surrounded by molecules of propane, two side reactions can occur, according as the methyl group combines with a primary hydrogen atom or with a secondary hydrogen atom; and if all the hydrogen atoms of propane were exactly alike, the relative probabilities of the two reactions would be 6:2. The experimental results[8] for small fractional decompositions of propane show that

---

[7] See Lewis, THIS JOURNAL, 52, 3120 (1930).

[8] Pease and Durgan, *ibid.*, 52, 1266 (1930).

the gases contain about 30% CH_4 and 20% H_2 and if we assume that all the hydrogen atoms are alike the calculated values are 37.5% CH_4 and 12.5% H_2; but undoubtedly the secondary hydrogen atoms are more loosely bound and if we assume that the strength of the secondary C–H bond is 1200 cal. less than the primary C–H bond, the calculated and the experimental values agree.

This value of 1200 cal. was therefore fixed arbitrarily and was assumed to be the same for all secondary C–H bonds; similarly, the strength of a tertiary C–H bond was taken arbitrarily as 4000 cal. less than the strength of a primary C–H bond. Table I was drawn up on the basis of these figures; a primary C–H bond is supposed always to have the same strength, a secondary C–H bond 1200 cal. less and a tertiary C–H bond 4000 cal. less. It is not true, of course, that all primary C–H bonds or all secondary C–H bonds have the same strength, but we can reasonably assume that the difference between two primary C–H bonds is small compared with the difference between primary and secondary C–H bonds. When measurements of the strengths of bonds can be made more precise it will no doubt be possible to assign slightly different values within the different classes of C–H bonds.

Column *2* gives the relative chance of loss of one particular hydrogen atom from a hydrocarbon, leaving a free radical, at 550° and columns 3 and 4 contain the same calculations for 600 and 650°; column 5 contains a statistical factor to take care of the number of hydrogen atoms of the particular kind available; multiplying by this factor we obtain columns 6, 7 and 8 which give the relative probabilities of radical formation by loss of any hydrogen atom of a particular kind from the different hydrocarbons at 550, 600 or 650°, respectively.

TABLE I

RELATIVE PROBABILITIES OF RADICAL FORMATION FROM DIFFERENT HYDROCARBONS

The remaining part of this paper will be devoted to applying this concept to particular examples. In each case a series of equations will be given representing the course of the decomposition. The primary reactions are designated by the letter P and consist of the breaking of a C–C bond in different ways depending on the complexity of the molecule. Usually some of these radicals decompose or react with the surrounding hydrocarbon molecules in such a manner that they are not regenerated and these secondary reactions (S) are also given. However, the chain reactions designated by the letter A are the most important because they determine principally the composition of the products. An examination of these chain reactions will show that many of the radicals produced in the primary or secondary changes disappear in one chain cycle and the carriers formed determine the amount of saturated hydrocarbons and hydrogen in the products. The relative probabilities of the different chain reactions are given in Table I and determine the composition of the products; this has been calculated for different hydrocarbons and compared with such experimental data as are available.

Ethane.—The thermal decomposition of ethane may be represented as

P_1 $CH_3CH_3 \longrightarrow 2CH_3-$
S_1 $CH_3CH_3 + CH_3- \longrightarrow CH_4 + CH_3CH_2-$
S_2 $CH_3CH_2- \longrightarrow CH_2{=}CH_2 + H$
A $CH_3CH_3 + H \longrightarrow H_2 + CH_3CH_2- \longrightarrow H_2 + CH_2{=}CH_2 + H$

The decomposition of ethane is particularly simple because there is only one kind of chain cycle and one carrier, namely, the hydrogen atom. The decomposition should produce, therefore, ethylene and hydrogen in equal proportions providing the chains are fairly long, consisting of perhaps one hundred or more cycles. If the chain is very short and consists of only three or four cycles, there should be a considerable amount of methane present in the gases. The amount of methane present is of very great importance in connection with this proposed mechanism, because it enables us to calculate the number of chain cycles per hydrogen atom produced from a primary and secondary reaction or, in other words, the length of the chain. One molecule of methane is formed for every atom of hydrogen produced from the primary decomposition, and one molecule of hydrogen is produced in each chain cycle; consequently the ratio of H_2 to CH_4 should be the length of the chain.

Propane.—The mechanism for the decomposition of propane may be represented as

P_1 $CH_3CH_2CH_3 \longrightarrow CH_3CH_2- + CH_3-$
S_1 $CH_3CH_2- \longrightarrow CH_2{=}CH_2 + H$
S_2 $CH_3CH_2- + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH_2CH_2- \longrightarrow C_2H_6 + CH_2{=}CH_2 + CH_3-$
S_3 $CH_3CH_2- + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH(CH_3)- \longrightarrow C_2H_6 + CH_3CH{=}CH_2 + H$

$$A_1\quad CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH_2CH_2- \longrightarrow RH + CH_2{=}CH_2 + CH_3-$$
$$A_2\quad CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH(CH_3)- \longrightarrow RH + CH_3CH{=}CH_2 + H$$
$$R = CH_3-,\ H$$

The decomposition is somewhat more complicated than that of ethane since two alternative chain mechanisms A_1 and A_2 can occur depending on whether the carrier group reacts with the primary or secondary hydrogen atom of propane. Assuming the chains to be fairly long, the products must be mainly determined by Equations A_1 and A_2, and must consist of $50\%(CH_4 + H_2) + 50\%(CH_2{=}CH_2 + CH_3CH{=}CH_2)$. The ratio of methane to hydrogen and of ethylene to propylene should vary with the temperature and is given by the relative probabilities of reactions A_1 and A_2. Using the relative probabilities given in Table I, the analysis of the products has been calculated, and is given in Table II together with some experimental results taken from a paper by Pease and Durgan.[8] Since reactions S_2 and S_3 produce ethane, we should find a small percentage of this substance in the products, the amount depending upon the length of the chain; this will be given by the ratio $(CH_4 + H_2) : C_2H_6$.

TABLE II

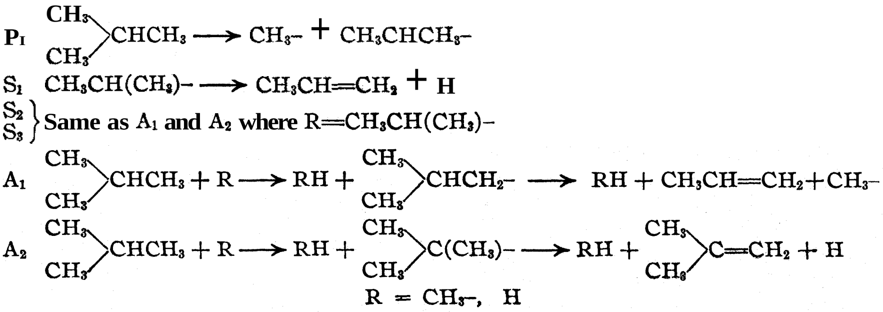
DECOMPOSITION OF PROPANE

Upper Part: Pease and Durgan's results
Lower Part: Values calculated from Table I

Temp., °C.	Decomp., %	H_2, %	CH_4, %	C_2H_4, %	C_2H_6, %
625	17	21	31	48	
625	26	18.5	34.5	47	
650	15	22	28	50	
650	21	21.5	31	47.5	
550	5-10	21.4	29.6	29.6	20.4
600	5-10	20.0	30.0	30.0	20.0
650	5-10	19.6	30.5	30.5	19.5

Some C_2H_6 will be present, since it is formed in reactions S_2 and S_3.

Isobutane.—The decomposition of isobutane may be represented as



$$P_1\quad \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>CHCH_3 \longrightarrow CH_3- + CH_3CHCH_3-$$
$$S_1\quad CH_3CH(CH_3)- \longrightarrow CH_3CH{=}CH_2 + H$$
$$\left.\begin{matrix}S_2\\ S_3\end{matrix}\right\}\text{Same as } A_1 \text{ and } A_2 \text{ where } R{=}CH_3CH(CH_3)-$$
$$A_1\quad \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>CHCH_3 + R \longrightarrow RH + \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>CHCH_2- \longrightarrow RH + CH_3CH{=}CH_2 + CH_3-$$
$$A_2\quad \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>CHCH_3 + R \longrightarrow RH + \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>C(CH_3)- \longrightarrow RH + \begin{matrix}CH_3\\ \\ CH_3\end{matrix}\!\!>C{=}CH_2 + H$$
$$R = CH_3-,\ H$$

The chain mechanism is given by Equations A_1 and A_2, from which it will be seen that the only carriers are CH_3^- and H. The decomposition products should consist therefore of 50% (H_2 + CH_4) + 50% (CH_2=$CHCH_3$ + $(CH_3)_2C$=CH_2) and the ratio of methane to hydrogen should be the same as the ratio of propylene to isobutylene. Table III contains some experimental results taken from a paper by Pease and Durgan and also the calculated results. Pease and Durgan find small quantities of ethane in the products but there does not seem to be any way of accounting for this on the basis of the proposed mechanism; methane together with a small quantity of propane produced by reactions S_2 and S_3 should be the only paraffin hydrocarbons present.

TABLE III

DECOMPOSITION OF ISOBUTANE

Upper Part: Pease and Durgan's results
Lower Part: Calculated using Table I

Temp., °C.	Decomp., %	H_2, %	CH_4, %	C_2H_6, %	C_2H_4, %	C_3H_8, %	C_4H_{10}, %

600	5–10	26.2	23.8	0	0	26.2	23.8
650	5–10	24.5	25.5	0	0	24.5	25.5

n-Butane.—The decomposition may be represented as

P_1 $CH_3CH_2CH_2CH_3 \longrightarrow CH_3{-} + CH_3CH_2CH_2{-}$
P_2 $CH_3CH_2CH_2CH_3 \longrightarrow 2CH_3CH_2{-}$
S_1 $CH_3CH_2CH_2{-} \longrightarrow CH_2{=}CH_2 + CH_3{-}$
$\left.\begin{matrix}S_2\\S_3\end{matrix}\right\}$ Same as A_1 and A, where $R{=}CH_3CH_2CH_2{-}$

$$A_1\quad CH_3CH_2CH_2CH_3 + R{-} \longrightarrow RH + CH_3CH_2CH_2CH_2{-} \longrightarrow$$
$$RH + CH_2{=}CH_2 + CH_3CH_2{-} \begin{cases} \nearrow CH_3CH_2{-} & A_1' \\ \searrow CH_2{=}CH_2 + H & A_1'' \end{cases}$$
$$A_2\quad CH_3CH_2CH_2CH_3 + R \longrightarrow RH + CH_3CH(CH_2CH_3){-} \longrightarrow$$
$$RH + CH_3CH{=}CH_2 + CH_3{-}$$
$$R = CH_3{-},\quad CH_3CH_2{-},\quad H$$

Equations A_1 and A_2 give the chain mechanism in which the carrier groups are methyl and ethyl groups and hydrogen atoms. A complication is introduced into reaction A_1 because the carrier group may react with the surrounding butane molecules or may decompose into ethylene and hydrogen atoms. If none of the ethyl groups produced in the chain mechanism decomposes, the products would consist of 50% (CH_4 + C_2H_6) + 50% (CH_2=CH_2 + CH_3CH=CH_2). On the other hand, if all of the ethyl groups produced in the chain mechanism decomposed, the products would consist of 40% (H_2 + CH_4) + 60% (CH_2=CH_2 + CH_3CH=CH_2). Table IV contains some experimental results obtained by Pease and Durgan on the decomposition of n-butane and also the calculated results using Table I. Since we do not know the relative probabilities of reactions

A_1' and A_1'', we cannot calculate the relative amounts of ethane and hydrogen; however, it is clear that raising the temperature should favor the production of hydrogen because ethylene becomes relatively more stable than ethane at higher temperatures: dilution with an inert gas would have the same effect because the bimolecular formation of ethane would be retarded and the unimolecular formation of hydrogen atoms would not be affected. The products should contain a small amount of propane produced by reactions S_2 and S_3 and this amount will be determined by the length of the chain.

TABLE IV

DECOMPOSITION OF *n*-BUTANE

Upper Part: Pease and Durgan's results
Lower Part: Calculated using Table I

Temp., °C.	Decomp.. %	CH_4, %	H_2, %	C_2H_6, %	C_2H_4, %	C_3H_6, %
600	18.5	33.5	4.5	11	51	
625	22.0	31.0	5.0	13	51	
650	26.0	30.0	6.0	12	52	
550	5–10	29.0	21.0		21.0	29.0
600	5–10	28.5	21.5		21.6	28.5
650	5–10	28.0	22.0		22.0	28.0

The relative amounts of H_2 and C_2H_6 cannot be predicted, but increase in temperature or dilution with an inert gas would increase the ratio of H_2 to C_2H_6. The figures for C_2H_4 and C_3H_6 have been calculated assuming that reaction A_1 is negligible. The products will contain a small amount of propane produced by S_2 and S_3.

***n*-Pentane.**—The decomposition may be represented as

P_1 $\mathrm{CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_3CH_2CH_2CH_2{-} + CH_3{-}}$

P_2 $\mathrm{CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_3CH_2CH_2{-} + CH_3CH_2{-}}$

S_1 $\mathrm{CH_3CH_2CH_2CH_2{-} \longrightarrow CH_2{=}CH_2 + CH_3CH_2{-}}$

S_2 $\mathrm{CH_3CH_2CH_2{-} \longrightarrow CH_2{=}CH_2 + CH_3{-}}$

$\left.\begin{array}{l} S_3 \\ S_4 \\ S_5 \end{array}\right\}$ Same as A_1, A_2 and A_3 where $\mathrm{R{=}CH_3CH_2CH_2CH_2{-}}$

A_1 $\mathrm{CH_3CH_2CH_2CH_2CH_3 + R{-} \longrightarrow RH + CH_3CH_2CH_2CH_2CH_2{-} \longrightarrow}$

$$\mathrm{RH + CH_2{=}CH_2 + CH_3CH_2CH_2{-}} \begin{array}{ll} \nearrow \mathrm{CH_3CH_2CH_2{-}} & A_1' \\ \searrow \mathrm{CH_2{=}CH_2 + CH_3{-}} & A_1'' \end{array}$$

A_2 $\mathrm{CH_3CH_2CH_2CH_2CH_3 + R{-} \longrightarrow RH + CH_3CH_2CH_2CH(CH_3){-} \longrightarrow}$

$$\mathrm{RH + CH_3CH{=}CH_2 + CH_3CH_2} \begin{array}{ll} \nearrow \mathrm{CH_3CH_2{-}} & A_2' \\ \searrow \mathrm{CH_2{=}CH_2 + H} & A'; \end{array}$$

A3 $\mathrm{CH_3CH_2CH_2CH_2CH_3 + R{-} \longrightarrow RH + CH_3CH_2CH(CH_2CH_3){-} \longrightarrow}$
$\mathrm{RH + CH_3CH_2CH{=}CH_2 + CH_3{-}}$

$\mathrm{RC = H_3{-},\quad CH_3CH_2{-},\quad CH_3CH_2CH_2{-},\quad H}$

We have now a considerably more complicated reaction and it seems desirable to discuss in some detail the reactions that the different radicals can undergo. The methyl group probably does not decompose, and therefore reacts only with the surrounding pentane molecules according to reactions A_1, A_2 and A_3. The ethyl group can either decompose into an ethylene molecule and a hydrogen atom or it can take a hydrogen from the surrounding pentane molecules. We do not know the relative probability of these two reactions and in the calculations I have neglected the decomposition into ethylene and hydrogen atoms. The normal propyl group can react with the surrounding pentane molecules to form propane or it can decompose into propylene and hydrogen atoms; probably both of these reactions occur but here also I have neglected the decomposition into propylene and hydrogen atoms. High temperatures will favor reactions A_1 and A_2 since ethylene becomes relatively more stable at higher temperatures; furthermore, dilution with an inert gas will have the same effect, since it does not affect the unimolecular formation of ethylene but retards the reaction between the radicals and the surrounding hydrocarbon. If we wish to avoid the production of methane and hydrogen the best conditions, so far as reactions A_1 and A_2 are concerned, would be low temperatures and high pressures.

All three amyl radicals produced can decompose through scission of a C—C bond and it is probable that they decompose practically completely in this way. Thus the n-amyl radical would decompose into ethylene and the *n*-propyl radical, and only to a very small percentage into 1-pentene and a hydrogen atom; the first reaction requires a minimum activation energy of 71.0 − (123.8 − 71.0) = 18.2 kg. cal., whereas the second reaction requires 93.3 − (123.8 − 71.0) = 45 kg. cal.; similar considerations govern the decomposition of the other two amyl radicals, so that pentenes should be entirely absent from the reaction products in the early stages of the decomposition.

The chain mechanism gives the following composition for the products: 50% ($CH_4 + C_2H_6 + C_3H_8 + H_2$) + 50% ($CH_2{=}CH_2 + CH_3CH{=}CH_2 + CH_3CH_2CH{=}CH_2$). We have neglected reactions A_1'' and A_2'' which produce ethylene, methane and hydrogen instead of ethane and propane. Table V contains some experimental results obtained by Calingaert[^]

TABLE V

DECOMPOSITION OF *n*-PENTANE

Upper Part: Calingaert's results
Lower Part: Calculated from Table I

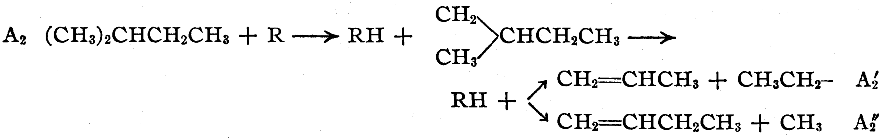
Temp., °C.	Decomp., %	H_2	CH_4	C_2H_6	C_3H_8	C_2H_4	C_3H_6	C_4H_8	C_4H_6
	30	5	12	26	10	10	24	3	6
550	5–10	0"	11.2	22.5"	16.3^b	16.3"	22.5	11.2	0
600	5–10	0"	11.1	22.2"	16.7^b	16.7^c	22.2	11.1	0
650	5–10	0^a	11.0	21.9"	17.1^b	17.1^c	21.9	11.0	0

[a] The calculated % H_2 should be higher and the calculated % C_2H_6 should be lower, because reaction A_2 has been neglected. [b] The % C_3H_8 is too high and the % CH_4 ***too*** low because reaction A_1 has been neglected. [c] C_2H_4 is produced in reactions A_1 and A_2 which have been neglected; this would make the calculated % **still** higher.

aert,[9] who has made a careful study of the decomposition of n-pentane; for comparison the calculated results are also given using the probability values in Table I.

Isopentane.—The decomposition may be represented as

P_1 $(CH_3)_2CHCH_2CH_3 \longrightarrow (CH_3)_2CHCH_2- + CH_3-$
P_2 $(CH_3)_2CHCH_2CH_3 \longrightarrow CH_3CH(CH_2CH_3)- + CH_3-$
P_3 $(CH_3)_2CHCH_2CH_3 \longrightarrow CH_3CH(CH_3)- + CH_3CH_2-$
S_1 $(CH_3)_2CHCH_2- \longrightarrow CH_3CH{=}CH_2 + CH_3-$
S_2 $CH_3CH(CH_2CH_3)- \longrightarrow CH_3CH{=}CH_2 + CH_3-$
S_3 $CH_3CH(CH_3)- \longrightarrow CH_3CH{=}CH_2 + H$
A_1 $(CH_3)_2CHCH_2CH_3 + R \longrightarrow RH + (CH_3)_2CHCH_2CH_2- \longrightarrow RH + CH_2{=}CH_2 + CH_3CH{=}CH_2 + H$



$$A_2 \quad (CH_3)_2CHCH_2CH_3 + R \longrightarrow RH + \begin{matrix}CH_2\diagdown\\ CH_3\diagup\end{matrix}CHCH_2CH_3 \longrightarrow RH + \left\{\begin{matrix}\nearrow CH_2{=}CHCH_3 + CH_3CH_2- & A_2' \\ \searrow CH_2{=}CHCH_2CH_3 + CH_3 & A_2''\end{matrix}\right.$$

A_3 $(CH_3)_2CHCH_2CH_3 + R \longrightarrow RH + (CH_3)_2CHCH(CH_3)- \longrightarrow RH + CH_3CH{=}CHCH_3 + CH_3-$
A_4 $(CH_3)_2CHCH_2CH_3 + R \longrightarrow RH + (CH_3)_2C(CH_2CH_3)- \longrightarrow RH + (CH_3)_2C{=}CH_2 + CH_3-$
$R = H,\ CH_3-,\ CH_3CH_2-$

The chain mechanism is given by Equations A_1, A_2, A_3 and A_4, from which it will be seen that the carrier groups are H, CH_3 and CH_3CH_2. There is no difficulty in deciding how the amyl groups in Equations A_1, A_3 and A_4 will decompose because they can dissociate in only one way if a C–C bond is broken and a compound and a radical formed; on the other hand, the radical $—CH_2(CH_3)CHCH_2CH_3$ can dissociate according to Equations A_2' and A_2'' and in each case a C–C bond is broken and a compound and a free radical formed. As we do not know the relative probability of these two dissociations, reaction A_2'' has been neglected in the calculations. Table VI shows Calingaert's experimental results and the calculated results using the relative probabilities given in Table I.

TABLE VI

DECOMPOSITION OF ISOPENTANE

Upper Part: Calingaert's results
Lower Part: Calculated using Table I

Temp., °C.	Decomp., %	Ha	CH_4	C_2H_6	C_2H_4	C_3H_6	C_4H_8[a]	C_4H_8[b]	C_5H_{10}
600	30	6	30	24	..	15	20		4
550	5–10	6.1	31.6	12.3[c]	6.1	18.4	8.4	24.2	0
600	5–10	6.5	30.4	13.1[c]	6.5	19.6	8.7	21.7	0
650	5–10	7.0	29.1	13.9[c]	7.0	20.9	8.9	20.2	0

[a] $CH_3CH{=}CHCH_3$. [b] $(CH_3)_2C{=}CH_2$. [c] Since reaction A_2'' has been neglected, the % C_2H_6 is too high and the % CH_4 too low; this reaction also produces butene-1.

---

[9] Calingaert, THIS JOURNAL, **45**, 130 (1923).

Neo-pentane.—The decomposition may be represented as

P_1 $(CH_3)_3CCH_3 \longrightarrow (CH_3)_3C- + CH_3-$

S_1 $(CH_3)_3C- \longrightarrow (CH_3)_2C{=}CH_2 + H$

S_2 $(CH_3)_4C + H \longrightarrow H_2 + (CH_3)_3CCH_2-$

S_3 $(CH_3)_3CCH_2- \longrightarrow (CH_3)_2C{=}CH_2 + CH_3-$

A_1 $(CH_3)_4C + R \longrightarrow RH + (CH_3)_3CCH_2- \longrightarrow RH + (CH_3)_2C{=}CH_2 + CH_3-$

$R = CH_3-$

Neo-pentane is of special interest because of the simplicity of the reaction, and it seems surprising that it has not been studied experimentally. There is only one primary reaction, namely, scission into a methyl and a *tert.*-butyl group; this can decompose in only one way, forming isobutylene and a hydrogen atom, which in turn forms a CH_3^- group according to Reactions S_2 and S_3.

Equation A_1 represents the chain mechanism, from which it will be seen that the methyl group is the only carrier and that the products of the reaction should be 50% methane and 50% isobutylene. The amount of hydrogen present is determined by the length of the chain.

Discussion

The application of the concept of chain reactions to the thermal decomposition of organic compounds gives a very satisfactory mechanism for these reactions and it becomes important therefore to consider whether organic compounds really decompose in this manner, especially in view of the fact that the experimental evidence supports the view that paraffin hydrocarbons undergo a simple unimolecular decomposition.[10] In this connection it may be pointed out that whenever two radicals collide, the reaction $2C_nH_{2n+1} = C_nH_{2n+2} + C_nH_{2n}$ can occur by transfer of a hydrogen atom and this reaction liberates a great deal of energy. Consequently we may assume that every collision[11] between two radicals is effective in forming hydrocarbons and, in this way, the chains are broken rather than by collision with the wall. The ordinary way to test for chain reactions is to increase the surface area per unit volume of the containing vessel and this method would fail if the chains are terminated chiefly by collisions between the alkyl radicals. The most promising method of verifying experimentally these proposed mechanisms would appear to be an attempt to prove the existence of the carriers and other fragments by conducting experiments similar to those of Paneth and his co-workers but using hydrocarbons instead of lead alkyls.

Summary

1. When a hydrocarbon decomposes, we may assume that it dissociates into two free radicals which fly apart. Comparison of the strength of a

---

[10] Hurd, "Pyrolysis of Carbon Compounds," Chemical Catalog Co., 1929, pp. 64-68.

[11] Probably a small correction would be necessary to take care of the steric factor.

C–H bond (93.3 kg. cal.) with that of a C–C bond (71.0 kg. cal.) shows that the dissociation occurs only through rupture of a C–C bond; any breaking of a C–H bond is wholly negligible compared with that of a C–C bond.[12]

2. The probability that the two radicals collide again is negligibly small and therefore free radicals produced in this way can only decompose or react with the surrounding hydrocarbon molecules. For example, a free methyl group can take a hydrogen atom from the surrounding hydrocarbon and form methane and a hydrocarbon radical. An ethyl group produced in this way can undergo two reactions; the first is similar to the methyl group and produces ethane and a hydrocarbon radical; the second is a dissociation into ethylene and hydrogen atoms. Radicals higher than ethyl can decompose in a similar manner into an ethylene hydrocarbon and either *a* hydrogen atom or a free radical.

3. This dissociation of free radicals is possible because, in the process, a single bond becomes a double bond; this process of internal compensation releases 52,800 cal. which can contribute to the minimum activation energy (93,000 cal.) necessary to break a C–H bond, or to the minimum activation energy (71,000 cal.) necessary to break a C–C bond.[12]

4. The decomposition of paraffin hydrocarbons is represented as a chain type of reaction in which free hydrogen atoms or free radicals combine with one of the hydrogen atoms of the surrounding hydrocarbon molecule. The hydrocarbon radical then decomposes into a compound and either a smaller free radical or a hydrogen atom. Thus we have a cycle of changes in which certain groups called carriers are regenerated and start a new cycle and this process presumably may go on for a great number of times.

5. The composition of the products is determined therefore almost exclusively by the chain cycle and is practically independent of the primary decomposition of the hydrocarbon. It is possible to calculate the composition of the products when a hydrocarbon is allowed to decompose to a small extent. In these calculations all primary C–H bonds are considered to have the same strength, all secondary C–H bonds 1200 cal less and all tertiary C–H bonds 4000 cal. less than a primary C–H bond. The only arbitrary assumption made in the calculations is the assignment of the relative strengths to the different classes of C–H bonds.

BALTIMORE, MARYLAND

---

[12] The actual values given need not be accepted since it is only the relative strengths of the bonds which are important; it is only necessary that the C–H bond and the C=C bond are each at least 10,000 to 15,000 cal. stronger than the C–C bond.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, UNIVERSITY OF CINCINNATI]

THE ACTION OF HYDROGEN PEROXIDE UPON SIMPLE CARBON COMPOUNDS. I. METHYL ALCOHOL, FORMALDEHYDE AND FORMIC ACID

BY H. SHIPLEY FRY AND JOHN H. PAYNE[1]

RECEIVED MARCH 16, 1931 PUBLISHED MAY 6, 1931

Some perplexing anomalies are found in the reactions of hydrogen peroxide with simple carbon compounds. For instance, as naturally expected, formaldehyde is directly oxidized to formic acid and the latter in turn to carbonic acid, thus

$$HCHO + H_2O_2 \longrightarrow HCOOH + H_2O$$
$$HCOOH + H_2O_2 \longrightarrow H_2CO_3 + H_2O$$

but hydrogen peroxide may, on the one hand, *oxidize* formaldehyde to formic acid *with the liberation of hydrogen*

$$2HCHO + H_2O_2 \longrightarrow 2HCOOH + H_2$$

while on the other hand it will *reduce* carbonic acid to formic acid *with the liberation of oxygen*

$$H_2CO_3 + H_2O_2 \longrightarrow HCOOH + H_2O + O_2$$

Since hydrogen peroxide may thus react either as an oxidizing agent or as a reducing agent, and in some instances in both capacities concurrently, it is not surprising to find in the literature many conflicting reports as to *the* exact character of its reactions; and, too frequently, few if any quantitative data are given to establish the nature of the reactions in question.

Therefore, an extended quantitative study of the action of hydrogen peroxide upon (A) formic acid, (B) formaldehyde and (C) methyl alcohol under a standardized method of procedure in a closed system was undertaken with the following objectives: (1) to determine the yields of all of the products formed, (2) to indicate the equations for all reactions occurring, successively or concurrently, or both, and (3) to check the respective yield of each product formed with the respective quantity of the hydrogen peroxide required in conformity with the equation for the reaction postulated for its formation.

Experimental

Each reaction investigated was run in duplicate with 0.25 mole of the pure carbon compound in a 250-cc. round-bottomed Pyrex flask and successively increasing amounts, from one-sixteenth to one mole, of 30–33% hydrogen peroxide free from organic preservatives. Sufficient water and dilute sulfuric acid were added to make the total volume of each reaction mixture equal to 125 cc. and 0.35 normality.

---

[1] Summary of Doctorate Thesis of John H. Payne, read before the Organic Division of the American Chemical Society, Cincinnati, September 9, 1930.

The flask containing the standardized reaction mixture, submerged in a water-bath, was connected by way of a 30-cm. upright Liebig condenser to calcium chloride drying tubes and thence to a **28-cm.** U-tube filled with granular soda lime for absorption and subsequent weighing of evolved carbon dioxide. The soda lime tube was connected in train to another calcium chloride safety tube and thence to a gasometer for collection over water of the other evolved gases, hydrogen and oxygen, the yields of which were determined by standard methods of gas analysis.

Through the top of the condenser, a glass inlet tube with stopcock extended to the bottom of the reaction flask, thus making provision for the passing of a current of pure nitrogen through the train of apparatus to displace all air before the reaction began and to carry through all evolved gases after completion of the reaction.

After heating the reaction flask until cessation of evolution of any gases, pulverized silica (5 g.) was added to the reaction mixture to effect complete decomposition of any remaining hydrogen peroxide. From the difference between the initial amount of hydrogen peroxide used and the amount equivalent to the oxygen liberated through its direct decomposition, the total quantity of hydrogen peroxide actually engaged in reaction with the carbon compounds, *i. e.*, the *active* hydrogen peroxide, was determined.

The difference between the weights of the soda lime tubes before and after the runs gave the measure of the extent of the oxidation of the carbon compounds to carbonic acid. The yields of the other oxidation product, formic acid, were determined by the standard alkaline permanganate titration method.

Since the products of oxidation of methyl alcohol are successively formaldehyde and formic acid, the first experiments were with formic acid, the second with formaldehyde and the third with methyl alcohol.

A. Formic Acid.—The oxidation of formic to carbonic acid by hydrogen peroxide in acid solution has been studied by several investigators,[2] but in no instance was the amount of *active* hydrogen peroxide correlated quantitatively with the yield of carbonic acid to establish the following equation (a) for the assumed reaction

$$HCOOH + H_2O_2 \longrightarrow H_2CO_3 + H_2O \qquad (a)$$

To verify this equation, duplicate runs were made, as previously described, with pure formic acid (b. p. 100.5°). Five hours' heating of the reaction mixture at 100° were required for the apparent completion of the reaction. The reaction mixtures were diluted to 250 cc. and aliquot portions of 10 cc. were titrated for the unreacted formic acid content, which, subtracted from the initial quantity of formic acid used, gave the quantity

[2] Kastle and Loevenhart, This Journal, 21, 262 (1899); *Am. Chem. J.*, *29*, *424* (1903); Batelli, *Compt. rend.*, 138, 651 (1904); Dakin, *J. Biol. Chem.*, *4*, *227* (1908); Holden and Hatcher, *Trans. Roy. Soc. Canada*, III, 18, *231* (1924).

oxidized to carbonic acid. Neither hydrogen nor carbon monoxide **was** obtained. The data are embodied in Table I.

TABLE I

FORMIC ACID

Run	I Initial H_2O_2, mole	II Initial HCOOH, mole	III H_2CO_3 found mole	IV % Oxidation $HCOOH \rightarrow H_2CO_3$	V $H_2O_2 \propto H_2CO_3$ (Eq. a), mole	VI $H_2O_2 \propto O_2$ (Eq. z), mole	VII Total H_2O_2 Eq. (a) + (z)
a	0.2500	0.2500	0.1896	76.20	0.1896	0.0670	0.2566
b	.2500	.2500	.1883	76.36	.1883	.0666	.2549

It will be noted that the total quantity of hydrogen peroxide used in the closed reaction system, Column VII, is distributed between only two reactions in conformity with the equations (a) and (z)

$$HCOOH + H_2O_2 \longrightarrow H_2CO_3 + H_2O \qquad (a)$$

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \qquad (z)$$

and it is practically equal to the initial quantity of hydrogen peroxide employed, Column I. While only 76% of the initial formic acid was oxidized to carbonic acid, its oxidation conforms completely to Equation a. This confirmation necessarily precedes Parts B (Formaldehyde) and C (Methyl Alcohol) wherein the intermediate formation of formic acid occurs but with the concurrent liberation of hydrogen.

B. Formaldehyde.—Kastle and Loevenhart[2] reported the oxidation of formaldehyde to formic acid but did not mention the liberation of hydrogen, which reaction in basic solution according to Equation b

$$2HCHO + H_2O_2 \longrightarrow 2HCOOH + H_2 \qquad (b)$$

is commonly used for the quantitative determination of formaldehyde. On the other hand, Geisow[3] was unable to isolate any formic acid from either acid or alkaline reaction media, but, obtaining carbonic acid, he assumed the reaction to be represented by the equation *(c)*

$$HCHO + H_2O_2 \longrightarrow H_2CO_3 + H_2 \qquad (c)$$

A few years later, Lyford[4] disputed Geisow's results and postulated a primary reaction liberating hydrogen, Equation b above, to be followed by direct oxidation of formic to carbonic acid, Equation a above. He also assumed direct oxidation of formaldehyde to formic acid according to the equation (d)

$$HCHO + H_2O_2 \longrightarrow HCOOH + H_2O \qquad (d)$$

Notwithstanding the above and other contradictory findings, it appears that the interaction of hydrogen peroxide and formaldehyde involves the reactions represented by Equations b and d, but no conclusions have been drawn previously as to the extent of their concurrence in acid media and in a closed system under standardized conditions.

To this end, six duplicate runs (I–VI) with formaldehyde in the readily

---

[3] Geisow, *Ber.*, 37, 515 (1904).

[4] Lyford, THIS JOURNAL, 29, 1227 (1907).

weighable form of trioxymethylene were conducted with one-sixteenth, one-eighth, one-fourth, one-half, three-fourths and one mole, respectively, of hydrogen peroxide, thereby securing quantitative data indicating the effect of increasing concentrations of hydrogen peroxide upon one-fourth molar quantities of formaldehyde. All reactions proceeded smoothly, being completed after five hours' heating at 60°. In each run the reaction products were formic and carbonic acids, hydrogen and oxygen, and it was possible with the analytical data obtained (Tables II and III) to correlate all of the occurring reactions with the equations

$$\begin{array}{rlllr}
2HCHO + H_2O_2 & \longrightarrow & 2HCOOH & + H_2 & \text{(b)} \\
HCHO + H_2O_2 & \longrightarrow & HCOOH & + H_2O & \text{(d)} \\
HCOOH + H_2O_2 & \longrightarrow & H_2CO_3 & + \text{H20} & \text{(a)} \\
2H_2O_2 & \longrightarrow & 2H_2O & + O_2 & \text{(z)}
\end{array}$$

Table II records the molar quantities of hydrogen peroxide and formaldehyde initially present in the reaction mixtures of the six sets of runs, in duplicate, with the molar quantities of the products formed. The complementary Table III gives the percentage yields of the products as calculated from the respective equations for the proposed reactions, thus facilitating comparison of the extents of the occurrence of the concurrent reactions as affected by the increasing concentrations of hydrogen peroxide. The quantities of hydrogen peroxide reacting according to the several equations are separately recorded in Table III, Columns 4, 5, 6 and 7, and are also totaled in Column 8 in order to check the sum of the ***active*** quantities and the ***inactive*** quantities with the ***initial*** quantity employed.

Table IV summarizes the average percentage extent to which each of the three principal reactions occurred in the presence of the increasing molar concentrations of the hydrogen peroxide employed.

TABLE IV

FORMALDEHYDE: SUMMARY

Run	Mole of H_2O_2	Percentage HCOOH by Reaction (b)	Percentage HCOOH by Reaction (d)	Percentage H_2CO_3 bv Reaction (a)
I	$^1/_{16}$	95.23	4.77	0.00
II	$^1/_8$	92.38	7.62	0.46
111	$^1/_4$	68.33	31.67	23.76
IV	$^1/_2$	35.97	64.03	66.04
V	$^3/_4$	24.09	75.91	87.04
VI	1	18.62	81.38	95.40

The following conclusions may be drawn: (1) in all runs Reactions b and d were concurrent because the ratios of the moles of formic acid formed to the moles of hydrogen liberated were greater than 2:1, the ratio required by Equation b.

(2) Reaction a did not occur in Run I and only to a slight extent in Run II, but with increasing concentrations of hydrogen peroxide, the extent of the occurrence of Reactions a and d regularly increases while that of Reaction b regularly decreases. In other words, the liberation of hydrogen is apparently favored by the lower concentrations of hydrogen peroxide.

(3) In Column 8 of Table III, the sums of the *active* and *inactive* quantities of hydrogen peroxide as calculated in terms of the assumed equations (a), (b), (d) and (z) are equal, within the limits of experimental error, to the initial quantities of hydrogen peroxide employed. Thus these results serve to check the experimental procedure and data with the occurrence of the postulated reactions.

C. Methyl Alcohol.—A review of the literature pertaining to the action of hydrogen peroxide upon methyl alcohol[5] is disconcerting since reaction is both affirmed and denied; some do and others do not record the liberation of hydrogen; the formation of formaldehyde and formic acid is noted, and but few, if any, exact quantitative data and descriptions of experimental conditions have been recorded.

The oxidation of methyl alcohol should first yield formaldehyde according to the equation (f)

$$CH_3OH + H_2O_2 \longrightarrow HCHO + 2H_2O \qquad \text{(f)}$$

Formaldehyde would subsequently be oxidized to formic and carbonic acids in conformity with the previously recorded equations (b), (d), and (a), accompanied by some direct decomposition of hydrogen peroxide, equation (z), as described in the preceding Section B, formaldehyde. Thus, five reactions are involved.

Accordingly, a series of four runs in duplicate were made, as previously described, using one-fourth mole of methyl alcohol with one-eighth, one-fourth, one-half and three-fourths mole of hydrogen peroxide. Longer times were required for the completion of the successive runs at 100°, namely, twenty-four, thirty-six, forty-two and forty-eight hours, respectively. These periods would have been much longer had not the acidity of the reaction mixtures been reduced from 0.35 N to 0.05 N, since the higher acidity stabilizes the hydrogen peroxide and thus retards its oxidizing action.

Another difficulty, the intermediate formation of very volatile methyl formate ($HCOOH + CH_3OH \quad H_2O + HCOOCH_3$) and its possible absorption in the soda lime tubes, was overcome by inserting a Milligan wash-bottle containing concentrated sulfuric acid in the apparatus train between the condenser and first calcium chloride tube. The methyl formate thus was hydrolyzed and yielded carbon monoxide, which was collected in the gasometer, quantitatively determined in the subsequent gas analyses, and its formic acid equivalent added to the yield of formic acid. The yields of formaldehyde were determined by the method of Haywood and Smith.[6]

With the analytical data obtained, it was possible to correlate all of the reactions occurring in terms of the five previously described equations, (f), (b), (d), (a) and (z). The data, calculated equivalents and percentage yields are recorded in Tables V and VI, similarly to the method employed in Tables III and IV of the preceding Section B. For convenience in reference to data, the five reactions are retabulated

IVb	0.05	35.86	64.14	83.54	25.51	4.57	16.38	21.31	31.17	98.94

The following conclusions are drawn from the above data. (1) The products of the oxidation of methyl alcohol are formaldehyde (equation f), formic acid (equations b and d), carbonic acid (equation a) and hydrogen (equation b).

(2) Here also, as in the formaldehyde runs of Part B, the reactions represented by Equations b and d decrease in extent while those represented by Equations a and z increase in extent with increasing concentrations of hydrogen peroxide. Reaction d, however, always occurs to a greater extent than Reaction b, again showing that the liberation of hydrogen is favored by the lower concentrations of hydrogen peroxide.

(3) Column 10 of Table VI affords data showing close agreement between the initial amounts of hydrogen peroxide employed in the several

runs and the sums of the amounts required for the several reactions as calculated on the basis of the proposed equations for the reactions involved.

Grateful acknowledgments are extended to Professor John Uri Lloyd, whose Fellowship in Chemistry made this study possible, and to Dr. H. P. Carveth, President of the Roessler–Hasslacher Chemical Co., who generously donated several shipments of the specially prepared hydrogen peroxide used in this study.

Summary

An extended study of the nature and extent of the action of increasing molar concentrations of hydrogen peroxide in acid media upon methyl alcohol, formaldehyde, and formic acid has confirmed the occurrence of a series of postulated reactions.

The equations for these reactions have been verified by the experimental data with respect not only to the yields of the several products obtained, but also to the quantities of hydrogen peroxide participating in the postulated reactions.

THE ACTION OF HYDROGEN PEROXIDE UPON SIMPLE CARBON COMPOUNDS. II. THE MECHANISM OF THE REACTIONS[1]

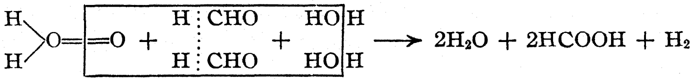
BY H. SHIPLEY FRY AND JOHN H. PAYNE

RECEIVED MARCH 16, 1931 PUBLISHED MAY 6, 1931

Two reaction mechanism schemes have been proposed previously to explain the apparently anomalous liberation of hydrogen when hydrogen peroxide and formaldehyde interact according to equation (b)

$$2HCHO + H_2O_2 \longrightarrow 2HCOOH + H_2 \qquad (b)$$

Briefly stated, Traube's explanation[2] postulates the liberation of hydrogen through the decomposition of water in conformity with the following scheme wherein the hydroxyl radicals of water combine with the aldehyde radicals of formaldehyde to produce formic acid



$$\begin{matrix}H\\ \\ H\end{matrix}\!\!>\!O=\boxed{\begin{matrix} & H\,\vdots\,CHO & & HO \\ =O\ + & \vdots & + & \\ & H\,\vdots\,CHO & & HO\end{matrix}}\begin{matrix}H\\ \\ H\end{matrix} \longrightarrow 2H_2O + 2HCOOH + H_2$$

This scheme also involves, as indicated by the dotted line, dissociation of the aldehyde hydrogen atoms, which combine with the peroxide oxygen atom to form water.

In the other reaction mechanism, Wieland[3] postulates, first, the con-

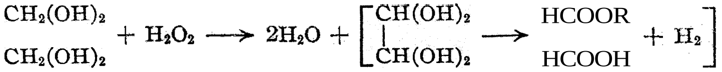
---

[1] Presented before the Organic Division of the American Chemical Society, Cincinnati, September 9, 1930.

[2] Traube, Ber., 16, 123 (1883).

[3] Wieland, *ibid.*, 45,484, 679, 2606 (1912); 46, 3327 (1913); 47, 2085 (1914); 54, 2353 (1921).

version of formaldehyde to formaldehyde hydrate, $CH_2O + H_2O \longrightarrow CH_2(OH)_2$, which then reacts with hydrogen peroxide according to the following scheme wherein the intermediately formed oxidation product, $[CH(OH)_2]_2$, decomposes yielding formic acid and hydrogen



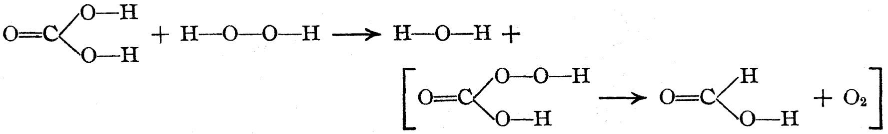
$$\begin{array}{c}CH_2(OH)_2\\ \\ CH_2(OH)_2\end{array} + H_2O_2 \longrightarrow 2H_2O + \left[\begin{array}{c}CH(OH)_2\\ | \\ CH(OH)_2\end{array} \longrightarrow \begin{array}{c}HCOOR\\ \\ HCOOH\end{array} + H_2\right]$$

The change noted within the brackets involves not only decomposition, but also rearrangement reactions.

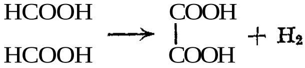
A third reaction mechanism scheme, less involved than the preceding schemes, is now proposed. It explains not only the liberation of hydrogen when formaldehyde is oxidized to formic acid, but also the liberation of oxygen when carbonic acid is reduced to formic acid, as well as other reactions wherein neither hydrogen nor oxygen is evolved. The latter, or the normal oxidation reactions, will be considered first.

It is here assumed that hydrogen peroxide displays a type of reaction which may be termed "*perhydrolysis*," that is, *a* double decomposition reaction involving *hydrogen peroxide* in precisely the same manner that *hydrolysis* is a double decomposition reaction involving *water*. Thus, for instance, the normal oxidation of formaldehyde to formic acid is a *perhydrolysis* reaction

The reduction of carbonic acid by hydrogen peroxide with the liberation of oxygen, $H_2CO_3 + H_2O_2 \longrightarrow HCOOH + H_2O + O_2$, may likewise involve *perhydrolysis*, forming percarbonic acid, which, in turn, yields formic acid through the liberation of oxygen, all in conformity with the reaction scheme

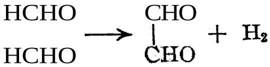


An explanation of the other apparently anomalous reactions, namely, the oxidation of formaldehyde to formic acid with the liberation of hydrogen (equation b), requires an additional assumption which is suggested by the well-known decomposition of sodium formate yielding sodium oxalate and hydrogen



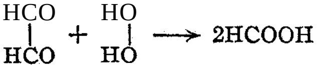
$$\begin{array}{c}HCOOH\\ \\ HCOOH\end{array} \longrightarrow \begin{array}{c}COOH\\ | \\ COOH\end{array} + H_2$$

The parallel reaction with formaldehyde would yield hydrogen and glyoxal



$$\begin{array}{c}HCHO\\ \\ HCHO\end{array} \longrightarrow \begin{array}{c}CHO\\ | \\ CHO\end{array} + H_2 \qquad (n)$$

to be followed immediately by the *perhydrolysis* of the intermediately formed glyoxal, yielding two molecules of formic acid



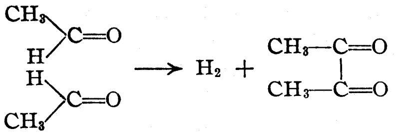
$$\begin{array}{c}\mathrm{HCO}\\|\\\mathrm{HCO}\end{array} + \begin{array}{c}\mathrm{HO}\\|\\\mathrm{HO}\end{array} \longrightarrow \mathrm{2HCOOH} \qquad \text{(o)}$$

The summation of the two equations (n) and (o) gives the complete equation (b)

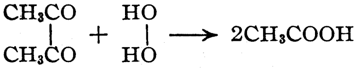
$$\mathrm{2HCHO + H_2O_2 \longrightarrow 2HCOOH + H_2} \qquad \text{(b)}$$

That no intermediately formed glyoxal was isolated is presumably due to the fact that the speed of the perhydrolysis reaction (o) is greater than that of the preceding reaction (n).

Now, if this proposed reaction mechanism has any validity, it should at least predict that the interaction of acetaldehyde and hydrogen peroxide would yield hydrogen or methane, or both hydrogen and methane, in conformity with the following completely parallel reaction mechanism schemes, wherein equations (n') and (n″), (o′) and (o″) and (b') and (b″) are exactly parallel to the above equations (n), (o) and (b), respectively.

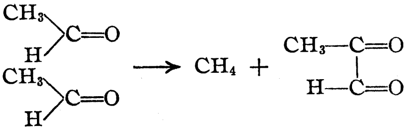


(n′)

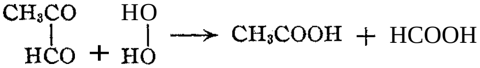


$$\begin{array}{c}\mathrm{CH_3CO}\\|\\\mathrm{CH_3CO}\end{array} + \begin{array}{c}\mathrm{HO}\\|\\\mathrm{HO}\end{array} \longrightarrow \mathrm{2CH_3COOH} \qquad \text{(o′)}$$

$$\text{(n′) + (o′)} \quad \mathrm{2CH_3CHO + H_2O_2 \longrightarrow 2CH_3COOH + H_2} \qquad \text{(b′)}$$



(n″)



$$\begin{array}{c}\mathrm{CH_3CO}\\|\\\mathrm{HCO}\end{array} + \begin{array}{c}\mathrm{HO}\\|\\\mathrm{HO}\end{array} \longrightarrow \mathrm{CH_3COOH + HCOOH} \qquad \text{(o″)}$$

$$(n'' + o'') \quad \mathrm{2CH_3CHO + H_2O_2 \longrightarrow CH_3COOH + HCOOH + CH_4} \qquad \text{(b″)}$$

The liberation of ethane, a third possibility, would necessitate a linkage of carbon atoms, which seems improbable, at least not so likely as the liberation of hydrogen and methane.

The predictions, with respect to the action of hydrogen peroxide upon acetaldehyde in conformity with the above equations (b′) and (b"), derived through the proposed reaction mechanism scheme, were confirmed by extending the experimental method, previously described in Part I, to acetaldehyde which gave the predicted products, hydrogen, methane, acetic acid and formic acid, thus indicating the concurrence of reactions (b') and (b'').

Before tabulating the confirmatory data, it should be noted that the literature affords only one observation[4] of the liberation of hydrogen when hydrogen peroxide interacts with acetaldehyde. No data were recorded.

Geisow[5] attempted to carry the analogy of the liberation of hydrogen according to the formaldehyde reaction, equation (b), to the liberation of methane from acetaldehyde but did not obtain any methane.

Other investigators[6] have severally recorded the formation of acetic, formic and carbonic acids, but none mentions the liberation of hydrogen or methane.

Experimental

Three sets of duplicate runs were conducted using one-fourth mole of pure paraldehyde in each case, varying the quantity of hydrogen peroxide from one-eighth to one-fourth, and one-half mole in solutions of 125 cc. volume containing 0.306 g. of sulfuric acid. In this acid solution the paraldehyde depolymerized to acetaldehyde and the time required for completion of the reaction varied from eighteen to twenty-four hours.

Some of the very volatile acetaldehyde escaped reaction with the hydrogen peroxide. To prevent its absorption in the soda lime tubes, two Milligan wash bottles were interposed as previously described in the runs with methyl alcohol (Part I, Section C). The first wash bottle contained ethyl alcohol, which collected the acetaldehyde vapor; the second contained sulfuric acid, which retained any traces of alcohol or acetaldehyde escaping from the first wash bottle.

The products of the reaction in each run were hydrogen, methane, formic and acetic acids, as predicted in equations (b') and (b''). The predominating reaction, however, was the direct oxidation of acetaldehyde to acetic acid

$$CH_3CHO + H_2O_2 \longrightarrow CH_3COOH + H_2O$$

Formic and carbonic acids were also formed in secondary reactions between acetic acid and hydrogen peroxide without the accompanying evolution of hydrogen or methane, as was confirmed in separately conducted runs with acetic acid.

Aliquot fractions of the reaction mixtures in all runs were analyzed for their combined formic acid and acetic acid contents by titration with standard alkali. The formic acid content was determined as previously noted by the mercuric chloride method; the acetic acid content was obtained by difference. All of the analytical data are embodied in Table I.

IIa	2500	.2500	.1422	.0075	.0211	.0044	.0026
IIb	2500	.2500	.1422	.0078	.0231	.0038	.0022
IIIa	,5000	2500	.1870	.0082	.0444	.0035	.0007
IIIb	,5000	.2500	.1775	.0080	.0471	.0036	.0006

Summary

Without attempting to correlate, exactly quantitatively, the molar yields of the products obtained with the reactions involved in their formation, which is not possible because the extreme volatility of the acetaldehyde made its retention in the reaction mixtures impossible, the following conclusions may be drawn from the available data.

1. The yields of the two chief reaction products, *acetic* and *carbonic* acids, increase as increased quantities of hydrogen peroxide are used.

2. Since separately conducted runs with acetic acid and hydrogen peroxide gave formic and carbonic acids without the liberation of hydrogen or of methane, it follows that the hydrogen arises from the oxidation of acetaldehyde to acetic acid as indicated in the proposed equation

$$2CH_3CHO + H_2O_2 \longrightarrow 2CH_3COOH + H_2$$

3. While the maximum yields of hydrogen were obtained with equimolar concentrations of acetaldehyde and hydrogen peroxide, another striking parallel to the formaldehyde reaction (Part I, Section B) is found in the fact that the volumes of methane liberated according to the proposed equation, $2CH_3CHO + H_2O_2 \longrightarrow CH_3COOH + HCOOH + CH_4$, *decrease* with *increasing* concentrations of hydrogen peroxide.

In conclusion, the formation of acetic and formic acids with the concurrent liberation of both hydrogen and methane appears to be in conformity with the above equations for the reactions which were predicted by extending the proposed reaction mechanism scheme to acetaldehyde.

In proposing a new type of reaction mechanism, termed "perhydrolysis," to explain some of the normal and also apparently anomalous reactions of hydrogen peroxide, the authors would guard against the assumption that all reactions of hydrogen peroxide involve "perhydrolysis," for many do not.

Further confirmation of the perhydrolysis mechanism is under way in an extended study of the action of hydrogen peroxide upon other simple carbon compounds.

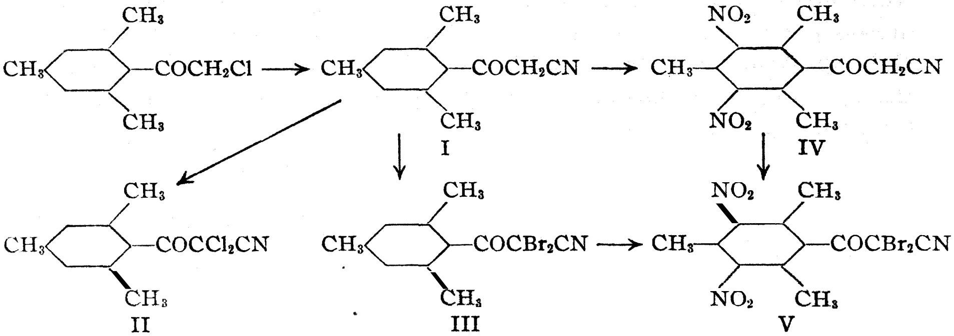
DIHALOCYANOACETYL DERIVATIVES OF MESITYLENE

BY REYNOLD C. FUSON AND REID G. BEVERIDGE

RECEIVED MARCH 16, 1931 PUBLISHED MAY 6, 1931

It has been shown that the halogenation of methyl phenyl ketones by solutions of hypohalites becomes possible when the action of the alkali on the carbonyl group is hindered by the presence of ortho substituents in the benzene ring. Thus when acetomesitylene is shaken for two days with an aqueous solution of sodium hypobromite, tribromoacetylmesitylene is formed.[1] Although the trihaloacetyl compounds so obtained are stable to cold alkali, they can be cleaved in the normal manner by long treatment with hot concentrated solutions of alkali. Work on the cleavage of these and similar trihalomethyl compounds will be reported elsewhere.[2]

A natural extension of this study of halogenation by solutions of hypohalites was its application to ketones having active methylene groups adjacent to the hindered carbonyl. Of these the cyanomethyl ketones offered particular interest because of the remarkable activity of the methylene group. In α-cyanoacetophenone, for example, the hydrogens of the methylene group enolize so readily as to render the compound soluble in alkali. It was to be expected from this that halogenation might proceed much more rapidly with this type of ketone than with those previously examined.



I II III IV V

Accordingly, cyanoacetylmesitylene (I) and di-(cyanoacetyl)-mesitylene (VI) have been prepared and their reaction with hypohalite solutions has been studied. When chloroacetylmesitylene, obtained from mesitylene and chloroacetyl chloride by the method of Collet,[3] is treated with potassium cyanide, cyanoacetylmesitylene (I) is obtained in good yield.

[2] In a recent article Houben and Fischer, *Ber.*, **63B**, 2458 (1930), reported the cleavage of trichloroacetylmesitylene by boiling with a 40% sodium hydroxide solution for two hours.

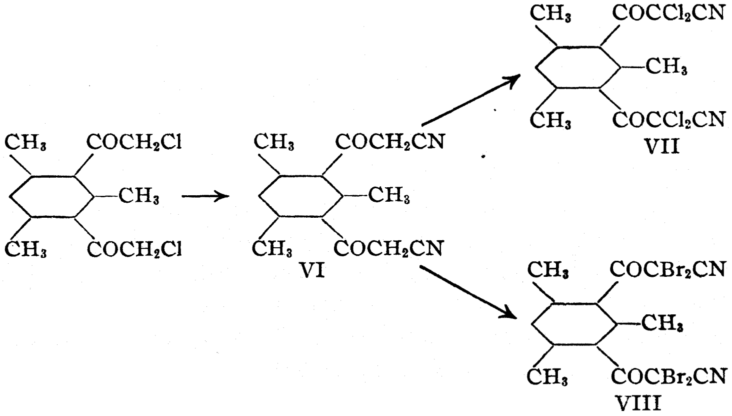
[3] Collet, *Bull. soc. chim.*, [3] 17, 510 (1897).

The cyano ketone is sufficiently acid to decompose potassium cyanide and for this reason it is necessary in the preparation to employ two molecular proportions of the salt for one of the chloro compound.

In an exactly similar fashion, di-(cyanoacetyl)-mesitylene (VI) is obtained from the corresponding dichloro compound.[4] Here, of course, four molecular proportions of potassium cyanide are necessary for every mole of di-(chloroacetyl)-mesitylene used. Both the cyano and the dicyano compounds are readily soluble in aqueous alkali and this property has been used in separating them from impurities such as the unchanged chloro compounds.

The action of hypohalite solutions on these cyano ketones is remarkable because of its rapidity. When the cyano ketone is added to a solution of sodium hypochlorite, for example, the crystals dissolve immediately but the material is almost at once reprecipitated in the form of the chlorinated derivative, dichlorocyanoacetylmesitylene (II). Both this compound and the dibromocyanoacetylmesitylene (111), obtained in an exactly similar manner, are stable to cold solutions of alkalies and are obtained in good yields even when the hypohalite solution is strongly alkaline.

The position of the two bromine atoms in dibromocyanoacetylmesitylene has been checked by the use of dinitrocyanoacetylmesitylene (IV). This compound, which was obtained from cyanoacetylmesitylene by direct nitration, was found to give dinitrodibromocyanoacetylmesitylene (V) when treated with a solution of sodium hypobromite. This same dinitrodibromo compound was obtained when dibromocyanoacetylmesitylene (III) was treated with fuming nitric acid. There can be no doubt then that the two bromine atoms in dibromocyanoacetylmesitylene are situated in the acetyl group.



---

[4] The dichloro compound was prepared by the method of Breed (Bryn Mawr College Monographs, 1, No. 1, p. 7).

Di-(cyanoacetyl)-mesitylene (VI) when treated with solutions of sodium hypochlorite and sodium hypobromite yielded, respectively, di-(dichlorocyanoacetyl)-mesitylene (VII) and di-(dibromocyanoacetyl)-mesitylene (VIII). This process, however, presented a rather puzzling phenomenon. The crystals of the dicyano compound when added to a solution of a sodium hypohalite first dissolved completely. Then after a few seconds the solution became milky as though the neutral tetrahalo compound werd being precipitated. However, this precipitate redissolved rapidly and finally the expected tetrahalo compound separated and remained insoluble. This process is being studied.

Experimental

Cyanoacetylmesitylene[5] (I).—Ten grams of chloroacetylmesitylene was dissolved in 300 cc. of alcohol by boiling under a reflux condenser Four and a half grams of potassium cyanide was dissolved in a small amount of water and the solution was added through the condenser. After the solution had boiled for four hours, the alcohol was evaporated and the residue dissolved in 200 cc. of water. The crude material was precipitated by adding hydrochloric acid. After filtering, the material was dissolved in methyl alcohol and clarified by boiling with bone black. It was recrystallized from dilute methyl alcohol. The compound melted at 108–109° and the yield was 50 to 60% of the theoretical.

Anal. Calcd. for $C_{12}H_{13}ON$: C, 77.0; H, 7.0. Found: C, 76.8; H, 6.8.

Dibromocyanoacetylmesitylene (III).—A solution of sodium hypobromite was made by slowly adding 15 g. of bromine to a cold solution of 15 g. of sodium hydroxide in 150 cc. of water. To this solution 1 g. of cyanoacetylmesitylenewas added. A white crystalline substance formed and after being filtered it was recrystallized from dilute methyl alcohol. The substance melted at 81–82' and the yield was 50 to 60% of the theoretical.

Anal. Calcd. for $C_{12}H_{11}ONBr_2$: Br, 46.4. Found: Br. 46.3.

Dichlorocyanoacetylmesitylene (XI).—A solution of sodium hypochlorite was prepared by bubbling chlorine through a cold solution of 15 g. of sodium hydroxide dissolved in 150 cc. of water. One gram of cyanoacetylmesitylene was added to this solution. A white crystalline substance formed which went into solution on shaking. The solution was allowed to stand for twenty-four hours and was then filtered. The material was recrystallized from dilute methyl alcohol, The substance melted at 38–39° and the yield was 45 to 50% of the theoretical.

Anal. Calcd. for $C_{12}H_{11}ONCl_2$: Cl, 27.7. Found: Cl, 27.6.

Dinitrodibromocyanoacetylmesitylene (V).—One gram of dibromocyanoacetylmesitylene was added to 20 cc. of cold fuming nitric acid (sp. gr. 1.49–1.50). After being allowed to stand for fifteen minutes, the solution was poured into ice water and filtered. The compound was recrystallized from dilute methyl alcohol; it melted at 97–98°. The yield was 85% of the theoretical.

Dinitrocyanoacetylmesitylene (IV).—One gram of cyanoacetylmesitylenewas added to 20 cc. of cold fuming nitric acid (sp. gr. 1.49–1.50). The mixture was allowed to stand for a few minutes, was poured into ice water and filtered. The compound was recrystallized from dilute methyl alcohol. It melted at 170.3 to 171.3° (corr.) and the yield was 35% of the theoretical.

---

[5] This preparation was first carried out by Mr. A. E. Knauf.

Anal. Calcd. for $C_{12}H_{11}O_5N_3$: C, 52.0; H, 4.0. Found: C, 51.8; H, 3.7.

Dinitrodibromocyanoacetylmesitylene.—One gram of dinitrocyanoacetylmesitylene was added to a solution of sodium hypobromite. The solution was allowed to stand for twenty-four hours and then filtered. . The substance was recrystallized from aqueous methyl alcohol and melted at 94–95". The yield was 45% of the theoretical.

Anal. Calcd. for $C_{12}H_9O_5Br_2N_3$: Br, 36.8. Found: Br, 36.6.

Di-(cyanoacetyl)-mesitylene (VI).—Ten grams of di-(chloroacetyl)-mesitylene was dissolved in 300 cc. of alcohol by boiling under a reflux condenser. Five and a half grams of potassium cyanide dissolved in a small amount of water was added through the condenser. After boiling for four hours the alcohol was evaporated and the residue dissolved in 200 cc. of water. The substance was precipitated by adding hydrochloric acid. After filtering, the crude material was dissolved in alcohol and clarified by boiling with bone black. The substance was recrystallized from dilute alcohol and melted at 156–157° (corr.). The yield was 70 to 80% of the theoretical.

Anal. Calcd. for $C_{15}H_{14}O_2N_2$: C, 70.9; H, 5.5. Found: C, 70.6; H, 5.3.

Di-(dichlorocyanoacetyl)-mesitylene (VII).—A solution of sodium hypochlorite was prepared by bubbling chlorine through a cold solution of 15 g. of sodium hydroxide dissolved in 150 cc. of water until the solution became yellow. One gram of di-(cyanoacetyl)-mesitylene dissolved in sodium hydroxide was added to this solution. A white substance formed but went into solution on shaking The solution was allowed to stand for twenty-four hours and then filtered. The substance was recrystallized from dilute methyl alcohol. It melted at 52–53° and the yield was 50 to 60% of the theoretical

Anal. Calcd. for $C_{15}H_{10}O_2N_2Cl_4$: Cl, 36.2. Found: Cl, 36.0.

Di-(dibromocyanoacetyl)-mesitylene (VIII).—A solution of sodium hypobromite was prepared by slowly adding 15 g. of bromine to a cold solution of 15 g. of sodium hydroxide dissolved in 150 cc. of water. One gram of di-(cyanoacetyl)-mesitylene dissolved in sodium hydroxide was added to this solution. After being allowed to stand for a few minutes the substance was filtered and recrystallized from methyl alcohol. The compound melted at 121.2–122.2' (corr.). The yield was 30 to 35% of the theoretical.

Anal. Calcd. for $C_{15}H_{10}O_2N_2Br_4$: Br, 56.1. Found: Br, 55.9.

Summary

1. Cyanoacetylmesitylene and di-(cyanoacetyl)-mesitylene have been prepared from chloroacetylmesitylene and di-(chloroacetyl)-mesitylene, respectively, by treatment with potassium cyanide.

2. Cyanoacetylmesitylene when treated with solutions of sodium hypochlorite and sodium hypobromite has been found to yield, respectively, dichlorocyanoacetylmesitylene and dibromocyanoacetylmesitylene.

3. Dinitrodibromocyanoacetylmesitylene has been prepared, (a) by nitration of dibromocyanoacetylmesitylene and (b) by treating dinitrocyanoacetylmesitylene with a solution of sodium hypobromite.

4. Di-(dichlorocyanoacetyl)-mesitylene and di-(dibromocyanoacetyl)-mesitylene have been obtained from di-(cyanoacetyl)-mesitylene by treatment of the latter with solutions of sodium hypochlorite and sodium hypobromite, respectively.

5. All of these dihalocyanoacetyl compounds have been found to be stable to cold solutions of alkalies.

RESEARCHES ON PYRIMIDINES. CXXII. IMPROVED METHODS FOR THE SYNTHESIS OF OROTIC ACID[1]

BY TREAT B. JOHNSON AND ELMER F. SCHROEDER[2]

RECEIVED MARCH 18, 1931 PUBLISHED MAY 6, 1931

Uracil-4-carboxylic acid (orotic acid) III is the only carboxylated derivative of the pyrimidine cycle which has thus far been shown to occur in nature. It was discovered in milk by Biscaro and Belloni[3] in 1905. Regarding its origin or its function in the animal organism we have at present no information. Chemically speaking, it is an oxidation product of 4-methyl-uracil I, bearing the same structural relationship to this pyrimidine as uracil-5-carboxylic[4] acid IV does to thymine II. Behrend showed in 1910 that 4-methyluracil can be oxidized to the amide of uracil-4-carboxylic acid by potassium ferricyanide, but no one has succeeded in oxidizing thymine to the corresponding uracil-5-carboxylic acid. Furthermore, no one has, thus far, been successful in showing that 4-methyluracil occurs in nature.

(Found in nature)

III

(Found in nature)

IV

The first investigator to prepare a derivative of uracil-4-carboxylic acid III was Müller,[5] who synthesized its ethyl ester by condensation of urea with diethyl oxaloacetate in acid solution. Müller did not prove, however, that he was dealing with a pyrimidine condensation product and it remained for Wheeler[6] of the Yale Laboratory to show, in 1907, that this ester of Müller's yields on saponification a true pyrimidine acid, namely, uracil-4-carboxylic acid III. Behrend and Struve[7] later found

that the amide of this pyrimidine acid is formed by oxidation of 4-methyluracil with potassium ferricyanide in ammoniacal solution, and showed that this is converted into the acid III by the action of alkali. The last investigator to describe the synthesis of uracil-4-carboxylic acid III was Bachstez,[8] who first prepared the ester by Muller's method and then transformed this into its acid III according to the procedure of Wheeler. Bachstez was the first one to prove that this pyrimidine acid III is identical with orotic acid previously separated from milk by Biscaro and Belloni. Behrend and Struve's oxidation method is of no practical value for the synthesis of uracil-4-carboxylic acid and to obtain it in quantity by condensation according to the Müller reaction is difficult on account of the low yield of pyrimidine formed. This is only about 15 to 20% of the theoretical amount.

By reconsideration and extension of our researches on pyrimidine aldehydes, which were discontinued in 1915, we have now been successful in developing a procedure for synthesizing orotic acid which is a great improvement over the methods of preparation described above. Our method is based on the discovery that the 4-aldehydic derivatives of uracil and 2-thiouracil,[9] which can be derived easily from ethyl-γ,γ-diethoxyacetoacetate by condensation with thiourea, are oxidized smoothly to orotic acid by chromic acid without destruction of the pyrimidine ring. The methods of synthesizing 2-thiouracil-4-aldehyde VI and uracil-4-aldehyde V first described by Johnson and Cretcher have been so greatly improved for practical application that orotic acid III can now be made in quantity without any difficulty. Various modifications in technique have been introduced for preparing the acid from different derivatives and these will be discussed in the experimental part of this paper. In every case the pyrimidine acid obtained has been found to be identical with the natural orotic acid. We are greatly indebted to Dr. Bachstez for sending us a generous supply of natural orotic acid obtained from milk, and also its potassium salt, for comparison with our synthetical product.

VI

Experimental Part

Ethyl Diethoxyacetate, $(C_2H_5O)_2CHCOOC_2H_5$.—This ester was prepared by the method of Johnson and Cretcher.[9] The experience of former workers in this Laboratory

---

[8] Bachstez, *Ber.*, 63, 1000 (1930); *Giornale di Chimica Industriale, Ed. Applicata*, 12, 174 (1930).

on the failure of commercial dichloroacetic acid to give satisfactory yields was verified. A very pure acid, best prepared from chloral hydrate according to the directions of Pucher,[10] is necessary. Attempts made to alkylate the moist silver salt of diethoxyacetic acid were not successful. The silver salt must be carefully dried before alkylation by spreading it out in thin layers and allowing it to stand in a vacuum desiccator over sulfuric acid in a dark place for several days. Due to the ease of decomposition, it cannot be dried by heating in a vacuum oven. Working in lots of 200 g. of dichloroacetic acid, 150 g. of the pure ester having a boiling point of 94–98" at 18 mm. pressure is easily obtained. This represents a yield of 55% of the theoretical.

Ethyl-γ,γ-diethoxyacetoacetate, $(C_2H_5O)_2CHCOCH_2COOC_2H_5$.—This β-ketone ester was prepared according to the directions of Johnson and Mikeska.[11] It was found very advantageous to wash the ethereal solution of the β-ketone ester with dilute sodium carbonate until free from acid, then to dry with sodium sulfate for ten to twelve hours. By this operation, a large part of the objectionable coloring matter is removed, resulting in a purer pyrimidine condensation product. One hundred and fifty grams of ethyl diethoxyacetate yield 150 g. of ethyl-γ,γ-diethoxyacetoacetate, or 80% of the theoretical amount.

Diethylacetal of 2-Thiouracil-4-aldehyde.—This pyrimidine was prepared by condensation of the above β-ketone ester with thiourea according to the method of Johnson and Cretcher[9] One hundred and fifty grams of the β-ketone ester gave 110 g. of the pyrimidine, corresponding to 70% of the theoretical. It was recrystallized from 95% alcohol, separating in the form of thick, rhombic blocks, colorless or slightly yellowish and sparingly soluble in water. It melted at 160°.

2-Thiouracil-4-aldehyde. VI.—Twenty-five grams of recrystallized diethylacetal of 2-thiouracil-4-aldehyde is dissolved in 500 cc. of dilute hydrochloric acid (1:1). The solution is then heated to boiling and rapidly filtered through glass wool. On cooling, this pyrimidine aldehyde separates in the form of golden-yellow plates containing one molecule of water of crystallization. The yield is 18.0 g. or practically quantitative, and it melts with decomposition at 250".

Diethylacetal of 2-Ethylmercaptouracil-4-aldehyde.—A solution of 2.5 g. of sodium in 250 cc. of absolute alcohol is prepared and cooled to room temperature. Twenty-five grams of the diethylacetal of 2-thiouracil-4-aldehyde is dissolved in the resulting solution and 15 g. of ethyl bromide is then added and the whole refluxed for two hours on the steam-bath. At the end of this period the reaction mixture is cooled, the precipitated sodium bromide filtered off and the filtrate evaporated to an oil on the steam-bath. On the addition of water, the oil solidifies to a white solid. It is recrystallized from a 40% alcohol–water solution and separates in the form of needles; yield, 24 g. or 85% of the theoretical. It melts at 128".

2-Ethylmercaptouracil-4-aldehyde (V).—This pyrimidine aldehyde was first obtained by Johnson and Cretcher[9] by hydrolysis of the diethylacetal of 2-ethylmercaptouracil-4-aldehyde in hydrochloric acid solution. A better yield is obtained by using dilute acetic acid. Ten grams of the diethylacetal of 2-ethylmercaptouracil-4-aldehyde is dissolved in 100 cc. of dilute acetic acid (1:1) and the solution evaporated to dryness on the steam-bath. The aldehyde remains as a yellowish residue, soluble in hot water and alcohol, slightly soluble in ether and benzene. It is recrystallized from hot water, separating in the form of colorless, elongated prisms. It melted at 148–149° and the yield was 5.3 g. or 75% of the theoretical.

Oxidation of 2-Thiouracil-4-aldehyde to Orotic Acid, III.—An oxidizing solution is prepared by dissolving 25 g. of sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$) and 30 g. of

---

[10] Pucher, THIS JOURNAL, 42, 2251 (1920).

[11] Johnson and Mikeska, *ibid.*, 41, 810 (1919).

concentrated sulfuric acid in 115 cc. of water. The solution is cooled to room temperature. Five grams of 2-thiouracil-4-aldehyde is now added in small portions at such a rate that the temperature does not rise above 75°. The solution is constantly stirred during the addition. A vigorous reaction occurs, which is soon completed. When all the aldehyde has been added the solution is allowed to stand for ten minutes, after which it is heated to boiling for one minute. During this time the orotic acid partially separates. After cooling, the solution is filtered with suction, and the precipitate washed with water. The crude orotic acid (4.1 g.) is obtained in quite pure form as a slightly yellowish powder. It is purified by dissolving in 350 cc. of water, decolorizing with norite, filtering and cooling the filtrate rapidly. The acid is obtained as a white crystalline powder. The yield was 3.8 g. or 76% of the theoretical. The melting point was 345° (corr.).

The essential points in this technique are the portionwise addition of the aldehyde, and the short period of boiling. If the aldehyde is added all at once, yields are decreased to about 40%. Furthermore, since orotic acid is slowly attacked by boiling chromic acid solutions, prolongation of the boiling period beyond one minute also slowly decreases the yield.

Identification of the Product.—The synthetic acid was shown to be identical in every respect with natural orotic acid sent us by Dr. Bachstez. Its melting point is 345° (corr.); that of natural orotic acid is 345–347° (corr.); a mixed melting point shows no depression, melting at 345" (corr.). It crystallizes from hot water in rhombic prisms often exhibiting a characteristic twinning habit similar to that of the natural product. It is soluble in potassium hydroxide solution, from which acetic acid precipitates, not the free acid, but the potassium salt as a mass of fine needles. Similarly, acetic acid precipitates the ammonium salt from a solution of the synthetic acid in aqueous ammonium hydroxide. The acid is soluble in cold concentrated sulfuric acid, from which it is precipitated unchanged (m. p. 344°) on addition of water. It is tasteless. It reacts neither with Fehling's solution, nor with ammoniacal silver nitrate. Silver nitrate precipitates an amorphous white solid, soluble in nitric acid, from its aqueous solution. Similarly, barium chloride precipitates a crystalline barium salt. According to the methods of Bachstez, the bromine derivative, dibromobarbituric acid and the potassium salt of 5-nitro-orotic acid were prepared from the synthetic acid. The former melted at 235" (uncorr.) and the latter showed the characteristic color change to yellow accompanying its decomposition to potassium nitro-uracil when heated to 130°.

Heated at 130°, the synthetic orotic acid loses one molecule of crystal water. 0.2240 g of substance lost 0.0233 g. of H_2O: Calcd. for $C_5H_4O_4N_2 \cdot H_2O$: H_2O, 10.3 Found: H_2O, 10.4.

The acid was titrated in hot aqueous solution using phenolphthalein as an indicator. 0.3215 g. of substance required 18.7 cc. of 0.1295 *N* NaOH. Calcd. for $C_5H_4O_4N_2 \cdot H_2O$: 18.5 cc. 0.2582 g. required 14.9 cc. of 0.1295 *N* NaOH. Calcd., 14.8 cc.

Oxidation of 2-Thiouracil-4-aldehyde-diethylacetal, **2-Ethylmercaptouracil-4-aldehyde-diethylacetal** and 2-Ethylmercaptouracil-4-aldehyde to Orotic Acid.—The 2-ethylmercaptouradl-4-aldehyde was oxidized by the method previously described for the oxidation of 2-thiouracil-4-aldehyde. Three grams of the ethylmercapto-aldehyde gave 1.4 g. of pure orotic acid, corresponding to 55% of the theoretical. It was found that in the case of the acetals, portionwise addition of the solid acetal to the oxidation mixture gave very low yields. However, fairly good yields could be obtained by boiling the acetals for a few minutes in dilute sulfuric acid to effect hydrolysis of the acetal grouping, and then adding the oxidizing mixture to the resulting solution.

Three grams of 2-thiouracil-4-aldehyde-diethylacetalis suspended in a solution of 20 cc. of concentrated sulfuric acid in 50 cc. of water. The mixture is boiled for several minutes, when most of the acetal dissolves and the solution assumes the bright yellow color of the free aldehyde. The solution is now removed from the flame, allowed to cool somewhat, and a solution of 15 g. of sodium dichromate in 30 cc of water added at such a rate that the temperature remains between 80 and 90°. At the end of the addition, the solution is boiled for another minute. The orotic acid is recovered as previously described; yield, 1.5 g. or 68%.

Similarly, by the above procedure, 3 g. of 2-ethylmercaptouracil-4-aldehyde-diethylacetal gave 1.0 g. of pure orotic acid, corresponding to 53% of the theoretical.

Preparation of the Diethylacetal of Uracil-4-aldehyde from the Diethylacetal of **2-Thiouracil-4-aldehyde.**—Two grams of 2-thiouracil-4-aldehyde diethylacetal is covered with 60 cc. of 3% hydrogen peroxide and 15 cc. of 20% sodium hydroxide. The pyrimidine readily dissolves, yielding a colorless solution. Considerable heat is developed, the temperature rising to about 50°. The solution is now heated to a gentle boil for three minutes. It is then cooled in ice water and acidified with concentrated hydrochloric acid. Large amounts of sulfur dioxide are evolved, and separation of the sulfur-free acetal usually begins spontaneously. Occasionally vigorous scratching of the sides of the beaker with a glass rod is necessary to induce crystallization. The latter appears to be favored by a considerable excess of hydrochloric acid. The reaction mixture is allowed to stand at room temperature for several hours. The crude acetal is then filtered off, washed with cold water and recrystallized from a small amount of hot water. The diethylacetal of uracil-4-aldehyde separates in the form of colorless hexagonal prisms, melting sharply to a clear oil at 179°: yield, 1.8 g., or practically quantitative. The purified product gives no test for sulfur. It is easily soluble in the cold in methyl alcohol, ethyl alcohol, acetone and acetic acid, and insoluble in ether, benzene and ligroin. By oxidation with a $Na_2Cr_2O_7$–H_2SO_4 mixture as previously described, a good yield of orotic acid is obtained.

Anal. (Kjeldahl). Calcd. for $C_9H_{14}O_4N_2$: N, 13.08. Found: N, 13.05, 13.15.

Uracil-4-aldehyde, V.—A quantitative yield of this interesting pyrimidine aldehyde may be obtained by the careful hydrolysis of the corresponding uracil-4-aldehyde-diethylacetal. Two grams of the latter compound is dissolved in 25 cc. of dilute hydrochloric acid (one part concentrated acid and two parts water) and the solution finally heated to boiling for one minute. The solution assumes a pinkish color, which deepens on prolonged boiling. On cooling in ice water and scratching the beaker with a glass rod, the uracil-4-aldehyde separates out as a white solid. After standing for several hours, the reaction product is filtered off, washed with cold water and recrystallized from a small amount of hot water or dilute hydrochloric acid. The aldehyde separates in the form of colorless elongated prisms arranged in rosets; yield, 1.5 g. It does not possess a sharp melting point, but turns yellow when heated to about 260° and carbonizes without melting at 273–275°. This behavior is not changed by repeated crystallization from dilute hydrochloric acid. Uracil-4-aldehyde reduces Fehling's solution on warming, and ammoniacal silver nitrate in the cold. It gives a good Schiff's aldehyde reaction. With phenylhydrazine it yields a crystalline yellow hydrazone in the cold, decomposing at 330°. The aldehyde is very sensitive to the action of hot mineral acids. When boiled for a short time with concentrated hydrochloric acid its solution assumes a deep red color. It is much less soluble in the common organic solvents than the corresponding acetal, being insoluble in ether, benzene, ligroin and acetone, and moderately soluble in hot methyl and ethyl alcohol and hot acetic acid. By means of $Na_2Cr_2O_7$–H_2SO_4 mixture, it is easily oxidized to orotic acid. The aldehyde contains a molecule of water of crystallization, which it loses when heated to 120° for one hour.

Anal. (Kjeldahl). Calcd. for $C_5H_4O_3N_2\cdot H_2O$: N, 17.72. Found: N, 17.66, 17.80
0.4320 g. of substance lost 0.0497 g. of H_2O. Calcd.: 0.0492 g.

Summary

1. Uracil-4-carboxylic acid (orotic acid) known to occur in milk is most easily prepared in quantity by oxidation of 2-thiouracil-4-aldehyde or uracil-4-aldehyde with chromic acid.

2. The uracil-4-carboxylic acid thus obtained is identical with the natural orotic acid from milk furnished to us for comparison by Dr. Bachstez of Italy.

3. This is the only pyrimidine carboxylic acid thus far known to occur in nature.

NEW HAVEN, CONNECTICUT

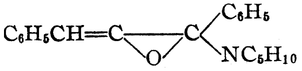
[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY]

ALPHA PIPERIDINO BENZALACETOPHENONE

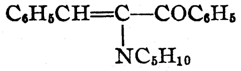
BY E. P. KOHLER AND W. F. BRUCE

RECEIVED MARCH 19, 1931 PUBLISHED MAY 6, 1931

In a recent paper Kohler and Addinall[1] expressed the opinion that a peculiar red piperidine derivative which was first described by Watson[2] and later studied with care by Dufraisse and Moureu[3] is an unsaturated ethylene oxide (I). This view is erroneous; the substance is an unsaturated ketone and it has the structure assigned to it by Dufraisse and Moureu (II).



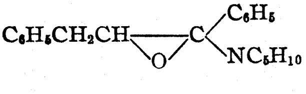
I



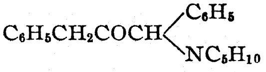
$$C_6H_5CH{=}\underset{NC_5H_{10}}{\underset{|}{C}}{-}COC_6H_5$$

II

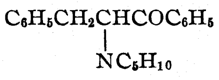
As a means of discrimination between the two formulas all methods of degradation by oxidation proved useless, but fairly convincing evidence was obtained from a series of transformations based on hydrogenation. In the presence of platinum the red compound combines with two atoms of hydrogen and forms a yellow addition product which reacts with a mole of methyl magnesium iodide without liberating gas. This compound might, therefore, be either a saturated oxide or one of two saturated ketones.



III



IV



$$C_6H_5CH_2\underset{NC_5H_{10}}{\underset{|}{C}}HCOC_6H_5$$

V

The yellow reduction product can be made by the action of piperidine on *α*-bromo benzylacetophenone and it reacts with hydroxylamine like

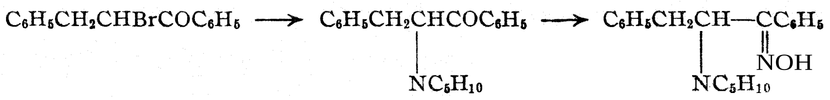
---

[1] Kohler and Addinall, THIS JOURNAL, 52, 3728 (1930).

[2] Watson, *J. Chem. Soc.*, 85, 1322 (1904).

[3] Dufraisse and Moureu, Bull. sac. *chim.*, [4] 41, 457 (1927).

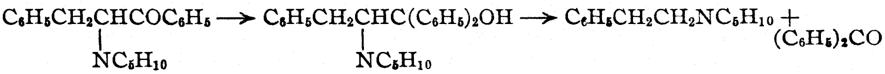
a ketone. Ordinarily this would be regarded as adequate evidence that the substance is the ketone V and the sequence of reactions would be represented as follows



$$C_6H_5CH_2CHBrCOC_6H_5 \longrightarrow C_6H_5CH_2\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}HCOC_6H_5 \longrightarrow C_6H_5CH_2\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}H{-}\underset{\displaystyle NOH}{\underset{\|}{C}}C_6H_5$$

VI VII VIII

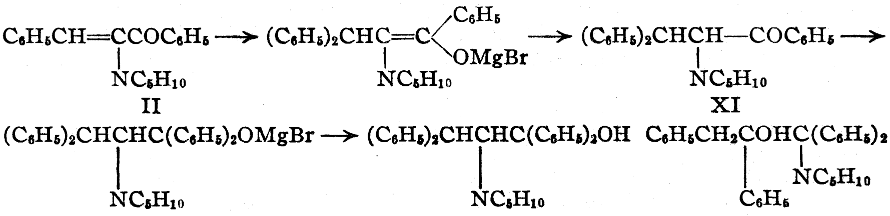
But unfortunately in this case the evidence is inconclusive, because the reaction between piperidine and the bromo compound might lead to the formation of the oxide III,[4] and it was not possible to regenerate the yellow compound from the product obtained in the reaction with hydroxylamine. Additional evidence as to the structure of the reduction product was obtained by treating it with phenyl magnesium bromide. It combined very readily with one equivalent of the reagent. The product of this reaction is colorless. It is stable to fairly high temperatures but above 280° it decomposes, giving mainly benzophenone and β-phenylethyl piperidine



$$C_6H_5CH_2\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}HCOC_6H_5 \longrightarrow C_6H_5CH_2\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}HC(C_6H_5)_2OH \longrightarrow C_6H_5CH_2CH_2NC_5H_{10} + (C_6H_5)_2CO$$

VII IX X

These transformations are difficult to reconcile with any formula other than VII; but since the final step involved the use of high temperatures and we were reluctant to accept this formula without the best of evidence, we decided to study another series of transformations. To this end we treated the red compound itself with excess of phenyl magnesium bromide. It combined with but one mole; but the yellow compound that was obtained by decomposing the resulting magnesium derivative was capable of combining with a second equivalent of the reagent. This is the characteristic behavior of α,β-unsaturated ketones with which organic magnesium compounds form 1,4-addition products



$$C_6H_5CH{=}\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}COC_6H_5 \longrightarrow (C_6H_5)_2CH\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}{=}C\begin{smallmatrix}C_6H_5\\ OMgBr\end{smallmatrix} \longrightarrow (C_6H_5)_2CH\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}H{-}COC_6H_5 \longrightarrow$$

II XI

$$(C_6H_5)_2CH\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}HC(C_6H_5)_2OMgBr \longrightarrow (C_6H_5)_2CH\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}HC(C_6H_5)_2OH \qquad C_6H_5CH_2\underset{\displaystyle C_6H_5}{\underset{|}{C}}OH\underset{\displaystyle NC_5H_{10}}{\underset{|}{C}}(C_6H_5)_2$$

XII XIII

Since ethylene oxides are capable of combining with organic magnesium derivatives, it is possible to imagine a similar series of reactions beginning with an oxide like I and ending with the carbinol XIII. Between these two possible carbinols it was easy to decide, because when the final product of the reaction was oxidized with chromic acid, it yielded two molecules

---

[4] Ref. 1, p. 3730.

of benzophenone. It is therefore the carbinol XII, and **the** red piperidine derivative must be the unsaturated **ketone** II.

Experimental Part

On the assumption that the red piperidine derivative has the structure assigned to it by Dufraisse and Moureu, the simplest and best proof of its structure would be its synthesis by the condensation of benzaldehyde and w-piperidino acetophenone

$$C_6H_5CHO + \underset{\underset{NC_5H_{10}}{|}}{CH_2}COC_6H_5 \longrightarrow C_6H_5CHOH\underset{\underset{NC_5H_{10}}{|}}{CH}COC_6H_5 \longrightarrow C_6H_5CH{=}\underset{\underset{NC_5H_{10}}{|}}{C}{-}COC_6H$$

Since the red compound is readily hydrolyzed by acids, it was necessary to undertake the condensation in the presence of bases; all attempts to effect condensation under these conditions were unsuccessful.

Another relatively simple method of differentiating between the two possible formulas of the red compound might be ozonization. This also was tried; a solution of the substance in carbon tetrachloride absorbed ozone with avidity. After removing the solvent and manipulating the residue in the usual manner, the products were benzaldehyde, benzoic acid and an oil which could not be purified but which gave piperidine and phenyl glyoxylic acid when it was digested with alkali. Inasmuch as these products might be formed both from the ketone and from the oxide the results are inconclusive.

Hydrogenation.—The red compound was hydrogenated in methyl alcohol with Adams' platinum oxide as the catalyst. It absorbed hydrogen rapidly at first, but the rate gradually fell off and there was no sharp break in the rate curve at the point representing the addition of two hydrogen atoms. After some preliminary experiments it was found advantageous to interrupt the operation when one mole of hydrogen had been absorbed, even though not all of the substance had been hydrogenated. Thus, a solution of 10 g. of the red compound in about 300 cc. of methyl alcohol was shaken with 0.2 g. of platinum oxide and hydrogen until 840 cc. of the latter had been absorbed Most of the catalyst was then removed by filtration, the remainder with active charcoal. The clarified solution, on concentration, deposited a mixture which was partially separated by crystallization. It yielded 7.1 g. of pure saturated ketone and 1.5 g. of a mixture of the original substance and its reduction product that was difficult to separate.

a-Piperidino Benzylacetophenone, **VII.—The** hydrogenation product is readily soluble in ether, moderately soluble in methyl alcohol. It crystallizes in pale yellow needles and melts at 81°. It dissolves readily both in dilute and in concentrated hydrochloric acid. The solution in 6 N acid deposited a colorless solid in large hexagonal prisms—doubtless the hydrochloride—from which alkalies regenerated the yellow base.

Anal. Calcd. for $C_{20}H_{23}ON$: C, 81.8; H, 7.9. Found: C, 81.9; H, 7.9.

Preparation from **α-Bromobenzylacetophenone.**—One gram of the bromo compound was added to **3** cc. of piperidine; it dissolved with cooling but the temperature soon rose rapidly and the solution became yellow. After half an hour it was diluted with water, whereupon it deposited an oil that soon solidified. After recrystallization from methyl alcohol the product melted at 80–81° and a mixed melting point determination proved its identity with the substance obtained by hydrogenation.

Reaction with **Hydroxylamine.**—A solution of 0.5 g. of the substance. 0.8 g. of hydroxylamine hydrochloride and 2 g. of potassium hydroxide in 25 cc. of methyl alcohol was boiled for half an hour, then poured into water. The product was recrystallized from methyl alcohol, from which it separated in colorless needles melting at 141–142°.

Anal. Calcd. for $C_{20}H_{24}ON_2$: C, 77.9; H, 7.9; N, 9.1. Found: C, 77.9; H, 8.0; N, 9.1.

The substance is, doubtless, the oxime VIII, which might be expected to resist hydrolysis. It is slightly soluble in 30% potassium hydroxide, and soluble in both dilute and concentrated acids—as would be expected in view of its piperidine group. In an attempt at hydrolysis it was heated overnight at 100° with 6 N hydrochloric acid. The result was a white solid melting at 240° which was not attacked by sodium bicarbonate but from which potassium hydroxide regenerated the oxime. With concentrated hydrochloric acid the result was the same.

Attempts to effect a Beckmann rearrangement were equally unsuccessful. Phosphorus pentachloride in cold ether immediately produced a white precipitate—doubtless the chloride—and when the solution was heated the result was a mixture of decomposition products among which benzonitrile was recognized by the odor. Hot formic acid merely transformed the substance into a salt—the formate—from which bases regenerated the oxime. After recrystallization from 5% aqueous formic acid the salt melted at 177–178".

Anal. Calcd. for $C_{21}H_{26}O_3N_2$: C, 71.2; H, 7.4. Found: C, 71.1; H, 7.4.

Action of Phenyl Magnesium Bromide, **α,α,γ-Triphenyl-β-piperidinopropanol, IX.**—An ethereal solution of 2.9 g. of the reduction product was added to a solution of the reagent that had been prepared from 0.96 g. of magnesium. Reaction occurred readily at 10° but the mixture was boiled for half an hour after all of the ketone had been added. The magnesium derivative was decomposed with ammonium chloride in the usual manner. The ethereal layer on evaporation left a solid and a small quantity of yellow oil. By recrystallization from methyl alcohol the solid carbinol was obtained in colorless plates melting at 148–149°.

Areal. Calcd. for $C_{26}H_{29}ON$: C, 84.1; H, 7.9. Found: C, 84.2; H, 7.8

Pyrolysis of the **Carbinol.**—A tube containing 1.6 g. of the carbinol was exhausted to 11 mm., then scaled and heated at 260–280° for seven hours in a Carius furnace. It was thus converted into a slightly discolored oil which was almost completely volatile with steam. In order to separate basic and non-basic constituents, the ethereal extract of the distillate was shaken with dilute hydrochloric acid The non-basic residue (0.82 g.) was identified as benzophenone by a mixed melting point. The acid solution, on treatment with alkali, yielded 0.50 g. of an oily base. The base formed a hydrochloride which crystallized in pearly plates, melting at 223° when crude and at 228° after recrystallization from methyl alcohol and ether. In the literature the melting point of β-phenylethyl piperidine hydrochloride is reported as 223°.[5]

Anal. Calcd. for $C_{13}H_{20}NCl$: C, 69.2; H, 8.9. Found: C, 69.1; H, 8.7.

Action of Phenyl Magnesium Bromide on the Unsaturated **Ketone.—α-Piperidino-β,β-diphenylpropiophenone,** XI.—A solution of 11 g. of the red ketone in 85 cc. of ether was added slowly to a solution of the reagent which had been made from 2.5 g. of magnesium. A deep blood-red coloration appeared where the solution met the reagent. At 0° this color persisted, but at the boiling point of the mixture it disappeared almost immediately. The mixture was boiled for an hour, then decomposed with ice and ammonium chloride. The ethereal layer was washed, dried and evaporated. It left a yellow solid and an oil. The oil was removed with methyl alcohol, and the solid was recrystallized from benzene and methyl alcohol. The ketone crystallized in yellow needles melting at 163°; yield, 61%.

Anal. Calcd. for $C_{26}H_{27}ON$: C, 84.5; H, 7.4. Found: C, 84.6; H, 7.3.

Action of Phenyl Magnesium Bromide, **α,α-Diphenyl-β-piperidino-γ,γ-diphenyl-**propanol, XU.—No perceptible reaction occurred when a benzene solution of one gram

---

[5] **Kindler,** *Arch. Phurm.*. 265, 405 (1927).

of the yellow ketone was added to a solution of the reagent containing 0.2 g. of magnesium, but when the solution was boiled the yellow color gradually disappeared. After an hour's boiling, the solution was treated with ammonium chloride in the usual manner. The ethereal layer, on evaporation, left an oil which could not be induced to crystallize.

In the hope of securing a solid, an ethereal solution of the oil was treated with hydrogen chloride gas. The acid converted it into a product which likewise had a tendency to separate from solutions as an oil but which was finally obtained as a solid by the addition of petroleum ether to its solution in chloroform. An analysis of this solid, which melted at 162–164°, indicated that it was not a simple hydrochloride of the piperidine compound but that the strong acid had also replaced the hydroxyl group of the carbinol with chlorine.

Anal. Calcd. for $C_{32}H_{33}NCl_2$: C, 76.5; H, 6.6. Found: C, 75.5; H, 6.8.

From the chloro compound the carbinol was regenerated by shaking a suspension of the substance in ether with 10% sodium hydroxide. The ethereal layer, on evaporation, left an oil, but this was finally converted into a solid by dissolving it in benzene, concentrating and adding petroleum ether to the solution. The solid separated gradually in large and well-defined crystals melting at 136–137°.

Anal. Calcd. for $C_{32}H_{33}ON$: C, 85.9; H, 7.4. Found: C, 85.6; H, 7.8.

Oxidation of the Carbinol.—To a solution of 0.45 g. of the carbinol was added 1.1 g. of powdered sodium bichromate; the solution was kept at 44–45° for an hour, then diluted with 100 cc. of water, made alkaline with sodium hydroxide and distilled with steam. The distillate was thoroughly extracted with ether, and the dried extract evaporated. The oily residue was kept over potassium hydroxide in a vacuum desiccator until entirely dry. It solidified completely when touched with benzophenone and a mixed melting point showed that it was pure. The yield was 0.35 g. instead of 0.36 g. calculated on the assumption that one molecule of carbinol yields two molecules of benzophenone.

Summary

The brilliant red compound which is formed by the action of piperidine and bases on a-bromobenzalacetophenone is α-piperidino benzalacetophenone. It has the structure assigned to it by Dufraisse and Moureu.

DECARBOXYLATION STUDIES ON PECTINS AND CALCIUM PECTATES"

BY C. M. CONRAD

RECEIVED MARCH 24, 1931 PUBLISHED MAY 6, 1931

The acid hydrolysis of pectin and its various derivatives is accompanied by a certain amount of decarboxylation. With 12% hydrochloric acid the decarboxylation is complete and quantitative in five hours or less. However, the extent of decarboxylation in concentrations of mineral acids ordinarily used in hydrolysis of complex carbohydrates has not been reported except in a few isolated cases. Thus, Link and Niemann,[2] using lemon pectin, noted that **33.85%** of the galacturonic acid present was destroyed in fifteen hours by boiling 2% sulfuric acid and Link and Dickson,[3] with the same material and conditions except using 2.5% sulfuric acid, noted the same loss; again, Nelson and Cretcher,[4] noted a loss of carbon dioxide during the hydrolysis of algin.

In connection with certain studies it was desirable to know the extent of decarboxylation of pectins when boiled with different concentrations of hydrochloric and sulfuric acids. The data obtained are believed to be of sufficient interest to warrant publication.

Experimental Part

Materials.—Two samples of pectin were used. A purified apple pectin was kindly furnished by the Pectin Sales Company, since incorporated as General Food Sales Company of Fairport, N. Y. A rather pure lemon pectin was kindly supplied by Messrs. C. P. Wilson and H. W. Hall of the California Fruit Growers Exchange. These pectins gave the following analyses.

	Apple pectin	Lemon pectin
Moisture	11.55	10.50
Ash	7.80	7.85
Galacturonic acid (dry, ash-free)	74.30	85.70

Besides the pectins, several samples of calcium pectate were used. These were obtained in the course of *the* quantitative determination of pectin in fruit or vegetable tissues.

Apparatus and Method of Procedure

Figure 1 shows the apparatus employed to follow the decarboxylation. It was modeled somewhat after that described by Dickson, Otterson and Link,[5] differing es-

sentially in the following features. Absorption of carbon dioxide occurs in an inclined 11-mm. glass tube without glass beads, platinum gauze, or other inclusions. Since the inclination of the tube from horizontal is only slight the bubbles travel up very slowly and absorption of carbon dioxide is complete. The reaction flask, usually a 300-cc. Erlenmeyer, rests on a 3-mm. sand-bath in a 20-cm. sand dish and is heated by a small carefully adjusted gas flame. A rubber stopper is used in the reaction flask. No appreciable error was found to result. It is renewed at intervals as it begins to show wear. All the bottles containing solutions used in the determination, together with burets, are permanently attached to the apparatus so that exposure to the air is avoided.

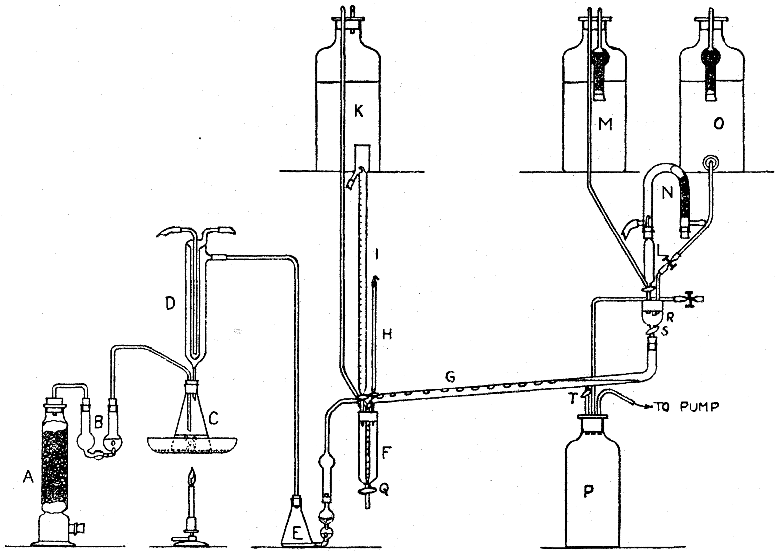

Fig. 1. –Apparatus used for decarboxylation studies: A, soda lime tower; B, trap with barium hydroxide solution; C, reaction flask; D, condenser; E, trap with 10% silver nitrate solution; F, titration chamber; G, absorption tube; H, buret for indicator; I, buret for standard hydrochloric acid; K, reservoir for standard hycrochloric acid; L, automatic pipet; M, reservoir for standard barium hydroxide; N, soda lime guard tube; O, reservoir for CO_2-free water; P, air chamber.

In determining the extent of decarboxylation the sample is placed in the reaction flask C and covered with 100 cc. of the acid solution desired. The flask is tightly fitted to its stopper and the sand-bath raised until the sand makes good contact with the bottom of the flask With stopcock Q closed and S open, 15 to 20 cc. of carbon dioxide-free water from reservoir O is allowed to flow through absorption tube G into the titration chamber F. Stopcock S is closed and the water pump turned on. T is almost closed, causing a partial vacuum in the trap P. S is now cautiously opened so that the distilled water is drawn from chamber F slowly up into tube *G*. As the last of the water passes into the tube, bubbles follow and the number and size of these are regulated by adjusting S. Carbon dioxide-free air is thus drawn through the system for fifteen minutes to sweep out all carbon dioxide. Stopcocks T and **Q** are then opened in the order named, allowing the distilled water to flow out. Stopcock **Q** is closed and a measured quantity of approximately 0.2 N barium hydroxide is allowed to flow from pipet I through chamber R into the absorption tube G. The stopcock of L is closed and the barium hydroxide is rinsed out of R with 4–5 cc. of water from O. Stopcock S is then closed and T again adjusted until only a small amount of air passes into P. Stopcock S is again cautiously opened and the barium hydroxide solution is drawn up into G, followed by a slow stream of bubbles. Cold water is passed through condenser D and the burner is lighted under the reaction flask. In actual runs boiling began in about twelve minutes. The flame was not changed after once having been adjusted.

When the reaction is finished, the flame is turned out and the stream of air drawn through the apparatus for about fifteen minutes longer. Stopcock T is then opened, followed by S, allowing the barium hydroxide carrying any carbonate to flow into the titration chamber. Buret I is filled with standard 0.2 *N* hydrochloric acid from the reservoir K A drop or two of phenolphthalein solution is introduced from H and the residual alkali in F is titrated. Frequently during the titration stopcock T is momentarily closed, thus drawing part of the titration mixture up into G. As T is opened, the mixture flows back into the chamber and mixing is readily accomplished. By proper manipulation of stopcock T in conjunction with stopcock S it is easy to control the movement of liquid in G. Especially near the end-point the liquid should be drawn entirely into *G* several times so that neutralization shall be complete. The end-point having been reached, the buret reading is taken and the titrated mixture discharged. The apparatus is then ready for another determination. The presence of a small amount of barium carbonate in *G* is not detrimental. However, this may be removed by means of water and acid from the reservoirs.

Repeated blank determinations with 100 cc. of 12% hydrochloric acid over the period used showed that barium hydroxide was neutralized equivalent to 0.0013 g. of carbon dioxide. All determinations were corrected for this amount.

Results

Decarboxylation of Pectins with Different Concentrations of Hydrochloric and Sulfuric Acids.—Samples of both apple and lemon pectins weighing from 0.3–1.0 g. were gently boiled with different concentrations of hydrochloric and sulfuric acids for sixteen hours in the apparatus previously described. The amounts of carbon dioxide produced, corrected for blank and calculated to one gram of dry ash-free pectin are shown in Tables I-III.

According to Ehrlich[6] and others pectins contain a complex consisting of four molecules of galacturonic acid joined in a ring. As the carboxyl groups are not concerned in the linkage, it is conceivable that decarboxyl-

12.0	.1769	.7784	90.8

ation of pectin might take place entirely independent of the hydrolysis of pectin into galacturonic acid. However, it was observed that practically no carbon dioxide was formed until after some minutes of heating. Then if the acid was sufficiently strong it began to be evolved more rapidly, as was shown by the separation of barium carbonate in the absorption tube. This would suggest that hydrolysis precedes decarboxylation; however, it is not impossible that the hydrolytic products act catalytically.

It is seen from the tables that decarboxylation occurs already in very weak concentrations of hydrochloric and sulfuric acids and increases rapidly with increasing concentration of acid. Hydrochloric acid of a given percentage concentration is much more effective than sulfuric acid of the same percentage value but this is due principally to the greater hydrogen-ion concentration of the hydrochloric acid. Hydrochloric acid of 12% or more probably yields a little carbon dioxide from other sources than the carboxyl groups when the pectin is heated for sixteen hours. This is indicated by the high calculated values for galacturonic acid. In the case of sulfuric acid even as high as 18% fails to give the theoretical yields of carbon dioxide. It is therefore not appropriate for use in place of hydrochloric acid for determining uronic acids.

Decarboxylation of Calcium Pectate from Several Sources.—Pectins plant gums and similar complex polysaccharides are very generally hydrolyzed with 2% sulfuric acid.[7] Periods of heating vary from a few

[7] Ehrlich and Sommerfeld, Biochem. Z, 168, 263 (1926); Butler and Cretcher, THIS JOURNAL, 51, 1519 (1929); Sands and Klass, ibid., 51, 3441 (1929); Bowman and McKinnis, *ibid.*, 52, 1209 (1930); Link and Niemann, *ibid.*, 52, 2474 (1930).

hours to as many as thirty, with a majority approximating sixteen hours. Inasmuch as the foregoing results showed so large a decarboxylation of apple and lemon pectin with this concentration of acid it was interesting to inquire whether this was a general property of the pectic substances from various sources. Therefore samples of calcium pectate which had been obtained in a rather pure condition in the course of other investigations were boiled with 2% sulfuric acid under the conditions previously described for pectins. The results are brought together in Table IV.

TABLE IV

DECARBOXYLATION OF CALCIUM PECTATE FROM VARIOUS SOURCES BY BOILING WITH 2% SULFURIC ACID FOR SIXTEEN HOURS

Calcium pectate from	Sample, g.	CO_2 obtained, g.	Galacturonic acid decomposed Weight, g.	Part of sample, %
Peach fruit	0.2665	0.0101	0 0444	16.7
Apple fruit	.3892	.0130	0572	14.7
Tomato fruit	.1528	0066	.0290	19.0
Strawberry fruit	.1999	.0075	.0330	16 5
Carrot root	.1674	.0053	.0233	13 9
Beet root	.1653	,0068	.0299	18.1

The results indicate that within the experimental error about the same percentage of galacturonic acid is decomposed in each case.

Summary and Conclusions

1. Decarboxylation of apple and lemon pectins with mineral acids occurs at low concentration of acid and is very appreciable with as weak as 0.1% sulfuric acid. The extent of decarboxylation of apple pectin in various concentrations of sulfuric and hydrochloric acids and of lemon pectin in various concentrations of sulfuric acid has been determined for a sixteen hour period of boiling.

2. **A** comparative study of the calcium pectate from several sources shows that the rate of decarboxylation with 2% sulfuric acid is approximately the same in each.

COMMUNICATIONS TO THE EDITOR

OPTICAL ROTATION AND ATOMIC DIMENSION. IX. HALOGENO-TETRA-ACETYL DERIVATIVES OF MANNOSE. THEIR CONFIGURATIONAL PECULIARITIES

Sir:

In continuation of my investigations on Optical Rotation and Atomic Dimension [last publication, VIII, THIS JOURNAL, **51,** 1820 (1929)], there have been prepared the pure crystalline substances α-fluorotetraacetylmannose and a-iodotetraacetylmannose and their specific rotations measured. Further, we have revised the value for crystalline α-bromotetraacetylmannose as first measured by Micheel [Ber., **63,** 390 (1930)] and later by Levene and Tipson [*J. Biol.* Chem., 90, 93 (1931)]. As I prepared several years ago crystalline a-chlorotetraacetylmannose and measured its rotation, a series of values is available for comparison with the atomic dimension values.

It has been established in my former investigations on this subject that for all the investigated halogen derivatives of the monosaccharides (glucose, fructose, xylose and arabinose) the differences in specific rotation, Cl–F, Br–Cl and I–Br, are proportional to the corresponding differences in atomic diameters. These differences in the specific rotations have the same ratio to each other as the corresponding differences in the atomic diameters, namely, 41:17:21. By using the values for the neutral atomic diameters of Goldschmidt [see Wherry, Am. Mineralogist, **14,** 54 (1929)], the proportionality existing between the differences of specific rotation and atomic diameter values holds very accurately for the derivatives of these four monosaccharides. However, the values for the mannose derivatives give the ratio 41:25:35. These experimental results point to the explanation that for the mannose derivatives the halogens on the one hand and the atoms of the second carbon on the other influence each other, as will be discussed in detail in the forthcoming paper. The results of Freudenberg [*Naturwissenschaften,* **18,** 393 (1930)] and Haworth [J. Chem. *Soc.,* 1395 (1930)] are of interest in this connection. They found for the structure of some mannose derivatives that even ring formation occurs between the adjacent groups of the first and second carbon atoms. An explanation of the different behavior of the mannose derivatives in comparison with the other monosaccharide derivatives could be obtained by model studies (detailed in the forthcoming article) which show that for the α-halogen derivatives of mannose the acetyl group of the second carbon is directed through its CH_3 group to the halogens of the first carbon with a resulting influence; whereas for the a-halogen derivatives of glucose, arabinose and xylose, the acetyl group of the second carbon is directed through its CH_3 group to the ring or another oxygen atom and also that the detailed structure of the halogen derivatives of fructose (β-derivatives) does not show a similar influence on the halogen atoms.

If we consider the consequences of this explanation it is seen that for the α- and β-mannose pentaacetates the acetyl group of the second carbon atom has a different position for the α-compound in comparison with the @-derivative, as its CH_3 group is directed by the respective places of the oxygen atoms of the first carbon acetyl group, whereas such a difference does not exist (or is of another nature) for the other discussed monosaccharides. Hence the testing of the principle of optical superposition in the mannose and rhamnose series should be taken up with caution, taking into account these configurational peculiarities.

THE VARIATION OF ELECTRIC MOMENT WITH TEMPERATURE

Sir:

Because of the uncertainty which has recently arisen in regard to the possible temperature variation of the moments of molecules in which two dipoles may rotate relative to one another, it has seemed of immediate importance to investigate this effect in such molecules. Ethyl acetate, the moment of which should depend, to a considerable extent, upon the position of the moment of the $O—C_2H_5$ bond relative to that of the C=O group, is found to show no significant variation of moment with temperature between -70 and $+30°$ when measured in dilute solution in heptane. The moment of ethylene chloride in solution in heptane is found to increase uniformly from 1.07×10^{-18} at $-70°$ to 1.41×10^{-18} at $+30°$ in satisfactory agreement with the measurements of Meyer [*Z. physik. Chem.*, [B] 8, 27 (1930)]. In similar fashion the moment of ethylene chlorobromide in heptane solution is found to increase from 0.92×10^{-18} at $-50°$ to 1.19×10^{-18} at $+30°$. This change is in accord with Meyer's idea that the mutual potential energies of the doublets in the two halves of the molecule cause these halves to occupy such positions relative to one another that the moments are partially canceled. The increase in rotational energy with rising temperature tends to overcome this effect of the mutual potential energies and so increase the moment.

Diethyl succinate which was found to have a moment lower than those of the other dicarboxylic acid esters and, apparently, increasing with temperature [Smyth and Walls, THIS JOURNAL, 53, 527 (1931)], has been measured over a wide range of temperature in solution in kerosene. The moment increases regularly from 2.01×10^{-18} at 0° to 2.47×10^{-18} at 180°, the latter value being practically identical with the moments of the higher members of the series. The tendency of the succinate molecule to bend in such a way that the doublets partially oppose and cancel one another at the lower temperatures is evidently overcome by the increased vibrational and rotational energy acquired within the molecule as the temperature rises.

THE ENTROPY OF POLYATOMIC MOLECULES

Sir:

The theoretical entropy of diatomic molecules has been calculated and discussed quite extensively,[1] but so far as I am aware, no one has as yet tackled the problem presented by the polyatomic molecule. I have recently computed the entropies (at 298.1°K.) of ammonia and of methane and find quite good agreement with the experimental thermochemical values. As such an agreement represents one of the few possibilities of actual check on the conclusions of band spectra as applied to chemistry, I am writing up the calculation in detail for publication, probably in the *Physical Review.*

The same formulas that were used for diatomic molecules[2] are applicable here but a double summation is necessary, corresponding to the two rotational quantum numbers, j and τ, in the symmetrical top type of rotator. When plausible assumptions are made for converting these summations to integrals, the absolute rotational entropy of each symmetry[3] modification (nuclear quartet and doublet forms in the ratio of 1:2, *respectively,* at high temperatures for ammonia and nuclear quintet, triplet and singlet forms in the ratio of 5:27:4, respectively, at high temperatures for methane) may be calculated. From this was subtracted the "zero point" entropy which is the correction term necessary on account of the experimental difficulties of reaching temperatures sufficiently near the absolute zero and in measuring the extremely small heat effects.

Using the moments of inertia of ammonia as given by Badger and Mecke,[4] the total effective entropy of ammonia is 44.0 E. U. and compares very favorably with the value derivable from the data in Lewis and Randall (p. 557), 43.5.

For methane, three values were computed, depending on which line spacing one assumes to be representative of the moment of inertia. They are 44.1, 42.3 and 42.0; for $I = 10.2$, 5.66 and 5.17×10^{-40}. The last corresponds to the spacing most accurately measured (Raman effect)[5] and, for various reasons, is probably the correct one. In fact, the agreement with the observed entropy[6] 42.5 may be adduced as additional evidence for the reliability of this choice.

These results indicate that the actual calculation of thermodynamic equilibria[7] from band spectra data is not to be much longer limited to reactions between molecules having a maximum of two atoms.

2,4,5-TRIMETHOXYBENZOIC ACID: A DERIVATIVE OF DEHYDRODEGUELIN

Sir:

It has been shown by LaForge and Smith[1] that, through a series of reactions, the rotenone molecule may be ruptured in a manner which yields derric acid, $C_{12}H_{14}O_7$. Derric acid represents the half of the rotenone molecule which contains the methoxyl groups, but as yet the exact nature of the acid is unknown.

Recently three other insecticides of the same type as rotenone, namely, deguelin, tephrosin and toxicarol, have been described.[2] It has also been shown that structural relationships exist common to the entire molecule of rotenone, deguelin and tephrosin;[3] but the fact which is of immediate interest is that the derric acid portion of the molecule is common to all three substances.

It is desired at this time to report in a preliminary way the results of some experiments which clarify to a considerable degree the problem of the derric acid portion of rotenone and allied materials.

Permanganate oxidation of dehydrodeguelin in acetone solution yields two hydroxy acids, one of which contains the two methoxyl groups present in the starting material and thus represents the derric acid portion of the molecule. This acid crystallizes in plates which may be roughly described as rectangular with notched ends and with constrictions in the center of their long axis. It melts at 210° with decomposition and gives an intense blue color with ferric chloride.

[3] Clark, *Science*, 73, 17 (1931); also a paper now being submitted to THIS JOURNAL for publication.

Analysis proved the material to be an hydroxydimethoxybenzoic acid. Methylation of the free hydroxyl group gave a trimethoxybenzoic acid which was shown by its melting point and derivatives obtained by bromination and nitration to be asaronic acid, 2,4,5-trimethoxybenzoic acid.

The hydroxydimethoxybenzoic acids which could give this acid are 2-hydroxy-4,5-dimethoxy-, 5-hydroxy-2,4-dimethoxy- or 4-hydroxy-2,5-dimethoxybenzoic acid. It is thought that because of the ferric chloride reaction given by the acid from dehydrodeguelin it is 2-hydroxy-4,5-dimethoxybenzoic acid. Work upon its synthesis is in progress, and it is hoped that a report upon its structure can be made shortly

SYNTHESIS OF GAS–METAL COMPOUNDS BY SPUTTERING

Sir:

In connection with a somewhat extensive study of cathodic sputtering [see Phys. *Rev.*, 32, 649 (1928); 34, 972 (1929); Nature, 126, 204 (1930)], the writer has recently found that this process has remarkable possibilities as a method of chemical synthesis. This applies particularly to the formation of metal–gas compounds such as nickel and similar metals with hydrogen, nitrogen, etc. Nickel sputtered in nitrogen under rather special conditions of current, voltage and gas pressure gives a dark, somewhat metallic-looking film which shows on x-ray examination a crystal structure distinctly different from that of the pure metal. Heating to about 350° decomposes this compound, which gives off its gas and reduces to metallic nickel. Upon heating such a nitride film to 150° in hydrogen, ammonia is formed and in an amount which agrees reasonably well with the quantity of nitrogen absorbed in sputtering. Compounds of cobalt and iron with nitrogen have likewise been produced, as well as of nickel and hydrogen—this latter showing on crystal structure examination a lattice spacing some 6% larger than for pure nickel.

It seems certain then that we are dealing here with such unusual compounds as nitrides and hydrides of these metals. Moreover, they are formed, not at the expense of a difficult and special technique of synthesis [see A. C. Vournasos, Compt. rend., 168, 889 (1919)] but by a simple process of wide applicability, for the conditions encountered in sputtering, with the metal in the vapor state and the gas largely excited by the discharge, would seem to be ideal for the formation of a compound if this is chemically possible. Indeed one series of experiments yielded considerable evidence for the formation of compounds with even helium and argon, and, while this evidence was later vitiated by the discovery of impurities, the question is by no means as yet settled in the negative. Compounds with excited helium or argon are at least not unthinkable, and this is probably the most promising way of forming them.

A word of caution may not be out of place as to the use of this method of synthesis. Metals ordinarily contain a great deal of absorbed gas and while the usual baking (at say 500°) may remove the bulk of such impurity adsorbed on the surface, it will probably take little from the interior. Then as layer after layer of atoms is removed from the cathode in the sputtering process, fresh supplies of gaseous impurity are released, so when purity of product is a main factor some provision must be made to eliminate this source of trouble. It may be possible to secure nearly gas-free metal for the cathode, or to outgas it effectively by having it in the form of a thin strip which can be heated electrically to a high temperature, but probably the most feasible method is to dilute the impurity to a point where it becomes negligible by a continuous flow of fresh gas through the chamber during the sputtering.

A RELATION CONCERNING ATOMIC NUCLEI

Sir:

An interesting numerical relation of known atomic species is to be found in the helium–thorium series. The atomic nuclei of this series have a composition represented by the general equation

$$a_{(Z/2+n/4)} + (e_2)_{n/4}$$

in which e is an electron, a represents a group of 4 protons and 2 electrons, Z is the atomic, and n, the isotopic number. For thorium Z is 90 and n is 26, so the specific formula is $a_{58}e_{26}$ In a recent paper Latimer develops a model for the nuclei of this series. He bases his model not only on the general hydrogen–helium theory[1] developed in 1915 by the writer, but he also makes use of the very specific features of this theory, such as the pairing of the nuclear electrons,[2] the introduction of the first pair of extra or cementing electrons in the argon nucleus[3] of mass 40, and the later addition of still other pairs of electrons as the atomic number increases.[4]

Latimer also uses the idea that the abundance of an atomic species is

related to its stability,[6] and considers that the stability is related to the intranuclear spins,[6] which are supposed to be due to the protons.

It is of interest to see if any known relations, other than those upon which the model is based, agree with the interesting tetrahedral model. Figure 1 gives a representation of the helium–thorium series, taken largely from an early paper," but extended to fit the most recent data of Aston.[8] It may be noted that this series is found only on levels 0, 4, 8, 12, etc., which correspond to 0, 1, 2, 3, etc., pairs of extra or cementing electrons. The length of the series at any level will be considered to be given by the number of places for members of the series beginning and ending with known species. The values are collected in Table I.

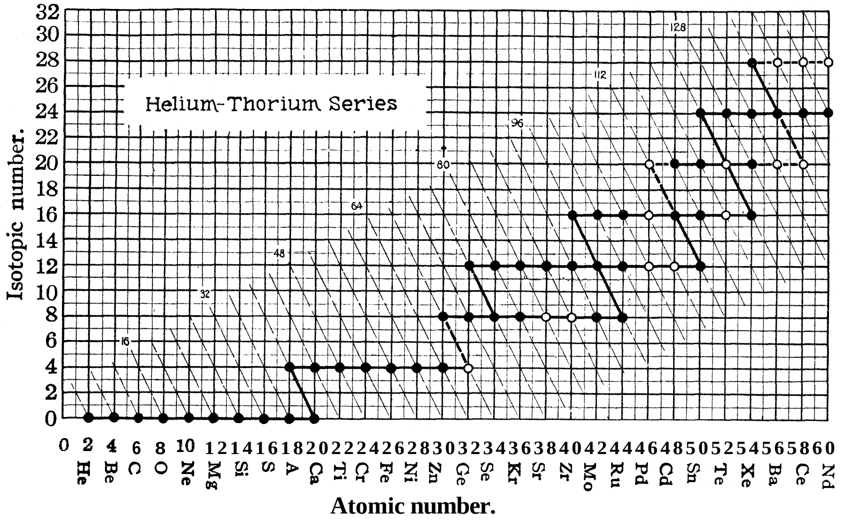

Fig. 1.—Open circles represent species as yet undiscovered.

Table I

1 Isotopic number, *n*	2 Number of cementing electrons, *n*/2	3 Number of species in known series	4 Number of species in Fig. 1
0	0	10	10
4	2	7	8
8	4	8	8
12	6	10	10
16	8	8	8

In explanation of Column 4 it may be said that Fig. 1 represents undiscovered species by open, and known species by black, circles.

[7] Harkins, J. Franklin *Inst.*, 195, 554 (1923).

[8] Aston, *Nature*, 127, 233 (1931).

Thus the number of species is **10** for either zero or three pairs of cementing electrons, and eight (possibly seven for one pair) for one, two, or four pairs. This agrees with the writer's early idea that the zero level should be a long one, and with Latimer's idea that the level for three pairs of cementing electrons should also be long. While later discoveries may change these limits, they will probably not destroy the validity of the general relations.

It may be noted that Latimer[9] makes no attempt to explain the most fundamental relation which concerns nuclear stability, the pairing of electrons in the nucleus. Also Dirac's principle of superposition, mentioned by Rodebush,[10] has not been developed to the extent necessary to explain this phenomenon. It is not improbable that the two electrons in an alpha particle move through the whole volume of the particle, but the distribution of electron density is entirely unknown. It is not intended to imply that the electron pairing cannot later be treated in terms of an overlapping of the eigenfunctions of the single electrons.

THE STRUCTURE OF THE a-PARTICLE

Sir:

In the March number of THIS JOURNAL, W. M. Latimer has written an article in which he refers to a suggestion of mine. Inasmuch as one might infer therefrom that I considered the idea of the tetrahedral form of a-particle to be original with me, may I state that this was not the case. What I did suggest and discuss with Professor Latimer and others was the orientation of the spins of the proton, as used by Latimer, in which the spin of each proton was supposed to point out from the center of the tetrahedron. This was some time ago, and Professor Latimer writes me that our discussion was only recalled to him by our correspondence after this article was in manuscript form.

In view of this paper of Latimer's and recent discussions of nuclear spin [Bartlett, *Phys.* **Rev.,** 37, **327 (1931);** Gibbs and Kruger, *ibid* , 37, **656** (1931)], **a** word as to my reason for making this suggestion may not be out of place. I wished to have the resultant spin for one, two or three protons the same (and the same as that of the electron, equal to $^1/_2$ unit), and the spin for four protons equal to zero. This is a natural result of the tetrahedral structure though requiring some "distortion" of the angle (if such language has any meaning) between two protons in the case of two. This would explain the anomalous spin in the case of nitrogen (3 a-particles, 2 extra protons, 1 extra electron, resultant spin

---

[9] Latimer, THIS JOURNAL, 53, 987 (1931).

[10] Rodebush, *ibid.*, 53, 1611 (1931).

2/2 units) and, in fact, accounts for the spin in all the cases considered by Bartlett. However, these cases will also fit into a scheme in which the electrons have no spin, and the proton spins behave like ordinary electron spins (Bartlett, *loc. cit.*). Both proposals will meet with difficulties in the case of Al (Gibbs and Kruger, *loc. cit.*). I think we must simply admit that we do not know how the spins in nuclei are produced. In the meantime, speculations regarding nuclear structure, such as Latimer's, which are based on other data, are of interest.

THE PREPARATION OF COPPER–CHROMIUM OXIDE CATALYSTS FOR HYDROGENATION

Sir:

The new and very efficient catalyst for the hydrogenation of various organic compounds in the liquid phase [Adkins, Connor and Folkers, THIS JOURNAL, 53, 1091, 1095 (1931)] referred to as "copper chromite" suffers under the disadvantage that in the hydrogenation of certain compounds (ethyl phenylacetate to phenylethyl alcohol, for example), there occurs reduction of the catalyst to a red inactive compound. This undesirable feature is not present in a modified catalyst containing barium, for example, which was prepared by replacing 10% of the copper nitrate with a molecularly equivalent amount of barium nitrate using 750 ml. of water at 70° per mole of nitrate. The preparation of a copper-chromium catalyst: as originally described by us was based upon the method patented by Lazier for obtaining catalysts from certain chromates. Recently it has been found in this Laboratory that an equally if not more efficient copper-chromium catalyst may be prepared by a more convenient and simple method which is as follows. Seventy-one grams of ammonium carbonate monohydrate in 400 ml. of water was added to a solution containing 50 g. of copper nitrate trihydrate, 5.4 g. of barium nitrate and 77 g of chromium nitrate ($Cr_2(NO_3)_6 \cdot 15H_2O$) in 575 ml. of water. After thorough mixing of the reactants, the precipitate was filtered with suction on a Büchner funnel, and washed twice with 50-ml. portions of water. The solid was dried overnight at 100–110°, ground to a powder and heated to approximately 230° in order to expel ammonia, carbon dioxide, etc. The catalyst was then used as previously described.

NEW BOOKS

General Chemistry for Colleges. By B. SMITH HOPKINS, Professor of Inorganic Chemistry in the University of Illinois. D. C. Heath and Company, 285 Columbus Avenue, Boston, Massachusetts, 1930. x + 757 pp. 242 figs. 14.5 X 22 cm, Price, $3.72.

This is an excellent text for beginning classes in colleges and universities. While in arrangement it is like most American texts and therefore displays no marked originality, yet the writing has been well done and in some respects the book is an improvement over other texts. One of the main difficulties which the teacher of beginning chemistry encounters is to make his course adapt itself not only to the average student but also to the above average student. In the introduction attention is called to the cross references which encourage the student who is willing to do that sort of thing to make comparisons and to do independent thinking. The book also has references which call attention to the practical applications of chemistry. This arrangement enables the practical minded student to go out into the literature with a minimum of difficulty and initiates him, as it were, into the research attitude toward his work. The book proper is prefaced by two chapters of interesting historical matter. Following this we have the conventional arrangement of topics and of material which is carried throughout the rest of the text. The writer is to be congratulated upon the early introduction of the idea of equilibrium, which is perhaps the most important of the conceptions presented to the beginning student. It is questionable however whether atomic theory ought to be postponed to as late a point as is indicated by the position in the book. It has always seemed to the reviewer that a statement at least of atomic theory should be given early in the course and that this theory should be established by its application to the laws and phenomena which are discussed later.

The question may be raised whether or not the use of the term "plus and minus valence" in connection with the balancing of oxidation and reduction equations does not create a wrong impression regarding valence. If the word polar number should be substituted for plus and minus valence (as suggested by Bray), the objection to giving valence a minus value would be obviated. Dr. Hopkins has made some steps toward clearing up the inconsistencies of the old idea of partial dissociation which for an elementary class is still a very difficult task. He seems to have gone as far as is possible under the circumstances. The periodic arrangement suggested is simple and clear, and is to be commended as against some efforts which have been made to involve too many factors in the table.

The chapter on the structure of atoms, crystals, etc., might as well have been put anywhere else in the book as where it is. The information is apparently not made use of later; in fact what little use is made of the work on crystals comes earlier in the text. It is apparent however that any chapter of this type which is put into a book on freshman chemistry is put there largely for the purpose of including interesting material, not because of its direct value to the student. Inasmuch as practically every text written in recent years has contained this material either as a part of the text or in an appendix, its inclusion can hardly be criticized.

The book is well illustrated and contains many valuable diagrams. The chapters on the metals are exceptionally well done. All of the elements are included in the discussion at least by means of brief notes and the text is entirely up to date in this respect. It is to be noted that production figures are given for the various elements and important compounds, which always adds interest to the discussion of chemical substances. Taken as a whole the book is to be considered as one of the best of our modern American chemistries.

P. A. BOND

Leçons de chimie analytique. (Textbook of Analytical Chemistry.) By ALCIDE JOUNIAUX, Professor in the Faculty of Sciences of the University of Lille. Librairie Scientifique Hermann et Cie., 6 Rue de la Sorbonne, Paris, France, 1931. viii + 350 pp. Illustrated. 16 × 25 cm. Price, 60 fr.

The title of this book seems too general for its content. The author has presented only gravimetric and electrolytic analysis. A supplement on volumetric methods is perhaps planned, but there is no clear indication of this intent. Electrometric and other physicochemical methods are also passed over in silence.

The book is divided into four parts: (I) (100 pages) a general discussion of standard gravimetric operations; (II) (130 pages) a systematic review of methods for the various cations and anions; (III) (50 pages) gravimetric organic analysis; (IV) (30 pages) electrolytic analysis.

The first part includes a very interesting discussion of common ion effect and complex formation and of the physical state of precipitates, adsorption and colloidal phenomena. The treatment of the other general topics is less original. The discussion of errors and averaging is very brief and simple, and there is no mention of methods of sampling, of the properties of different types of laboratory ware, of the purity of reagents or of methods of preparing the solution for analysis.

The author's method of arrangement is as follows. Under "1st group metals" he treats successively Ag^+, Cl^-, Br^-, $I-$, CN^-, SCN^-, $Fe(CN)_6^{4-}$, $Fe(CN)_6^{3-}$, ClO_3^-, IO_3^-, IO_4^-, ClO_4^-, mixed halides, Hg^{++}, $PO_3^{\equiv}$, HCO_2^- and Pb^{++}. In other words, not only the cations but the anions which may be precipitated with their aid are included. In this first treatment of the analysis of lead, only the gravimetric sulfate method is given, apparently on the assumption that no interfering substances are present other than organic or mineral acids. Later, under the copper group, we find a brief mention of the separation of lead from the other metals, with no discussion of contamination by bismuth, alkaline earths or silica. Finally, in the last section, the electrolytic separation of lead from other metals and its determination by electrolysis are described. The treatment throughout is very brief, and seems insufficiently detailed and documented to be a safe guide even for the analyst who is interested only in gravimetric methods. Even for beginning students, working on carefully prepared solutions, the detail seems inadequate, as for example in the treatment of the gravimetric determination of copper as oxide (which seems to be the favorite method for copper), no mention is made of contamination by the alkali hydroxide used as precipitant, and no procedure is recommended which would reduce the error from this cause. Many of the newer organic reagents for the metals are discussed briefly. The section on electrolytic methods is relatively satisfactory.

In summary the reviewer feels that the omission of volumetric procedures and the inclusion of so much organic analysis constitute an undesirable choice of material for a beginner's text, while for such a text there is little advantage in the inclusion (without thorough discussion) of numerous methods for each ion. On the other hand, if the work is intended as a reference book for practical analysts, the omission of volumetric methods, the somewhat uncritical choice of gravimetric methods, and the lack of documentation and critical discussion, constitute serious defects.

NORRIS P. HALL

Lehrbuch der Thermodynamik für Studierende der Chemie und verwandter Wissenschaften. (Textbook of Thermodynamics for Students of Chemistry and Related Sciences.) By A. MAGNUS, Professor at the University of Frankfort-on-Main, Akademische Verlagsgesellschaft m. b. H., Schlossgasse 9, Leipzig C 1, Germany. 1929. xii + 288 pp. 23 figs. 16 X 24 cm. Price, unbound, RM. 16; bound, RM. 18.

This is an interesting and useful book. There is a brief and excellent mathematical introduction. After a discussion of the ideal gas and the van der Waals' equation, the first and second laws are developed in the classical manner and applied to chemical problems by the use of the usual thermodynamic functions. The explanations are full and seem to be the result of the author's own study; the student will doubtless find welcome help in the comprehension of details on which many books are silent.

There are sections on the van Laar–Richard Lorenz treatment of equilibrium in condensed systems, on entropy and probability, thermodynamics of radiation, and the specific heats of solids in relation to quantum theory.

There is a chapter on the Nernst heat theorem, developed in the Nernst manner (rather than the simpler manner of G. N. Lewis). Here the

Planck formulation ($S = 0$ at $T = 0$) is stated to go a step further than the Nernst formulation ($AS = 0$ at $T = 0$), in affirmation of Nernst's distinction, which the reviewer is unable to appreciate. Theodore W. Richards is not mentioned for his basic experimental contribution. The American work on supercooled liquids and the consequent limitation of the principle to pure crystalline solids are not discussed. In general, the author has drawn too much on German sources, and the book, at least to an American reader, seems to bear a very strong impress of nationality.

The author has not always been careful with regard to the historical inferences that would be drawn from his statements. Thus the Gibbs fundamental equation is discussed without reference to Gibbs, but (page 191) as "an equation, which Planck has called a canonical equation." Admirers of Gibbs will learn with surprise (page 200) that he devised an arrangement involving moving semipermeable membranes, for mixing gases reversibly, but will hardly regard this as compensation, if indeed they regard the statement as complimentary to Gibbs. The author discusses not only the thermodynamic potential $(U - TS + pV)$, but also the therefore superfluous function obtained by dividing this by minus the temperature, which he calls as usual the Planck function, although it is one of Massieu's characteristic functions, as noted by Gibbs, who preferred the function $U - TS + pV$.

L. J. GILLESPIE

Photo-electric Cells and their Applications. A Discussion at a Joint Meeting of the Physical and Optical Societies, June 4–5, 1930. Edited by JOHN S. ANDERSON, M.A., D.Sc., F.Inst.P. Published by The Physical and Optical Societies, 1 Lowther Gardens, Exhibition Road, South Kensington, London, S. W. 7, England, 1930. 236 pp. Illustrated. 18 X 26 cm. Price, 12 s./6 d. to non-members.

These thirty-one papers by experts from England, America and continental Europe will interest chiefly those who make and use photo-electric cells, including selenium cells. After an introductory lecture by Professor H. S. Allen, on the "Early History of Photo-Electric and Selenium Cells," there follows: one paper on a theory of selective photo-electric emission, ten papers on the manufacture, characteristics, testing and use for sound reproduction, eleven papers on various phases of photo-electric photometry, three papers on other applications including biology, four papers on the amplification of varying photo currents. The general discussion which concludes the volume is perhaps as interesting as any single paper. It would seem desirable to have included a greater number of papers by experts in the science of photo-electric action. It would also seem that the subject matter and price would warrant something better than a paper cover binding.

J. A. BECKER

Alcoholometry. An Account of the British Method of Alcoholic **Strength Determination.** By FRANCIS G. H. TATE, Government Laboratory, London. With historical introduction by the author in collaboration with George H. Gabb. Published by His Majesty's Stationery Office, Adastral House, Kingsway, London, W. C. **2,** England, 1930. xviii + **93** pp. Illustrated. **15.5** X **24 5** cm. Price, **5** s. net.

This work is largely an historical description of the development of the hydrometer as applied to the determination of alcohol in potable spirits. The historical portion of the work is very complete and is very interesting to those who may be doing work of this character. There are several very fine reproductions of early types of hydrostatic balance and several early hydrometers, some of which are 200 years old at present. The book contains an interesting chapter on the standardization of hydrometers. One chapter, two and one-half pages in length, is devoted to the use of the refractometer in connection with the hydrometer in order to obtain a correct alcohol percentage when the spirit is "obscured" with sugar or similar substances.

HERMANN C. LYTHGOE

Organic Syntheses. **An** annual publication of satisfactory methods for the preparation of organic chemicals. Vol. XI. Edited by CARL S. MARVEL, with ROGER ADAMS, W. H. CAROTHERS, H. T. CLARKE, J. B. CONANT, HENRY GILMAN, C. R. NOLLER and F. C. WHITMORE. John Wiley and Sons, Inc., **440** Fourth Ave., New York, 1931 vii + 106 pp. **15.5** X **23.5** em. Price, **$1.75.**

The eleventh annual volume of "Organic Syntheses" has appeared, as usual, in good time. The list of preparations which have been supplied by an unusually large number of contributors and checked by the self-sacrificing board of editors is as follows: acrolein acetal, a-aminoisobutyric acid, 1-amino-2-naphthol hydrochloride, 1,2-naphthol-4-sulfonic acid, azoxybenzene, a-bromoisovaleric acid, bromomesitylene, β-chloropropionaldehyde acetal, citraconic anhydride and citraconic acid, cyanogen bromide, 2,4-diaminotoluene, ethyl ethylenetetracarboxylate, ethyl phenylcyanopyruvate, ethyl pimelate, fumaric acid, dl-glyceric aldehyde, dl-glyceric aldehyde acetal, heptaldoxime, n-heptylamine, $-iodoaniline, isodurene, itaconic anhydride and itaconic acid, mesaconic acid, 3-methylpentanoic acid, a-naphthoic acid, n-pentane, symmetrical and unsymmetrical o-phthalyl chlorides, isopropyl thiocyanate, thiobenzophenone, o-toluic acid, triethylcarbinol.

E. P. KOHLER

Kleines Praktikum der Kolloidchemie. (Brief Laboratory **Manual** of Colloid Chemistry.) By PROF. DR. WOLFGANG OSTWALD, University of Leipzig, with the coöperation of Dr. P. Wolski and Dr. **A.** Kuhn. Seventh edition. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, **1930.** xii $ **174** pp. **21** figs. **15** X **23** cm. Price, unbound, RM. 3.60.

The first edition of this book was published in 1920. This **was** soon followed by the second and third editions, then after a limited revision and the addition of some fifteen experiments, a fourth edition appeared in 1922. This latter edition was translated into English by Kugelmass and Cleveland and was published by E. P. Dutton and Company, New York (1924) under the title "Practical Colloid Chemistry." Subsequent editions, including the present one, have appeared practically unchanged. The general topics covered come under the following heads: I, Preparation of Colloidal Solutions; II, Diffusion, Dialysis and Ultrafiltration; III, Surface Tension and Viscosity; IV, Optical Properties; V, Electrical Properties; VI, Experiments with Gels; VII, Adsorption; VIII, Coagulation, Peptization and Related Phenomena. All told, there are 183 individual experiments which are described in commendable detail and are well distributed over the above-mentioned general topics. In addition, a brief treatment is given of certain commercial colloids and of methods of capillary analysis.

The author has taken care to include only such experiments as can be carried out with comparatively simple apparatus, such as can be found in almost any chemical laboratory. This feature will be appreciated by those who are about to introduce a laboratory course in colloid chemistry. For use in well-established courses a greater number of strictly quantitative experiments would materially enhance the value of this book.

F. E. BARTELL

Jahrbuch der organischen Chemie. (Yearbook of Organic Chemistry.) By Professor DR. JULIUS SCHMIDT, Stuttgart. Vol. 15, 1928. Verlagsbuchhandlung von Franz Deuticke, Vienna, Austria, 1930. xvi + 245 pp. 17.5 X 25.5 cm. Price, unbound, M. 24; bound, M. 27.

The fifteenth volume of Schmidt's ***Jahrbuch,*** dealing with the developments in organic chemistry during 1928, is similar in character to its predecessors. Since this is the most extensive survey of its kind it is a great pity that it cannot be made more useful by bringing it more nearly up to date.

E. P. KOHLER

The Microbiology of Starch and Sugars. By A. C. THAYSEN and L. D. GALLOWAY, Oxford University Press, 114 Fifth Avenue, New York, 1930. viii + 336 pp. 14.5 X 22 cm. Price, $8.50.

This book is a companion volume of "The Microbiology of Cellulose, Hemicelluloses, Pectin and Gums" mitten by Thaysen and Bunker and published in 1927. As stated in the preface, the book has been written for the research worker. It is an excellent monograph, bringing together in compact, correlated form a great mass of valuable information appearing in botanical, bacteriological, chemical and technological journals. In reviewing this bulk of literature it is hardly possible to avoid omissions and errors, but those that have been noted were, for the most part, of minor importance.

The material in the book is divided into five parts: Part I deals with the constitution and microbiological hydrolysis of starch, glycogen, inulin, the tetra-, tri-, and disaccharides, and the glucosides. The discussion includes a consideration of the enzymes present in the hydrolyzing organisms. Brief descriptions of saké and soya manufacture are given, also the Amylo process for alcohol production, and the biological manufacture of indigo and gallic acid. In discussing the action of actinomycetes on saccharose, the authors state on p. 49 that "generally speaking, however, saccharose cannot be regarded as a carbohydrate favoring the growth of actinomycetes." No mention is made of the monograph on the actinomycetes by R. Lieske, Leipzig, 1921, in which the statement is found that "Sucrose is a good C source for all actinomycetes, but it appears to be assimilated without being inverted by an exoenzyme." In Chapter III the authors question the evidence for a direct fermentation of saccharose. Thus on p. 41 in criticizing the work of Gayon and Dubourg, who observed that certain mannitol-producing bacteria could ferment saccharose readily without producing mannitol, but yielded considerable quantities of this alcohol when acting on fructose, the authors advance the argument that fructose as liberated from saccharose might 'act differently *in* statu *nascendi* from the fructose from which the mannitol bacteria yielded mannitol. While Gayon and Dubourg present direct experimental evidence, the authors offer no data for their assumption. In the mind of the reviewer the burden of proof rests with the authors. In citing the papers on this subject, no reference is given to Miiller-Thurgau and Osterwalder [*Centr.* Bakt., 2 Abt., 48, 10 (1917–1918)] and Stiles, Peterson and Fred [*J. Biol.* Chem., 64, 649 (1925)], who substantiated Gayon and Dubourg's observations.

In Part II, consisting of nine chapters, the authors have adopted the Kluyver and Donker "working theory" of microbiological fermentation to explain the mechanism of the fermentation of monoses. It is unfortunate that the signs in the explanatory text, pp. 86–89, giving a method of constructing a balance sheet for the action of a particular organism on glucose, do not correspond with those of the accompanying table. On p. 133 the authors give an excellent classification of the lactic acid bacteria, namely, "The safest subdivision of the lactic acid bacteria remains at present the division based partly on their morphological characters and partly on their mode of action on fructose, whether they are capable of producing mannitol or not." In listing *Cl. acetobutylicum* as one of the names used to designate the commercial butyl alcohol organism, p. 147, the authors omit the paper on 'which the name is based [McCoy, Fred, Peterson and Hastings, *J.* Infect. *Dis.*, **39,** 457 (1926)]. In the list of products of a typical fermentation of starch by the acetone–butyl alcohol organism, p. 159, no mention is made of ethyl alcohol, although it is well known that this substance makes up 8–10% of the fermentation products.

Part III is a short section dealing with the microbiological synthesis of glycogen, starch, fat and mucus.

Part IV presents a discussion of the microbial flora and general microbiology of grain and flour, sizing materials, adhesive pastes, dough and bread. Part V similarly deals with sugar manufacture and storage.

Among the numerous fungi mentioned in the book, the ubiquitous *Penicillium glaucum* occupies a prominent place. It is unfortunate that the authors did not mention that this is an indeterminate species; a term which most investigators agree does not accurately describe any species of mold and which should be abandoned.

The book, as a whole, is well written and the Index of Authors and Subject Index facilitate easy reference to the original papers given at the ends of the various chapters. The book is a valuable addition to the reference shelf of every worker in the field of fermentation.

L. M. PRUESS

Entstehung, Veredlung und Verwertung der Kohle. (Origin, Processing and Utilization of Coal.) Edited by K. A. REDLICH, J. C. BREINL and H. TROPSCH. Verlag von Gebrüder Borntraeger, W 35 Schoneberger Ufer 12a, Berlin, Germany, 1930. vii + 359 pp. 86 figs. 16 X 25 cm. Price, unbound, M. 30; bound, M. 33.

This volume is based on a series of lectures given at the Deutsche Technische Hochschule at Prague, by leaders in different fields of coal technology and research. These lectures have been expanded and published in this book as the following separate papers: "Relation between Properties of Coal and its Geological History," by Dr. W. Petrascheck, Professor of Geology, Montanistischen Hochschule, Loeben, 21 pages. "The Representation of the Degree of Coalification (the Rank of Coal) by the Ternary Diagram and its Application to Coal Processing," by Dr. H. Apfelbeck, Director of Lanzer Kohlen-A.-G. Falkenau a.d.E., 40 pages. "The Present Status of our Knowledge of the Chemical Constitution and Origin of Coal," by Dr. H. Tropsch, Director of the Coal Research Institute, Prague, 20 pages. "The Drying and Carbonization of Brown Coal," by Dr. R. Heinze, Director, Kohlenverschwelungs-A.-G. Halle a.d.S., 357 pp. "The Synthesis of Organic Compounds Derived from Gases Obtained from Coal," by Dr. H. Tropsch, 53 pp. "The Economic and Energy-Economic Significance of Coal," by Dr. Kothny, Professor, Deutsche Technische Hochschule, Prague, 17 pp. "Combustion of Solid Fuels," by Dr. H. Löffler, Vienna, 11 pp. "The Szikla-Rozinek Process of Pulverized Coal Firing," by Dr. A. Rozinek, Budapest, 14 pp. "Theoretical Fundamentals of Mechanical Combustion Control," by Dr. J. C. Breinl, Professor, Deutsche Technische Hochschule, Prague, 17 pp.

From a chemical point of view, the outstanding contribution is the article by Tropsch on the Synthesis of Organic Compounds from Gases

Derived from Goal. This paper is the first well-digested review of the world literature on this important subject. It fills an urgent need. No one is more competent for this job than Tropsch, and it is hoped that it is a forerunner of a comprehensive monograph. The paper is replete with original refercnres to American, British and French, as well as German work and covers the purification of gases for synthetic purposes, the separation of the components of coke-oven gas by liquefaction and fractional distillation, the chemical utilization of ethylene, the pyrolysis of methane and higher hydrocarbons, the partial oxidation of methane, and the synthesis of hydrocarbons and alcohols from water gas. The chemist will also be interested in Apfelbeck's examples of the use of ternary diagrams in expressing the relation of the elementary composition of coal to its classification and properties, and in Tropsch's excellent review of the chemical constitution of coal, in particular the work of recent German investigators. The geologist's point of view on the origin and metamorphism of coal is well presented by Petrascheck in his paper on the Relation between Properties of Coal and its Geological History. The paper by Heinze on the Drying and Carbonization of Brown Coal contains a discussion of the colloidal nature of these high moisture coals that is of special interest in connection with the utilization of American lignites. However, the section on carbonization does not apply to American lignites because of their leanness with respect to oils and tars. The other papers in the volume are of an engineering nature.

A. C. FIELDNER

Alkylperoxyde und Ozonide. Studien uber peroxydischen Sauerstoff. (Alkyl Peroxides and Ozonides. Studies on Peroxide Oxygen.) By Dr. ALFRED RIECHE, Lecturer in Chemistry at the University of Erlangen. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1931. viii + 172 pp. 14 figs. 15 × 23 cm. Price, unbound, RM. 10.

A monograph that does not contain long lists of compounds which are treated as if they were museum specimens, that aims to be selective rather than comprehensive, critical rather than objective, is a refreshing novelty in modern chemical literature. And when it deals with subjects so actively under investigation as are peroxides, autoxidation and ozonides, it is certain to be useful to many who find it difficult to keep abreast of the numerous and widely scattered publications on these subjects.

Dr. Rieche explains that his little treatise naturally assumed its present form because it represents an expansion of his "habilitationsschrift." It begins with a survey on alkyl peroxides, the class which is most significant in biochemical oxidations and which has received the most attention in recent years. This section includes a discussion of the formula of hydrogen peroxide and an account of all peroxides that can be regarded as substitution products of hydrogen peroxide in which one or both of the hydrogen atoms have been replaced by alkyl, hydroxy alkyl and alkylidene groups. It also includes an interesting chapter on autoxidation—its role in biochemical oxidations, in the explosion of mixtures of oxygen and hydrocarbons, and in the chemistry of free radicals.

A second section deals with the investigation of peroxides by optical methods—refraction and absorption in the ultraviolet. Here the author adopts Fajans' interpretation of refraction and frequently employs electronic formulas "in order to be able to formulate matters that cannot well be represented in terms of the classical doctrine of valence."

A final section containing a chapter on ozonization as a source of peroxides and another devoted to general conclusions complete the volume. In this concluding chapter the author, with some reserve, expresses the opinion that there are two kinds of alkyl peroxide: the well-known type which is related to the common form of hydrogen peroxide, and another—"alkyl oxoxides"—of which no representative has been isolated but which can be inferred from the behavior of many substances toward activated oxygen.

This little treatise can be heartily recommended to all who are interested in these important subjects.

E. P, KOHLER

Bioassays. A Handbook of Quantitative Pharmacology. BY JAMES C. MUNCH, Director of Pharmacological Research, Sharp and Dohme; Pharmacologist, Bureau of Biological Survey, U. S. Department of Agriculture. The Williams and Wilkins Company, Mt. Royal and Guilford Aves., Baltimore, Maryland, 1931. x + 958 pp. 15.5 X 23.5 cm. Price, $10.00.

Chemical knowledge of some of the most important drugs used in medicine has not advanced to a point where it is possible to determine by chemical analysis whether they are of suitable strength and purity to be used in the treatment of disease. This is the case, for example, with the most important drugs used in diseases of the heart and in child-birth, the various gland products and vitamins. In many cases, however, such information may be obtained by experiments upon lower animals and in some cases upon isolated organs (for example, the heart).

So important have some of these biological assay methods become that they are included in the U. S. Pharmacopoeia, the legal standard for medicines sold in the United States. The Health Committee of the League of Nations also has a committee on this subject in order to secure international uniformity in the case of a number of important drugs. Some of the methods are also indispensable in the detection of powerful poisons.

This volume of Dr. Munch is by far the most complete and authoritative work ox this subject which has appeared in any language. The enormous amount of work which has been done on this subject is evident from the fact that the author states that he bas consulted 17,000 references; 5000 of these are cited in the volume. The work is, however, much more than *a* compilation; the author concludes each chapter with a critical summary of the data presented and an expression of his own views based upon years of experience in this field.

Not only is the work remarkably complete and well illustrated but it seems to be peculiarly free of errors of any kind; the motto of the publishers, "Sans Tache" seems to be justified (although "Cod Liver Oil" dots not appear in the index).

It is safe to predict that this volume will for many years be the recognized authoritative work on this important subject.

[CONTRIBUTION FROM THE CHEMISTRY LABORATORY OF THE JOHNS HOPKINS UNIVERSITY]

THE OSMOTIC PRESSURE OF DILUTE BENZENE SOLUTIONS BY THE POROUS DISK METHOD[1]

BY WILLIAM C. EICHELBERGER

RECEIVED AUGUST 30, 1930 PUBLISHED JUNE 8, 1931

Introduction

An accurate method of measuring a colligative property (1) of very dilute solutions in order to test the Debye–Hückel theory of solutions at low concentrations and (2) of colloidal solutions is very desirable. Heretofore, none of the colligative properties could be investigated at sufficient dilutions for these purposes. Furthermore, a method is needed which is applicable over a range of temperature, concentration and kind of solvents. Osmotic pressure is one property which can be so studied.

Measurements of osmotic pressures of non-aqueous solutions have been very few, due mainly to the fact that no suitable membrane could be found. Usually the membrane either dissolved slightly in the solvent, or was nearly impermeable to it. A brief survey of the work with non-aqueous solvents is given by Bartell and Osterhof[2] and also by Murray.[3]

In order to overcome the difficulties of membranes in osmotic pressure measurements Townend,[4] working under the direction of Professors J. C. W. Frazer and W. A. Patrick, developed a new method of measuring these pressures in which the ideal membrane is used, that is, the vapor of the solvent itself. It is known as the "porous disk method" of measuring osmotic pressures and should be applicable to solutions of any volatile solvent and non-volatile solute. The method was improved by Martin and Schultz.[5] The apparatus used in the present series of measurements was designed after that used by the latter two workers, with the neces-

---

sary modifications and improvements needed for use with non-aqueous solvents.

Temperature Regulation

In this method of measuring osmotic pressures it is very essential that the temperature of the osmometer (the instrument used to measure the osmotic pressure), including all parts having the vapor state in contact at any point with either the solution or the solvent, be kept very constant throughout the measurement of a tension (see Frazer and Patrick[6] and Martin.)[7]

For this purpose there was constructed a large thermostat 127 cm. high by 86 cm. in diameter, heavily insulated with hair-felt Instead of the usual type of toluene–mercury thermoregulator, which has presented a number of difficulties when attempts have been made to secure regulation better than 0.001°, a new method of temperature control, proposed by Dr. D. H. Andrews of this Laboratory, was tried. Using the principle of the Wheatstone bridge, a resistance thermometer was constructed of four 900-ohm coils, alternately nickel and constantan. No. 36 nickel wire was used and No. 30 constantan Each coil was wound on a sheet of asbestos board **15** X 15 × 0.32 cm. The four coils were mounted in a thin, water-tight copper shield filled with transformer oil. This was suspended in the thermostat in a location similar to that of the osmometer flask. The wires from the coils were led through a brass tube to the top of the thermostat. An e. m. f. of 12 volts was impressed across two sides of the bridge and a sensitive galvanometer was connected across the other two sides. A change in temperature unbalanced the bridge, causing the mirror of the galvanometer to move. Light was reflected from this mirror upon a photoelectric cell in such a manner as to move on the cell when the thermostat cooled down and to move off when it warmed up. The weak current of the cell was amplified by a vacuum tube and relays which cut on and off the current to the electric heater in the thermostat[8]

A stream of water, several degrees cooler than the main thermostat and held constant to ±0.02° by means of a small auxiliary thermostat, was circulated continuously through a coil in the center of the bottom of the main thermostat.

With this method of temperature control, regulation to ±0.002° was the best which could be secured. Applying the principle of the Gouy oscillating contact[9] for toluene–mercury thermoregulators, a "shutter," consisting of a metal strip 5.2 X 7.6 cm., was suspended in front of the photoelectric cell in the path of the beam of light. This shutter was connected to a crank on a reducing gear-box driven by an electric motor. Its amplitude was less than the operating width of the photoelectric cell and its frequency was about 45 cycles per minute. It operated in such a manner that, as the thermostat cooled down, the beam of light shone on the cell for larger fractions of each cycle; and as the thermostat warmed up, the light hit the cell for smaller fractions of each cycle When the temperature of the thermostat became very constant, the beam of light was practically stationary, shining on the position of the cell all the time and being cut off from the cell by the shutter at definite intervals. By this method it was possible to hold the temperature constant to ±0.0002°, or better, for several hours at a time.

[6] J C. W. Frazer and W. A. Patrick, *Z. physik. Chem.*, 130,691 (1927).

[7] F. T. Martin, "Dissertation," Johns Hopkins University, 1929.

[8] Details of this method of temperature regulation have appeared in the literature since this work was done.

[9] Sligh, THIS JOURNAL, **42,** 60 (1920); also Gouy, *J. phys.*, 6,479 (1837).

A differential thermometer, consisting of a capillary of a 360" thermometer seated to a number of short, parallel tubes filled with an alcoholic solution of a dye, was used to read the temperature variations in the thermostat to 0.0002°.

Glass Apparatus.—The main change in the glass apparatus over that used by Martin and Schultz[5] with aqueous solutions was the elimination of all stopcocks where they might in any way come in contact with benzene, the solvent in the present experiments, because stopcock grease is soluble in benzene. This required an additional valve in the mercury traps. The osmometer was also changed slightly.

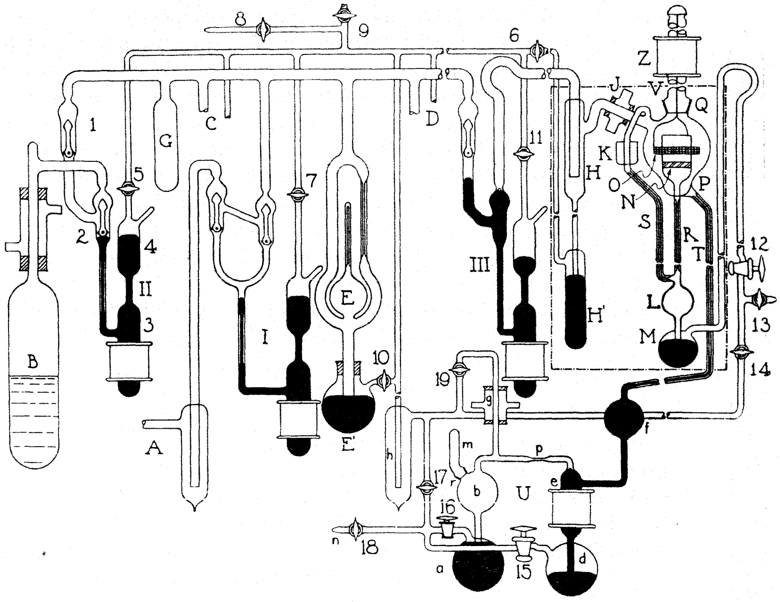

Fig. I.

A diagram of the apparatus is shown in Fig. I. The trap **A,** cooled with solid carbon dioxide, led to a two-stage mercury diffusion pump backed by a Cenco Hyvac oil pump. The mercury trap I connected the pumps to the main system. **A** bulb B of about 800-cc. capacity was a benzene reservoir. Another such bulb and trap were connected at D. At C was connected a mercury trap like trap I and a new type of deaerating apparatus. E was a McLeod gage. G was a 60-cc. bulb for condensing benzene vapor in the main system and as an approximate measure of benzene for diluting the solutions. Mercury trap III led to the apparatus in the thermostat H was a mercury cut-off in the thermostat for enclosing the vapor system entirely under water.

The main part of the apparatus, that used for the measurements, was the "osmometer." It consisted of a liter flask, P, inside of which was sealed a cup containing the porous disk, N. Near the top of the flask was a tube connecting it to the trap H. Over this tube was a small condenser, J, for distilling benzene into the solution. On the upper side of the tube, near the osmometer, was connected a small tube leading to the capillary S and around which was another condenser, K, which was used to distil benzene under the disk. Into the top of the osmometer was fitted a ground-glass, mercury-scaled stopper, Q, sealed to a tube, V, shown in detail in Fig. 2. In V was mounted the mechanism for operating the stirrer, O, in the solution. O was a platinum gauze bent in a circle around the cup containing the disk. Platinum wires supporting the gauze were welded together above the cup and hooked over F, a tungsten wire sealed into a glass rod, Y.

Martin and Schultz[5] observed during their measurements that liquid condensed in the tube containing the stirrer mechanism, at the point where the tube came through the water of the thermostat, and which caused an erroneous rate of distillation. Hence, a mercury seal had to be placed inside this tube. The detail of V, Fig. 2, shows the inverted glass cup at W fitted over a small tube. The cup was sealed to a glass rod, Y, which was sealed to a glass tube containing a bar of iron, X. The entire stirrer was suspended from a phosphor-bronze spring supported at the top of V. The bottom of the cup rested in mercury, thereby sealing off the benzene vapor in the osmometer from the remainder of the stirrer tube. This cup was below the water level of the thermostat. The stirrer was operated by means of a solenoid mounted around V just below the center of the iron bar, X. The solenoid was connected to the 14-volt line and in series with an eccentric driven by a motor and reducing gears. This cut on and off the current through the solenoid, thereby pulling the stirrer down and up and hence agitating the solution. The inverted cup was raised and held above the mercury seal by means of the solenoid when the osmometer was being evacuated or when benzene was being distilled into it in order that pressure equilibrium could be established in the top of V.

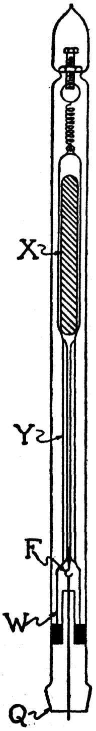

Fig. 2.—Stirrer mechanism.

R was the "inner" and S was the "outer" capillary of the osmometer. These two capillaries formed the manometer for measuring the osmotic pressure and they were about 65 cm. long. R was sealed to the cup supporting the disk. R and S met above the small bulb L whose mercury reservoir was M. A capillary tube T led from the solution side of the osmometer to the solution-introducing apparatus, U. These capillaries and the osmometer flask as high as the disk were visible from outside the thermostat through a narrow window. Doors in front of the window insulated it from without.

All the apparatus within the broken line in Fig. 1 was inside the thermostat and below the water level.

The Porous Disk.—A description of the porous disk, used to support the pure solvent and made from equal parts of Pyrex glass and a special clay, is given by Martin and Schultz.[5]

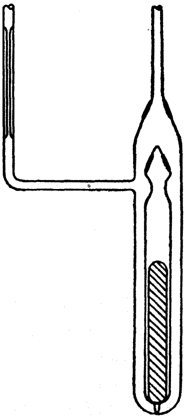

Fig. 3.—Valve for mercury traps.

Mercury Traps.—The mercury traps were similar to those designed by Martin and Schultz[5] except for the extra valve necessary for the elimination of a stopcock in contact with mercury. This valve (bulb **3**, Fig. 1, and shown in detail in Fig. **3**) was a ground-glass stopper sealed to a glass tube containing a bar of iron. This stopper, which floated in mercury, fitted into its ground-glass seat at the top of the bulb. It was pulled down by passing a current through a solenoid mounted around the bulb, **3**.

To close the trap, atmospheric pressure was admitted to bulb 4, Fig. 1, through stopcocks 5 and 8 and the stopper in **3** was pulled down by passing a current through the solenoid. Then the mercury was allowed to rise in *2* until the stopper was seated and mercury-sealed. To open the trap, the procedure was the same except that instead of atmospheric pressure, vacuum from an oil pump for the "secondary system" was admitted to bulb 4 through stopcocks 5 and 9

The mercury for the traps was purified by allowing it to drop through a long column of dilute nitric acid and then through distilled water, and finally distilling it under vacuum The mercury for the bulbs of the osmometer and of the solution-introducing apparatus was similarly purified, except that it was redistilled three times.

The Solute

The solute used in osmotic pressure measurements by this method obviously must be as nou-volatile as possible. Inorganic salts are the most desirable to use because of their low vapor pressure, but unfortunately very few of them are soluble to any extent in benzene. Furthermore, many of those which are soluble are associated in benzene solution.

An organic compound of high molecular weight and of high boiling point was selected as the solute: tetraphenylethylene. It melts at 221°, boils at 425° ("International Critical Tables") and has a molecular weight of 332.16. Hence it was felt that its vapor pressure at 25° and in dilute solutions would be sufficiently low for use in the present experiments. It is very soluble in benzene.

A freezing-point lowering determination of it in 0.1 molar benzene solution was made and it was found to behave normally. Its calculated molecular weight was 320.4 which, for the method employed, was considered within experimental error of the theoretical value.

The tetraphenylethylene had been carefully purified by Smith[10] for specific heat measurements. It gave a good freezing-point curve, so no further purification of the substance was deemed necessary.

Experimental

Purification **and** Deaeration of **the** Benzene.—The benzene used was Baker's *c.* P. benzene. It was purified according to Dr. Greer's method[11] and was stored over calcium chloride. Just before use the benzene was distilled off phosphorus pentoxide, the fraction boiling within 0.04" or less, of the boiling point being collected.

About 400 cc. of this benzene was poured into the bulb B, Fig. 1, and subsequently frozen. The top of the bulb was then sealed off and most of the air pumped out of the bulb. The benzene was further cooled with solid carbon dioxide and the space above it in the bulb was highly evacuated. After closing trap II, the benzene was allowed to melt. Water was circulated through the condenser above the bulb and a small electric light beneath the bulb supplied heat for refluxing the benzene. At frequent intervals the air above the benzene in the bulb was expanded into the outer evacuated system by closing trap I and opening trap II. The benzene could not be opened directly to the pumps, as there would have been a very rapid distillation of benzene into the solid carbon dioxide trap, A. This process was repeated for a number of days until less than 0.001 mm. of mercury air pressure developed overnight. This benzene was then distilled into another bulb connected to the main system and containing phosphorus pentoxide by placing ice around the phosphorus pentoxide bulb and warm water around the bulb B and opening the proper traps. The benzene was refluxed over the phosphorus pentoxide for about a week to dry it completely and remove the last traces of sulfur impurities. Then the benzene was distilled back into the first bulb and its deaeration was continued for several weeks until the air pressure which accumulated above it after stand-

[11] E. Juanita Greer, THIS JOURNAL, 52,4191 (1930).

ing two days was of the order of 10^{-5} mm. of mercury. Thereafter, the air was removed at less frequent intervals.

A new deaerator, designed by Dr. Taylor[12] of this Laboratory for the preparation of air-free liquids, was used in the deaeration of the benzene for the last experiment.

Cleansing and Deaeration of the Osmometer.—The osmometer, before mounting in the thermostat, was treated with a saturated solution of chromic oxide in concentrated nitric acid for four days, allowing the solution to run through the disk to the bulbs below. Then it was cleaned with dilute nitric acid for a day. It was then washed with distilled water and finally with conductivity water until the water which ran through the disk had practically the same conductivity as that put in the flask above the disk.

The osmometer was evacuated continuously for a couple of days to remove most of the air. Then benzene from one of the reservoir bulbs was distilled into it by closing trap I, opening the main system to one of the benzene reservoirs and running ice water down the sides of the osmometer flask in order to remove the last traces of grease and impurities in the flask. After admitting air to the osmometer, this wash benzene was drained out. The disk and disk cup also were carefully rinsed with pure benzene.

The osmometer was reevacuated for several days, at the end of which time an air pressure of only 2×10^{-4} mm. of mercury developed upon standing overnight. Air-free benzene from one of the reservoir bulbs was then distilled into the bulb below the disk by running ice water through condenser K, and then the benzene was raised upon thr mercury from the bulb M into the space under the disk. By pumping this benzene through the disk, out of the osmometer, most of the air left in the disk was removed and afterwards an almost negligible air pressure developed in the osmometer, which was now ready for measurements.

Procedure in Making Measurements.—Air-free benzene from a reservoir bulb was distilled under the disk by a method similar to that by which Martin and Schultz introduced water under the disk in their apparatus.[5] When sufficient benzene had been placed under the disk the mercury in R (and S) was pumped up by pumping air through stopcocks 13 and 12 until most of the benzene had been forced through the disk.

Air which had accumulated in the osmometer during this distillation was removed by evacuating the main system to a flat gage and then expanding the air in the osmometer into the evacuated system. After letting the benzene stand over the disk for half a day, the liquid was pulled down slowly through the disk by placing small tension5 (two centimeters of mercury) upon the benzene; that is, by lowering the mercury level in the outer capillary S a couple of centimeters below that in R. After all the benzene had been pulled through the disk, it was possible to place tensions up to 60 cm. of mercury upon the pure benzene without its breaking away from the disk.

Next, the solution was introduced into the osmometer, using the apparatus shown at U. Fig. 1. A solution of the desired concentration and volume was prepared under as dry conditions as possible. The benzene was protected from moisture by transferring it from one flask to another through small tubing and drying with phosphorus pentoxidc the air which was used to force over the liquid.

The solution-introducing apparatus was evacuated to dry the bulbs completely and the mercury. Air was readmitted to it through trap *h* which was surrounded with solid carbon dioxide. The solution was transferred from the flask in which it had been prepared into the bulb b, taking precautions to exclude as much moisture as possible. After mercury-sealing the stopper *m* at r, ice water was circulated through the condenser *g* and the solution was partially evacuated by opening and closing stopcock 19 frequently. This stopcock could not be left open continuously, or too much benzene would have distilled into the solid carbon dioxide trap, h.

---

[12] R. K. Taylor, THIS JOURNAL, 52, 3576 (1930)

When most of the air had been removed from the solution, the mercury in T and f was lowered until the stopper in the valve e was released from its seat. The solution in b was then raised slowly by admitting air to the mercury bulb *a*, thereby forcing the solution into *f*, stopping before the mercury ran from *b* to *e*. Then air was admitted to *d* slowly, which forced the stopper in e into its seat and raised most of the solution into the osmometer. By means of a hand air pump, air pressure was pumped into d sufficient to force all the solution and about 100 cc. of mercury into the osmometer flask. The solution was floated on mercury to give better thermal equilibrium between the solvent under the disk and the thermostat. The mercury level was just below the disk. In this manner was introduced into the osmometer 200 cc of solution.

The deaeration of the solution was completed in the osmometer by repeatedly expanding the air into the outer evacuated system until no air pressure in the system was observed when it was tested with the McLeod gage. The stirrer for the solution was started and the air was again removed until an air pressure of the order of only 10^{-5} mm. of mercury developed after several hours of stirring

Meanwhile, the thermoregulator equipment was set in operation. When the temperature had been regulating for an hour to within ±0.0005° or less, measurements of the osmotic pressure of the solution were begun. Temperature variations of less than ±0.0002° were secured part of the time and gave much more reliable results.

Various tensions were placed upon the pure solvent and their corresponding rates of distillation were measured. Using tensions less than that corresponding to the osmotic pressure of the solution, distillation from the solvent to the solution took place; conversely, using tensions greater than that corresponding to the osmotic pressure of the solution, distillation from the solution to the solvent occurred. Distillations in both directions were measured in order to keep the concentration of the solution as nearly the same as possible; however, the maximum amount of benzene distilled in either direction was never over several tenths of a cubic centimeter.

Positions of the upper meniscus (that in the capillary R under the disk) and of the lower meniscus (that in the outer capillary S) were read to hundredths of millimeters with a cathetometer, and the times of reading the upper meniscus were noted. A reference line on the apparatus was also read each time because the apparatus shifted slightly and all the readings had to be corrected to the initial, or "zero," position of the osmometer.

After applying a tension, about an hour was allowed before readings were begun, in order that constant conditions would be established. Three readings of each meniscus and reference line were made at approximately hourly intervals. After determining the average of each set of readings, the height through which the upper meniscus had moved was calculated. This height was immediately plotted against its corresponding time. When three or four points lying approximately on a straight line were obtained, the slope of the best line drawn through them gave the rate of distillation for that tension and further readings on that tension were discontinued. A new tension was then applied and its rate was determined. The rates were plotted against their corresponding tensions and a line was drawn through these points. When a straight line was obtained from a number of rates, the measurements on that solution were complete. The point at which the line crossed the zero-rate axis gave the tension corresponding to the osmotic pressure of the solution — the observed osmotic pressure.

The tension exerted upon the pure solvent is made up of three parts: (a) the length of the mercury column from the lower to the upper meniscus; (b) the benzene column from the upper meniscus to the surface of the disk; and (c) the net height of benzene vapor from the surface of the disk to the surface of the solution, which, from equilibrium considerations and the laws of thermodynamics, must be equal to a benzene column of the same height. The mercury equivalents of parts (b) and (c) were calculated and added to (a) to determine the actual tension on the solvent.

The mean time for the tension and the mean position of the lower meniscus were determined for the points used in drawing the rate curve. All calculations were made at the temperature of the thermostat, namely, 26.85°.

The theoretical value of the osmotic pressure was calculated from the equation

$$PV_0 = xRT = (N/N_0)RT, \text{ or}$$
$$P = NRT/V_0N_0$$

where P = osmotic pressure in atmospheres, V_0 = molar volume of solvent, x = mole fraction of solute, N = number of moles of solute, N_0 = number of moles of solvent, R = gas constant and T = absolute temperature.

After starting a series of measurements, readings were taken on as many tensions as possible, usually three or four, so long as the thermostat was working properly. From four to six hours were needed for the measurement of each tension.

Analysis of Solution.—After completing the measurements of the tensions, three samples of the solution were removed for analysis in order to determine its concentration. The same apparatus that was used for introducing the solution was used for removing it. The solution was lowered into bulb *f*, Fig. 1, and then permitted to run slowly from f to b, by lowering the mercury level in *e* sufficiently to release the stopper in *e* from its seat. When enough solution had run into b, the remainder was forced back into the osmometer. After admitting air to b and removing the stopper *m*, the solution was sucked from b into three glass-stoppered flasks which held about 50 cc. each.

The weight molar concentration of the solution was determined by weighing (1) the flask and solution, (2) the flask and solute after evaporating off the solvent, and (3) the empty flask after dissolving out the solute and drying the flask.

Dilution of the Solution.—Knowing the approximate concentration of the solution in the osmometer, from the way in which it had been prepared, it was possible to calculate the approximate amount of solution which must be removed from the osmometer to leave the correct amount of solute for the next lower concentration. This calculated amount was the volume removed for analysis and was divided into the three samples. Also, this was the volume of pure benzene which had to be added to the solution for the next dilution.

To dilute the solution the outer system was evacuated to a flat gage, trap I was closed and trap II was opened. Ice water was placed around bulb G and the benzene for diluting the solution was distilled from a reservoir bulb into G. Trap II was closed when the proper amount of benzene was in G. Traps III and H were opened, water at a temperature of **31–35'** was placed around G and ice water was circulated through condenser J. This caused the benzene to distil from G to J and from there it ran into the solution. Reflux action between the benzene under the disk and the condenser J caused benzene to be distilled from under the disk into the solution. This was later replaced by more benzene.

When the dilution was completed, traps III and H were closed. The outer system was evacuated to a flat gage and any air in the osmometer was removed by repeated expansions into the outer evacuated system. The stirrer in the solution was set in motion and when the solution was as air-free as possible, measurements on this concentration were made.[13]

Experimental Results

A preliminary experiment was performed using pure benzene as the "solution" in order to test the possibilities of the apparatus and to learn how to manipulate it. Then the osmotic pressures of five solutions of tetraphenylethylene in benzene were measured, starting with the most concentrated solution and diluting down. The results of these experiments are given in Table I. The concentrations are weight molar and the osmotic pressures are millimeters of mercury at the temperature of the experiments, 26.85°.

The results of one experiment are given in detail in Table II. In the columns are listed, from left to right, the times at which the upper meniscus was read, the positions of the upper meniscus, of the lower meniscus and of the reference line, and the temperature variations of the thermostat as observed during the course of the experiment. Data for the other experiments were recorded in the same way.

TABLE I

Experiment number	Concentration, weight molar	Osmotic pressure, mm. Observed	Osmotic pressure, mm. Calculated
2	0.01919	313.2	312.7
3	.01502	242.9	244.8
4	.01007	162.1	164.1
5	.004057	66.7	66.1
6	.000466	10.5	7.6

As explained previously, from these data were calculated the distances through which the upper meniscus moved. By plotting these results the osmotic pressures, that is, the tensions for zero rates of distillation, were determined.

---

[13] For a more detailed discussion of the operation of the apparatus see the author's dissertation, W. C. Eichelberger, "Dissertation,"The Johns Hopkins University, 1930.

Figure 4 is a graph of the height–time curves for Table II, illustrating the method of determining the rates of distillation. Figure 5 is a graph of the rate–tension curves for all the experiments, from which the osmotic pressures for Table I could be read. From this last figure one may observe the nearness of the points obtained to their respective lines and hence the relative accuracy of the results. The results of experiments 2 to 5 are within 1% of their values as calculated from the equation $PV_0 = xRT$. The result of the last experiment has about the same absolute

error as some of the others, but its percentage error is much greater because of the very dilute solution.

2.032	361.72	416.18	215.97	± .0004
3.038	362.56	416.19	215.96	± .0002

Average tension (mm. of mercury).............77.48 mm.
Rate of distillation.........................−0.76 mm./hr.

By examining the graphs and the data sheets it was observed that in nearly every case where a point did not fall on or very close to the line drawn through the other points there were temperature variations greater than ±0.0005° in the thermostat. Very small temperature fluctuations would tend to compensate each other to some extent, but this was not usually the case with larger ones.

Considering the behavior of the apparatus and the results obtained, the author considers the apparatus suitable for measuring the osmotic pressures of dilute solutions over a certain range of concentration, the upper value of which is governed by the length of the capillary tubes R and S in the osmometer, Fig. 1. Better temperature regulation must be secured before very dilute solutions, those below **0.001** molar, can be measured accurately.

In conclusion the author wishes to express his great appreciation to Professors J. C. W. Frazer and W. A. Patrick, who suggested the problem and under whose kindly direction and counsel it was carried out.

Summary

1. An apparatus was developed with which it was shown possible to measure, with a fair degree of accuracy, the osmotic pressures of dilute solutions, benzene solutions of tetraphenylethylene being those measured. Greater precision should be possible if better temperature regulation could be secured.

2. **A** new type of thermoregulator employing a resistance thermometer and photoelectric cell was constructed for accurately controlling the temperatures of thermostats.

3. The elimination of stopcocks in vacuum systems containing vapors which will dissolve stopcock grease was successfully accomplished bv means of a modification of mercury traps.

THERMAL EXPANSION AND THE DEBYE-HÜCKEL HEAT OF DILUTION

BY GEORGE SCATCHARD

RECEIVED JANUARY 20, 1931 PUBLISHED JUNE 8, 1931

The calculation of the heat of dilution from the Debye–Hückel theory has been based on the calculation[1,2,3,4] of the energy U from the work content A by the Gibbs–Helmholtz equation, that is, through a differentiation ***at constant volume.*** However, the experimental data used are the change in heat content H, the dielectric constant and its temperature coefficient, all measured ***at constant pressure.*** The difference between the two heat quantities is small and can be determined, that between the two dielectric constants is probably also very small, but that between the temperature coefficients at constant pressure and at constant volume is generally more important. The difficulty is removed most simply by carrying out the calculations, like the experiments, at constant pressure. This involves the addition of a term dependent on the thermal expansion of the solution.

The present treatment will be limited to the case of a single electrolyte which does not change the dielectric constant of the solution. The fundamental equation of the Debye–Hückel theory, in the extended form of Gronwall, La Mer and Sandved,[5] may be written

$$\psi_j = \frac{-KT}{\epsilon z_j} \sum_{m=1}^{\infty} \left(\frac{\epsilon^2 z_j^2}{-KTDa}\right)^m X_m(x) \tag{1}$$

where ψ_j is the potential at the distance a from the center of the j'th ion, k is Boltzmann's constant, T the absolute temperature, ϵ the charge on the proton, z_j the valence of the j'th ion (negative for a negative ion), D is the dielectric constant of the solvent, a the mean collision diameter of the ions, which we will assume to be the same for both ions. Each $X_m(x)$ is a function of the ratio z_1/z_2 and of x, which latter is defined by the equation

$$x = \kappa a = \sqrt{\frac{-4\pi N\epsilon^2\nu\, z_1 z_2\, a^2 n}{1000\, KTDV}} \tag{2}$$

where N is Avogadro's number, ν the number of ions formed from one molecule of electrolyte, n the number of moles of electrolyte in V liters of solution.

[4] Lange and Meixner, *Physik. Z.*, **30**, 670 (1929).

[5] Gronwall, La Mer and Sandved, *ibid.*, **29**, 358 (1928)

If we define a new variable as

$$Y_m(x) = \frac{1}{x^{2m}} \int_0^x y^{2m-1}\, X_m(y)\, \mathrm{d}y \tag{3}$$

the work of charging all the ions reversibly at the same rate is

$$W_e = -NKTn \sum_{j=1}^{2} \sum_{m=1}^{\infty} \nu_j \left(\frac{\epsilon^2 z_j^2}{-KTDa}\right)^m Y_m(x) \tag{4}$$

where ν_j is the number of ions of the j'th kind formed from one molecule of electrolyte.

The electrical contribution to the heat content may be obtained by the Gibbs–Helmholtz equation at constant pressure written in the form

$$H_e = \frac{\mathrm{d}(W_e/T)}{\mathrm{d}(1/T)} \tag{5}$$

where W_e varies with the temperature directly, and also because of the temperature variation of D, V and a. All four of these quantities occur in x and therefore in each $Y_m(x)$. Gronwall, La Mer and Sandved give the relation

$$\frac{\mathrm{d}Y_m(x)}{\mathrm{d}x} = \frac{X_m(x)}{x} - \frac{2mY_m(x)}{x} \tag{6}$$

The differentiation of x is obvious and

$$If, = -NKTn \sum_{j=1}^{2} \nu_j \sum_{m=1}^{\infty} \left(\frac{\epsilon^2 z_j^2}{-KTDa}\right)^m \left[\left(1 + \frac{\mathrm{d}\ln D}{\mathrm{d}\ln T}\right)\frac{X_m(x)}{2} + \frac{\mathrm{d}\ln \mathrm{V}}{\mathrm{d}\ln \mathrm{T}}\left(\frac{X_m(x)}{2} - mY_m(x)\right) - \frac{\mathrm{d}\ln a}{\mathrm{d}\ln T}\left(X_m(x) - 3mY_m(x)\right)\right] \tag{7}$$

The total heat of dilution to zero concentration per mole Q_c^0 is

$$Q_c^0 = (H_e - H_e^0)/n \tag{8}$$

where II_e^0 is the value of II_e when x = 0.

Let us consider the Debye–Hückel approximation (m = 1). Since

$$x_1(x) = 1/(1 + x) \tag{9}$$

$$Q_c^0 = -NKT \sum_{j=1}^{2} \frac{\epsilon^2 \nu_j z_j^2}{2KTDa} \left\{ \frac{x}{1+x}\left(1 + \frac{\mathrm{d}\ln D}{\mathrm{d}\ln T}\right) + \frac{1}{x^2}\left[1 + x - \frac{1}{1+x} - 2\ln(1+x)\right]\frac{\mathrm{d}\ln V}{\mathrm{d}\ln T} + \frac{2}{x^2}\left[\frac{x^2}{1+x} + \frac{x^2}{2} - 3x + 3\ln(1+x)\right]\frac{\mathrm{d}\ln a}{\mathrm{d}\ln T} \right. \tag{10}$$

$$= -NKT \sum_{j=1}^{2} \frac{\epsilon^2 \nu_j z_j^2}{2KTD}\left[\left(1 + \frac{\mathrm{d}\ln D}{\mathrm{d}\ln T} + \frac{1}{3}\frac{\mathrm{d}\ln V}{\mathrm{d}\ln T}\right)\kappa - \left(1 + \frac{\mathrm{d}\ln D}{\mathrm{d}\ln T} + \frac{1}{2}\frac{\mathrm{d}\ln V}{\mathrm{d}\ln T} - \frac{1}{2}\frac{\mathrm{d}\ln a}{\mathrm{d}\ln T}\right)\right]\kappa^2 a + \ldots \tag{11}$$

The earlier calculations all omit the term in d ln V/d In T.[6] Gross and Halpern[1] apparently used the rest of equation (10) although they

---

[6] If the heat quantities on the left-hand side are energies rather than heat contents, and if the dielectric constant and its temperature coefficient are also measured at constant volume, the equations are correct with this omission.

did not publish their equation. Adams[2] gave the rest of the first term of equation (11) as the limiting law. Bjerrum[3] gave the first term of equation (10) and Lange and Meixner[4] gave the first term of equation (7). Bjerrum and Lange and Meixner drop the term in d ln a/d ln T because this coefficient cannot be determined independently and because it does not appear in the limiting law. Since $X_m(x)$ and $Y_m(x)$ for m greater than one disappear at $x = 0$ (they do not even appear in the limiting law) the complete value of Q_c^0 may be obtained by adding to Q_c^0 for $m = 1$ the contribution of the higher terms to H_e.

We are particularly interested in the term in d ln V/d ln T which has previously been omitted. We may note that it is in general, including the higher terms of equation (7), proportional to one minus the osmotic coefficient or to the j of Lewis and Randall. From the first term of equation (11) we see that it appears in the limiting law, and by comparing the two terms of this equation we see that for more concentrated solutions it increases less rapidly than the term in $(1 + \text{d ln } D/\text{d ln } T)$. A detailed study of the higher terms shows that its relative importance decreases with increasing values of m. The relative value of the two terms depends, of course, upon the two temperature coefficients. For water at 25° $\frac{1}{3}\frac{\text{d ln } V}{\text{d ln } T}$ is 0.0256, and Wyman's value[7] for $(1 + \text{d ln } D/\text{d ln } T)$ is -0.371, so that the error in the limiting law due to the neglect of the thermal expansion is +7.2%. This is about the difference between $(1 + \text{d ln } D/\text{d ln } T)$ of Wyman and of Drude,[8] and about the error of measurement of the heat of dilution in very dilute solutions.[9] It is probable that in the near future both of these experimental uncertainties will be reduced. For other substances the measurements of the temperature coefficient of the dielectric constant are less certain. The values for ethyl alcohol given in the "International Critical Tables"[10] indicate an error of 13% if the thermal expansion is neglected.

Summary

It is pointed out that it is incorrect to calculate the heat of dilution from the Debye–Hückel theory by differentiating at constant volume. The complete equation is derived for a solution containing a single electrolyte with the dielectric constant independent of the concentration. It is shown that neglect of the thermal expansion leads to a considerable error even in the limiting law.

THE ACTIVITY COEFFICIENTS AND HEATS OF TRANSFER OF CADMIUM SULFATE FROM ELECTROMOTIVE FORCE MEASUREMENTS AT 25 AND 0°. APPLICATION OF THE EXTENDED THEORY OF DEBYE AND HÜCKEL

BY VICTOR K. LA MER AND W. GEORGE PARKS[1]

RECEIVED JANUARY 30, 1931 PUBLISHED JUNE 8, 1931

Introduction

The activity coefficients of many typical electrolytes have been determined in both dilute and concentrated solutions, but few results have been reported for cadmium sulfate. The only available data are found in the work of Getman[2] on the electromotive force of galvanic cells and in the table of activity coefficients compiled by Lewis and Randall.[3] The latter results were calculated from the freezing point data collected in the paper of Lewis and Linhart.[4] The results of Getman are not consistent, while those tabulated by Lewis and Randall do not extend below a concentration of 0.01 molal.

Since it is well known that the halides of cadmium are somewhat anomalous in their behavior as electrolytes, this research was undertaken to establish the activity of the sulfate over the entire concentration range by measuring the electromotive force of the cell

$$\text{Cd-Hg (2 phase)} \mid CdSO_4\ (M) \mid PbSO_4\ (s) \mid \text{Pb-Hg (2 phase)} \qquad (1)$$

and to obtain data on an electrolyte of the symmetrical (2–2) valence type, which are well suited for testing the mathematical extension of the Debye–Hückel theory given by Gronwall, La Mer and Sandved.[5]

The previous electromotive force studies on cadmium sulfate have always involved the mercurous sulfate half-cell, but since lead sulfate is about one-tenth as soluble as mercurous sulfate, it is obvious that precise measurements can be extended to much lower concentration with the lead sulfate–lead half-cell.

If the temperature coefficient of such a cell is also measured, it becomes possible to determine not only the change in heat content of the reaction through the Gibbs–Helmholtz equation, but also to evaluate the electrical heat of transfer arising from electrostatic interaction by taking advantage of the accurate extrapolation afforded by the extension of the Debye–

Hückel theory given by Gronwall, La Mer and Sandved. Although free energy measurements at two temperatures alone afford only a partial answer to the question of electrical heats of dilution, they are sufficient to determine the temperature coefficient of the parameter "a" representing the distance of closest approach of the ions. The value of ∂"a"$/\partial T$ is of considerable theoretical interest in considering heats of dilution.

Theoretical

Although there have been many experimental investigations which have demonstrated that the activity coefficients of strong electrolytes in aqueous solution agree with the predictions given by the equations of Debye and Hückel sufficiently well to establish inter-ionic attraction as the explanation of the anomalies of strong electrolytes, nevertheless, it is true that experimental data exist which exhibit serious discrepancies from these equations in regions of high dilution. These discrepancies are quite unexpected on the basis of the Debye–Hückel equations. They appear most conspicuously in the case of high valence types in water as well as for univalent types in media of lower dielectric constant. On the other hand, data on higher valence types furnish the most convincing tests of the theory since the deviations measured are more significant and not subject to the same degree of experimental uncertainty that accompanies the data for lower valence types.

In this Laboratory we have held that the incomplete mathematical solution for the Poisson–Boltzmann equation as given by Debye and Hückel should first be completed and the data tested from that viewpoint, before ascribing the discrepancies between the abridged theory and experiment to new physical hypotheses such as incomplete dissociation, deformability of the ions, or even the ion-association hypothesis of Bjerrum.[6] This procedure has the advantage that the theory is not weakened by the immediate introduction of further arbitrary parameters which accompany new physical assumptions. Evidence that a more complete mathematical treatment without further assumptions is sufficient to account for data which are in apparent disagreement with the theory should furnish one of the most satisfying experimental proofs possible.

Whenever it is found that the general solution of the Poisson–Boltzmann equation is incapable of describing the behavior quantitatively on the basis of a constant and physically reasonable value of "a," it then becomes appropriate to ascribe such discrepancies to incomplete dissociation as embodied in the term "weak salt."[7]

---

[6] Bjerrum, *Det. Kgl. Danske Videnskab. Math.-fys. Medd.*, *VII*, No. 9 (1926). Bjerrum's ion-association introduces no new parameter but necessitates an arbitrary distinction between free and associated ions which becomes superfluous in the extension of Gronwall, La Mer and Sandved.

[7] Randall and Scott, THIS JOURNAL, 49, 647 (1927); Randall and Allen, *ibid.*, 52, 1814 (1930).

Since the extended theory of Debye and Huckel makes no pretense of dealing with factors other than electrostatic interaction it is important to ascertain to what concentration limit it is competent to account for the facts under the present incorrect but necessary approximation that the dielectric constant of the solution D is equal to the dielectric constant of the pure solvent D_0.

We shall be primarily concerned with the error introduced by Debye and Hiickel in retaining only the linear term of the expansion of the expression for the density of electricity ρ valid for a symmetrical electrolyte like cadmium sulfate where $z_1 = -z_2 = z = 2$

$$\rho = nz\epsilon\,(e^{-z\epsilon\psi/kT} - e^{z\epsilon\psi/kT}) \cong -2n\epsilon^2z^2\psi/kT \tag{2}$$

when this approximation for ρ is introduced into the Poisson equation

$$\nabla^2\psi = \frac{-4\pi\rho}{D} \cong \kappa^2\psi \tag{3}$$

where

$$\kappa = \sqrt{\frac{8\pi n\epsilon^2z^2}{DkT}} \tag{4}$$

The complete solution[5] of (2) and *(3)* for the activity coefficient of a salt of the symmetrical type takes the form

$$\log f = \frac{-\epsilon^2z^2}{kTDa}\cdot\frac{1}{2}\cdot\frac{x}{1+x} + \sum_{m=1}^{\infty}\left(\frac{\epsilon^2z^2}{kTDa}\right)^{2m+1}\left[\frac{1}{2}X_{2m+1}(x) - 2m\,Y_{2m+1}(x)\right] \tag{5}$$

where x = "a"κ and $X(x)$ and $Y(x)$ are functions of x defined and tabulated through the fifth approximation,[5] *i. e.*, $m = 2$. Employing Drude's value of D = 78.77 for 25°, $\kappa = 0.3283\,z\sqrt{M}$, we get the working equation suitable for numerical calculation

$$-\log_{10} f = 1.53636\left(\frac{z^2}{a}\right)\frac{x}{1+x} - 0.15382\left(\frac{z^2}{a}\right)^3\cdot 10^3\left[\frac{1}{2}X_3(x) - 2Y_3(x)\right] - 0.0770\left(\frac{z^2}{a}\right)^5\cdot 10^5\left[\frac{1}{2}X_5(x) - 4Y_5(x)\right] \tag{6}$$

A rough computation will show that whenever a/z^2 is assigned values **>1.5 Å.,** only the first term corresponding to the Debye–Hückel approximation need be considered in most work. However, when $a/z^2 <$ **1.5 Å.,** which means "a" < 6 Å. for a bi-bivalent salt, the contribution of the higher **terms** cannot be neglected. They will be important for **(2–2)** salts since **6** . is a large ion size. In low dielectric solvents the higher terms become important, in fact, may occasionally predominate over the first approximation even for **(1–1)** valence types, since the significant parameter is Da/z^2.

In the first approximation as given by Debye and Hiickel the limiting law is the asymptote when either "a" or the concentration factor $\kappa =$ **0.3283** $z\sqrt{M}$ is assigned values approaching zero, whereas in the general development of Gronwall, La Mer and Sandved, the limiting law is the asymptotic form *only* when κ approaches zero. In the general solution the correction terms assume infinite values ***whenever*** "a" ⟶ 0. The correctness[8] of this latter statement will be immediately evident when one recognizes that the field strength at the surface of a point charge is infinite. An assembly of point charges would condense together and it would require an infinite amount of work to separate such hypothetical ions. In other words, the logarithm of the activity coefficient would be infinite when "a" is set equal to zero. The indiscriminate use of the Debye–Hückel approximation may therefore easily yield absurd values for "*a*" when their equations are employed in the computation of experimental data on higher valence electrolytes. The general solution[5] overcomes this mathematical difficulty and should yield positive and physically reasonable values for "*a*" which are constant over a legitimate concentration range, provided the theory is correct in its fundamental postulates. It is our purpose to test this point.

The electromotive force of the cell (1) corresponding to the process

$$\mathrm{Cd\ (solid)} + \mathrm{PbSO_4\ (solid)} = \mathrm{Pb\ (solid)} + \mathrm{CdSO_4}\ (M) \qquad (7)$$

is given by the equation valid for 25°

$$E = E_0 - 0.05915 \log m - 0.05915 \log f \text{ (volts)} \qquad (8)$$

For convenience in plotting and calculating the activity coefficient $f_{\mathrm{CdSO_4}} = \sqrt{f_{\mathrm{Cd}^{++}} \cdot f_{\mathrm{SO_4''}}}$, we calculate the quantity E_0', where

$$E_0' = E + 0.05915 \log M, \text{ and} \qquad (9)$$

$$E_0' = E_0 - 0.05915 \log f \qquad (10)$$

If we use the Debye–Hückel limiting law valid for a bi-bivalent salt, namely

$$\log f = -4.04 \sqrt{M} \qquad (11)$$

we get

$$E_0' = E_0 - 0.239 \sqrt{M} \qquad (12)$$

It is evident that a plot of E_0' against $\sqrt{M}$ should approach a limiting tangent with slope 0.239, the intercept being E_0. Although this method of extrapolating for E_0 is widely used, it is open to the objection that it places the most weight upon the points in dilute solution, which are the most difficult to determine with accuracy. Furthermore, it assumes that the Debye–Hückel limiting law is obeyed exactly throughout the region of extrapolation.

A consideration of the magnitude of the third and fifth approximations ($m = 1$ and 2) in equation (5) shows that this assumption is not justified for any physically attainable concentration for a (2–2) salt. In fact, it cannot be emphasized too strongly that the *percentage error* in log *f* due to the neglect of the higher terms is most significant in the region of highly dilute solutions, *i. e.*, from about *0.0001* to 0.001 molal. The first approximation as given by Debye and Hückel predicts just the opposite.

---

[8] La Mer, *Trans. Am. Electrochem. Soc.*, **61**, **543** (1927). A mathematical proof is given in Ref. 5, Chapt. 2, p. 360.

We therefore employ the method of assuming an "a" value and calculate the value of E_0 through equations (6) and (10). That value of "a" which gives a constant E_0 value over the range of concentration for which it is legitimate to employ equation (6) under the assumption $D = D_0$ is taken as the true value. This method assigns equal weight to all the experimental points, and is not open to personal interpretation as is a graphical extrapolation.

From the data it is possible to compute the free energy of transfer accompanying changes in concentration of the solution. The free energy change $AF = \Delta\bar{F}_{CdSO_4}$ involved in transferring a mole of salt from a molality M_1 to a molality M_2 is given by the formula

$$-\Delta F = \frac{2 \times \Delta E \times 96{,}500}{4.182} \text{ calories} \tag{13}$$

where AE is the electromotive force of the cell

$$\text{Pb, PbSO}_4 - \underset{M_1}{\text{CdSO}_4} - \text{Cd} - \underset{M_2}{\text{CdSO}_4} - \text{PbSO}_4\text{, Pb}$$

corresponding to the process $CdSO_4$ (MI) ⟶ $CdSO_4$ (M_2).

The thermal change accompanying a chemical reaction can be calculated readily from the temperature coefficient of the electromotive force of a cell in which the particular reaction takes place. Thus, on substituting in the Gibbs–Helmholtz equation

$$-\Delta H = n\mathrm{F}\left(E - T\frac{\partial E}{\partial T}\right) \tag{14}$$

the observed value of E, at the temperature T, and the value of $(\partial E/\partial T)$ derived from the observed variation of E with T, we calculate the value of AH at the temperature T and molality M, where the solid cadmium and lead are saturated with mercury.

Owing to experimental difficulties which will be discussed later, sufficient data have not as yet been obtained for an exact calculation of the heat of the reaction. However, as a first approximation we may assume that $(\Delta E/\Delta T)_M = (\partial E/\partial T)_M$ and complete the calculation indicated by Equation 14, taking E for 12.5° as the mean of $E_{25°}$ and $E_{0°}$.

Preparation of Materials

Lead Nitrate.—The best grade of C. P. salt was recrystallized three times from boiling distilled water and the crystals were dried in air.

Cadmium Sulfate.—Since cadmium sulfate has a negative temperature coefficient of solubility, forming solid hydrates at low temperatures, the best grade of salt was recrystallized three times from boiling distilled water by slowly evaporating the solution to about one-third of its original volume. The crystals were then powdered in an agate mortar and heated in a large quartz dish to about 250° for six hours, forming anhydrous cadmium sulfate. According to Mellor,[9] when cadmium sulfate is recrystallized from water above 74" the product obtained is $CdSO_4 \cdot H_2O$. This monohydrate Mylius and

---

[9] Mellor, "Treatise on Inorganic and Theoretical Chemistry," Vol. IV, p. 616.

Funk[10] found decomposed into the anhydrous salt at 112°. Coniglio[11] reports for this transition temperature 150 to 170°. Partridge[12] in preparing his highly purified cadmium sulfate heated it to 200° for six hours. The prepared salt was preserved until used in a weighing bottle over phosphorus pentoxide.

Lead Sulfate.—The lead sulfate was precipitated from a cadmium sulfate solution by adding a 5% solution of the purified lead nitrate to an excess of a 10% solution of the purified cadmium sulfate. The solution containing the precipitate was heated to boiling for fifteen minutes, at the end of which time the lead sulfate had assumed a definite crystalline form. It was washed with distilled water, drained on a Biichner funnel, and preserved under distilled water in a Non-Sol battle until needed in the electrodes.

Mercury.—Redistilled mercury was stirred under dilute nitric acid for twenty-four hours and then twice redistilled by the Hulett[13] method in a slow current of air.

Lead Amalgam.—Lead amalgam was prepared by electrolyzing the purified lead nitrate solution using purified mercury as the cathode. The anode consisted of a platinum wire placed in another beaker filled with 1 *N* nitric acid, and connected to the first beaker by means of a Y-tube. This was necessary because lead peroxide forms at the anode during electrolysis. A paddle stirrer was placed in the cathode beaker to slowly stir the mercury. A current of 0.2 ampere was run until the concentration of lead in the amalgam was about 6%. Fay and North[14] report that all amalgams between the limits of 2 and 55% of lead form a two-phase system at 25°, consisting of a granular phase of constant composition represented by Pb_2Hg, and a liquid phase which also has a definite composition when equilibrium is reached. Puschin[15] found that all amalgams between 1.8 and 66% lead have the same electromotive force. Likewise Henderson and Stegeman[16] report that in their work they found the same value for the electromotive force of any amalgam containing between 2.5 and 6% lead.

The prepared amalgam was washed, dried, heated until it became one phase and filtered through a capillary tube into the evacuated reservoir, which was then filled with purified nitrogen and stored ready for use.

Cadmium Amalgam.—Using a mercury cathode, as in the case of the lead amalgam, cadmium was electrolyzed from a solution of purified cadmium sulfate. The anode consisted of a bar of C. P. cadmium, scraped clean of oxide. A current of 0.2 ampere was employed until the concentration of cadmium in the amalgam was about 11%. Frilley[17] reports that all amalgams of less than 5% are liquid. The solubility of cadmium in mercury was found by Hulett and deLury[18] to be 5.574 g. per 100 g. of mercury at 25°. Bijl[19] shows that all amalgams between 5 and 14% of cadmium have the same electromotive force when measured against any constant electrode at room temperature. The solid phase in the amalgam is reported by Kerp and Böttger[20] to have the composition represented by Cd_2Hg_7. However, they admit that there is some evidence that the solid phase may be a mixed crystal.

This amalgam was washed, dried, heated and stored under nitrogen in the same way

as the lead. In the preparation of both amalgams the concentration of electrolyte was kept high and the potential drop between the electrodes low so that the deposition of possible impurities was negligible. **A** concentration of metal in the amalgams was used such that the temperature could be varied from 0 to 50° and a two-phase system would result when equilibrium was attained.

Nitrogen.—Tank nitrogen was purified by passing it first through potassium pyrogallate, freshly prepared according to the method of Berthelot,[21] and then over-heated copper gauze in a quartz tube. The gas passed through a gas washing bottle filled with dilute sulfuric acid, followed by a tower filled with soda lime. Before entering the cell vessel the gas bubbled through a long upright tube filled with some of the solution in the cell to ensure the same aqueous tension

Experimental Method

Cell and Electrodes.—Although the attempts of some previous investigators to use the lead–lead sulfate electrode were unsuccessful, Henderson and Stegeman[16] obtained constant and reproducible results with the electrode in the presence of sodium sulfate. U. B. Bray[23] made a careful study of the electrode in the presence of zinc sulfate. He found that: (1) oxygen must be excluded. (2) A definite crystalline form of lead sulfate is essential. **(3)** It is best to establish equilibrium between the solid lead sulfate and the solution before the electrode is made up. (4) The use of two-phase amalgams is highly desirable, making the electrode easily reproducible without analysis. We confirm Bray's findings that the lead sulfate electrode is highly reproducible if these conditions are observed, but since his experimental details are scanty and we also had initial difficulties we give our procedure in some detail.

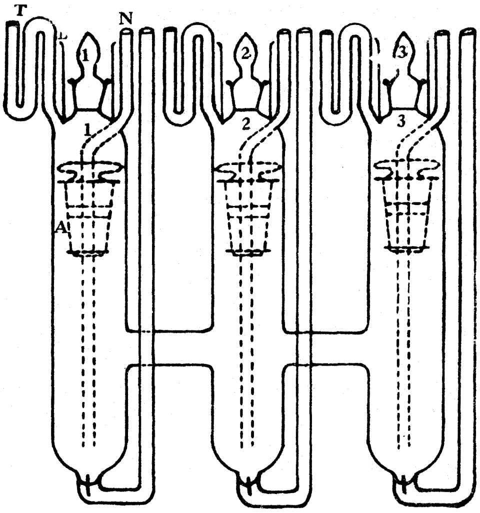

Fig. 1.

Figure 1 is a side view; Fig. *2* is a top view of the cell used. It is composed of six electrodes divided into two groups of three each by the stopcocks at A. On one side three similar lead electrodes, on the other side three similar cadmium electrodes were set up. These served as a convenient and satisfactory means of checking the constancy and reproducibility of each half-cell. Through the tubes marked N nitrogen could be

[23] U. B. Bray, *ibid.,* 49, 2372 (1927).

passed through the solutions to remove oxygen and facilitate equilibrium by stirring. These tubes were connected to a glass manifold made of Pyrex tubing carrying capillary tubing outlets for equalizing the flow of gas. The connections to the cell vessel were made with small bits of rubber tubing carrying pinch clamps to further regulate the flow when necessary. All rubber tubing was painted with castor oil and shellac. Small glass traps, marked T, were sealed on each electrode so that when the flow of nitrogen was stopped a few drops of mercury in each trap would prevent the diffusion of air into the cell. The lines on Fig. i marked B designate short pieces of large glass tubing sealed on each electrode with "picein" cement so that a mercury seal could be made over each ground glass joint. Later this method was discarded, the tubes were removed, and a few drops of castor oil placed in the gutter of each ground joint, a method which proved entirely satisfactory.

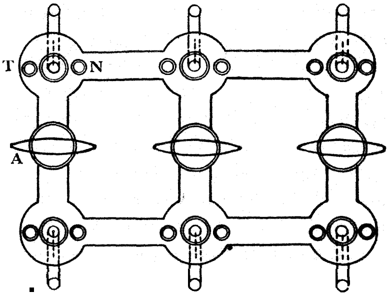

Fig. *2.*

The technique for filling the cell was as follows. The cadmium sulfate solution to be used was divided into two parts. To one part was added several grams of solid lead sulfate which had previously been washed with the cadmium sulfate solution, and the mixture rotated for fourteen hours in the thermostat. After carefully cleaning and drying the electrode vessel it was filled with nitrogen. One side of the cell was then filled with the cadmium sulfate solution saturated with lead sulfate and the other side with the pure cadmium sulfate solution. The cell was put in the thermostat and nitrogen bubbled through for one hour. At the end of this time the amalgams were added from the reservoirs in which they were stored. **A** sketch of one of these reservoirs is given in Fig. **3.** Boiling water was poured into the outside jacket marked A in order to heat the amalgam until it became one phase. Then after a few drops had been run out at the stopcock B to remove any amalgam that may have been in the tube in contact with the air, the electrode vessel **was** placed under the reservoir and the required amount of amalgam dropped through a very small funnel into the proper cell. Any oxide which is formed in the preparation of the amalgams is almost entirely removed on filling the reservoirs through the fine capillary tube C (Fig. **3).** The possibility of contamination from the traces of oxide remaining on the surface of the amalgams in the reservoirs is eliminated by filling each electrode with amalgam drawn from the bottom (stopcock B) and by passing the amalgam through the small funnel holding a filter paper with a pin hole opening. The cell was replaced in the thermostat, nitrogen continued for two hours more and the apparatus **then** sealed. Gas was passing through each electrode while the amalgams were being added. Large stopcocks (5 mm. bore) and short tubes at A (Fig. **2)** made it possible to measure the electromotive force with the stopcocks closed in all cases except for the solutions of about 0.002 molal and less. For these solutions, the hole in each stopcock held ***a*** plug of cotton previously soaked in the cadmium sulfate solution being used; also the level of the solution on the side containing no lead sulfate was made higher so that when the

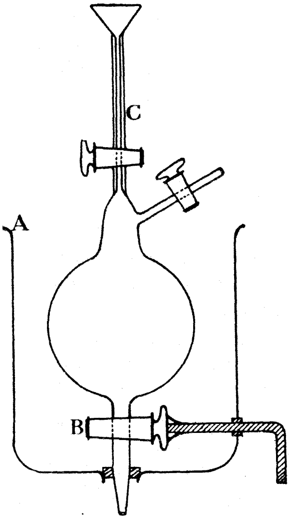

Fig. **3.**

stopcocks were temporarily opened for making a reading no lead sulfate could possibly siphon over to the cadmium side. A slight movement of the solution in the other direction is of no consequence, since it soon becomes saturated with lead sulfate.

The reproducibility of the cadmium electrodes was usually to within 0.01 millivolt. In the more dilute solutions a check of 0.06 millivolt was considered satisfactory for the lead electrodes. In the more concentrated solutions the agreement was much better. Frequently, as with the cadmium electrodes, no difference greater than ±0.01 millivolt was observed. Readings were taken for at least twenty-four hours after the cells had reached their final constant value, which was usnally about six hours after preparation. In the concentrated solutions, 1 molal and greater, this time of equilibrium was extended over forty-eight to seventy-two hours. The average reading of the nine combinations remained constant to 0.04–0.05 millivolt for from thirty-six to forty-eight hours after the equilibrium value was reached. In nearly all of the solutions below 0.008 molal check determinations were made. The values for the lowest three concentrations reported were not as reproducible as desired and will be discussed in more detail later.

When attempts were made to measure the electromotive force at 37.5 and 50° the agreement was never better than one to two millivolts, so no results are recorded for these temperatures. This failure at the higher temperatures is attributed to the transition of a-cadmium to β-cadmium. Getman[24] reports that α-cadmium is the stable form at ordinary temperatures and that this form changes to β-cadmium at 37 to 40° depending upon the thermal history of the metal employed, whereas Cohen and Helderman[25] give the transition point in the vicinity of 64°.

In making the measurements at the different temperatures, the cell vessel, after the electromotive force had been measured at 25°, was treated in the following manner. In order to prevent the change in pressure from drawing the mercury from the traps into the cell or forcing out of any of the cell contents, small corks were forced into the traps on top of the mercury and capped by a few drops of castor oil. The glass stopcock on the nitrogen inlet manifold was closed. The slight change in pressure in the system due to changing temperature was too small to produce a measurable change in volume of the liquid and solid reactants.

The equilibrium value at 0" was usually reached in from twelve to sixteen hours. No measurements were attempted below a concentration of 0.0007 molal at 0° because the internal resistance of the cell was then too great. A variation of from 0.05 to 0.1 millivolt in the most dilute solutions was considered satisfactory at this temperature.

Preparation and **Analysis** of **Cadmium** Solutions.—For all concentrations above **0.1** molal the solutions were made up by direct weighing of the salt and water. For the concentrations below 0.1 molal stock solutions of cadmium sulfate were diluted by weight. The distilled water averaged 1.2 X 10^{-6} reciprocal ohms for the specific conductivity; occasionally water with *a* specific conductivity of 0.7 × 10^{-6} r. o. was obtained.

The stock solutions were analyzed electrolytically by depositing the cadmium on a platinum gauze electrode from *a* cyanide bath. A weighed sample of the solution to be analyzed was made decidedly alkaline with potassium hydroxide and then just enough potassium cyanide added to dissolve the precipitate. A current of 0.5 ampere was passed through the solution for twenty-four hours using a platinum wire anode and a platinum gauze cathode of 30 sq. cm. in area. The solution was slowly stirred all the time. At the end of this time not the faintest trace of color could be obtained by passing hydrogen sulfide into the solution. The cathode was then washed with alcohol and ether,

[24] Getman, THIS JOURNAL, 39, 1806 (1917).

[25] E. Cohen, "Physico-Chemical Metamorphosis and Problems in Piezochemistry," McGraw-Hill Book Co., Inc., New York, 1928, pp. 40–50.

dried and weighed. It was possible to obtain triplicate determinations which agreed to within 0.1%. On several occasions the results checked to 0.05%. Using this method of analysis the average cadmium content of the purified anhydrous cadmium sulfate agreed within one part in 20,000 of the theoretical value.

Other methods of analysis were tried, including the precipitation of cadmium as cadmium sulfide and the precipitation of sulfate as barium sulfate. These methods were not as reproducible as the electrolytic method nor did they check well with one another.

The Apparatus.—For measurements at 25° a large water thermostat was maintained to ±0.01°. The Beckmann thermometer was checked against the laboratory standard, and also against a thermometer calibrated by the Bureau of Standards. For the measurements at 0° a small bath of ice and water mush was used, having air lift pumps to provide adequate circulation. This bath was maintained to ±0.05°. The potentiometer was a Leeds and Northrup type K, with a high resistance galvanometer No. 2500 type R, having a sensitivity of 424 megohms, a period of 2.8 seconds, and an external critical damping resistance of 2000 ohms. The potentiometer was calibrated, and the Weston standard cell was certified by the Bureau of Standards. The standard cell was kept in an insulated, water-tight, copper container in the thermostat at 25° The entire measuring apparatus was protected from stray electrical effects by the equipotential shielding method recommended by White.[26]

Experimental Data

The experimental values of the electromotive force at 25° are given in Table I, along with the value of the calculated function E_0'. The observed electromotive force given in Column *3* is in each case the average of the six electrodes previously described. A correction for the solubility of lead sulfate is necessary at concentrations of 0.0056 molal and less. This was made by calculating the increase in sulfate-ion concentration in the solution arising from the solubility of the lead sulfate, and calculating the potential resulting therefrom. Böttger[27] reports the solubility of lead sulfate at 25° to be 1.34×10^{-4}, while Kohlrausch[28] finds 1.45×10^{-4} mole per liter. The value used in these calculations is the average, namely, 1.4×10^{-4} mole per liter. The Debye–Hückel theory gives 0.90 for f_{PbSO_4} at this concentration, assuming a value of *3* Å. for "a." Making use of f_{PbSO_4} we find the activity solubility product of lead sulfate to be 1.59×10^{-8}. In order to calculate the increase in sulfate-ion concentration we made use of the equation

$$M_{Pb^{++}} . f_{\pm} . M_{SO_4''} f_{\pm} = a_{Pb^{++}} . a_{SO_4''}$$

or

$$M_{Pb^{++}} = \frac{K(a)}{M_{SO_4''} \cdot (f_{\pm})^2}$$

By successive approximations the concentration of sulfate ion from the lead sulfate is found, since it is equal to the concentration of lead ion in the cadmium sulfate solution. The ideal individual ion potentials for the cadmium and sulfate ions are calculated in Columns 5 and 6. These two

[28] Kohlrausch, *ibid.*, **64**, 129 (1908).

factors when added to the observed electromotive force give E'_0 (equation 9). Since these calculations were completed, another determination of the solubility of lead sulfate has been reported[29] which agrees very well with the results of Kohlrausch. If these calculations were to be repeated, even more weight would now be placed on the data of Kohlrausch. The effect on the final result is too small to make recalculation worth while.

Table II gives the experimental values of the electromotive force at 0° along with the calculated function E'_0. The solubility of lead sulfate at 0° is 1.08×10^{-4} mole per liter. This value was obtained by plotting the data of Böttger[27] and Kohlrausch[28] as shown in Fig. 4 and extrapolating to the desired temperature, taking the average of the results thus obtained.

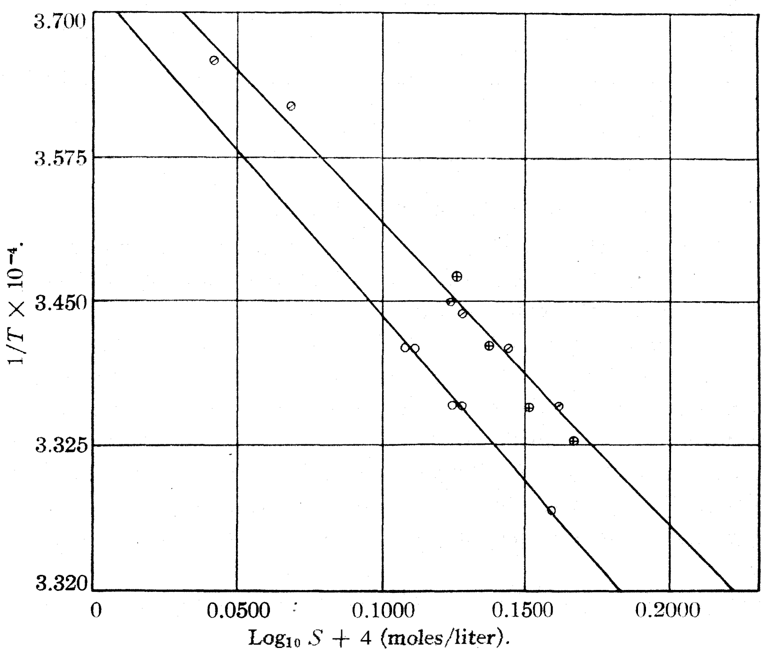

Fig. 4.—Solubility of lead sulfate in water. ⊖, Kohlrausch; ○, Böttger; ⊕, Huybrechts and de Langeron.

The data of Huybrechts and de Langeron are also given on this plot but were not used in the calculations. The Debye-Huckel theory gives 0.913 for f_{PbSO_4} at 0°, and the activity solubility product is 0.972 X 10^{-8}.

The values of E_0' for dilute solutions at both temperatures (Tables I and II) are shown graphically in Fig. 5. The Debye–Huckel limiting law is shown by the broken line. The insert at the lower right-hand portion is for concentrated solutions and shows that the curves for 0 and 25° cross above 1 molal.

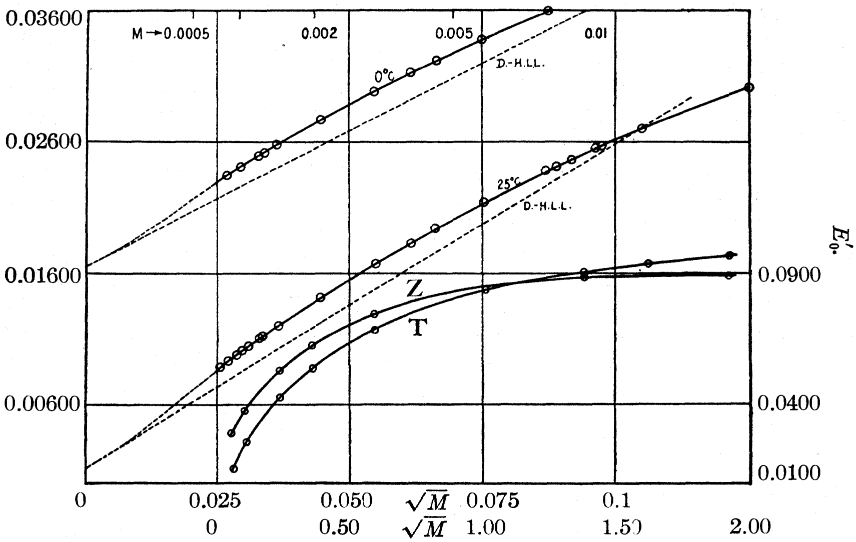

Fig. 5.—The cadmium–lead cell. T, 25°; Z, 0°.

Discussion of Results

Table III gives the values of E_0 obtained when we insert the arbitrary values for "a" = **3,** 3.6 and 4 Å. for cadmium sulfate in expression 6 in order to determine the value of log f.

When the molality of cadmium sulfate is less than 0.0006 molal, the dissolved lead sulfate constitutes more than 6% of the total sulfate-ion concentration. At such very low concentrations of cadmium sulfate the cell can no longer be considered strictly as one without transfer and liquid junction potential, and the cell process would not correspond exactly to the one given in Equation **7.** Since the experimental data were also somewhat erratic we have not included the first three measurements in our computations.

The values of E_0 computed in Table III are plotted in Fig. 6 as a function of $\sqrt{M}$. It is clearly evident that the correct value for E_0 is 0.00142 volt at 25° and that an ion size corresponding to "a" = 3.6 Å. yields values of E_0 having an average deviation of only 0.06 mv. for the nineteen determina-

tions extending from 0.0006070 to 0.01096 molal. The maximum deviation is 0.1 mv. for the measurement corresponding to M = 0.0006070.

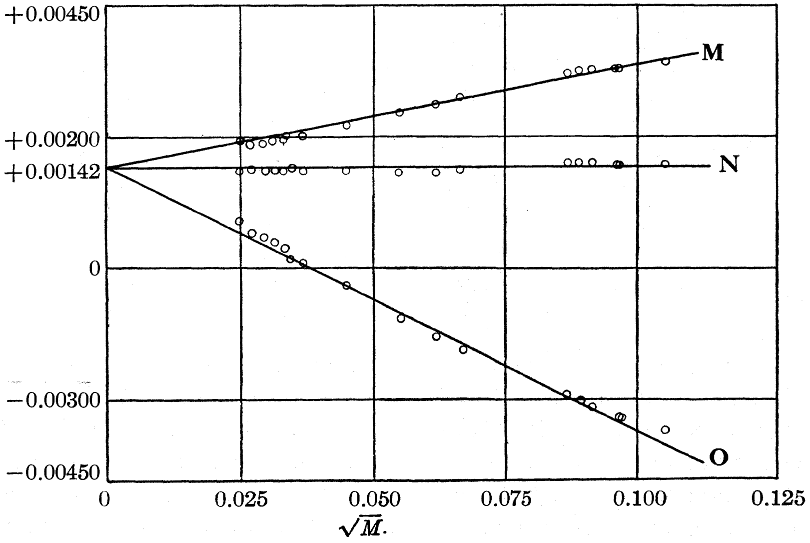

Fig. 6.—M, 4.0 Å.; N, 3.6 Å.; O, 3.0 Å.

In other words, E_0 is constant within the limits of experimental error under the assumption "a" = 3.6 Å., whereas the values of E_0 drift when other values of "a" are employed in Equation 6. Had we extrapolated the E_0', $\sqrt{M}$ curve in Fig. 6 to zero concentration using a Debye limiting law slope passing through the points of lowest concentration, as previous investigators have done, we would obtain the erroneous value $E_0 = 0.00180$ volt, differing from our E_0 by 0.00038 volt, which is about six times the experimental error. The apparent slope of the E_0' against $\sqrt{M}$ curve at 25° between $M = 0$ to $M = 0.0006$ is 0.275 instead of 0.239 as predicted by the Debye limiting law (equation 11), and emphasizes that this law is not obeyed even at such a low concentration range.

In Table IV are given the calculated values of "a" both from the Gebye approximation $[-\log f = 1.53636 z^2\kappa/(1 + \kappa\text{“}a\text{”})]$ and the Gronwall, La Mer and Sandved extension[6] through a fifth approximation.

TABLE IV

COMPARISON OF THE "a" VALUES FOR CADMIUM SULFATE AT 25° COMPUTED FROM THE DEBYE AND FROM THE FIFTH APPROXIMATION ($E_0 = 0.00142$)

No.	Molality	"a" (Debye), Å.	"a" (fifth approx.), Å
4	0.0006070	−9.74	+3.72
5	.0007267	−9.78	+3.64
6	.0008675	−8.74	+3.68

8	.0009819	−8.35	+3.68
9	.001077	−7.90	+3.68
10	.001119	−8.02	+3.60
11	.001332	−7.08	+3.64
12	.001993	−5.58	+3.62
13	.002994	−4.11	+3.61
14	.003807	−3.28	+3.61
15	.004371	−2.89	+3.60
16	.005618	−2.18	+3.56
17	.007544	−1.27	+3.52
18	.007901	−1.14	+3.56
19	.008351	−0.98	+3.56
20	.009307	− .65	+3.52
21	.009409	− .64	+3.52
22	.01096	− .23	+3.52
23	.02237	+1.18	+3.04

It is readily seen that the Debye approximation gives values for "a" (Column 3) which drift steadily from −9.78 to −0.23 Å. at 0.01 molal. These values are physically absurd. On the other hand, use of the higher terms gives constant, physically plausible, positive values of "a" as shown in Column 4. The slight drift in these values of "a" may be due to neglecting the seventh approximation. These data (Table TV), although they emphasize the inadequacy of the Debye approximation in dilute solution in a very striking manner, nevertheless confirm in an equally striking manner the validity of the basic assumptions of the theory when given simply the more complete mathematical treatment.

From a large scale plot of E_0' against $\sqrt{M}$, values of E_0' at round concentrations were read, and the corresponding activity coefficients were calculated by Equation 10, using the value of E_0 obtained by extrapolation. These values are given in Table V along with the activity coefficients calculated from the theory.

TABLE V

THE ACTIVITY COEFFICIENTS OF CADMIUM SULFATE AT 25°

No.	Molality	Calculated activity coefficient (equation (5), "a" = 3.6 Å.)	Observed activity coefficient (from e. m. f., equation (10)) $E_0 = 0.00142$	Difference
1	0.0005	0.775	0.774	−0,001
2	.001	.700	.699	− .001
3	.003	.549	.551	+ .002
4	.005	.476	.476	± .000
5	.01	.384	.383	− .001
6	.03	.265	.254	− .011
7	.05	.220	.199	− .021
8	.1	.166	.137	− .029
9	.5		.0605	
10	1.0		.0418	
11	1.5		.0385	
12	2.0		.0304	
13	2.5		.0282	
14	3.0		.0261	
15	3.5		.0260	

Up to 0.01 molal (ionic strength of 0.04) the agreement is within 0.4%, which is well within the experimental error. This is striking when one considers that even at 0.01 molal the activity coefficient has fallen to 0.383.

The results obtained by repeating this method of extrapolation for E_0 at 0° are summarized in Table VI and are shown graphically in Fig. 7. Evaluating the constants in Equation 5 for use at 0° we obtain the following

$$-\log f = \frac{z^2}{a}\,1.49701\,\frac{x}{1+x} - \left(\frac{z^2}{a}\right)^3 0.142297\cdot 10^3 \left[\frac{1}{2}X_3(x) - 2Y_3(x)\right] - \left(\frac{z^2}{a}\right)^5 0.06763\cdot 10^5\left[\frac{1}{2}X_5(x) - 4Y_5(x)\right] \tag{15}$$

The best value for "a" at this temperature is certainly between 3.6 and 3.7. The change in "a" from 25 to 0° is then less than 0.1 Å., which means that $(\partial\text{“}a\text{”}/\partial T)$ is very small, that is, of the order of 0.004 Å. per degree as a maximum. As far as we are aware this is the first time that $(\partial\text{“}a\text{”}/\partial T)$ has been determined directly in a region of concentration where it can be interpreted theoretically. The fact that $(\partial\text{“}a\text{”}/\partial T)$ for cadmium

sulfate is virtually zero lends support to the hypothesis that the value "a" is primarily a measure of the distance of closest approach of the ions without including their surrounding shells of polarized water molecules. Otherwise, larger values of "a" would be demanded which should decrease with rising temperature owing to decreasing hydration.[30a]

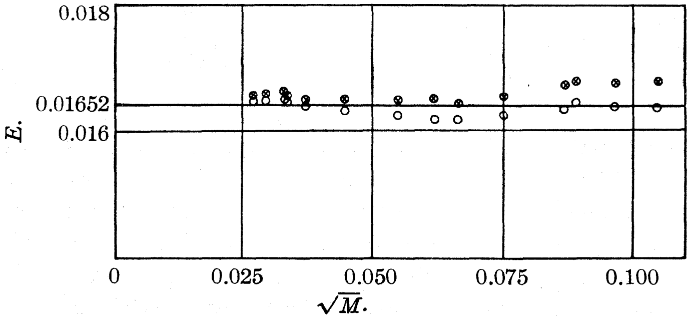

Fig. 7.—○, a = 3.6 Å.; ⊗, a = 3.7 Å.

A comparison of the experimental and theoretical activity coefficients at round concentrations is given in Table VII. The agreement is satisfactory to concentrations including 0.01 molal.

Gronwall, La Mer and Sandved[5] found for Bray's data on zinc sulfate that Equation 5 does not fit the experimental data when M exceeds 0.01096 or κ exceeds 0.0687. Tables III and VI show that the same is true for cadmium sulfate. There are several reasons for this failure of Equation 5 to hold above this concentration. First, this concentration corresponds

to a value of $x = "a" \times \kappa = 3.6 \times 0.0687 = 0.25$. Although a 0.01 M or 0.04μ solution is ordinarily considered a quite dilute solution from a chemist's standpoint, nevertheless it is concentrated from the standpoint of the Debye–Hückel theory. Thus, when x reaches a value of 0.25 the fundamental approximations of the theory certainly can no longer hold exactly, for this value of x means that $1/\kappa$, namely, the distance from a given ion at which the electric potential due to the ion atmosphere has fallen to $1/e$ of its value at the distance r = "a," is equal to four times the value of "a." Secondly, a comparison of Equation 5 with the unabridged Equation (34a) of Gronwall, La Mer and Sandved[5] shows that each approximation contains the factor $\left(1-10^{-3}c\frac{\partial V}{\partial n}\right)\left(1-\frac{c\mathrm{d}D}{D\mathrm{d}c}\right)$. The quantity $\left(1-10^{-3}c\frac{\partial V}{\partial n}\right)$ is known to be negligible in dilute solutions, but the quantity $\left(1-\frac{c\mathrm{d}D}{D\mathrm{d}c}\right)$ representing the change in dielectric constant with concentration is very likely not equal to unity at concentrations above 0.01 molal. Unfortunately, no one has succeeded as yet in measuring accurately the dielectric constant of conducting solutions at appreciable concentrations.[31] Until this question has been defined and settled experimentally one must make the approximation that $\left(1-\frac{c\mathrm{d}D}{D\mathrm{d}c}\right)$ is equal to unity, with the result that we cannot expect Equation 5 to hold precisely above 0.01 molal.

To avoid misunderstanding it is important to emphasize that the assumption $\left(1-\frac{c}{D}\frac{\mathrm{d}D}{\mathrm{d}c}\right) = 1$ is equivalent to the customary one that $D = D_0$ where the subscript zero refers to the pure solvent. The major effect of this assumption will usually reside in the first approximation and not in the higher terms, *i. e.*, in the difference between the first and last terms of Equation 34a of Reference 5. The unabridged Equation 34a thus embodies

the well-known dielectric correction suggested by Hiickel [*Physik. Z.*, 26, 93–147 (1925)] but does it in a more general manner since no restrictions, such as the linear variation of D with c assumed by Hiickel, are made in obtaining the final equation. To employ 34a it will be necessary to know D and dD/dc only at the concentration in question.

Other factors such as the employment of local smoothing in calculating the charge density, the forces resulting from the deformability of the ions and the interpretation of the dielectric constant in the neighborhood of an ion undoubtedly influence the value of "*a*" computed by equations $(6)_{25°}$ and $(15)_{0°}$. However, unless some peculiar and unlikely effects are just compensating one another in the case of cadmium sulfate as well as for zinc sulfate,[32] it hardly seems necessary to take the extreme view given by Fowler[33] that "*a*" is only an "*omnium gatherum*" correction and does not have the significance of an ionic diameter. The evidence now at hand indicates that this viewpoint and the one by Bjerrum,[30b] namely, that "*a*" is "stark temperatur empfindlich" appear to have been based too much

[32] Cowperthwaite and La Mer (to be published) in their studies on the corresponding zinc sulfate cell find the following values for "a": 3.6 Å. (0°), 3.64 Å. (12.5°), 3.64 Å. (25°), 3.60 Å. (37.5°), 3.73 Å. (50°).

[33] Fowler, "Statistical Mechanics," Cambridge University Press. London. 1929. p. 322.

upon results obtained by using the Debye approximation without giving sufficient weight to the contribution of the higher approximations. It will be highly important to ascertain what the same simple state of affairs obtains for the "*a*" value of other 2-2 electrolytes.

In Table VIII are given the calculated values of the free energy of transfer of one mole of cadmium sulfate from concentration M_1 to concentration M_2 at 25°. The excess free energy of transfer is given in Column 5. Table IX gives the corresponding values at 0°.

The Gibbs–Helmholtz Equation (14) enables one to calculate the heats of transfer arising from electrical interaction. Substituting for E in (14) its value

$$E = E_0 - \frac{RT}{nF}\ln M - \frac{RT}{nF}\ln f \tag{16}$$

we get

$$\Delta H = nF\left[E_0 - T\frac{\partial E_0}{\partial T} + \frac{RT^2}{nF}\frac{\partial \ln f}{\partial T}\right] \tag{17}$$

Now

$$E_0' = E_0 - \frac{RT}{nF}\ln f \tag{18}$$

so Equation 17 can be written in a form more directly applicable to the experimental data, namely

$$-\Delta H = nF\left[E_0' - T\frac{\partial E_0'}{\partial T}\right] \tag{19}$$

Since measurements were made at only two temperatures we are obliged to assume that $(\Delta E/\Delta T)_M = (\partial E/\partial T)_M$, an approximation which will be most nearly correct for 12.5°. We have therefore calculated the mean heat of transfer for the total process (7) defined as

$$\begin{aligned} -\Delta H_{285\cdot 6} &= nF\left[\frac{E'_{0(25°)} + E'_{0(0°)}}{2} - T\,\frac{E'_{0(25°)} - E'_{0(0°)}}{25}\right] \\ &= nF\left[E'_{0(12\cdot 5°)} - T_{285\cdot 6}\frac{\Delta E_0'}{\Delta T}\right] \end{aligned} \tag{20}$$

These values are given in Table X, Column 6.

When M = 0, Equation 20 gives $-\Delta H^{\circ}_{285.6} = 8375$ cal., that is, the value of $-\Delta H$ for the total process (7), which is free from any contribution due to electrical interaction.

In Column 7 (Table X) we give the values of the excess or electrical partial molal heat of transfer $-\overline{H}_{(e)}$, defined as

$$-\Delta H - (-\Delta H^{\circ}) = \overline{H}_{CdSO_4} - \overline{H}^{\circ}_{CdSO_4} = -\overline{H}_{(e)} \tag{21}$$

$(-\overline{H}_{(e)})$ is the quantity of heat which is liberated by the forces of electrical interaction when one mole of cadmium sulfate is reversibly transferred from a very large volume of solution of molality M to a similar volume of solution where M equals zero.

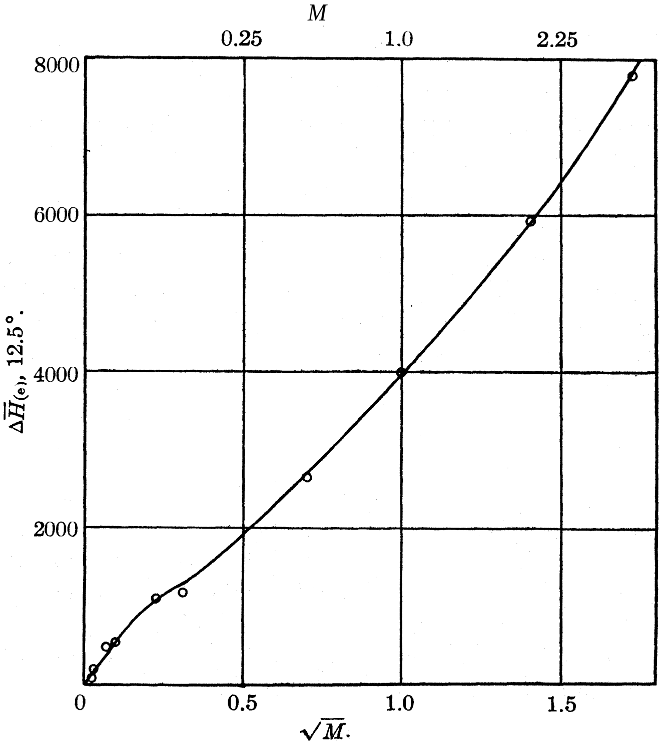

Fig. 8.

Summary

Precise electromotive force measurements are reported at 25 and 0° for the cell Cd–Hg (2 phase), $CdSO_4$ (M), $PbSO_4$ (s), Pb–Hg (2 phase) over the

concentration range 0.0004580 to 3.698 molal. The potential of the cell (E_0) when the ion activities of cadmium sulfate are hypothetically one molal has been found to be 0.00142 volt at 25° and 0.01652 volt at 0°.

The experimental results furnish excellent confirmation of the extension of the Debye–Huckel theory as given by Gronwall, La Mer and Sandved for the region 0.0006 to 0.01 molal, since their extension yields constant and positive, physically plausible values of "*a*" (3.6 Å.) where "*a*" is the distance of closest approach of the ions. The Debye–Huckel approximation gives steadily drifting and physically absurd, negative values of "*a*." This extension furnishes an excellent control on the extrapolation to infinite dilution, since constant values for E_0 are obtained up to 0.01 molal.

The activity coefficients and the partial molal free energies of transfer of cadmium sulfate have been computed at 25 and 0° for the concentration range 0.0005 molal to saturation.

If cadmium sulfate is incompletely dissociated in the classical sense, this influence on the activity coefficient is too small to be detected below 0.01 molal.

It has been shown by direct measurement that $(\partial``a"/\partial T)$ is very small, if not actually zero. This may be taken as support for the view that hydration of the ions is not involved in the value "*a*."

The mean heat of the cell reaction, Cd (solid, satd. with Hg) + $PbSO_4$ (solid) = $CdSO_4$ (M) + Pb (solid, satd. with Hg), for 12.5" and the corresponding excess electrical heats of transfer of cadmium sulfate have been computed using the Gibbs–Helmholtz equation.

THE THERMAL DECOMPOSITION OF DIMETHYL-TRIAZENE. A HOMOGENEOUS UNIMOLECULAR REACTION

BY H. C. RAMSPERGER AND J. A. LEERMAKERS

RECEIVED FEBRUARY 4, 1931 PUBLISHED JUNE 8, 1931

During the past four years a considerable amount of experimental data has given support to certain theories of unimolecular reaction velocity which postulate that activation occurs by kinetic theory collisions. The rate of production of activated molecules by collisions is a second order process but if only a very small fraction of those molecules which become activated decompose spontaneously the rate of decomposition is first order. At sufficiently low pressures collisions can no longer maintain the Maxwell–Boltzmann quota of activated molecules; consequently the rate falls off until finally at still lower pressures the rate approaches the rate of activation and is second order.

Now that the rate of decomposition of nitrogen pentoxide has at last also been shown to decrease at very low pressures,[1,2] every example of a homogeneous unimolecular reaction shows such a decrease or else theory does not require it in the pressure range studied.

We have now studied the decomposition of dimethyl-triazene and find that this reaction also is first order at high pressures but falls off in rate at pressures below about one centimeter. Rate measurements have been made at temperatures from 200 to 230° and at pressures from 0.02 to 8.0 cm. of mercury.

Preparation of Dimethyl-triazene.—Dimethyl-triazene was prepared by the method of Dimroth.[3]

The copper salt of dimethyl-triazene was first prepared. Methyl azide was formed by dropping dimethyl sulfate upon a stirred and refluxed aqueous solution of sodium azide. The gas was passed through a warm tube containing calcium chloride and into an ice cooled solution of methylmagnesium iodide ($CH_3—N=N\equiv N + CH_3MgI = CH_3—N=N—NCH_3MgI$). The resulting ether solution was hydrolyzed at zero degrees with an aqueous solution of ammonium chloride and ammonium hydroxide, and the dimethyl-triazene so formed was converted to its copper salt by shaking with ammoniacal cuprous chloride solution. The copper salt was separated from the water layer by repeated extraction with ether; the ether solution was dried with anhydrous sodium sulfate and the ether distilled from the salt. The solid green copper salt was recrystallized from warm anhydrous ether and dried over concentrated sulfuric acid.

The free dimethyl-triazene was prepared from its copper salt by warming it with solid diazoaminobenzene prepared according to Fischer.[4] The liberation and purification of the dimethyl-triazene was carried out on a vacuum line.

The vacuum system was of Pyrex glass and consisted of a 30-cc. flask connected in series with a 3 × 1-cm. tube filled with C. P., ground, fused calcium chloride; a receiver of 3-cc. capacity; a 12 X 1-cm. tube filled with calcium chloride; and a small combination distilling flask of 3-cc. capacity and water-cooled reflux column. The exit tube of the reflux column led to another 3-cc. receiver which was separated from the high-vacuum line by a stopcock. Equivalent quantities, *2* g. of the copper salt and 3 g. of diazoaminobenzene, were mixed and introduced into the flask and the latter was sealed off at the neck. The system was evacuated and the flask heated slowly to a temperature of 90° by means of a glycerin bath. The dimethyl-triazene vapor was allowed to pass through the first tube of calcium chloride and was condensed in the first receiver by a mixture of solid carbon dioxide and ether at −78°. When the vapor had all been condensed the receiver was sealed off from the flask and its contents were allowed to distil through the second larger calcium chloride tube into the distilling flask, where they were recondensed with the ether–carbon dioxide mixture. The liquid was allowed to distil back to the receiver in the same manner, this process was repeated several times, and with the liquid finally frozen out in the distilling flask the latter was sealed off from the calcium chloride tube. The amount of liquid dimethyl-triazene was about 1.5 cc. Air was then let into the system at a pressure of 75 mm. and the liquid was slowly distilled into the second receiving flask, which was cooled as before to −78°. During the distilla-

[4] Fischer, *ibid.*, **17**, 641 (1884).

tion a glycerin bath served to control the temperature of the distilling flask, and water was run into the condenser around the reflux column to insure careful fractionation. About three drops of a liquid which did not solidify at −78° came over below 40°. These were pumped out and rejected. With the exception of the last several drops, which were also rejected, the remainder of the liquid boiled between 43.0 and 43.1° under 75 mm. pressure. The distilling flask was finally sealed off from the receiver. The solid in the receiving flask melted fairly sharply at about −12.0° to give a perfectly clear, colorless liquid. In order to free the dimethyl-triazene from any dissolved air. the liquid was distilled into the top of the container by means of a bath of solid carbon dioxide and the flask was evacuated. This process was repeated several times. The sample was used for the rate determinations without further treatment.

Nature of Reaction

When dimethyl-triazene is completely decomposed at constant volume, the final pressure is 2.175 times the initial pressure. This fact, together with a titration for basic constituents and some freezing-out data, make possible a rough estimate of the reaction products.

The gas resulting from the complete decomposition of dimethyl-triazene was collected in a 120-cc. bulb at 9.60 cm. pressure. A tube sealed to the bottom of the bulb was surrounded with baths at various temperatures and the pressure was read on an attached mercury manometer. The following readings (corrected for the lower temperature of the gas in the cold bath) were obtained.

t, °C.	P, cm.	% Uncondensed
20	9.60	100
−20	9.05	94
−79	6.80	71
−111	6.25	65
−183	5.25	55

Titration with 0.01 N hydrochloric acid and phenolphthalein showed that 29.6% of the gas was basic, assuming one equivalent of acid per mole of base.

When dimethyl-triazene spontaneously decomposes it may be expected to break up into various radicals which may combine with one another or react with one another so as to give the reaction products. We shall try to represent the reaction products which seemed likely to form from such a process by stoichiometric equations and then test these equations with the above data.

$$\text{(a)}\quad 0.82\ CH_3—N{=}N—NHCH_3 = 0.82\ N_2 + 0.41(CH_3)_2NH + 0.205\ C_2H_6 + 0.205\ CH_3—NH—NH—CH_3$$

$$\text{(b)}\quad 0.18\ CH_3—N{=}N—NHCH_3 = 0.18\ CH_4 + 0.27\ N_2 + 0.09\ C_2H_6$$

$$\text{(c)}\quad 0.18\ CH_3—N{=}N—NHCH_3 = 0.18\ C_2H_6 + 0.27\ N_2 + 0.09\ H_2$$

The number of moles in each equation (0.82 and 0.18) has been so chosen that a combination of equation (a) with (b) or of (a) with (c) will give the correct ratio of final to initial pressure. Equation (a) gives some dimethylhydrazine (supposedly by a combination of two CH_3NH radicals) and thus accounts for the gas which freezes out at −20°. With phenolphthalein it would neutralize an equivalent of acid and together with the $(CH_3)_2NH$ accounts for 27% of the gas which is nearly equal to the 29.6% observed. The combination of (a) with (b) gives 58% non-condensable with liquid air ($N_2 + CH_4$), while (a) with (c) gives 54% ($N_2 + H_2$), both of which are close to the value found (55%). Evidently no choice can be made between (b) and (c). It is not claimed that the agreement found with these stoichiometric equations is a very accurate description of the nature of the reaction.

Apparatus and Procedure

The rate of decomposition was followed by the increase in pressure at constant volume. The 250-cc. Pyrex reaction flask was placed in an oil-bath the temperature of which was automatically controlled to 0.05'. The thermometer used was calibrated against a Bureau of Standards thermometer.

In the high-pressure runs Nos. 39 to 50 the supply bulb was connected to a metal stopcock of the Bodenstein type,[5] which was connected directly to the cell. One arm of a mercury U-trap was sealed to this connecting tube and the other arm led to the high-vacuum line. The stopcock and mercury trap were surrounded by a cardboard structure containing a glass window. Warm air was circulated through this structure so as to maintain a temperature of about 50°. This was necessary to prevent condensation of dimethyl-triazene in the system outside the thermostat. The volume outside the thermostat was at most 1% of the total volume. In making a run the cell was evacuated to about 1×10^{-5} mm., mercury was let up into the trap, the desired amount of gas let into the reaction vessel through the metal stopcock and the stop watch started. The pressure in the U-trap was read immediately and at intervals during the course of the run.

The low-pressure measurements were made with a clicker system.[6] The supply was connected to an ordinary vacuum stopcock. This led to one arm of a mercury trap, the other arm of which was connected directly to the cell. A lead to vacuum was sealed in about 3 cm. above the bottom of the U-tube on the reaction vessel side. This lead had a stopcock separating it from the vacuum line. The clicker of about 0.5-cc. capacity and having a click constant of 0.150 cm. pressure was sealed by a small tube to the reaction vessel. A larger tube fitting around the clicker, and sealed to it by *a* ring seal at its base, was connected to a McLeod gage of 130-cc. capacity and to a number of capillary tubes. By evacuating through these capillary tubes it was possible slowly to change the pressure on the clicker as the critical clicking pressure was approached. Air could be let in through another capillary to reset the clicker. The limit of accuracy of this pressure measurement system was the reproducibility of the clicker,

---

[5] Bodenstein and Dux, *Z. physik. Chem.*, 85, 305 (1913).

[6] Smith and Taylor, THIS JOURNAL, 46, 1393 (1924).

which appeared to be better than 0.001 cm. The outside volume was less than 1% of the total volume of the reaction vessel. After letting the desired amount of gas into the reaction cell the mercury was raised in the U-trap and the air pressure surrounding the clicker was adjusted to get the click. Due to the fact that a short time was required to obtain the first click it was necessary to extrapolate the pressure readings back to zero time. The extrapolation was usually only about 2 to 3%, even at the higher temperatures. A similar extrapolation was sometimes necessary for the high pressure experiments.

Experimental Data

The partial pressure of dimethyl-triazene (P_T) was calculated for each reading by the expression $P_T = (2.175P_0 - P)/1.175$, where P_0 is the initial pressure at zero time and P is the total pressure at that reading. The factor of 2.175 is required because the final pressure is 2.175 times the initial pressure. First order rate constants were calculated by the interval method, that is, by using the equation

$$k_1 = \log_{10} P_{T_t}/P_{T_{t'}} \times 2.303/(t' - t)$$

where P_{T_t} is the partial pressure of dimethyl-triazene at time t, and $P_{T_{t'}}$ is its partial pressure at the following reading taken at time t'. First order

49	200.0	2.46	5	1.05 $\times 10^{-5}$	8.93 $\times 10^{-5}$
50	230.0	2 24	7	0.87 $\times 10^{-4}$	7.09 $\times 10^{-4}$

The first thirteen preliminary runs were carried out with an impure sample and a rough method of following the pressure. They differed but little from the later runs. Runs 45 to 48 will be discussed later.

While no trend in the constants during a given run was common to all of the runs, there seems often to have been a slightly higher rate at the start of the run as shown by run 17.

In runs 45 to 50 the surface was increased by adding Pyrex tubing, thus increasing the surface to volume ratio by 11.5 fold. The first run made after introducing the extra surface (Run 45) was 12% higher in rate but this effect disappeared gradually during the next three runs and then the rate constants were identical with runs made without extra surface. Earlier preliminary runs had likewise shown that opening the cell to the air or washing it out gave a slightly higher rate for the next two or three runs, so that apparently some conditioning of the surface or removal of impurities was necessary to eliminate catalysis completely. We conclude that the reaction rates reported were not influenced by the extent of wall surface and that the reaction is therefore homogeneous.

Runs 39 to 50 were made with a different sample of dimethyl-triazene and were made with the arrangement of apparatus described for the high-pressure measurements, while all the others reported were made with the low-pressure arrangement. Although the initial pressure to final pressure ratio was uniformly 2.175 for the first sample, it was not constant for these later runs but varied from 2.06 to 2.19. The experimental accuracy was not quite as good and they are all uniformly lower in rate than the earlier runs at similar pressures. It seems likely that this sample was impure. The metal stopcock became discolored and may have affected the sample. These runs show, however, that the first order rate constant has become independent of pressure above about 1 cm.

Interpretation of the Data

This reaction has the same characteristics as many other unimolecular reactions, namely, a true first order rate only at high pressures and a falling of the first order rate constant at lower pressures. In Fig. 1 is plotted the log of the rate constant against the reciprocal of the absolute temperature. Only the rate constants at the higher pressures where the first order rate is independent of pressure have been used in this plot. Prom the slope of the best straight line through the points we find for the heat of activation Q = 33,800 cal. per mole. The equation for the high pressure rate constant is given by the expression $k_\infty = 4.05 \times 10^{11}e^{-33,800/RT}$

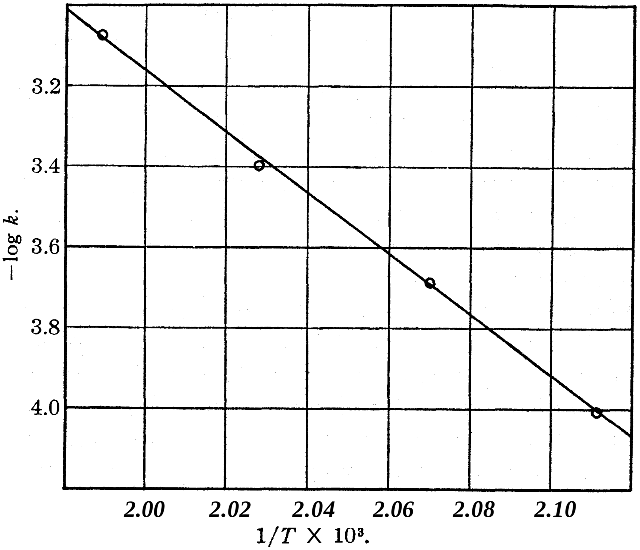

Fig. 1.

Figure 2 shows the usual plot of log k/k_∞ against log P. The curves are theoretical and the points are the experimental values for the runs at 200 and 230° with the first sample. The lower curve is for Theory I and the upper two curves are for Theory II.[7] The uppermost curve is for 200° and the other one close to it is for 230°. The number of squared terms chosen to fit the data best was 14 and the diameter of the molecule 10.0 X 10^{-8} cm. for Theory I and 6.0 X 10^{-8} cm. for Theory II. For Theory I the critical energy ϵ_0 is 39,800 cal. per mole and for Theory II $\epsilon_0 = 33,300$ cal. per mole. It is evident that it is not possible to decide definitely between the two theories on the basis of the data shown.

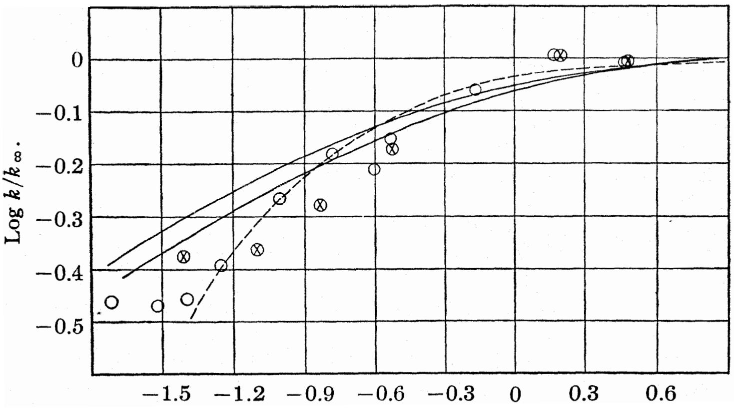
Discussion

During the past six years the experimental data on unimolecular reactions have been increased from one single reaction, namely, the decomposition of nitrogen pentoxide, to at least thirteen reactions that are

---

[7] Rice and Ramsperger, THIS JOURNAL, 49, 1617 (1927).

now definitely recognized as being of this type. These reactions are listed in Table III. The pressure and temperature range over which they have been investigated are given and the constants in the rate expression $k_\infty = Ae^{-Q/RT}$ are listed. The values given for n designate the number of squared terms required to fit the data with either Theory **11**[7] or Theory III.[8] Ordinary kinetic theory diameters are used throughout.



Log P,,.

Fig. 2.

All but three of these thirteen reactions show a falling off in rate at low pressures. Of these three, ethylene oxide and pinene have not been investigated at sufficiently low pressures and azoisopropane is sufficiently complex a molecule that it is not required that its rate of decomposition fall off until very low pressures **are** reached. Thus from a qualitative point of view the experimental data are in complete accord with the present theoretical method of treatment. Furthermore, with the possible exception of the decomposition of nitrogen pentoxide, there is no quantitative disagreement with Theories II or III or their modified quantum treatments. As Kassel[9] has indicated, it is possible even to account for the rate of decomposition of nitrogen pentoxide if one uses Kassel's quantum treatment[10] and permits the use of a vibrational specific heat of at least 20 cal./mole and a molecular diameter of 17 X 10^{-8} cm. There are no specific heat data for nitrogen pentoxide but it seems likely that 20 cal./mole of vibrational specific heat will be found too high. In this connection it must be remembered that the requirement of an exact numerical agreement can be carried too far, since any actual molecule is not exactly of the type postulated either by the classical or quantum theory.

$CH_3—O—CH_3$[13]	3.0 to 90.0	422 to 552	1.52×10^{13}	58500	11–12
$CH_3—O—C_2H_5$[14]	2.6 to 54.0	386 to 460	$>9.23 \times 10^{11}$	47000	9
$CH_3—O—C_3H_7$[14]	2.2 to 33.6	400 to 450	$>2.21 \times 10^{12}$	49000	12
$CH_3—N{=}N—CH_3$[15,16]	0.026 to 70.79	278 to 327	1.07×10^{16}	51200	25
$CH_3—N{=}N—C_3H_7$[17]	0.0058 to 13.12	250 to 332	2.80×10^{15}	47480	33
$C_3H_7—N{=}N—C_3H_7$[18]	0.025 to 4.60	250 to 290	5.6×10^{13}	40900	>40
$CH_3—N{=}N—NHCH_3$[19]	0.019 to 8.0	200 to 230	4.05×10^{11}	33800	14
d-Pinene[20,21]	17.0 to 116.0	184 to 237	5.40×10^{14}	43700	>20
Ethylene oxide[22]	2.4 to 90.5	378 to 445	9.9×10^{12}	52000	>14
N_2O_5[23,24,25]	0.00056 to 70.0	0 to 65	4.5×10^{13}	24700	30^9
N_2O[26,27]	8.1 to 800	560 to 667	4.0×10^{9}	53000	2

The mass of evidence so far presented indicates strongly that activation is by collision and that reaction occurs when the critical energy becomes localized in a particular part of the molecule.

Summary

The thermal decomposition of dimethyl-triazene has been studied at temperatures from 200 to 230° and at pressures of 0.019 to 8.0 cm.

The reaction has been found to be homogeneous and first order at high pressures, but the rate begins to decrease at pressures below about 1 cm. and has dropped to about one-third of the high pressure value at the lowest pressures studied. The high pressure rate constant is given by the expression $k_\infty = 4.05 \times 10^{11}e^{-33,800/RT}$.

THE TEMPERATURE COEFFICIENT OF THE THERMAL DECOMPOSITION OF AMMONIA ON PLATINUM

BY J. K. DIXON[1]

RECEIVED FEBRUARY 27, 1931 PUBLISHED JUNE 8, 1931

The heat of activation of the thermal decomposition of ammonia on the surface of a number of metals is about 40,000 to 50,000 calories per mole up to 800°. In particular, Kunsman has found this to be true for tungsten, molybdenum, nickel, iron and supported iron catalysts.[2] The same value was found for a copper catalyst.[3] At pressures below 25 mm. Schwab and Schmidt found 44,000 calories per mole for platinum; but above 25 mm. the value observed was 144,000.[4] No intermediate values for the heat of activation were observed. Since facilities were at hand it seemed well worth while to confirm or correct this abnormally high temperature coefficient.

Experimental

Experiments were carried out by a dynamic method which has been described.[3] The only changes made were in the catalyst and the tube which held the catalyst. A platinum wire gauze was made into a small roll, 6 cm. long, and placed in a fused quartz tube of 10-mm. bore. The platinum wire was 0.010 cm. in diameter and its total apparent surface 310 sq. cm. This catalyst approximates that used by Schwab and Schmidt. The quartz tubing was connected to the rest of the apparatus by means of graded quartz–Pyrex seals. The rate of decomposition of ammonia on this catalyst was determined in the way previously described, with and without added hydrogen or nitrogen, at the temperatures 776, 826 and 858".

Results

A summary of a number of typical experiments is given in Table I. The first column gives the number of the experiment; the second the barometric pressure in centimeters of mercury; the third, fourth and fifth

columns give the inlet flow rates of ammonia, nitrogen and hydrogen, respectively, each in cc. per minute reduced to 25° and 760 mm.; the sixth column gives the percentage decomposition in passing through the catalyst tube; the seventh, the temperature in degrees centigrade; and the eighth column gives the velocity constant. The constants were calculated according to the assumption that the rate of decomposition was proportional to the ammonia partial pressure and independent of the pressure of hydrogen and nitrogen. That is

$$k = (v'_N + v'_H + 2v') \ln \frac{v^1}{v_f} + v_f - v'$$

where v'_N, v'_H and v' are the inlet flow rates of nitrogen, hydrogen and ammonia, respectively, and v_f is the outlet flow rate of ammonia.[3] The small changes in barometric pressure were neglected.

TABLE I

THE RATE OF DECOMPOSITION OF AMMONIA ON PLATINUM WIRE

Expt.	Barometric pressure, cm.	Inlet NH_3, cc./min.	Inlet N_2, cc./min.	Inlet H_2, cc./min.	% NH_3 decomposed	t, °C.	k
33, 35	76.1	40.4	0.0	0.0	21.50	858	10.6
34	76.0	40.4	.0	25.0	13.80	858	10.2
36	76.2	40.4	.0	14.0	16.90	858	10.9
37	76.1	15.5	.0	14.0	14.15	826	4.7
38	76.1	15.5	.0	0.0	22.65	826	4.4
46	75.6	21.9	.0	.0	29.45	858	8.8
47	75.6	21.9	7.3	.0	28.35	859	10.8
48	75.7	43.4	0.0	.0	16.43	858	8.4
52	75.8	43.4	.0	.0	16.83	858	8.7
53	75.8	43.4	.0	60.5	8.86	858	8.9

Apparently the addition of hydrogen has no effect other than that of reducing the ammonia pressure. With nitrogen present, the rate of decomposition is higher than expected. Since nitrogen reduces both the partial pressure of the ammonia and that of the hydrogen formed by decomposition, we can explain the increased velocity in the presence of nitrogen by assuming that hydrogen actually inhibits the decomposition process. At low pressures of hydrogen the rate of decomposition is inversely proportional to these pressures, but at high pressures the inhibiting effect reaches a constant value and the reaction proceeds as if it were unimolecular with respect to the ammonia. A calculation shows that when the average hydrogen pressure falls below about 10 cm., the constants, according to Equation 1, begin to increase. In between the low and high pressure regions the hydrogen should inhibit in a way which is intermediate between the two extreme cases.[5] Over the length of the catalyst each of the three cases may exist, but the constants, such as are given in Table I,

---

[5] Hinshelwood, "Kinetics of Chemical Changes in Gaseous Systems," Oxford Press, p. 196.

are sufficiently comparable and accurate to determine the temperature coefficient of the reaction.

The experiments were complicated because of a small amount of decomposition of the ammonia on the quartz tube which held the catalyst. The area of the quartz surface was 78 sq. cm. At the end of the experiments with platinum, the wire gauze was removed, the tube cleaned with aqua regia, the empty tube sealed to the apparatus again and the amount of decomposition determined. The results are given in Table II.

TABLE II

THE DECOMPOSITION OF AMMONIA ON QUARTZ

Expt.	Barometric pressure, cm.	Inlet NH$_3$, cc./min.	% NH$_3$ decomposed	t, °C.
1, 4	76.9	43.4	2.58	858
2	76.9	43.4	4.72	902
3	76.9	43.4	1.99	826

If hydrogen inhibits the decomposition on quartz, the values of the percentage decomposition due to quartz in Table II would have been even smaller if the platinum had been present. The figures in Table I have not been corrected for the decomposition on quartz.

Since the catalyst showed a decrease in activity during the course of its entire use, the temperature coefficient has been determined from comparable experiments at different temperatures. Table III shows clearly which experiments have been compared, excepting that the runs with added nitrogen have been omitted. The first column gives the experiments from which the constants in columns two, four and six were calculated. The temperatures of the experiments are given at the top of the table and the ratios of the constants for two successive temperatures are given in columns three and five. The inlet flow rate of ammonia is given in the last column.

TABLE III

TEMPERATURE COEFFICIENT OF THE DECOMPOSITION OF AMMONIA ON PLATINUM WIRE

Expt.	t = 772°C. k	Ratio	t = 826°C. k	Ratio	t = 858°C. k	Inlet NH$_3$, cc./min.
23–30	2.4	2.34	5.6	1.75	9.9	30.4
31–36	2.5	2.72	6.8	1.57	10.6	40.4
37-44			4.6	1.71	7.8	15.5
45–47			*5.2*	1.70	*8.8*	21.9
48–53	hi		5.0	1.72	8.6	43.4
Mean		2.53		1.7		

The heat of activation calculated from the temperature coefficient between 772 and 826° is **39,000** calories per mole and between 826 and 858° is **41,000** calories per mole. The average hydrogen pressure increases with the temperature and consequently the calculated temperature coefficients may be slightly low. The heat of activation which was found by Schwab and Schmidt at low pressures was 44,000 calories; hence the agreement is good.

The fact that the temperature coefficient is nearly the same for all metals seems to indicate that the mechanism of the ammonia decomposition is the same on each metal. Since experiments on different metals have not been carried out under comparable conditions, it is fruitless to attempt to find a relation between the velocity of decomposition and the heat of reaction.

Summary

The decomposition of ammonia on platinum gauze has been studied by a flowing method between 772 and 858°. The rate of decomposition is proportional to the ammonia pressure and inversely proportional to the hydrogen pressure. As the pressure of the hydrogen increases, its inhibiting effect reaches a constant value and the reaction proceeds unimolecularly with respect to the ammonia. The heat of activation of the reaction is 40,000 calories per mole. This value is in agreement with those found for a number of other metals.

REACTIONS INVOLVING HYDROGEN PEROXIDE, IODINE AND IODATE ION. IV. THE OXIDATION OF IODINE TO IODATE ION BY HYDROGEN PEROXIDE[1]

BY HERMAN A. LIEBHAFSKY

RECEIVED MARCH 5, 1931 PUBLISHED JUNE 8, 1931

A preliminary study of the reaction

$$I_2 + 5H_2O_2 = 2H^+ + 2IO_3^- + 4H_2O \qquad (1)$$

has led Bray and Caulkins (II) to conclude from the rate law

$$-\frac{dI_2}{dt} = k\,(I_2) \qquad (2)$$

which it obeys in a rather large region of concentrations, that its principal rate-determining steps are the reactions

$$I_2 + H_2O \xrightarrow{k_1} HIO + I^- + H^+ \qquad (3a)$$

and

$$HIO + H^+ + I^- \xrightarrow{k_2} I_2 + H_2O \qquad (3b)$$

which taken together constitute the hydrolysis equilibrium of iodine. They found reasonable agreement between their value of k(k = 0.6 at 25°) and the value of the specific rate for the iodine hydrolysis (k_1 = 0.25 at

---

[1] The earlier papers of this series are (a) Bray and Liebhafsky, THIS JOURNAL, 53, 38 (1931); (b) Bray and Caulkins, ibid., 53, 44 (1931); (c) Liebhafsky, *ibid.*, 53, 896 (1931).

25°), which Abel[2] has deduced from another reaction system. In this paper are presented the results of a more extended investigation of Reaction 1. It was hoped that k_1 could be determined as a maximum limiting value of k, and that a study of the variation of k under extreme concentration conditions might cast some light upon the mechanism of the various rapid reactions following the rate-determining steps 3a and **3b.**

When hydrogen peroxide and iodine solutions are mixed[3] with the peroxide in moderate excess, no great change in the concentration of iodine occurs even after several weeks, but the hydrogen peroxide gradually disappears. For the oxidation of iodine to iodate, therefore, such a reaction system passes through an infinite induction period. If the mixture is made acid, this induction period may be greatly shortened; if iodate ion is added also, and in sufficient quantity, the initial delay may be eliminated entirely and iodate is formed. The time then required, at room temperature, for half the iodine to be oxidized is approximately one minute.

Accurate measurements of the rate of this reaction are best undertaken at zero degrees for two reasons: first, the rate at that temperature is low enough to permit of careful manipulation, and, second, the concentration of iodine at the steady state is smaller at zero degrees than at room temperature, so that relatively a larger range of iodine concentrations can be covered before catalytic decomposition of hydrogen peroxide complicates the pure oxidation of iodine. The experimental method employed in following the rate of disappearance of iodine in a given reaction mixture consists simply in withdrawing samples of it at known intervals, "freezing" the reaction by shaking the sample with carbon tetrachloride to extract the iodine, and titrating the iodine thus obtained with thiosulfate solution.

Reagents and Analytical Methods.—C. P. chemicals not further purified were used in all work. Perchloric and iodic acids were used as sources of hydrogen ion. For certain of the experiments requiring a high concentration of both iodine and iodate ion, a solution of iodine and potassium iodate, saturated with respect to both, was employed.

Sodium thiosulfate solutions were standardized through permanganate against sodium oxalate according to the method of Bray and Miller.[4] Sodium carbonate prepared by fusing the pure bicarbonate was the reference substance for all standard acids. The hydrogen peroxide was determined with permanganate; the iodate solutions were standardized iodimetrically.[5] An iodimetric method was used in the determinations of total oxidizing power.

[3] For a more comprehensive summary of the reactions which may take place in this system see I, Table I.

[4] Bray and Miller, THIS JOURNAL, 46, 2204 (1924).

[5] A method identical in all essential respects with the method of **this** paper was used by Bray and Livingston [*ibid.*, 50, 1654 (1928)] to determine hydrogen peroxide.

The determination of the iodine in the reaction mixture was carried out according to a method elsewhere described.[6]

Experimental Method

The reaction vessel was a 500-cc. glass-stoppered flask placed in the large Dewar flask which served as thermostat. With finely divided ice in the Dewar, the temperature in the flask was 0.1 ± 0.1°. In all experiments, except in those done to ascertain the effect of the order of mixing the reagents, the peroxide, at 0°, was added to the rest of the reaction mixture, also at 0°, in order to start the reaction. Immediately after the rapid addition of the peroxide, the flask was vigorously shaken; the time of shaking was taken as the initial time for the reaction. Samples were withdrawn in the following manner: fifteen seconds before the minute which was to be the time of the sample, a 20-cc. pipet was placed in the reaction mixture and filled. This volume of reaction mixture was then blown into a separatory funnel having a short, beveled exit tube so that the tip of the pipet was below the surface of the 25 cc. of cold carbon tetrachloride in the funnel. The reaction was "frozen" on the minute by shaking the separatory funnel vigorously enough to insure virtually instantaneous extraction of the iodine. The carbon tetrachloride layer was then run into a 125-cc. glass-stoppered flask containing 50 cc. of distilled water. After the small amount of carbon tetrachloride from a second extraction of the reaction mixture had been added to the flask, it was vigorously shaken in order that the carbon tetrachloride layer might be washed free of iodate and peroxide. After allowing the carbon tetrachloride to settle, the water was carefully poured off, and the washing process twice repeated. Care must be observed in the washing—first, that the flasks are scrupulously clean to prevent adhesion of the carbon tetrachloride; second, that the shaking is not violent enough to emulsify the carbon tetrachloride; and third, that no carbon tetrachloride remains on the surface of the water layer. No correction need be applied for the iodine dissolved in the water since its concentration, assuming equilibrium, will always be proportional to the (I_2) in the carbon tetrachloride layer: the first order rate constant will thus not be affected so long as the volume of carbon tetrachloride, size of sample, amount of water used for washing and similar factors remain the same.

The samples obtained in this manner were titrated with 0.004 N sodium thiosulfate by the method previously mentioned.[6] As the reaction neared completion, the concentration of iodine became so small that samples larger than 20 cc. had to be taken to secure sufficient accuracy in the titration of the iodine; since, at low (I_2)[7] speed in manipulation is less imperative, this could conveniently be done.

Detailed Experimental Results.—The detailed results of several of the rate experiments performed by the above method are shown in Figs. 1 and 2, and Table I. In Fig. 1 (I_2) as ordinate is plotted on semi-logarithmic paper against the time *t*, in minutes, to give a conventional rate plot for a first order reaction. Zero time for each succeeding experiment is placed further to the right to prevent superposition of the curves. Results as concordant as those shown in the plot were obtained only after long practice had improved the experimental technique. The slope of the steepest line through the experimental points (multiplied by 2.3) was taken for the

---

[6] Liebhafsky, THIS JOURNAL, 53, 165 (1931).

[7] ( ) denotes "concentration of"; thus, (I_2) is "concentration of iodine." The units, when such are necessary, are moles per liter.

[a] Titrations during the next twenty-four hour period gave no indication of a further change in (I_2); k is given by the first four points.

value of k as defined in the rate law (Equation 2) previously established for Reaction 1.

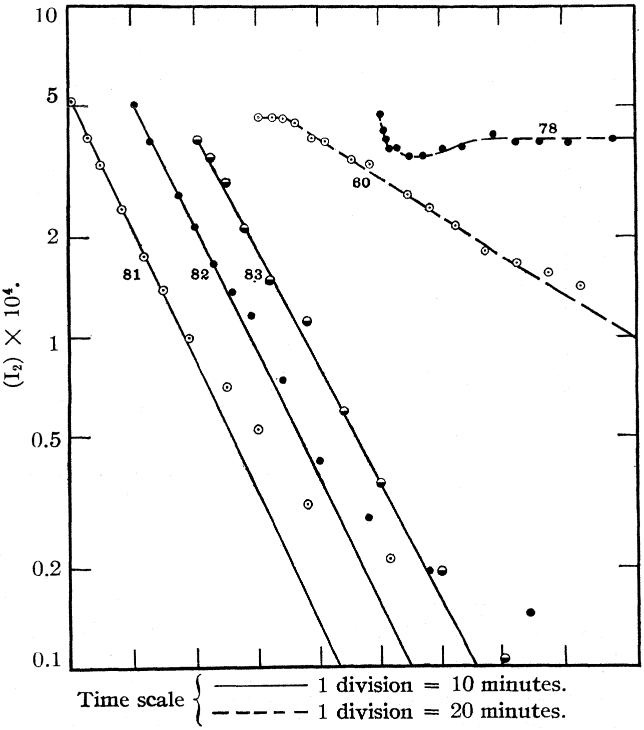

Fig. 1.—Typical experiments. (The plot is on semi-logarithmic paper; for composition of reaction mixtures, see Table I.)

The curves in Fig. 2 represent the dependence of *k* on (I_2) (*cf.* II, Fig. 1) for a number of experiments carried out under various concentration conditions. The values of k for any one experiment were computed from tangents to a smooth curve drawn through the experimental points plotted as in Fig. 1. Because of the erratic nature of many results at low (I_2) (i.e., approximately $5(10^{-5})$ M), this procedure was not generally adopted; even a qualitative interpretation of these results was usually impossible. The behavior of k as the reaction proceeds is typified by Nos. 74 and 83 rather than by the other experiments: *i. e.*, k usually remained constant until 50–75% of the iodine had been consumed, and then decreased. This decrease began at higher values of (I_2) the higher (H_2O_2) (as is shown by Nos. 71, 73 and 74), and the higher (H^+) (as is shown by Nos. 74, 83, 71 and 32). For (IO_3^-) variation no such conclusion could be drawn. We shall revert to this behavior of k in a later section.

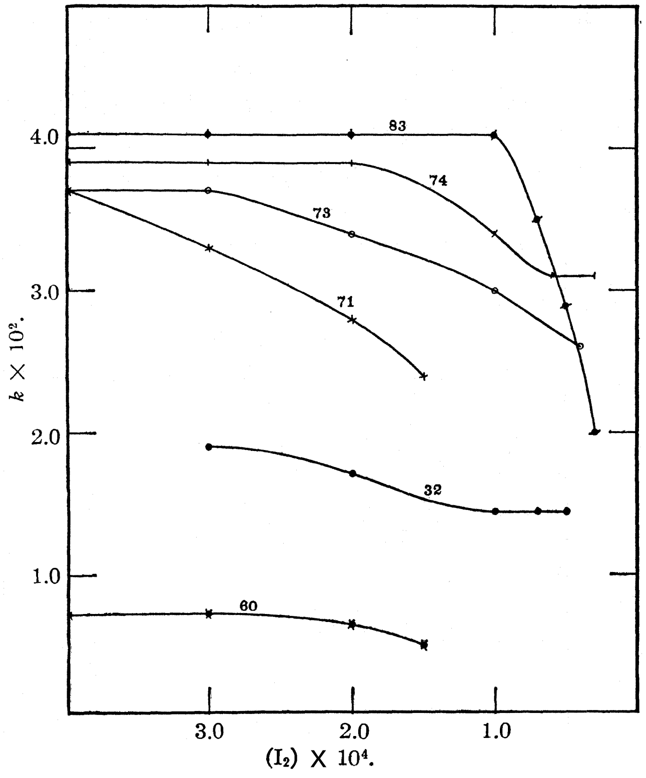

Fig. 2.—Variation of k with (I_2) (see Table I).

It follows at once from the conclusion drawn in 11—namely, that the ***principal*** rate-determining steps for Reaction 1 are Reactions 3a and b—that Equation 2 may be written

$$-\frac{d(I_2)}{dt} = k(I_2) = k_1(I_2) - k_2(H^+)(I^-)(HIO) \tag{4}$$

Were our reaction system a simple one, we should accept as conclusive the close agreement of experiments like Nos. 81, 82 and **83** with a first order rate law, and we should identify the highest (constant) values of k with k_1, the specific rate for the iodine hydrolysis. We should say that k decreases at very low concentrations of iodine because of iodine formation from the Reaction 3b, and that such iodine formation is negligible in the region where k is truly constant. Unfortunately, the complexity of the reaction system precludes the complete acceptance of this simple explanation, and we shall, in a later section, be forced to examine the possibility that Reaction 3b is of importance throughout the entire range of iodine concentrations.

Effect of External Factors on the Reaction.—Experiments designed to reveal any effect on the reaction of either light or glass wool gave conclusive negative results.

Experiments on the effect of different orders of mixing the reagents resulted as follows. If the peroxide was added to an acid iodine solution containing iodate ion (the method of mixing previously described), reproducible results were obtained in all cases where the oxidation of iodine began immediately and was unaccompanied by too much catalytic decomposition of hydrogen peroxide. If an *acid* iodine–peroxide mixture was allowed to stand, and iodic acid added to start the reaction, reproducible results were likewise obtained. If an iodine–peroxide solution is allowed to stand, and iodic acid added as before, there is an increase of iodine (which is caused by oxidation of the iodide ion formed on standing) on mixing; the rate constant in such an experiment was often low. If 30% hydrogen peroxide is added to an iodine solution containing iodic acid, and the reaction mixture is neither stirred nor shaken, the entire rate curve may be altered. (This effect will be mentioned again later.)

Variation of the Rate Constant with Changes in (10,–).—The effect on the rate constant of a variation in the iodate concentration is given in Fig. **3** by Curve I for very low, and by Curve II for moderate, concentrations of peroxide. Whether k has a finite value at zero concentration of iodate ion cannot be settled by our experimental methods for the induction periods at low (IO_3^-) are long enough to permit of some iodate formation.

Curve I shows that the value of the rate constant increases from 0.015 to 0.06 as the iodate concentration is increased from a very small value to that for a saturated solution of potassium iodate; Curve II indicates that k approaches a limiting value, k = 0.03 when the same change is made. If Curve II, which was first established, were the only experimental evidence for the dependence of k on (IO_3^-), we should conclude—in agreement with II and with Abel's results—that k = 0.03 was the value of the specific rate for the iodine hydrolysis at 0°. Curve I, however, does not agree with this simple conclusion. An inspection of the concentration conditions obtaining for the curves will show that, although the acid concentrations differ somewhat, the chief difference lies in the concentration of hydrogen peroxide, which is approximately forty times greater for the experiments on Curve II than for those on Curve I. How this difference in peroxide concentrations may explain the difference in the curves will be mentioned in a later section.

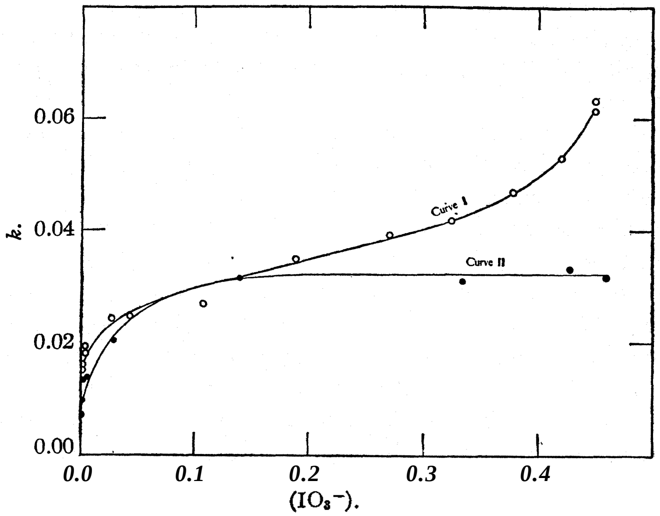

Fig. 3.—*Variation of k* with change in (IO_3^-). Curve *I*, $(H^+) = 0.0268$; $(H_2O_2) = 0.0039\text{-}0.0018$; Curve II, $(H^+) = 0.054\text{-}0.071$; $(H_2O_2) = 0.10$.

The Removal **of Iodide** Ion.—We shall now consider evidence for the assumption that the primary function of IO_3^- is to assist in the removal of the iodide ion formed by the hydrolysis of iodine. Abel[8] and his co-workers, in revising Dushman's[9] work, have shown that the rate law for the oxidation of iodide ion by iodate ion in acid solution is the following

$$-\frac{d(IO_3^-)}{dt} = (IO_3^-)(I^-)(H^+)^2[\kappa f^2 + k'F(I^-) + k''F(I_3^-)] \tag{5}$$

where, at 25°

$$\kappa = 2.4(10^4);\quad k' = 7.6(10^{10});\quad k'' = 5.5(10^{10})$$

(The "f" terms involve activity coefficients.) For the **very** approximate calculation which we shall make, I_3^- will be considered simply as I^- and the factors involving activity coefficients will be neglected. The 25° values of the constants will be changed to corresponding values for 0° by employing the temperature coefficient 1.3 found by Dushman in a region of $(I-)$ where the fifth order reaction is of primary importance.

[8] (a) Abel and Stadler, *Z. physik. Chem.*, 122, *49 (1926)*; (b) Abel and Hilferding, *Z. physik. Chem.*, 136, *186 (1928)*.

[9] Dushman, *J. Phys. Chem.*, *8,453 (1904)*.

Equation (5) may now be written

$$-\frac{d(IO_3^-)}{dt} = (IO_3^-)(I^-)(H^+)^2[3(10^{10})(I^-) + 1(10^4)] \text{ at } 0^\circ \qquad (6)$$

In order to apply this equation to our reaction system, we must write it to give the number of moles of iodide reacting directly with iodate per minute in a liter of reaction mixture. Since two molecules of iodide are involved in the fifth order reaction, the value $3(10^{10})$ must be doubled. We now have.

$$\text{moles of } I^- \text{ reacting with } IO_3^-/\text{min.} = (IO_3^-)(I^-)(H^+)^2[6(10^{10})(I-) + 10^4] \qquad (6a)$$

The oxidation of iodine through its hydrolysis products to iodate ion requires the oxidation of one mole of I^- and of one mole of HIO for every mole of iodine consumed in Reaction 1. If we now assume that all the I^- which is transformed into iodate reacts first with iodate ion, we may calculate an approximate upper limit for the (I–) in our reaction system; for we may then write

$$-\frac{d(I_2)}{dt} = k(I_2) = \text{moles } I^- \text{ reacting with } IO_3^-/\text{min.} = (IO_3^-)(I^-)(H^+)^2[6(10^{10})(I^-) + 10^4] \qquad (7)$$

Using this equation and the values of k given by Curve I, Fig. **3,** for different values of (IO_3^-), the last column of Table II was computed.

TABLE II

MAXIMUM (I–) IN THE REACTION SYSTEM AT VARIOUS (IO_3^-)

(IO_3)	(H^+)	(H_2O_2)	(I_2)	k	(I^-)
$2(10^{-1})$	0.0268	0.0034	$5(10^{-4})$	0.060	$1.8(10^{-6})$
$1(10^{-2})$	.0268	.0034	$5(10^{-4})$	.020	$4.8(10^{-6})$
$1(10^{-3})$	.0268	.0034	$5(10^{-4})$	.015	$1.4(10^{-5})$
$1(10^{-5})$	.0268	.0034	$5(10^{-4})$	.016	$1.3(10^{-4})$

The (I–) values calculated for the two highest iodate concentrations in Table II are of a reasonable order of magnitude; we shall therefore assume that the chief function of iodate ion is to assist in the removal of iodide ion. If iodide is oxidized to a valence above zero by other substances also, the actual (I–) obtaining in the reaction mixture will be less than that calculated from Equation 7.

When (IO_3^-) decreases below 10^{-2}, however, the (I–) values of Table II become much too large. The value $(I-) = 1.3(10^{-4})$ calculated for $(IO_3^-) = 10^{-5}$ represents an appreciable part of the initial (I_2); this concentration of iodide could never be established in such a reaction mixture, for the iodide initially present from hydrolysis is less than 0.01% of the iodine with which it was in equilibrium, and the amount of iodine disappearing during an induction period is always relatively small. The maintenance of the concentration of iodide ion at a reasonable value in these reaction mixtures therefore requires the action of another oxidizing agent in addition to iodate ion. Hydrogen peroxide is far too slow;[10] but HIO_2 remains as a

---

[10] References 12a, 12b, 12c, from Ref. 1a.

logical possibility. We shall assume that, at low (IO_3^-), iodous acid reacts first with the major part of the iodide which is converted finally into iodate. The importance of this reaction at higher (IO_3^-) is uncertain; the greater its importance, the farther will the (I–) of the reaction system be below that calculated from Equation 7.

An examination of the work of Abel and Hilferding[Sb] shows that iodate ion cannot to an appreciable extent oxidize HIO. If this reaction were of importance, they could not have found their simple fourth order rate law for the oxidation of iodide by iodate, since the concentration of HIO in their experiments ((H^+) and (I–) were sensibly constant) must have undergone a concentration variation parallel to that of iodine.

The relation of the curves of Fig. **3** to the value of the specific rate for the iodine hydrolysis will be discussed later.

Catalysis in Relation to the Rate Measurements.—Whenever, in a reaction system involving the action of hydrogen peroxide as an oxidizing agent, that substance acts as a reducing agent also, the catalytic decomposition of hydrogen peroxide will constitute a side reaction taking place in the system. So long as there is no appreciable decomposition of iodine compounds to liberate oxygen, the decrease in the oxidizing power of our reaction mixture will furnish a quantitative measure of the amount of peroxide reduced, which will be half that catalytically decomposed. This method of determining the amount of such catalysis will cease to be accurate when the total oxidizing power is very much greater than the decrease due to such catalysis.

In Table III some of the catalysis results are given. The seventh column shows the amount of catalysis, expressed as an increment of the peroxide concentration, observed for each reaction mixture during the time interval given in the sixth column. In the last column are given the ratios (R's) of this concentration change to the amount of peroxide, equal to $5(I_2)$, which is equivalent in Reaction 1 to the iodine initially present in a liter of reaction mixture.

TABLE III

CATALYSIS RESULTS

No.	(H^+)	(IO_3^-)	$(H_2O_2)10^3$	k	Time, hrs.	$\Delta(H_2O_2)(10^3)$	R
97	0.0268	0.0017	3 9	0.018	20	0.27	0.14
103	.0268	.00108	3.4	(018)	8	.43	.22
104	.0268	.00053	3.4	.015	8	.33	.17
107	.0677	.0142	110	.023	15	4.4	2 2
108	.0677	.0142	560	.0067	7	77	39

In each case $2(10^{-3})$ moles of hydrogen peroxide would be required to oxidize the iodine initially present to iodate; the initial (I_2) was approximately $4(10^{-4})$.

The titrations of oxidizing power carried on during the course of the two experiments involving the largest absolute amounts of catalysis show that the rate of this catalysis diminishes markedly as the concentration of iodine decreases. **A** comparison of Experiment 108 with No. 107 (Table III) shows that a large absolute amount of catalysis brings with it a sharp reduction in k; the iodine formation causing this decrease in k we attribute to the increased rate of Reaction 3b brought about by the higher (I^-) which obtains in the system when the absolute amount of catalysis is large. These low constants at high (H_2O_2) were generally observed and will again be mentioned in a later section. Titration of samples from an initially neutral iodine solution, 0.005 *M* in peroxide, over a period of days showed the catalysis to be proportional to (H_2O_2). The (I_2) of the solution underwent little change during the experiment.

From these facts we conclude that the major part of the catalysis encountered in our reaction system is due to those steady states which Abel[11] has so thoroughly investigated. The fact that this catalytic rate may be made very low shows, according to conclusions presented in Part I, that hydrogen peroxide cannot, in our reaction system, oxidize HIO. Neither can it oxidize the I^- in this system[12] at a rate comparable with the dI_2/dt measured. Since changes in (H_2O_2) do not proportionately alter k (see the section on variation of k with (H_2O_2)), we conclude that hydrogen peroxide cannot oxidize iodine directly with sufficient speed to explain the removal of iodine. Yet for every mole of iodine disappearing by hydrolysis, one mole of I^- and one mole of HIO must be removed. We have, therefore, to devise a mechanism by which the oxidation of iodine to iodate can be accomplished in our reaction system without *appreciable* direct oxidation of either I_2, I^- or *HIO* by hydrogen peroxide, the only oxidizing agent appearing as reactant in the stoichiometric equation for the change.

We have found such a mechanism only by assuming that the fourth order $IO_3^- - I^-$ reaction proceeds as follows

Relatively rapid equilibrium $IO_3^- + I^- + 2H^+ \rightleftharpoons H_2I_2O_3$ (8a)

Rate-determining step $H_2I_2O_3 \longrightarrow HIO + HIO_2$ (8c)

This formulation of the fourth order reaction indicates that $H_2I_2O_3$ decomposes the more readily into iodate and iodide ions. In our reaction system hypoiodous acid is removed as rapidly as it is formed; we shall assume that this removal is accomplished by the reaction

$$HIO_2 + HIO = H_2I_2O_3 \qquad (8b)$$

---

[11] For bibliography see 1a. Two differences between Abel's system and ours must here be observed. In the former, much of the HIO must be formed by the oxidizing action of H_2O_2 on I^-; the rate of this step governs the rate of the catalysis. In our system, HIO can be formed from I^- by the action of IO_3^-, HIO_2 and $H_2I_2O_3$; the rate of the catalysis is here governed by the rate at which H_2O_2 reduces HIO at the extremely small concentration obtaining for the latter in this system. Here, also, H_2O_2 may possibly reduce IO_3^-, HIO_2 and $H_2I_2O_3$; these reactions may account in part for the catalysis observed.

[12] See 1a, References 12a, 12b, 12c.

which is the reverse of Reaction 8c. Bray,[13] in correlating a number of halogen reactions, has rendered plausible the assumption of Reaction 8b. In order to accomplish iodate formation, the oxidizing action of hydrogen peroxide need now be assumed only in the reactions

$$H_2I_2O_3 + H_2O_2 = 2HIO_2 + H_2O \qquad (9)$$

and

$$H_2O_2 + HIO_2 = H^+ + IO_3^- + H_2O \qquad (10)$$

If the oxidation of iodine is to proceed, these reactions must be rapid enough to keep $H_2I_2O_3$ at or below the equilibrium concentration for Reaction 8a; this restriction imposes a lower limit on the values we may assume for the specific rates of Reactions 9 and 10 in order that the oxidation of iodine by hydrogen peroxide may take place in the manner above prescribed. Its applicability to this reaction system is strong additional evidence for the mechanism assigned by Bray to the IO_3^-–I^- reaction.

Using measurements made in Experiments 107 and 108, Table III, on the rates of decrease in oxidizing power, we may, on the assumption that all of the hydrogen peroxide is oxidized according to the equation

$$HIO + H_2O_2 = H^+ + I^- + O_2 + H_2O \qquad (11)$$

calculate a value[14] for (HIO) in the reaction system; the value 10^{-8}–10^{-9} M thus obtained sets an upper limit for the concentration of hypoiodous acid.

The Induction Period.—Most of the experiments proceeded without an appreciable induction period; in general, if there was an induction period, it was longer the lower the (IO_3^-), the lower the (H^+) (as is shown in Tables IV and V), and the higher the (H_2O_2). The shape of the induction period curves (Experiment 60, Fig. 1, is an example) shows that it is terminated by an autocatalytic reaction. At low (H^+) (Expts. 17, 19 and 21, Table IV), and high (H_2O_2), it is particularly unreproducible.

A comparison of experiments at low (IO_3^-) shows that the concentration of iodate ion in the system is not, other initial concentrations being con-

---

[13] Bray, THIS JOURNAL, 52, 3580 (1930). For purposes of this paper $H_2I_2O_3$ and I_2O_2 may be considered identical.

[14] In Experiment 108, $-dH_2O_2/dt$ in moles/min./liter calculated for Reaction 11 from the decrease in oxidizing power is $4.4(10^{-4})$; in Experiment 107, it is $1.3(10^{-5})$. Taking the value $3(10^4)$ for the specific rate of Reaction 11 at 0° [Abel, Ref. 2, gives $3.3(10^5)$ for this specific rate at 25°; at our acid concentrations (0.01 M and over) the oxidation of H_2O_2 by IO^- may be neglected], we obtain for 108, $(HIO) = 2.6(10^{-8})$, and for 107, $(HIO) = 4(10^{-9})$ on substitution of the (H_2O_2) values from Table III. Using the value

$$K = \frac{(HIO)(I^-)(H^+)}{(I_2)} = 9(10^{-15}) \text{ at } 0°$$

[Grinnell Jones, THIS JOURNAL, 37, 256 (1915)] we find that, at $(H^+) = 2(10^{-2})$ and $(I_2) = 5(10^{-4})$, the limiting value of the product $(HIO)(I^-)$ is $2.3(10^{-16})$. If (I^-) is 10^{-6} in order of magnitude, as the previous section would indicate, (HIO) cannot be above 10^{-10}. This calculation would indicate either that (I^-) of the previous section is too high, or that some of the catalysis does not involve HIO, or both.

stant, the only factor in determining whether or not the reaction is to suffer an induction period, for the amount of iodine disappearing before smooth oxidation begins is, in an experiment such as 106 or 104, Table IV, far less than the amount initially present in an experiment such as 97, Table IV, which also has an induction period. A comparison of the first group of experiments with the second shows how markedly the induction period is lengthened at low (H^+); the experiments in Table V, which were done at room temperature without initial iodate, show this also.

TABLE IV

LENGTH OR INDUCTION PERIOD IN VARIOUS RATE EXPERIMENTS

No.	(H^+)	(IO_3^-)	(H_2O_2)	k	**Induction period**
57	0.0546	0.00109	0.103	0 0133	8 min.
59	.0540	.00055	.103	.0096	24 min.
60	.0537	.00022	.103	0081	22 min
61	.0535	.000035	.103	.0081	31 min.
93, 94, 95, 96	.0268	.135–0.0135	.002–0.004	.039–0.024	Below 2 min.[a]
97	.0268	.0017	.0038	.018	27 min.
104	.0268	.00053	.0034	.015	Approx. 6 hrs.
106	.0268	None initially	.0034	.016	Approx. 9 hrs.
17	.0142	.0142	.112	.017	44 min.
19	.0142	.0142	.112	[b]	8 hrs.
21	.0142	.0142	.112		2 hrs.
35	.0677	.0142	.056	.021	None
30	.0677	.0142	.065	.015	10 min.[c]
28	.0677	.0142	.065	.015	12 min [c]

[a] The (IO_3^-), (H_2O_2) and k values for these experiments are concordant and lie within the limits given. [b] No rate constants obtained in these two experiments. [c] 30% hydrogen peroxide allowed to remain in contact with reaction mixture for several minutes without shaking; irregular induction often encountered at high (H_2O_2).

TABLE V[a]

INDUCTION PERIOD EXPERIMENTS WITHOUT INITIAL IODATE ION

(H^+)	(H_2O_2)	**Induction period**
0.9	0.005	8 hrs.
.2	.005	9 hrs.
.02	.005	14-21 hrs.[b]
.004	.005	8-11 days[b]
.0004	.005	m[c]
Neutral	.005	∞[c]

[a] These experiments were carried out at room temperature. [b] Induction period within these limits. [c] These experiments will be mentioned in the section on mechanism.

Since an induction period is usually required to establish the necessary concentrations of those intermediate products essential to a reaction, it is logical here also to ascribe the initial delay to this cause. We shall assume that an induction period is necessary to build up the concentration of HIO_2 requisite to the oxidation of iodine. This assumption is entirely in accord with our previous conclusion that at low (IO_3^-) HIO_2 oxidizes a large part of the iodide ion converted finally into iodate, for every experiment with $(IO_3^-) = 0.001$ *M* or less suffered an induction period.

The building up in the reaction system of appreciable concentrations of HIO_2 entails the lowering of (I^-); for if (I^-) is relatively high, the iodide ion will by reduction remove the first named substance. For this reason any factor tending toward either an increased initial (I^-) (*e.* g., low H^+), or an incomplete removal of I^- (again low (H^+), and low (IO_3^-)), or an increased formation of I^- (such as increased catalysis in which Reaction 11 is concerned) tends to lengthen the induction period.

In a system so complex that a large number of reactions is possible, the value of the rate constant may depend markedly on what reactions are favored in mixing the reactants. Experiments 35, 30 and 28, Table IV, represent one of two groups in which anomalous results were obtained because the 30% hydrogen peroxide used as a stock solution was left for an appreciable time in contact with the reaction mixture before shaking. Experiments 30 and 28 differ from 35 only in that respect. (The small difference in (H_2O_2) is unimportant since experiments with (H_2O_2) above 0.065 also gave constants of 0.02.) The induction period and the decrease in k which the first two experiments suffered we believe to be due to the large initial catalysis (with its consequent I^- formation) brought about by leaving the 30% peroxide in contact with the reaction mixture for several minutes.

Lower values of rate constants usually accompanied induction periods; if, in duplicate experiments, only one went through an initial delay, that one had the lowest k (e. g., No. 35 as contrasted with Nos. 28 and 30). This behavior was general enough to warrant the belief that the subsequent (I^-) concentration in an experiment with induction period was higher than it would have been had the smooth reaction begun immediately on mixing the reagents.

Because of the extreme unreproducibility of induction periods at high (H_2O_2), no data are given for induction periods of experiments with (H_2O_2) above 0.112 M. We shall say only that, if 30% hydrogen peroxide is added to make a reaction mixture concentrated in that substance, it must be so added as to secure thorough initial mixing; for there may otherwise be a long delay before the oxidation of iodine begins.

The autocatalytic reaction terminating the induction period is, we believe, concerned with the removal of I^-. While an autocatalytic removal of I^- can be accomplished in devious ways, its beginning could well depend on the reaction

$$HIO_2 + I^- + H^+ = 2HIO \qquad (12)$$

which has already been postulated to explain the removal of I^- at low (IO_3^-); assigning this function to Reaction 12 harmonizes with the idea that an induction period is necessary primarily to build up the concentration of HIO_2.

HIO_2 formation through Reaction 9 will explain the fact that the oxidation of iodine proceeds at all when (IO_3^-) is initially very low; if HIO_2 formation only through the IO_3^-–I^- reaction is assumed, no such simple explanation is possible. Building up an appreciable (HIO_2) by the latter mechanism might take months[15] instead of the ten hours or so actually observed. These considerations furnish further evidence for the existence of $H_2I_2O_3$.

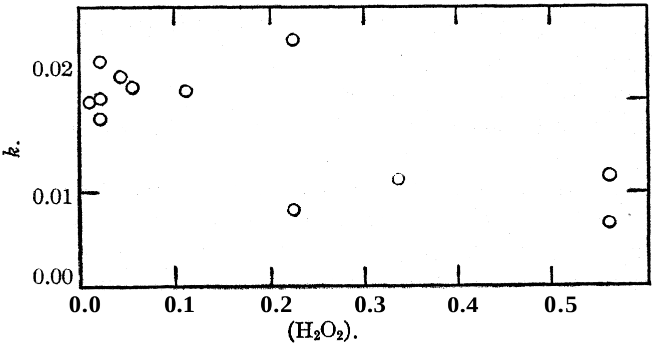

Fig. 4.—Variation of k with change in (H_2O_2). $(H^+) = 0.0677$; $(IO_3^-) = 0.0142$.

Variation of the Rate Constant with (H_2O_2) and (H^+).—The behavior of k as (H_2O_2) is changed is shown in Fig. 4, as (H^+) is changed, in Fig. 5. The curves show definitely that, for a rather large concentration range ((H_2O_2) from 0.01 to 0.56 *M*; (H^+) from **0.015** to 0.9 **M**) neither hydrogen peroxide nor hydrogen ion exerts on the rate of Reaction **1** an effect proportional to the change in concentration. The figures show, however, that increasing (H_2O_2) or (H^+) does result in a lower value of k. In experiments at the higher concentrations of acid, k often fell off to a reasonably constant lower value as the reaction proceeded; for such experiments both the higher and the lower values are plotted in Fig. 5—the lower value is indicated by a dot.

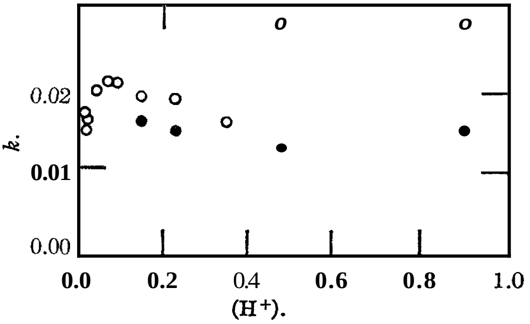

Fig. 5.—Variation of k with change in (H^+). ○, Earlier part of run, or complete run; ●, middle part of run.

---

[15] At $(IO_3^-) = 10^{-8}$, $(I^-) = 10^{-6}$, $(H^+) = 2(10^{-2})$, dI^-/dt calculated from Equation 6 is $3(10^{-13})$ moles/liter/min.

The tendency for k to decrease in a run, causing the experimental points to diverge from straight lines (*cf.* Figs. 1 and 2, especially Expts. 32, 73 and 71 in the latter figure) is probably related to the lower values of k obtained at high (H^+) and high (H_2O_2). Both effects can be explained in terms of iodine formation through Reaction 3b; k will remain constant as long as this iodine formation remains proportional to (I_2), and k will become smaller when such iodine formation becomes relatively greater. These effects are found at high (H^+) because hydrogen ion is involved in Reaction 3b, and at high (H_2O_2) because catalytic decomposition of the peroxide brings about iodine formation in a manner already explained (see the section dealing with catalysis).

Results obtained in experiments where the initial (H_2O_2) was insufficient for the complete oxidation of I_2 are of interest. Experiment 78, Fig. 1, has a reaction curve typical for such experiments. The fact that the initial portions of the curves for these experiments are straight lines show that k is independent of (H_2O_2) even to very low concentrations of that substance. The peculiar character of the reaction curve after the initial straight line portion is doubtless due to a readjustment of the intermediate iodine compounds in the system.

Mechanism of the Oxidation.—The foregoing sections have served to indicate certain reactions which may be assumed to explain the oxidation of iodine to iodate ion by hydrogen peroxide. The mechanism which has been devised to explain the empirical fact that iodine is oxidized to iodate ion in our reaction system must explain, qualitatively at least, the diverse experimental results obtained and be in harmony with past work on the chemistry of iodine. This mechanism will now be summarized.

Rate-determining step $I_2 + H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H^+ + I^- + HIO$ **(3a and b)**
Iodide removal $IO_3^- + I^- + 2H^+ = H_2I_2O_3$ (8a)
Oxidation to HIO_2 by H_2O_2 $2(H_2I_2O_3 + H_2O_2 = 2HIO_2 + H_2O)$ (9)
Oxidation of HIO $HIO_2 + HIO = H_2I_2O_3$ (8b)
Iodate formation $3(HIO_2 + H_2O_2 = IO_3^- + H^+ + H_2O)$ (10)
Main reaction (sum of above) $I_2 + 5H_2O_2 = 2IO_3^- + 2H^+ + 5H_2O$

I^- removal is accomplished also by

$$HIO_2 + I^- + H^+ = 2HIO \qquad (12)$$
$$H_2I_2O_3 \text{ (or } I_2O_2 + H_2O) + I^- = I_3O_2^- + H_2O \text{ (See Ref. 13)}$$

I^- formation is accomplished also by

$$HIO + H_2O_2 = H^+ + I^- + H_2O + O_2 \qquad (11)$$

I_2 formation is accomplished only by

$$H^+ + I^- + HIO = I_2 + H_2O \qquad (3b)$$

We may explain finally in terms of this mechanism why iodine is reduced to iodide by hydrogen peroxide, in dilute acid solution (below $4(10^{-3})$ *N*) although that same oxidizing agent will convert it to iodate at concentrations of hydrogen ion greater than this. The two last experiments in Table IV show an infinite induction period with respect to iodate formation because at this low (H^+) the iodide formed by the Reaction 11 cannot be effectively removed, and continues to accumulate until the "main" reaction occurring in the system is the catalytic decomposition of hydrogen peroxide by the I_2–I^- couple. When all the peroxide has been thus decomposed, the system consists of I_2, $\underline{H}^+$, $\underline{I}^-$ and HIO, with the substances underlined present at higher concentrations than obtain in an aqueous iodine solution.

As (H^+) is increased, the formation of $H_2I_2O_3$ in the second stage of the reaction mechanism is favored. When the $(H_2I_2O_3)$ has been thus sufficiently augmented to permit of the establishment of the (HIO_2) essential to iodate formation, the iodine will, by the action of hydrogen peroxide, be converted to iodate instead of to iodide ion.

The Specific Rate of Iodine Hydrolysis.—Although the preceding sections have yielded a plausible mechanism for the oxidation of iodine by hydrogen peroxide, they have not established definitely the specific rate of the hydrolysis of iodine, the rate-determining step in that mechanism. With regard to the value of that constant, two possibilities, now to be sketched, present themselves.

The first of these, and the simpler, would assign to this specific rate the limiting value 0.03 given by Curve II, Fig. 3; the higher values on Curve I must then be attributed to an unknown reaction which consumes iodine and, directly or indirectly, involves iodate ion. Adopting this conclusion, we bring the investigations of Abel and investigations previously carried out in this Laboratory into complete agreement with the present work. We leave unsettled, however, not only the nature of this reaction, but a more troublesome matter as well, namely, why this reaction did not affect the experiments on Curve II; for these experiments differ essentially from the others only in a higher (H_2O_2) 0.1 M compared with 0.0034 M on Curve I.

The other possibility would say that the limiting rate which should be reached at sufficiently high (IO_3^-) had not yet been attained, that iodine formation from Reaction 3b is important at the beginning of an experiment as well as at the end,[16] and that the specific rate of the iodine hydrolysis is, at 0°, much greater than 0.06. The lower results on Curve II would be attributed to iodide formation resulting from the relatively larger amount of catalysis there obtaining. As arguments against this interpretation

---

[16] The high values calculated for (I^-) and (HIO) in this reaction system (see footnote 14) support the conclusion that iodine formation from Reaction 3b is never negligible; but it must be remembered that the (I^-) and the (HIO) calculated were both upper limits.

we may mention its disagreement with conclusions of other investigators, the excellent agreement of many experiments in this paper with a first order rate law, and the definite character (which may be fortuitous) of the limiting value approached by Curve II. One argument for this interpretation is the simplicity of the resulting mechanism, for then iodine need be assumed to disappear only in the step

$$I_2 + H_2O \longrightarrow HIO + I^- + H^+ \qquad (3a)$$

and to be formed only in Reaction 3b. Experimental work, principally in other reaction systems, which should eliminate one of these possibilities has been undertaken in this Laboratory. Present indications point to a specific rate for Reaction 3a much greater than 0.6 at 25°, or 0.06 at 0°.

In the course of this investigation, and in the preparation of this paper as well, I have had the benefit of many conferences with Professor William C. Bray, and for these conferences I now wish to thank him.

Conclusion

From an extensive investigation of the oxidation of iodine by hydrogen peroxide, evidence has been adduced for each step in a mechanism involving $H_2I_2O_3$ as one of several intermediate products. While the complexities encountered have precluded the mathematical treatment essential to a definite establishment of this mechanism, the fact that it affords a qualitative explanation of these complexities justifies both its adoption and the further use of $H_2I_2O_3$ as an intermediate step. Since the rate constant for the reaction should approach the specific rate for the iodine hydrolysis as a limit if the latter is the only rate-determining step, its failure to do so at low concentrations of peroxide could not be reconciled with previously measured values of this specific rate.

THE USE OF BROMATE IN VOLUMETRIC ANALYSIS. V. INTERNAL INDICATORS SUITABLE FOR USE IN DIRECT TITRATIONS

BY G. FREDERICK SMITH AND H. H. BLISS[1]

RECEIVED MARCH 16, 1931 PUBLISHED JUNE 8, 1931

Introduction

The present paper is the continuation of a series of studies dealing with the extended application of the use of bromates in volumetric analysis.[2] Undesirable features previously associated with the use of bromate in volumetric analysis have been the following: first, that the reduction of bromic acid may take either of two courses, reduction to bromide as in the oxidation of trivalent arsenic or antimony or to free bromine as in the oxidation of ferrous iron or chromic salts, oxalic and nitrous acids; second, that many of the possible applications of bromate in volumetric analysis involve the use of an excess of bromate followed by back titration requiring the undesirable use of an additional standard solution; third, suitable indicators have not been found for bromate oxidation reactions except in the case of the determination of arsenic and antimony, in which case methyl orange and indigo-sulfonic acid are employed which require undesirably high concentrations of hydrochloric acid at temperatures near the boiling point.

The first of these undesirable features has been eliminated by the use of the mercuric ion,[2] which brings about the reduction of bromate to bromide rather than to free bromine as in the cases already cited. The present paper has for its object the elimination of the second and third difficulties by the selection of a number of organic dyes suitable for use as indicators in bromate reactions. Back titrations following the use of an excess of bromate can be shown in various cases to be unnecessary through the use of these new indicators. Cold titrations at lower acid concentrations are possible. By selection of the indicator having the most desirable color transformation the interference of foreign colored ions is eliminated. It is to be observed that the application of the electrometric determination of the end-point would in many cases solve the problems. Visual end-point phenomena are more difficult to devise but are more practical in application.

In subsequent papers of this series, specific applications of the new indicators to individual determinations will be disclosed.

Method Used in Selection of Dyes

In the familiar bromate titration of trivalent arsenic or antimony in hot concentrated hydrochloric acid solution using methyl orange as indicator, the end-point reaction consists in the liberation of bromine from the action of the first drop excess of bromate on the hot hydrochloric acid of the solution. Under these conditions the helianthin indicator is destroyed by halogenation and the end-point of the reaction is defined. It is, therefore, logical in the study of possible new dyes for similar bromate reactions to select from that group least "fast" in color when chlorinated. Such use was made of the "Colour Index."[3]

This method of attack was found to be satisfactory after it was learned that a "chlorine fastness" number of 5 indicated too great ease of halogenation and that the red and yellow colors seemed better adapted than colors of the remainder of the spectrum. Quite as certain selections were subsequently made from those dyes unclassified in chlorine fastness by the British Colour Index (wool and silk dyes), using other and more intuitive methods of selection. The list of dyes about to be described is only a small portion of those examined and is not supposed to be an exhaustive one. The selections made, however, are thought to cover a wide range of possible working conditions and to include desirable color changes. With a single exception the color change is from colored to colorless. This naturally follows from the nature of the reaction bringing about the end-point change. The dyes examined and found satisfactory are classified and identified in Table I.

In the data of Table I the first column is given for convenience in referring to the various dyes in the British Colour Index and in the second column the compact formula is given for convenience in referring to the compounds in Beilstein. In column three a common name is given which seems to be quite generally accepted. In most cases it seems best to refer to the indicators by their British Colour Index number. Column four indicates that the chemical classifications most abundantly represented are the mono-azo dyes and those of the triphenylmethane series. Column four indicates the variety of colors to be selected from the various classes of dyes and it is observed that the greatest variety in color is shown by the triphenylmethane class. Chief qualifying characteristics for the various indicators are given in column six. As indicated in column five all the indicators are sufficiently soluble in water and the color produced is not materially affected by the addition of hydrochloric acid. In some cases the depth of color is favorably affected by the addition of hydrochloric acid and in the other cases the color is unfavorably affected. In general those indicators are most desirable which produce the deepest color, since this is less masked by colored ions.

[3] "Colour Index," The Society of Dyers and Colourists, 1924.

TABLE I

NEW INTERNAL OXIDATION INDICATORS FOR USE IN VOLUMETRIC BROMATE REACTIONS

British Colour Index number	Compact formula	Common name	Chemical Classification	Color in water and HCl solution	Remarks
21	$C_{13}H_{15}N_4Cl$	Chrysoidine R	Mono-azo	Yellow-red	Color bleached with reducing agents. Restored at end-point, then destroyed
27	$C_{16}H_{10}N_2O_7S_2Na_2$	Rainbow Orange G	Mono-azo	Orange-yellow	Suitable at moderate P_H and temp.
56	$C_{18}H_{13}N_3O_9S_2Na_2$	Chromotrope 6 B	Mono-azo	Violet red	Bright red to colorless, moderate P_H, low temperature
88	$C_{20}H_{12}N_2O_7S_2Na_2$	Bordeaux	Mono-azo	Red	Suitable at moderate P_H and low temperature
128	$C_{24}H_{14}N_3O_7ClS_3Na_2$	Diamine pink	Mono-azo	Red	Unsuited to low P_H and temp.
184	$C_{20}H_{11}N_2O_{10}S_3Na_3$	Amaranth	Mono-azo	Red	Suitable at moderate P_H and low temperature
185	$C_{20}H_{11}N_2O_{10}S_3Na_3$	Brilliant Ponceau 5R	Mono-azo	Scarlet red	Advantageously resists fading
246	$C_{22}H_{14}N_6O_9S_2Na_2$	Naphthol Blue-black	Di-azo	Blue	Quite satisfactory under ordinary conditions
375	$C_{32}H_{21}N_5O_7S_2Na_2$	Congo Corinth	Di-azo	Red-blue	Satisfactory for moderate P_H and boiling temperature
471	$C_{34}H_{25}N_5O_8S_2Na_2$	Bensoasurin 3 R	Di-azo	Violet	Faint color but satisfactory end-pt.
657	$C_{23}H_{25}N_2Cl$	Malachite green	Triphenylmethane	Green-reddish yellow	Satisfactory at moderate P_H and boiling temperature
667	$C_{37}H_{34}N_2O_6S_2ClNa$	Fast Acid Green B	Triphenylmethane	Blue-green	Satisfactory only at lower P_H
678	$C_{22}H_{24}N_3Cl$	Fuchsine	Triphenylmethane	Red-yellow	Very satisfactory. For lower temperature only
683	$C_{31}H_{34}N_3Cl$	Methyl violet	Triphenylmethane	Violet-brown	Very satisfactory at low P_H and boiling temperature
698	$C_{41}H_{44}N_3O_6S_2Na$	Acid violet	Triphenylmethane	Violet-green	Satisfactory at low P_H and higher temperature
793	$C_{19}H_{16}N_4O_3$	Phosphine	Acridine	Orange (fluorescent)	Satisfactory at low temp. and high P_H

A selection of indicators shown in Table I consists in a preference for the three numbers 185, **246** and **678.** Indicator number **678** serves admirably for the oxidation of trivalent to pentavalent arsenic and antimony. For this determination it is much more satisfactory than the commonly employed methyl orange since titrations may be made at room temperature and at lower acidities as was done electrometrically by Zintl and Wattenberg.[4]

Further data of a comparative nature relating the speed of the reaction of the oxidation of the indicators under varying conditions of hydrogen-ion concentrations are given in Table II.

TABLE II
CONDITIONS PRODUCING END-POINT INDICATOR OXIDATIONS AT VARIOUS ACID CONCENTRATIONS

0.2 cc. of 0.2% solution in water per 100 cc. of solution of chosen P_H = indicator concentration. Oxidizing agent, 0.05 cc. of $N/10$ solution of $KBrO_3$ or $HgOHBrO_3$. Temperatures in degrees centigrade ±5°. One star, slow reaction; two stars, moderately fast reaction; three stars, fast reaction

Indicator number	Equivalent normality of acid					
	0.1-0.15	0.25-0.3	0.5-0.6	0.9-1.0	1.5	3.0
21	..	80°*	..	60°**	45°**	45°**
27	..	90°**	...	55°**	65°***	...
56	..	**90°***	...	65°**	25°*	...
88	..	80°**	...	55°***	25°**	...
128	..	85°**	85°**	85°**	...	...
184	..	75°*	...	50°***	25°**	5°**
185	..	80°**	...	60°***	25°**	...
246	..	75°**	...	45°**	25°**	...
375	..	**100°****	40°**	....	...	...
471	100°*	80°**	55°**	....	...	...
657	..	90°***	85°**	55°**	...	25°**
667	..	75°**	...	60°**	45°**	...
678	..	....	...	25°**	...	25°**
683	..	75°***	...	25°**	...	...
698	..	80°**	...	60°**	60°**	...
793	**95°***	80°**	55°**	50°**	...	...

Interesting comparisons result upon examination of the data of Table II. All the indicators are rapidly destroyed in one normal acid by a concentration of 5 X 10^{-5} of bromate ion at a temperature ranging from 25–85'. Helianthin requires the same concentration of bromate ion at an acid concentration of three normal and a temperature not less than 60°.

It is not necessary to build up the required concentration of hydrogen ion using only hydrochloric acid. For example, it may be provided using sulfuric acid and enough hydrochloric acid added to increase the acid normality 0.1–0.2 unit just before the titration is begun or at a point slightly before the titration is complete, other conditions being equal. The same principle is applied in the following section of this paper and the results are similar to those reported in Table III.

---

[4] **Zintl and Wattenberg, Ber., 56, 472 (1922).**

Indicator Oxidation Conditions Using Sulfuric and Hydrobromic Acid Solutions.—It would be a distinct advantage in many cases to be able to adjust conditions for the indicator oxidation in the absence of hydrochloric acid. The use of hydrobromic acid would be undesirable if it were substituted for hydrochloric acid without limiting the necessary concentration to a small amount for two reasons. One, because of the increased cost, and the other as a result of the low solubility of mercuric bromide. The reduction of bromate to bromide as influenced by the presence of mercuric mercury is more satisfactory in the absence of hydrochloric acid, as proved in previous papers of this series,[2] since mercuric bromide is less dissociated in solution than mercuric chloride.

A study was therefore made of the oxidation of the various indicators as influenced by moderate concentrations of sulfuric acid and small additions of hydrobromic acid. The results are recorded in Table III.

TABLE III

CONDITIONS PRODUCING END-POINT INDICATOR OXIDATIONS AT VARIOUS CONCENTRATIONS OF SULFURIC AND HYDROBROMIC ACIDS

0.2 cc. of 0.2% solution of indicator per 100 cc. of solution at normality of acid given. Oxidizing agent, 0.05 cc. of $N/10$ solution of $HgOHBrO_3$. Temperature in degrees centigrade ±5°. One star, slow reaction; two stars, moderately fast reaction; three stars, fast reaction

	1.5	50°***	....	.	30°**	
	2 0	....	....	40°***	25°**	

All the indicators described were employed under the various conditions given using the oxidation of trivalent arsenic (and in some cases trivalent antimony) and quantitative results obtained within a maximum error of 0.2 mg. in the titration of 100 milligrams of the element determined. More complete quantitative data using the indicators studied will appear in subsequent papers of this series.

Summary

1. Description has been given of the selection of a group of sixteen organic dyes suitable for use as internal indicators for volumetric bromate reactions.

2. The dyes described have been tabulated by chemical classes and the mono-azo dyes and those of the triphenylmethane series shown to be most abundantly represented.

3. A study has been made of the limitations of temperature and acidity for which the various indicators are suitable.

4. Colors ranging from red through yellow, green, blue and violet are included. Interfering colored ions may therefore be counteracted by the selection of the proper indicator color from the group described.

5. All the indicators described are suitable for use in the quantitative estimation of trivalent arsenic with an accuracy ordinarily required from the usual volumetric determinations.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. XII. DIPOLE MOMENT DATA FOR (A) NAPHTHALENE AND CERTAIN OF ITS DERIVATIVES. (B) ALPHA AND BETA BENZENE HEXACHLORIDES

BY JOHN WARREN WILLIAMS AND JOHN M. FOGELBERG

RECEIVED MARCH 19, 1931 PUBLISHED JUNE 8, 1931

In the last years it has been amply demonstrated that the symmetrical hydrocarbons have zero dipole moments. Such a molecule will become electrically dissymmetrical and possess a finite dipole moment if one of its hydrogen atoms is replaced by another atom or group of atoms; furthermore the moment will vary with the nature of the substituent. When two of its hydrogen atoms are replaced by these substituents, it will not generally be possible to compute the electric moment of the resulting molecules from the assumption that it is the vector sum of individual moments characteristic of the substituent groups because (a) it is necessary to take into account the stereochemistry of the atoms forming the substituent group and (b) it is necessary to take into account mutual attractions or repulsions between the groups unless they be sufficiently removed from one another in the molecule. These factors, first suggested by one of us[1] as possibilities in order to explain the fact that hydroquinone diethyl ether possesses a finite dipole moment, have now been quite completely described.[2,3] These studies, and now many others, have assisted materially in assigning configurations to benzene, methane and ethane, cyclohexane and certain of their derivatives.

In a few individual cases difficulties with the measurement and interpretation of the electric moment data have been encountered. Thus, iodine, symmetrical trinitrobenzene, and naphthalene have appeared to

possess finite dipole moments although one would expect them to be non-polar from structural considerations. In a review of earlier work from this Laboratory,[4] these molecules were classified as being molecules for which the existence of a finite moment seemed questionable. There has been a considerable amount of work done since in order to clear up this apparent difficulty. In the case of trinitrobenzene Parts[6] has made a careful study of the polarization at several temperatures and has verified the value previously reported for its electric moment, ($\mu = 0.8 \times 10^{-18}$ e. s. u.) assuming that the atom polarization is zero. In order for the moment to be zero the atom polarization would have to be 14 cc., a value which is probably much too high. It appears therefore that the molecule actually is polar. Interpreted, this would mean that the vectors characteristic of the three NO_2 groups do not act in the plane of the benzene ring.

The difficulty in the case of iodine was assumed to be the result of chemical changes due to the solvent. This has definitely been established by Müller and Sack,[6] who found that when either hexane or cyclohexane was used as solvent the moment was zero. They were also able to find finite values of like magnitude as those reported by us when the iodine was dissolved in benzene.

The data of this article show conclusively that naphthalene has no moment. The value reported by Williams and Ogg,[7] $\mu = 0.7 \times 10^{-18}$ e. s. u., is too high because at the time the measurements were made it was impossible to measure with sufficient accuracy the dielectric constant changes produced in extremely dilute solutions. For this reason in the earlier papers the molar polarization of the solute molecule was determined by taking a tangent to the $P_{1,2}$ curve (molar polarization of the solution) at the point where the mole fraction of the reference liquid is unity, and prolonging it until it cut the axis where the mole fraction of the solute is unity. This is also the explanation for the fact that in so many cases the molar polarization of the solute appeared to be exactly constant. More recently the measurement of the dielectric constant in these extremely dilute solutions has been improved to such an extent that it has been possible to obtain the molar polarizations of the solute molecules for each concentration by means of the equation

$$P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{f_1M_1 + f_2M_2}{d} = f_1P_1 + f_2P_2$$

where the symbols have their usual significance. The P_2 values, obtained in this manner, are extrapolated back to zero concentration in order to measure the molar polarization of a free polar molecule not in interaction

with any other polar molecules of the same kind. The use of a non-polar solvent precludes the possibility of the polar molecule being in interaction with other polar molecules of unlike kind.

The data of Section **A** give definite information with regard to, first, the importance of the so-called atom polarization, and, second, the structure of naphthalene and certain of its simple derivatives. The data of Section B are of interest in connection with the stereochemistry of derivatives of cyclohexane.

Experimental

The electric moments of naphthalene, 2,6-dichloronaphthalene, ***a***-benzene hexachloride and @-benzknehexachloride have been determined by the method of the binary mixture, using benzene as solvent. All dielectric constant and density determinations were made in a thermostat carefully regulated to **25** ± 0.05°. All chemicals were subjected to rigorous purifications—in short it may be claimed that every known precaution for precision measurements was taken. **A** frequency of 10^6 cycles was used for the dielectric constant measurements. The dielectric constant differences, obtained using the heterodyne beat method consisting of standard oscillator, variable oscillator and detector-amplifier circuits previously described,[8] are believed to be accurate to ±0.0002.

The dielectric constant and density data are presented in Table I. The symbols of the previous articles have been retained throughout, f_1 is the mole fraction of the solvent, in this case benzene; d_4^{25} is the density of the solution; ϵ is its dielectric constant; $P_{1,2}\left(=\frac{\epsilon - 1}{\epsilon + 2}\cdot\frac{f_1M_1 + f_2M_2}{\mathbf{d}}\right)$ is the molar polarization of the solution; and P_2 is the molar polarization of the solute molecule.

In Table II are presented the electric moments of the solute molecules, calculated from the P_2 values in infinitely dilute solution. The latter were obtained by direct extrapolation of the P_2 values calculated for the dilute solutions. The quantity P_2'' is that part of the total polarization of the solute molecule contributed by the deformation of the molecule and is given by the quantity $\frac{n_D^2 - 1}{n_D^2 + 2} \cdot \frac{M}{d}$, where n_D is the refractive index for the "D" line at 25°, and P_2' is that part of the total polarization of the solute molecule contributed by its actual orientation in the field and is given by the quantity $\frac{4s}{3} N \frac{\mu^2}{3kT}$ where μ is the electric moment of the molecule in question.

TABLE II

ELECTRIC MOMENTS OF SOLUTE MOLECULES

Molecule	P_2	P_2''	Po'	$\mu \times 10^{18}$
$C_{10}H_8$	43.3	43.3	0	0
2,6-$C_{10}H_6Cl_2$	54.3	54.2	0.1	0
α-$C_6H_6Cl_6$	156	57.5	98.5	2.15
β-$C_6H_6Cl_6$	66.9	57.5	9.4	0.70

Discussion, Section A

The molar polarization is made up of two parts, a polarization due to deformation or distortion, and a polarization due to orientation. In order to determine the electric moment of a molecule from dielectric constant and density data at a single temperature, it is necessary to be able to evaluate the polarization by deformation. The latter may be defined as the limiting value that the optical polarization (obtained by means of the Lorentz–Lorenz formula) attains on passing to the limit for zero frequency when the orientation effect which would set in for smaller frequencies is disregarded. But this extrapolation cannot be carried out accurately with the dispersion measurements now at our disposal, so that the extrapolation to zero frequency cannot be used when *absolute* accuracy is necessary. From a practical standpoint, however, this aspect is entirely changed, for if we take non-polar molecules and compare the value of the dielectric constant with the square of the refractive index for the "D" line, the differences are found to be small. The method of the Lorentz–Lorenz formula will therefore be very satisfactory for the determination of the distortion contribution to the polarization except in the case when it is necessary to decide whether a molecule is but slightly polar or not polar at all. In the latter case there is considerable difference of opinion concerning the magnitude of the inaccuracy introduced. Thus Smyth[9] considers the difficulty to be a serious one, while the authors are of the opinion that even here the difficulty can have but little practical importance, especially now that it is possible to make very accurate determinations of the dielectric constant differences between that of the pure solvent and the extremely dilute solutions. An inspection of the data for the naphthalene and 2,6-dichloronaphthalene molecules shows that the difference between the total polarization of each, determined from dielectric constant studies, and the polarization due to deformation of each, calculated from the Lorentz–Lorenz formula using the refractive index for the "D" line, is so small as to be absolutely negligible, leaving no doubt that the polarity of each is zero.

It may be mentioned here that Morgan and Lowry,[10] in trying to account for the moment, $\mu = 0.7 \times 10^{-18}$ e. s. u., previously reported for the naphthalene molecule, have assumed the difficulty to be a result of the fact that this deformation part could not be calculated in the way described above. That this cannot be true is evident from the original data[7] which are reproduced in Table III. The only change that has been made is in the determination of P_2, which this time is simply calculated for each concentration of naphthalene in solution without any attempt being made to determine the limiting value.

TABLE III

DIELECTRIC CONSTANT AND DENSITY DATA FOR NAPHTHALENE SOLUTIONS IN CARBON BISULFIDE

f_1	d_{25}^{25}	ϵ	$P_{1,2}$	P_2
1.000	1.2591	2.633	21.27	...
0.999	1.258	2.641	21.37	120
.994	1.255	2.646	21.55	66
.983	1.246	2.654	21.93	46
.973	1.240	2.663	22.25	45
.965	1.235	2.673	22.59	45
.935	1.225	2.680	23.30	42

If the last four values of P_2 had been used to determine the limiting value instead of having to make use of a value weighed by the first two values

as well in the extrapolation there would have been little, if any, doubt that naphthalene was non-polar. The result of early experimental difficulties was quite often a molar polarization, and therefore an electric moment, which was somewhat high. The calculation of a moment for the anthracene molecule was not attempted[7] because it was realized that the solutions were too dilute for determinations of the dielectric constant differences with sufficient accuracy for the purpose.

Smyth, Morgan and Boyce[11] in presenting their result for the electric moment of monochlorobenzene ($\mu = 1.56 \times 10^{-18}$) make the statement "The value for the moment of monochlorobenzene agrees well with the figure 1.58×10^{-18} recently published by Höjendahl[12] and by Williams and Krchma[13] who, being unable to take into account the small quantity P_A, obtained a slightly high value." The value reported from this Laboratory was $\mu = 1.55 \times 10^{-18}$. The quantity P_A referred to is the atom polarization, which is ordinarily defined as the difference between the total induced polarization and that due simply to electronic shifts, that is, it is a quantity which measures the polarization due to the shifting of position of atoms and groups of atoms. Values of P_A have been determined by Errera[14] by making the assumption that when the molecules are held in the solid state they are unable to orient themselves in an applied field and therefore cannot contribute to the dielectric constant of a solid. The difference between the total polarization in the solid state and the electron polarization calculated from optical data should therefore be atom polarization. The assumption that molecules in solid substances are unable to orient themselves in an alternating field is hardly a safe one, for as Errera[15] himself has shown the dielectric constant of ice varies with the applied frequency. Furthermore, unpublished work from this Laboratory shows definitely that the dielectric constant of solid nitrobenzene changes with frequency. In all probability the orientation of molecules in the solid state will prove to be quite a general phenomenon and an excellent way in which to study it will be by means of dielectric constant determinations. This rotation of molecules in the solid state has recently been discussed from a theoretical point of view by Pauling.[16] For the problem at hand it is evident that care will have to be exercised in assigning a magnitude to P_A. It may also be claimed that other methods of determining it are not without difficulty. In this series of articles the molar refraction for the "D" line has been subtracted from the total polarization, and the electric moment has been calculated from the difference. This procedure certainly

reduces any error caused by the failure to subtract the atom polarization to a quantity of little or no practical significance. The data for the electric moment of monochlorobenzene introduced at the beginning of this chapter and the data of Table II for naphthalene and 2,6-dichloronaphthalene demonstrate the truth of this statement.

The data of this section are also of interest in connection with the structure to be assigned to naphthalene and its derivatives. There is certain chemical evidence that the 2,6 and 2,7 positions are closer than the ordinary plane formula appears to indicate, and that the 1,8 positions have a relationship approaching that of an ortho compound.[17,18] This is interpreted to mean either that the two rings are completely folded over each other, or make a very small angle with each other. The data of Höjendahl[2] for α-nitronaphthalene, $\mu = 3.6 \times 10^{-18}$ e. s. u., 1,5-dinitronaphthalene, $\mu = 0.6 \times 10^{-18}$ e. s. u. and 1,8-dinitronaphthalene, $\mu = 7.1 \times 10^{-18}$ e. s. u., and the data of this article indicate that in these simpler compounds the two rings must be extended. The most important fact leading to this conclusion is the absence of a finite moment in the case of 2,6-dichloronitronaphthalene. If the rings were folded, either completely or in such a way as to make a small angle with each other, a finite moment would have to exist. If they were folded completely, that is, superimposed on one another, the moment should correspond almost identically with that of *o*-dichlorobenzene, for which $\mu = 2.3 \times 10^{-18}$ e. s. u.

The data of Höjendahl alone are probably insufficient to distinguish between a completely folded and a completely extended model if we assume with Höjendahl that the moment reported for 1,5-dinitronaphthalene should be zero, rather than the small finite value reported, $\mu = 0.6 \times 10^{-18}$ e. s. u. The latter value has resulted from experimental inaccuracy in the earlier work of the type referred to in the case of naphthalene itself. It is evident that if the rings were completely folded, the moment of the molecule would correspond to that of *p*-dinitrobenzene, which is known to be zero. The moment for 1,8-dinitronaphthalene is approximately, though not quite, twice that of a-nitronaphthalene. Considered vectorially, each nitro group is acting to produce its characteristic electrical dissymmetry in the same direction, instead of in opposite directions as in the case of 1,5-dinitronaphthalene. This result might have been expected either on the basis of a folded or extended structure. The situation may be compared with that of benzene itself in which it has been pointed out[4] that data for like para disubstituted benzenes are insufficient to determine whether or not the six carbon atoms lie in a plane, but when data for the corresponding symmetrically trisubstituted benzenes are considered the plane formula is definitely indicated.

Discussion, Section B[19]

In one of the previous papers of this series[z0] electric moment data for cyclohexane and some of its simple derivatives were presented and discussed. It was stated that the extension of these studies to more complicated derivatives will be difficult and somewhat involved because of the possibilities of isomerism in these compounds. There should, for example, be four benzene hexachlorides. In addition to the more common *a*- and β-forms having melting points 157 and 310°, respectively, two other forms[z1] having melting points 112 and 129° have been prepared.

From theoretical considerations there should be four principal isomers, one in which all six chlorine atoms lie above the plane of the carbon atoms, one with five above and one below, one with four above and two below, and finally a symmetrical form with three above and three below.

X-ray data[a2] have shown that the β-isomer is the symmetrical form having the chlorine atoms evenly distributed above and below the plane of the carbon atoms. No definite conclusions have been drawn concerning the structure of the other three isomers, although attempts have been made by studying the trichlorobenzenes obtained when the various benzene hexachlorides are treated with alcoholic potassium hydroxide.[21]

In this work the α- and 8-isomers were prepared according to the method of Mathews[23] and their electric moments measured in benzene solutions. Their melting points agreed excellently with the values previously reported. Owing to the limited solubility of the 8-compound in benzene, a maximum concentration of only **0.3** mole per cent. could be obtained, so that the moment, 0.7×10^{-18} e. s. u., may be appreciably in error. However, the

---

[19] Since the completion of this manuscript the authors have noted that Hassel and Naeshagen [*Tids. Kemi Bergvesen, 10,* **126–127** (1930)] have made similar measurements for these compounds. The agreement is excellent in the case of the a-derivative but not in the case of the @-derivative. For the α-compound there is reported $\mu = 2.20 \times 10^{-18}$ e. s. u., but for the @-compound the value $\mu = 0$ is insisted upon. There are given reasons why the moment should be zero, then the statement is made, "the measurement has been carried out and it was found that this is certainly the case." An inspection of the data is not convincing. The melting point of the compound used is given as 297° but the commonly accepted value for the pure substance is **310°.** The dielectric constant data are given not by recording the actual figures but by saying that the difference between the value for pure benzene and the value for a solution containing **1.2** g. per **100** cc. of benzene is less than **0.05.** The data have been collected in such a way that one would have to assume the dielectric constant value of the solution to be the larger. (The $\Delta\epsilon$ value intended should undoubtedly be **0.005.)** But in order for the electric moment of this molecule to be zero, the dielectric constant of the solutions must always be *less* than that of the pure benzene. Our As would be less than **0.005** for a solution of this same concentration, yet it corresponds to a moment, $\mu = 0.7 \times 10^{-18}$ e. s. u.

measurements were of sufficient accuracy to show that the moment is not zero as might have been expected on the basis of the x-ray structure reported for the solid material. It does not necessarily follow, of course, that because a substance is symmetrical as a solid it should also be symmetrical in the dissolved state. Thus this case is quite analogous to that of the symmetrical trinitrobenzene referred to in the introduction. The measurements were repeated in dioxane, in which the hexachloride was more soluble, and a value of 2.0×10^{-18} was obtained. This was evidently due to an influence of the solvent on the somewhat non-rigid structure of the benzene hexachloride.

If there be assumed for the a-compound a configuration having all six of the chlorine atoms on the same side of the plane of the carbon atoms (this seems justified by the work of van der Linden), it is possible to calculate the angle that the vector characterizing the carbon to chlorine linkage makes with the plane of the carbon atoms. Taking the value of each carbon to chlorine linkage as 2.3×10^{-18} e. s. u., its value in chlorocyclohexane, an angle of 9° is obtained. This is considerably smaller than the 55° angle which would be predicted on the basis of tetrahedral carbon atoms with no mutual repulsion between the chlorine atoms. The small angle, 9°, is interpreted to mean that there is powerful mutual interaction between the chlorine atoms, a fact which might have been predicted because of the number and size of the latter. Also, it further emphasizes the fact pointed out in other papers from this Laboratory that the electric moment of a molecule cannot be properly calculated without taking into account mutual attractions and repulsions between substituted atoms and groups.

Summary

The method of the binary liquid mixture has been used to determine the electric moments of the naphthalene, 2,6-dichloronaphthalene, a-benzene hexachloride and β-benzene hexachloride molecules. In the discussion it has been shown that in order to account for the experimental data there must be considered both the spatial configurations of these molecules and the mutual interactions between their polar substituents.

In the case of the substituted naphthalenes the data indicated an extended arrangement of the benzene rings rather than a partially or completely folded one. The data for the benzene hexachlorides did not show what might have been predicted, namely, that the form in which the six chlorine atoms were located on one side of the plane of the six carbon atoms of cyclohexane would be very strongly polar, while the form in which three chlorine atoms were located on either side of the plane would be completely non-polar. The explanation is undoubtedly to be found in mutual interactions between the substituents, the chlorine and hydrogen atoms.

THE ELECTROMETRIC TITRATION OF URANIUM WITH CERIC SULFATE

BY DWIGHT T. EWING AND MRS. MABEL WILSON

RECEIVED MARCH 23, 1931 PUBLISHED JUNE 8, 1931

In a previous publication[1] it was shown that the electrometric titration curves for uranium and potassium permanganate, and potassium dichromate, had two inflection points. The first denoted the complete oxidation of trivalent uranium to the tetravalent form and the second point, the complete oxidation of the tetravalent form. Gustavson and Knudson[2] and Miiller and Flath[3] titrated uranium electrometrically, but did not note the first inflection point. In commenting on this point of difference it was correctly pointed out by Kolthoff and Furman[4] that the presence of carbon dioxide and the correct acidity must be obtained in order to form and titrate trivalent uranium. In our previous investigation we used a special titration cell designed to eliminate oxygen and the titration was only successful when made in an atmosphere of carbon dioxide or nitrogen.

Preparation of Solutions.—The ceric sulfate solution was prepared by the method that was used by Willard and Young.[5]

The ceric sulfate solution was standardized against 0.05 N sodium oxalate solution made from a Bureau of Standards product in a carefully calibrated flask, at 25.0°. This ceric sulfate solution was found to be 0.05326 *N*.

The uranium solution was prepared by dissolving 28.283 g. of uranyl acetate in a little distilled water containing 9.8 g. of sulfuric acid and carefully diluting to 2 liters.

The uranium solution was standardized by evaporating two 2-ml. portions of stock solution to dryness and then igniting to the oxide. From these data the normality of the uranium solution was found to be 0.07113.

An approximately 0.1 N solution of ferrous ammonium sulfate solution was prepared with an excess of free sulfuric acid. It was standardized against the ceric sulfate solution and was found to be 0.1041 N.

Apparatus.—The *e.* m. f. of the titration cell was determined with a potentiometer which read to one-half of a millivolt.

The titration vessel consisted of a 400-cc. beaker with a large cork stopper with six holes for the following pieces: a buret, a zinc reductor, a mechanical stirrer, an inlet for an inert gas and two electrodes. The standard

electrode was a tenth-normal calomel half cell, and a small bright platinum wire was used for the other electrode.

Experimental Procedure

1.06 ml. of concentrated sulfuric acid was added to 30 ml. of the uranium solution and evaporated almost to dryness. This was diluted to 50 ml., heated nearly to boiling and forced through a 50-cm. zinc reductor with nitrogen or carbon dioxide. The zinc reductor was washed with 2% sulfuric acid until the total volume of solution in the titrating vessel was 100 ml. This solution while warm was titrated with the standard cerium sulfate reagent. During this procedure nitrogen or carbon dioxide was run through continuously.

The first end-point was approached rather slowly and usually required about **3** ml. of the cerium solution. After each addition it was necessary to wait for a few moments for an equilibrium reading. After the first end-point was established, the cerium solution could be added quite rapidly until near the second end-point. The behavior of the reaction as the second end-point is approached is quite similar to that of any other cerium electrometric titration where equilibrium conditions must be carefully noted.

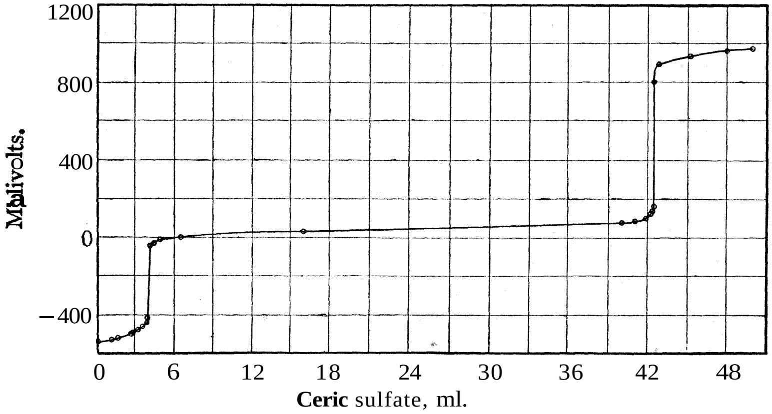

Fig. 1.

The volume of ceric sulfate represented by the difference between the two end-points was carefully computed, corrected for calibration errors, etc., and from this value the concentration of the uranium solution was found.

Graph 1 (Fig. 1) is typical of the results of many titrations which were made. In Table I are given the results of seven consecutive titrations.

Discussion of the Results

The stock solution of uranium used in this investigation was prepared from the acetate. Irregular results were obtained in the first titrations.

TABLE I

Total volume of solution titrated, 100 ml.; contained 2% sulfuric acid

Titration number	Uranium solution, ml.	Ceric sulfate, ml. By expt.	Ceric sulfate, ml. Calcd.	a/b
1	29.95	39.88	39.86	1.336
2	29.85	39.83	39.86	1.334
3	29.85	39.98	39.86	1.339
4	29.85	39.84	39.86	1.335
5	29.85	39.64	39.86	(1.327)
6	29.85	39.93	39 86	1.338
7	29.85	39.86	39 86	1.336
Mean		39.87		1.336

[a] Ml. of ceric sulfate solution. [b] Ml. of uranium solution.

In Experiment 5 trouble was encountered with the mechanical stirrer.

The second end-point was uncertain and the results low. This difficulty was not overcome until the acetate was removed. This was accomplished by evaporating the solution with sulfuric acid until the acetate had disappeared. The concentrated solution was diluted with water just previous to reduction.

The color of the freshly reduced acid uranium solution was a dark olive green and it was slightly opaque. Upon addition of ceric sulfate solution it gradually cleared and became of a very light green color at the first end-point. As oxidation proceeded the color became less intense and gradually changed to a greenish-yellow at the second end-point.

Due care must be taken in this titration to make certain that the e. m. f. measurements represent an equilibrium condition. Furman[6] in titrating ferrous sulfate allowed one to four minutes after each addition before making the e. m. f. measurements. In titrating uranium with cerium even more time was required for the e. m. f. reading, especially at the first end-point.

The initial e. m. f. of the reduced solution was usually -500 to -450 mv. This changed gradually about 100 mv. to the first end-point when an abrupt change of approximately 400 mv. was noted. A small fraction of a drop of ceric sulfate solution is sufficient to cause this abrupt change. The second end-point was also very definite and usually the addition of a small fraction of a drop of the ceric sulfate solution was sufficient to cause the e. m. f. to increase 500 or 600 mv.

Higher concentrations of sulfuric acid, 6, 15 and 30% by volume, were later titrated. The amount of uranium solution, the total volume and conditions of titration remained the same. In all cases both end-points were definite, and the amount of ceric sulfate used between end-points was the theoretical. Formerly reported titrations[1] stated that high acid concentrations caused the voltage to rise rapidly and the second end-point

---

[6] N. H. Furman, THIS JOURNAL, 50, 755 (1928).

consequently disappeared. In all cases of the higher acid concentrations just mentioned, the shape of the curves remained the same, and all three corresponded closely to the curves obtained from the 2% titration data. The only noticeable effect was the time required for equilibrium to be established at the end-points. As the percentage of acid was increased, a longer time was required for equilibrium. This was particularly noticeable at the second end-point, which was fairly rapid in the 2% solution. In this respect the work of Gustavson and Knudson[2] has been confirmed.

Titration in Hydrochloric Acid Solution.—Hydrochloric acid may also be used in the titration of uranium with cerium sulfate. Titrations were made using 2, 4, and 6 *M* hydrochloric acid and a combination of 2 M for the first end-point, with an increase to 4 *M* immediately after reaching the first end-point.

In each case 30 ml. of the uranium solution was heated to boiling with half the acid, and put through the reductor. This was washed with the remainder of the acid in solution, making a total volume of 100 ml. for titrating. In each case more reduction to trivalent uranium was noted than in the case of the sulfuric acid titrations. The color of the reduced solution was a very dark red-brown and was opaque. Upon the addition of ceric sulfate, the color rapidly changed to the same olive-green noted in the case of sulfuric acid. Colors at the end-points were identical.

In no case was the titration with hydrochloric acid as satisfactory as with 2% sulfuric acid. The great difference in effect of these two acids on the titrations was that upon the change of voltage' at the end-points and the time required for equilibrium to be established.

Graph Number 2 gives a comparison between the deflections in voltage at the two end-points in the 2% sulfuric acid and in the 4 M hydrochloric acid titrations. It is noted that the rise in the e. m. f. at the first end-point in the hydrochloric acid solution is approximately 100 mv. and in the sulfuric acid solution the rise is 400 mv. At the second end-point the rise in the hydrochloric acid solution is 450 mv., which compares with a rise of about 675 mv. in the sulfuric acid solution.

In all cases where hydrochloric acid was used, the first end-point was too slow to be of practical use. In the 2 M solution, the first end-points covered about 400 mv., in the 4 *M*, 100–200 mv., and in 6 *M*, 50–75 mv. With higher acid concentrations, the time required for equilibrium was greater. This was also true of the sulfuric acid solutions, although it did not seem to affect the voltage greatly in case of the sulfuric acid solutions. In exact contrast to the first end-point, the stronger the hydrochloric acid, the sharper and quicker the second end-point. This is also in exact contrast to the second end-point when sulfuric acid was used. In 2 M hydrochloric acid, the equilibrium was very slow, and the change in voltage was approximately 300–400 mv.; in 4 M it was 400–500 mv. and more rapid;

in 6 *M*, which compared with 2% sulfuric acid, the change was 600 mv. and more rapid.

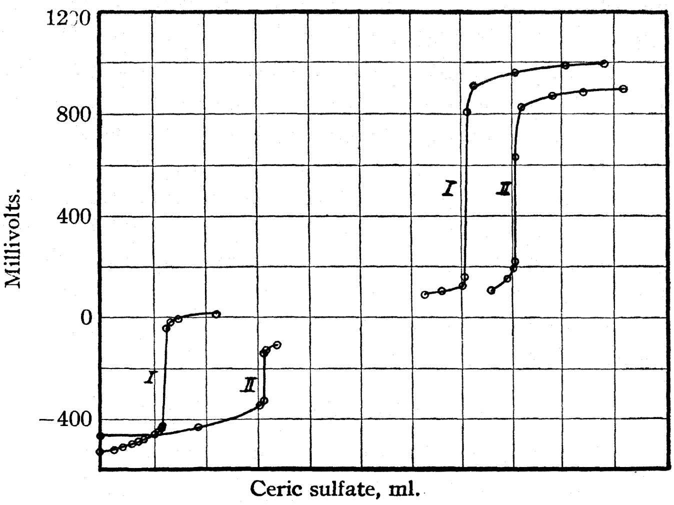

Fig. 2.—I, H_2SO_4, 2%; II, HCl, 4 *M*.

It was found that for hydrochloric acid solutions a concentration of about 2 *M* in hydrochloric acid gave the most definite e. m. f. change for the first end-point. For the second end-point the optimum concentration of hydrochloric acid seemed to be about 4 M.

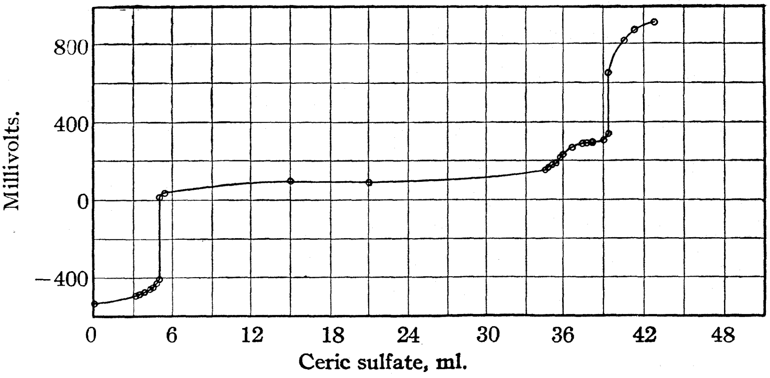

Fig. 3.

A few titrations were made with a combination of the uranium with ferrous ammonium sulfate. Thirty ml. of the uranium solution was prepared and reduced as in the 2% sulfuric acid titrations. Before washing the reductor, 5 ml. of the iron solution was added. The titration was performed in 100 ml. volume, 2% sulfuric acid.

Three end-points were obtained: one when trivalent uranium was oxidized to tetravalent, another when tetravalent was oxidized to hexavalent, and a third when the ferrous iron was oxidized to ferric iron. Because of the closely corresponding voltage of the second and third oxidations, it is advisable to plot also, Δmv./Δml., the change in millivolts per change in ml. This gave three definite end-points. The amount between the first and second corresponded closely to the theoretical amount of ceric sulfate necessary to oxidize the uranium present; and the amount between the second and third, very nearly to the amount required to oxidize the ferrous iron present. Graph Number **3** shows this titration.

Nitrogen was used to exclude the air from the cell during the titration. This is essential for titrating the small amount of trivalent uranium present in the reduced solution, due to the rapid oxidation of trivalent uranium in air, as shown by McCoy and Bunzel.[7]

Summary

1. When a hot acid solution of uranium sulfate is reduced in a Jones reductor and is titrated in an atmosphere of nitrogen with ceric sulfate as an oxidizing agent, two end-points are obtained. The amount of uranium oxidized between the two end-points corresponds exactly to the amount of uranium present. **A** 2% sulfuric acid of uranium sulfate gave satisfactory results.

2. Uranium acetate in hydrochloric acid solution, when treated in the same way, also gives two end-points, the difference between which is the amount of uranium present. A concentration of 2 M for the first and 4 M for the second gave the best results.

3. Sharper end-points were obtained for the titrations in sulfuric acid, and less time was required for the e. m. f. to come to equilibrium, than in hydrochloric acid. More consistent results were also obtained with 2% sulfuric acid.

4. Ferrous ammonium sulfate was added to the reduced 2% uranium solution and three end-points were obtained: (1) when trivalent uranium was oxidized to tetravalent, (2) when tetravalent was oxidized to hexavalent and (3) when ferrous was oxidized to ferric iron.

OXYCYANOGEN. I

BY HERSCHEL HUNT

RECEIVED MARCH 25, 1931 PUBLISHED JUNE 8, 1931

The field of inorganic free radicals contains, as is pointed out by Walden and Audrieth,[1] one piece of work, namely that of Lidov,[2] which must be substantiated or disproved before the properties of the radical CNO can be definitely established. Since no mention of Lidov's work is made by Birckenbach and Kellermann,[3] I thought it advisable to check this work before proceeding farther into the field.

Lidov did not hint that the substance with which he was dealing was a free radical. All evidence offered by him for the existence of a substance composed of carbon, nitrogen and oxygen hinges on density determinations of a gas. No chemical composition is proved by analysis. The electronic structure of OCN shows it to have an odd electron and hence we would expect it to be very active chemically unless polymerized. That such is not true of Lidov's substance is apparent since he prepared it in aqueous or alcoholic solutions without hydrolysis. He described his product as being a homolog of carbon dioxide, and names it oxan or monocyan.

Oxan is described as being a gas which polymerizes on standing, yet Lidov never obtained a greater density than 1.974 g./l. It is not decomposed by phosphoric acid or by temperatures up to 375°. It is precipitated by silver or barium ion and absorbed by an alkali. By long boiling with sodium hydroxide and zinc dust its salts will give ammonia. The nitrogen of beta-oxan is easily determined by burning it with magnesium powder.

The greatest care was taken to repeat most of Lidov's work, even in the most illogical cases, in order that I might definitely say that his work was correct or incorrect. The detailed results are as follows.

Paper Number 1.—A. In neutral solution, aqueous or alcoholic

$$2KCNO + H_2O_2 = K_2CNO_2 + H_2O + CNO \text{ (gas)}$$

The oxanate, K_2CNO_2, may be decomposed with phosphoric acid to give CNO also. The author found the following

$$KCNO + xH_2O_2 = KCNO + xH_2O + \frac{x}{2}O_2$$

The effluent gas supports combustion and is absorbed completely by alkaline pyrogallol. No precipitate was obtained by passing the gas into

---

[3] Birckenbach and Kellermann, *Ber.*, 58, 786 (1925).

barium hydroxide solution. The remaining salt was then decomposed by phosphoric acid as described and the gas evolved passed into barium hydroxide. The precipitate was washed and then digested with potassium hydroxide and aluminum dust. Not a trace of ammonia could be detected with Nessler's solution. When the Kjeldahl method failed to give ammonia, I also failed to get any Mg_3N_2 formed by burning the gas with magnesium.

B. In alkaline solution, aqueous or alcoholic

$$2KCNO + 2NaOH + H_2O_2 = K_2CNO_2 + Na_2CNO_2 + 2H_2O \text{ (corrected)}$$

I repeated this reaction, in a closed vessel, in dry, cold alcoholic solution. The hydrogen peroxide was added slowly but oxygen was persistently given off. The concentrated solution was decomposed with phosphoric acid. The resulting gases were passed into barium hydroxide solution. The barium salt was then boiled with aluminum dust in strong alkali, but no trace of ammonia was given off (Nessler test). Therefore it is quite evident that the evolving gases are carbon dioxide and nitrogen and not CNO. Lidov's trouble of having an extra amount of barium salt precipitated in the reaction flask, which he calls $BaCNO_3$, would have been overcome if he had allowed the gas to escape and pass into barium hydroxide solution instead of trying to precipitate the effluent gas in the reaction flask.

Paper Number 2.—(See part **5** of Number **3.)**

Paper Number 3.—A. Lidov claims that the familiar reaction

$$3NaOBr + CO(NH_2)_2 = CO_2 + N_2 + 2H_2O + 3NaBr$$

is not correct but that as we increase the dilution of the solution (alcoholic), we have more and more CNO formed. He supports this assumption by the meager evidence that he did not find the theoretical amount of carbon dioxide formed but a gas weighing (1.974, 1.945, 1.925, 1.921 and 1.911) g. per liter. "Further dilution, however, does not bring near the weight of the gas and the weight of a liter of pure oxan—1.875 g."

This titration was carefully repeated and the gases formed passed into barium hydroxide. The precipitate was tested for nitrogen content in the usual manner and was found to contain none.

B. Sodium cyanamide was claimed to give oxan on oxidation with hydrogen peroxide (perhydrol) or sodium hypobromite, very small quantities of nitrogen being liberated. However, I found the reactions to proceed as follows in aqueous solution

$$Na_2CN_2 + 3NaOBr = 3NaBr + Na_2CO_3 + N_2$$
$$Na_2CN_2 + 3H_2O_2 = Na_2CO_3 + 3H_2O + N_2$$

If the cyanamide or a cyanate is converted to an ammonium compound the strong oxidizing agents will oxidize it to free nitrogen, reducing agents giving ammonia. The sodium salts left were decomposed and the gas evolved proved to be pure carbon dioxide.

C. Other simple ways of preparing the gas are

(a) $2KCNO + H_2O_2 = K_2CNO_2 + CNO + H_2O$ (in water solution)

"There is always more or less potassium carbonate and ammonium carbonate formed," Lidov reports.

(b) $2KCNO + 2NaOH + H_2O_2 = K_2CNO_2 + Na_2CNO_2 + 2H_2O$ (in alcoholic solution in a hermetically closed vessel)

"No nitrogen is expelled and 15–20% extra Ba salt is precipitated." In checking these experiments I obtained the same results as described in paper I.

D. In this section properties of oxan salts are given. Lidov obtained his oxan salts, $BaCNO_2$, K_2CNO_2, etc., as shown in reactions above, but I was unable to separate any new salts.

E. By heating a mixture of KCNO and CuO to 375° in a stream of dry nitrogen, Lidov found

$$2KCNO + CuO = K_2CNO_2 + CNO + Cu$$

"That the reaction is really so, is confirmed as well by the weight of the gas expelled (1.900) by the heating, as by the weight of the gas produced from the remaining salts." I find the reaction to proceed as follows

$$2KCNO + 3CuO + N_2 = K_2CO_3 + CO_2 + 2N_2 + 3Cu$$

when everything is carefully dried and protected from water vapor. Otherwise I find

$$4KCNO + 3H_2O + 3CuO + N_2 = 2N_2 + 2NH_3 + 3Cu + 2K_2CO_3 + 2CO_2$$

The expelled gases in the former reaction were passed through barium hydroxide. No trace of nitrogen was found in the precipitate. No evidence of CNO_2, or CNO_3, as reported, was found. (No oxidizing salt was left in the tube.)

F. When Lidov used oxygen instead of nitrogen, as in V, he found

$KCNO + CuO + O_2 = K_2CNO_2 + CNO + CO_2 + Cu +$ (a heavier gas, 2.590, precipitated with Ba^{++})

I found the simple conditions

$$4KCNO + 2CuO + 3O_2 = 2K_2CO_3 + 2CuO + 2N_2 + 2CO_2$$

which is in accord with all Dumas' determinations.

G. "Of the Formation of Oxan by the Reciprocal Action of Nitrogen Dioxide with Charcoal." Lidov learned in the following year that he was using nitric oxide and not nitrogen dioxide (see paper No. 6).

"The simplest way of obtaining oxan ... if we judge by weight of the gas" is to pass NO (not NO_2) over charcoal at 150°. "If the solution of sodium hydroxide, which has absorbed the gas, is immediately decomposed by phosphoric acid, in most cases pure oxan, if we judge by weight, is obtained." I followed Lidov's explicit directions for the best method of getting the pure gas (see part VII of paper 3 and paper 6) and absorbed it in alkali as stated. It was then precipitated as the Ba salt and carefully washed to get rid of any nitrates or nitrites. It was then decomposed by phosphoric acid, the evolved gas passed through a vapor trap and then through long tubes of phosphorus pentoxide and finally frozen out in a liquid air trap. The density of the gas was determined as described by Schumb and Gamble.[4] The gas was found to have a density of 1.9693 g. per liter, which is within 0.4% of the determined density of carbon dioxide ("International Critical Tables," Vol. III, p. 1). The gas was allowed to stand for several days and its density determined at two-day intervals. No polymerization takes place as evidenced by the various determinations.

June	17	19	21	23	25
Density	1.9693	1.9693	1.9693	1.9693	1.9693

These latter experiments disprove Lidov's sole argument for the existence of a gas, CNO, homologous with CO_2.

Paper Number 4.—Since there is no evidence for the formation of the salts described in this paper by the given methods, I will not try to explain how he obtained the peculiar properties listed. Perhaps the compounds listed will have the properties described, but I have proved that such compounds cannot be prepared by the methods given.

Paper Number 5.—By passing nitrogen dioxide over charcoal at room temperature and collecting the gas in alcoholic sodium hydroxide, Lidov did not obtain oxan but beta-oxan, ONC. In repeating this work with carefully prepared gases and solutions, and pure dry sugar charcoal, I obtained a mixture of $C_2H_4NaNO_2$, $NaNO_2$ and Na_2CO_3, the two former occurring in the first few hours of reaction and the last after fifteen to twenty hours. My organic salt was identified by its reactions and properties identical to those listed for $C_2H_4NaNO_2$. The mixture on decomposition gave no gas of the nature of CNO, only oxides of nitrogen and carbon. The first-named compound will explain the explosive properties of beta-oxan salts.

Paper Number 6.—The foregoing experiments show that Lidov was dealing with impure carbonates in this paper, and not new compounds. By treating the solution mixture described in Paper 5 with ferric chloride, Lidov obtained a ferric salt which he called iron beta-oxanate, I found simply ferric hydroxide, the explosive properties being due again to $C_2H_4NaNO_2$.

Passing pure nitrous oxide over charcoal at 150° gave only carbon dioxide and nitrogen and not CNO as claimed by Lidov.

Paper Number 7.—A review of previous work with a few new methods of preparing oxan, such as heating phosphorus pentoxide and urea.

Papers Number 8 and 9.—To confirm the contents of these two papers, namely, that CNO is a product of all combustions in air along with carbon dioxide and carbon monoxide, and of respiration of animals, would prove all

---

[4] Schumb and Gamble, THIS JOURNAL, 52, 4302 (1930).

Dumas' determinations inaccurate and calorific values subject to error. It would proclaim a new property of nitrogen, which has been proved not to be possible by thousands of able chemists, namely, the ability to support combustion. Therefore I wish to point out the fallacies of Lidov's writings.

Summary

1. The author has shown that $(CNO)_x$ cannot he obtained by any of the methods described by Lidov.

3. He has proved that salts, such as Na_2CNO_2, $Fe(NCO)_3$ or $BaCNO_2$, cannot be prepared as described.

3. He has shown that Lidov's peculiar observations are due to inaccurate work. This is particularly true of the density determinations.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. IV. THE GLYCOLS

BY C. P. SMYTH AND W. S. WALLS

RECEIVED MARCH 26, 1931 PUBLISHED JUNE 8, 1931

In the lirst paper[1] of this series the effect upon the resultant electric moment of the molecule produced by separating the component moments by a carbon chain of varying length was investigated, the complex $-COOC_2H_5$ group being placed at each end of the chain. In the present investigation the simpler $-OH$ group has been attached to the carbon chain. The low solubility of the glycols in the non-polar liquids, benzene and heptane, usually used as solvents in the determination of electric moments, has made it desirable to use 1,4-dioxane, which has been employed by Williams for a similar purpose.[2] Williams found values for the moments of chlorobenzene, chlorocyclohexane, diethyl o-phthalate, and water measured in dioxane in good agreement with the values obtained in other ways. It was feared, however, that the glycols might form addition products with the dioxane which would lead to incorrect values for the moments. In order to test the possibility of such errors, *n*-butyl alcohol, which had been thoroughly investigated in the vapor state[S] and in solution in other solvents,[4] was measured in dioxane. The monohydric alcohol would be expected to resemble to some extent, at least, the glycols in the possible formation of addition products and, therefore, in the error in the moment arising from such formation. The resemblance should be close in the case of the long-chain glycols.

Preparation of Materials

The refractive indices and densities of the pure liquids, which give evidence of the purity of the materials, are listed in Table I. Other criteria of purity are given under each substance below.

1,4-Dioxane.—1,4-Dioxane from the Eastman Kodak Company, m. p. 9.5–10.5°, was dried over sodium and fractionally distilled; b. p. 100.5–100.7°.

***n*-Butyl Alcohol**,---n-Butyl alcohol from the Commercial Solvents Corporation was refluxed over freshly ignited calcium oxide and fractionally distilled three times; b. p 117.2–117.4'.

Ethylene Glycol.—Material from the Carbide and Carbon Chemicals Corporation was fractionally distilled under reduced pressure and the middle fraction collected. This fraction was dried over anhydrous sodium sulfate, decanted and twice fractionally distilled; b. p. 197.2–197.3°.

Propylene Glycol.—Material from the Eastman Kodak Company, b. p. 85–86' (10 mm.), was fractionally distilled under reduced pressure, dried over anhydrous sodium sulfate, decanted and twice redistilled; b. p. 104° (32 mm.).

Trimethylene Glycol.—Material from the Eastman Kodak Company, b. p. 123–125° (30 mm.), was twice fractionally distilled under reduced pressure. The middle fraction was dried over anhydrous sodium sulfate, decanted and twice fractionally redistilled under reduced pressure; b. p. 127° (33 mm.).

Hexamethylene Glycol.—Material kindly loaned to us by Dr. Wallace H. Carothers of E. I. du Pont de Nemours & Company, b. p. 145–147° (13 mm.), was twice fractionally crystallized and allowed to stand in an evacuated desiccator; m. p. 42.8°.

Decamethylene Glycol.—Material loaned by Dr. Carothers was crystallized from hot, dried benzene, washed twice with cold benzene and carefully dried in an evacuated desiccator; m. p. 72.2°.

Experimental Results

The densities and dielectric constants of these solutions were measured with the apparatus and methods previously employed,' a wave length of 1000 meters being used in the dielectric constant determinations. The refractive indices for the D sodium line and the densities of the pure liquids determined for use in the calculation of the molar refractions MR_D and as criteria of purity are listed in Table I. Similar measurements on the solutions of the solids made possible the calculation of MR_D, the values of which are listed in Table II. In Table I the first column gives the mole fraction c_2 of the butyl alcohol or the glycol in the dioxane solution and the succeeding columns give the values at 25 and 50° of the dielectric constants ϵ and the densities d of the solutions and the polarizations P_2 of the polar substance. P_2 is calculated by means of the usual equations

$$P_{12} \quad \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \text{ and } P_2 \quad \frac{P_{12} - P_1}{c_1} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2, and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The extrapolation of the P_2–c_2 curve to infinite dilution, that is, $c_2 = 0$, gives the value of P_∞ at the absolute temperature T, from which the electric moment μ is calculated by means of the equation

$$\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - MR_D)T}$$

The absolute values of the moments are probably a little high because of the neglect of the atomic polarization P_A.

Discussion of Results

The values given for 1,4-dioxane under $P_\infty - MR_D$ are the differences between the polarizations of the pure liquid and the refraction. As the unknown atomic polarization P_A is disregarded in the calculation of the moment, the result merely shows that the value of the moment is not far from zero. Williams[6] reports a decrease in the polarization of dioxane with decreasing concentration in dilute benzene solution, which seems curious in view of the small or zero moment of the molecule. However, his value of P_∞, 26, is in excellent agreement with the values in Table II for P_1, which might be expected to be practically identical with P_∞ in this case. Williams calculates a value, $\mu = 0.4 \times 10^{-18}$, but concludes that the moment "can differ but slightly, if at all, from zero." The apparent symmetry of the molecule would lead one to expect a small or zero moment.

The values of P_2 for n-butyl alcohol in Table II show a minimum, as do those for the alcohol in benzene solution[4] in the same region of temperature and concentration. The values at 25° are 3 or 4 units higher than those at the same concentrations in benzene solution, probably because of a slightly high value used for P_1 in the latter, while the polarizations in the two solvents at 50° differ from one another by less than one unit. In both solvents the minimum in the P_2–c_2 curve at such low concentrations makes

---

[6] Williams, This Journal, 52, 1831 (1930).

difficult an accurate extrapolation to obtain P_∞. The value of the moment found in dioxane solution at 25° is a little high, but that at 50° is in excellent agreement with the mean value, 1.74×10^{-18}, obtained from the benzene solutions. As benzene is the most generally used solvent and as this value of the moment is in fair agreement with the value, 1.65×10^{-18}, found by Miles[3] for the vapor, dioxane appears to be an adequate solvent for the alcohol. As the glycols should resemble the monohydric alcohols in their action upon the solvent, it may be concluded that dioxane solutions of the glycols should give satisfactory values of the moments. The previously mentioned work of Williams gives further justification for the conclusion.

The moment found for ethylene glycol is much higher than the value 1.5×10^{-18} obtained by Williams[7] from measurements in benzene solution. However, the very low solubility of the glycol in benzene renders it difficult to obtain an accurate value in this solvent. It had been hoped that some of the higher glycols would prove sufficiently soluble in benzene to render measurements possible for comparison with those in dioxane, but the insolubility was such that no accurate determination could be made.

The moment of a monohydric alcohol is, in the main, the resultant of the moments of two doublets, one in the line of the C–O bond and the other in that of the H–O bond.[8] By empirical methods, Eucken and Meyer[9] have calculated the moment of the former doublet as 0.7×10^{-18} and that of the latter as 1.6×10^{-18}. The method is necessarily somewhat arbitrary, the moments of ethyl ether and of water being used for the calculation and the two oxygen valences being assumed to act at an angle of 110° to one another. When these assumptions, together with the assignment of a moment, 0.4×10^{-18}, to the H–C bond, are used to calculate the moment of a monohydric alcohol, the value obtained, 1.61×10^{-18}, agrees satisfactorily with those observed, which, for the most part, lie between 1.65×10^{-18} and 1.70×10^{-18}. Calculation further shows that the resultant of the C–O and H–O moments, 1.52×10^{-18}, should make an angle of 84° with the direction of the C–O bond. This angle has been suggested as the reason for the absence of induced moments along the carbon chains of the alcohols as shown by the absence of increase in the moment of the alcohols with increase in the number of carbons.

The resolution of the two C–O and the two H–O moments in ethylene glycol is a complicated matter because the angle between the two resultants, 1.52×10^{-18}, of the C–O and H–O moments is variable as the result of the rotation about the C–O and C–C bonds. Moreover, there is a small mutual inductive effect of the moments in the two halves of the molecule upon one another. In view of these complexities which cannot be treated

---

[7] Williams, *Z. physik. Chem.*, **[A]** *138*, 75 (1928).

[9] **Eucken** *and* Meyer, *Physik. Z.*, **30**, 397 (1929).

accurately, it seems best to attempt to obtain merely a rough idea of the magnitude of the resultant moment. It has been shown that the resultant of the C–O and H–O moments acts nearly at a right angle to the direction of the C–O bond, which makes an angle to that of the C–C bond. If the total resultant moment in each half of the molecule is taken equal to that of a monohydric alcohol, 1.7×10^{-18}, and assumed to act at right angles to the C–C bond and if all positions of one moment relative to the other around the C–C bond are assumed to be equally probable, the average moment found for the molecule should be $1.41 \times 1.7 \times 10^{-18} \times \sin 90° = 2.4 \times 10^{-18}$.[10]

When the doublets are close together, as in ethylene and propylene glycol, their considerable mutual potential energies tend toward a minimum by bringing the doublets as far as possible into opposition to one another and so reducing the resultant moment. As would be expected, the replacement of a hydrogen in ethylene glycol by a methyl group to form propylene glycol has a negligible effect upon the moment as it does not alter the positions of the hydroxyl groups relative to one another. This should not be the case, however, if the replacement of the hydrogen by methyl produced any considerable change in the energies of the other bonds. Similarly, practically identical values were found by Gross[11] for the moments of ethylene chloride, 1.86×10^{-18}, and propylene chloride, 1.85×10^{-18}. When the doublets are more widely separated as in trimethylene glycol, their mutual potential energies are less and, indeed, appear to be so small as to have a negligible effect upon the positions of the doublets relative to one another. This is evident in the higher moment found for trimethylene glycol and in the fact that the further separation of the hydroxyl groups in hexamethylene and decamethylene glycol has no apparent effect upon the moment. The rough value 2.4×10^{-18} calculated for the moment of ethylene glycol is evidently of the right order of magnitude for it lies between those of the glycols in which the hydroxyls are on adjacent carbons and those in which the hydroxyls are more widely separated.

It is of interest now to consider qualitatively the effect of the valence angles of the carbons and the possible bending of the carbon chains. Of the dihydroxybenzenes, only the ortho compound, catechol, has been measured,[12] the moment found being 2.16×10^{-18}, a value higher than that for phenol, 1.70×10^{-18},[13] by an amount slightly less than the difference between ethylene glycol and the monohydric alcohols. The angle between the two C–O valences in catechol is fixed at 60°, while in ethylene glycol it may vary from 40 to 180°. The moments of the ethers of the

[13] Williams, *ibid.*, 29, 174 (1928); Smyth and Morgan, THIS JOURNAL, 49, 1030 (1927).

dihydroxybenzenes are smaller because the C–O moment is smaller than the H–O but the valence angles involved and the dependence of the moments upon these angles should be much the same. o-, *m*- and p-dimethoxybenzene have the moments 1.31, 1.58 and 1.81 X 10^{-18}, respectively, while o-, m- and *p*-diethyoxybenzene have the values 1.37, 1.70 and 1.76 X 10^{-18}.[12] The moments of the ortho compounds may be somewhat lowered by the mutual inductive action of the moments and by the tendency of their mutual potential energies to reach a minimum by bringing the doublets as far as possible into opposition to one another. Lowering due to these causes should be slight, if not negligible, in the meta compounds where the separation of the doublets is greater, and certainly negligible in the para compounds. Although this lowering of the moment reduces the significance of the differences between the ortho, the meta and the para compounds, it would appear that the moment increases as the angle between the lines joining the oxygens to the ring carbons increases from approximately 60 to 120, to 180°.

The fact has been cited in the first paper of this series[1] that dimethyl *o*-phthalate has a moment *2.5* X 10^{-18}, while that of dimethyl terephthalate is 2.2 × 10^{-18}, that is, when the two $-COOCH_3$ groups are attached to the ring in such a way that the group bonds make an angle of about 60° with one another, the moment is a little higher than when the group bonds point in opposite directions. This behavior was contrasted with that of the substituted benzenes in which the substituent could be regarded as giving rise to a single moment in the plane of the ring. In such cases the behavior is very different, as illustrated by the moments of the dichlorobenzenes, the ortho compound having *a* moment, *2.25* X 10^{-18}, the meta, 1.48 X 10^{-18} and the para, 0.[14] The behavior of the di-ethers is in even more marked contrast to that of the dichlorobenzenes for the change of moment with change in the angle between the group bonds is different not only in magnitude but also in direction.

Evidently, rotation around the C–O bonds makes possible so many different orientations of the hydroxyl moments relative to one another in a dihydroxy compound that the angle between the C–O bonds does not have a large effect upon the moment. When to this is added the effect of the rotation about the C–C bonds in the glycols, it appears that lengthening of the carbon chain between the two hydroxyls should have little effect upon the resultant moment once the hydroxyls are so far removed from one another that the mutual potential energies of their doublets are small. The marked increase in moment observed when the number of carbons between the hydroxyl groups is increased from two to three may result in **part** from change in the angles between the C–O bonds because of the valence angles of the added carbon, but is probably due mainly to the

---

[14] Smyth, Morgan and Boyce, This Journal, 50, 1536 (1928).

greater distance between the doublets, which permits freedom of rotation and orientation relative to one another and renders negligible the lowering of the moments by mutual inductive action. Further lengthening of the chain should have little effect unless it should give rise to bending to form a ring-like structure. Unfortunately, the tetra- and pentamethylene glycols, which should be most apt to form a ring structure, have not been secured for measurement. In spite of the smallness of the effect of the angle between the C–O bonds upon the moment, it would seem that any very pronounced bending of the carbon chain might cause noticeable differences between the moments of molecules possessing chains of different lengths. Certainly, if any one molecule were so bent as to bring its hydroxyl groups into contact with each other, its moment would be materially different from those in which such proximity between the hydroxyl groups did not occur.

The difference between the value found for hexamethylene glycol and that for decamethylene glycol, though slightly greater than the probable experimental error, is too small to be significant. The differences between all the values found at 25° and those at 50° are no greater than the experimental error, although measurement over a wide temperature range should show an increase in the moments of ethylene and propylene glycol if they are low because of the mutual potential energies of their doublets. If there were any pronounced ring formation in the longer molecules, they might be expected to be affected by change of temperature and show a change of moment such as was found for diethyl succinate.[1] It may be concluded that the moments of the glycols give no indication of ring formation in the molecule or of very pronounced bending of the carbon chain, although they do not preclude the possibility of some bending of the chain.

Summary

The dielectric constants and densities of n-butyl alcohol and of five glycols have been measured in solution in 1,4-dioxane at 25° and at 50° and the refractive indices of the substances in the pure liquid state or in solution have been determined.

The data have been used to calculate the electric moments of the molecules and the agreement of the value for n-butyl alcohol with that obtained by other methods is regarded as evidence of the correctness of the results for the glycols.

Because of rotation around the bonds the relative positions of the two hydroxyl groups in the molecule do not have large effects upon the moment, but the absence of any significant difference in moment between trimethylene, hexamethylene and decamethylene glycol is regarded as indicating that there is no very pronounced bending of the carbon chain.

THE STRUCTURE OF GROUPS XO_3 IN CRYSTALS

BY W. H. ZACHARIASEN

RECEIVED MARCH 26, 1931 PUBLISHED JUNE 8, 1931

In this paper will be presented the general results of a series of x-ray investigations which have been carried out with the object of determining the structures of radicals XO_3 in crystals.

Previously it was generally believed that the structures of the groups XO_3 were different principally in the absolute dimensions, *i. e.*, that they all were built like the CO_3-group with the cation situated in the center of an equilateral triangle formed by the 3 oxygens. In 1928 I was able to show from an examination of the atomic arrangement in $KBrO_3$ that the BrO_3 group had the shape of a low trigonal pyramid.[1] As a consequence of this result I classified the groups XO_3 in two classes: one including the co-planar groups and the other including all pyramidal groups. From considerations to be given later I referred to class 1 the $(NO_3)^{-1}$-, $(CO_3)^{-2}$- and $(BO_3)^{-3}$-groups; to class 2 the groups $(PO_3)^{-3}$, $(SO_3)^{-2}$, $(ClO_3)^{-1}$, $(AsO_3)^{-3}$, $(SeO_3)^{-2}$, $(BrO_3)^{-1}$ and $(SbO_3)^{-3}$. The empirical material upon which this classification was founded was very meager; my later investigations have, however, confirmed my predictions completely.

At present we have x-ray data on the following groups: $(NO_3)^{-1}$, $(CO_3)^{-2}$, $(BO_3)^{-3}$, $(ClO_3)^{-}$, $(SO_3)^{-2}$, $(BrO_3)^{-1}$, $(AsO_3)^{-3}$ and $(SbO_3)^{-3}$. In the following section I will describe the experimental results for the individual groups.

Experimental Data on the Structure of the Individual Groups XO_3

NO_3 Group.—Sodium nitrate and lithium nitrate are the two crystals which have given the most reliable data on the NO_3 group. In the first place the atomic arrangement is characterized by only one degree of freedom, and in the second place the oxygens have a large effect on the intensities of reflection, so their positions can be determined with accuracy.

According to the symmetry of the space group the NO_3 radical in these two crystals is planar with nitrogen in the center of an equilateral oxygen triangle. The dimensions of the group were determined as

$NaNO_3$[2]	N–O, 1.22 Å.	O–O, 2.11 Å.
$LiNO_3$[3]	N–O, 1.25 Å.	O–O, 2.17 Å.

We have reason to believe that the NO_3 group will not be influenced very much by the surrounding atoms in the lattices because of the strength

---

[1] W. H. Zachariasen, *Norske Vid. Akad. Skr. Oslo*, No. 4, p. 90 (1928).

[2] R. W. G. Wyckoff, *Phys. Rev.*, 16, 149 (1920).

[3] W. H. Zachariasen, Ref. 1, p. 53.

of the bonds inside the group. V. M. Goldschmidt[4] has suggested that the dimensions of the group should be greater in compounds containing small cations; e. g., we should expect to find a larger NO_3 group in lithium nitrate than in sodium nitrate. Definite proof of the effect of Goldschmidt's contrapolarization is, however, still lacking. If such an effect exists, it must at any rate be small.

Due to the small scattering power of nitrogen it has been impossible to prove definitely that the NO_3 group always is a planar group. It seems, however, justifiable to assume that the NO_3 group will possess the same structure in all compounds (small deformations may of course be present in some compounds).

CO_3 Group.—In carbonates with calcite structure a planar CO_3 group follows from the space group symmetry. The dimensions of the group are found to be the same as for the NO_3 group within the limits of error. Wyckoff[5] determined from calcite:

$CaCO_3$	C–O, 1.23 Å.	O–O, 2.13 Å.

For the struciure of the CO_3 group in other compounds the same considerations that were given for the NO_3 group will be valid.

W. L. Bragg[6] has determined the dimensions of the CO_3 and the NO_3 groups also from the refractive indices of crystals with calcite or aragonite structure. In the CO_3 group he finds, in agreement with the x-ray data, C–0 1.25 Å. For the NO_3 group, however, he calculated N–O 1.10 Å., which is in definite disagreement with the x-ray determinations 1.24 Å. This result is not suprising when we consider that the center of the oxygen atom determined according to these two methods need not be identical.

BO_3 Group.—Indirect evidence that the BO_3 group is analogous to that of the carbonate group we have from the fact that the two compounds, dolomite, $CaMg(CO_3)_2$, and nordenskjöldine, $CaSn(BO_3)_2$, are isomorphous. Only one x-ray determination of the BO_3 group exists, namely, from the compd $Be_2(BO_3)(OH)$ (the rare mineral hambergite). The atomic arrangement in hambergite is characterized by twenty-one degrees of freedom, so the accuracy necessarily is not very great. A conscientious determination of the parameters led to a planar BO_3 group, however. This result combined with the indirect evidence should be sufficient proof of the analogy to the NO_3 and CO_3 groups. The dimensions of the BO_3 group from hambergite are

$Be_2(BO_3)(OH)$[7]	B–0, 1.35 Å.	O–O, 2.35 Å.

ClO_3 Group.—The earlier x-ray investigations on sodium chlorate led to very divergent structures of the ClO_3 group. Kolkmeijer, Bijvoet and Karssen[8] found Cl–O 0.93 Å., O–O 1.56 Å.; Dickinson and Goodhue,[9] Cl–O 1.43, O–O 2.34 Å.; Vegard[10] Cl–O 1.85 Å., O–O 1.17 Å. The two former sets of values result in nearly planar groups, while Vegard's ClO_3 values lead to an extremely acute trigonal pyramid. I have determined the atomic arrangement in sodium chlorate with the greatest care, using absolute intensity measurements and applying two-dimensional Fourier analysis of the electron distribution.[11] My results were in fairly good agreement with those of Dickinson and Goodhue, but differ in one essential point. My observations show definitely that the ClO_3 group is not planar, but has the shape of a low trigonal pyramid.

From an investigation on potassium chlorate, which has an atomic arrangement completely different from sodium chlorate, I have also determined the structure of the ClO_3 group, making use of the same experimental methods.[12] These two independent determinations of the ClO_3 group agree very well

$KClO_3$	Cl–O, 1.48 Å.	O–O, 2.38 Å.	*h*, 0.50 Å.
$NaClO_3$	Cl–O, 1.48 Å.	O–O, 2.38 Å.	*h*, 0.48 Å.

h being the displacement of chlorine out of the oxygen plane.

SO_3 Group.—Recently Mr. Buckley and I have determined the atomic arrangement in sodium sulfite.[13] Our results for the SO_3 group are

Na_2SO_3	S–O, 1.39 Å.	O–O, 2.24 Å.	h, 0.51 Å.

It is to be remarked that the dimensions of the SO_3 group in sodium sulfite probably are too small due to the fact that the sodium atoms surround the group in an unsymmetrical way. If the SO_3 group is surrounded by the neighboring ions in a more symmetrical way (as is the case for the ClO_3 group in sodium chlorate and potassium chlorate), we might expect dimensions more close to those of the ClO_3 group.

BrO_3 Group.—The structure of the BrO_3 group was determined from the atomic arrangement in potassium bromate. The results obtained were

$KBrO_3$	Br–O, 1.68 Å.	O–O, 2.76 Å.	h, 0.56 Å.

AsO_3 Group and SbO_3 Group.—The crystal lattices of arsenic trioxide and antimony trioxide were determined by Bozorth.[14] The lattice can be considered as composed of molecules As_4O_6 or Sb_4O_6. As the coordination numbers are 3 and 2, each molecule is built up of 4 AsO_3

---

[8] Kolkmeijer, Bijvoet, Karssen, *Proc. Roy. Acad.* Amsterdam, *23,* 644 (1921).

or SbO_3 groups, each oxygen being divided between two groups. It is thus not correct to speak of the radicals AsO_3 and SbO_3 existing in these lattices, but only about groups of the said composition.

Bozorth's results for the structure of the groups were

As_2O_3	As–O, 2.01 Å.	O–O, 3.28 Å.	h, 0.67 Å.
Sb_2O_3	Sb–O, 2.22 Å.	O–O, 3.62 Å.	h, 0.75 Å.

Among important radicals XO_3 for which experimental data are lacking we have $(PO_3)^{-3}$ and $(SeO_3)^{-2}$.

Considerations on **the** Structure of Groups **XO_3**.—The experimental data at once suggest the classification of the groups introduced by the **author**.[15] The groups examined are divided between the two classes in the following way: Class 1, planar groups, BO_3, CO_3, NO_3; Class 2, pyramidal groups, SO_3, ClO_3, AsO_3, BrO_3, SbO_3.

The following regularity exists: if we consider the groups to have the valence usually ascribed to them (indicated throughout the paper), the number of valence electrons in the groups of class 1 is 3×8; in the groups of class 2 the number of valence electrons is $3 \times 8 + 2$. This feature is so striking that it seems natural to seek the cause of the differentiation in planar and pyramidal structures in the number of the valency electrons.

It is not surprising to find that the symmetry of the group has to be correlated with the number of valence electrons. A rigorous explanation of the rule cannot, however, be given until a wave-mechanical treatment of such groups has been carried out. In the meantime we must be content with rough approximations.

It is well known that the greater part of the inorganic non-metallic crystal structures can be treated successfully by introducing the conception of ions, ionic dimensions and polarizability. The results obtained from this point of view may be considered as an approximation to the correct ones. It would be incorrect to consider the bonds within the radicals dealt with here to be of a purely ionic character; therefore we have to take into account also the deformations taking place in the electron clouds of the ions.

Let us consider the ClO_3 group as an example. The constituents are Cl^{+5} and O^{-2}. The polarizability is related to the mole refraction by the well-known expression

$$R = \frac{4\pi}{3} N\alpha$$

α is again defined by the relation $m = \alpha F$, where m is the moment induced in an atom under the influence of the force F. The moment we must consider to be due to a displacement of the centers of the positive and negative charges in the atom. Practically this will mean a displacement

---

[15] Zachariasen, *Norske Vid. Akad. Skr. Oslo, No. 4*, p. 136 (1928).

of the core relative to the center of the outer electron shell. If there are v valence electrons and if the amount of displacement is d, we have

$$m = dxv \text{ or } d = \frac{3RF}{4\pi Nve}$$

i. e., the displacement is proportional to the molar refraction, and inversely proportional to the number of valence electrons. It is evident therefore that the polarizability constants do not give us directly the degree of deformation in the outer electron shell.

The molar refraction values for O^{-2} and Cl^{+5} are 3.3 and 1.5 cc.[16] If we consider that oxygen has an outer shell of 8 electrons while chlorine has only 2, we derive from our result above that deformation on the outer shell is greatest for Cl^{+5}. It has been shown that groups with a polarizable central ion will have an unsymmetrical structure, so that a pyramidal ClO_3 group is just what we should expect.[17] The deformations taking place are easy to picture. The field intensity due to the three oxygen ions will polarize the chlorine ion, and in such a way that the outer electron density (the two valence electrons) is pushed away from the oxygens. The chlorine ion on the other hand will to some extent attract the electron density corresponding to the valence electrons of oxygen. The relative displacement of core and valence electrons is, however, much greater in the Cl^{+5} ion both because of the stronger force acting upon it and also because of the small number of valence electrons.

As a final result we obtain a ClO_3 group which roughly can be pictured as a tetrahedral arrangement; three of the corners are occupied by oxygen ions, the center by a Cl^{+7} ion and the fourth corner by the two valence electrons of chlorine. If this tetrahedron were accurately regular and if we could consider the ions and the two electrons to be point charges, the center of the positive and negative charges would coincide. It has, however, been definitely shown that unsymmetrical molecules have a permanent dipole moment. The observed moment is very small and corresponds to only a few hundreths of an Ångström unit displacement between the centers of the negative and positive charges. For rough considerations of the structure of such groups we may therefore disregard this displacement. The conception of a tetrahedral ClO_3 group as presented above would give the following relation between the oxygen–oxygen distance (a) and the height h of the Cl^{+7} core above the plane of the oxygens

$$h = \frac{a}{12}\sqrt{6} \qquad (1)$$

From x-ray determination we will obtain the position of the Cl^{+7} core, as the two valence electrons have no detectable effect on the scattering power. The centers of the oxygens fixed by the same method on the

---

[16] From paper submitted to *Phys. Rev.*

[17] Van Arkel and de Boer, *Ree. trav. chim.*, 47,593 (1928).

other hand must correspond very closely to the center of electron density as the valence electrons in this case have **an** appreciable effect. The experimentally determined values of h and a are thus within the limits of error identical with those of Equation (1). In the table is shown how closely the relation I holds for all the groups examined, so that there seems to be justification for the conception of tetrahedral groups.

Group	a	h	$\frac{a}{12}\sqrt{6}$	r
SO_3	2.24	0.51	0.46	1.39
ClO_3	2.38	.49	.49	1.48
AsO_3	3.28	.67	.67	2.01
BrO_3	2.76	.56	.56	1.68
SbO_3	3.62	.75	.74	2.22

The picture given for the structure of pyramidal groups XO_3 must not be taken too literally. To say that the two valence electrons of Cl^{+5} lie at the fourth corner of the tetrahedral structure is naturally incorrect, and must be interpreted as meaning a concentration of electron density in that region. If we use interpretations of that kind, I believe that the picture can be considered as an approximation toward the true distribution of electron density in the group.

In a following paper[16] I am trying to locate the positions of the displaced electrons in the ClO_3 group from the strength of the birefringence in potassium chlorate. The result of that calculation supports the considerations given here.

A Relation between the Symmetry of Groups and Molecules XY_2, XY_3 and the Number of Valence Electrons

In the previous section we found that groups $(XO_3)^{-m}$ had a co-planar structure if the total number of valence electrons was 24 (3 X 8), while the groups were pyramidal if there were 26 (3 X 8 + 2) valence electrons in the group.

A more general formulation of this empirical rule will now be considered. We will confine ourselves to groups and molecules of the form XY_2 and XY_3, in which all atoms Y are chemically identical and are related to atom X in the group in an identical way. Furthermore, we will make the restriction that the atomic numbers are relatively small.

The existing reliable observations then show:

$$\text{A group or molecule}\left\{\begin{matrix}(XY_2)^{-m}\\(XY_3)^{-m}\end{matrix}\right.\text{ is }\left\{\begin{matrix}\text{co-linear}\\\text{co-planar}\end{matrix}\right.\text{ if }\left\{\begin{matrix}\Sigma v = 2p\\\Sigma v = 3p\end{matrix}\right.$$

Σv is the total number of valence electrons in the group or molecule; p represents the number of valence electrons in the inert gas following atom Y in the periodic system. If, on the other hand, the relation between Σv and p takes the form $\left\{\begin{matrix}\Sigma v = 2p + \Delta\\\Sigma v = 3p + \Delta\end{matrix}\right.$ the group or molecule is $\left\{\begin{matrix}\text{angular}\\\text{pyramidal}\end{matrix}\right.$.

Because these rules have been derived from empirical data, we may with reason use it as a guiding principle until an exact formulation on the basis of wave mechanics can be given, or until we have experimental evidence that the rule does not hold.[18]

In the following table I have listed a number of groups and molecules according to the kind of structure which should be expected if the rule holds.

TABLE I

Co-linear	Angular
CO_2, ON_2, CS_2	SO_2, NO_2, SH_2, OH_2, OO_2 ? (ozone)
$(NN_2)^-$, $(HF_2)^-$	$(NO_2)^-$
Co-planar	**Pyramidal**
SO_3, BH_3, BF_3, BCl_3, AlF_3	NH_3, PH_3, AsH_3, PF_3, PCl_3
$(BO_3)^{-3}$, $(CO_3)^{-2}$, $(NO_3)^-$	$(OH_3)^+$, $(PO_3)^{-3}$, $(SO_3)^{-2}$, $(ClO_3)^-$
	$(AsO_3)^{-3}$, $(SeO_3)^{-2}$, $(BrO_3)^-$

Mr Ziegler in this Laboratory is at present working on the crystal structure of sodium nitrite. The investigation is not quite completed yet, but his results so far do not seem to be compatible with a co-linear $(NO_2)^-$ group.

Groups XO_2 for which $\Sigma v = 2 \times 8 + 2$ can be pictured as an equilateral triangle. The center of the triangle will be occupied by the core of the central ion, two of the corners by oxygens and the third corner by the two displaced valence electrons. The angle between the two cation–oxygen bonds would thus be 120 degrees.

Since the above paper was written, valuable contributions to the quantum mechanical treatment of shared electron bonds have been made by Slater[19] and Pauling.[20]

Pauling has applied the theory on groups XO_3 with the following results. For groups XO_3 of class 2 in my notation he finds that the angle between the X–O bonds is $109^1/_2$ (the tetrahedral angle), in excellent agreement with the experimental results I have obtained. In groups of class 1, however, the central atom according to Pauling is oscillating with a very small amplitude perpendicular to the oxygen plane, again in accordance with the results of this paper.

There are thus two ways of interpreting the structure of groups XO_3, which both lead to the same result: one being the conception of shared electron bonds (naturally in the quantum mechanical treatment), the other being the conception of ions and their deformation in the field of the surrounding ions. These two methods of attack are dualistically related to each other.

---

[18] It is to be remarked that the above rule for the structure of groups XY_2 and XY_3 can be deduced directly from considerations of ions and their polarizability.

[19] Slater, Phys. *Rev.*, **37**, 481 (1931).

[20] Pauling, THIS JOURNAL, 53, 1367 (1931).

Summary

The general results concerning the structure of groups XO_3 in crystals are given. The groups are found to be of two kinds, one kind of groups has a co-planar structure, the other a low pyramidal structure. In the following table *a* denotes the oxygen to oxygen distance; *r* the cation to oxygen distance and h the displacement of the cation out of the plane of the oxygens.

Co-planar groups

	a	F
$(BO_3)^{-3}$	2.35 Å.	1.35
$(CO_3)^{-2}$	2.13	1.23
$(NO_3)^{-}$	2.14	1.23

Pyramidal groups

	a	r	b
$(SO_3)^{-2}$	2.24	1.39	0.51
$(ClO_3)^{-}$	2.38	1.48	.49
$(AsO_3)^{-3}$	3.28	2.01	.67
$(BrO_3)^{-}$	2.76	1.68	.56
$(SbO_3)^{-3}$	3.62	2.22	.75

It is pointed out that groups $(XO_3)^{-m}$ are co-planar if the number of valence electrons in the groups is 3×8, while a pyramidal arrangement seems to be connected with $3 \times 8 + 2$ valence electrons. An explanation of the formation of the asymmetrical groups in terms of ions and their polarizability is given. The displacement h is related to the oxygen–oxygen distance *a* by the expression $h = (a/12)\sqrt{6}$. This relation suggests a simple picture of the pyramidal groups; they can be considered as tetrahedral groups, with three of the corners occupied by oxygen ions, the center by the cation core and the fourth corner by two displaced electrons.

It is shown that the symmetry of groups $(XY_2)^{-m}$ and $(XY_3)^{-m}$ can be correlated with the number of valence electrons. The result is expressed in the following rule: A group or molecule $\left\{\begin{matrix} XY_2 \\ XY_3 \end{matrix}\right.$ is $\left\{\begin{matrix} \text{co-linear} \\ \text{co-planar} \end{matrix}\right.$ if the number of valence electrons in the group or molecule (Σv) can be expressed by $\left\{\begin{matrix} \Sigma v = 2p \\ \Sigma v = 3p \end{matrix}\right.$, *p* being the number of valence electrons in the inert gas following atom Y in the periodic system. If the number of valence electrons has to be written in the form $\left\{\begin{matrix} \Sigma v = 2p + \Delta \\ \Sigma v = 3p + \Delta \end{matrix}\right.$ the group or molecule is $\left\{\begin{matrix} \text{angular} \\ \text{pyramidal} \end{matrix}\right.$.

THE VOLUMETRIC ESTIMATION OF FLUORINE BY MEANS OF CEROUS NITRATE

BY GEORGE BATCHELDER AND V. W. MELOCHE

RECEIVED MARCH 30, 1931 PUBLISHED JUNE 8, 1931

Among the compounds which have been employed in the gravimetric determination of fluorine are: calcium fluoride,[1] barium fluoride,[2] lanthanum fluoride,[3] thorium fluoride[4] and lead chlorofluoride.[5] While good results have been reported in most cases, none of the gravimetric methods seems to possess the accuracy and general applicability that are necessary for a standard determination.

Omitting acidimetric titrations of hydrofluoric and fluosilicic acids, a list of volumetric procedures includes the methods of Hempel and Scheffler,[6] Wagner and Ross,[7] Penfield,[8] de Boer,[9] Steiger[10] and Merwin,[11] Guyot[12] and Greeff[13] and Fairchild.[14] The first three mentioned involve the evolution of silicon tetrafluoride which is either measured or absorbed and determined acidimetrically. Such procedures possess the advantage of being applicable in the presence of phosphates, but have the disadvantage that their accuracy depends to no small degree upon the skill and experience of the analyst. The method of de Boer depends upon the fact that the color produced by a zirconium solution when treated with sodium alizarin sulfonate is bleached by fluoride ions but not by other halogens at low acid concentrations.

The Steiger–Merwin and Guyot–Greeff methods are probably the two most widely used at the present time. The former involves the removal of the yellow color from a hydrogen peroxide titanium solution by fluorides, while the latter consists in the formation of FeF_6^{---} ion when ferric chloride is added to a fluoride solution, the indicator according to Greeff being SCN^-. Critical studies of these two procedures have been made by Fresenius[15] and by Treadwell and Köhl,[16] who employed

the potentiometer as an end-point indicator for the ferric chloride titration. In a more recent modification of the Guyot–Greeff method, Fairchild added an excess of ferric chloride to the fluoride solution, estimating the excess of ferric chloride by the addition of potassium iodide and titration of liberated iodine by means of thiosulfate. Good results were obtained when the variables, temperature, time and concentration were carefully controlled. Although very satisfactory under the proper conditions, the limited ranges of these two methods and the existence of several variables affecting their accuracy make the development of better procedures for the analysis of fluorides highly desirable.

Trivalent Cerium as a Precipitant.—The use of lanthanum acetate as a precipitant for fluoride ions by Meyer and Schulz suggested to us possibilities in the use of cerium. Attempts at a gravimetric separation of cerous fluoride were, however, unsatisfactory on account of the gelatinous character of the precipitate. What results were obtained indicated a high degree of adsorption on the surface of the cerous fluoride. This was borne out by further attempts to obtain a potentiometric end-point without filtration.

A Back Titration Method.—Since the gravimetric separation of cerous fluoride proved to be impracticable due to adsorption, a volumetric modification was investigated. It was hoped that the error introduced in the gravimetric method by adsorption might be eliminated in the volumetric procedure.

Materials.—The sodium fluoride which was used as a primary standard was prepared by adding an excess of hydrofluoric acid to sodium bicarbonate, the fluoride thus formed being dried and finally fused in platinum. The reagent quality hydrofluoric acid was specially purified for the above preparation by repeated distillation. Sodium fluoride obtained by this method gave a clear water solution. The purity of this salt was checked by conversion to the sulfate.

White reagent quality cerous nitrate was'used in these experiments. Samples of this material were ignited to the oxides and the cerium content determined by Metzger's bismuthate method[17] and the method of Lenher and C. Meloche.[18] The results of these analyses showed the residue to consist of 98.6% CeO_2. The remainder of the sample was found to be oxides of the rare earths. Calculations indicate that in the case of the largest samples reported in the table error due to rare earth content is not greater than 0.0002 g. (about 0.00003 g. of NaF per 10 cc. of the titrating solution used). This is due to a proximity of molecular and atomic weights. Correction for impurities was therefore neglected.

Method.—The proposed method involved the addition of an excess of a known cerous nitrate solution to a neutral solution of sodium fluoride, and titration of the excess cerium by means of potassium permanganate, according to the method of Lenher and C. Meloche. This method depends upon the equations

---

[17] Metzger, THIS JOURNAL, 31, 523 (1909).

[18] Lenher and C. Meloche, *ibid.*, **38**, 66 (1916).

$$6Ce(NO_3)_3 + 2KMnO_4 + 4H_2O = 4Ce(NO_3)_4 + 2Ce(OH)_4 + 2KNO_3 + 2MnO_2$$

and

$$Ce(NO_3)_4 + 4H_2O = Ce(OH)_4 + 4HNO_3$$

An excess of zinc oxide is added to take care of the nitric acid produced.

Before application of the permanganate titration to the indirect determination of fluoride, it was necessary to test the accuracy of the cerium determination. Table I contains a few typical results obtained by the direct titration of cerous nitrate solutions with permanganate. The titrations were made in the usual way in the presence of zinc oxide at a temperature of 80°. The addition of 0.5–1.0 g. of zinc sulfate to the solution aided materially in the coagulation of the precipitate. In this and in all subsequent work the concentration of stock solutions was carefully checked by weighing the residues resulting from the evaporation of measured volumes.

TABLE I

CeO_2 added, g.	CeO_2 calcd., g.	Vol. of sample, cc.	CeO_2 added, g.	CeO_2 calcd., g.	Vol. of sample, cc.
0.0302	0.0301	50	0.00152	0.00160	50
.0151	.0150	50	.00114	.00110	50
.0075	.0075	50	.00076	.00071	50
.0038	.0035	50	.00076	.00068	50
			.00076	.00065	50

An examination of data indicates that under optimum conditions an agreement of 0.0001 g. of CeO_2 may be expected. Since this represented a satisfactory value, the method was next applied to the estimation of excess Ce^{+++} in the fluoride titration.

The Indirect Titration of Fluorides—A neutral solution of sodium fluoride having a volume of about fifty cubic centimeters was treated with an excess of a known solution of cerous nitrate. The solution was then heated to about 80°, 0.5 g. of zinc oxide was added and the titration was made with $N/40$ potassium permanganate. Instead of titrating the solution to the first detectable change of color in the supernatant liquid, the precipitated MnO_2, CeF_3 and $Ce(OH)_4$ were removed by means of a Gooch crucible slightly before the equivalence point was reached. The filtrate was then reheated, a slight excess of zinc oxide was added and the titration with permanganate completed. Filtration was necessary at this point since it was discovered that otherwise an over-titration was obtained due to adsorption of MnO_4^- ion.

Using this method it was possible to detect quantities of fluoride ranging from 0.1 to 0.001 g. with an accuracy of about 0.0003 g. Characteristic results are given in Table II.

Although exhibiting a fair degree of accuracy, this procedure is rather cumbersome and difficult for one not familiar with it. The color and

TABLE II

.0108	.0108	50	.0072	.0072	100

extent of coagulation of the precipitate give some indication of the point at which filtration should be made, but this cannot usually be determined without two or three trials upon fluoride solutions of equal concentration. This necessitates the use of aliquots. It is important that the filtration be performed as close to the equivalence point as possible, since the error due to adsorption is then at a minimum. Ions such as phosphate and oxalate which precipitate cerium interfere with the determination. This includes hydroxyl ion since if the PH be greater than the value resulting from the buffering effect of ZnO, $Ce(OH)_3$ will be precipitated.

Direct Titration.—In the search for a better scheme of analysis it was decided to try adsorption indicators, hoping that a direct titration with cerium would be possible. Samples of fluoride were titrated with cerous nitrate at room temperature, using a variety of indicators. Among these two were discovered which exhibited a color change at the stoichiometric point: ampho magenta and diiodophenylsulfonephthalein. After trying various concentrations of the phenolsulfonephthalein, the end-point (from a reddish-brown to a yellow) was not thought to be sufficiently sharp to warrant further investigation.

Ampho Magenta as an Indicator.[19]—The ampho magenta in a concentration of 20 mg. to a liter was found to give a very satisfactory indication of the equivalence point at which it changed from a deep blue to a less intense purple. Results using this indicator are given in Table III.

[19] Ampho magenta was obtained from the National Aniline and Chemical Company and was described by them as made by diazotizing *p*-aminoethylacetanilide and coupling with 1,8-dihydroxynaphthalene-3,6-disulfonic acid.

The accuracy of this determination is seen to be about 0.0001 g. of sodium fluoride under the best conditions. Although more dilute solutions of magenta were tried, the end-point seemed most satisfactory at the concentration given. A very slight decrease in the sharpness of the color change was observed in the case of the smaller quantities of fluoride.

Methyl Red as an Indicator,—Kurtenacker and Jurenka[20] have recently published a procedure involving the use of methyl red as an indicator for the titration of fluorides with cerous nitrate. Samples of sodium fluoride were analyzed according to their procedure and very satisfactory results obtained. Titrations were made at a temperature of 80° *as* recommended. The results are given in Table IV.

TABLE IV

Stock solution $Ce(NO_3)_3$—10 cc. = 0.0401 g.

Using macroburet		Using microburet	
Stock solution NaF—10 cc. = 0.1502 g.		Stock solution NaF—10 *cc.* = 0.0015 g.	
NaF added, g.	NaF found, g.	NaF added, g.	NaF found, g.
0.1502	0.1505	0.00075	0.00071
.1502	.1500	.00075	.00071
.0300	.0297	.00030	.00044
0300	.0298	.00030	.00023
.0300	.0296	.00030	.00022

These results exhibit an accuracy of about 0.0001, with the microburet and 0.0004 g. with the macroburet. It will be noticed that the procedure is satisfactory for the detection of quantities of fluoride amounting to less than a milligram.

It was impossible to compare these values with those of Kurtenacker and Jurenka, since similar data were not published by them. Although claiming an ability to detect a few milligrams of fluorides, Kurtenacker and Jurenka reported difficulty in obtaining results in agreement with the theoretical values based upon the cerium content of the solution added in the titration. A deviation of as much as 4% was reported in some cases. Our results were not in agreement with these findings since no such discrepancy was observed.

The anomalous results obtained by Kurtenacker and Jurenka may possibly be explained in the following manner. The change of the methyl red at the end-point was apparently attributed by them to hydrolysis of the cerous nitrate, the nitric acid liberated causing a change of PH. In case the end-point is due to a change of PH, it would seem logical to run a blank titration in order to determine what excess of cerous nitrate was necessary to change the color of the indicator. When an aqueous solution of the indicator was titrated with the standard cerous nitrate solution, 2.5 cc. was required to change the color of the methyl red. No color change occurred under similar circumstances with the ampho ma-

---

[20] Kurtenacker and Jurenka, *Z. anal. Chem.*, 82,210 (1930).

genta. If, however, fluoride is present, the titration with cerous nitrate gives a color change with the indicator when an equivalent amount of cerous nitrate has been added to the fluoride. When quantities of cerous nitrate which were insufficient to convert the indicator to the acid form were titrated with a sodium fluoride solution, the color of the methyl red gradually changed from yellow to red and at the equivalence point the solution again became yellow. The addition of excess cerium or excess fluoride now caused a change, respectively, from yellow to red or from red to yellow. From this point on the end-point was reversible. Thus it seems likely that in the presence of Ce^{+++} ions, precipitated cerous fluoride preferentially adsorbs indicator and in the presence of fluoride ions, the cerous fluoride preferentially adsorbs fluoride.

No end-point was obtained in the presence of sulfate ion either in the case of the ampho magenta or in the case of the methyl red. Attempts at varying the P_H resulted either in the precipitation of cerous hydroxide or in a change of the color of the indicator. In addition to sulfate ions, in general, any ion such as phosphate or oxalate capable of precipitating cerium will interfere with the determination.

Summary

An indirect method and two direct methods for the volumetric estimation of fluorides with cerous nitrate are given. Neutral solutions must be used in all cases.

The indirect method consists of adding a known excess of cerous nitrate to a fluoride solution and determining the excess cerium by means of a back titration with permanganate. This method is not recommended because it is cumbersome and the chance for error is relatively large.

The direct methods involve the titration of neutral fluoride solutions with cerous nitrate using methyl red and ampho magenta as indicators. These methods are very satisfactory for ordinary quantities of fluoride. The methyl red seems to be slightly better in the case of the smaller samples. Explanation of the indicator change on the basis of adsorption seems plausible.

THE INTERACTION BETWEEN NITROGEN TRICHLORIDE AND NITRIC OXIDE AT −150°. III. INTERACTION OF NITRIC OXIDE AND CHLORINE AT −80 AND AT −150°

By William Albert Noyes

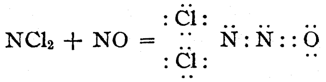
Received April 8, 1931 Published June 8, 1931

In the papers already published[1] it has been shown that at −80 and −150° nitric oxide reacts with nitrogen trichloride chiefly in accordance with the equations

$$\text{At } -80^\circ \qquad 2NO + NCl_3 = N_2O + NOCl + 2Cl$$
$$\text{At } -150^\circ \qquad 3NO + NCl_3 = N_2O + 2NOCl + Cl$$

The difference in conduct of the compounds at the two temperatures was explained by assuming that the primary reactions, in both cases, are expressed by the equations

$$NO + NCl_3 = NOCl + NCl_2$$



$$NCl_2 + NO = \begin{matrix} :\ddot{Cl}: \\ \because \\ :\underset{\cdot\cdot}{\ddot{Cl}}: \end{matrix}\ \ddot{N}:\ddot{N}::\underset{\cdot\cdot}{\ddot{O}}$$

The difference in conduct at the two temperatures was explained in the second paper by assuming that the dichlorodinitrogen oxide formed in the second reaction is so unstable at −80° that it decomposes at once to nitrous oxide and chlorine, while at −150° it is sufficiently stable to yield a second atom of chlorine to the nitric oxide before it decomposes. It was also assumed that nitric oxide reacts more rapidly with dichlorodinitrogen oxide than it does with chlorine at −150°.

As it has not been possible to isolate either of the intermediate products, nitrogen dichloride and dichlorodinitrogen oxide, it has seemed desirable to obtain further evidence for their existence. This has been accomplished in three ways: by studying the reaction between chlorine and nitric oxide at −80, −150 and −180°; by using purified carbon tetrachloride instead of the mixture of chloroform and carbon tetrachloride as the solvent for the nitrogen trichloride; and by an improved technique in carrying out the reaction and in separating the products formed.

Chlorine and Nitric Oxide at −80, −150 and −180°.—Eight to ten grams of carbon tetrachloride was frozen on the inner wall of the bulb shown in Fig. 2 of the last paper.[2] After immersing the bulb in liquid air, from 0.4 to 1.4 g. of chlorine was introduced through the long capillary tube of a small bulb in which it was weighed. The chlorine condensed and froze on the surface of the carbon tetrachloride. In the experiments at −80° the chlorine liquefied and ran to the bottom of the bulb when it

---

[2] Noyes, *ibid.*, 52, 4299 (1930).

was warmed to that temperature or during the reaction with nitric oxide. In all experiments an excess of chlorine was used. In the first experiments the nitric oxide was completely converted to nitrosyl chloride within a few hours. In later experiments a rough determination of the rate of combination was made.

At —80°, 1.403 g. of chlorine (39.5 mg.-atoms) and 36.3 mg.-moles of nitric oxide were used. After thirty-three minutes from the beginning of the introduction of the nitric oxide only 7% of the latter was recovered uncombined.

At —150°, 1.402 g. of chlorine (39.5 mg.-atoms) and 35 mg.-moles of nitric oxide were used. In thirty-five minutes from the beginning of the introduction of the nitric oxide, 81% of the gas was recovered uncombined.

At —180°, 20.9 mg.-atoms of chlorine was frozen on the walls of the bulb without the use of carbon tetrachloride. After an hour and a half 67% of the nitric oxide was recovered uncombined. As some combination doubtless took place during the fractional distillation carried through the U-tubes to separate the nitric oxide from the chlorine and nitrosyl chloride, the combination which had occurred at —180° must have been less than 33% in one hour and a half.

Because of the difference in the physical conditions at —80 and at —150°, the results give only a rough approximation as to the rates of reaction at these two temperatures but the experiments show conclusively that nitric oxide and chlorine combine much more rapidly at —80 **than** at —150°.

To secure further evidence for the course of the reaction, thirteen new experiments have been carried out at —150° and nine at —80°, using carbon tetrachloride as the solvent for the nitrogen trichloride.

At the close of the reaction the bulb in which it was carried out contained six or seven substances: nitrogen, which boils at —196°; nitric oxide, which boils at —150.3'; nitrous oxide, which boils at —89.4'; chlorine, which boils at —33.6'; nitrosyl chloride, which boils at —5.4'; nitrogen trichloride, which distils easily with carbon tetrachloride; and carbon tetrachloride, which boils at 76.8°.

It has been found advisable to carry out the operations in such a manner that by using an excess of nitrogen trichloride and waiting until the reaction is complete before distilling the products, no nitric oxide is left in the mixture to be distilled.

The U-tube, H,[2] which was connected to the set of U-tubes by rubber tubing in the experiments previously described, was replaced by a smaller U-tube sealed to the end of the system. This had a capacity of 18 cc. and was connected to a manometer, drying towers and a mechanical pump. When the system was exhausted and the connection between the drying towers and the pump was closed, on allowing the air in the

U-tube to pass into the system four times the manometer rose 30 mm. Hence 1 mm. on the manometer corresponded to 2.4 cc. of air. By allowing the nitrogen present at the end of an experiment to pass through the U-tube, immersed in liquid air to remove other gases, the rise of the manometer gave a rough determination of the amount of nitrogen present. This was always small in satisfactory experiments. It may have been present in the nitric oxide used or may have been formed by the decomposition of a little of the nitrogen trichloride.

The distillation of the other substances through the series of U-tubes is best carried out in a rather high vacuum and many tedious experiments have been tried and many analyses of products have been made to secure a quantitative determination of the course of the reactions.

In carrying out the separation the reaction bulb was at first surrounded with carbon dioxide snow in acetone while most of the nitrous oxide distilled into the first U-tube surrounded with liquid air. The nitrous oxide was then distilled to the second tube, also surrounded with liquid air. The liquid air was replaced around the first U-tube and an acetone bath at $-50°$ placed around the reaction bulb. After a time the liquid air around the first U-tube was transferred to the third, the nitrous oxide in the second allowed to distil into that and the carbon dioxide–acetone mixture placed around the first tube. When a considerable part of the chlorine and nitrosyl chloride had distilled into the first U-tube, the reaction bulb was allowed to warm up slowly and the distillation of the chlorine and nitrosyl chloride continued till the latter was completely removed from the bulb as shown by the disappearance of the red color. The connection between the reaction bulb and the U-tubes was then closed and the nitrogen trichloride remaining in the former was later determined by methods which have been described. A little of the trichloride which distilled into the U-tubes with some carbon tetrachloride was unavoidably lost.

By distilling the nitrous oxide rather rapidly through the six U-tubes, using two Dewar cylinders containing liquid air, one with carbon dioxide snow and acetone and one with acetone at $-50°$, it was possible to bring the nitrous oxide into the last, 18-cc. U-tube, with only a little chlorine and nitrosyl chloride. By allowing this gas to evaporate into an empty bottle connected with a second bottle containing water, the water displaced from the latter gave a means of determining the number of moles of gas which had been condensed. The chlorine and nitrosyl chloride were absorbed in dilute sodium hydroxide. By determining the amounts of chlorine and nitrogen in aliquot portions of the solution the number of moles of each could be calculated. By subtracting the sum of these from the total moles of gas the moles of nitrous oxide were given.

In the experiments with chlorine and nitric oxide, it was necessary to use two empty bottles between the 18-cc. U-tube and the bottle of water because the heat of the reaction between the nitric oxide and the oxygen of the air caused the nitrogen dioxide and tetroxide formed to mix with the air of the first bottle. The mixture, cooled as it passed into the second bottle, remained in the lower part of that, displacing only air to the bottle containing water.

After removing the nitrous oxide as described above, the residue of chlorine, nitrosyl chloride and carbon tetrachloride was distilled back to the first two U-tubes and the fractionation was repeated to concentrate the chlorine and nitrosyl chloride in the 18-cc. tube with only a little of the carbon tetrachloride. From this the two were distilled into a solution of sodium hydroxide and the chlorine and nitrogen were determined in the latter. The following reports of two experiments illustrate the degree of separation sometimes secured. The results are given in mg.-atoms and moles.

DEGREE OF SEPARATION OF SUBSTANCES PRESENT AFTER REACTION

Temp., −80". **Initial** mg.-moles NCl_3, 13.6; **NO,** 23.3

	N_2O fraction	NOCl fraction	NCl_3 fraction	Total
N_2O **recovered** (mg.-moles)	8.1	..	...	8.1
Cl recovered (mg.-atoms)	2.2	12.5	1.1	15.8
NOCl **recovered** (mg.-moles)	0.6	12.5	...	13.1
NCl_3 **recovered** (mg.-moles)	...	..	2.9	2.9

Temp., −150°. Initial mg.-moles NCl_3, 18.4; **NO,** 35.3

	N fraction	N_2O fraction	NOCl fraction	NCl_3 fraction	Total
N (mg.-atoms)	1.6	...	...	...	1.6
N_2O	...	9.6	...	...	9.6
Cl	...	1.0	8.7	1.4	11.1
NOCl	...	0.3	21.8	...	22.1
NCl_3	...	...	...	7.2	7.2

Two experiments at −80° and three at −150° have been selected for the final report. The results were as follows.

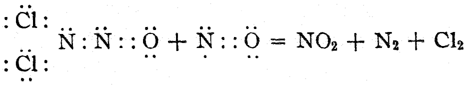
MOLECULAR AND ATOMIC RATIOS BETWEEN NITROGEN TRICKLORIDE, NITRIC OXIDE AND THE REACTION PRODUCTS

t, °C.	NCl_3	NO	N	N_2O	NOCl	Cl
− 80	1	2.18	...	0.76	1.48	1.23
− 80	1	2.49	0.2	.86	1.57	1.25
−150	1	3.15	.15	.86	1.97	0.99
−150	1	3.38	.20	.82	2.20	.67
−150	1	3.59	.05	.85	2.39	.61

A further explanation of these results will be given later.

In one experiment at −150°, a slight leakage of air caused the formation of some blue nitrogen trioxide, N_2O_3. This evidently reacted later with chlorine, forming nitrogen tetroxide and dioxide, N_2O_4 and NO_2. These were separated quite completely by fractional distillation through the

U-tubes. This result made it seem possible that dichlorodinitrogen chloride may react with nitric oxide to form nitrogen dioxide, nitrogen and chlorine



$$\overset{:\ddot{\mathrm{Cl}}:}{\underset{:\ddot{\mathrm{Cl}}:}{\ddot{\mathrm{N}}:\ddot{\mathrm{N}}::\ddot{\mathrm{O}}}} + \ddot{\mathrm{N}}::\ddot{\mathrm{O}} = \mathrm{NO_2} + \mathrm{N_2} + \mathrm{Cl_2}$$

To test this possibility, three experiments ware carried through at −150° and 9 g. of the mixture of nitrosyl chloride and chlorine obtained was carefully fractionated for the presence of nitrogen dioxide. The ratio of nitrogen to chlorine in the last portion was 1:0.985 The amount of nitrogen dioxide present, if any, must have been very small.

Structure of Nitrous Oxide.—In the first paper[1] the electronic formula, $:\mathrm{N}:::\overset{+}{\mathrm{N}}:\ddot{\mathrm{O}}:^{-}$, was proposed as probable. R. Mecke[3] and C. P. Snow[4] think that a linear formula with the oxygen between the two nitrogen atoms is indicated strongly by the infra-red spectra and the fact that the molecule has no electrical moment or only a very small one. In addition to the reasons given in the first paper, four facts about the chemical conduct of nitrogen seem inconsistent with such a formula.

(1) Nitrogen trioxide, N_2O_3, nitrogen tetroxide, N_2O_4, and nitrogen pentoxide, N_2O_5, in which nitrogen atoms are held together by oxygen atoms, dissociate very easily, nitrogen trioxide almost completely, below zero.

(2) Lochte, Noyes and Bailey[6] have shown that a double covalence between two nitrogen atoms in 2,2′-azobispropane, $(CH_3)_2CH:N::N:CH(CH_3)_2$, is much more stable than a double covalence between carbon and nitrogen in the isopropyl hydrazone of acetone, $(CH_3)_2CH:NH:N::C(CH_3)_2$. The stability of nitrous oxide, which dissociates only slightly even at 500°,[6] also points very strongly toward a union between the nitrogen atoms rather than to one between nitrogen and oxygen

(3) The electronic structure of N—O—N should be, in accordance with the rules for shared electrons,[7] $:\ddot{\mathrm{N}}:\ddot{\mathrm{O}}:\ddot{\mathrm{N}}:$. K. F. Schmidt[8] has assumed a compound of similar structure, $:\ddot{\mathrm{N}}:\mathrm{H}$, as an intermediate in many reactions of hydrazoic acid, N_3H, but it is so reactive that it has not been isolated. If nitrous oxide has the structure suggested, it should also be very reactive. The comparative indifference of carbon monoxide weakens this argument, however.

---

[3] R. Mecke, *Z. Physik.*, 64, 173 (1930). A little earlier, Z. *physik. Chem.*, [B] 7, 114 (1930), he suggested the formula N≡N=O, for chemical reasons.

[4] C. P. Snow, *Proc. Roy. Soc.* (London), [A]128,294 (1930).

[5] Lochte, Noyes and Bailey, THIS JOURNAL, 44,2557 (1922).

[6] Berthelot, *Compt. rend.*, 77,1448 (1874).

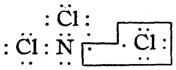
[7] Noyes, *Z. physik. Chem.*, 130,323 (1927)

[8] K. F. Schmidt, *Ber.*, 57,704 (1924).

(4) The formula N—O—N implies that both the trivalent nitrogen of the nitrogen trichloride and the bivalent nitrogen of nitric oxide have been changed to univalent nitrogen. Both chlorine and nitrogen trichloride are powerful oxidizing agents and such a result seems very improbable. The electronic formula of these papers represents one of the nitrogen atoms of nitrous oxide as trivalent and the other as quinquevalent. The quinquevalent nitrogen atom has one polar valence. This seems to be true of all quadrivalent or quinquevalent nitrogen atoms. This is clearly recognized for ammonium salts by everyone who does not claim that polar valences are not true valences. The parachors show that it is also true for nitro compounds, nitric acid, etc., which have a semipolar oxygen atom.

The discrepancy between the interpretations of the chemical and the physical evidence for the structure of nitrous oxide should lead us to hold our minds open for the present. Possibly some form of the old formula, which is, electronically,  $\underset{:\dot{O}:}{:N::N:}$, may reconcile the two views.

R. G. W. Norrish[9] has recently found a photochemical reaction between nitrogen trichloride and chlorine which he explains by assuming that nitrogen dichloride is formed. The action of light on chlorine splits it into neutral atoms having odd electrons. Heat alone has the same effect at high temperatures:



Norrish's work offers very welcome support for the explanations offered in these papers.

Small losses of nitrogen, oxygen and chlorine were observed in nearly all experiments. Whether this was merely due to errors in the difficult and complicated technique involved or whether it may be due to other reactions or other compounds which have not been discovered is worthy of careful consideration by other experimenters who may find better methods of approach to the problem. It is not the intention of the author to continue the experiments further at the present time.

Summary

1. It has been shown that in the presence of carbon tetrachloride, nitric oxide and chlorine combine rather rapidly at $-80°$, much more slowly at $-150°$ and, in the absence of any solvent, very slowly at $-180°$.

2. By means of experiments with a solution of nitrogen trichloride in carbon tetrachloride, further evidence has been obtained in support of the hypothesis that the primary reaction with nitric oxide gives nitrosyl

---

[9] J G. A. Griffiths and R. G. W. Norrish, *Proc. Roy. Soc. (London)*, **A130**, 608 (1931).

chloride and nitrogen dichloride; that the dichloride combines with nitric oxide to form dichlorodinitrogen oxide; that this compound decomposes very rapidly at –80° but that it is sufficiently stable at –150° to yield a second chlorine atom to nitric oxide before it decomposes; and that this reaction is much more rapid than the combination of nitric oxide and chlorine at that temperature.

3. The rather rapid combination of nitric oxide with chlorine at –80° explains the excess of nitric oxide used and the excess of nitrosyl chloride found as compared with those required by the equation given. It also explains the deficiency of chlorine. The excess of nitric oxide and nitrosyl chloride and deficiency of chlorine at –150° may be explained in the same way or by supposing a further reaction of nitric oxide with a hypothetical monochlorodinitrogenoxide.

4. No satisfactory evidence was obtained that nitrogen dioxide is formed in the reactions studied.

HEIDELBERG, GERMANY

THE POSSIBILITY OF BIMOLECULAR ASSOCIATION REACTIONS

BY LOUIS S. KASSEL

RECEIVED APRIL 9, 1931 PUBLISHED JUNE 8, 1931

It seems to have been first pointed out by Herzfeld[1] that the recombination of atoms to form a diatomic molecule could not be a bimolecular process, but must occur either on the walls or at triple collisions; Herzfeld calculated the mean life of the molecules which could result from simple collisions and obtained values of the order of 10^{-12} sec.; such a time is scarcely greater than the rather indefinite duration of a collision, which has, of course, exact meaning only after an arbitrary definition has been given. The details of this calculation might be changed slightly if it were to be repeated in the light of more recent knowledge, but the result would surely be unchanged. Furthermore, there is a considerable body of experimental material, all of which shows that diatomic molecules are not ordinarily formed at binary collisions.

There has been some tendency to generalize this statement and say that no bimolecular association reaction is possible, or at least that it will occur with only a negligible rate.[2] Now it is certainly true that bimolecular association reactions can occur, because this process is the reverse of unimolecular decomposition, and there are known some dozen reactions which are of this type, beyond any reasonable doubt. Such an argument

---

[1] Herzfeld, Z. *Physik*, 8, 132 (1922).

[2] This view has been frequently expressed by H. S. Taylor and recently by Taylor and Emeléus, THIS JOURNAL, 53, 562 (1931). It has been held by numerous other workers also.

has been, and still remains, of a rather academic character, because of the known unimolecular reactions not one leads to a measurable equilibrium at the temperatures of the rate measurements; it is true that the dissociation of nitrogen tetroxide is very probably a unimolecular reaction, but this hypothesis does not have a shred of experimental evidence to support it. The study of polymerization processes in hydrocarbon vapors which has been made at Princeton during the last few years is making association reactions accessible to reaction-rate studies; fairly recently Pease[3] has presented rather definite evidence that under suitable circumstances the polymerization of ethylene is a second order reaction. The question whether such a reaction can have a true bimolecular mechanism thus becomes of real interest. It will be shown in the present paper that such a mechanism is perfectly possible, at least on general theoretical grounds.

From a practical consideration the reason why a diatomic molecule cannot be formed at a binary collision is that the energy of the reaction, which is necessarily greater than the heat of dissociation, cannot be removed from the molecule's only bond. For although it may possibly be emitted as radiation, or stored either as electronic or as rotational energy, detailed analysis shows that the probability of any of these occurrences is very small; hence, except at a minute fraction of all collisions, the molecule formed must dissociate immediately. That is to say, if a diatomic molecule has enough energy to dissociate, it will do so at once; there is, in the reverse case, no time lag between activation and reaction. Since it is upon the existence of such a time lag that the possibility of unimolecular reaction rests, we know experimentally that for more complex molecules there is such a time lag. The order of magnitude of this lag can be computed from experimental data without reference to any detailed theory of unimolecular reaction, because in any case it must be, on the average, not much different from the mean free time at pressures such that the reaction is just beginning to deviate from a first order course. In most cases, the time lags found in this way are of the order of 10^{-9} to 10^{-7} sec. A complex molecule, once formed at a binary collision, may then be stabilized at any subsequent collision within this period; the stabilizing molecule may thus have been, in some cases, as much as 0.01 cm. distant at the instant of formation of the complex; such a process can hardly be considered a triple collision.

We must next consider the second objection to such a process; this is that in the large majority of binary collisions no complex can be formed because of quantum restrictions. This objection also seems to disappear upon analysis. The restrictions which have to be considered are the conservation of energy, of momentum and of angular momentum, to-

---

[3] Pease, THIS JOURNAL, 52, 1158 (1930); 53, 613 (1931).

gether with the quantization of rotation and of vibration. It has already been shown by Beutler and Rabinowitsch[4] that the quantum mechanical uncertainty principle completely destroys the restriction based on the conservation of angular momentum and the quantization of rotation This principle will at the same time relax somewhat the restriction arising from conservation of momentum, though it is not clear just how this is to be treated. There remains to be considered the possibility of satisfying at once the conservation of energy and the vibrational quantum conditions. Now it must be remembered that the quantum states in which we are interested are not real stationary states, because they have finite mean lives; this has the important result that they do not possess sharply defined energy; the relation between the mean life and the vagueness in the energy is given by the well-known equation

$$\tau = h/\Delta E \tag{1}$$

There will thus be a finite chance that the energy available for the vibrational degrees of freedom will lie within some quantum state. It is important to try to form some estimate of the actual magnitude of this chance, and to do this we need to know how closely the vibrational states are spaced. Consider a molecule with s vibrational degrees of freedom and a total of n quanta of energy distributed among them. If all of the associated frequencies are different, then each distribution will have a different total energy; it is well known that the number of such distributions is

$$\frac{(n + s - 1)!}{n!\,(s - 1)!} \tag{2}$$

Now, since the various frequencies are all different, there will not be any simple relation between the total energy of a distribution and the number of quanta which it involves; that is, there will be pairs of states such that the one with more quanta has less energy. Nevertheless, it seems that no great error will be made in taking the total number of distributions whose energy is between that of n and $n + 1$ mean quanta as given by (2). Numerical tests in several cases, for moderate values of n and s, always gave divergences in the direction of slightly greater numbers than predicted by (2). By using (2) in connection with an estimated (or assumed) mean quantum for the molecule concerned, we are able to calculate the average spacing between energy levels; this may be combined with the average width of energy levels to give the fraction of energy values within a given range which correspond to a quantum state. We shall proceed to make such calculations.

The most satisfactory energy unit for these purposes is the reciprocal second—that is, the energy of the quantum with unit frequency; this value is equal to 6.55×10^{-27} ergs, or about 10^{-10} cal./mole. Suppose

---

[4] Beutler and Rabinowitsch, *Z. physik. Chem.*, 8B, 231 (1930).

that the heat of reaction plus the heat of activation is 10^{15} sec.$^{-1}$, or about 100,000 cal./mole. If we take the rather large value of 10^{14} sec.$^{-1}$ for the mean energy of a vibrational quantum, we will then have $n = 10$; the value will in most cases be rather larger than this, but we purposely begin with an unfavorable case. The value to be used for s is $3(m - 2)$, where m is the number of atoms in the molecule being formed; to allow for the fact that all of the vibrational states may not have different frequencies, we take a somewhat smaller value; thus a molecule with 10 atoms might have $s = 24$; we shall make the calculations for $s = 6$. 8 and 10. Taking $s = 6$, we see by (2) that the number of different energy levels with 10 quanta will be $15!/5! \times 10! = 3003$; these states are within an energy range of 10^{14} sec.$^{-1}$, so that the mean distance between adjacent states is 3×10^{10} sec.$^{-1}$; this is rather larger than the width of a level, and under such circumstances only a small fraction of all collisions could result in reaction. With $s = 8$, however, we find a mean spacing of 5×10^{9} sec.$^{-1}$, and with $s = 10$ we get 10^{9} sec.$^{-1}$. If we use instead of $n = 10$ the more likely value $n = 15$, and keep $s = 10$, we find for the mean spacing a value 8×10^{7} sec.$^{-1}$. If we push the values of n and s anywhere near the upper limits of plausibility, we obtain values for the mean distance between levels much less than the mean width of a level as determined from the time lag. It is thus possible that in some cases any energy value will correspond to some quantum state, while in other cases the chance for such a correspondence may be 0.1, 0.01 or even less. As a general rule, we should expect that the chance for correspondence would increase with the complexity of the molecule being formed, though the influence of specific factors will probably be a great one. This calculation tells us nothing, of course, about the efficiency with which reaction will occur even when all the energy and quantum conditions are satisfied.

We may consider in a little more detail the application of these ideas to Pease's work on ethylene polymerization. This reaction is second order between 2.5 and 10 atm.; at 1 atm. there is some evidence for a rate less than that predicted by the second order equation. The energy of activation determined from the temperature coefficient is given by Pease as 35,000 cal.; when this value is used in the simple expression $Ze^{-E/RT}$ to calculate the reaction rate, a value is found about 2000 times that observed. Pease interprets this as meaning that only in $^1/_{2000}$ of the collisions can the energy **and** quantum conditions be satisfied. He gives also an interpretation suggested by Taylor; this is that every collision which supplies the necessary reaction energy leads to formation of an unstable complex which either dissociates spontaneously, or survives until it colloids with a molecule of ethylene, whereupon it may be stabilized or may be destroyed; if the odds in favor of destruction are 2000:1, this mechanism gives a reaction which will be second order at high pressure, but will deviate when the pressure is low enough, and will give the correct absolute rate. The interpretation which the present writer would suggest is of an intermediate nature. There does not seem to be sufficient evidence to decide how the low efficiency is apportioned between a low yield for the formation of the dissociable complex and a low yield for the stabilization process; if the formation of the complex has a low yield, however, this need not necessarily be blamed on the necessity of satisfying a quantum condition, as Pease has suggested; in the decomposition of nitrogen dioxide, a bimolecular reaction which is not an association, the rate is only about $^1/_{200}$ of that calculated in the usual way from the activation energy and recent work by Hartel and Polanyi[5] furnishes other examples of low efficiencies. We thus suppose that collisions which are able to supply the necessary activation energy result, with an unknown efficiency, in formation of a complex which is capable of spontaneous dissociation; this complex may, however, be stabilized by collision with a molecule of ethylene; here again the process may not be 100% efficient; the product of the two efficiencies is about $^1/_{2000}$. The experiments do not supply any evidence in favor of a specific effect of ethylene in stabilization; it is quite probable, however, that ethylene and the reaction product, butene, are more efficient than inert gases, because in almost all unimolecular reactions it has been found that the reacting substance and its decomposition products are more effective in maintaining the rate than are indifferent gases; this means, of course, that the efficiency of energy transfer at collision is greater. If the second order reaction rate falls off at a pressure as high as one atmosphere in this case, then the mean time lag between formation of a complex and its dissociation is about 3×10^{-10} sec., and the mean width of a quantum state 3×10^9 sec.$^{-1}$. With a value this large, it should be easy for the energy and quantum conditions to be satisfied. The distance of the stabilizing molecule at the instant of formation of the complex would then be rather smaller than usual, about 10^{-5} cm. Even in this case, however, it would seem an exaggeration to speak of the event as a triple collision.

Summary

Calculations have been presented to show that the formation of complex molecules by a bimolecular association process should be possible at a considerable fraction of all collisions so far as the conservation laws and the quantum conditions are concerned. The polymerization of ethylene appears to be an example of such a reaction.

THE ANHYDROUS LOWER BROMIDES OF ZIRCONIUM

BY RALPH C. YOUNG

RECEIVED APRIL 23, 1931 PUBLISHED JUNE 8, 1931

The present paper is the second[1] of a series dealing with a general study of the lower anhydrous bromides of the elements of the titanium family, and considers the preparation and properties of the lower bromides of zirconium.

The lower chlorides of zirconium were prepared by Ruff and Wallstein,[2] who allowed aluminum powder to react with zirconium tetrachloride in an evacuated tube in the presence of aluminum chloride as a catalyst. On account of the oxide of aluminum in the powder and because of the method of introducing the reactants into the reaction tube, resulting in hydrolysis, the product obtained by Ruff and Wallstein after sublimation of the unchanged zirconium tetrachloride and aluminum chloride was inevitably rendered impure by aluminum oxide and zirconium oxide.

In order to prevent hydrolysis and oxidation as far as possible, it was planned to prepare the bromides by a method which would enable one to obtain the product without the necessity of transfer from one apparatus to another and also by a method which would not require the placing of the reactants in that part of the apparatus in which the products would be collected

The general procedure adopted for the preparation of zirconium tribromide consisted essentially of the passing of zirconium tetrabromide with hydrogen over aluminum metal (wire) in a hot tube and of quickly chilling the volatile products of the reaction upon a tube kept cold by a current of water. The apparatus was so devised that the products could then be transferred in the presence of an inert gas to a tube joined to the reaction tube and the *former* tube could then be drawn nut and sealed. The procedure and results in detail are described below, after a consideration of the preparation and degree of purity of the zirconium tetrabromide used.

Zirconium tetrabromide was prepared from zirconium dioxide which had been shown by analysis to be free from impurities other than hafnium. Nitrogen saturated with bromine was allowed to pass through a 30-mm. Pyrex tube filled with an intimate mixture of four parts of dry sugar charcoal to one of dry zirconium dioxide, the tube being heated in a combustion furnace to the temperature at which the glass begins to soften. The zirconium tetrabromide sublimed and was collected at the end of the

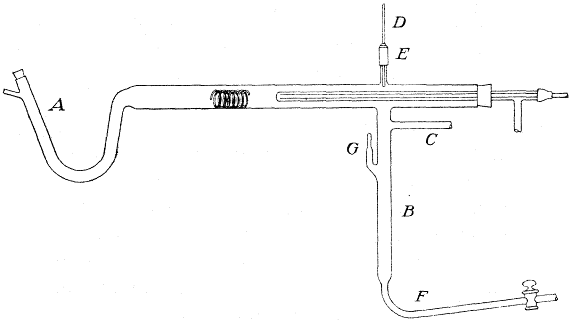
tube. The crude material was purified by sublimation in *vacuo,* the white product obtained was analyzed for zirconium by the selenious acid method, and found to be pure. The bromine was determined separately as silver bromide.

Anal. Calcd. for $ZrBr_4$: Zr, **22.20;** Br, 77.79. Pound: Zr, **22.30,** 22.33; Br, 77.68, 77.76.

Preparation of **Zirconium Tribromide.**—Referring to Fig. 1, at A, 30 g. of zirconium tetrabromide was introduced into the curved 22-mm. Pyrex tube which had been sealed directly to the larger (28 mm.) horizontal Pyrex tube. A current (about 200 cc. per min.) of dry, oxygen-free hydrogen was passed through the apparatus which, after the air had been displaced, was heated in a hinged-type electric furnace until the temperature of the furnace measured a minimum of 450°. Then the zirconium tetrabromide was slowly volatilized by means of a free flame and as it passed with the hydrogen through the furnace reacted in part with aluminum wire placed in the tube so that the wire would be in the center of the furnace. The wire consisted of four concentric coils, each coil 5 cm. long, of No. 18 wire, the diameter of the largest coil being 18 mm. The total weight of aluminum was 14 g. The cooling tube through which the water circulated was 9 mm. in diameter and extended to within approximately one inch of the wire. It was noted that satisfactory results were obtained only when this distance was carefully observed. A black to blue mass collected on the cold tube. Some of the aluminum bromide formed was carried by the hydrogen into the tube B and out the smaller tube C. The metal at the end farthest from the cold tube became incandescent during the reaction. Some of the zirconium tetrabromide was reduced to zirconium metal which alloyed with the aluminum.



Pig. 1.—Apparatus for the preparation of zirconium tribromide.

After all the zirconium tetrabromide had been volatilized in about one-half to three-quarter hour, the furnace was cooled to room temperature and dry carbon dioxide was substituted for the hydrogen. Tube C was closed and the cooling tube was partially withdrawn through the cork stopper. Part of the product usually clung to the tube, and sometimes it was necessary to use the glass rod D, which could be worked up and down in the tube E, to dislodge it and break the large pieces into smaller ones which would be able to enter tube B. Thick-walled rubber tubing connecting the apparatus with the drying train allowed the apparatus to be tipped so that all the product could be made to enter B, after which it was sealed just below side tube C.

The contents of the tube were now shaken to the end opposite the stopcock and the tube containing aluminum bromide, zirconium tetrabromide and reduced product was placed in a furnace and evacuated while being heated. About 6 cm. of the large tube was allowed to protrude beyond the furnace and after the temperature had reached approximately 140°, the aluminum bromide began to condense in the cold end. After the temperature had reached 200° the tube was sealed at F and the temperature raised to 290° and held there while the tube was gradually withdrawn from the furnace so that the zirconium tetrabromide which collected in the tube at the end of the furnace would not cause the tube to crack. It was noticed that a blue color always developed where aluminum bromide was in contact with zirconium tetrabromide.

Heating at 290° was continued until no more sublimate formed in the tube just outside of the furnace. In determining this fact, the tube was withdrawn from the furnace a distance of 1 cm., thus presenting a clear and transparent surface. If at the end of fifteen minutes a coating of zirconium tetrabromide formed, the tube was pushed back 1 cm., thus causing the compound to be volatilized forward and after thirty minutes a second test was made as before. About sixteen hours were required for the complete removal of the aluminum bromide and zirconium tetrabromide.

After the volatile products had been sublimed to the cold end of the tube, the furnace was allowed to cool to room temperature and the small tube G was connected by means of thick-walled tubing to a source of dry nitrogen and the narrow part of the tube *G* was broken thus allowing the gas to enter. The large tube was then sealed just beyond tube G and then tube G also was sealed. The sample now was in a sealed tube in an atmosphere of nitrogen and appeared as a blue-black powder. Crystalline form could not be distinguished with a magnification of 300 diameters.

The tube was filed at the tip, weighed, the tip was broken and the sample weighing approximately 0.5 g. introduced at once into ice water. The reaction was vigorous; a yellow to orange solution was formed, hydrogen was evolved and the color faded and disappeared completely in about five minutes. The solution was filtered and the gray to black residue was ignited. Dilute ammonium hydroxide solution was added to the filtrate and the precipitated hydrous oxide of zirconium was also ignited. The bromide contained in the filtrate from this precipitate was determined as silver bromide. The results of careful investigation showed that the dark insoluble matter amounting to as much as 5% of the sample (which after ignition proved to be zirconium dioxide) could be accounted for by the presence of a small amount of zirconium metal and of zirconium dibromide in the original reaction product. It was found that zirconium dibromide. the preparation of which will be given later, reacts so violently with water even at 0° that some zirconium dioxide is produced directly. The fact that, in the analysis, the zirconium was higher than the theoretical for zirconium tribromide and the bromine lower indicated that zirconium dibromide was present and the fact that the insoluble matter was dark showed the presence of zirconium metal.

To avoid the presence of zirconium metal and zirconium dibromide in the sample, the following procedure was adopted. In the preparation of the tribromide a great excess of the tetrabromide was allowed to accumulate in the product; the usual proportion would be 25 g of zirconium tetrabromide to 0.5 to 1.0 g. of the reduced material The tube with contents after being evacuated as described above was sealed and heated for eight hours at 300° in the center of a long electric sleeve with the view of converting any zirconium metal and zirconium dibromide to the tribromide.

$$3ZrBr_4 + Zr \longrightarrow 4ZrBr_3$$
$$ZrBr_4 + ZrBr_2 \longrightarrow 2ZrBr_3$$

Tests had been carried out to show that the first of these reactions **will take** place and it had been shown previously that the second reaction proceeds in the case of the titanium bromides.

After the eight hours' heating at 300°, the aluminum bromide and unchanged zirconium tetrabromide were sublimed away from the reduced product and the resulting sample was analyzed as described. The water insoluble matter now amounted to only a milligram in a 0.2-g. sample, the solution being clear and transparent.

Anal. Calcd. for $ZrBr_3$: Zr, 27 55; Br, 72.45. Found: Zr, 27.79, 27.77; Br, 72.35, 72.27.

The zirconium tribromide with the dibromide and metal eliminated appeared as a blue-black powder similar in color to the tribromide of titanium. When subjected to a slight amount of hydrolysis it took on a brown appearance and upon further hydrolysis turned red.[3] It dissolved in water to give a yellow to orange colored solution which was acid to litmus and evolved hydrogen. The color faded quickly. On the addition of the compound to a cold dilute solution of ammonium hydroxide, an orange precipitate was formed which persisted only momentarily.

In the formation of a 0.5-g. sample of the tribromide, **3** to 5 g. of aluminum hromide was obtained; the aluminum metal gained in weight slightly due to the substitution of some zirconium metal for the aluminum. Larger yields of the tribromide were obtained by volatilizing the tetrabromide more slowly. The production of 1 g. was the maximum obtained in one hour.

As a test of its reducing power small samples were added to the following dilute solutions arranged in order of increasing difficulty of reduction: sodium chromate, ferric chloride, bismuth chloride, copper chloride, titanium tetrabromide, stannous chloride and zinc sulfate. The change from yellow to green in the first case showed that chromium had been reduced from valence 6 to valence **3.** A blue precipitate formed on the addition of potassium ferrocyanide in the second test solution proved that ferric iron had been reduced to ferrous. Metallic bismuth was obtained in the third test; a precipitate of cuprous chloride in the fourth. A violet color formed in the test with titanium bromide indicated reduction to trivalent titanium. Negative results were obtained with stannous chloride and zinc sulfate. Since zirconium tribromide caused the evolution of hydrogen from water—due to hydrolysis, the solution is acid—the molal reduction potential of Zr^{+++}/Zr^{++++} can be approximately placed as above that of hydrogen but below that of tin.

Other reducing substances were tried in place of aluminum in the preparation of zirconium tribromide. Iron wire reacted with the zirconium tetrabromide to produce the lower bromides and ferrous bromide.

---

[3] Ruff and Wallenstein[2] describe the trichloride of zirconium as brown in color Inasmuch as the tribromide and trichloride of titanium and the tribromide of zirconium have all been found to be blue-black in color, it seems possible that the brown color of the trichloride of zirconium prepared by these authors was due to partial hydrolysis.

The product, however, was freed from the latter with great difficulty. An alloy of zirconium and aluminum was successfully used. Magnesium metal produced a much larger percentage of the dibromide than did aluminum.

Zirconium tetrabromide is insoluble in carbon tetrachloride, benzene, and ethyl bromide and the metals mercury, aluminum, and silver caused no reducing action, when added to the tetrabromide in the presence of these liquids, even when heated to the boiling point of the liquid. In solvents in which the salt did dissolve, such as glacial acetic acid, acetic anhydride, and acetone there was no indication of any tribromide formation by the reducing action of the metals given above.

Considerable effort was made to reduce zirconium tetrabromide with hydrogen alone by use of the hot–cold tube principle and a resistance-wound silica tube as the reaction tube, which was heated to 1100°. No evidence of reduced product was obtained, nor did any reaction occur when the tube was heated to such a temperature that the silica softened in spots.

Zirconium Dibromide.—The preparation of the dibromide of zirconium involved heating the tribromide. obtained in the evacuated tube as previously described, to a temperature at which decomposition into the dibromide and tetrabromide took place and of keeping the material at that temperature until decomposition was complete.

$$2ZrBr_3 \rightleftharpoons ZrBr_4 + ZrBr_2$$

After all the unchanged zirconium tetrabromide had been evolved from the tribromide as already described, the temperature of the furnace was gradually raised and at 310° the tetrabromide began to deposit again at the end of the furnace, but very slowly. The rate increased as the temperature was further raised. At 350° from ten to fifteen hours were required to decompose a 0.5-g. sample of zirconium tribromide and at 390° about six hours.

In appearance the dibromide is a lustrous black powder. It was obtained in an atmosphere of nitrogen in a sealed tube exactly as in the case of the tribromide. On exposure to the air the dibromide catches fire. It was therefore introduced into ice water saturated with nitrogen by breaking the tube under water. As the water vapor came in contact with the solid there was a very vigorous reaction, part of the solid became incandescent and hydrogen was liberated.[4]

There was in this case considerable dark gray to white insoluble residue consisting mainly of the oxide of zirconium with a very small amount

---

[4] J. H, de Boer and J. D. Fast[5] in an article on the preparation of pure metals of the titanium group through the thermal decomposition of their iodides briefly mention the preparation of the dibromide of zirconium by the action of zirconium tetrabromide on zirconium metal. They however report the dibromide of zirconium as reacting slowly with water to give off hydrogen, and as forming an orange colored solution which slowly decolorized. The analyses given differ considerably from the theoretical.

[5] J. H. de Boer and J. D. Fast, *Z. anorg. allgem. Chem.*, **187**, 177 (1930).

of zirconium metal, which caused the dark appearance of the oxide. In the analysis of a sample of the dibromide weighing 0.1745 g., 0.0283 g. of zirconium dioxide was obtained on ignition of the water-insoluble material and 0.0604 g. was obtained on ignition of the precipitate formed by addition of ammonium hydroxide solution to the filtrate from the water-insoluble matter. The total zirconium calculated from these two weights gives a percentage of zirconium of the sample as 36.41%, the theoretical percentage of zirconium in zirconium dibromide being 36.18. Since the percentage of bromine determined as silver bromide corresponded with that required for the dibromide, it is evident that not all of the zirconium dibromide dissolves as zirconyl bromide but that part of the compound reacts with the water to form zirconium dioxide with the formation of hydrogen bromide and liberation of hydrogen.

$$ZrBr_2 + H_2O \longrightarrow ZrOBr_2 + H_2$$
$$ZrBr_2 + 2H_2O \longrightarrow ZrO_2 + H_2 + 2HBr$$

Anal. Calcd. for $ZrBr_2$: *Zr*, **36.33;** Br, 63.67. Found: *Zr*, 36.41, **36.34;** Br, **63.98, 63.45.**

If the decomposition of zirconium tribromide is carried out at too high a temperature, considerable zirconium metal will be formed due to the reaction $2ZrBr_2 \longrightarrow ZrBr_4 + Zr$. This takes place very slowly at 350° but does go on as the somewhat dark appearance of the zirconium dioxide before ignition indicates. At temperatures of 400° and above, the decomposition of the dibromide proceeds quite rapidly. One sample heated at 410° for twenty-four hours gave, on analysis, 44.5% of zirconium and 57.2% of bromine.

Summary

Anhydrous zirconium tribromide has been prepared by the reduction of the tetrabromide with aluminum in an atmosphere of hydrogen in the hot-cold tube. Appropriate apparatus and manipulation are described. The compound is a blue-black powder which dissolves in water with the evolution of hydrogen, producing a yellow to orange colored solution, the color of which quickly disappears. Trivalent zirconium was found capable of bringing about the following reductions: $CrO_4^{=}$ to Cr^{+++}, Fe^{+++} to Fe^{++}, Bi^{+++} to Bi, Cu^{++} to Cu^{+}, TiO^{++} to Ti^{++} and $2H^{+}$ to H_2. Negative results were obtained in the attempts to reduce stannous chloride.

The dibromide of zirconium is formed by the decomposition of the tribromide at 350°, the tetrabromide being formed at the same time. Zirconium dibromide is a lustrous black powder which catches fire in the air and reacts with water so vigorously as to cause incandescence even in an atmosphere of nitrogen. Hydrogen is evolved and considerable dioxide of zirconium is formed.

THE QUINHYDRONE ELECTRODE. III.

BY J. LIVINGSTON R. MORGAN AND OLIVE M. LAMMERT

RECEIVED APRIL 24, 1931 PUBLISHED JUNE 8, 1931

Introduction

The first papers of this series[1] were concerned chiefly with the reproducibility in 0.1 N hydrochloric acid of the quinhydrone half-cell prepared under varying conditions from different pieces of the same sample of metal. While metals of different ages, sizes, and compositions were used, no intercomparisons between the different series of electrodes were reported. Therefore, except in the case of those series of electrodes which were made up of odd pieces of metal of unknown history, no conclusions could be drawn as to whether the age, size, and composition of the metal base affects the actual value of the potential difference developed or, whether as long as the electrodes are inert with respect to the solutions used, the potentials developed are the same. It is the object of this paper, then, to present the results obtained from an intercomparison not only of the electrodes of different ages, sizes, and compositions used in the first papers of this series but also of electrodes of gold, gold-plated platinum, and graphite not reported upon heretofore. Upon no point in connection with the quinhydrone electrode has there been such a divergence in opinion among earlier investigators as upon the substance to be used as the base of the electrode.

Materials and Apparatus

The materials and apparatus used have been described in the first and second papers of this series with the exception of the following new electrodes:

Gold Electrodes.—Small *Wires* (approximately *0.38* mm. in diameter and **1.5** cm. in length). ***Series Au,*** Nos. *7–12,* six pieces of new 24K gold purchased from Baker and Co. ***Series Am–Au,*** Nos. **7–12,** six pieces of new 24K gold purchased from American Platinum Works. ***Series B–Au,*** Nos. *7–12,* six pieces of new 24K gold purchased from **J.** Bishop and Co. ***Series C–Au,*** Nos. **7-12** six pieces of new 24K gold purchased from Sigmund Cohen. *Large Wires* (approximately *1* mm. diameter, *2* cm. length). ***Series Au,*** Nos. 1–6, ***Series Am–Au,*** Nos. 1–6, ***Series B–Au,*** Nos. 1–6, ***Series C–Au,*** Nos. 1–6, six pieces in each series of new 24K gold purchased from Baker and Co., American Platinum Works, Bishop and Co., and Sigmund Cohen, respectively. In each case the electrodes prepared were of the type heretofore described as short electrodes.

Gold–Plated Electrodes.—Wires (approximately **1** mm. diameter, **2** cm. length). ***Series G-P Nos. 1-12:*** for this series two platinum electrodes were selected from each of the A, B, and Pt series, and six new platinum electrodes were made from a sample of new C. P. platinum wire furnished by Baker. The electrodes were plated with a potas-

---

[1] Morgan, Lammert and Campbell, THIS JOURNAL, 53, **454, 597 (1931).**

sium cyanide solution, approximately 2 g. in 100 cc. water, in which some 24K gold was dissolved by electrolysis. A gold anode and three volts were used and the plating continued for some time after the platinum was covered. For one set of data the time was five minutes, for another ten, the electrode being turned during the electrolysis. The plate was perfectly adherent in all cases, although on those electrodes which were plated for the longer time the gold was somewhat darker in color.

***Foils.—Series** G-P_{11}* (approximately 1 X 1 cm.) and ***Series** G-P_{12}* (approximately 1 X 2 cm.). For these series two of the platinum electrodes series P_{11} and P_{12} were chosen at random and plated by the method just described.

Graphite Electrodes (approximately 2.6 mm. diameter; 2 cm. length). —The lead was removed from 4B Venus pencils made by the American Pencil Company. About one cm. from one end of a three cm. length the lead was ringed with the wax-like substance "piecein" (purchased from Schroder and Ehlers) in the same manner that sealing-in-glass is used. The graphite was then pushed into a length of glass tubing of somewhat greater diameter than the lead while the piecein was still soft, until the ring of piecein was partly in the tube and partly out. More piecein completed the seal, the joint being "wiped" before the substance hardened. The glass tube was then filled with mercury through which connections were made to the potentiometer system.

Because of the sealing wax used for these electrodes the cleansing procedure was modified to some extent. In the first place while the piecein is not attacked by dilute acids, even when in contact with them for many hours, nor by dichromate cleaning mixture over a short time, it is attacked to some extent by cleaning mixture if allowed to stand in it overnight. It is only slightly soluble in cold alcohol. For this reason the graphite electrodes were short-circuited, pair by pair, and immersed in the cleaning mixture for about five minutes, after which they were rinsed hastily in alcohol and dried with purified air.

Procedure and Results

Our procedure for the measurements reported in this paper did not, in general, differ from that reported in the first two papers of this series except that in the case of the intercomparisons, rather than placing six electrodes of one series in one electrode vessel, we placed one pair of each of three series in each vessel. The potential differences between the two like electrodes were measured until the difference was constant, and then the potential differences between all possible combinations of electrodes, taken pair by pair, were measured.

Gold Electrodes.—In view of the fact that the investigators[2] who express a definite preference for gold or gold plate as a metal base for the quinhydrone electrode, particularly in body fluids, outnumber those[3] who state a preference for platinum, and in view of the fact that of the other group[4] who report equally successful results with either gold or

platinum, La Mer and Baker make the distinction that while the potentials are the same with either gold, gold plate, or platinum, gold and gold-plated platinum give sharper readings, we did not feel satisfied to confine our investigation to the samples of gold reported in the first paper. Most of the gold electrodes reported upon in that paper were made from 24K gold supplied by Baker and Co., the small and large wires Series Au and the foils Series G_{11}, G_{12}, G_{13}, G_{22} and G_{23}. The source and purity of the larger wires Series St was unknown and the Series L & N were gold electrodes supplied by Leeds and Northrup Co. The foils and the L & N electrodes gave excellent results, although a few inexplicably erratic results were obtained with the foils. The small gold wires were extremely erratic and unreliable and the larger wires, while fairly good, were also somewhat erratic. Therefore wires of the same size and specifications were obtained from three other companies and the electrodes already described prepared. Wires were selected rather than foils since it was among the wires that the greatest differences in reproducibility appeared. A comparison of their reproducibility in air and in nitrogen follows in Table I. Results for the Series Au are included since many beyond those reported in the first paper have been obtained.

Among the small wires (7–12) the series Am-Au and B-Au were much more readily reproducible than the Series Au which continued to be erratic, although, like the Series Au, Am-Au, B-Au and C-Au gave cells of much smaller current capacities than the platinum wires of the same size The C-Au series, however, gave results more nearly like the Au series although neither the averages, ranges, nor average deviations were quite as large.

Among the large wires (1–6), on the other hand, the Au series gave the lowest averages, ranges and average deviations. The values for all three of the other series were not only higher than the large wires of the Au series but were higher than the small wires of the same series, although the range on the bridge wire over which there was no deflection on the galvanometer was always greater with the small wires.

All in all, then, there seems to be no doubt that, in so far as our results in 0.1 N hydrochloric acid are typical, wire electrodes of small surface made of 24K gold from any source are likely to be extremely erratic in their behavior and that in systems where its presence does not cause difficulty platinum is greatly to be preferred. In the first place, platinum can be sealed into the glass directly whereas gold must be welded to platinum; in the second place, the gold is easily alloyed with mercury,

a contamination which greatly alters the potential difference of the electrode; in the third place, a cell prepared with platinum wires has a larger current capacity than a cell prepared with the same size gold wire; and in the fourth place, the gold electrodes exhibit a capriciousness in behavior which is extremely annoying. On the other hand, it is to be noted that the effect of nitrogen upon the gold electrodes is not as definite as upon the platinum electrodes. While the effect of oxidizing agents upon the electrode is a matter still under investigation and will be reported upon at some future date, it seems probable that the reproducibility of the electrode is not altered to the same extent by the presence or absence of oxidizing agents when gold is used as when platinum is used. This fact may account for the disagreement among earlier investigators as to the metal to be used.

As to the cause of the variability of the gold electrodes, we have as yet no explanation to offer. There seem to be at least two effects of the metal upon the cells constructed. One effect is upon the current capacity; cells constructed with platinum wires of a given size have greater current capacities than those with gold of the same size; for other conditions being the same there is with the smaller electrodes a greater range on the bridge over which there is no deflection of the galvanometer of the type we are using (Leeds and Northrup Type 2500 c). With a more sensitive galvanometer of the type 2285Å, however, this range becomes much smaller.

The second effect is upon the reproducibility of the electrode potentials and may be catalytic in nature. This effect may be a combination of more than one catalytic effect, one possibly involving the quinone–hydroquinone equilibrium and the other involving some reaction with the oxygen, possibly oxidation of the quinone. Since the results with platinum are very much improved with nitrogen, it seems probable that the platinum catalyzes the reaction with oxygen more effectively than the gold. On the other hand, since the large electrodes of both kinds give much better results than the small it seems probable that the metal is instrumental in bringing the quinhydrone system to equilibrium.

We have worked for some time on the theory that gold electrodes which were contaminated with even very small amounts of mercury exhibit an erratic behavior but we can find no connection between their behavior and such contamination. Electrodes which we knew to be alloyed with mercury never improved until the mercury was removed, whereas the electrodes, which we have described as erratic, would give quite consistent results, then one or more inexplicably large potential differences, and then become quite normal. Furthermore some gold electrodes were consistently good throughout the entire research.

Gold–Plated Electrodes.—Enough investigators[6] have used gold-plated electrodes to make it seem advisable to include some work on these in this paper.

Biiimann and Jensen[5] found greater deviations between the potentials of quinhydrone half-cells prepared with gold-plated electrodes than with polished platinum electrodes. Biilmann[5] states that while there are solutions in which platinum cannot be used, and in which gold plate may be used, platinum gives, when it can be used, more precise results. He states further that a concentration of quinhydrone sufficient to give exact potentials with bare platinum electrodes will not give exact potentials with gold-plated electrodes.

Chem.*.*83*,*535* (1929).

In our experience the gold-plated electrodes give results in air similar to the gold electrodes until they become scratched, with the exception of the foils, which do not give as good results as the gold foils. These electrodes differ from the gold electrodes, however, in that their reproducibility improves in nitrogen. As soon as the electrode is scratched it must be replaced, since a very small scratch seems to change greatly the potential developed. This seems strange in view of the fact that a platinum and a gold electrode may be connected and treated as one electrode and the potential of this combination found not to differ from a single platinum or gold electrode by any amount greater than the latter differ from each other or other platinum or gold wires. Furthermore, we find no difference in reproducibility in those gold electrodes which are prepared with some platinum exposed to the solution from those prepared in such a way that all the gold is covered, and finally, the L & N electrodes which have given such consistently good results throughout the entire investigation have more platinum exposed to the solution at the ends of the gold wire than was exposed by the scratch on a foil.

Our results for the gold-plated electrodes are collected in Table II. The results obtained from electrodes known to be scratched were not included in the average. The electrodes were deplated and tested as platinum electrodes after the results in the table were obtained. Since they were in every case normal it was evident that the results were characteristic of the gold plate and were not due to electrodes faulty in construction.

Table II

Comparison of the Potential Differences Obtained After Sixty Minutes in 0.1000 N Hydrochloric Acid Solution Saturated with Quinhydrone between gold-plated Electrodes; Solutions Stirred in Air and with Nitrogen; Electrodes Dried in Air; Electrodes Short-Circuited

Electrode series	Electrodes in series	Values in average	Identical cleaning and drying operations between meas.	Av. potential diff., volt	Ranges of diff. 0.000000 to .... volt	Av. dev., mv.	Number of results discarded in average

Air G-P$_{12}$	**2**	13	3	.000032	.000150	.032	0
Nitrogen G-P$_{12}$	2	12	4	.000002	.000016	.002	0

Unless the conditions in other solutions differ greatly from those in 0.1 N hydrochloric acid, we can see no advantage in using gold-plated electrodes and a number of disadvantages. In the first place, the electrodes possess most of the disadvantages of the gold electrodes to which are added the disadvantages that the plating is troublesome, that the plate is fragile, and that the electrodes are not as reproducible as the gold.

Finally, as we shall see in Table IV of this paper, the potentials of the gold-plated electrodes deviate from the potentials obtained with other metals to a far greater extent than they do with any other metals. Of course, it is possible that some special conditions of plating may give far better results but as soon as the reproducibility of an electrode depends upon a method of metal deposition, an uncertainty arises, creating a situation similar to the one which exists with respect to the hydrogen electrode, and removes one of the greatest advantages of the quinhydrone electrode, that of simplicity. Our experience very nearly corroborates that of Biilmann, who took some five or six hours to plate his electrodes. We found the gold-plated electrodes sensitive to the oxygen of the solution, however, and suspect that our more rapidly deposited plate was rougher and hence catalyzed the oxygen reaction more readily. If gold plate must be used for some reason (although we cannot foresee any condition under which gold welded to platinum would not be preferable), we suggest that it be plated very slowly.

Graphite Electrodes.—Except for the work of Flexner and Barron,[6] we are not aware of any attempt having been made to use a carbon electrode as the base of the quinhydrone half-cell. Flexner and Barron report two results in 0.1 N hydrochloric acid, one (0.38835 volt) obtained when a quinhydrone half-cell prepared with carbon was measured against a saturated calomel cell, the other (0.3886 volt) when the half cell was prepared with gold plate They state that the purity of the carbon is unimportant, the rods of a carbon arc lamp or the core of a lead pencil giving identical results.

We prepared a series of carbon electrodes using arc carbons, some carbon electrodes of different cross sections found in the laboratory, and some graphite electrodes prepared from different lead pencils. The carbons were connected directly to the potentiometer wires with binding posts; the cores of the lead pencils were sealed as already described into glass tubing with picein.

While the lead pencil graphite cores gave promising results from the first, all of the other forms of carbons gave poor results. Moreover, it was observed that when these carbons were immersed in the same electrode vessel with a pair of platinum or gold electrodes, not only did the potentials of the carbon electrodes differ from one another, but the potentials of the platinum electrodes also differed greatly from one another even after they had given low potential differences before the carbon electrodes were introduced. This observation suggests that the carbons absorbed material from the solution, which fact affected not only the potentials of the carbon electrodes but of the others in the same vessel. Graphite not being wetted by water as is carbon and not absorbing ma-

---

[6] Flexner and Barron, THIS JOURNAL, 52, 2773 (1930).

terial to the same extent, could be expected to yield more readily reproducible potentials.

We tried a number of pencil leads but were most successful in sealing in the 4B Venus pencil leads, possibly fortuitously. possibly because the leads were corrugated on the surface. At any rate, as we wished to examine the properties of these electrodes before we compared the lead from different sources and of different degrees of hardness, we selected from the lot those electrodes which had good seals and had given good results, which happened to be those carrying the 4B Venus leads. It is our present plan to try other forms of graphite after we have seen whether the electrode proves of enough value to justify such a research.

Our results for these electrodes are collected in Table III.

Table III

Comparison of the Potential Differences Obtained after Sixty Minutes in 0.1000 *N* Hydrochloric Acid Solution Saturated with Quinhydrone between Graphite Electrodes. Solutions Stirred in Air and with Nitrogen; Electrodes Dried in Air; Electrodes Short-Circuited

	Electrodes in series	Values in average	Identical cleaning and drying operations between meas.	Av. potential diff., volt	Ranges of diff. 0.000000 to .... volt	Av. dev.. mv.
Air 4 B	**14**	**86**	**12**	**0.000005**	**0.000033**	**0.005**
Nitrogen 4 B	**14**	**256**	**22**	.000032	.000620	.038

These lead pencil electrodes have been in constant use for four or five months, and cleaned and measured many times. Prepared in the way we have described, they seem to be just as rugged as the gold or platinum electrodes and to lend themselves to the same cleaning treatments. They resemble the gold electrodes in that the results obtained in air are always as satisfactory and frequently more satisfactory than those obtained in nitrogen. This suggests that they will not be as sensitive to oxidizing agents as platinum and consequently may be more valuable in determinations in body fluids. Electrodes of the size we used give cells with a sufficiently large current capacity to be used with the Type K potentiometer and 2500 ***e.*** galvanometer; the region on the wire over which there is no current deflection is small and of about the same magnitude as that observed with the large platinum wires and much less than the gold. They are, of course, unaffected by mercury and are so readily available and so simply and cheaply constructed that they have everything to recommend them. They differ from the gold and the platinum in that the initial potential difference between two electrodes is usually higher but this large difference rapidly disappears and they soon behave in a manner quite similar to the metal electrodes.

It is our plan to try other samples of graphite. It seems quite possible that excellent micro electrodes might be prepared with blocks of graphite, indentations in which hold the liquid–quinhydrone mixture.

Comparison of the Potential Differences Developed in the Quinhydrone Half-Cell by Different Electrode Substances.—In Table IV are collected the results of a rather extended comparison of the potentials developed by electrodes of different compositions, 24K gold, c. p. platinum, platinum–10% iridium alloy, platinum–10% rhodium alloy, gold-plated platinum, and graphite, of different sizes, ages, and sources in air and in nitrogen. While in our earlier papers we showed that the precision of the quinhydrone half-cell is very great, we hope in this table to give some idea of the probable accuracy among the results obtained in different laboratories. In this table ate given only the results of the intercomparisons between electrodes of different series; for the results within any one series the reader is referred to the tables given in the first two papers of this series and to the tables given in the first part of this article. The signs of the potential differences of the cells are reported in this table, the sign being given to the first mentioned electrode. When the average deviation is of the same order of magnitude as the average potential difference, it seems probable that a sign in any direction does not represent an actual difference of potential developed but merely a deviation; when however, the average potential difference is in one direction and is larger than the average deviation, we have considered that there was an actual difference in potential developed with the two metals.

TABLE IV

The following conclusions may be drawn from the results in this table. The small (Au, 7–12, Am–Au, 7–12, B–Au, 7–12, and C–Au 7–12) and large (Au, 1–6, Am–Au, 1–6, B–Au, 1–6, C–Au, 1–6 and St, 1-6) gold wires from different sources do not differ from each other to any greater extent than they differ among themselves. The reproducibility of the quinhydrone half-cell prepared with gold electrodes is not, in general, improved in nitrogen.

The large C. P. platinum wires (A, 1–6, B, 1–6, Pt, 1–6) give practically the same differences of potential no matter what the source or the age of the platinum. Quinhydrone electrodes prepared with these wires are reproducible with great precision, particularly when the solution is stirred with nitrogen.

When the large gold and platinum wires are compared, the average potential differences are of the same order of magnitude as the average deviations and are no larger than the differences among the gold electrodes measured by themselves, from which it may be concluded that, within the limits of experimental error, gold and platinum electrodes develop the same potential difference in the quinhydrone half-cell.

When, however, the C. P. platinum (Pt 1–6) and platinum–10% iridium (Ir 1–6) and platinum–10% rhodium (Rh 1–6) alloys are intercompared, the C. P. platinum is negative to the alloy in air and more negative to the iridium alloy than to the rhodium alloy Quite consistently the rhodium alloy is negative to the iridium alloy. In nitrogen these differences disappear almost entirely, although there are a few more negative results than positive.

Other actual differences in potential developed appear when the large C. P. platinum (A, 1–6, B, 1–6, Pt, 1–6) or gold (Au, 1–6) wires are compared with the gold-plated wires (G-P). Here again the C. P. platinum and 24K gold are negative to the gold-plate and again the difference disappears in nitrogen.

Among the foils and longer wires (L & N) all electrodes, old and new, seem to give the same potential differences and with great precision with the exception of the gold plates. Again the gold wires, in this case L & N, are negative to the gold plate.

The potential differences obtained with the graphite electrodes (4B) deviate from those obtained with gold or platinum wires. but the deviations are both positive and negative. They give, however, with great precision, the same results as the gold foils (G_{11}) and long wires (L & N).

An intercomparison of sizes indicates that there is no difference in the potential developed, but merely the difference in range and deviation expected of the smaller wires from the previous results.

Of course, there is the possibility in an intercomparison such as this, when electrodes being compared are in the same vessel, that if the effect of the electrode substance is catalytic in nature, a small electrode, for instance, will be affected by the presence in the vessel of a large electrode. While an effect on the gold and platinum electrodes was obvious in the vessels containing the carbon electrodes, in other cases the electrodes seem to retain their own characteristics regardless of the properties of their neighbors. Any catalytic effect seems to be upon the medium immediately surrounding the electrode.

The results given in this paper indicate that, in so far as results obtained in 0.1000 N hydrochloric acid are typical, an investigator in one laboratory may select either gold, platinum, or graphite for the base of a quinhydrone electrode and expect the potential of such an electrode to agree with that obtained in another laboratory with the same precision with which electrodes prepared from different samples of the same metal or graphite agree. Further work in other solutions will be reported in another paper.

We are greatly indebted to the Special Research Fund of Columbia University for a grant for this work and to Miss Margaret Campbell, who, as research assistant, made the measurements and compiled the results for this paper.

Summary

A study has been made of the comparative potential differences obtained for the quinhydrone electrode in 0.1000 *N* hydrochloric acid when prepared with metals and graphite of different sizes, ages, sources and compositions, from which study the following conclusions may be drawn.

1. Gold electrodes, from whatever source, are likely to give erratic results unless the electrode is a foil or wire as large or larger than 1 sq. cm.
2. Gold electrodes give cells of lower current capacities than do platinum electrodes of the same size under the same conditions.
3. Very satisfactory quinhydrone electrodes may be prepared from the graphite core of a lead pencil but not from lamp carbons, etc., since the latter seem to absorb the electrolyte, affecting not only their own potentials but the potentials of any metal electrodes immersed in the same solution.
4. The reproducibility of gold-plated electrodes is not as satisfactory as either gold, platinum or graphite.
5. The reproducibility of quinhydrone electrodes prepared with gold or with graphite is not in general improved in nitrogen, whereas that of electrodes prepared with c. p. platinum, platinum–iridium, platinum–rhodium alloys, or with gold-plated platinum is very decidedly improved.
6. 24K gold and c. p. platinum develop, within the limits of the reproducibilities possible with different samples of the same substance, the same potential differences, no matter what the size, age or source of the substance. Lead pencil graphite also seems to develop the same potential difference, although that from only one source has been thoroughly tested.

Platinum–10% iridium, platinum–10% rhodium alloys and gold-plated electrodes do not develop the same potentials, the c. p. platinum or 24K

gold being negative to the alloys and plate. This difference, however, disappears almost entirely if the solution is stirred with nitrogen.

Further work in other solutions and on the effect of oxidizing agents is in progress.

MOLECULAR AND ACTIVATED ADSORPTION OF HYDROGEN ON MANGANOUS OXIDE SURFACES

BY HUGH S. TAYLOR AND ARTHUR TANDY WILLIAMSON

RECEIVED APRIL 28, 1931 PUBLISHED JUNE 8, 1931

In a recent communication,[1] the rapidly accumulating data relative to the variation of adsorption and heats of adsorption of gases on numerous surfaces with variation in temperature and pressure as well as data on the velocities with which adsorption and desorption equilibria are attained have been collected and analyzed. The data have been shown to be a necessary consequence of a modified theory of adsorption which differs from the classical theory in the introduction of the concept of activation energy into adsorption processes. On classical theory, the activation energy of adsorption is zero and that for desorption is X, which is identical in magnitude with the usual heat of adsorption. The modification proposed is to require an activation energy, E, for adsorption and, consequently, an activation energy, E + X, for desorption processes. This introduction of the activation energy concept does not change the theoretical equilibrium value for adsorption in its dependence on λ. On the other hand, the individual rates of adsorption and desorption will decrease exponentially as E increases, so the rate of attainment of equilibrium may vary within wide limits which will be dependent upon the magnitude of E.

It was shown in the earlier paper that this method of treatment could be applied to a gas whose adsorption on a given surface was of two types, one involving a low heat of adsorption and a low activation energy, the other a high heat of adsorption and a high heat of activation. It was shown that this led to two theoretical adsorption isobars, that with the high heat of adsorption involving greater amounts of adsorbed gas at a given temperature and pressure. Dependent on the magnitude of the two activation energies it was shown that, at sufficiently low temperatures, the lower adsorption would be the only type occurring, at higher temperatures the higher adsorption, while, in an intermediate temperature range, dependent on the respective magnitudes of the two activation energies, a transition region of pseudo-equilibrium adsorption values would be

---

[1] Taylor, THIS JOURNAL, 53, 578 (1931).

obtained, showing increasing amounts of gas adsorbed with increase in temperature, the velocity of adsorption at a given temperature being determined by the activation energy of the high temperature adsorption. An examination of data for hydrogen adsorption on various surfaces abundantly confirmed the general conclusions thus reached. There were, however, no data of a quantitative nature relative to the *velocity* of adsorption. It was primarily to ascertain if such could be secured that the present work on manganous oxide surfaces was performed. This surface was chosen because of its known efficiency in hydrogenation reactions, involving activated hydrogen, and also because of its known resistance to reduction by hydrogen in the temperature range to be studied, It was anticipated and actually found that the transition from one type of adsorption to another would occur in a temperature range above room temperature. This permits a more easily operable experimental technique than is possible with such surfaces as nickel where, as Benton and White have already shown,[2] the transition interval from one to the other type of adsorption occurs below −110°. Our choice was a fortunate one in that, on a manganous oxide surface and on a surface of manganous oxide promoted with chromic oxide, we have been able to segregate the two types of hydrogen adsorption and separately examine their heats of adsorption and activation energies of adsorption. We also have made excellent measurements of the velocity of activated adsorption and from them deduced the activation energy of the process as a function of the extent of surface covered.

Experimental Details

Apparatus.—The adsorptions were measured in an apparatus of the type frequently used[3] in our work with catalytic surfaces. The adsorbent was contained in a 25-mm. Pyrex tube attached through capillary tubing and suitable stopcocks to a gas buret graduated in 0.10 cc., a mercury manometer of 10 mm. bore, an evacuation system and a gas supply and purification train.

For evacuating the system when collection of the gas was not necessary, a two-stage mercury diffusion pump was used in series with a Hyvac oil pump. To recover the adsorbed gas on evacuation, use was made of an automatic Sprengel pump built according to the plans given by Dunoyer.[4] With this, the system could be exhausted to very low pressures in a relatively short time, the pump pulling steadily as fresh gas was released from the surface of the adsorbent. Even the last small stubbornly held portion of the adsorbate could be removed completely by holding the adsorbent at 450° overnight with the Sprengel pump operating.

The adsorbent was heated by a close-fitting cylindrical electric furnace whenever the contact material was to be freed of adsorbate. When isotherms and isothermal rates were being studied, much closer temperature control was required. At the lower temperatures this was obtained by immersing the tube in a Dewar flask filled with solid

[4] Dunoyer-Smith, "Vacuum Practice," G. Bell and Sons, London, 1926.

carbon dioxide–ether, water–ice or pure water as the regulating media. At higher temperatures excellent isothermal baths could be obtained by refluxing pure materials at their boiling points. The boiler was a Pyrex "test-tube," 50 mm. in diameter, which was equipped with an asbestos jacket and a reflux tube sealed into its shoulder. It was closed at the top by a plug formed of asbestos tape. An electric heater, moulded to fit snugly, could be regulated to give steady ebullition which would fill the whole tube with saturated vapor, this vapor being completely condensed after moving a few centimeters up the reflux tube.

Materials.—Manganous oxide was prepared by ignition of manganous oxalate, made[5] by the interaction of concentrated solutions of potassium permanganate and oxalic acid in presence of acetic acid. On ignition above 300° the oxalate decomposes yielding the gray-green monoxide. In the air this material, when active, takes up oxygen, changing to a darker color. Sabatier[6] found that it was stable in the presence of hydrogen at a red heat, while Meyer[7] found no evidence of reduction by hydrogen below 1200°. The samples used were submitted to a final reduction in *situ* with hydrogen at 350°.

Manganous-chromic oxide was prepared by ignition of manganous ammonium chromate formed as a dark precipitate by mixing solutions of manganous nitrate and ammonium chromate, ammonia being then added until the supernatant solution gave a neutral reaction to litmus.[8] The filtered precipitate was washed with ammonium nitrate solution to prevent the formation of suspensoids, dried and then decomposed at about 400°. The product contains approximately two moles of MnO to one oi Cr_2O_3. Prior to use it was given a final reduction in *situ*, yielding a grayish-brown powder. When exposed to air it oxidized to a velvety black higher oxide of manganese.

Manganous pyrophosphate was prepared hy ignition of manganese ammonium phosphate at 650°.

Electrolytic hydrogen, carbon monoxide from formic acid, cylinder nitrogen and ethylene were subjected to careful purification and drying before use.

Procedure.—The adsorptions were in all cases measured by comparison of the quantities of adsorbable gas required to produce a given pressure at a stated temperature with those required for a non-adsorbed gas (nitrogen). The pressures and volumes recorded have all been reduced to standard conditions. It was found necessary to evacuate the surfaces prior to a measurement for many hours at 450° in order to ensure reproducibility of experimental results.

In the determination of adsorption isotherms measurements were made in some cases with ascending pressures and in other cases by removal of measured amounts of gas from the surface saturated with a known volume of gas at moderate pressures. The chosen procedure is indicated in the tabulated results by ascending or descending values of the pressure.

The velocities of adsorption were generally determined by introducing a known volume of gas, measuring the pressures produced by such gas over certain time intervals. The pressure at zero time was calculated from the data obtained under the given conditions with nitrogen.

Experimental Results

The data presented below are a summarized form of the detailed experimental results by one of us (A. T. W.) elsewhere.[9]

[9] Williamson, "Thesis," Princeton, 1931.

A. Manganous **Oxide.** I.—Mass of sample, 22.8 grams: no measurable quantity of hydrogen was adsorbed by this surface at 0°, even over a period of several hours. At 184° no observable adsorptions were recorded at 101 mm. and 296 mm. pressure after fifteen minutes' time of contact but at 393 and 615 mm. adsorptions of 0.8 and 1.0 cc., respectively, were recorded after the system had stood for two or three hours under the given conditions. It was evident that slow activated adsorption was making its appearance so that an experiment, using a large volume of hydrogen (V), was made, pressures being recorded at stated intervals. The data obtained together with similar data at 305° are presented in Table I.

TABLE I

VELOCITY OF ADSORPTION OF HYDROGEN ON MANGANOUS OXIDE I AT 184 AND 305°

T, 184"; V, 358 cc.			T, 305°; V, 37.7 cc.		
Time, hours	P_{mm}	$V_{ads.}$, cc	Time, hours	$P_{mm.}$	$V_{ads.}$, cc.
0	595	0.0	0	760	0.0
5	559	2 2	<1	668	4.5
8	543	3.1	2	618	7.0
22	525	4 2	3	613	7 3
26	523	4 3	8	581	8.9
35	516	4.8	10	577	9.1
46	508	5 2	16	566	9.6
51	506	5.4	22	562	9.8

It is evident from these data that the rate of adsorption at 305° is much greater than at 184°. In addition, a higher pseudo-equilibrium adsorption is approached. The velocity of adsorption at 305° suggested the possibility of obtaining an adsorption isotherm by removal of successive measured amounts of gas, allowing between each a period of from two to three hours for the reestablishment of equilibrium. The data thus obtained are presented in Table II. It will be realized that the amounts adsorbed represent upper limits for the isotherm at each pressure owing to the operation of the high activation energy of desorption as discussed in the introduction. The data do show, however, a normal adsorption and also illustrate the reversibility of the process.

TABLE II

ADSORPTION ISOTHERM OF HYDROGEN ON MANGANOUS OXIDE I AT 305°

V, cc.	$V_{ads.}$	P	V, cc.	$V_{ads.}$	P
37.7	9.5	567	14.0	4.8	186
32.2	8.6	476	10.8	4.1	134
28.5	8.1	412	7.4	3.6	77
25.1	7.5	355	5.3	3.1	44
20.6	6.5	284	3.4	2.7	14
17.2	5.9	228	2.0	2.0	0

The last two cc., which were held with an equilibrium pressure of less than 1 mm., were recovered by evacuation at 400°. There was no evidence of any water formation. Further experiments with this preparation were precluded by the accidental introduction of mercury into the adsorbing system.

Manganous oxide II was prepared by ignition of a commercial preparation of c. P. manganous oxalate. The product was very inert, difficult to reduce to the lowest state of oxidation, showed no tendency to take up oxygen on exposure to air and adsorbed no measurable amount of hydrogen even after seven hours' contact at 184°.

Manganous oxide III was a sample, 34.1 g. in weight, prepared in the same manner as manganous oxide I. To determine more accurately the energy of activation of the slow adsorption, rates of adsorption were measured carefully at 184 and 218°. The hydrogen was introduced in such a quantity that the pressure range would be approximately the same for each temperature, thereby eliminating any corrections for the variation of rate with pressure and permitting the study of the variation in rate with temperature and extent of surface covered. The data obtained are presented in Table III.

TABLE III

VELOCITY OF ADSORPTION OF HYDROGEN ON MANGANOUS OXIDE III AT 184 AND 218°

T, 184°; V, 37.0 cc.			T, 218; V, 36.4 cc.		
Time, hours	P_{mm}	$V_{\text{ads.}}$, cc.	Time, hours	$P_{\text{mm.}}$	$V_{\text{ads.}}$, cc.
0.0	633	0.0	0.0	659	0.0
1.0	613	1.2	.25	644	.8
2.0	607	1.5	.4	639	1.1
3.0	603	1.7	.9	631	1.5
12.3	585	2.7	1.4	627	1.8
16.3	581	3.0	3.0	614	2.5
19.8	577	3.2	4.5	605	3.0
27.0	570	3.6	6.5	596	3.4
38.0	563	4.0	8.5	588	6.9
			13.75	580	4.3

Comparison of the data at 184° with those in Table I shows that this preparation is not quite as active as manganous oxide I, so far as velocity and extent of adsorption are concerned. From a plot of these values it is possible to determine the time necessary to adsorb a given amount of gas on the surface at each temperature. The ratio of the required lengths of time is the inverse ratio of the average velocities of adsorption. By direct substitution of such ratios in the equation

$$\ln \frac{v_2}{v_1} = \frac{E}{R}\left[\frac{1}{T_1} - \frac{1}{T_2}\right]$$

the following values for E, the activation energies of adsorption, were obtained.

These results show clearly that adsorption of hydrogen on manganous oxide at temperatures in the neighborhood of 200° requires a high activa-

TABLE IV

ACTIVATION ENERGIES OF ADSORPTION OF HYDROGEN ON MANGANOUS OXIDE III

Adsorbed amount, cc.	Time required, hours 218°	184°	E, cal. per mole, adsorbed
First two	1.8	4.6	12,400
Third	2.7	11.7	19,400
Fourth	4.7	21.7	20,800

tion energy, which is a minimum for the first areas covered and rises to higher values for less active areas of the surface.

Adsorption is still marked at 444°. A single charge of hydrogen was left in the system at this temperature for seven hours, at the end of which time the rate of adsorption had become negligible. The adsorption amounted to 7.3 cc. at a pressure of 706 mm. On removing a sample of gas a new equilibrium at the end of twelve hours showed an adsorption of 6.8 cc. at a pressure of 495 mm.

Experiments at −78.5° showed no measurable adsorption of hydrogen even after five hours' contact time at a pressure of 330 mm.

The data obtained with this sample and manganous oxide I have been utilized to construct an adsorption isobar of hydrogen on manganous oxide in the temperatue range −78–444° at a pressure of 506 mm. The data are collected in Table V.

TABLE V

ADSORPTION ISOBAR OF HYDROGEN ON MANGANOUS OXIDE AT p = 506 MM.

Temperature, ° Abs.	194.5	273	457	578	717
$V_{ads.}$, cc./g.	0.000	0.000	0.024	0.039	0.020

Since the value at 578° Abs. is on manganous oxide I, the sample of greater activity (see page 2171), the table has only semi-quantitative significance. It serves well to indicate however the increase of pseudo-equilibrium adsorption with increase of temperature. A more quantitative exemplification will now be presented for the case of hydrogen adsorption on a manganous-chromic oxide surface.

B. Manganous-Chromic Oxide.—Weight of sample, 46.5 g.: with this material a striking experimental demonstration of slow adsorption increasing in velocity with rise of temperature has been performed. Hydrogen was introduced into the adsorption vessel at room temperature until a pressure of approximately 500 mm. was obtained. The vessel was then heated very gradually by the electric furnace and the accompanying pressure change was noted. Up to about 100° the gas pressure increased normally. Shortly after this temperature was passed the expansion ceased and, with the temperature still rising, a contraction took place. This contraction accelerated and, between 200 and 300°, the gas was adsorbed with great rapidity. A minimum pressure of 10 mm. was reached between 350 and 400°. Above 400° the pressure slowly increased again although to only a slight degree and at 430° it had built up to approximately 20 mm. This experiment constitutes startling evidence of activated adsorption. It also indicates the necessity of high temperature evacuation for complete removal of adsorbed gas. In preparing the surface for the experiments now to be presented, evacuation was effected at 450–470°.

An adsorption measurement at 184° revealed the tremendous adsorptive capacity of the sample. In all a volume of 179 cc. of hydrogen was admitted to produce a pseudo-equilibrium pressure of 209 mm. after five days of adsorption. The adsorption was very rapid in the first stages, subsequent quantities of hydrogen being taken up at progressively decreasing rates. Desorption of successive samples gave the following pseudo-equilibrium data which show the tenacity with which hydrogen is held.

TABLE VI

ADSORPTION ISOTHERM OF HYDROGEN ON MANGANOUS–CHROMIC OXIDE AT 184°

V, cc.	$V_{\text{ads.}}$, cc.	P_{mm}
173.9	166.3	209
173.6	166.3	121
169.6	166.2	57
166.1	165.6	8

On cooling the system to 0° and holding at that temperature for twenty hours, no desorption occurred, although, as will later be shown, only minor amounts of the gas can be adsorbed in reasonable time intervals at this lower temperature.

High Temperature Isotherms.—Adsorption isotherms at 305 and 444° were next obtained by saturating at a given pressure and then removing the gas adsorbed in measured amounts by means of the Sprengel pump. Suitable time intervals were allowed between each successive removal to permit the approximate establishment of equilibrium. The data are presented in Table VII.

TABLE VII

ADSORPTION ISOTHERMS OF HYDROGEN ON MANGANOUS–CHROMIC OXIDE AT 305 AND 444°

22.5	410	14.4	8	417	13.7
29	396	15.4	13	382	16.0
36	382	16.4	20	347	18.3
49.5	361	17.9	24.5	330	19.5
67	341	19.4	43	280	22.8
98	313	21.4	49	269	23.5
127	293	22.8	51	265	23.8
153	278	23.9	61	249	24.8
185.5	263	25.0	71	235	25.8

These velocity data yield, by the same type of calculation used in the case of manganous oxide III, the following results for the activation energies of adsorption on successive areas of the surface.

TABLE IX

ACTIVATION ENERGIES OF ADSORPTION OF HYDROGEN ON MANGANOUS–CHROMIC OXIDE

Adsorbed amount	Time required, min. 132°	100°	*E*. cal. per mole adsorbed
First 10 cc.	3.2	6.0	5,920
10th–15th	7.3	20.0	9,500
15th–20th	15.9	48.0	10,400
20th–25th	37.2	111.5	10,400

As with manganous oxide, the activation energy is lowest for the first portions of gas adsorbed, which signifies that the velocity of adsorption is most rapid on the most active areas of the surface. With increased covering of the surface, E rises to a value which is constant for a considerable region of covered surface. Undoubtedly, with additional areas covered, the value of *E* would rise still further. The absolute values of the numerical results for E differ widely in the two cases and the same is true for the quantities adsorbed. With the single oxide, the activation energy ranges over the first four cc. adsorbed from 12,000 to 20,000 calories per mole. With the mixed oxide surface the range is from 6000–10,000 for the first twenty-five cc. adsorbed. The effect of this divergence on the velocity of adsorption at, for example, 177° = 450°Abs., on the areas having E = 6000 and 12,000 cal., respectively, is best exhibited by reference to the relation

$$v_{\text{MnO-Cr}_2\text{O}_3} : v_{\text{MnO}} = e^{-6000/2 \times 450} : e^{-12000/2 \times 450} = e^{6000/900} = e^{6.6} = 750$$

where v is the velocity of adsorption and is proportional to the expression $e^{-E/RT}$. This enormous effect of the admixture of chromic oxide with manganous oxide on both the velocity and extent of adsorption is undoubtedly of fundamental importance in the phenomenon of promoter action in the field of heterogeneous catalysis.

Low Temperature Adsorption.—The magnitude of the activation energy on the manganous–chromic oxide, $E = 6000$, indicates that this type of adsorption will be very slow indeed at −78.5°, actually e^{-15} or 3×10^{-7} of that at 132°. It might therefore be possible to measure the molecular adsorption of hydrogen at such temperatures. An isotherm was, therefore, measured. An immediate rapid adsorption, complete in a few minutes, occurred. In addition there appeared a very slow adsorption which continued for many hours and which is probably adsorption of the activated type on areas of the surface on which the activation energy is even less than 6000 calories. The following Table X which records results obtained both with increasing and decreasing pressure indicates the existence of the secondary type by reason of the divergence between the two sets of data, ascending and descending. That even the activated adsorption involved low activation energies is evident from the fact that the residual 3.2 cc. of gas indicated in the table was almost completely recovered by Sprengel evacuation at 0°.

TABLE X

ADSORPTION ISOTHERM OF HYDROGEN ON MANGANOUS–CHROMIC OXIDE AT −78.5°

V, cc.	$V_{\text{ads.}}$, cc.	P	V, cc.	$V_{\text{ads.}}$, cc.	P
4.1	2.6	12	22.1	10.4	91
15.7	7.6	63	17.1	9.9	56
33.4	10.2	181	10.1	6.5	28
38.7	11.2	215	8.0	5.8	17
35.0	11.3	185	4.8	4.4	3
27.7	10.9	131	3.2	3.2	0

The change in adsorption with time at −78.5' and the rapid desorption of gas on heating to 0° is indicated in Table XI, which also shows that at 0° the desorption of gas is followed by its slow readsorption in the activated form.

TABLE XI

EFFECT OF TEMPERATURE CHANGE ON HYDROGEN ADSORPTION AT −78.5° AND 0°

.45	183	12.0	29.5	237	13.0
.82	182	12.1			

Heat of Low Temperature Adsorption.—On a clean surface of the mixed oxide, hydrogen was rapidly adsorbed at 0° to the extent of 7 cc. at a pressure of 165 mm. From the previous data at —78.5' we find that the same quantity of gas is adsorbed at a pressure of approximately 40 mm. Substituting these values in the Clapeyron–Clausius equation

$$\frac{d \ln P}{dt} = \frac{\lambda_{L.T.}}{RT^2}$$

we obtain as an approximate value for the heat of low temperature adsorption the value, $\lambda_{L.T.} = 1900$ calories per mole.

Heat of High Temperature Adsorption.—A similar calculation is possible for the high temperature data already presented in the isotherms at 305 and 444'. For 100 cc. of adsorbed gas the pressures at 578 and 717' Abs. are <5 mm. and 140 mm., respectively. Substitution of these data in the above equation gives $\lambda_{H.T.} \sim 20{,}000$ calories per mole. The ten-fold variation between the two magnitudes $\lambda_{L.T.}$ and $\lambda_{H.T.}$ is the best evidence of the fundamental distinction between the two types of adsorption.

The Adsorption Isobar.—The data in the several regions of temperature may be utilized to construct adsorption isobars. The data of Table XII present the values obtained at a pressure of 165 mm. **A** graph of these data is given in Fig. 1.

TABLE XII

ADSORPTION ISOBAR OF HYDROGEN ON MANGANOUS–CHROMIC OXIDE AT $P = 165$ mm

Temp , °Abs.	Amount adsorbed, cc.	Nature of adsorbed gas
194.5	10.6	Molecular
273	7.0	Molecular
273	14.0"	Molecular + activated
457	166[a]	Mainly activated
578	170	Mainly activated
717	101	Mainly activated

[a] These values represent only pseudo-equilibria.

The data and diagram give a clear picture of the temperature range where molecular, mixed and activated adsorptions occur. The transition from one form to another is shown to cover a range of several hundred degrees.

Adsorption of Carbon Monoxide.—With carbon monoxide, an orientation experiment similar to that performed initially with hydrogen on manganous–chromic oxide also showed that two types of adsorption occur. Adsorption at —78.5' took place almost instantaneously and produced **a** low equilibrium pressure in a few minutes. On heating from —78.5 to 100°, the adsorbed quantity decreased normally, a normal pressure increase also occurring. Above 100° activated adsorption appeared, as evidenced by the increase in adsorption and decrease in pressure with rise of temperature. At 225° the transition seemed to be complete and at

450° desorption of the activated form was occurring. We can, therefore, conclude that carbon monoxide shows adsorption phenomena paralleling, qualitatively, those of hydrogen on manganous-chromic oxide. A quantitative study is being undertaken.

Adsorption of Ethylene.—With ethylene vigorous adsorption occurred at —78.5'. On warming the catalyst as far as 300° nothing but steady desorption was observed. Above 300° there was a slight decrease in pressure. This may have been due, however, to incipient polymerization,

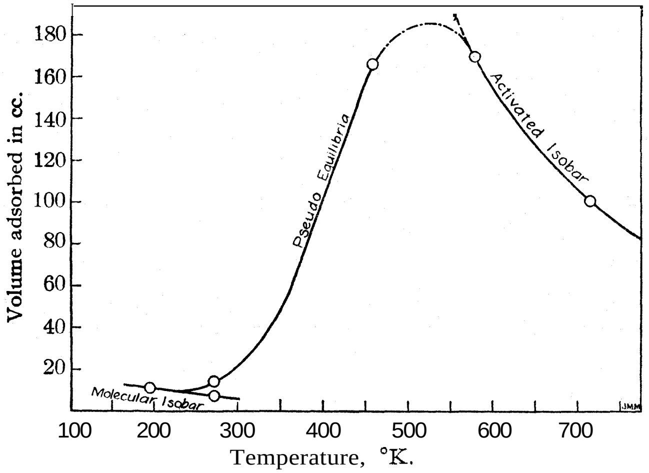

Fig. 1.—Adsorption isobar of hydrogen on manganous-chromic oxide at P = 165 mm.

C. Manganous Pyrophosphate.—Weight of sample, 34.7 g.: with this material a slow adsorption of hydrogen occurred at 305 and 444'. In magnitude and velocity it was far less than that obtained even with the single manganous oxide. The adsorption would appear to be activated since no hydrogen was adsorbed at 0°. The low magnitude and velocity of adsorption are consistent with the absence of dehydrogenation activity found for this material in other work to be reported elsewhere.

General Conclusions

The present investigations on manganous oxide and manganous-chromic oxide surfaces decisively demonstrate the adsorption of hydrogen on such surfaces in two different forms which are sharply differentiated. At low temperatures on manganous-chromic oxide the hydrogen is adsorbed rapidly with a negligible activation energy and with a heat of adsorption of approximately 1900 calories per mole. Adsorption of hydrogen in this form is readily reversible, for the gas can be completely recovered by evacuation at low temperatures. We describe such adsorption as "molecular" adsorption, The second type of adsorption predominates at higher temperatures. On manganous-chromic oxide surfaces it makes its appearance at 0° as a slow drift in pressure after the initial rapid adsorption of the molecular form. . The adsorption occurs with a definite velocity determined by the magnitude of an activation energy and the temperature. in its turn, the activation energy is a function of the surface area being covered. The first portions covered, with the mixed oxide, have a mean activation energy of 6000 calories; successive portions are associated with values rising gradually to higher magnitudes, for example, 10,400 calories. Over a range of several hundred degrees this activated adsorption apparently increases in magnitude with the temperature, a phenomenon to be ascribed to the influence of the activation energy on the velocity of adsorption.' Above 300° with manganous-chromic oxide the isobar begins to show a normal decrease with increase in temperature, and from isotherms in this temperature range heats of adsorption of the activated form of the order of 20,000 calories have been deduced. These high heats of adsorption coupled with the activation energy of adsorption adequately account for the observation that desorption of the activated adsorbate requires an evacuation lasting for several hours at temperatures above 450°.

With manganous oxide the results are similar in character but differ greatly in magnitude. There is no measurable adsorption of the molecular form at $-78.5°$. The activated form makes its appearance first in the neighborhood of 100°. The initial velocity of adsorption is some 750 times slower at 450° Abs. than on the mixed oxide since the initial activation energy is 12,000 calories, rising to 20,000 calories on successive areas covered. The quantities of adsorbed hydrogen on the single oxide are much smaller than those taken up by the mixed oxide at corresponding temperatures.

These experiments represent the first decisive measurements of thr velocity of gaseous adsorption at surfaces and have yielded the first unequivocal calculations of the activation energies of adsorption processes. They yield abundant experimental proof of the theory of activation energy of adsorption recently put forward by one of us (H. S. T.). They introduce into the problem of gaseous reaction velocities at surfaces the velocity of activated adsorption, a factor of fundamental importance, hitherto ignored, of especial significance in the so-called problem of promoter action and in the specificity of reactions at such surfaces.[10]

Since the phenomena observed with hydrogen are also shown, qualitatively at least, by carbon monoxide, it is evident that the type of investigation here initiated with hydrogen can be extended to other gases activated at surfaces. Such studies are in progress.

[10] See Taylor, *Chem. Reviews*, August, 1931.

Summary

1. The adsorptions and velocities of adsorption of hydrogen on manganous oxide and manganous-chromic oxide have been measured in the temperature range −78.5 to 444°.

2. Two forms of hydrogen adsorption have been demonstrated and differentiated, each with characteristic heats of adsorption and activation energies of adsorption on a given surface.

3. The activation energy of adsorption is a function of the composition of the surface and of the physical state of the surface; the velocity of adsorption is small on sintered surfaces and decreases rapidly with increased surface area covered.

4. Activated adsorption of the type here studied is not necessarily a rapid process but may, at certain temperatures, occur at rates so slow as to be immeasurable over periods even of years.

5. Similar observations have been made, qualitatively, with carbon monoxide. This type of investigation can, therefore, probably be generalized for various gases and surfaces.

PRINCETON, NEW JERSEY

NOTES

A Micro Hydrogen Electrode.—The electrode described in this paper was designed to be used where small amounts of liquid were available for the determination. The electrode was made from an ordinary platinum hypodermic needle. The tip was cut off and the needle was threaded for about 5 mm. on the outside. A small shield made of platinum was made to screw on the needle over the tip. A short length of copper wire was soldered to the side of the nub of the needle, leaving enough room at the end to attach a rubber tube for the hydrogen. The entire electrode and cap were insulated by covering with bakelite paint. The electrode was then platinized on the inside. The potassium chloride can be brought into the vessel by means of a capillary or a piece of cotton string soaked in the potassium chloride.

A Lampbank Rheostat.—A system of lamps in parallel makes a serviceable laboratory rheostat for use with magnetic stirrers, electric furnaces, motors, etc. The figure illustrates an easily and cheaply constructed lampbank that has proved to be very convenient. It avoids the use of the switches, sockets and wiring that the ordinary form of lamp board requires, occupies less area per lamp and its resistance can be more easily and rapidly altered.

On a narrow baseboard B whose length depends on the number of lamps it is desired to use are fastened two brass or copper "bus bars" A and C. The lower (C) is flat and serves as a contact for the lamp base terminals. The upper (A), which is round, is set out from the board and so forms a rack on which to hang the lamps. To the side terminal of each lamp is soldered a short hook made of narrow copper strip which hooks over C and so completes the circuit through the lamp. A light strip of wood D is set out about half the length of a lamp from the board and is pivoted at one end, the other being free to move. By raising and lowering the free end of D any required number of lamps may be instantly thrown in or out in a manner made obvious by the diagram. By means of pulleys and a cord attached to D the rheostat may be operated from a distance. The lamps may be adjusted easily to hang freely at right angles to the board by bending the hooks with a pair of pliers. For large resistance steps it has been found convenient to make up spools of nichrome wire equivalent to a given number of lamps that can be hooked over A and thrown in or out with the lamps by raising or lowering D.

THE OXIDATION OF DITHIOPARACHLORAL

BY FREDERICK DANIEL CHATTAWAY AND EDWIN GEOFFREY KELLETT

RECEIVED SEPTEMBER 11, 1930 PUBLISHED JUNE 8, 1931

Dithioparachloral (2,4,6-tris-trichloromethyl-1,3,5-oxadithiane) (I) does not form a stable sulfone but easily breaks down under the influence of oxidizing agents.

When, however, the inhibiting influence of the trichloromethyl groups on the adjacent sulfur atoms is diminished by loss of hydrogen chloride, oxidation of one sulfur atom can occur with formation of a stable, partly unsaturated monosulfone.

Thus when 2,6-bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane (II) is submitted to the action of hydrogen peroxide at the ordinary temperature, it is oxidized to a monosulfone (2,6-bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide (III).

If dithioparachloral (I) is dissolved in acetic acid and kept at 60° for some hours, small quantities of hydrogen peroxide being added from time to time, it is partly destructively oxidized, but to some extent the same unsaturated sulfone (III) is formed, showing that loss of hydrogen chloride is necessary either as a preliminary to, or as a consequence of, oxidation of the sulfur atom.

The sulfone group in this compound (III) exerts upon the neighboring chlorine atoms an even more potent[1] negative activating influence than does a bivalent sulfur atom, an influence equivalent indeed to that produced by two adjacent bivalent sulfur atoms,' since under the influence of alcoholic potassium acetate or aqueous caustic soda the compound loses hydrogen chloride from the 2-position, yielding 6-trichloromethyl-2,4-bis-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide (IV).

When dithioparachloral is subjected to the more powerful oxidizing action of chromic acid in hot acetic acid solution, complete destructive oxidation of the molecule occurs to a predominant extent, but an unsaturated disulfone (2,6-bis-dichloromethylene-1,3,5-oxadithiane-3,3,5,5-tetroxide (VI)) is also produced in small amount. In the formation of this compound, the introduction of two sulfone groups not only necessitates the removal of chlorine as hydrogen chloride from both the 2- and 6-position but also its removal by hydrolysis of the trichloromethyl group in the 4-position (V), loss of carbon dioxide subsequently occurring.

The two hydrogen atoms in the 4-position in (VI) show a positive activation like the hydrogen in the 2-position in (111), but, naturally, in an even more marked degree. The compound (VI) dissolves in aqueous sodium carbonate, and is recovered unchanged on acidification; while on chlorina-

---

[1] Chattaway and Kellett, J. *Chem. Soc.*, 2909 (1929).

tion the two hydrogen atoms are replaced by chlorine, yielding 2,6-bis-dichloromethylene - 4,4 - dichloro - 1,3,5, - oxadithiane - 3,3,5,5 - tetroxide (VII), which does not dissolve in aqueous alkalies.

These reactions of the disulfone (VI) serve to explain the curious behavior on chlorination of the monosulfone (III) which, in warm solution, produces the same compound (IV) as is obtained by the action of alcoholic potassium acetate or of aqueous caustic soda. In this reaction, the activated hydrogen atom in the 2-position must first be substituted by chlorine, forming (VIII). In the $=CClCCl_3$ group of this compound, the a-chlorine atom is positively, and the 8-atom negatively, activated, so that a molecule of chlorine splits off between these two positions, leaving the bis-unsaturated compound (IV).

On the same view, double bonds in positions adjacent to a sulfone group (as the 2- and 4-positions in (IV), and the 2- and 6-positions in (VI)) would not be expected to add on chlorine; and they are actually found not to do so.

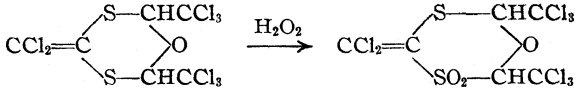
When the monosulfone (III) is treated with alcoholic caustic soda, the dichloromethylene group in the 4-position (which is subject to negative activation both by the sulfone group and the bivalent sulfur atom) is hydrolyzed; loss of hydrogen chloride also occurs from the 2- and 6-positions, yielding 2,6 - bis - dichloromethylene - 4 - carbethoxy - 1,3,5 - oxadithiane - 3,3 - dioxide (IX).

This compound, having a positively activated hydrogen atom in the 4-position, dissolves in aqueous caustic soda (not however, in sodium carbonate: it is therefore less acidic than the disulfone (VI)). On regulated chlorination, two atoms of chlorine are first added on—presumably to the double bond more remote from the sulfone group, giving 2-dichloromethylene - 6 - trichloromethyl - 6 - chloro - 4 - carbethoxy-1,3,5 - oxadithiane-3,3-dioxide (X), which is still soluble in aqueous alkali. On further chlorination, the acidic hydrogen atom is replaced by chlorine, giving 2 - dichloromethylene - 6 - trichloromethyl - 4,6 - dichloro - 4 - carbethoxy-1,3,5,-oxadithiane-3,3-dioxide (XI), which is not soluble in aqueous alkali.

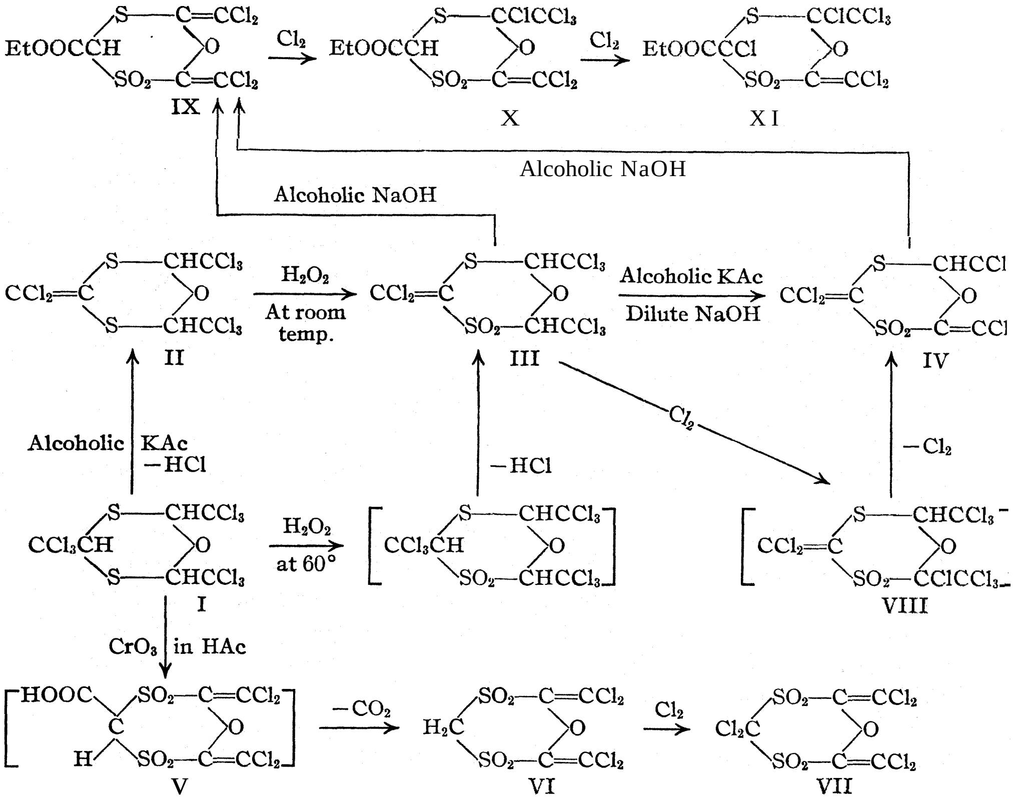
The reactions are represented in the scheme given.

Experimental

Oxidation of 2,6-Bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane to the Dioxide.—Eight grams of finely powdered β-2,6-bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane was suspended in 100 cc. of cold acetic acid and 10 cc. (excess) of 30% aqueous hydrogen peroxide added. The mixture was allowed to remain at the



II III

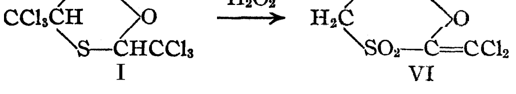


ordinary temperature for fourteen days, during which time the suspended solid passed into solution. The liquid was then diluted with water, and the 2,6-bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide, which separated as a colorless solid, crystallized from ligroin, in which it is somewhat sparingly soluble, and from which it separates in clusters of slender colorless prisms, m. p. 166–167°; yield, 7 g.

Anal. Calcd. for $C_6H_2O_3Cl_8S_2$: C, 15.3; Cl, 60.4; S, 13.6; mol. wt., 470. Found: C, 15.6; Cl, 60.8; S, 13.8; mol. wt., cryoscopic in benzene, 451.

This compound does not react with chlorine or bromine in the cold, nor is it reduced by tin in a boiling mixture of hydrochloric and acetic acids. After heating for thirty minutes at 100" with acetic anhydride and a little strong sulfuric acid, it crystallizes unchanged on cooling. It dissolves readily in cold strong sulfuric acid, and is recovered unchanged on pouring the solution over crushed ice.

Oxidation of Dithioparachloral to **2,6-Bis-dichloromethylene-1,3,5-oxadithiane-3,3,5,5-tetroxide.**—Five grams of **β-dithioparachloral** was dissolved in 60 cc. of acetic



acid at 100°; 10 g. of anhydrous chromic acid was added in small portions during one hour, after which heating was continued on the water-bath for another hour. Some carbon dioxide was evolved during this process, and sulfate ion could be detected in the solution, showing that disruptive oxidation had occurred to some extent.

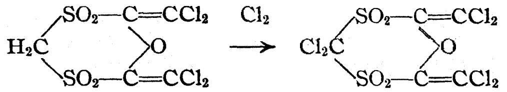
The reaction mixture was cooled and diluted with water, when the *tetroxide,* mixed with the dioxide (above) separated as a colorless solid. It was washed with aqueous sodium carbonate, which dissolves the tetroxide but not the dioxide; the filtrate was acidified with hydrochloric acid, and the tetroxide which again separated was crystallized from mixed chloroform and ligroin. It is only sparingly soluble in organic solvents, and separates as a felt of colorless silky needles, m. p. 185"; yield, 0.4–0.8 g.

Anal. Calcd. for $C_5H_2O_6Cl_4S_2$: Cl, 40.8; S, 18.4. Found: Cl, 40.5; S, 18.3.

The tetroxide may also be isolated by repeatedly recrystallizing the crude oxidation product from ligroin; showing that the bis-dichloromethylene structure arises in the actual oxidation process, and is not merely introduced by the use of the alkaline carbonate solvent in working up.

An identical product was similarly obtained from α-dithioparachloral.

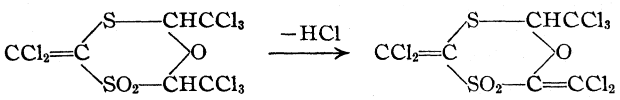
Chlorination of the **Tetroxide.**—Five grams of the tetroxide was dissolved in 4 cc. of warm acetic acid, and a rapid stream of chlorine passed through the solution for one hour. Hydrogen chloride was evolved during the chlorination. The solution was allowed to stand overnight, when 4,4-dichloro-2,6-bis-dichloromethylene-1,3,5-oxadithiane-3,3,5,5-tetroxide separated in large colorless rhombs, m. p. 143°. It is very readily soluble in acetic acid, and moderately easily soluble in alcohol, from which it is best recrystallized; it does not dissolve in cold aqueous caustic soda.



VI VII

Anal. Calcd. for $C_5O_5Cl_6S_2$: Cl, 51.1; S, 15.4. Found: Cl, 51.4; S, 15.5.

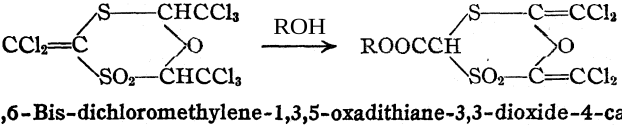
Preparation of **2,4-Bis-dichloromethylene-6-trichloromethyl-1,3,5-oxadithiane-3,3-dioxide.**—One gram of the dioxide (III) was suspended in 20 cc. of 10% aqueous caustic soda, and warmed gently for a few minutes at 40–50°. After cooling and acidifying with hydrochloric acid, the solid was separated and crystallized from petroleum, in which it is somewhat sparingly soluble, and from which it separates as *a* felt of colorless needles, m. p. 148°.



Anal. Calcd. for $C_6HO_3Cl_7S_2$: Cl, 57.3. Found: Cl, 57.6.

The same compound was obtained by heating the dioxide with alcoholic potassium acetate, and also by chlorinating it in warm acetic acid solution; hydrogen chloride is evolved during the chlorination.

Hydrolysis of the Dioxide.—To obtain a clean workable product in these hydrolyses, the procedure given below must be followed with some care. It is especially essential to work in dilute solution.



Ethyl 2,6-Bis-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide-4-carboxylate.—Eight grams of the dioxide was dissolved in 800 cc. of cold ethyl alcohol, and aqueous caustic soda (10%) added until the mixture was permanently alkaline. It was then bright yellow in color; 350 cc. of water, followed by 100 cc. of strong hydrochloric acid, was then added. The solution became practically colorless and on diluting with about 3 liters of water, the ester separated as a flocculent precipitate. It was crystallized from ligroin (500 cc.), from which it separates in plume-like clusters of colorless needles, m. p. 112.5°; yield, 4 g.

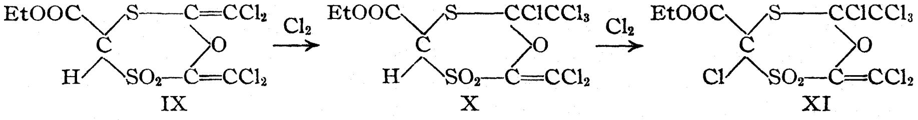
Anal. Calcd. for $C_8H_6O_5Cl_4S_2$: C, 24.9; H, 1.3; Cl, 36.6; S, 16.6. Found: C, 25.0; H, 1.9; Cl, 37.0; S, 16.8.

Methyl **2,6-Bis-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide-4-carboxylate.**—This ester was similarly prepared by using methyl alcohol instead of ethyl alcohol as the solvent. It crystallizes from ligroin, in which it is sparingly soluble, in colorless needles, m. p. 126°.

Anal. Calcd. for $C_7H_4O_5Cl_4S_2$: Cl, 38.2; S, 17.2. Found: Cl, 38.5; S, 17.2.

The ethyl and methyl esters are somewhat unstable and turn brown on long exposure to air. Attempts to prepare the free carboxylic acid from them were unsuccessful. On heating with acids or alkalies, they are decomposed and tarry products formed. Similarly, when the hydrolysis of the dioxide was carried out in aqueous acetone instead of an alcohol with a view to obtaining the free acid directly, only an uncrystallizable tarry product was obtained.

Chlorination of the Ethyl Ester



First Stage.—One gram of the ethyl ester (IX) was suspended in 5 cc. of cold acetic acid, and a slow stream of chlorine bubbled through for half an hour. During this time the solid went into solution, and on allowing the mixture to stand for two hours, ethyl 6-chloro-6-**trichloromethyl**-2-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide-4-carboxylate crystallized out. This was filtered off and recrystallized from ligroin, in which it is moderately easily soluble, and from which it separates in slender colorless prisms, m. p. 151–152°.

Anal. Calcd. for $C_8H_6O_5Cl_6S_2$: Cl, 46.6. Found: Cl, 47.0.

This compound dissolves in aqueous alkalies, but decomposes rather rapidly in alkaline solution, and consequently separates in an impure brownish state on acidification. It is somewhat unstable, and even when kept in a sealed tube decomposes in time into a brown tarry mass.

Second Stage.—Two grams of the ester (IX) was suspended in 20 cc. of acetic acid and chlorinated as above. After the chlorine addition product had crystallized out, chlorine was again passed through. Hydrogen chloride was slowly evolved, and the crystals again went into solution. When all had dissolved, the solution was very gradually diluted by addition of cold water, when ethyl **4,6-dichloro-6-trichloromethyl-2-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide-4-carboxylate** separated. It was recrystallized from alcohol, in which it is readily soluble, and from which it separates in colorless rhombic plates, m. p. 161.5°.

Anal. Calcd. for $C_8H_5O_5Cl_7S_2$: C, 19.4; H, 1.0; Cl, 50.2; S, 12.9; mol. wt. 493. Found: C, 19.8; H, 1.1; Cl, 50.5; S, 13.0; mol. wt., cryoscopic in benzene, 452.

This compound is insoluble in aqueous alkalies, and, unlike the compounds above, which contain the acidic hydrogen atom, it is perfectly stable at the ordinary temperature.

Summary

Dithioparachloral does not form stable sulfoxides or sulfones owing to the mutual influence of the chlorine and bivalent sulfur atoms. Oxidation only occurs when some of the chlorine is removed either by previous treatment or in the oxidation process itself.

On oxidation with hydrogen peroxide it yields 2,6-bis-trichloromethyl-4-dichloromethylene-1,3,5-oxadithiane-3,3-dioxide, and with hot chromic acid 2,6-bis-dichloromethylene-1,3,5-oxadithiane-3,3,5,5-tetroxide.

The behavior of these oxidation products toward alkaline reagents and on chlorination illustrates both the activating influence of bivalent sulfur and the alternating effect originating from sulfone groups.

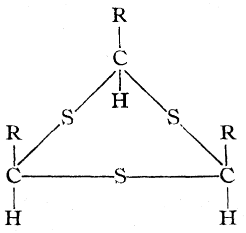
THE SUPPOSED ISOMER OF 1,3,5-TRITHIANE

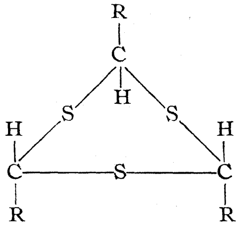
BY FREDERICK DANIEL CHATTAWAY AND EDWIN GEOFFREY KELLETT

RECEIVED SEPTEMBER 11, 1930 PUBLISHED JUNE 8, 1931

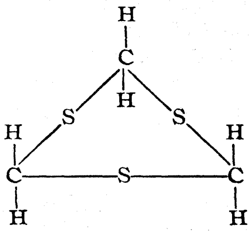
Accepting the view that the trithioaldehydes are 1,3,5-trithianes, strictly analogous in their isomerism to the paraldehydes, there can be no *cis-trans* isomerism of 1,3,5-trithiane itself.



Cis



Trans



1,3,5-Trithiane

Hinsberg,[1] however, has stated that this compound, which melts at 216°, is converted under the influence of hydriodic acid (which converts *a*- into *β*-trithioacetaldehyde) into an isomeric modification which melts with decomposition at 247°. It is reconverted into the "stable form" on crystallization from benzene.

Fromm and Schultis,[2] and Bell and Bennett,[3] have since reëxamined this phenomenon without arriving at any satisfactory conclusion.

Since, however, by the action of other reducing agents upon 1,3,5-trithiane, a product of the same or only slightly lower m. p. (247°) is ob-

---

[1] Hinsberg, *J. prakt. Chem.*, *85*, 341 (1912).

[2] Fromm and Schultis, *Ber.*, *56*, 937 (1923).

[3] Bell and Bennett, *J. Chem. Soc.*, 19 (1929).

tained and this compound on mild oxidation yields again the original material of m. p. 216,° it seems probable that the supposed higher-melting isomer is actually an unstable reduction product (or mixture of products) of 1,3,5-trithiane, and that the latter compound exists as the theory demands in only a single modification.

Experimental

The Alleged Isomerism of 1,3,5-Trithiane.—When hydrogen sulfide is passed into a mixture of 1 volume of formalin with 2 volumes of strong hydrochloric acid, the colorless solid which separates (after washing with air-free water and drying in *vacuo*) melts at 247° (decomp.). After crystallization from any solvent, it melts at 216°; the same lowering of the melting point takes place on solution even at the ordinary temperature,' since if the compound of m. p. 247° is dissolved in cold benzene and precipitated out with ligroin, the product melts at 216°. The compound of m. p. 247° is also converted into ordinary pure 1,3,5-trithiane, m. p. 216°, on exposure to air for about twenty-four hours, or on heating for more than a short time on the steam-bath, or on shaking for a minute with cold dilute aqueous hydrogen peroxide. The high-melting product can be obtained from normal 1,3,5-trithiane, m. p. 216°, not only (as Hinsberg found) by the action of hydriodic acid, but also by the action of other reducing agents, *e.* g., stannous chloride, or metals and hydrochloric acid, reagents which do *not* effect steric inversion in the trithioacetaldehydes. The melting point is not perfectly constant, and may be as low as 243°, but there appears to be no reason to doubt that the same compound is present in each case.

If a weighed quantity of the freshly-prepared substance of m. p. 247° is shaken with a known amount of dilute aqueous hydrogen peroxide, filtered and washed, and the filtrate back-titrated against standard permanganate, an appreciable decrease in the amount of available oxygen present is observed; but no consistent analyses have been obtained by this method.

These observations appear to show that the compound, m. p. 247°, is of the nature of an unstable reduction product (or mixture of products) of 1,3,5-trithiane.

Summary

The compound of m. p. 247°, which Hinsberg supposed to be isomeric with 1,3,5-trithiane, has not the properties of an *isomer* of the latter compound but rather those of an unstable *reduction product.*

THE EQUILIBRIUM $C_6H_6 + CO_2 \rightleftharpoons C_6H_5COOH$[1]

BY CORLISS R. KINNEY AND DAVID P. LANGLOIS

RECEIVED NOVEMBER 17, 1930 PUBLISHED JUNE 8, 1931

The decomposition of organic acids into carbon dioxide has been studied extensively, as has the decomposition of malonic acid and derivatives into carbon dioxide and monobasic acids; but we are not aware of any attempt to determine whether the reaction is reversible and if so whether the reaction proceeds sufficiently far to be of practical value.[2] With these points in view several investigations have been started.

The reaction of benzene with carbon dioxide was chosen for the first study because of the adaptability of the substances involved. An approximate calculation of the free energy of the reaction

$$C_6H_6 + CO_2 \rightleftharpoons C_6H_6COOH$$

showed that the position of equilibrium would be far to the left, but that provided an equilibrium could be established, a small amount of benzoic acid would be produced.

The search for an appropriate catalyst was made by studying the rate of decomposition of benzoic acid in contact with various catalytic mixtures at various temperatures, assuming that an active catalyst for the reverse reaction would catalyze the forward reaction as well. The percentage decomposition at various time intervals and temperatures for some of the better catalysts are listed in the experimental part. The most effective were of the Zn–Cu–Cr oxide type used in methanol synthesis. Such catalysts produced considerable decomposition of benzoic acid at temperatures as low as 250°, the boiling point of the acid. This temperature is much lower than any recorded previously. The rate of decomposition at 300° is shown in the accompanying diagram. The shape of the curve indicates that after about five days of heating, an equilibrium was being approached.

The forward reaction was studied by heating benzene and carbon dioxide in glass bomb tubes containing the catalyst to pressures between 17 and 35 atmospheres. At 300° and about 35 atmospheres' pressure the crude yield of acid products amounted to 0.13% based on the weight of benzene

---

[1] Presented at the Cincinnati meeting of the American Chemical Society, September, 1930.

[2] Two patents on the reaction of methane with carbon dioxide are of interest in this connection. Plauson and Vielle, Brit. Pat. 156,148 (1920); *Chem. Abstracts*, 15, 1726 (1921), and H. Dreyfus, Brit. Pat. 226,248 (1923); *Chem. Abstracts*, 19, 2057 (1925). Friedel and Crafts [*Ann. chim. phys.*, [6] *14*, 1441 (1887)] found that benzoic acid was produced in traces by the action of aluminum chloride on benzene and carbon dioxide. An attempt to use the method commercially was unsuccessful [Frydlender, *Revue des Produits Chimiques*, 21, 24 (1918)].

used. When the crude acid product was heated, benzoic acid sublimed, giving a yield of 0.08%.

Since benzoic acid has been obtained from benzene and carbon dioxide, and benzoic acid is decomposed by heat into those substance, it should be possible to establish an equilibrium. The determination of the position of equilibrium under various conditions has not been attempted, because, unfortunately, catalysts sufficiently active for a rapid attainment of equilibrium have not been found.

The search for more active catalysts is being continued, as well as the extension of the method to the formation of other acids.

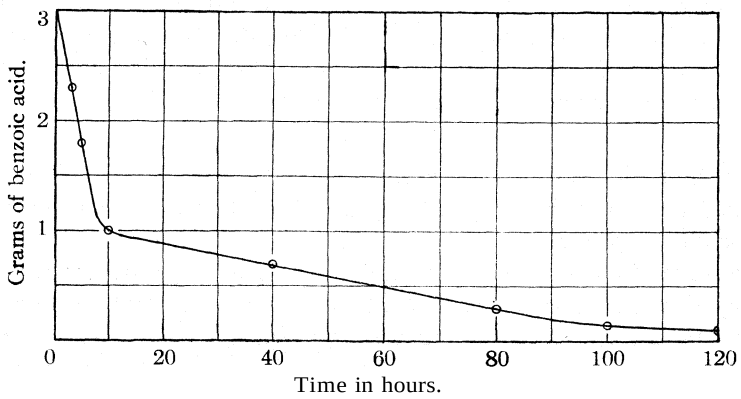

Fig. 1.—Rate of drcomposition of benzoic acid at 300° in contact with a Zn–Cu–Cr oxide catalyst.

Experimental Part

After a number of preliminary experiments, the two reactions were studied by heating pairs of bomb tubes, both of which contained a given catalyst, together with **3** g. of pure benzoic acid in the first tube, and 2 g. of pure benzene and 2.2 g. of carbon dioxide[3] (introduced as snow) in the second. The two tubes were then heated in a Carius furnace at as nearly a constant temperature as possible. This seldom varied more than three or four degrees in either direction. After heating, the tubes were opened and the contents digested for several minutes with boiling potassium hydroxide. The solution was cooled, filtered and extracted twice with ether. The potassium hydroxide was neutralized with dilute hydrochloric acid and if there was sufficient benzoic acid present to be precipitated, it was filtered out before extracting the remaining acid with two portions of ether. The ether was evaporated and the weight combined with that of the precipitated acid. In the experiments on the decomposition of benzoic

---

[3] In several experiments 4 4 g. of carbon dioxide was introduced. The pressure in these tubes was calculated to be about **35** atmospheres at 300° and about **17** atmospheres in the tubes containing 2.2 g. of carbon dioxide.

acid an odor of phenol was often pronounced, although the amount actually produced was quite small. The more characteristic of the results obtained are listed in Table I.

TABLE I

CHARACTERISTIC RESULTS

[a] Prepared by the method of Fenske and Frolich, *Ind. Eng. Chem.*, 21, 1052 (1929), except that the oxides were reduced by heating them with benzoic acid. [b] Same as [a] except that the oxides were reduced with benzoic acid in a stream of carbon dioxide. [c] Same as [a] except that the oxides were not reduced, but were heated in air until the mixture turned black. [d] Made by heating the carbonate in a stream of hydrogen. [e] Made by heating the nitrate in an open crucible until all of the nitrogen oxides were driven off.

In order to determine the yield of benzoic acid from benzene and carbon dioxide, six tubes, each containing 2 g. of benzene and 4.4 g. of carbon dioxide, were heated with catalyst (c) for ten hours at 300°. The pressure was calculated to be about 35 atmospheres. Upon opening the tubes, the acid produced in four of them was extracted with hot sodium hydroxide, the solution cooled, filtered, acidified, and extracted four times with ether. The ether was evaporated and the weight of the brown crystalline mass remaining was 0.0165 g. The ether extract from the last two tubes was extracted four times with dilute sodium carbonate, the sodium carbonate solution acidified and extracted four times with ether. Upon removing the ether, the residue was no purer than that obtained by extracting with dilute sodium hydroxide. There was no odor of phenol. The crude acid weighed 0.0080 g. and was sublimed onto a cold watch crystal. The weight was 0.0050 g. and the melting point 103–108°. Mixed with pure benzoic acid, the melting point was raised to 110–114°. A second sublimation did not raise the melting point.

Summary

Catalysts have been found which initiate the decomposition of benzoic acid into benzene and carbon dioxide at temperatures as low as 245–250°. The reaction was found to be slightly reversible, benzoic acid being produced by the reaction of benzene on carbon dioxide in small amounts.

SOME SUBSTITUTED DI-(BETA-PHENYLETHYL)-AMINES AND BENZYL-BETA-PHENYLETHYLAMINES

BY JOHANNES S. BUCK

RECEIVED DECEMBER 15, 1930 PUBLISHED JUNE 8, 1931

A great deal of attention has been given to derivatives of β-phenylethylamine, particularly to their physiological action. This group contains compounds such as epinine, hordenine, tyramine, etc., and may also be considered as related to the hydrastinines (for example, Lodal), so that it is of great importance.

Much less work appears to have been done on secondary amines containing more than one benzene nucleus, of the type of di-(β-phenylethyl)-amine and benzyl-β-phenylethylamine, although a small number of these compounds is described in the literature and in some cases their pharmacological action has been examined. Di-(β-phenylethyl)-amine has been described by many workers; benzyl-b-phenylethylamine, *p*-methoxy-benzyl-β-phenylethylamine, *p*-hydroxybenzyl-β-phenylethylamine, *o*-hydroxybenzyl-β-phenylethylamine, and 3-methoxy-4-hydroxybenzyl-β-phenylethylamine, by Shepard and Ticknor;[1] o-veratrylhomopiperonylamine by Kaufmann and Miiller;[2] benzyl-*p*-hydroxy-β-phenylethylamine, piperonyl-*p*-hydroxy-β-phenylethylamine, veratryl-*p*-hydroxy-β-phenylethylamine, and *o*-hydroxybenzyl-*p*-hydroxy-β-phenylethylamine, by Hoffmann and La Roche;[3] and *p*,*p*′-diamino-di-(β-phenylethyl)-amine and *p*,*p*′-dihydroxy-di-(β-phenylethyl)-amine by von Braun and Blessing.[4] The last authors also prepared cyclohexyl-*p*-hydroxy-β-phenylethylamine and cyclohexyl-*p*-amino-β-phenylethylamine. No compound containing the physiologically important catechol group (adjacent hydroxyl groups, usually in the 3,4-positions) appears to have been described. It was with the idea of prepar-

[4] Von Braun and Blessing, *Ber.*, 56, 2153 (1923).

ing such compounds that the present work was undertaken. A number of the desired amines (as salts) have been obtained and their pharmacological properties will be described in another place.

The usual method for preparing benzyl-β-phenylethylamines is to condense a phenylethylamine with an aldehyde to form the Schiff base and then to reduce this, usually with sodium amalgam or (in the author's experience by far the better way) by the Adams method. This route has also been used for di-(β-phenylethyl)-amine by Rupe and Hodel.[5] In the majority of compounds prepared by the present author, this method was adopted to obtain the ethers of the hydroxyamines, and the ethers were then demethylated. Another reaction was sometimes employed. This consisted of combining a primary amine with the requisite ω-halide, to give the secondary amine salt, and this was then demethylated as before. The direct combination of a 3,4-dihydroxyamine with an aldehyde to form the Schiff base was not investigated closely as the method held little promise. Which of the two methods is used is a matter of expediency, although naturally the Schiff base method offers fewer chances of secondary reactions. In the direct combination of an amine and a halide, the formation of tertiary and quaternary compounds was not observed under the conditions employed. In the case of homoveratrylhomoveratrylamine, however, considerable amounts of homoveratrylamine hydrochloride were produced, indicating either the liberation of free secondary amine or the decomposition of the chloride into dimethoxystyrene.

Experimental

Starting Materials

β-Phenylethylamine.—Some was obtained from Kahlbaum, but most of it was prepared by a Hofmann reaction on phenylpropionamide.

Homoveratrylamine.—This was prepared as described by Buck[6] by a Hofmann reaction on dimethoxyphenylpropionamide.

Homoanisylamine.—Anisaldehyde, heated with malonic acid and pyridine (Rupe method) gave *p*-methoxycinnamic acid in 79% yield. On reduction (sodium amalgam) p-methoxyphenylpropionic acid was obtained (86% yield). Heated in a stream of dry ammonia at 210° for two hours, this gave the amide (62% yield with one heating) which was then converted, by the theoretical amount of sodium hypochlorite, into the amine; yield, 56%; b. p. 132° (10 mm.).

β-Phenylethyl chloride was prepared by the method of Barger,[7] which proved to be satisfactory.

β-Phenylethyl bromide was obtained from the Eastman Kodak Co.

3,4-Dimethoxyphenylethyl Alcohol.—Homoveratrylamine, in dilute acetic acid solution, was converted into the alcohol by the addition of the theoretical amount of sodium nitrite. The product (90% yield) boiled at 180–193° (13 mm.). Redistilled,

[7] Barger, *J. Chem. Soc.*, 95,2193 (1909).

it forms a faint yellowish viscous oil, with only a slight odor; b. p. 166–168" (8 mm.); d_{20}^{20} 1.1426; n_{15} 1.5409.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.89; H, 7.74. Found: C, 65.94; H, 7.61

The **p-nitrobenzoate,** prepared by the Schotten-Baumann method, and recrystallized from alcohol, forms bright yellow, glittering, jagged plates, melting at 81° and readily soluble in the usual solvents to colorless solutions.

Anal. Calcd. for $C_{17}H_{17}O_6N$: C, 61.61; H, 5.18; N, 4.23. Found: C, 61.44; H, 5.66; N, 4.03.

The **urethan** was prepared by warming molecular amounts of the alcohol and phenyl isocyanate and washing the product with carbon bisulfide. Recrystallized from alcohol it forms white, pearly aggregates of thin plates, somewhat soluble in hot water and readily soluble in the usual solvents. It melts at 98–99".

Anal. Calcd. for $C_{17}H_{19}O_4N$: C, 67.74; H, 6.31; N, 4.65. Found: C, 67.62; H. 6.44; N, 4.47.

3,4-Dimethoxy-β-phenylethyl chloride could not be obtained in the pure state. The material used was obtained by treating the alcohol in carbon tetrachloride solution with the theoretical amount of phosphorus pentachloride and then removing all volatile matter under reduced pressure at 100°. A thick, reddish oil was obtained.

Schiff Bases.—In general these compounds were prepared by mixing the reactants in molecular proportions and then heating at 100° under reduced pressure until all water was evolved (usually thirty minutes). The yield is practically the theoretical. The compounds are well defined and are readily soluble in the usual solvents. They are best recrystallized by allowing their solutions in ether to evaporate spontaneously. They are tabulated below. Most of those previously known may be found in connection with the amines derived from them (see above). It is interesting to note that phenylacetaldehydes appear to give oily or ill-defined Schiff bases.[5,8]

TABLE I

[8] Späth and Berger, *Ber.*, 63,2098 (1930).

Amines.—The Schiff bases are very readily reduced in acetic acid solution by platinum oxide and hydrogen, after the method of Adams. Excess acetic acid was removed under reduced pressure, the acetate dissolved in water and aqueous ammonia or sodium hydroxide solution added. The amine was then extracted with ether, the extract dried over potassium hydroxide and the ether removed. The amine was then recrystallized from alcohol–aqueous ammonia mixture or distilled under reduced pressure. The yield is practically the theoretical. Those amines not prepared *via* the Schiff base were obtained from the salts in an analogous manner.

In the second method of preparation, the halide and amine were mixed in molecular amounts and heated on the water-bath until the reaction was complete. Bromides react much more rapidly than the chlorides and the reaction mixture may not require heating. With the chlorides up to twenty hours' heating may be required. Usually the amine hydrobromide separates in the solid state, but the hydrochlorides remain oily. In all cases, ether is added to the reaction mixture and the salt filtered off and recrystallized.

The amines tend to form carbonates in air. Two salts were made from each amine, the hydrochloride, wherever possible, for pharmacological test, and another salt for analytical check. The amines and salts are tabulated.

Phenolic **Amines.**—β-Phenylethylamine derivatives are somewhat unstable to strong acids, but by carefully regulating the reaction it was found possible to obtain, in most cases, the demethylated (phenolic) derivatives in good yield. The demethylation, which goes extraordinarily easily, was carried out by means of hydriodic acid (52%, *d* 1.7), which must be colorless. The amine, mixed with ten times its weight of acid, was cautiously heated in a current of carbon dioxide until the evolution of methyl iodide had ceased. One-fifth of the acid was then distilled over and the rest removed under reduced pressure. The hydriodide usually remained as a crystalline mass.

The phenolic amine salts are generally well-defined, crystalline compounds, stable when quite pure. They possess, as might be expected, powerful reducing properties, reducing gold and silver salts in the cold. Those containing two adjacent hydroxyl groups give intense green colors with ferric chloride. Aqueous alkalies, when not present in excess, give white precipitates of the bases, at once soluble in excess to unstable yellowish solutions which rapidly oxidize.

In one case, 4-hydroxybenzyl-4'-hydroxy-β-phenylethylamine, no adjacent hydroxyl groups are present and only a faint violet color is obtained with ferric chloride. The powerful reducing properties are also absent and the base is stable.

[a] This demethylation was carried out by adding 3.3 moles of hydriodic acid (as 52% solution) to the amine, and keeping the mass just fused for five minutes. On adding alcohol the product crystallized.

In general, the solubility of all the salts is of the same order. They are readily soluble in warm water, warm alcohol and warm acetic acid, but are much less soluble in a dilute solution of the acid from which they were formed. A number of the salts have distinct colors when freshly recrystallized (usually a pink tint) due to water of crystallization. The color disappears on drying the salt at 110°.

Veratrylphenylethylamine and homoveratrylphenylethylamine failed to demethylate normally with hydriodic acid. The products formed are being examined.

The melting points above cited are corrected. Boiling points were taken on Anschütz thermometers. The author is indebted to Mr. Walter S. Ide for the majority of the micro analyses in this paper.

Summary

A series of 3,4-dihydroxybenzyl-β-phenylethylamines and 3,4-dihydroxy-di-(β-phenylethyl)-amines is described, together with the intermediate Schiff bases and secondary amines.

CATALYSIS IN ORGANIC CHEMISTRY. IV. DECOMPOSITIONS OF ESTERS AND ACIDS BY ANHYDROUS ZINC CHLORIDE

BY H. W. UNDERWOOD, JR., AND O. L. BARIL

RECEIVED DECEMBER 29, 1930 PUBLISHED JUNE 8, 1931

The types of decomposition of esters by anhydrous zinc chloride described in a previous paper[1] may be represented by the equations

$$RCOOC_nH_{2n+1} = RCOOH + C_nH_{2n} \qquad (I)$$
$$RCOOC_nH_{2n+1} = RH + CO_2 + C_nH_{2n} \qquad (II)$$
$$RCOOC_nH_{2n+1} = RC_nH_{2n+1} + CO_2 \qquad (III)$$

The transformation of ethyl benzoate into benzoic acid, benzene and ethylene and the conversion of methyl salicylate into o-cresol and carbon dioxide are typical decompositions. It has been noted that diethyl oxalate and succinate react with anhydrous zinc chloride, yielding ethyl chloride and zinc salts. The present paper gives an account of the behavior of twelve esters and seven acids.

Discussion of Experiments

Pure freshly distilled or crystallized esters or acids and 0.5 mole of anhydrous zinc chloride per mole of ester or acid were used. Unless otherwise stated, the decomposition products were isolated by the proced-

ures described in a previous paper.[1] The results of our experiments with esters are given in Table I.

TABLE I

RESULTS WITH ESTERS

Carbon dioxide was evolved in all the decompositions except that of benzyl acetate. In the calculation of yields of products allowance was made for the ester recovered. The volatile unsaturated hydrocarbons were collected as dibromides. No evidence of decomposition was found in experiments with diethyl carbonate and ethyl *m*-nitrobenzoate.

				Products					
No.	Ester	Moles	Time of heating, hours	Hydrocarbon	%	Unchanged ester, %	Acids and other products	%	Type of decomp.

[a] The mixture of the ester and anhydrous zinc chloride evolved gases spontaneously until none of the liquid was left in the flask; a 50% aqueous solution of pyridine was used to absorb the hydrogen chloride. The decomposition of ethyl chlorocarbonate has been noted previously by Butlerow [Bull. *soc. chim.*, 586 (1863)] and Ulsch [Ann., **226**, 281 (1884)]. [b] The tests described by Mulliken ["Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, 1916, 1922, Vols. I, II and IV] were used for the identification of this compound. [c] The liquid secured by distillation of the reaction mixture was fractionated three times. [d] Evidently zinc chloride converts some of the benzoic acid formed by the decomposition of the ester into benzene and carbon dioxide. The presence of isopropyl chloride in the reaction products indicates that zinc chloride reacted with some of the isopropyl benzoate. [e] The phthalic anhydride sublimed in the neck of the flask and was removed before the reaction mixture was distilled. Phthalic and benzoic acids were separated by means of cold chloroform. Evidently anhydrous zinc chloride splits the ester into phthalic acid and butylene; the water formed in the transformation of some of the phthalic acid into the anhydride converts some of the butylene into *sec.*-butyl alcohol. The presence of n-butyl chloride in the products indicates that zinc chloride reacted with a small amount of di-*n*-butyl phthalate. [f] Apparently isoamyl salicylate does not undergo the previously noted type of decomposition[1] which converts methyl and ethyl salicylates into o-cresol and *o*-ethylphenol, respectively. [g] The reaction mixture was cooled and extracted with

two 100-cc. portions of ether; the solution thus formed was shaken with three 80-cc. portions of water to remove zinc chloride, dried overnight with 5 g. of anhydrous sodium sulfate and fractionated. [h] o-Toluidine and o-ethylaniline were identified by the preparation of acetyl derivatives. [i] It is interesting to note that the ethyl ester of an alkyl substituted acetic acid can be prepared in one step from the diethyl ester of an alkyl substituted malonic acid. [j] The residue in the reaction flask was dark colored and tarry; possibly this was formed from the fragments of the benzyl groups by the zinc chloride. [k] The reaction mixture was cooled and extracted with two 75-cc. portions of ether. The ether solution was shaken with six 30-cc. portions of water to remove zinc chloride and dried with 5 g. of anhydrous sodium sulfate. The solvent was subsequently removed by distillation on a water-bath. Evidently the presence of the nitro group in this ester makes it more stable than ethyl benzoate.

Formic, Acetic, Propionic and *n*-**Butyric** Acids.—No evidence of decomposition was found in experiments with these compounds.

Benzoic, Salicylic **and Cinnamic** Acids.—From one-fourth mole of benzoic acid which had been refluxed with anhydrous zinc chloride for half an hour we obtained five-hundredths mole (20%) of benzene[b] and carbon dioxide. A mixture containing one-fourth mole of salicylic acid was refluxed for one and one-half hours and distilled. Thirteen-hundredths mole (52%) of phenol[b] and carbon dioxide were obtained. One-fourth mole of cinnamic acid was refluxed with anhydrous zinc chloride for an hour. The products were five-hundredths mole (20%) of styrene, six-hundredths mole (48%) of distyrene, carbon dioxide and 6 g. of a dark brown material which had the properties of metastyrene. The styrene and distyrene were identified by the procedures cited in a previous paper.'

Anhydrous zinc chloride acts partly as a catalyst and partly as a reagent in some of the decompositions described in this paper.

The authors wish to express their thanks for a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences which partly defrayed the cost of this work.

Summary

This paper describes the decompositions of a series of esters and acids by anhydrous zinc chloride; the transformations observed involve the elimination of an aliphatic unsaturated hydrocarbon or carbon dioxide or both. Alkyl chlorides, apparently formed by the reaction of zinc chloride with the ester, are found in the products obtained from two of the compounds studied. Several aliphatic acids remain unchanged when heated with anhydrous zinc chloride.

STEREOCHEMISTRY OF DIPHENYLBENZENES. THE CIS AND TRANS FORMS OF 2,5-DI-(3-BROMO-2,4,6-TRIMETHYLPHENYL)-1,3,4,6-TETRAHYDROXYBENZENES AND THE CORRESPONDING ACYLATES. XV[1]

BY P. R. SHILDNECK[2] AND ROGER ADAMS

RECEIVED JANUARY 22, 1931 PUBLISHED JUNE 8, 1931

In previous papers the various possibilities for stereoisomerism in the diphenylbenzenes[1a,d] have been discussed and compounds have been synthesized which indicate the validity of the theoretical speculation. The compounds thus far studied have been of the general type (I) and have been found in meso and racemic modifications. Another very interesting type (II) is that in which all four groups on the central ring are the same and each of the two end rings is asymmetrically substituted. Assuming the same restricted rotation between the rings as in the diphenyl series, and therefore that the two end rings are not co-planar with the central ring, it would be impossible to obtain any compound the mirror image of which would not be identical with the object, so that optical isomerism is excluded. On the other hand there are two forms possible, represented by Formulas (III) and (IV). These correspond directly to *cis–trans* isomers of the usual type, and neither is resolvable. If each of the two end rings in such molecules were symmetrically substituted, however, the two isomers indicated would become identical.

In this communication are described the synthesis and properties of cis and *trans* modifications of compounds falling in this group. The 2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,5-dibromoquinones (V) and (VI) described in the last publication in this series are readily converted by means of dilute sodium hydroxide solution into the corresponding hydroxy-

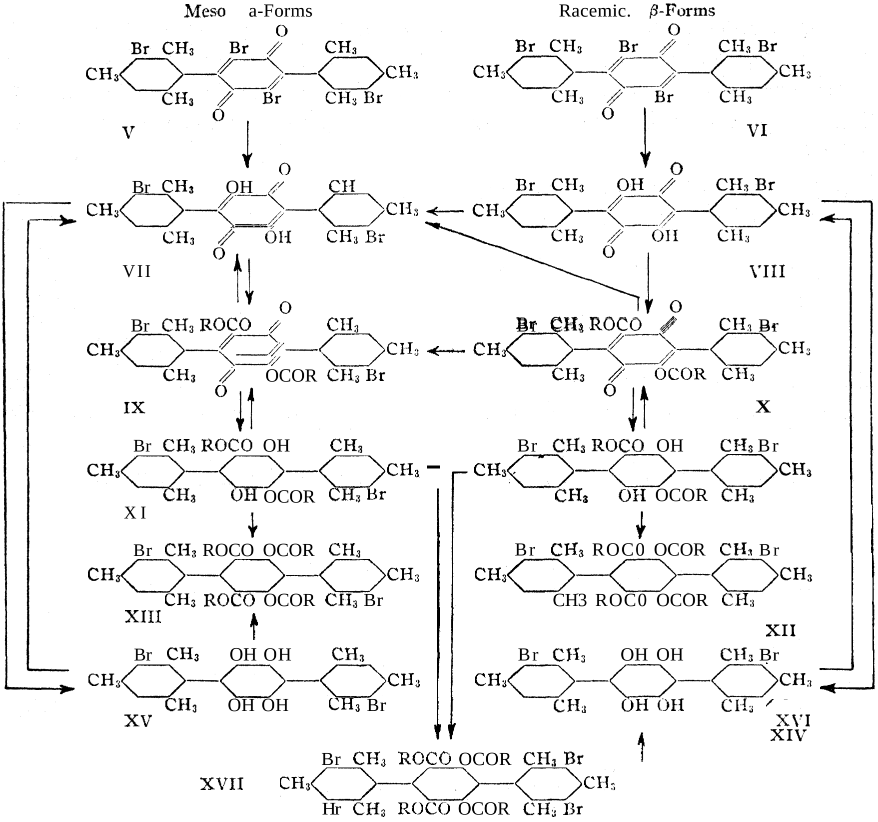
[1] For the last papers in this series see: (a) Browning and Adams, THIS JOURNAL, 52, 4098 (1930); (b) Steele and Adams, *ibid.*, 52, 4528 (1930); (c) Stoughton and Adams, *ibid.*, 52, 5263 (1930); (d) Shildneck and Adams, *ibid.*, 53, 343 (1931); (e) Bock and Adams, *ibid.*, 53, 374 (1931).

[2] This communication is a portion of a thesis submitted by P. R. Shildneck in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

quinones, (VII) and (VIII). These, in turn, may be acylated to the diacyloxyquinones (IX) and (X) or reduced to the tetrahydroxybenzenes (XV) and (XVI). Moreover, the diacyloxyquinones may be hydrolyzed to the corresponding hydroxyquinones or reduced to the diacyloxyhydroquinones (XI) and (XII), which may be hydrolyzed to the corresponding tetrahydroxy compounds or acylated to the tetraacyloxy derivatives (XIII and (XIV).



Each of the original dibromoquinones gives its own characteristic derivatives in the series of reactions just described. The tetrahydroxy compounds and the tetraacyloxy compounds, therefore, represent the cis and *trans* modifications (III) and (IV); the hydroxyquinones, the acyloxyquinones and the acyloxyhydroquinones represent stereoisomers corresponding to type (I).

To show that such isomerism will disappear upon making the two ends symmetrical, the two tetraacetoxy compounds (XIII) and (XIV), were brominated with liquid bromine and there was thus obtained a single 2,5-di-(3,5-dibromo-2,4,6-trimethylphenyl)-1,3,4,6-tetraacetoxybenzene (XVTI).

The derivatives from the less soluble dibromoquinone have been denoted as the α- and from the more soluble as the β-forms. Throughout the series with one exception a decided difference in solubility in the two forms is to be found.

Most of the compounds melt very high, generally in between 250 and 400°. The difference in the melting points of the *a*- and the β-forms of any of the substances varies usually from 10–25°. In the case of the diacetoxyquinones, however, the melting points are essentially identical and it was necessary to convert each of the compounds to the corresponding tetraacetoxy analog in order to show definitely that one was different from the other. The stereoisomeric dibutyroxyquinones, however, have a difference of 20" in the melting points. The use of mixed melting points in this work was more or less excluded since it was shown that in many instances it was impossible to get a lowering of the melting point from the mixture of a pair of isomers. In the case of the tetrabutyroxy compounds, however, which were comparatively low melting, five parts of the higher melting and 95 parts of the lower melting melted about 5° below the lower melting form. The identification of any individual compound was always made by conversion to the corresponding tetraacetoxy derivative, which was markedly different in melting point and solubility from its isomer. Owing to the high melting point of some of these compounds the Bloc Maquenne was employed for melting points above 350°.

In the examples of *cis–trans* isomerism known in other fields of organic chemistry the *trans* form is usually the higher melting of the two. **As** a consequence, the higher melting tetrahydroxy and tetraacyloxy compounds were assumed to be the *trans* modifications and the stereoisomeric forms the *cis* modifications. All of the a derivatives would, therefore, be *trans* modifications and all of the β derivatives *cis* modifications. Since, from the standpoint of optical isomerism, the *trans* modifications are meso forms, all of the compounds of the *a* series should be non-resolvable. The *cis* modifications or β forms on the other hand would be racemic derivatives and these should be capable of resolution. The decision as to whether the assumptions just made are correct or not will depend upon the results of resolution studies.

In most cases of *cis–trans* isomerism where one form is less stable than the other under action of heat or catalysts of the ordinary type, the *cis* is usually the unstable modification and is convertible into the *trans* form. It might be anticipated, therefore, that in these compounds certain of the *cis* derivatives might be converted into the *trans* modifications or from the standpoint of optical isomerism the racemic forms might be convertible into the meso forms, providing conditions could be found which would allow free rotation between the rings.

An attempt was made to convert each of the β derivatives into the corresponding α derivatives.[*] This was done by heating the β form, usually in mesitylene, sometimes in glacial acetic acid or in sodium hydroxide solution, for many hours at the boiling temperature. By this procedure it was found that the β-diacetoxyhydroquinone (XII), the β-tetrahydroxy (XVI), the β-tetraacetoxy (XIV) and the β-dibromoquinone (VI) "derivatives were apparently, perfectly stable under the conditions used and no conversion took place. On the other hand, the β-dihydroxyquinone (VIII), the β-diacetoxyquinone (X) and the β-dibutyroxyquinone (X), when treated in the manner described were readily converted into the corresponding α modifications. By holding the β-dibutyroxy compound 20° above its melting point for three hours, a product resulted which after two crystallizations gave pure a form. Moreover, upon hydrolyzing the β-diacetoxyquinone (X) in glacial acetic acid and hydrochloric acid, the a-dihydroxyquinone (VII) was obtained.

It is interesting to consider these experiments from the standpoint of x-ray data which have been discussed from time to time in the previous communications. In the case of the β-diphenylbenzene compounds which were not convertible to a forms and which, therefore, resisted tendency to any free rotation between the rings, there are, with the exception of the β-dibromoquinone, between each of the two end rings and the center ring either two methyl groups and two hydroxyl groups or two methyl groups and one hydroxyl and one acylated hydroxyl group. On the assumption that the acylated hydroxyl group does not have an appreciably greater interference value than the unacylated group, the tetrahydroxy (XVI) compound may be considered to be characteristic of the three stable β compounds. The x-ray data show that there is appreciable interference on either side of each pair of rings in the molecule as follows: $C—CH_3$, 1.73 Å. + C—OH, 1.54 Å. = 3.19 Å. Subtracting from this value 2.90 Å. (the distance between the 2,2′-carbon atoms in the two rings) there is obtained a difference of 0.37 Å. on each side. This is, apparently, sufficient to prevent any rotation under the conditions used. On the other hand, in the case of the corresponding quinones the following interferences would be in force. On one side of each pair of rings in the molecule where the methyl and the hydroxyl meet, there would be an interference of 0.37 Å. On the other side, however, there would be $C—CH_3$, 1.73 Å. + C=O, 1.15 Å. = 2.88 Å., which is –0.02 Å. when the distance between the 2,2′-carbon atoms is subtracted from the total value. It follows, therefore, that if the rings are held in a more or less fixed relative position to one another, free rotation could not take place because one or the other of the methyl groups would interfere with the hydroxyl group and convertibility of the β-form to the a-form would be prevented. On the other hand, if the molecule is heated so that the rings may be bent toward each other in one or another direction, it is possible to reach a position where there is only

0.175 Å. interference simultaneously on each of the two sides [(0.37 Å. − 0.02 Å.)/2 = 0.175 Å.]. It may, therefore, be either that an interference of 0.175 Å. can be overcome by a high temperature so as to allow free rotation, or that free rotation is possible on account of the quinone ring, about which comparatively little is known as far as its exact structure is concerned. It may be expected that a quinone nucleus is more mobile within itself than a benzene ring and, therefore, might readily be distorted somewhat by a decided temperature change. On the other hand, the stability of the β-dibromoquinone to rearrangement indicates that the size of the groups even in the quinones is an important factor. The interference in this compound ($C-CH_3$, C–Br and $C-CH_3$, C=O) when the rings are in a relative position most advantageous for free rotation is 0.39 Å., [(0.80 Å. − 0.02 Å.)/2 = 0.30 Å.], a value which has been shown in previous diphenyl compounds to be sufficient to prevent free rotation under ordinary methods of treatment. The 0.80 Å. represents the interference between the methyl and bromine groups ($C-CH_3$, 1.73 Å. + C–Br, 1.97 Å. = 3.70 Å. —2.90 Å. = 0.80 Å.) and the —0.02 Å. that between the methyl and carbonyl group as indicated above.

Experimental

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dihydroxyquinone (a-Form), **(VII).**—In a 5-liter, two-necked flask equipped with a mechanical stirrer and reflux condenser, were placed 35 g. of α-2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromoquinone, V, m. p. 295–296° (corr.), 2 liters of 95% ethyl alcohol and a solution of 300 g. of sodium hydroxide in 1200 cc. of water. The mixture was stirred and refluxed for eight hours. During this time the dibromoquinone dissolved, forming a deep red solution, and a portion of the dihydroxyquinone precipitated in small flakes as the scarlet sodium salt.

After filtration and drying, the sodium salt amounted to 20 g. The clear red filtrate was diluted with 2 liters of water, and acidified with concentrated hydrochloric acid. Upon heating nearly to boiling a flocculent, orange precipitate coagulated. The product was filtered on a Büchner funnel, washed free of chloride with hot water and sucked to a completely dry powder on the filter paper. The sodium salt obtained from the original reaction mixture was dissolved in hot water and acidified with 6 N hydrochloric acid and the hydroxy compound washed and dried as described. The yield amounted to 25.4 g. (7 g. from the filtrate and 18.4 g. from the filtered sodium salt) of the α-dihydroxyquinone or 90% of the theoretical. The dihydroxyquinone as obtained was essentially pure and was used directly for conversion into derivatives.

The a-dihydroxyquinone is practically insoluble in all the common organic solvents except nitrobenzene, from which it crystallizes in very minute yellow needles. It is sparingly soluble in ether, glacial acetic acid and mesitylene. One hundred cc. of boiling mesitylene dissolves about 0.05 g. The needles from mesitylene are larger than those obtained from nitrobenzene and are orange in color. Samples recrystallized to purification from either solvent decomposed on the Bloc Maquenne at 397–400° (obs.).

Anal. (Parr Bomb) Calcd. for $C_{24}H_{22}O_4Br_2$: Br, 29.93; C, 53.93; H, 4.16. Found: Br, 29.85; C, 53.42; H, 4.18.

Sodium Salt of the **α-Dihydroxyquinone, (VII).**—The sodium salt obtained from the hydrolysis of the a-dibromoquinone was purified by recrystallization from an alkaline water–alcohol mixture (2 g. of salt in 600 cc. of 50% alcohol and 5 g. of sodium hydroxide). The red flakes were washed with acetone and air dried. For analysis 0.5 g. was finely pulverized and dried under reduced pressure at 110°.

Anal. (Parr Bomb). Calcd. for $C_{24}H_{20}O_4Br_2Na_2$; Br, 27.65. Found: Br, 27.28.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-diacetoxyquinone (or-Form), **(IX).**—A mixture of 4 g. of the α-dihydroxyquinone VII was placed in a 300-cc. Erlenmeyer flask with 80 cc of acetic anhydride and brought to a boil under a reflux condenser. Through the condenser was added 80 cc. of pyridine, the solution again brought to a boil and held for one minute. The orange solution was then poured rapidly with stirring into 1 liter of 4 N hydrochloric acid. The yellow, crystalline product was filtered from the hot mixture and washed with 4 N hydrochloric acid, followed by cold water. The yield was quantitative, the weight of air-dried product amounting to 4.7 g. Two recrystallizations from 200 cc and 150 cc., respectively, of n-butyl alcohol yielded a product consisting of yellow plates melting constantly at 272–273° (corr). It is very soluble in mesitylene, somewhat less soluble in toluene, moderately soluble in glacial acetic acid and acetone and sparingly soluble in 95% ethyl alcohol.

Anal. (Parr Bomb). Calcd. for $C_{28}H_{26}O_6Br_2$: Br, 25.86,. Found: Br, 25.71.

Hydrolysis of **α-Diacetoxy** Compound, **(IX).**—The diacetoxy compound is hydrolyzed rapidly upon heating for twenty to thirty minutes in a mixture consisting of 80% of glacial acetic acid and 20% of 6 N hydrochloric acid (50 cc. of glacial acetic acid, 10 cc. of 6 N hydrochloric acid, 0.25 g. of diacetoxy quinone) to the insoluble **α-dihydroxy**-quinone (VII) melting at 397–400° on the Bloc Maquenne. **A** portion of the dihydroxyquinone so obtained (0 21 g.) was reacetylated to an acetyl derivative identical with the above in melting point, solubility and crystalline appearance.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetrahydroxybenzene (a-Form), **(XV).**—A mixture of 5 g. of the a-dihydroxyquinone (VII), 500 cc. of 95% ethyl alcohol and 10 g. of stannous chloride was refluxed for fifteen minutes. A greenish-yellow precipitate formed Addition of 10 cc. of 6 N hydrochloric acid dissolved the precipitate About 40 cc. more of the acid was then added. This was followed by ten minutes of refluxing, after which a clear, colorless solution had formed. Hot water was gradually added to the boiling solution until a faint turbidity appeared. The condenser was removed and alcohol removed by distillation until a considerable crop of white crystals appeared in the boiling mixture The mixture was cooled and filtered. The minute, crystalline flakes were washed several times with 6 N hydrochloric acid and finally with cold water. The white product so obtained was air dried in the dark, since light discolored it; yield, 4.8 g. Two recrystallizations from dilute alcohol containing hydrochloric acid and a trace of stannous chloride yielded small, white, shining flakes melting with decomposition at 360–362° (obs.) on the Bloc Maquenne.

It is readily soluble in alcohol, acetone and pyridine. The pyridine solution rapidly turns dark red in air

Anal (Parr Bomb). Calcd for $C_{24}H_{24}O_4Br_2$: Br, 29.82. Found: Br, 30.14.

Oxidation of the **α-Form** of the **Tetrahydroxy** Compound, **(XV).**—Addition of *p*-benzoquinone to an alcoholic solution of the a-tetrahydroxy compound caused an immediate precipitate of the orange, insoluble or-dihydroxyquinone melting with decomposition at 397–400° on the Bloc Maquenne.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetraacetoxybenzene (a-Form), **(XIII).**—A mixture of 4 g. of the a-tetrahydroxy compound (XV) and 50 cc. of acetic anhydride was placed in a 300-cc Erlenmeyer flask and brought to a boil under a reflux condenser. Then 50 cc of pyridine was added through the condenser and the solution was refluxed for one minute. The solution was then added with stirring to 750 cc. of 4 N hydrochloric acid. The white, crystalline product was filtered from the hot solution, washed twice with 4 N hydrochloric acid and then free of the acid with water. A quantitative yield, 5.2 g., of the air-dried tetraacetate was obtained. The crude product was recrystallized first from a mixture of 50 cc. of acetic anhydride and 50 cc. of pyridine and then from 50 cc. of acetic anhydride. Finally one crystallization from n-butyl alcohol gave a pure product consisting of long. white needles, melting constantly at 294–295° (corr.)

Anal. (Parr Bomb). Calcd. for $C_{32}H_{32}O_8Br_2$: Br, 22.76. Found: Br, 22.93.

2,5-Di-(3,5-dibromo-2,4,6-trimethylphenyl)-1,3,4,6-tetraacetoxybenzene, (XVII). In a 20-cm. test-tube was placed 1 5 g of the crude a-tetraacetoxy compound (XIII) and 3 cc. of dry, liquid bromine was added with stirring in 1-cc. portion. The contents were thoroughly stirred and allowed to stand for thirty minutes at room temperature. Hydrogen bromide was freely evolved. The excess bromine was removed by suction and the light yellow solid material remaining was removed and triturated with a saturated solution of sodium bisulfite It was then filtered, washed with hot water and air dried. The yield of crude product amounted to 1.8 g. It was recrystallized twice from a mixture of 45 cc. of acetic anhydride and 5 cc. of pyridine and a third time from 70 cc. of acetic anhydride alone. There was obtained 1 g. of short white needles melting constantly at 347–348° (corr.).

Anal (Parr Bomb) Calcd. for $C_{32}H_{30}O_8Br_4$: Br, 37.09. Found: Br, 36.76.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-diacetoxyhydroquinone (a-Form), (XI).—A mixture of 3 g. of the α-diacetoxyquinone (IX), 200 cc. of 95% ethyl alcohol and 5 g. of stannous chloride was refluxed for fifteen minutes. Then 25 cc. of 6 N hydrochloric acid was added to discharge the pale yellow color and hot water immediately and gradually added to precipitate the product as white, short, slender needles. The mixture was quickly cooled under the tap and filtered. The mat of needles was washed with 4 N hydrochloric acid and then with hot water. The yield was 2.9 g. Two recrystallizations from 75 cc. and 60 cc. of carbon tetrachloride, respectively, gave a white product consisting of short, slender needles, melting constantly at 251–252° (corr.). The compound is readily soluble in acetone, ethyl alcohol and pyridine. The pyridine solution remains colorless in air, in contrast to the pyridine solution of the tetrahydroxy derivative, which quickly turns deep red when exposed to the air.

Anal. (Parr Bomb). Calcd. for $C_{28}H_{28}O_6Br_2$: Br, 25 78. Found: Br, 25.61

Hydrolysis of **a-Diacetoxyhydroquinone,** (XI).—A mixture of 0.1 g. of the α-diacetoxyhydroquinone (XI), 30 cc. of glacial acetic acid and 5 cc. of 6 N hydrochloric acid was refluxed for fifteen minutes. The product was precipitated by adding water. The crude product thus obtained showed no signs of melting or charring at 325" (obc.) in a paraffin-bath and yielded an acetyl derivative with acetic anhydride and pyridine which, when recrystallized from n-butyl alcohol, was identical with the a-tetraacetate (XIII) in melting point, solubility and crystalline appearance.

Acetylation of a-Diacetoxyhydroquinone, (XI).—The a-diacetoxyhydroquinone (XI) yielded an acetyl derivative with acetic anhydride and pyridine identical in melting point, solubility and crystalline appearance with the a-tetraacetoxy compound (XIII) obtained by acetylation of the a-tetrahydroxy compound (XV).

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dihydroxyquinone (β-Form), (VIII).—In a 5-liter, round-bottomed flask equipped with a mechanical stirrer were placed 30 g. of β-2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromoquinone (VI), m. p. 284–285" (corr.), 2 liters of 95% ethyl alcohol and a cold solution of 300 g. of sodium hydroxide in 1500 cc. of water. The mixture was stirred at room temperature for forty-eight hours. As with the a-bromoquinone, the β-bromoquinone slowly dissolved, forming a deep red solution from which part of the β-dihydroxyquinone crystallized in flakes as the deep red sodium salt. Only 7 g. of the sodium salt was thus obtained. The filtrate from this was diluted with 4 liters of water, allowed to stand for twenty-four hours, decanted and filtered from a small amount of insoluble material and acidified with concentrated hydrochloric acid. The orange, flocculent precipitate was sucked dry on a Biichner funnel. The sodium salt was converted to the dihydroxy compound as described under the alpha compound. The yield of free β-dihydroxyquinone amounted to 22 g. (91%). This material was used for preparing derivatives. It was purified by crystallization from benzene or toluene and formed minute yellow needles melting with decomposition at 387–390" on the Bloc Maquenne.

Anal. (Parr Bomb). Calcd. for $C_{24}H_{22}O_4Br_2$: Br, 29.93; C, 53.93; H, 4.16. Found: Br, 30.03; C, 53.48; H, 4.20.

The difference in solubility in acetone of the a- and 8-forms of the dihydroxyquinone is quite marked: 0.05 g. of the 8-form dissolved in 10 cc. of hot acetone to a clear, orange-colored solution; 0.05 g. of the a-form would not form a clear solution in 150 cc. of boiling acetone. Likewise the β-form was found to be more soluble in benzene and toluene, in both of which solvents the a-form is practically insoluble. The 8-form is also slightly soluble in glacial acetic acid and mesitylene but when attempts were made to crystallize from those solvents a partial conversion of the β-form into the a-form was found to take place.

Sodium Salt of the **β-Dihydroxyquinone, (VIII).**—The sodium salt of the β-dihydroxyquinone (VIII) was recrystallized from 3% sodium hydroxide solution (4 g. of salt in 150 cc. of alkaline solution). For analysis 0.5 g. was finely pulverized and dried at 110° under reduced pressure.

Anal. (Parr Bomb). Calcd. for $C_{24}H_{20}O_4Br_2Na_2$: Br, 27.65. Found: Br, 27.32.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-diacetoxyquinone (8-Form), **(X).—The** β-dihydroxyquinone (VIII) was acetylated with acetic anhydride and pyridine under the same conditions as the a-form. Purification from 70% acetone gave light yellow prisms melting constantly at 272–273° (corr.).

Anal..(Parr Bomb). Calcd. for $C_{28}H_{26}O_6Br_2$: Br, 25.86. Found: Br, 25.70.

It is to be noticed that the β-diacetoxyquinone melts at the same point as the α-form. However, there can be no doubt about the existence of two forms, since the solubility of the β-form in acetone is four times as great as the a-form and in 95% ethyl alcohol three to four times greater. Moreover, conversion into various derivatives showed the β-form to be different.

Hydrolysis of **β-Diacetoxyquinone, (X).**—Upon refluxing 0.25 g. of the β-diacetoxyquinone X for one hour with a mixture of 50 cc. of glacial acetic acid and 10 cc. of 3 N hydrochloric acid, the a-dihydroxyquinone (VII) separated as an orange, crystalline precipitate in the boiling solution and separated completely on cooling (0.22 g.). The product was insoluble in acetone. To identify further the a-dihydroxyquinone prepared in this way, it was reduced and acetylated in the manner used previously for this compound and yielded, after purification from n-butyl alcohol, long white needles (0.22 g.) which melted at 294–295° (corr.) and proved to be identical with the a-tetraacetoxy compound (XIII).

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetrahydroxybenzene (β-Form), (XVI).—The β-dihydroxyquinone (VIII) was reduced to the tetrahydroxy derivative in the same manner as the a-form. The β-tetrahydroxy compound crystallized from dilute alcohol in white, shining plates melting constantly at 355–357° (obs.) on the Bloc Maquenne.

Anal. (Parr Bomb). Calcd. for $C_{24}H_{24}O_4Br_2$: Br, 29.82. Found: Br, 29.62.

It is readily soluble in acetone, ethyl alcohol and pyridine. As with the a-form, the pyridine solution of the β-form rapidly turns red in air. The β-form is more soluble in dilute alcohol, dilute acetone and glacial acetic acid than the a-form.

Oxidation of the β-Tetrahydroxy Compound, (XVI).—Addition of *p*-benzoquinone to an alcoholic solution of the β-tetrahydroxy compound (XVI) immediately caused a precipitate of the orange, insoluble β-dihydroxyquinone (VIII). That it was the β-dihydroxyquinone rather than the a-form was determined by the fact that the product had the proper melting point and solubility.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetraacetoxybenzene (β-Form), (XIV).—The β-tetrahydroxy compound (XVI) was acetylated with pyridine and acetic anhydride, following the procedure employed for the a-form. After two recrystallizations from n-butyl alcohol, a product consisting of long, white needles was obtained, melting constantly at 269–270° (corr.) without decomposition.

Anal. (Parr Bomb). Calcd. for $C_{32}H_{32}O_8Br_2$: Br, 22.76. Found: Br, 22.61.

Of all the derivatives of the two series the tetraacetates differ most widely with respect to melting point and solubility; 0.05 g. of the β-form dissolves in 2 cc. of boiling n-butyl alcohol, whereas 0.05 g. of the a-form requires 10–12 cc. of boiling n-butyl alcohol. There exists a similar difference in solubility in glacial acetic acid and acetic anhydride.

Bromination of the β-Tetraacetoxy Compound, (XIV).—The β-tetraacetoxy compound (XIV) was brominated in the same way as the a-form. The product was identical with that obtained from the a-form with respect to melting point, solubility, crystalline appearance and bromine content.

Anal. (Parr Bomb). Calcd. for $C_{32}H_{30}O_8Br_4$: Br, 37.09. Found: Br. 36.86.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-diacetoxyhydroquinone (@–Form), **(XII).**—The β-diacetoxyquinone (X) was reduced and the product purified according to the procedure used for the a-form. After two recrystallizations from carbon tetrachloride, a product consisting of short, fine, white needles was obtained melting constantly at 240–241° (corr.).

Anal. (Parr Bomb). Calcd. for $C_{28}H_{28}O_6Br_2$: Br, 25.78. Found: Br, 25.65.

The two forms have approximately the same solubility in carbon tetrachloride, ethyl alcohol and glacial acetic acid, but the β-form is more soluble in acetone. The pyridine solution of the diacetoxyhydroquinone remains colorless in air in contrast to the tetrahydroxy compound which turns red.

Hydrolysis of the β-Diacetoxyhydroquinone, (XII).—A mixture of 0.1 g. of the β-diacetoxyhydroquinone (XII) with 30 cc. of glacial acetic acid and 5 cc. of 6 N hydrochloric acid was refluxed for thiiy minutes. The product was precipitated with water. In the crude state it showed no sign of melting at 325° in an oil-bath. It was acetylated with pyridine and acetic anhydride and the crude product recrystallized from n-butyl alcohol. It melted constantly at 269–270° (corr.), the pure β-tetraacetoxy compound.

Acetylation of β-Diacetoxyhydroquinone, (XII).—Acetylation of 2 g. of the β-diacetoxyhydroquinone (XII) with pyridine and acetic anhydride according to the procedure employed for acetylation of the a-tetrahydroxy compound (XV) yielded an acetyl derivative identical in melting point, solubility and crystalline appearance with the β-tetraacetate.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibutyroxyquinone (a–Form), **(IX).**—A solution of 1.5 g. of the a-dihydroxyquinone (VII) in 20 cc. of pyridine and 10 cc. of n-butyric anhydride was boiled for one minute and immediately thrown into 250 cc. of 6 N hydrochloric acid. The mixture was shaken until all of the butyric anhydride was decomposed and the light yellow product solidified. The crude yield amounted to 2.0 g.

It was recrystallized twice from 95% ethyl alcohol, using 80 cc. the first time and 65 cc. the second. One and one-half grams of yellow plates melting constantly at 167° (corr.) was obtained.

Anal. (Parr Bomb). Calcd. for $C_{32}H_{34}O_6Br_2$: Br, 23.72. Found: Br, 23.92.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibutyroxyquinone (β-Form), (X).—The β-dibutyroxy form was made in exactly the same way as the a-form. It was crystallized twice from 95% ethyl alcohol. From 1.4 g. of β-dihydroxyquinone (VIII) 1.1 g. of large yellow needles of the β-dibutyroxyquinone melting constantly at 147° (corr.) was obtained. The 8-form is more soluble in ethyl alcohol, methyl alcohol and acetone than the α-form.

Anal. (Parr Bomb). Calcd. for $C_{32}H_{34}O_6Br_2$: Br, 23.72. Found: Br, 23.80.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetrabutyroxybenzene (a-Form), **(XIII).**—A mixture of 1.5 g. of the a-dihydroxyquinone (VII), 150 cc. of 95% ethyl alcohol, and 3.0 g. of stannous chloride was refluxed for fifteen minutes. Fifteen cc. of 6 *N* hydrochloric acid was added and refluxing continued until a colorless solution had formed. The a-tetrahydroxy compound was precipitated by adding hot water. It was filtered and treated with a mixture of 10 cc. of n-butyric anhydride and 20 cc. of pyridine. The 2.0 g. of crude product was isolated in the same way as the dibutyroxyquinones and crystallized three times from methyl alcohol, using 15 cc., 12 cc. and 9 cc., respectively. One gram of white prisms melting constantly at 124° (corr.) was obtained.

Anal. (Parr Bomb). Calcd. for $C_{40}H_{48}O_8Br_2$: Br, 19.58. Found: Br, 19.57.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-1,3,4,6-tetrabutyroxybenzene (β-Form), (XIV).—Two and one-half grams of the β-dihydroxyquinone (VIII) was reduced and converted to the tetrabutyrate following the method used for the a-form. The crude product was colored dark blue, but three crystallizations from methyl alcohol, using 15 cc., 10 cc. and 5 cc. respectively, yielded 1.3 g. of pure white prisms melting constantly at 103° (corr.). The p-form is more soluble in methyl alcohol than the a-form. A mixture of 95 parts of this β-form and 5 parts of the corresponding a-form melted 98–99.5".

Anal. (Parr Bomb). Calcd. for $C_{40}H_{48}O_8Br_2$: Br, 19.58. Found: Br, 19.64.

Conversion of the **β-Dihydroxyquinone** (VIII) to the a–Form in Boiling Mesitylene or in Boiling Glacial Acetic Acid.—A solution of 0.25 g. of the β-dihydroxyquinone (VIII) in 150 cc. of mesitylene was refluxed for ten hours. Then 125 cc. of mesitylene was distilled off. The distilling flask was cooled and the product filtered; 0.24 g. of fine orange needles was recovered. It was reduced with 95% ethyl alcohol, **6** *N* hydrochloric acid and stannous chloride. The white product thus obtained was acetylated with **5** cc. of acetic anhydride and 5 cc. of pyridine. The crude tetraacetate weighed 0.27 g. It was crystallized from 60 cc. of n-butyl alcohol, from which was obtained 0.23 g. of white needles melting constantly at 294–295" (corr.). This product had all the properties of the a-tetraacetate (XIII).

A solution of 0.25 g. of the β-dihydroxyquinone (VIII) in 250 cc. of glacial acetic acid was refluxed for ten hours. Initially all of the material was in solution. At the end of five hours a precipitate of short, fine, yellow needles appeared. By distillation 225 cc. of solvent was removed and the remaining mixture cooled and filtered; 0.24 g. of material was recovered. It was reduced and acetylated as usual The 0.25 g. of crude tetraacetate was crystallized from 60 cc. of n-butyl alcohol. There was obtained 0.21 g. of white needles of the a-tetraacetate melting at 294–295" (corr.) (XIII).

Conversion of the **β-Diacetoxyquinone (X)** to the a–Form in Boiling **Mesitylene.**—A solution of 0.25 g. of the β-diacetoxyquinone (X) in 50 cc. of mesitylene was refluxed for ten hours. Then 40 cc. of mesitylene was removed by distillation; the remainder was steam-distilled out The solid, yellow residue was reduced with ethyl alcohol, hydrochloric acid and stannous chloride The white diacetoxyhydroquinone was precipitated by adding water. The product was acetylated with pyridine and acetic anhydride and the tetraacetatc isolated as usual by pouring into excess 4 *N* hydrochloric acid. The yield of crude product amounted to 0 22 g This, when crystallized from 50 cc. of n-butyl alcohol, gave 0 18 g. of material melting at 292–294° (corr) Another crystallization gave the correct melting point of 294–295° for the or-tetraacetate (XIII)

Conversion of the β-Dibutyroxyquinone (X) to the **α-Form** in Boiling Mesitylene or by Heating.—A solution of 0.2 g. of the β-dibutyroxyquinone (X) in 50 cc. of mesitylene was refluxed for ten hours. By distillation 40 cc of mesitylene was removed and the remainder was steam-distilled out. There was thus obtained 0 17 g. of product which was crystallized from 8 cc. of methyl alcohol; 0.13 g. of yellow plates melting at 165–167° was obtained which was obviously the α-dibutyroxy form (IX)

One-tenth gram of the β-dibutyroxyquinone (X) was placed in a 2-inch test-tube and heated at 175–180° (corr.) for three hours. The tube was carefully broken and the contents crystallized twice from 95% ethyl alcohol There was obtained 0 04 g. of small yellow plates melting at 166–167° (corr.), the or-form (IX).

Attempted Conversion of **β-Forms** to or-Forms.—The β-diacetoxyhydroquinone (XII), the β tetrahydroxy (XVI) compound and the β-tetraacetoxy (XIV) compound could not be converted to the or-forms after ten hours in boiling mesitylene. Neither could the β-dihydroxyquinone in boiling 3 N sodium hydroxide solution be converted to the a-form. The procedures followed were those employed in the above conversions.

The conversion of the p-dibromoquinone (VI) was attempted in two ways. A solution of 0.50 g. of the β-dibromoquinone in 100 cc. of boiling glacial acetic acid was refluxed for ten hours. Upon cooling 0.25 g of orange prisms separated. The remainder in solution was precipitated by adding water to the mother liquor; total material recovered, 0.49 g. This was reduced with pyridine and stannous chloride. The white reduction product was crystallized from a mixture of 10 cc. of acetone and 2 cc. of water containing ten drops of 6 *N* hydrochloric acid and a trace (10 mg.) of stannous chloride. Upon standing, long, slender, white needles formed. The first crop amounted to 0.15 g. and melted at 294–295" (corr.), the pure β-dibromohydroquinone.

A solution of 1.5 g. of the p-dibromoquinone in 150 cc. of mesitylene was refluxed for ten hours. The orange tint of the solution deepened somewhat. The mesitylene was steam distilled out and the orange solid remaining, which could not be crystallized satisfactorily from toluene, was dissolved in 750 cc. of boiling 95% ethyl alcohol to which 0.5 g. of benzoquinone was added. The orange-colored solution was filtered and concentrated to 200 cc., during which time an orange, crystalline precipitate appeared. After cooling, this was filtered and washed with cold methyl alcohol (0.50 *g.).* In the same bath with the pure p-dibromoquinone the orange material isolated above melted with decomposition at 282–283° (corr.); the pure p-form at 284–285° (corr.). The product was reduced with pyridine and stannous chloride. The white hydroquinone was crystallized from a mixture of 10 cc. of acetone and 2 cc. of water containing ten drops of 6 N hydrochloric acid and 5 mg. of stannous chloride. The first crop of long, slender, white needles amounted to 0.13 g. and melted at 294–295° (corr.), the pure β-dibromohydroquinone.

Summary

1. By treatment of the two diastereoisomeric 2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinones (V + VI) with aqueous sodium hydroxide there were obtained two stereoisomeric 2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dihydroxyquinones (VII + VIII).

2. Each of these two latter compounds formed an individual series of derivatives—namely, the diacetoxyquinone, the dibutyroxyquinone, the diacetoxyhydroquinone, the tetrahydroxy compound, the tetraacetoxy and tetrabutyroxy compounds.

3. The two series were designated as *a* and β. The *a* denotation was given to the series of higher melting and less soluble compounds, the β was given to the series of lower melting and more soluble compounds. On the assumption that the higher melting tetrahydroxy and tetraacylated derivatives are the *trans* modifications, it follows that throughout the two series, the *trans* or α forms are meso, the *cis* or β forms. are racemic.

4. The α and β tetrahydroxy, tetraacetoxy and tetrabutyroxy derivatives represent pairs of *cis* and *trans* isomers. No individual in any pair is capable of resolution. On the other hand, the α and β hydroxyquinones, acetoxyquinones, butyroxyquinones and the acylated hydroquinones represent pairs of *cis* and *trans* forms, in each pair of which one is a meso and the other a racemic modification.

5. The β-dihydroxyquinone, the β-diacetoxyquinone and the β-dibutyroxyquinone can be converted to the corresponding α forms by heating in a high boiling solvent. The β-diacetoxyquinone on hydrolysis gives the α-dihydroxyquinone.

6. The a and β tetraacetoxy compounds, on bromination, give the same compound, 2,5-di-(3,5-dibromo-2,4,6-trimethylphenyl)-1,3,4,6-tetraacetoxybenzene.

DESOXYCODEINE STUDIES. I. THE DESOXYCODEINES[1]

BY LYNDON F. SMALL AND FRANK L. COHEN

RECEIVED FEBRUARY 9, 1931 PUBLISHED JUNE 8, 1931

The name desoxycodeine has been used to designate the compound $C_{18}H_{21}O_2N$, containing one less oxygen atom than codeine. It was first described and investigated by Knorr and Waentig,[2,3] who prepared it by refluxing a-chlorocodide (11), bromocodide, β-chlorocodide[4] or pseudo-

---

[1] This investigation was supported by a grant from the Committee on Drug Addiction of the National Research Council from funds provided by the Bureau of Social Hygiene, Inc.

[2] Knorr and Waentig, *Ber.*, 40, 3860 (1907).

[3] A base having the same formula was mentioned by Wright [*Proc.* Roy. *Soc.* (London), 19,371 (1870); J. *Chem. Soc.*, 24,404 (1871)] as being formed when codeine is heated with hydrobromic acid; Wright's desoxycodeine has never been further investigated.

chlorocodide[2,5] with zinc dust in absolute alcohol; the fact that the isomeric chlorocodides all yield the same desoxycodeine in this reduction has been taken as evidence that the fundamental carbon–nitrogen skeleton in all of them is the same.

Desoxycodeine is a phenolic base (Formula III) which must be formed from the halogenocodides by addition of one molecule of hydrogen and loss of hydrogen halide or the equivalent of this process.[6]

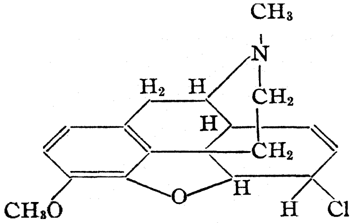
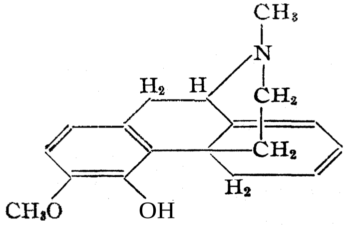
Numbering System[7]



II

α-Chlorocodide



III

Desoxycodeine-A[8]

a-Chlorocodide is derived from codeine through replacement of the alcoholic hydroxyl by chlorine, and is distinguished by the activity of this halogen atom. It may be hydrolyzed out by boiling with water[9] or with dilute acetic acid[4,10] to yield the isomers of codeine, or replaced with iodine[11] or the dimethylamino group[12] by suitable treatment with potassium iodide or dimethylamine, respectively. An experiment seemed warranted, therefore, to determine whether a-chlorocodide would react with methylmagnesium halide to yield, at least in part, a homolog of desoxycodeine,

in which the alcoholic hydroxyl of codeine would be replaced by a methyl group in the sense of the equation

$$C_{18}H_{20}O_2NCl + RMgX \longrightarrow C_{18}H_{20}O_2NR + MgXCl$$

a-Chlorocodide in absolute ethereal solution does, in fact, react vigorously with methylmagnesium iodide, with copious evolution of gas and separation of a powdery white solid. Decomposition of this solid in the usual way yields instead of the expected homodesoxycodeine, the known desoxycodeine in approximately 60% of the theoretical amount. The remaining 40% of the material consists of a clear basic oil which does not crystallize nor give crystalline salts.

When ethylmagnesium iodide is used, the same product, desoxycodeine, is obtained in somewhat better yields; it is evident from this that the organomagnesium halide functions in this reaction chiefly to remove the elements of hydrochloric acid, and to open reductively the 4,5-ether bridge of a-chlorocodide. Small amounts of iodocodide could frequently be isolated among the reaction products; further investigation has shown that iodocodide reacts with alkylmagnesium halide in the same way as *a*-chlorocodide to give desoxycodeine. It therefore seems probable to us that iodocodide, in which the halogen is very loosely bound, forms an intermediate in this reaction. As would be expected, in a reaction where methylmagnesium halide acts in a reducing capacity, considerable amounts of ethylene are present in the gases evolved in the reaction. β-Chlorocodide, an isomer of a-chlorocodide which is believed to differ from it only in the spatial arrangement of H- and Cl- on the asymmetric carbon atom in Position 6, does not react with alkylmagnesium halide. It is well known that the halogen in β-chlorocodide is far less active than that in α-chlorocodide;[13] it was further found in the present investigation that in contrast to the a-form, β-chlorocodide does not react with potassium iodide in boiling alcohol to give an iodocodide.

The iodocodide obtained as a by-product in the reaction of alkylmagnesium iodide with a-chlorocodide consisted of fine white needles, or clumps of thick white monoclinic prisms. The known iodocodide (from a-chlorocodide with potassium iodide)[11] is described as light orange needles, and it therefore seemed probable that our white iodocodide represented a stereoisomeric β-form, in analogy with α- and β-chlorocodide. This is, however, apparently not the case; careful comparison of physical and chemical properties of the bases and their salts indicates that they are identical. The orange color of the Knorr compound is due to traces of colored decomposition products formed through the use of higher boiling solvents.

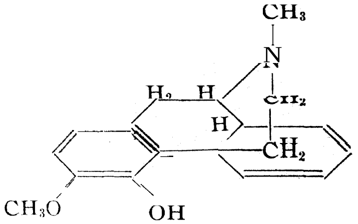
[13] Knorr and Horlein, *Ber.*, 41, 974 (1908) (hydrolysis); Knorr and Horlein, *ibid.*, 40, 4887 (1907) (rrduction): Mannich and Löwenheim, *Arrh. Pharm* , 258, 295 (1920) (reduction)

The desoxycodeine obtained from the Grignard reaction was identified by direct comparison with a sample prepared by refluxing α-chlorocodide with zinc dust in alcohol. With sodium and alcohol it reduced to the so-called α-tetrahydrodesoxycodeine,[14] which was also identified by direct comparison. By hydrogen and platinum, it was converted to @-tetrahydrodesoxycodeine (VI). The reduction products from desoxycodeine as well as those derived from the two new desoxycodeines described in this paper will be discussed in the following communication.

The Knorr desoxycodeine, as depicted in Formula III, represents one of the two possible phenolic desoxycodeines, the second of which may be conceived as having the conjugated double linkages in the hydroaromatic ring arranged in the alternative Positions, 5,6 and 7,8 (Formula IV). We propose for the present to name the Knorr compound of m. p. 126° desoxycodeine-A, the phenolic isomer, desoxycodeine-B,[15] and the non-phenolic desoxycodeine of the same empirical formula, to be described below, desoxycodeine-C.



IV

Desoxycodeine-B

Desoxycodeine-B, m. p. 119°, is formed when a-chlorocodide dissolved in 20% sulfuric acid is reduced electrolytically. Freund[16] first carried out this experiment, which he believed led to the formation of a dihydrodesoxycodeine, $C_{18}H_{23}O_2N + \frac{1}{2}H_2O$ of m. p. 117–119°, which is obviously the same as the compound which we describe. He claimed that the same substance resulted from the electrolytic reduction of @-chlorocodide(a statement which we have verified), of chlorodihydrocodide, and of desoxycodeine-A. Freund's evidence for considering his base of m. p. 117–119° as a dihydrodesoxycodeine was as follows. (1) Analyses: only those made on the 117° base prepared from α- and β-chlorocodides need be considered. These are in fair agreement with the value calculated for a dihydrodesoxycodeine containing one-half molecule of water. The bases prepared by electrolytic reduction of desoxycodeine-A and of chlorodi-

---

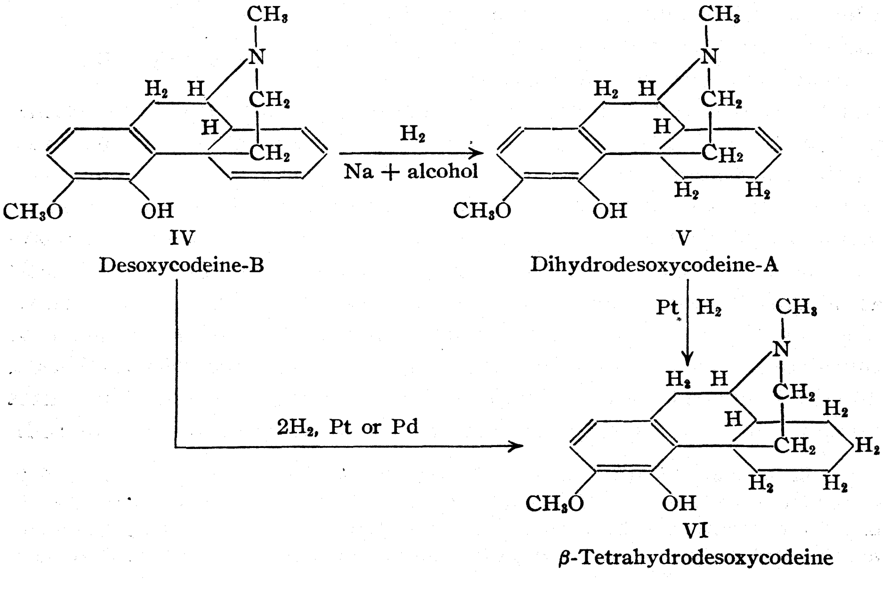
[14] Knorr and Waentig[2] reduced desoxycodeine with sodium in boiling alcohol to what they believed to be a dihydrodesoxycodeine, $C_{18}H_{23}O_2N$, which could also be obtained directly from a-chlorocodide through reduction with the same agents. This was disputed by Freund, who claimed that the reduction product was formed by addition of four atoms of hydrogen to desoxycodeine, and named it α-tetrahydrodesoxycodeine, to distinguish it from the tetrahydrodesoxycodeine which he obtained by reduction of desoxycodeine with palladium and hydrogen, and which was named β-tetrahydrodesoxycodeine.

[15] There is no evidence to show which of the Formulas III and IV should be assigned to desoxycodeine-A and which to desoxycodeine-B.

[16] Freund, J *prakt Chem*, **101,** 23 (1921).

hydrocodide which were thought to be identical with the 117° base are actually two different dihydrodesoxycodeines, of m. p. 134 and 111°, respectively, as will be shown in the next paper. (2) Catalytic reduction: this was carried out on but 0.4 g. of material, the source of which is not given. We can explain the absorption of but one molecule of hydrogen as noted by Freund only by the assumption that the sample taken for reduction was prepared from desoxycodeine-A or chlorodihydrocodide.

Since analytical proof of the presence of two hydrogen atoms more or less in a compound of molecular weight 292 is open to some question, we wish to stress the fact that our statement to the effect that the 119° base from electrolytic reduction of *a*- or *β*-chlorocodide is actually a desoxycodeine rests on reduction experiments. Desoxycodeine-B takes up two molecules of hydrogen on reduction by the catalytic method, using Adams' platinum oxide catalyst or palladium on barium sulfate, to give a quantitative yield of *β*-tetrahydrodesoxycodeine. When reduction of desoxycodeine-B is effected with sodium and alcohol, a dihydrodesoxycodeine (m. p. 134–136°) is formed, which may be further reduced by the catalytic method, with absorption of but one molecule of hydrogen to *β*-tetrahydrodesoxycodeine (VI).



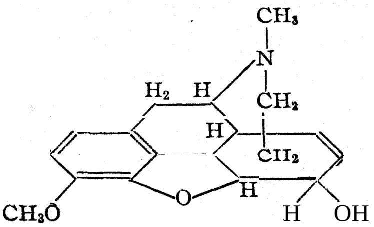
IV
Desoxycodeine-B

V
Dihydrodesoxycodeine-A

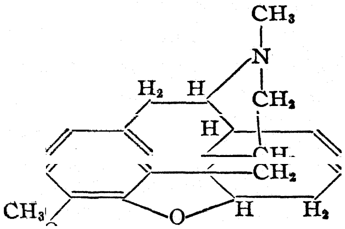
VI
β-Tetrahydrodesoxycodeine

The results of reduction, therefore, show beyond question that the phenolic base of m. p. 119° which Freund thought to be a dihydrodesoxycodeine is unsaturated to a degree corresponding to the presence of two double linkages, and is isomeric with desoxycodeine-A. It seems quite certain that the isomerism of these two phenolic desoxycodeines is due only to a difference in the arrangement of the unsaturated linkages in the hydroaromatic ring; on addition of two or four hydrogen atoms, the isomerism disappears.

The name desoxycodeine, which was introduced by Knorr, was somewhat unfortunately chosen. While the phenolic bases III and IV described above have the empirical formula $C_{18}H_{21}O_2N$ of codeine minus one oxygen, they correspond structurally to codeine less HOH, plus 2H. The name desoxycodeine should logically be applied to a compound derived from codeine (VII) through replacement of the alcoholic hydroxyl group by hydrogen (VIII) without scission of the 4,5-ether linkage.[17]



VII
Codeine



VIII
Hypothetical true desoxycodeine

We have been successful in preparing a compound of this nature, in whose structure, if the Gulland–Robinson formula (VII) for codeine be accepted, the only uncertain point is the position which the double linkage occupies in the hydroaromatic ring III. On the grounds given below, we consider it probable that the double bond lies between C-6 and C-7 (IX).

Desoxycodeine-C (IX) is prepared by treatment of chlorodihydrocodide in absolute methyl alcoholic solution with sodium methylate for twenty-four hours at 140°. Knoll and Co.,[18] heating chlorodihydrocodide with sodium methylate in methyl alcohol at 140° for forty-eight hours,[19] obtained a product of m. p. 111° which was called dihydrodesoxycodeine, and which is apparently identical with our desoxycodeine-C (whose melting point we have not been able to bring above 106°). The method of preparation of the two compounds is the same; the shorter period of heating was adopted by us because it resulted in better yields. The hydrochloride of desoxycodeine-C melts at the point given by Knoll and Co. for their dihydrodesoxycodeine hydrochloride (114°); the methiodide, on the other hand, we find to melt at 236–240°, in comparison with Knoll's 135–136°; we are forced to believe that this discrepancy in melting point of the methiodide arises from a misprint in Knoll and Co.'s patent. It is difficult

---

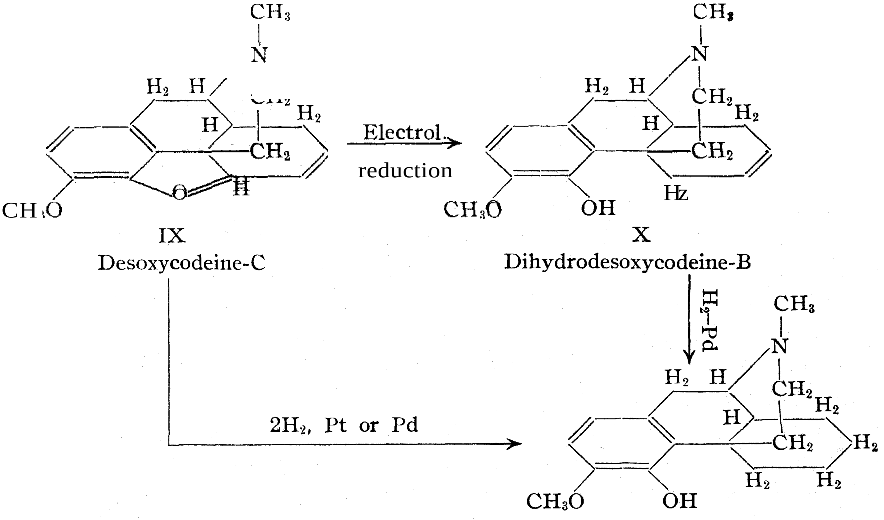
[17] Cf. Freund, *J. prakt. Chem.*, *101*, 7 (1921).

[18] Knoll and Co., German Patent 414,598 (1922); *Friedländer*, 15, 1518; *Jahresb. Chem. Tech.*, *71*, 123 (1925).

[19] Mannich and Löwenheim [*Arch. Pharm.*, 258, *295* (1920)] state that chlorodihydrocodide with sodium methylate at 120° forms no sodium chloride.

to explain, in any case, the formation of a dihydrodesoxycodeine, $C_{18}H_{23}O_2N$, as claimed by Knoll from chlorodihydrocodide, $C_{18}H_{22}O_2NCl$, through the agency of sodium methylate, since such a transformation involves reduction, *i. e.*, loss of HCl and addition of 2H, or direct replacement of Cl by H. The chemical behavior and analyses of desoxycodeine-C and its derivatives, on the other hand, show it to have been formed by loss of hydrochloric acid from chlorodihydrocodide.

Desoxycodeine-C (m. p. 105–106°) is not phenolic in nature. It is insoluble in alkali, and does not yield a methyl ether or acetyl derivative. In the presence of a palladium or platinum catalyst, it takes up two molecules of hydrogen, yielding β-tetrahydrodesoxycodeine (VI). By the electrolytic method, on the other hand, desoxycodeine-C is reduced to a new phenolic dihydrodesoxycodeine (X) of m. p. 128°, containing two more hydrogen atoms than desoxycodeine-C. This phenolic dihydrodesoxycodeine, on catalytic hydrogenation (palladium–barium sulfate catalyst), takes up one molecule of hydrogen to give β-tetrahydrodesoxycodeine. This may be represented by the following formulas, in which, however, we wish to make no claim concerning the exact location of the unsaturation in the hydroaromatic ring of desoxycodeine-C and its dihydro derivative.

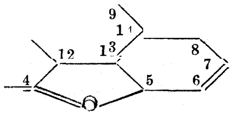


IX
Desoxycodeine-C

X
Dihydrodesoxycodeine-B

VI
β-Tetrahydrodesoxycodeine

The structure which we assign to desoxycodeine-C is based primarily upon its relationship to β-tetrahydrodesoxycodeine, and is put forward tentatively on the assumption that the latter substance actually possesses the generally accepted Formula VI. The fact that desoxycodeine-C cannot be reduced catalytically with saturation of the double bond only, to give a non-phenolic dihydrodesoxycodeine, recalls the similar behavior of other compounds in the codeine series. While codeine and isocodeine, and the methylmorphimethines, ci-, β-, γ- and 6-, can be reduced by simple saturation of the double linkages present, yielding non-phenolic hydrogenation products, pseudocodeine and allopseudocodeine, as well as ε- and ζ-methylmorphimethines take up two more hydrogen atoms than the corresponding isomeric substances mentioned above, to give phenolic hydrogenated derivatives. As Schöpf[20] has pointed out, the behavior of the grouping —O—CH—CH=CH—, generally accepted as being present in pseudo-, allopseudo-codeine, and ε- and ζ-methylmorphimethines, is to a certain degree comparable with that of a conjugated system of double linkages —CH=CH—CH=CH—, and the fact that hydrogenation of the substances mentioned takes place always with opening of the ether ring may be explained through the assumption that a 1,4-addition of hydrogen (at —O— and C-7) first takes place, followed by a saturation of the double linkage 5,6 in the intermediately formed compound. It is therefore not unreasonable to assume that in desoxycodeine-C the arrangement in the hydroaromatic ring corresponds to that shown in XI.



XI

There are at present three isomeric desoxycodeines known, two of which, desoxycodeine-A and desoxycodeine-B, are phenolic in nature. As will be shown in the next paper, the evidence which primarily led to the belief in an isomerism in the morphine series due to spatial differences in the hydrogen atom on C-14 is invalid. If this questionable configurational isomerism be disregarded, there are possible four non-phenolic desoxycodeines (isomerism due to differences in position of the double bond), only one of which is now known, and two phenolic desoxycodeines, as described above.

Experimental

a-Chlorocodide. —The a-chlorocodide used in these experiments was prepared by modifying the method of Freund,[16] in that the codeine and phosphorus pentachloride were allowed to react for only two hours instead of twenty-four hours as given by Freund. This resulted in an increased yield and less formation of amorphous by-products. Starting with crude codeine, the yield averaged 84–86% of the theoretical, while from pure codeine a 94% yield was obtained. The use of thionyl chloride'' proved to be less advantageous. Since no crystalline salts of α-chlorocodide have been previously described, we include the preparation of two of these.

α-Chlorocodide Acid Sulfate.—This salt was prepared by dissolving a-chlorocodide in the calculated amount of 20% sulfuric acid, whereupon the sparingly soluble acid sulfate separated as a white crystalline mass. It was purified from water; it softens at 135–140°, and melts with decomposition at 192–193°.

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}H_2SO_4 + 2H_2O$: H_2SO_4, 21.70. Found: H_2SO_4, 21.83.

The substance was dried to constant weight at 135–140°.

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}H_2SO_4 + 2H_2O$: H_2O, 7.97. Found: H_2O, 7.55.

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}H_2SO_4$: H_2SO_4, 23.02. Found: H_2SO_4, 23.61.

The hydrated salt in aqueous solution shows $[\alpha]_D^{20}$ +101.1°: $c = 2.720$, $l = 1$, a = +2.75°.

a-Chlorocodide Acid Tartrate.—This salt was prepared by dissolving the base in a dilute aqueous solution of the calculated amount of d-tartaric acid, evaporating to dryness in vacuum, and recrystallizing from water. It is very soluble in hot water; at 18° 100 cc. of water dissolves 1.36 g. of the salt. In aqueous solution, $[\alpha]_D^{27\ 5}$ −219.3": c = 1.856, $l = 1$, a = −4.07".

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}C_4H_4O_6$: Cl, 7.62. Found: Cl, 7.61.

β-Chlorocodide.—This substance was prepared by a method similar to that of Pschorr[22] and Speyer,[23] by sealing a-chlorocodide (5 g.) in thin-walled test-tubes and heating for twenty-five minutes after complete melting in a bath of boiling bromoform or bromobenzene. The test-tube was cut while the contents were still soft, and 96% alcohol added, whereupon the brownish mass crystallized; yield after one recrystallization from alcohol, 75% of the theoretical. No salts of β-chlorocodide have been described previously.

β-Chlorocodide Hydrochloride.[24]—On addition of the calculated amount of 3 N hydrochloric acid to the base the hydrochloride crystallized from the clear solution almost immediately, and was filtered off and washed with cold water. It was recrystallized from water or from a mixture of alcohol and acetone. The purified salt sinters slightly at 162°, and melts at 168–171° (decomp.); it is slightly levorotatory, $[\alpha]_D^{30}$ −3.85": c = 2.335, $l = 1$, a = −0.09".

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}HCl$: Cl, 20.03. Found: Cl, 19.99, 20.02.

β-Chlorocodide Acid Tartrate.—Prepared by dissolving β-chlorocodide in a dilute aqueous solution of the calculated amount of d-tartaric acid, evaporating to dryness in vacuum, and recrystallizing the glass-like product from a small amount of water. It is very soluble in cold water; in aqueous solution, $[\alpha]_D^{20}$ +8.3°; $c = 1.683$, 1 = 1, a = +0.14°.

Anal. Calcd. for $C_{18}H_{20}O_2NCl{\cdot}C_4H_4O_6$: Cl, 7.62. Found: Cl, 7.67.

Iodocodide.—(1) Orange form: this was prepared according to the directions of Knorr and Hartmann[25] and varied in color from yellow to red. It sintered strongly at 153–155°, formed a black solid at 159–162°, and melted with decomp. at about 200°: red crystals, $[\alpha]_D^{25}$ +134.1° in chloroform: $c = 3.72$, $l = 1$, a = +4.99°; yellow crystals, $[\alpha]_D^{26.5}$ +126.8° in chloroform: $c = 2.30$, 1 = 1, a = +2.92°. (2) White form: this was obtained when the yellow or red crystals were dissolved in boiling ligroin (90–110°) or ethyl acetate, filtered, and cooled quickly. White crystals were also obtained when a-chlorocodide (15 g.) with finely powdered potassium iodide (9 g.) was refluxed for ten hours in 150 cc. of methyl alcohol, yield 12.7 g., m. p. 159–160° after one recrystallization from methyl alcohol. The same substance was obtained as a by-product from the reaction of a-chlorocodide with methyl- or ethylmagnesium iodide. It is soluble in chloroform or benzene, slightly soluble in ethyl acetate, methyl alcohol, ethyl alcohol or

ligroin, almost insoluble in ether; $[\alpha]^{22.5}_{\mathrm{D}}$ +136.5° (chloroform): c = 2.62, l = 2, a = +7.15°.

Anal. Calcd. for $C_{18}H_{20}O_2NI$: C, 52.80; H, 4.93; I, 31.02. Found: C, 53.10; H, 5.04; I, 31.17.

When the white iodocodide was boiled in ethyl alcohol for a few minutes, the solution gradually turned yellow and the yellow or reddish crystals described by Knorr separated on cooling. After boiling in alcohol for three days, iodocodide could no longer be isolated.

Iodocodide Hydrochloride.—Five grams of pure iodocodide was treated with 10 cc. of cold 3 N hydrochloric acid. The gummy mass which first formed crystallized after a few minutes, and was recrystallized from methanol; yield 4.8 g.; after repeated crystallizations it melted at 190–191°. In water, $[\alpha]^{23}_{\mathrm{D}}$ +126.9°, +127.0°: c = 1.43, 0.693, l = 2, 1, α = +3.63°, +0.88'. It is soluble in water at 26° to the extent of 2.6 g. in 100 cc.

Anal. Subs., 0.1623 g. Calcd. for $C_{18}H_{20}O_2NI \cdot HCl + 2H_2O$: silver halide, 0.1275 g. Found: silver halide, 0.1257 g.

The salt lost weight corresponding to 2.5 H_2O (water could be observed) on heating to the point where decomposition started.

Iodocodide **Methiodide.**—Iodocodide in benzene solution was heated with an excess of methyl iodide in a sealed tube at 100° for three hours. The product was washed with ether and recrystallized from hot water, in which it is only very slightly soluble; m. p. 187–188°, yellow needles.

Anal. Calcd. for $C_{19}H_{23}O_2NI_2$: I, 46.06 Found: I, 46.22.

Iodocodide and **Methylmagnesium** Iodide: Desoxycodeine-A,—To a suspension of one gram of powdered iodocodide (white) in 50 cc. of dry ether was added 25 cc. of molar ethereal methylmagnesium iodide solution. After the mixture had refluxed for twelve hours, the excess of Grignard reagent and the powdery white addition compound were decomposed with a slight excess of 10% acetic acid, and concd. ammonia added dropwise with shaking until the solution was strongly alkaline. The ether layer was dried with sodium sulfate and distilled, leaving a yellow oil which soon crystallized. The addition of a small amount of cold methanol served to dissolve the desoxycodeine (0.4 g.) away from unreacted iodocodide (0.3 g.).

Iodocodide (white or orange) reacted with zinc dust in boiling absolute alcohol as does a-chlorocodide, to give desoxycodeine. In view of the unstable nature of iodocodide, the low yield of desoxycodeine (about 30%) is not remarkable.

Hydrolysis of Iodocodide: **Pseudocodeine.**—Eight grams of the white iodocodide was suspended in 40 cc. of hot water and 4 cc. of glacial acetic acid added. The clear yellow solution was refluxed for four hours, cooled, and treated with an excess of 15% potassium hydroxide. The resinous precipitate was extracted out with ether and the ethereal solution dried with potassium carbonate and distilled, yielding an oily solid. This was dissolved in the minimum amount of absolute alcohol and treated with alcoholic hydrochloric acid to acid reaction. After standing for twelve hours at 0°, the solution yielded 4.5 g. of crystalline pseudocodeine hydrochloride. About 2 g. of oily solid was obtained by treating the mother liquors with alkali, but the separation of isocodeine and allopseudocodeine from this was unsuccessful.

Iodocodide and Silver Chloride: **α-Chlorocodide.**—A small amount of white (or yellow) iodocodide was dissolved in 75% alcohol and shaken with freshly precipitated silver chloride. After a few minutes a change in color of the silver salt could be noted, and in three hours it had become quite yellow. The liquid on evaporation yielded α-chlorocodide, of m. p. 145–147°, which showed no depression with a-chlorocodide, but depressed the melting point of β-chlorocodide to about 120".

Desoxycodeine-A (Desoxycodeine).—The base prepared according to the directions of Knorr and Waentig, and Freund, by refluxing a-chlorocodide with zinc dust in absolute alcohol, showed the m. p. 121–122" even after the most careful purification by recrystallization from 50% methyl alcohol to constant rotation as well as over the hydrochloride or hydriodide; $[\alpha]^{22}_{\mathrm{D}}$ +118.1° $c = 3.32$ (96% alcohol), $l = 1$, or = +3.92° (Knorr, m. p. about 126° with previous sintering; $[\alpha]^{15}_{\mathrm{D}}$ +119°, +121°).

Preparation Using Methylmagnesium Iodide.—Eight grams of α-chlorocodide in 400 cc. of dry ether was treated with 75 cc. of molar methylmagnesium iodide solution. A precipitate formed immediately, the ether boiled, and considerable amounts of a gas which was largely unsaturated toward bromine were given off. The mixture was refluxed for six hours, the ether decanted from the heavy white precipitate and the latter brought into complete solution with 10% acetic acid. To the acid solution was added 100 cc. of ether, and an excess of ammonia sufficient to dissolve the magnesium hydroxide precipitate. The ammoniacal layer was extracted with a second 100 cc. of ether, and the combined dried ether distilled. The red oily residue crystallized on the addition of a little ether and was recrystallized from ether and then from 50% methanol. The product (5.5 g.) melted at 122°, $[\alpha]^{24}_{\mathrm{D}}$ +115 1°: c = 196 (96% alcohol), $l = 2$, α = +4.51°. The same product was obtained when ethylmagnesium iodide was used: 3 g. of a-chlorocodide yielded 2 g. of crude desoxycodeine and about 0.1 g. of white iodocodide. The iodocodide was separated from the desoxycodeine through its comparative insolubility in ether.

Desoxycodeine-A, prepared through the reaction of alkylmagnesium halide on a-chlorocodide, gave a hydrochloride of m p 265–270° and a hydriodide of m p. 255–260", identical with those obtained from Knorr's desoxycodeine Our product was further identified through its reduction products: with sodium and alcohol it reduced to the so-called a-tetrahydrodesoxycodeine, with hydrogen and platinum it took up two molecules of hydrogen to give a quantitative yield of β-tetrahydrodesoxycodeine of m. p. 143–145".

The reduction of desoxycodeine-A with sodium and alcohol as well as by the electrolytic method will be further described in the following paper.

Desoxycodeine-B.—Ten grams of pure or-chlorocodide was dissolved in 200 cc. of 20% sulfuric acid (separation of the sparingly soluble crystalline acid sulfate often caused difficulty at this point) and electrolyzed, using a current of 8 amperes and a prepared lead cathode of 60 sq. cm. area, in a cell which was kept at about 10 to 20°. Usually five to six hours was required for the reduction, which was complete when a small test portion dissolved to a clear solution in excess alkali. The acid solution from the reduction was filtered and treated with ammonia until barely alkaline to litmus. The base which precipitated was redissolved in the minimum amount of dilute hydrochloric acid, and the solution cooled to 0°; 200 cc of ether was added, and then 3 N ammonia dropwise with vigorous shaking. The clear yellow ether solution was dried with sodium sulfate and distilled, yielding 9.0 g of crude desoxycodeine-B of m. p. 110–115°. Two crystallizations from dilute alcohol gave a product melting at 118–119°, $[\alpha]^{24}_{\mathrm{D}}$ +42.4°. By exhaustive crystallization from dilute alcohol the melting point changed only slightly (119–120°), but the rotatory power rose to $[\alpha]^{22}_{\mathrm{D}}$ +71.3°: $c = 3.617$, $l = 1$, or = +2.58°.

Anal. Calcd for $C_{18}H_{21}O_2N + {}^1/_2H_2O$: C, 73.93, H, 7.58 Found C, 73 85; H, 7.84.

A dihydrodesoxycodeine $C_{18}H_{23}O_2N + {}^1/_2H_2O$ which Freund claimed this base to be would require *C*, 73.43; H, 8.21.

Desoxycodeine-B hydrochloride is formed when a saturated solution of the base in absolute alcohol is treated with alcoholic hydrochloric acid. The white crystals obtained darken rapidly on standing, and even after recrystallization from absolute alcohol are still unstable.

Desoxycodeine-B hydriodide results from treatment of a dilute acetic acid solution of the base with excess of aqueous potassium iodide. The oil which first separates crystallizes on standing, and may be purified by recrystallization from water, from which it separates as light yellowish-brown needles of m. p. 245°; $[\alpha]^{22}_{D}$ +38.3°: c = 1.698, l = 1, α = +0.65°.

Anal. Calcd. for $C_{18}H_{21}O_2N{\cdot}HI$: I, 30.87. Found: I, 30.92.

Desoxycodeine-B Methyl Ether Methiodide.—The methiodide of the desoxycodeine-B does not crystallize. The methyl ether methiodide, prepared in the usual way and recrystallized from dilute alcohol, melted at 242–243°. Freund gives the m. p. 245°.

Reduction of Desoxycodeine-B.—Nine and one-half grams of the base was dissolved in dilute hydrochloric acid to neutral solution, made up to 100 cc. with water, and hydrogenated in the presence of *2.5 g.* of palladium–barium sulfate; 1570 cc. *(2* moles) of hydrogen was absorbed in three hours (when platinum oxide was used the reduction ran to completion in twenty to thirty minutes). The filtered solution was made alkaline with ammonia and extracted with ether. The product, recrystallized from acetone, consisted of 9.5 g. of white crystals of m. p. 139–143°, which melted at 144–145° after further purification from acetone and were identical in every respect with β-tetrahydrodesoxycodeine; $[\alpha]^{20}_{D}$ −33.3": c = 1.499 (alcohol), l = 1, α −0.50°. The reduction of desoxycodeine-B with sodium and alcohol to a dihydrodesoxycodeine (the so-called α-tetrahydrodesoxycodeine) will be described in the following paper.

Desoxycodeine-C.—A solution of 9 g. of sodium in 400 cc. of methanol was prepared in a' steel autoclave, 5.0 g. of crystalline chlorodihydrocodide (m. p. 171–173°) added, and the mixture heated at 140° for twenty-four hours. After cooling, the clear deep red methanol solution was diluted with an equal volume of water, and the methyl alcohol removed with a bubble tube in vacuum at 40°. The alkali-insoluble desoxycodeine-C separated crystalline as the alcohol was removed, and was filtered out and purified by repeated crystallization from ethyl acetate. The yield of crude crystalline product was 4.2 g., of purified substance melting at 105–106°, 3.0 g.; in 95% alcohol. $[\alpha]^{20}_{D}$ −199.4°, −197.4': c = 1.745, 1.008; l = 1, 1; a = −3.48°, −1.99°.

Anal. Calcd. for $C_{18}H_{21}O_2N$: C, 76.28; H, 7.47. Found: C, 76.24; H, 7.65.

The formula of a dihydrodesoxycodeine, $C_{18}H_{23}O_2N$, as claimed by Knoll and Co., requires C, 75.74; H, 8.12.

It is extremely soluble in methyl or ethyl alcohol, ether, chloroform or benzene, moderately soluble in ethyl acetate, insoluble in alkali.

Desoxycodeine-C Hydrochloride.—A solution of the base in the minimum amount of 3 *N* hydrochloric acid was evaporated to dryness in vacuum and the white crystalline solid thus obtained was purified by recrystallizing from alcohol. It crystallizes with one molecule of water and melts at 114°; in aqueous solution $[\alpha]^{20.5}_{D}$ −132.7': c = 1.771, l = 1, a = −2.35°.

Anal. 0 1609 g. at 130" in vacuum lost 0.0088 g. Calcd. for $C_{18}H_{21}O_2N{\cdot}HCl + H_2O$: H_2O, 5.38 Found: H_2O, 5.50.

Anal. (dried substance) Calcd. for $C_{18}H_{22}O_2NCl$: Cl, 11.10. Found: Cl, 11.23.

Desoxycodeine-C Hydriodide.—The base was dissolved in dilute acetic acid and treated with an excess of potassium iodide solution. An oil separated, which crystallized on standing, and was purified by recrystallization from hot water. It consisted of fine light yellow prisms, sintering at 135–140°, melting at 160–165°, and containing one molecule of hydrate water; in 95% alcohol, $[\alpha]^{19}_{D}$ −131.6°: c = 1.401, l = 1, a = −1.84".

Anal. Calcd. for $C_{18}H_{21}O_2N{\cdot}HI + H_2O$: H_2O, 4.19. Found: H_2O, 4.18. Calcd. for $C_{81}H_{22}O_2NI$: I, 30.88. Found: I, 30.96.

Desoxycodeine-C Methiodide.—A solution of the base in methyl alcohol was boiled for ten minutes with an excess of methyl iodide. After removal of methyl iodide by distillation, water was added; the oily methiodide which separated was obtained crystalline by dissolving in hot water and cooling very slowly. The crude product melted at 210–211°; after crystallization to constant melting point from methyl alcohol it melted at 236–240°.

Anal. Calcd. for $C_{19}H_{24}O_2NI$: I, 29.86. Found: I, 30.22.

Reduction of **Desoxycodeine-C.**—One gram of desoxycodeine-C in 30 cc. of methyl alcohol with 0.1 g. of Adams' platinum oxide catalyst took up 180 cc. of hydrogen in twenty minutes. The calculated absorption for 2 moles of hydrogen is 176 cc. The mixture was filtered from the platinum and evaporated to dryness in vacuum, giving a quantitative yield of crystalline β-tetrahydrodesoxycodeine, which after one crystallization from acetone melted at 143–144°, showed no depression in m. p. with β-tetrahydrodesoxycodeine, and yielded a hydriodide of m. p. 251°, a methiodide of m. p. 263–265° identical with those from β-tetrahydrodesoxycodeine. The reduction product likewise showed the rotation of β-tetrahydrodesoxycodeine: $[\alpha]^{20}_{D}$ $-30.8°$, $c = 1.980$ (alcohol), $l = 2$, a $= -1.22°$. The reduction of desoxycodeine-C with the Willstatter platinum black catalyst, or in hydrochloric acid solution with a palladium-barium sulfate catalyst gave identical results. Desoxycodeine-C is recovered unchanged from treatment with sodium and alcohol, or zinc and acetic acid. The electrolytic reduction of desoxycodeine-C yields a dihydrodesoxycodeine of m. p. 128–131° which will be described in the following paper.

Summary

1. A study of the desoxycodeines and of their conversion to the dihydrodesoxycodeines and to β-tetrahydrodesoxycodeine has been made.

2. Desoxycodeine-A is shown to be the chief product of the reaction between a-chlorocodide and methyl- or ethylmagnesium iodide. Iodocodide, which is obtained as a by-product of the reaction, may play a part in the reaction mechanism.

3. The compound resulting from electrolytic reduction of α- or β-chlorocodide, which was formerly thought to be a dihydrodesoxycodeine, is shown to be a second, phenolic desoxycodeine. It can be reduced directly to β-tetrahydrodesoxycodeine, or indirectly, through an intermediate dihydrodesoxycodeine, to the same tetrahydrodesoxycodeine.

4. The action of sodium methylate on chlorodihydrocodide does not give a dihydrodesoxycodeine as claimed in the literature, but the nonphenolic desoxycodeine-C which reduces to a phenolic dihydrodesoxycodeine or to β-tetrahydrodesoxycodeine.

5. New crystalline salts of α-chlorocodide and of β-chlorocodide are described.

DESOXYCODEINE STUDIES. II. THE DIHYDRODESOXYCODEINES[1]

BY LYNDON F. SMALL AND FRANK L. COHEN

RECEIVED FEBRUARY 9, 1931 PUBLISHED JUNE 8, 1931

In the preceding paper[2] the preparation of three isomeric desoxycodeines, $C_{18}H_{21}O_2N$, was described. The present communication deals with the dihydrodesoxycodeines obtained by partial reduction of the desoxycodeines, as well as with certain dihydrodesoxycodeines whose relationship to the desoxycodeines is not certain. Any systematic nomenclature of the dihydrodesoxycodeines as derivatives of the desoxycodeines is complicated by the fact that two of the latter reduce to give the same dihydro derivative, whereas the third, non-phenolic desoxycodeine yields on reduction a phenolic product which must be regarded as a dihydro derivative of the phenolic desoxycodeines. Until evidence is available through which the structure of the individual dihydrodesoxycodeines can be demonstrated, we will designate them by Roman letters, which are arbitrary and imply no genetic relationship to the desoxycodeines already described by the same device.

If the possibility of isomerism in this series due to differences in the spatial arrangement of the hydrogen atom on C-14 be disregarded, there *are* theoretically possible[3] two phenolic desoxycodeines of the type shown in Formula II, both of which have been described (desoxycodeine-A and desoxycodeine-B), and four non-phenolic desoxycodeines of the type of Formula III, whose isomerism will be due to differences in position of the double linkage in Ring III. Only one of the non-phenolic desoxycodeines is known, desoxycodeine-C.

By addition of two hydrogen atoms to either of the phenolic desoxycodeines of type II, there are possible four isomeric phenolic dihydrodesoxycodeines (Formula IV), all of which still contain one double bond, which may be imagined as occupying any one of the four possible positions in the hydroaromatic ring, and all of which must reduce to the same tetrahydrodesoxycodeine, provided addition of hydrogen at C-14 takes place always in but

[3] No evidence exists in morphine chemistry which would make necessary the hypothesis of stereoisomerism at any other point, as at the asymmetric carbon atoms 5 or **9.** The recent work of Schopf and Pfeifer [**Ann.,** 483, 157 (1930)] on closure of the ether ring at C-5 includes theoretical speculations to the effect that but one configuration at C-5 is sterically possible (*loc. cit.,* page **164).** An arrangement of double linkages other than in conjugation in Ring III scarcely comes into consideration.

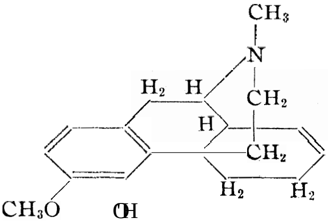
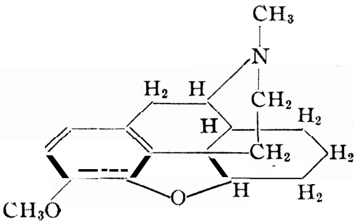
one way sterically. The four phenolic dihydrodesoxycodeines described below are, by addition of two hydrogen atoms, all converted to the same substance, β-tetrahydrodesoxycodeine (VI).

By addition of two hydrogen atoms to the double linkage of any of the hypothetical desoxycodeines of type III, only one non-phenolic dihydrodesoxycodeine (V) will be formed, again postulating addition of hydrogen in but one way at C-14 in the case where the double linkage lies between C-8



IV

Dihydrodesoxycodeine, phenolic



V

Dihydrodesoxycodeine, non-phenolic

β-Tetrahydrodesoxycodeine

and C-14. By further addition of hydrogen, conducted under such conditions that the 4,5-ether linkage is opened, the same phenolic tetrahydrodesoxycodeine (VI) as resulted from complete reduction of the hydroaromatic ring in type II must be formed.

Desoxycodeine-A (m. p. 126°, Formula II, or the alternative formula with double bond at C-5 and C-7), which was first prepared by Knorr and Waentig in 1907,[4] reduces with sodium and alcohol to give a product of m. p. 134–136° (Knorr, melting point about 132°),[4,5] which these investigators believed to be a dihydrodesoxycodeine, and which may be more conveniently prepared by direct reduction of a-chlorocodide with sodium and alcohol.[4] Fourteen years later Freund, Melber and Schlesinger[6] conducted an investigation on dihydro- and tetrahydrodesoxycodeines which must be briefly summarized here. The relevant experiments will be numbered and referred to in the discussion by these numbers.

§1. Chlorodihydrocodide, derived from dihydrocodeine by substitution of the alcoholic hydroxyl by chlorine, was reduced by the electrolytic method of Tafel, and yielded a pale brown crystalline solid, m. p. 117–119°, which analyzed approximately for a dihydrodesoxycodeine, $C_{18}H_{23}O_2N + {}^1/_2\ H_2O$.

$2. a-Chlorocodide, reduced electrolytically, gave a compound of m. p. 117–119°, which was claimed to be identical with the dihydrodesoxycodeine of $1.

$3. β-Chlorocodide, reduced electrolytically, gave a product of m p. 126–130°, which showed the m. p. 117–119" when mixed with the product from $2 and was therefore considered to be identical with it.

$4. Desoxycodeine (m p. 126°), on electrolytic reduction, gave a product of m. p. 117–119° which was said to be identical with the product from §1.

$5. Desoxycodeine (m. p. 126°), in the form of the hydrochloride, hydrogenated in the presence of palladium, took up two molecules of hydrogen to give a product $C_{18}H_{25}O_2N + {}^1/_2\ H_2O$, which was named β-tetrahydrodesoxycodeine.

$6. The supposed dihydrodesoxycodeine of m. p. 117–119°, source not given, on hydrogenation in the presence of palladium took up one molecule of hydrogen to give a substance which crystallized in leaflets or rods, sintered at 130° and melted at 132°, of which the authors write, "Die Base scheint danach identisch zu sein mit der von Knorr und Waentig aus Desoxykodein durch Reduktion mit Natrium und Alkohol hergestellten und von denselben als Desoxydihydrokodein bezeichneten Base." ("The base appears according to this to be identical with the base prepared by Knorr and Waentig from desoxycodeine by reduction with sodium and alcohol, and designated by them as desoxydihydrocodeine.") Nowhere in Freund's paper is a direct comparison of this substance, which he calls a-tetrahydrodesoxycodeine, with the desoxydihydrocodeine of Knorr mentioned, nor are analytical data on it given.

$7. a-Chlorocodide, hydrogenated in the presence of colloidal palladium, yielded an amorphous alkali-insoluble base which did not crystallize nor give crystalline salts. It analyzed very poorly for dihydrodesoxycodeine $+ {}^1/_2\ H_2O$, and was named α-dihydrodesoxycodeine.

$8. The amorphous so-called a-dihydrodesoxycodeine of $7, on further reduction

[4] Knorr and Waentig, ***Ber.***, 40, 3860 (1907).

[5] Cahn, *J.* ***Chem.*** *Soc.*, 2572 (1926), found it to sinter at 125° and melt at 134–135°.

[6] Freund. Melber and Schlesinger, *J prakt.* Chem., 101, 1 (1981).

by the electrolytic method, gave a crystalline product of m. p. 131–132°, whose hydrochloride melted at 155°, and methyl ether methiodide melted at 247°. The substance of m. p. 131–132° was considered to be identical with that mentioned under §6, and with Knorr and Waentig's desoxydihydrocodeine.

On the basis of the experimental evidence outlined above, Freund believed that the Knorr and Waentig desoxydihydrocodeine was actually formed by addition of four atoms of hydrogen to desoxycodeine, was *therefore a tetrahydrodesoxycodeine, and isomeric with the β-tetrahydrodesoxycodeine* obtained in \$5. The possibility of the appearance of stereoisomeric tetrahydrodesoxycodeines which might owe their existence to differences in the spatial arrangement of hydrogen at C-14 was not recognized by Freund, nor by Gulland and Robinson[7] in their first publication in this field. Freund[6] used the supposed isomerism of α- and β-tetrahydrodesoxycodeines as a support for the bridge bond formula (VII) for codeine which had already been developed in connection with phenyldihydrothebaine,[8] and represented the formation of the isomers as below, where in Formula VIII reduction was thought to take place in the one case with saturation of Δ^5, and opening of the linkage C-15, C-8 to give IX, in the other case A^S was saturated, but linkage C-15, 6-5 was opened and X resulted.

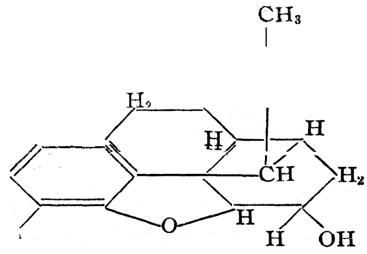
[7] Gulland and Robinson, *J.* Chem. *Soc.*, 123, 980 (1923).

[8] Freund and Speyer, *Ber.*, 49, 1287 (1916).

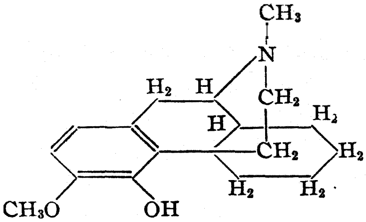
[9] Through a typographical error the double linkage between C-5 and C-6 was omitted in Freund's representation of desoxycodeine in Plate I (to page 9), J. *prakt. Chem.*. 101, 9 (1921).

Gulland and Robinson[10] adopted a similar hypothesis to account for the two tetrahydrodesoxycodeines; in this case C-15 was linked to C-13 and C-8 in codeine (XI), and the change from desoxycodeine to the two tetrahydrodesoxycodeines was explained by rupture of the bond C-15, C-13 or C-15, C-8, respectively. In a later publication by the same authors[11] the possibility of accounting for the isomerism through a stereochemical relationship, analogous to the decahydronaphthalene type of isomerism was recognized, with the implication that a- and β-tetrahydrodesoxycodeines should be represented as in XII and XIII a suggestion which was generally accepted by workers in the field of morphine chemistry.[12]

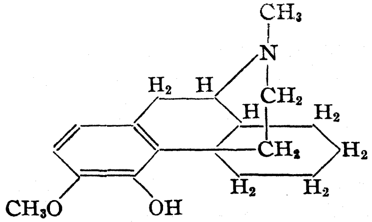


XI

Codeine
(Gulland–Robinson1923)



XII



XIII

In 1926, Cahn[5] conducted an investigation, the purpose of which was to show that the important isomerism of α- and β-tetrahydrodesoxycodeines actually existed. He prepared the supposed a-tetrahydrodesoxycodeine in a hitherto unattained state of purity, showed that it differed from β-tetrahydrodesoxycodeine, *but* failed to demonstrate that it was isomeric *with this* substance.

We find that the so-called a-tetrahydrodesoxycodeine of Freund is not a tetrahydro derivative of desoxycodeine, but is actually a *dihydro*desoxycodeine, as originally claimed by Knorr and Waentig. Hereby is eliminated a troublesome isomerism which has been difficult to explain on the basis of any of the existing structural formulas for morphine.

With the disappearance of the supposed isomerism of the tetrahydrodesoxycodeines, certain other difficultly explicable cases of isomerism in the morphine series, which have been more or less generally considered to be of the tetrahydrodesoxycodeine type, lose an important support. This is

especially true in the case of the isomers of dihydrothebainone, and the suggestion that the relationships in this series may be of the type represented by the tetrahydrodesoxycodeines[13] must be reconsidered.

Dihydrodesoxycodeine-A.—The so-called a-tetrahydrodesoxycodeine, which we will hereafter designate as dihydrodesoxycodeine-A, is formed in good yields by reduction of a-chlorocodide or of desoxycodeine-A with sodium and alcohol, as described by Knorr and Waentig.[4] Following the procedure of Cahn,[5] we purified it exhaustively through the hydrochloride, obtaining constants for this salt nearly identical with those given by this investigator for his purest substance. The free base was precipitated by addition of dilute ammonia to a dilute solution of the hydrochloride, as beautiful snow white crystals, which appeared under the microscope as chains or clumps of diamond-shaped plates. It was recrystallized to constant rotation from dilute methyl alcohol; further purification from acetone did not change the melting point or rotatory power. This base, which sintered at 120–125° and melted at 134–136°, and analyzed for a dihydrodesoxycodeine, $C_{18}H_{23}O_2N + {}^1/_2\,H_2O$, on reduction with hydrogen in the presence of a platinum catalyst *was found to absorb one molecule of hydrogen, to give a quantitative yield of β-tetrahydrodesoxycodeine.* Dihydrodesoxycodeine-A in the form of its hydrochloride of m. p. 158–160° may likewise be hydrogenated, using palladium, to give quantitatively β-tetrahydrodesoxycodeine. This end-product was identified by analysis, rotation, melting point and the melting points of its derivatives, and by its conversion to the crystalline anhydrous β-tetrahydrodesoxycodeine of sharp melting point 123–124' which will be described in our next paper. Since there is but one tetrahydrodesoxycodeine the use of the Greek letter becomes unnecessary, and we will hereafter refer to the β-tetrahydrodesoxycodeine discovered by Freund as tetrahydrodesoxycodeine.

Dihydrodesoxycodeine-A is also obtained in practically quantitative yield when desoxycodeine-B (m. p. 119°),[2] hitherto believed to be a dihydrodesoxycodeine, is reduced with sodium and alcohol. The reduction product was identified not only by melting point and rotation, but by melting point and rotation of the hydrochloride, analysis of the latter, and its further reduction to tetrahydrodesoxycodeine.

It is sufficiently demonstrated in the foregoing paragraphs that the so-called α-tetrahydrodesoxycodeine is non-existent. There remains only an examination of the evidence upon which its supposed existence rested. The confusion of dihydrodesoxycodeine-A with a tetrahydrodesoxycodeine arose primarily from the mistaken conception that the electrolytic re-

---

[13] *See,* for example, Gulland and Robinson, *J. Chem. Soc.,* **123,** 984, 1000 (1923); Schöpf and co-workers, *Ann.,* 452, 239, 240 (1927); 458, 155, 159, 164 (1927); Wieland and Kotake, *ibid.,* **444,** 80 (1925). The speculations of Schöpf, *Ann.,* 458, note 2, page 164 (1927), regarding the relationships between the tetrahydrodesoxycodeines and dihydrothebainone naturally become invalid.

duction products from a- and β-chlorocodides (§2 and 3), chlorodihydrocodide (§1) and desoxycodeine-A (§4) were identical, and from an insufficient examination of the end-product of catalytic reduction obtained in §6. Freund (§6) hydrogenated a "dihydrodesoxycodeine, m. p. 117–119°" to a base which was stated to melt at 130–132°. From the fact that one molecule of hydrogen was absorbed he concluded that the product was a tetrahydrodesoxycodeine, which on the basis of its melting point and the shape of its crystals he believed identical with the Knorr and Waentig desoxydihydrocodeine; he claimed that the latter was actually a tetrahydrodesoxycodeine and therefore isomeric with the (β-) tetrahydrodesoxycodeine obtained in §5.

It is certain that Freund obtained in this hydrogenation (β) tetrahydrodesoxycodeine (cf. diagram, page 2238) which when pure melts at 144–145°, but as obtained crude from catalytic reduction of all desoxy- and dihydrodesoxycodeines generally shows a melting point of about 130–133°.[14]

From the electrolytic reduction of a- and β-chlorocodides (§2 and 3), chlorodihydrocodide (§1) and desoxycodeine 126° (§4) Freund obtained bases which all showed the melting point 117–119°, gave no depression in melting point when mixed, and which he regarded as identical. In a repetition of these reductions we find: (a) that a- or β-chlorocodide, on electrolytic reduction, yield a base of m. p. 119°, which is however a desoxycodeine[2] (desoxycodeine-B, which reduces catalytically to tetrahydrodesoxycodeine by addition of two H_2); (b) that chlorodihydrocodide reduces electrolytically to give a dihydrodesoxycodeine, m. p. 111° (which in the crude state shows a melting point of 114–117°); (c) that desoxycodeine-A (126') reduces electrolytically with great difficulty to give dihydrodesoxycodeine-A (m. p. 134–136") in small amounts.

As a result of our experiments it seems very probable that the Freund "dihydrodesoxycodeine 117–119°" which was supposed to have reduced to "a-tetrahydrodesoxycodeine" actually was dihydrodesoxycodeine-C (m. p. 111°) in an impure state, which takes up one molecule of hydrogen to give a quantitative yield of "β-"tetrahydrodesoxycodeine.

Freund claimed further (§8) that an amorphous product which he called "a-dihydrodesoxycodeine" (§7) on electrolytic reduction, gave our dihydrodesoxycodeine-A. We have examined "a-dihydrodesoxycodeine" and find it to consist of a mixture of at least two hydrogenated desoxy-

---

[14] No mention is made in Freund's paper of a direct comparison of his 130–132° product with the Knorr–Waentig base. We have found that crude tetrahydrodesoxycodeine, m. p. *ca.* 130–133°, does not depress the melting point (134–136°) of pure dihydrodesoxycodeine-A, and that a mixture of pure tetrahydrodesoxycodeine (m. p. 144–145°) with dihydrodesoxycodeine-A melts at an intermediate temperature (138–140'). This lack of melting point depression in the desoxycodeine series is further discussed under dihydrodesoxycodeine-B.

codeines,[15] one of which reduces electrolytically to give tetrahydrodesoxycodeine (m. p. 144–145°). We are at a loss to explain the hydrochloride of m. p. 155" and methyl ether methiodide of m. p. 247° ($8) which Freund mentions.

We have been able to find in the literature only one other investigation where "α-tetrahydrodesoxycodeine" was claimed as the end-product of reduction. In 1923 Speyer and Krauss,[16] by catalytic reduction of what was then thought to be allopseudochlorocodide but was later[17] shown to be the well-known β-chlorocodide, noted an absorption of three molecules of hydrogen and the formation of the so-called α-tetrahydrodesoxycodeine (which was identified only by the melting point of the methyl ether methiodide). The identical reduction was carried out three years earlier by Mannich and Lowenheim,[18] who found as the products two alkali-insoluble substances, which were named dehydroxydihydrocodeine and dehydroxytetrahydrocodeine. Neither substance resembled "α-tetrahydrodesoxycodeine." We have carried out the hydrogenation of β-chlorocodide with palladium[19] and can confirm the experimental results of Mannich. The absorption of hydrogen amounts to about 2.5 moles, and the only isolable products are a dihydrodesoxycodeine (Mannich's dehydroxydihydrocodeine) to be described below, and the tetrahydrodesoxycodeine of m, p. 144–145° (Mannich's dehydroxytetrahydrocodeine).[20]

The desoxytetrahydropseudocodeine hydrochloride obtained by Speyer and Krauss[21] through reduction of tetrahydropseudochlorocodide and stated to be identical with "α-tetrahydrodesoxycodeine" hydrochloride is too inadequately described to permit of critical discussion. It is obviously impossible that a reduction product of tetrahydropseudochlorocodide can be identical with dihydrodesoxycodeine-A.

There is no convincing evidence in the literature to show that dihydrodesoxycodeine-A has ever been obtained as the final product of catalytic reduction.

Dihydrodesoxycodeine-B.—Dihydrodesoxycodeine-B m. p. 128°, results from the electrolytic reduction of desoxycodeine-C (m. p. 106°, nonphenolic) which was described in the preceding paper. It is a phenolic base, formed by addition of two hydrogen atoms at the 4,5-ether bridge

---

which must be present in the non-phenolic desoxycodeine-C. Dihydrodesoxycodeine-B differs from dihydrodesoxycodeine-A in its melting point. in its rotation and that of its hydrochloride, and in the melting point of its methiodide. The isomers give no depression in melting point when mixed; we have encountered this phenomenon frequently in this series, as has also Cahn.[22] Dihydrodesoxycodeine-B reduces catalytically, with the absorption of one molecule of hydrogen, to give a quantitative yield of tetrahydrodesoxycodeine.

Dihydrodesoxycodeine-C.—Dihydrodesoxycodeine-C (m. p. 111°) is a phenolic base which is formed when chlorodihydrocodide (XIV) is reduced by the electrolytic method. The crude product from the reduction melts at about 114–117°, a fact which we believe led Freund to confuse it with the base of m. p. 119° from the reduction of a-chlorocodide (see §1 and 6), desoxycodeine-B. Dihydrodesoxycodeine-C differs from desoxycodeine-B not only in melting point and in composition as determined by analysis, but in having a negative rotation, in forming a stable hydrochloride, in the rotation of its hydriodide and in forming a crystalline methiodide. In contrast to desoxycodeine-B, which absorbs two molecules of hydrogen, this base takes up but one molecule of hydrogen, giving tetrahydrodesoxycodeine.

Dihydrodesoxycodeine-D.—The only non-phenolic dihydrodesoxycodeine as yet prepared was first described by Mannich[18] under the name dehydroxydihydrocodeine. He recognized it as a dihydrodesoxycodeine, isomeric with those which had just been reported by Freund in a preliminary communication,[23] but did not demonstrate that it could be further reduced. The base, which we will designate as dihydrodesoxycodeine-D,[24] may be prepared according to the directions of Mannich, by reduction of β-chlorocodide with a palladium catalyst[25] and is most advantageously separated from the other products of the reduction through its beautifully crystallized acid tartrate. The preparation of dihydrodesoxycodeine-D from a-chlorocodide or by methylation of dihydrodesoxymorphine will be described in further papers from this Laboratory.

Dihydrodesoxycodeine-D (XV) must be derived from our desoxycodeine-C (III) by addition of two hydrogens to the one remaining double linkage in the hydroaromatic ring, although for reasons which are probably connected with the position of the double linkage relative to the ether ring[2] this conversion has not yet been experimentally realized.

All attempts to prepare dihydrodesoxycodeine-D by addition of two hydrogen atoms to the double bond in III resulted in unchanged material

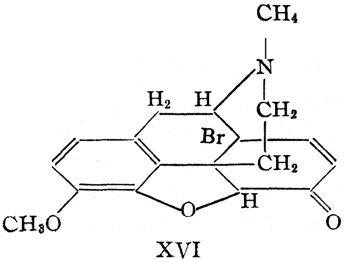
Dihydrodesoxycodeine-D

or in addition of four hydrogens, with reductive scission of the 4,5-ether bridge to give the end-product, tetrahydrodesoxycodeine.

The nature of dihydrodesoxycodeine-D as a dihydrodesoxycodeine is shown by its analyses, and by its further reduction. On treatment with sodium in methyl alcohol, as well as by electrolytic reduction in sulfuric acid, it adds two hydrogen atoms, presumably opening the ether linkage, to give a nearly quantitative yield of tetrahydrodesoxycodeine (VI). This reduction could not be accomplished by the use of catalytic hydrogen.

A fifth dihydrodesoxycodeine, of m. p. 139–140°, which we will designate as **dihydrodesoxycodeine-E**, whose discovery is due to Speyer,[26] has been described. We have verified its preparation by electrolytic reduction of bromocodeinone (XVI), and the fact that it hydrogenates with addition of one molecule of hydrogen to yield tetrahydrodesoxycodeine, as described by Speyer, but wish to leave the further investigation of this base to its discoverer. It must be formed from bromocodeinone (XVI) by reductive elimination of bromine, reduction of the carbonyl to a methylene group and reductive scission of the ether ring.



XVI
Bromocodeinone

The relationships of the various known desoxycodeines and dihydrodesoxycodeines are expressed in the diagram below, which is accompanied by a table showing in condensed form the properties of these compounds. It

---

[26] Speyer and Sarre, Ber., 57, 1404 (1924).

is a striking fact that all of the phenolic desoxycodeines and their hydrogenation products crystallize with one-half molecule of water; the two known non-phenolic members, desoxycodeine-C and dihydrodesoxycodeine-D, crystallize anhydrous.

As a result of the experiments described in this and the preceding paper, we believe that there is no evidence in the desoxycodeine series which warrants the assumption of an isomerism due to steric relationships on C-14 of the morphine structural skeleton, and we question seriously the validity of such an assumption in other series where the reality of otherwise unexplainable isomerism is less firmly established than it seemed to be in the case of the supposedly isomeric tetrahydrodesoxycodeines prior to the publication of the present account.

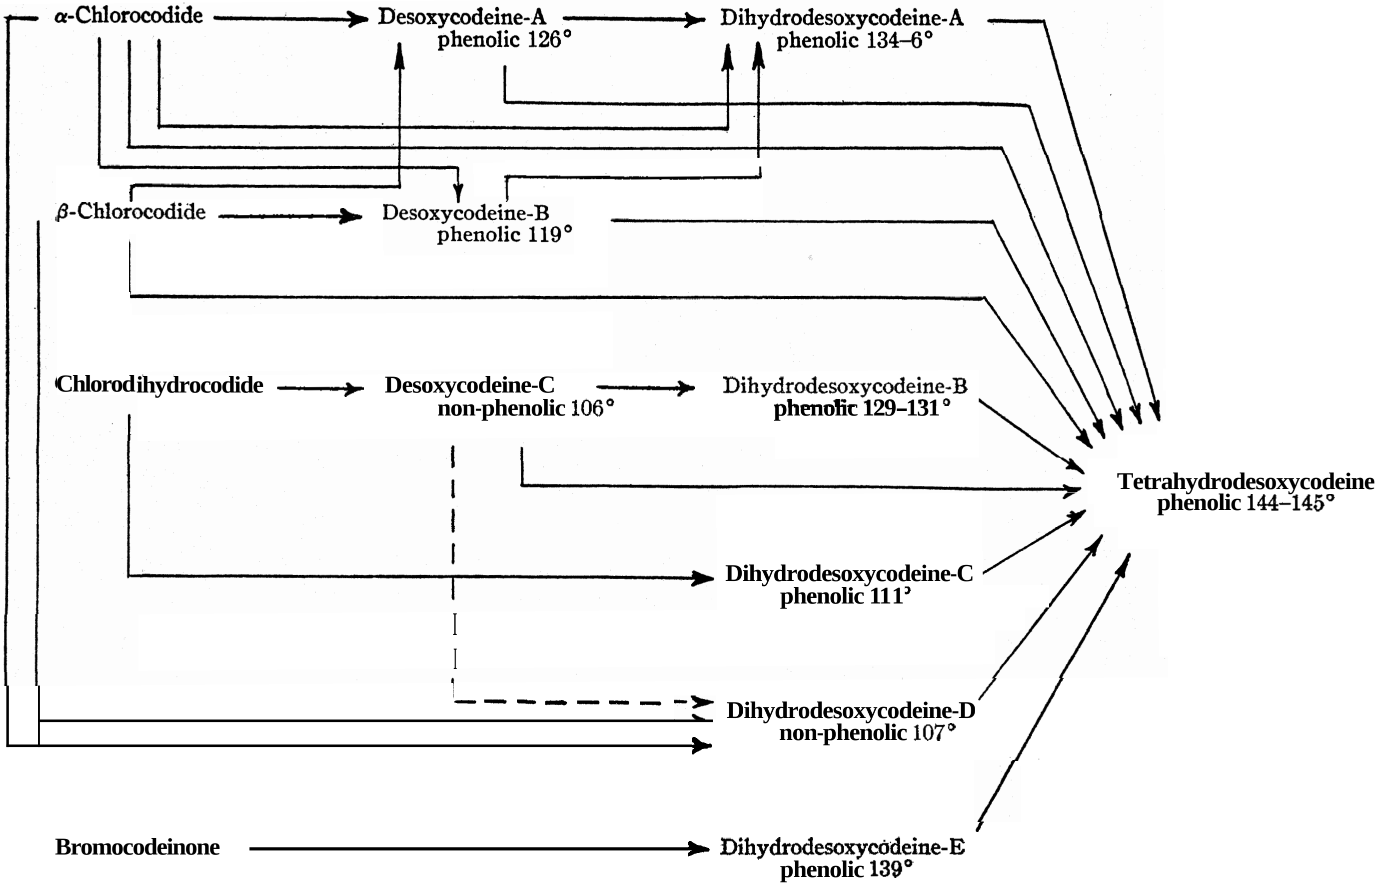
[a] Acid tartrate.

Experimental

Dihydrodesoxycodeine-A.—No detailed description of the preparation of the so-called a-tetrahydrodesoxycodeine is given in the literature. We prepared the base as follows: (1) from a-chlorocodide. Ten grams of pure α-chlorocodide was dissolved in 300 ec. of 95% alcohol, and to the boiling solution was added 50 to 60 g. of sodium in pieces of about 0.5 g. During the reduction the addition of three 100-cc. portions of alcohol was necessary. When all sodium was in solution, the mixture was diluted with 400 cc. of water, and concd. hydrochloric acid (about 220 cc.) added until the solution was just acid to Congo red. Most of the alcohol was removed by distillation in vacuum at 30–40°; a large amount of sodium chloride separated in this process, and the hydrochloride of dihydrodesoxycodeine-A, which is only sparingly soluble in saturated sodium chloride solution, precipitated as a yellow oil. The solution was poured off, layered over



α-Chlorocodide

Dihydrodesoxycodeine-E phenolic 139°

with ether, excess of ammonia added and the precipitate extracted. The oily hydrochloride was dissolved in water, treated in the same way, and the ether extracts combined. The ether was shaken out with two 15-cc. portions of normal hydrochloric acid, and then with successive small portions of 0.1 N hydrochloric acid until the acid layer gave no precipitate with Mayer's reagent The hydrochloric acid extract was evaporated to dryness in a vacuum desiccator, leaving a brittle glassy mass, which crystallized immediately on rubbing with absolute alcohol: 8 g. of crude hydrochloride was obtained, of m. p. 148–150°. After five recrystallizations from absolute alcohol this showed the m. p. 158–160° (gas evolution), and gave the value $[\alpha]^{22}_{\mathrm{D}}$ —41.4°: c = 5.289 (water), l = 1 a = —2.19". (Cahn found m. p. 158–159°, $[\alpha]^{17}_{\mathrm{D}}$ —40°.)

Eight and one-half grams of the purified hydrochloride was dissolved in 45 cc. of water, and treated dropwise with normal ammonia. The free base separated in the form of sparkling white flakes, which appeared under the microscope as chains and clumps of diamond-shaped plates. The base was recrystallized four times from dilute methyl alcohol and twice more from acetone. The last three fractions were identical in melting point and rotation. Due to the ease with which the base loses its hydrate water, the melting point is unsharp, as was observed by Cahn. Our purest product sintered and took on a wet appearance at 120–125°, and melted with slight gas evolution at 134–136°; $[\alpha]^{22}_{\mathrm{D}}$ —27.1°, —26.7°: c = 2.472, 2.472 (abs. alcohol), 1 = 2, 1; a = —1.34°, —0.66" (Cahn, m. p. 134–135"; Knorr, $[\alpha]^{15}_{\mathrm{D}}$ —24°).

Anal. Calcd. for $C_{18}H_{23}O_2N + {}^1/_2\, H_2O$: C, 73.43; H, 8.21. Found: C, 73.73, 73.79, 73.67; H, 8.24, 8.31, 8.16.

Attempts to determine the hydrate water failed because of the ease with which the base distils. At 70° in vacuum it slowly sinters together and melts to a colorless liquid, losing its hydrate water but also distilling to a slight extent. The anhydrous glassy solid crystallizes from dry petroleum ether in white granular crystals of unsharp m. p. 76–82"; on exposure to the air, the crystals change in form, and the melting point rises rapidly (after twenty minutes, m. p. 117–118°) until after several hours only the leaflets showing the normal melting point of the hydrated base are present. The base distils readily at 160–170° (1 mm.) as a colorless liquid, solidifying to a glass.

Anal. Calcd. for $C_{18}H_{23}O_2N$: C, 75.74; H, 8.12. Found: C, 75.84; H, 8.22.

(2) Dihydrodesoxycodeine-A from reduction of desoxycodeine-A: 5.5 g. of desoxycodeine-A of m. p. 122–124° was dissolved in 200 cc. of boiling alcohol and reduced with 30 g. of sodium, with addition of 200 cc. more of alcohol as necessary; the product was isolated and purified as in the case of the α-chlorocodide reduction above; 6.1 g. (86% of the calculated yield) of crude dihydrodesoxycodeine-A hydrochloride (m. p. 148–150°) was obtained, which melted with decomposition at 158" after three crystallizations from absolute alcohol.

Anal. Calcd. for $C_{18}H_{23}O_2N \cdot HCl + C_2H_5OH$: C, 65 28; H, 8.22. Found: C 65.10; H, 8.05.

The base precipitated from this hydrochloride and purified from dilute methyl alcohol and acetone sintered at 123–127° and melted at 133–135°; it did not depress the melting point of the product obtained by reduction of a-chlorocodide above. It gave $[\alpha]^{22}_{\mathrm{D}}$ —24.4': c = 4.068 (alcohol), l = 2, a = —1.99'.

(3) Dihydrodesoxycodeine-A from reduction of desoxycodeine-B (m. p. 119–120°): 5 g. of carefully purified desoxycodeine-B[27] was reduced in alcoholic solution with five

---

[27] The first time this experiment was carried out using slightly impure desoxycodeine-B, a reduction product of m. p. 126–128" having $[\alpha]_{\mathrm{D}}$ 0° was obtained which was regarded as a new dihydrodesoxycodeine. In the light of our theoretical conclusions, the existence of a fifth phenolic dihydrodesoxycodeine seemed very improbable, and

times its weight of sodium; 4 3 g. of a base of m. p. 120–126° was obtained, which was purified through the hydrochloride until the melting point of the latter was constant at 158–159°. This hydrochloride showed $[\alpha]^{21}_{\mathrm{D}}$ -39.9": c = 2.003 (water), l = 1, a = -0 80° The base precipitated from an aqueous solution of the salt by ammonia melted at 128–129°, $[\alpha]^{21}_{\mathrm{D}}$ -22.6": c = 2.834 (alcohol), l = 2, a = -1.28". These values approach closely our constants for the purest samples of dihydrodesoxycodeine-A and its hydrochloride. Mixed melting points showed no depression.

Anal. Calcd. for $C_{18}H_{23}O_2N{\cdot}HCl + C_2H_5OH$: C, 65.28; H, 8 22, Cl, 9 64. Found: C, 65.34; H, 8.09; Cl, 9.57.

(4) Dihydrodesoxycodeine-A from electrolytic reduction of desoxycodeine-A (compare § 4, page 2229): 5.5 g. of desoxycodeine-A (m. p. 121–122°, $[\alpha]^{22}_{\mathrm{D}}$ $+115.9$°) in 200 cc. of 20% sulfuric acid was reduced electrolytically for nine hours, using a prepared electrode of 60 sq. cm. and a current of 8 amp. The product, worked up as described in our other electrolytic reductions, was obviously a mixture; conversion to the hydrochloride and three crystallizations from absolute alcohol gave a salt of m. p. 155–157°, $[\alpha]^{19}_{\mathrm{D}}$ $+34.6$°, which yielded a base of m. p. 124–128°, $[\alpha]^{19}_{\mathrm{D}}$ $+41.3$°. By laborious fractional crystallization of the hydrochloride it could be shown that the dextrorotation was due to the presence of a large amount of unchanged desoxycodeine-A (3.3 g., m. p 121–122°, $[\alpha]^{21}_{\mathrm{D}}$ $+110$°). The levorotatory fractions finally yielded a base of m p. 126–129°, $[\alpha]^{22}_{\mathrm{D}}$ -18": c = 1.984 (alcohol), l = 2, a = -0 71°, whose hydrochloride melted at 155–157°, $[\alpha]^{20}_{\mathrm{D}}$ -38.5': c = 1.011 (water), 1 = 2, a = -0.78".

Anal. Calcd. for $C_{18}H_{23}O_2N{\cdot}HCl + C_2H_5OH$: *C*, 65.28; H, 8.22. Found: C, 65.36; H, 8.03.

On the basis of the rotations given above (mixed melting points have no significance) we are convinced that this product is identical with dihydrodesoxycodeine-A, but do not consider the point conclusively proved.

Catalytic Reduction of **Dihydrodesoxycodeine-A.—Three** grams of pure dihydrodesoxycodeine-A (the so-called a-tetrahydrodesoxycodeine), prepared by sodium and alcohol reduction of a-chlorocodide, was dissolved in 30 cc. of methanol and shaken under hydrogen in the presence of 0.10 *g.* of platinum oxide. The absorption proceeded rapidly, and in eighteen minutes 265 cc. of hydrogen was taken up (calculated for one mole of hydrogen, 257 cc.). The reduction proceeded very slowly for one hour longer, with an absorption of 35 cc. more, and then stopped completely. The reduction mixture was filtered, brought to the boiling point, and water added slowly; 2.85 g. of crystalline material separated; after one crystallization from acetone it softened at 135°, melted at 143–146°, and evolved gas at 151°. It did not depress the melting point of (β-)tetrahydrodesoxycodeine. The product was further identified by its rotation, $[\alpha]^{19}_{\mathrm{D}}$ -32.9' (c = 1.564 (alcohol), *1* = 2, *a:* = -1.03°), the melting point of its hydriodide, 243–245°, of its methiodide, 263°, and mixed melting points of these derivatives.

Anal. Calcd. for $C_{18}H_{25}O_2N + {}^1/_2H_2O$: C, 72.92; H, 8.84. Found: C, 72.85; H, 8.81.

The reduction product sublimed with loss of its hydrate water to give the anhydrous tetrahydrodesoxycodeine of sharp m. p. 125–126° which will be further described in our next paper.

Catalytic Reduction of Dihydrodesoxycodeine-A Hydrochloride.—2.7 **g.** of pure hydrochloride (from sodium–alcohol reduction of desoxycodeine-A) in 35 cc. of water with 0.4 g. of palladium on barium sulfate took up 190 cc. of hydrogen in thirty-five

---

investigation showed that the base of $[\alpha]_{\mathrm{D}}$ 0° showed a levorotation on laborious purification. **The** dextrorotatory persistent impurities do not appear when the desoxycodeine-B employed is purified to constant rotation.

minutes and stopped (calculated for one mole of hydrogen, 188 cc.); 2.5 g. of tetrahydrodesoxycodeine was obtained, which was purified as above described, melted at 143–145°, and had $[\alpha]^{21}_{D}$ −31.8" (c = 1.510 (alcohol), l = 1, a = −0.48°). In a similar reduction, 1.0 g. of dihydrodesoxycodeine-A hydrochloride prepared by sodium and alcohol reduction of desoxycodeine-B took up 85 cc. of hydrogen in thirty minutes (calculated for one mole, 80 cc.). The product was tetrahydrodesoxycodeine, m. p. 1.14–145".

Dihydrodesoxycodeine-B (m. p. 128–131°).—Three grams of desoxycodeine-C (non-phenolic, m. p. 105–106°) in 100 cc. of 20% sulfuric acid was reduced electrolytically, using an electrode of 60 sq. cm. area and a current of 8.2 amp. The reduction was carried out at 5 to 10°, and continued until a test portion was completely soluble in an excess of alkali, usually requiring three to four hours. The acid solution was filtered and treated with a slight excess of ammonia, a red oil separated, which soon solidified and could be collected on a filter. It was dissolved in 20 cc. of boiling alcohol, and water added dropwise until crystallization began. The yield was 2.4 g. of dihydrodesoxycodeine-B, melting at 117–120°. It was converted to the hydriodide, this salt recrystallized from water to constant melting point, and the free base liberated from the hydriodide, then crystallized several times from dilute alcohol. It separated in white flakes of m. p. 128–131°, and showed the rotation $[\alpha]^{20}_{D}$ −106.9° (c = 1.038 (96% alcohol), l = 1, α = −1.11°), $[\alpha]^{20}_{D}$ −69.1° (c = 0.680 (10% acetic acid), l = 1, a = −0.47°). Dihydrodesoxycodeine-B is very soluble in most organic media and soluble in alkali.

Anal. **Calcd** for $C_{18}H_{23}O_2N + {}^1/_2H_2O$: **C,** 73.43; **H,** 8.21. Found: **C,** 73.58, H, 8.19.

Reduction of Dihydrodesoxycodeine-B.—1.1 g. of the base was dissolved in 6 cc. of normal hydrochloric acid, the solution made up to 30 cc. with water, and shaken under hydrogen, using 0.3 g. of palladium–barium sulfate catalyst. In thirty-five minutes 103 cc. of hydrogen was absorbed (calcd. for 1 mole, 95 cc.). It yielded 1.0 g. of product melting at 140–145°, which after purification proved to be identical with tetrahydrodesoxycodeine in every respect, and gave a hydriodide of m. p. 245° and a methiodide of m. p. 265°.

Dihydrodesoxycodeine-C (m. p. 111°).—The starting material for the preparation of this base was chlorodihydrocodide. For the reduction of codeine, platinum oxide was found to be an excellent catalyst, 60 g. of codeine with 0.7 g. of platinum oxide took up 4750 cc. of hydrogen in sixty-five minutes, yielding 60 g. of dihydrocodeine, which was converted to chlorodihydrocodide (yields varying from 85 to 50%) by the method of *Freund*[6]

A solution of 10 g of chlorodihydrocodide in 300 cc. of 20% sulfuric acid was reduced electrolytically, using a current of 8 amp. and an electrode of 60 sq. cm. area, temperature maintained between 10 and 20°. For complete reduction, which was indicated by the alkali solubility of a small test portion, about eight hours was required. The acid reduction solution was filtered, brought to neutrality (litmus) with ammonia, and extracted with ether. The aqueous layer was acidified, and ammonia in excess added dropwise while shaking with ether. The combined ether extract was dried and distilled, yielding a reddish oil which was dissolved in hot alcohol and thrown out crystalline by slow addition of water; m. p. crude, 114–117°. The base was crystallized from dilute alcohol to constant m. p., 109–111°, yield 6 g.; 2.5 g. of tar-like residues was obtained: $[\alpha]^{24}_{D}$ −61.6° (c = 1.591 (96% alcohol). 1 = 1, α = −0.98°).

Anal. Calcd. for $C_{18}H_{23}O_2N + {}^1/_2H_2O$: C, 73.43; H, 8.21. Found: C, 73.30; H, 8.17.

Reduction of Dihydrodesoxycodeine-C.—A solution of 1 g. of the base in 30 cc. of methyl alcohol was hydrogenated in the presence of 0.05 g of platinum oxide. In seventeen minutes 80 cc. of hydrogen was absorbed (calcd. for one mole, 85 cc.). The product of the reduction was identified as "β"-tetrahydrodesoxycodeine by its melting point, 142–144°, its hydriodide of m. p. 245°, and its methiodide, m. p. 260°, none of which showed any depression of melting point with the corresponding "0"-tetrahydrodesoxycodeine derivatives. The reduction product showed the rotation $[\alpha]^{19}_{D}$ −33.1. (c = 1.544 (alcohol), l = 1, a = −0.51°).

Dihydrodesoxycodeine-D (m. p. lor^{o}).—Five grams of β-chlorococide in 100 cc. of 0.3 N hydrochloric acid was hydrogenated in the presence of 1.25 g. of palladium–barium sulfate catalyst.[28] The reduction was complete in two hours, with the absorption of 870 to 920 cc. of hydrogen (calcd. for two moles, 800 cc.). The excess absorption of 10 to 15% above the expected amount is accounted for by the formation of small amounts of tetrahydrodesoxycodeine. The reaction mixture was filtered, the mixed bases precipitated by a slight excess of ammonia, and extracted into ether. The residue from distillation of the ether was dissolved in 30 cc. of water containing approximately the amount of tartaric acid necessary for the formation of the acid tartrate, and cooled to 0°. After several hours the acid tartrate of dihydrodesoxycodeine-D separated nearly quantitatively as beautiful white needles, while the very soluble oily tartrate of tetrahydrodesoxycodeine remained in solution. The crystalline acid tartrate was further purified from hot water, and the base liberated from it with ammonia; yield, 3.5 to 4.0 g. It melts at 106–107°, and shows $[\alpha]^{20}_{D}$ −82.5" (c = 0.866 (96% alcohol), 1 = 2, a = −1.43°), (Mannich, $[\alpha]^{18}_{D}$ −81.47°).

Anal. Calcd. for $C_{18}H_{23}O_2N$: C, 75.74; H, 8.12. Found: C, 75.53; H, 8.22.

The method of preparation, melting point, rotatory power and analysis of dihydrodesoxycodeine-D show its identity with the dehydroxydihydrocodeine of Mannich.[18] The method of separation from tetrahydrodesoxycodeine given above is more effective than that described by Mannich. The tetrahydrodesoxycodeine was isolated from the mother liquors of the tartaric acid treatment by addition of excess ammonia, and purification of the crystalline precipitate from acetone; m. p. 143–145°, $[\alpha]^{25}_{D}$ −32.1° (c = 1.712 (alcohol), l = 1, a = −0.55").

Reduction of **Dihydrodesoxycodeine-D.—Two** grams of the base in 100 cc. of methyl alcohol was reduced with 12.5 g. of sodium, 100 cc. more of methyl alcohol being added during the reduction. The dark mixture was diluted with 150 cc. of water, acidified with hydrochloric acid, and a small amount of tarry material filtered out. The reduction product was isolated by precipitation with ammonia and extraction with ether. and after purification from acetone showed the m. p. 142–145' and did not depress the melting point of tetrahydrodesoxycodeine. The hydriodide melted at 243°, the methiodide at 260–263° and gave no depression with the same derivatives of known tetrahydrodesoxycodeine.

Reduction of 2.0 g. of dihydrodesoxycodeine-Din 250 cc. of 20% sulfuric acid with a current of 6 amp. on a 60 sq. cm. electrode for four hours gave a quantitative yield of tetrahydrodesoxycodeine, m. p. 144–145' (mixed m. p. 144–145").

Dihydrodesoxycodeine-D was regained unchanged from attempted hydrogenation with platinum oxide in methyl alcohol or methyl alcohol-acetic acid, or palladium barium sulfate in dilute hydrochloric acid.

Dihydrodesoxycodeine-E (m. p. 139°).—This was prepared by electrolytic reduction of bromocodeinone as described by Speyer[26] and was found to have the properties given by this author; 1.1 g. of the base in 30 cc. of 0.2 N hydrochloric acid with 0.3 g. of palladium barium sulfate took up 100 cc. of hydrogen (1 mol = 95 cc.) in thirty

[a] Precipitated from methanol solution with absolute ether, purified from water, white crystals. The methiodide degrades to a crystalline methine base which will be described in a later paper. [b] Precipitated as white crystals by addition of alcoholic hydrogen chloride to a hot absolute alcohol solution of the base. [c] Subst. dried in vacuum at 100°. [d] Purified from water, long white needles. [e] Cryst. from water, white needles. [f] Base in hot absolute alcohol with alcoholic hydrogen chloride; white crystals from absolute alcohol. [g] Purified from water, white prisms. [h] Excess methyl iodide boiled out of methanol solution, this diluted with an equal volume of water, and methanol distilled off; white needles separated on cooling. [i] **7.0** g. of base in **50** cc. of hot water with **4.0** g. of d-tartaric acid; recrystallized from water; soluble **4.5** g. in **100** cc. of water at 28°. [j] Crystallized from water in long yellow needles. The corresponding hydrochloride could not be obtained crystalline.

Summary

1. An exhaustive investigation of the dihydrodesoxycodeines has resulted in the preparation of certain new dihydrodesoxycodeines, and in a clarification of the confused and incorrect statements in the literature. The compound resulting from reduction of a-chlorocodide or of desoxycodeine-A with sodium and alcohol is shown to be a dihydrodesoxycodeine, and not a tetrahydrodesoxycodeine as heretofore believed. The important supposed isomerism of a-tetrahydrodesoxycodeine and β-tetrahydrodesoxycodeine which has exerted a strong influence on theories of morphine structure does not exist. The significance of this fact for other cases of isomerism believed to be of the same type, is pointed out.

2. The derivation of dihydrodesoxycodeine-A from desoxycodeine-B (formerly thought to be a dihydrodesoxycodeine) is demonstrated.

3. Dihydrodesoxycodeine-B, the electrolytic reduction product from desoxycodeine-C, is described, and its relationship to tetrahydrodesoxycodeine shown.

4. Dihydrodesoxycodeine-C, from electrolytic reduction of chlorodihydrocodide, is correctly described, and its relationship to tetrahydrodesoxycodeine shown.

5. The preparation of dihydrodesoxycodeine-D by catalytic reduction of β-chlorocodide is described, its relationship to the non-phenolic desoxycodeine-C pointed out, and its further reduction to tetrahydrodesoxycodeine accomplished.

6. The existence of dihydrodesoxycodeine-E is verified.

7. There is no evidence in the desoxycodeine series justifying the assumption of stereoisomerism due to spatial relationships on C-14. Until the existence of such an isomerism in the desoxycodeine or other series of morphine derivatives is demonstrated, it is improbable that more than six desoxycodeines can exist (three of which are known), and five dihydrodesoxycodeines, all of which have been described.

CONDENSATIONS BY SODIUM INSTEAD OF BY THE GRIGNARD REACTION. I. TERTIARY CARBINOLS

BY AVERY A. MORTON AND JOSEPH R. STEVENS

RECEIVED FEBRUARY 25, 1931 PUBLISHED JUNE 8, 1931

Sodium and magnesium show many similar properties in organic reactions, for example, in the Wurtz–Fittig synthesis, in the formation of pinacones, and in the condensation of acetylene derivatives. Many investigators[1] have observed the behavior of metal alkyls and aryls which may be likened to that of the Grignard reagent. The literature[2] also indicates that sodium may be used in mixtures of the halide and carbonyl compounds[3]

[3] Schorigin, *Ber.*, 40, 3111 (1907), has definitely stated that the halogen alkyls react with esters or acid chlorides in the presence of sodium in a manner similar to the behavior of the Grignard compounds. His conclusion is based on a limited number of experiments which included bromides only, and the aromatic esters and acid chlorides.

to give the same product as if the condensation had been brought about through the intermediate formation of a metal alkyl or aryl. We have begun, therefore, a systematic study of the use of sodium in such condensations as are commonly brought about step-wise through the Grignard reagent. Our work brings out several points which deserve special consideration. Thus very good results are obtained with chlorobenzene.[4] In fact, in the preparation of triphenylcarbinol from chlorobenzene and ethyl benzoate in the presence of sodium, neariy theoretical yields of crude material were obtained. This is in striking contrast to the great difficulty of causing any reaction between chlorobenzene and magnesium.[5] Again we may use solvents other than anhydrous ether. This fact has been observed before[2a,e,h] but has never been properly emphasized. We have obtained very good yields of triphenylcarbinol in benzene and in gasoline. One other very important point is the simplicity of carrying out the reaction. In contrast to the common practice with magnesium, which includes the initial preparation of the Grignard reagent followed by the addition of the carbonyl compound and the long period of refluxing and stirring necessary to complete the reaction, we obtain the carbinol by putting the organic halide, the carbonyl compound and sodium together in a bottle with ether, benzene, or other suitable solvent and setting aside for a day or such time as is necessary for the sodium to disappear completely.

In this paper we describe the preparation of triphenylcarbinol from phenyl halides with ethyl benzoate, diethyl carbonate, or diethyl oxalate and sodium. We also record a few experiments on the synthesis of some aliphatic and mixed tertiary carbinols, using reagents such as ethyl propionate and diethyl ketone, compounds which might be expected to enolize or polymerize in the presence of sodium. No attempt has been made to obtain maximum yields by this method. The work is intended to show the strength of sodium as a condensing agent, particularly in its action with chlorides. Without doubt a study of optimum conditions for some of these reactions would lead to good preparative methods.

We are continuing our studies in the use of sodium in condensations commonly carried out by the Grignard reaction, stressing those conditions in which its use appears to be of considerable advantage, *viz.*, the use of chlorides and of solvents other than ether. The more powerful action of

---

[4] The observation that chlorides may be used with sodium in these condensations has been made only once before by Rodd and Linch,[2h] who condensed chlorobenzene, chlorotoluene and similar compounds with Michler's ketone to form dyestuffs.

[5] Gilman and St. John, *Rec. trav. chim.*, 49, 717 (1930), and Gilman and Brown, THIS JOURNAL, 52, 3330 (1930), have published methods for improved yields of phenylmagnesium chloride from magnesium and chlorobenzene but the processes involve either very long heating to initiate and complete the reaction or heating in the absence of a solvent to 150–160° for three hours.

the sodium enables one to synthesize tertiary carbinols such as tribiphenylcarbinol, which have hitherto been prepared by a very long procedure, and to obtain organic acids from the reaction of carbon dioxide with chlorides. We have also studied the reaction with nitriles. The details of these and other reactions will be published in succeeding papers.

Experiments

The results in the preparation of triphenylcarbinol are grouped in Table I. The procedure was somewhat similar in all of these cases. The halide, carbonyl compound and sodium were usually put into a bottle or flask with the solvent. The container was then stoppered tightly and the mixture set aside until the sodium had reacted or longer. At the beginning some heat was evolved. It was therefore desirable to set the container in cold water for a time, although this was omitted frequently. When the reaction was completed the contents were decomposed with water (usually a little alcohol was added first to decompose any unchanged sodium) and the mixture steam distilled. Crude triphenylcarbinol was obtained in the residue, which was spread out on paper and left to dry. This crude carbinol

TABLE I

REACTIONS

Halide	Mole	Carbonyl compound	Mole	Sodium, mole	Solvent	Cc.	Time	Crude triphenylcarbinol, %
Chlorobenzene	0 2	Ethyl benzoate	0 1	0.4"	Ether	200	2 Days	73
Chlorobenzene	.2	Ethyl benzoate	.1	$.4^{b}$	Ether	200	2 Days	60

[a] Sodium sand. [b] Single lump of sodium. [c] Sodium wire 1½ mm. O. D. [d] Because of the larger quantity and the heat evolved, the sodium wire was added in four portions at intervals of two days.

---

[6] This experiment was suggested by the fact that Blicke, THIS JOURNAL, 46, 2560 (1924), obtained some triphenylcarbinol from bromobenzene, benzaldehyde and sodium. He also obtained benzyl benzoate from the reaction, which, as seen by our experiment, may have caused the formation of his triphenylcarbinol.

undoubtably contained some solvent and diphenyl. That it was chiefly the carbinol, however, is shown by the fact that in every case except in the product obtained from the reaction in gasoline, a single digestion with a small quantity of alcohol gave a product melting at 160° or better.

In Table II we have grouped the results obtained in the preparation of a few other tertiary carbinols. These experiments were intended to show that sodium could be used with aliphatic compounds in spite of the great tendency of the latter to enolize and condense with themseives. The runs were made with the bromide since at this stage of the work we held to the prevailing prejudice that chlorides were rather unreactive. As in the case of the preparation of triphenylcarbinol, no attempt was made to obtain optimum conditions. The solvent was 200 cc. of anhydrous ether. The reaction flask was set in an ice-bath and the mixture stirred for seven hours, after which the mass was allowed to stand overnight; 0.2 mole of sodium was used in each experiment. The usual method of isolation was to decompose the product with water, dry the ether layer over potassium carbonate and distil the product.

TABLE II

RESULTS IN PREPARATION OF TERTIARY CARBINOLS

Halide, 0.1 mole	Carbinol compound, 0.1 mole	Product	%
Bromobenzene	Diethyl ketone	Phenyldiethylcarbinol[a]	25
Ethyl bromide	Diethyl ketone	Triethyl carbinol[b]	17
Ethyl bromide	Ethyl propionate	Triethylcarbinol[b]	9
Ethyl bromide	Benzaldehyde	Phenylethylcarbinol[c]	14

[a] Boiling point 221–229°. Klages, *Ber.*, 36, 3692 (1903), records 223–224°. Distillation with a trace of hydrochloric acid formed the unsaturated compound, 3-phenylpentene-2, b. p. 104–107°. Klages records 107–108°.

[b] Boiling point 135–142°. Weigert, *Ber.*, 36,1009 (1903), records 142". When distilled with oxalic acid the unsaturated compound (b. p. 95–97°) was formed. Saytzeff, *J. prakt. Chem.*, [2] **57**, 39 (1898), records 97–98" for 3-ethyl pentene-2.

[c] Boiling point 208–214". Phenylethylcarbinol boils at 212° as shown by Schorigin, ***Ber.*, *41*,** 2721 (1908). When distilled from oxalic acid an unsaturated liquid (b. p. 175–177) was obtained. *Sym.*-phenylmethylethylene is reported by Klages, *Ber.*, 36,2574 (1903), as boiling at 177°.

Conclusions

A systematic study of the use of sodium as the condensing agent in reactions hitherto considered typical of magnesium through the Grignard reagent has been started.

Sodium has been found to be better than magnesium in the preparation of triphenylcarbinol in that chlorobenzene can be used, solvents other than ether are permissible and the reaction can be carried out in one step.

The preparation of some aliphatic and mixed tertiary carbinols by means of sodium is described.

PALLADIUM CATALYST. II. THE EFFECT OF HYDROGEN CHLORIDE IN THE HYDROGENATION OF ISONITROSO KETONES

BY WALTER H. HARTUNG

RECEIVED MARCH 9, 1931 PUBLISHED JUNE 8, 1931

It has been shown that benzaldoxime and benzonitrile when reduced catalytically, with palladium on charcoal, form pure primary benzylamine if the proper amount of hydrogen chloride is present, whereas in the absence of the acid a mixture of primary and secondary bases results.[1]

Profiting by this knowledge it has been possible to prepare a series of amino alcohols of considerable physiological interest by reducing isonitroso ketones of the general formula ARCOCR=NOH under similar conditions. The oximino ketone is dissolved in absolute alcohol containing three equivalents of hydrogen chloride and is then agitated with the catalyst in an atmosphere of hydrogen until reduction practically ceases. Under these conditions all isonitroso ketones in which the aromatic portion is a hydrocarbon radical, that is, is phenyl, *m*- and *p*-tolyl, naphthyl, the reduction goes smoothly and completely to the corresponding amino alcohol.[2] In those cases where the aromatic portion of the molecule is substituted by a phenolic hydroxyl or its methyl ether, the reduction stops at the amino ketone stage and the resulting compound may be isolated and purified, as its salt, and then in aqueous solution and with new catalyst reduced to the corresponding amino alcohol. The reduction of the phenolic compounds will be described in a subsequent paper, the reason for mentioning them at this time being to emphasize the fact that in each case pure primary amine is obtained.

A second point is that under the conditions employed the oximino group apparently is a readier receptor for hydrogen than is the ketonic portion. This is shown not only in the case of the phenolic derivatives but also with isonitrosoacetophenone and in isolated cases with isonitrosopropiophenone.

Isonitrosoacetophenone, as already described,[2] is as a rule first hydrogenated to the corresponding intermediate amino ketone stage. With isonitrosopropiophenone the rule is for the reduction to proceed to the corresponding amino alcohol, but in several instances out of many only two-thirds of the calculated hydrogen was taken up and the product when isolated proved to be pure hydrochloride of phenyl-α-aminoethyl ketone, $C_6H_5COCH(CH_3)NH_2{\cdot}HCl$. Hence the evidence would seem quite conclusive that under the conditions here employed, of the two groups capable of being hydrogenated the oximino is the more susceptible.

---

[1] Hartung, THIS JOURNAL, 50, 3370 (1928).

[2] Hartung and Munch, *ibid.*, 51, 2262 (1929); Hartung, Munch, Deckert and Crossley, *ibid.*, 52, 3317 (1930).

In neutral alcoholic solution, that is, in the absence of hydrogen chloride, the product isolated from the reduction of isonitrosoacetophenone was 2,5-diphenylpyrazine. But as already explained[2] this end-product results in the following manner

$$\text{Isonitrosoacetophenone} \longrightarrow \omega\text{-aminoacetophenone} \xrightarrow[\text{condensation}]{\text{spontaneous}}$$

$$\text{diphenyldihydropyrazine} \xrightarrow[\text{O}_2]{\text{atmosphere}} \text{diphenylpyrazine[3]}$$

that is to say, reduction in this case takes place at the oximino group, which is quite what one might expect in view of the foregoing discussion.

The hydrogenation of higher homologs in the absence of acid, however, follows a course that is most strikingly different, one which while theoretically possible was not anticipated because of the results already described.

A product obtained by the reduction of isonitrosopropiophenone, melting at 108–110° has been described as of unknown composition.[2] In a personal communication Dr. D. Holroyde Hey, of the University of Manchester, suggested that this product might be the oxime of phenylacetylcarbinol. Comparison with known phenylacetylcarbinol oxime supplied by him[4] indicated the correctness of this suggestion and preparation of the corresponding semicarbazone lent confirmation. This could mean only one thing, *viz.*, that in this instance the ketonic carboxyl was affected and the oximino group remained unchanged. Further proof of this was found in the fact that products similarly obtained from isonitrosobutyrophenone and isonitrosohexanophenone, hitherto also unidentified, turned out to be the oximes of phenylpropionylcarbinol and phenylvalerylcarbinol, respectively.

In neutral absolute alcoholic solution hydrogen absorption does not, as a rule, cease when one molar equivalent has been taken up, nor does it continue until three molar equivalents, the amount necessary for complete reduction to the amino alcohol, have been used. However, when reduction is stopped, of itself or deliberately, after somewhat more than one equivalent of hydrogen has been taken up, the yield of carbinol ketoxime is a maximum, approaching theory, although other products are also formed. On the other hand, if hydrogenation proceeds to any great extent beyond this point, the amount of carbinol ketoxime becomes proportionately less and the quantity of other products becomes correspondingly greater. These other products have been identified as an ammonia (odor) and a mixture of primary, secondary and tertiary amines, separated according to Hinsberg's classical method with benzenesulfonyl chloride.

Such results indicate that under these conditions the first product is that in which the ketonic carbonyl is reduced to the carbinol, and then if further

---

[3] Compare also references 16, 17, 18 and 19 cited in Ref. 2.

[4] Hey, J *Chem. Soc.*, 232 (1930).

reduction does occur, the oximino group is affected, and it, in the absence of hydrogen chloride, behaves quite as one might expect from the results of previous experimenters with oximes,[5] that is, it forms primary contaminated with secondary and tertiary amines.[6]

Another striking difference between reduction in neutral medium as compared to that in a solution containing hydrogen chloride is in the rate of hydrogen absorption. This is shown in Fig. 1, by the two representative curves. The conditions were identical except that in one three equivalents of hydrogen chloride were used, and in this one practically three times as much hydrogen was taken up in about one-third the time as in the other.

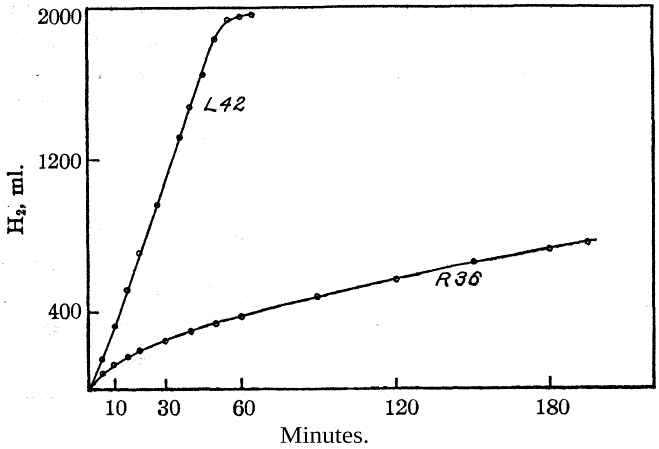

Fig. 1.—Curves showing difference in rates and extent of hydrogenation in absence and presence of hydrogen chloride. In each instance 4.9 g. of isonitrosopropiophenone (0.03 mole) in 100 ml. of absolute alcohol was used. R36 represents reduction in neutral medium and L42, in presence of 0.09 mole of hydrochloric acid.

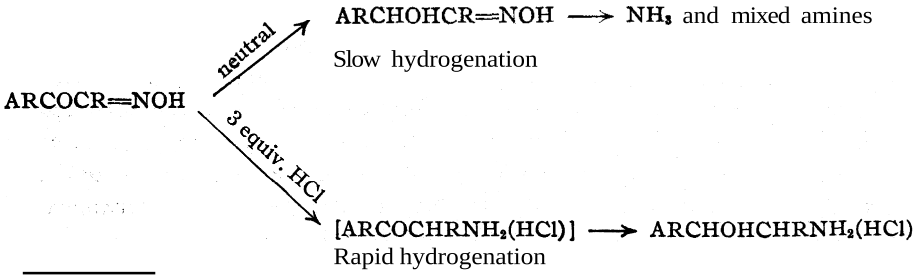
In substance, then, the reduction of isonitroso ketones in absolute alcoholic solution may follow one of two courses



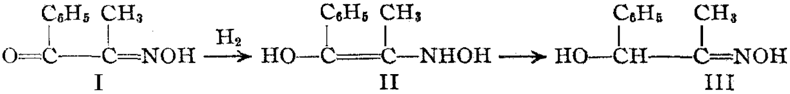
---

[5] See references 1, 2, 3, 4 and 5 in Ref. 1.

[6] It is of interest to note, in this connection, that Adkins and Cramer [THIS JOURNAL, 52, 4349 (1930)], with their nickel catalyst in neutral solvent, obtained pure primary amines from o-tolunitrile and isonitrosopropiophenone.

and the influence of the hydrogen chloride becomes apparent in three distinct ways. First, it is responsible for the hydrogenation of the oximino portion; second, it has a marked effect on the rate of hydrogenation; and, third, it prevents formation of contaminating secondary and tertiary bases.

In discussing the formation of the oxime of phenylacetylcarbinol, Hey[4] suggests that this need not "necessarily signify that the oximino group is less susceptible to the action of the reducing agent," for he postulates 1,4-addition with a subsequent rearrangement of the intermediate hydroxylamino-alkenol (II) to the carbinol oxime (III)



$$O{=}\overset{C_6H_5}{\overset{|}{C}}{-}\overset{CH_3}{\overset{|}{C}}{=}NOH \xrightarrow{H_2} HO{-}\overset{C_6H_5}{\overset{|}{C}}{=}\overset{CH_3}{\overset{|}{C}}{-}NHOH \longrightarrow HO{-}\overset{C_6H_5}{\overset{|}{CH}}{-}\overset{CH_3}{\overset{|}{C}}{=}NOH$$

Such an hypothesis is inadequate in that it does not show how the first intermediate (II) rearranges to form, in the presence of hydrogen chloride and after addition of another mole of hydrogen, the amino ketone ($ArCOCHRNH_2{\cdot}HCl$); and it fails to take into account the difference in rates of hydrogen absorption in neutral and acid media.

An explanation, not inconsistent with experimental results, might be given as follows. The oximino ketone and the hydrogen chloride form *a* complex or compound in which the electronic structure is so shifted as to make the oximino portion very susceptible to the entry of hydrogen. In the case where the aryl is a hydrocarbon, the susceptibility of the ketonic carbonyl may be unaffected or possibly also increased. If the aryl contains a phenolic hydroxyl or a methoxy group, this group may modify the degree but not the nature of this shift induced by the acid, so that the susceptibility of the carbonyl to reduction is reduced. Such an explanation is conceivable and does not complicate the picture.

Experimental

The apparatus and procedure for reduction have been described in the preceding papers. The only modification that need be mentioned is that the reaction flask was wrapped in a towel so that hydrogenation proceeded in the dark. Evidence, not yet conclusive, indicates that light may have an inhibiting effect; hence, in order to maintain external conditions as reproducible as possible the reduction was carried out in the wrapped flask.

Oxime of Phenylpropionylcarbinol, $C_6H_5CHOHC({=}NOH)C_2H_5$.—Isonitrosobutyrophenone, 8.9 g., in 100 ml. of absolute alcohol, took up 950 ml. of hydrogen during 445 minutes. The catalyst was filtered off and the solvent evaporated under reduced pressure over sulfuric acid, leaving a yellow crystalline residue. After crystallization first from benzene and then from benzene–petroleum ether (60:40), the gray crystals began to sinter at 92° and melted at 97°.[7]

Oxime of Phenylvalerylcarbinol, $C_6H_5CHOHC(=NOH)C_4H_9$ -Products obtained four years ago by the hydrogenation of isonitrosohexanophenone in neutral absolute alcoholic solution were recrystallized from toluene and melted at 97° (corr.).[8]

Oxime of **Phenylacetylcarbinol,** $C_6H_5CHOHC(=NOH)CH_3$ ----Only two representative experiments will be given.

Experiment R *36* (see Fig. 1). Three-hundredths mole (4.9 g.) of **isonitrosopropiophenone** in 100 ml. of absolute alcohol absorbed 760 ml. of hydrogen (0.0338 mole) during the course of 195 minutes. The catalyst was filtered off and the solvent evaporated. The larger portion of the residue, after recrystallization from toluene, was identified as the oxime of phenylacetylcarbinol, m. p. 113° (corr.). The toluene mother liquors were extracted with dilute hydrochloric acid; the acid extract on benzoylation formed a small amount of crystals which were very soluble in toluene, but could be forced from it by means of excess petroleum ether. These crystals formed an opaque melt at 164° (corr.) and are suspected of being a derivative of secondary amine. The benzoyl derivative of phenylpropanolamine melts at 143.5° (corr.).[9]

Experiment R 53. A twentieth mole (8.2 g.) of isonitrosapropiophenone in 100 cc. of absolute alcohol behaved as follows.

Hydrogen, ml.	Time, min.	Rate/min.	Hydrogen. ml.	Time, min.	Rate/min.
190	10	19	Fortified catalyst by adding 0.1 g. of $PdCl_2$		
410	30	10	1520	300	4
610	60	6	1900	450	3
870	120	4	Added 0.1 g. of $PdCl_2$		
1170	210	3	2010	480	3.7
			2060 (0.0915 mole)	510	1.7

The catalyst was filtered off. The filtrate had in it the odor of ammonia. The solvent was evaporated and the residue was taken up in hot toluene. On cooling, crystals settled out (4.1 g.), which were identified as phenylacetylcarbinol oxime. The toluene mother liquors were extracted with dilute hydrochloric acid to extract the bases. These were treated with benzenesulfonyl chloride in order to separate them by the well-known method of Hinsberg.[10] The derivative of the primary amine (1 g. isolated) after crystallization from toluene melted at 127° (corr.), agreeing with the corresponding derivative prepared from known phenylpropanolamine. The derivative which should be from the secondary amine was a brown, amorphous solid. By filtering it in hot dilute alcoholic solution through charcoal, it was possible to obtain a yellow-brown product of indefinite crystalline form that melted at 110° (uncorr.). The composition of this substance is unknown. Analysis showed it to contain 4 42% nitrogen, whereas $(C_6H_5CHOHCH—CH_3)_2NSO_2C_6H_5$ should contain but 3.3% nitrogen.

The tertiary amine was isolated by extracting it from ethereal solution with dilute hydrochloric acid and evaporating this in *vacuo* over sulfuric acid and finally over phosphorus pentoxide. The residue began to sinter at 82° and melted at 88° (corr.). Its identity is also unknown. It contained 4.63% nitrogen, while the calculated nitrogen content for $(C_6H_5CHOHCH—CH_3)_3N \cdot HCl$ is 3.07%.

Hydrolysis of the oxime of phenylacetylcarbinol by warming with dilute acid gave good yields of the corresponding ketone alcohol.

Phenyl-α-aminoethyl ketone hydrochloride was obtained in one instance in very

---

[8] Tiffeneau and Lkvy give the melting point 95–96'.

[9] Schmidt, ***Arch. Pharm.***, 255, 147 **(1917),** describes $C_6H_5CHOHCH(CH_3)NHCOC_6H_5$ as melting at 142°.

[10] Hinsberg, ***Ber.***, 23, 2962 (1890); 33,3526 (1900).

pure form. A catalyst, double the regular size, was being used for the third time to reduce 65.2 g. of isonitrosopropiophenone; initial hydrogen absorption was 90 ml./min; at the end of 220 minutes the rate was still 30 ml./min., but since 18,400 ml. of hydrogen had been taken up, that is, a slight excess over that calculated to give amino ketone, the reduction was purposely stopped at this point. The resulting product was purified by forcing it out of absolute alcoholic solution with ether and formed the characteristic red decomposing melt at 183.5° (corr.).[11]

Summary

The effect of the presence of hydrogen chloride during the hydrogenation of a-oximino ketones, by means of palladium catalyst, has been described. The effect is manifested in three distinct ways. (1) It promotes the reduction of the oximino group. (2) It increases many fold the rate of hydrogenation. **(3)** It prevents the formation of contaminating secondary and tertiary bases.

DERIVATIVES OF OPTICALLY ACTIVE TRIARYLCARBINOLS AND THEIR HALOCHROMIC SALTS[1]

BY EVERETT S. WALLIS

RECEIVED MARCH 12, 1931 PUBLISHED JUNE 8, 1931

Shortly after Gomberg's discovery of triphenylmethyl, Norris and Sanders[2] made the interesting observation that colorless triphenylchloromethane forms a dark brown crystalline salt with aluminum chloride of the formula $(C_6H_5)_3CCl\cdot AlCl_3$. Kehrman and Wentzel[3] soon showed that this was a general property of triphenylchloromethane and they prepared double compounds with other metallic salts. Since then many investigators[4] have studied these halochromic salts, and today we have **a** large number of colored double compounds of triarylmethyl halides with metallic salts, acids and halogens.

The question as to the constitution of these compounds and related substances such as the triarylmethyls and triphenylmethane dyes has long been debated. The problem has been approached both from the experimental and theoretical sides in the hope that a simple explanation for the color **and** salt-like nature of these compounds could be found. Following the observation that colorless triphenylchloromethane dis-

solved in concentrated sulfuric acid, and in liquid sulfur dioxide to give intense yellow solutions, Kehrmann[6] assumed a quinonoid constitution, , for the explanation of color. In concentrated sulfuric acid and in liquid sulfur dioxide a tautomerism of the molecule occurred, and in the halochromic double salts of the triarylmethyl compounds with metallic halides the presence of color was also due to this quinonoid modification. This theory was subsequently used to explain the formation of color in the sulfates, nitrates and perchlorates of the triarylcarbinols, and has received much attention and support especially from the work of Gomberg, Cone and Anderson.[6]

However, there are experiments[7] recorded in the literature which are difficult to explain on the basis of this theory of constitution. These results have led to a different interpretation for the formation of color in these compounds. On the basis of this "carbonium ion theory" it is assumed that triarylmethyl compounds can exist in two forms—a colorless modification in which the negative group, X, is directly bound to the central carbon atom, and a colored modification of a true salt-like character (carbonium salt). The colorless solutions of the triarylmethyl halides are of the former type. The colored solutions of these compounds as well as the colored sulfates, nitrates, perchlorates, and double salts are of the latter type. According to Hantzsch[8] and Dilthey[9] this colored form can be best represented by the formula,  $\left[\begin{matrix}R\\R\end{matrix}\!\!>C-R\right]X$, where X may be Cl, ClO_4, OSO_3H, $SnCl_5$, etc.

In the light of these two different interpretations, therefore, it seemed that it would be of interest if further investigations were made on this problem along somewhat different lines. If a triarylmethyl compound could be prepared in which the four groups around the central carbon atom were all different, the molecule would then contain an asymmetric carbon atom and it should be possible to resolve it into its enantiomorphic forms. Such a compound would still have the property of forming halochromic double salts with metallic halides, and the behavior of such salts toward polarized light could be easily studied. If the above quinonoid theory be correct for the explanation of color in halochromic salts, we would expect

such salts on hydrolysis to the colorless benzenoid form to give optically inactive products due to the fact that in the halochromic state the asymmetry of the central carbon atom has been destroyed. In the investigations which I now wish to report this was found under certain conditions not to be the case.

Phenylbiphenyl-a-naphthylcarbinol was prepared according to the method of Schlenk.[10] Several attempts were made to resolve the carbinol itself by combining it directly with brucine, quinine, camphorsulfonic acid, etc., but only negative results were obtained. Experiments were carried out in an attempt to make the carbinol in the form of its chloride combine with silver salts of optically active acids, but this method of approach proved unsatisfactory. Phenylbiphenyl-a-naphthylchloromethane, however, was found to combine with thioglycolic acid giving a stable derivative which was easily resolved.[11] *l*-Phenylbiphenyl-α-naphthylmethylthioglycolic acid, $(C_6H_5C_6H_4)(C_{10}H_7)(C_6H_5)C{-}SCH_2COOH$, has the following specific rotation in carbon tetrachloride: $[\alpha]^{20}_{D}$ −13.63°; in ether, $[\alpha]^{25}_{D}$ —12.93'. Experiments with this substance show that it forms halochromic salts. Concentrated sulfuric acid, perchloric acid and mercuric chloride unite with it forming deep blue-violet halochromic compounds which on pouring into ice water yield the carbinol, $(C_6H_5C_6H_4)(C_{10}H_7)(C_6H_5)COH$, in its optically inactive form. A solution of titanium tetrachloride in chloroform when added to a chloroform solution of *l*-phenylbiphenyl-a-naphthylmethylthioglycolic acid produces a deep blue-violet halochromic salt which on decomposition with ice water yields inactive phenylbiphenyl-α-naphthylmethylthioglycolic acid. However, when a solution of ferric chloride in glacial acetic acid is added to a chloroform solution of the levo thioglycolic acid derivative, the deep blue-violet halochromic compound so formed, on pouring into ice water, produces the original Lphenylbiphenyl-a-naphthylmethylthioglycolic acid with no racemization. This is also true in the case of the zinc chloride halochromic salt. If an ether solution of zinc chloride be added to an ether solution of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid, the deep blue-violet compound so produced is optically active and on hydrolysis produces the original I-thioglycolic acid compound with no change in rotation.

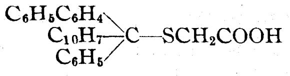
If we accept the statement that the formation of color in the double salt of triarylmethyl compounds with metallic halides is caused by a tautomerism of the molecule into a quinonoid modification, the two forms of phenylbiphenyl-a-naphthylmethylthioglycolic acid would be represented by the formulas[12]

---

[10] Schlenk, *Ann.*, 394,196 (1912).

[11] Wallis, *Proc. Nat. Acad. Sci.*, *16, 215* (1930).

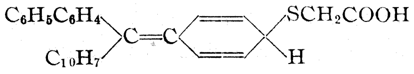
[12] Other possible quinonoid formulas can be written, but it makes no difference which group undergoes quinonoidation so far as the present discussion is concerned.



$(C_6H_5C_6H_4)(C_{10}H_7)(C_6H_5)C{-}SCH_2COOH$

I

Colorless benzenoid



II

Colored quinonoid

On hydrolysis of the colored double salts, which according to this theory are represented by form II, compounds of type I are produced. According to theories of stereochemistry the asymmetric carbon atom in I has lost its asymmetry in form II. However, a construction of a model of the molecule of form II shows that it possesses an asymmetry of a different type known as "centroasymmetry" or molecular asymmetry, although it contains no asymmetric carbon atom. Therefore, theoretically, it could exist in two optically active modifications, but these two modifications would in all probability be produced in the rearrangement of the colorless benzenoid form, and, therefore, a racemic product would result. The question as to what will occur when an optically active substance of which the enantiomorphism of molecular configuration is associated with one particular type of asymmetry is converted into a second substance of which the optical activity arises from the exhibition by the molecule of enantiomorphism of a quite different type is not new. Perkin and Pope[13] have shown that an optically active compound whose activity is due to molecular asymmetry undergoes racemization during its conversion into the isomeride which contains only an asymmetric carbon atom. *l*-1-Methyl-cyclohexylidene-4-acetic acid,  was found by them to rearrange to dl-1-methyl-Δ^3-cyclohexene-4-acetic acid, . During the rearrangement complete racemization took place, even though the rearrangement product contains a true asymmetric carbon atom. In the light of such experiments, if the quinonoid theory for the explanation of color be correct, we would expect that a compound of Formula I on conversion into its halochromic salt and subsequent hydrolysis would be racemized, and would yield an optically inactive product.[14] That this is not the case is readily seen from the experimental results on the halochromic compounds of ferric chloride and zinc chloride.[15] In these instances not even partial racemiza-

---

[13] Perkin and Pope, *Trans Chem. Soc.*, 99, 1515 (1911)

[14] Similar reasoning has been used by Phillips (*ibid* ,127, 2563 (1925)). to explain the fact that certain optically active sulphinates racemize rapidly.

[15] The fact that the double salt with titanium tetrachloride behaves differently than the double salts with ferric chloride and zinc chloride is perhaps to be expected. Titanium tetrachloride is a compound which is itself unstable in aqueous solution and is hydrolyzed with liberation of much energy and a large concentration of hydrochloric acid. Hydrolysis of the double salt of such a compound could easily be imagined to produce racemization. That this interpretation may be correct is strengthened by the

tion takes place. It therefore appears that whatever may be the cause of color in these halochromic compounds *we must not assign a structure or configuration which in any manner disturbs fundamentally the arrangement of groups around the central carbon atom.*

The alternative theory of color formation usually called the carbonium ion theory at first sight might not appear to be invalidated by these results. There is some evidence from optically active sulfonium compounds[16] that at least with a sulfur atom a positive ion maintains an asymmetric configuration. It is plausible that in both the optically active methylethylthetines and in the optically active sulfinates, the tercovalent sulfur atoms are associated with free electric charges. From this it might be imagined that a carbonium ion could maintain a structure approaching that of an asymmetric molecule. Experimental evidence[17] has been found* which seems to support this view. However, if this be true we would expect that the halochromic compounds produced by the action of sulfuric acid, perchloric acid and mercuric chloride on *l*-phenylbiphenyl-α-naphthylthioglycolic acid would produce on hydrolysis the optically active modification of the carbinol. But in these three cases the racemic compound is formed. It must be noted that the sulfonium ion if present in the thetines and sulfinates possesses a complete octet of valency electrons whereas in the carbonium ion only a sextet of valency electrons is present. Therefore the carbonium ion may possess a far less rigid structure than the sulfur atom in the thetine ion. In fact, recent evidence of Kenyon and Phillips[18] leads to the view that tercovalent carbonium ions are optically unstable.

Another argument which could be put forward against this view that a carbonium ion is always produced in the colored salts of the triarylcarbinols is the fact that the halochrornic compounds with zinc chloride and ferric chloride on hydrolysis do not produce the carbinol, but the original *l*-thioglycolic acid derivative. We should expect the carbinol to be formed if a carbonium ion were produced in the production of the halochromic salt, for hydrolysis of a compound containing the carbonium ion generally produces the corresponding carbinol.

It therefore would appear from these results on halochromic salts of an optically active derivative of a triarylcarbinol that the most likely representation for their structure is that one mentioned previously in this paper,  $\left[\begin{matrix}R\\R\end{matrix}\!\!>\!C-R\right]X$ in which the central carbon atom is coordinately un-

---

fact that an acetic acid solution of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid containing hydrogen chloride racemizes.

saturated. In such a compound the molecule is heteropolar as compared with the colorless homopolar modification. The C—X bond may or may not be a true ionic linkage depending on whether the particular inorganic acid or salt used causes a complete transference of an electron to the octet of the group X, or only a partial distortion from the normal position.

Experimental Results

Preparation of *l*-Phenylbiphenyl-α-naphthylmethylthioglycolic Acid, $(C_6H_5C_6H_4)(C_{10}H_7)(C_6H_5)C—SCH_2COOH$.—*l*-Phenylbiphenyl-a-naphthylmethylthioglycolic acid was prepared according to the method of Wallis.[19] Seventeen grams of the pure levo compound was obtained from 39 g. of the brucine salt; 1.0242 g. dissolved in 25 cc. of dry ether solution gave a rotation of —1.06 at 25° in a 2-dm. tube, $[\alpha]_D^{25}$ —12.93'; 1.0020 g. dissolved in 25 cc. of carbon tetrachloride solution gave a rotation of —1.09 at 20° in a 2-dm. tube, $[\alpha]_D^{20}$ —13.63°; 0.4215 g. dissolved in 25 cc. of glacial acetic acid solution gave the following rotations at 20° in a 2-dm. tube: α_{6563} —0.23, α_{5893} —0.29, α_{5463} —0.36, α_{4861} —0.50, α_{4358} —0.70; $[\alpha]_{6563}^{20}$ —6.82, $[\alpha]_{5893}^{20}$ —8.60, $[\alpha]_{5463}^{20}$ —10.68, $[\alpha]_{4861}^{20}$ —14.83, $[\alpha]_{4358}^{20}$ —20.76°.

An ether solution of this substance on standing at room temperature for two weeks showed no change in rotation. However, a solution of this material in glacial acetic acid on standing slowly decreased in rotatory power.

The residues from the fractional crystallizations were worked up and gave 20 g. of a mixed dextro phenylbiphenyl-a-naphthylmethylthioglycolic acid,[20] $[\alpha]_D^{20}$ +10.13° in ether.

Action of Concentrated Sulfuric Acid.—Two grams of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid was dissolved in 5 cc. of concentrated sulfuric acid previously cooled to —20°. A deep violet color developed. As soon as solution was complete the contents of the flask were poured into ice water. The deep violet color of the halochromic sulfate disappeared immediately and a white precipitate was formed. This was filtered off and dried; 1.7 g. of crude product was obtained. One-half gram of this material dissolved in 25 cc. of benzene solution gave no observable rotation in a 2-dm. tube. Recrystallization of a second portion from benzine gave a compound which melted at 161–162°. A mixed melting point determination of this substance with *dl*-phenylbiphenyl-a-naphthylcarbinol showed no change in melting point.

Action of Perchloric Acid.—Two grams of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid was dissolved in 30 cc. of glacial acetic acid and cooled to the freezing point of the mixture; 10 cc. of a 60% aqueous solution of perchloric acid previously cooled to 0° was then added, and the deep violet halochromic compound was poured immediately into ice water. It melted at 138–145°; 0.5 g. of this crude product in 25 cc. of benzene solution gave no observable rotation in a 2-dm. tube. Recrystallization of the material from benzine (60–80°) gave a compound which melted at 160–161°. A mixed melting point determination with the dl-carbinol showed no change in melting point.

Action of Mercuric Chloride.—A solution of 1.0 g. of mercuric chloride dissolved in 30 cc. of dry ether was cooled to 0° and added to a solution of 1.0 g. of *l*-phenylbiphenyl-or-naphthylmethylthioglycolic acid in 10 cc. of ether. The deep violet mixture was poured immediately into ice water. The ether layer was separated, washed and dried with anhydrous sodium sulfate. A portion of this solution in a 2-dm. tube gave

---

[19] Wallis, *Proc. Nat. Acad. Sci.*, 16, 215 (1930).

[20] The dextro modification was not obtained in a pure form. Fractional crystallization of the brucine salt gives only the pure 1-isomer.

no observable rotation. On partial evaporation a compound was deposited which contained ether of crystallization. It melted at 113° and contained no sulfur. The ether was removed by warming and the product crystallized from benzine (60–80°). The product so obtained melted at 160°. A mixed melting point determination of this substance with dl-phenylbiphenyl α-naphthylcarbinol[21] showed no change in melting point.

Action of Titanium Tetrachloride.—0.45 g. of titanium tetrachloride in 10 cc. of pure chloroform was cooled to 0° and added to a solution of 1.0 g. of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid dissolved in 15 cc. of chloroform. The deep violet solution was poured into ice water. The colorless chloroform layer was separated, washed three times with water and dried over anhydrous sodium sulfate. A portion of this solution in a 2-dm. tube gave no observable rotation. The chloroform was evaporated and the product crystallized from toluene. A white crystalline compound was obtained which melted at 114". This compound contained sulfur, and was identical in its properties with dl-phenylbiphenyl-a-naphthylmethylthioglycolic acid. Similar experiments at −70° gave the same results. The product formed was inactive.

Action of Ferric Chloride.—A qualitative study of the ferric chloride and zinc chloride double salts of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid showed that these compounds on hydrolysis gave solutions which were optically active. Therefore, quantitative experiments were carried out in order to determine whether partial racemization took place during the formation and hydrolysis of the double salts. The following experiments will serve as typical examples: 0.50 g. of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid was dissolved in dry ether The volume of the solution was made up accurately to 25 cc. A portion of this solution in a 2-dm. tube gave a, at 20° −0.59°. The two solutions were then carefully poured into a 50-cc. Erlenmeyer flask and cooled to 0°. All receptacles were washed with ether to insure no loss of the thioglycolic acid derivative. One gram of ferric chloride previously dissolved in 10 cc. of glacial acetic acid was added. A deep violet halochromic compound formed immediately. The mixture was then poured into ice water. The color disappeared at once. The ether layer was removed, washed with distilled water and dried with anhydrous sodium sulfate. The aqueous layer was extracted three times with ether. This extract was washed twice with distilled water and dried. The ether solutions were united and concentrated by evaporation to 20 cc. The solution was then made up accurately to a volume of 25 cc. and the rotatory power determined, $\alpha_{\rm D}^{20}$ −0.56. The solution was evaporated and the material which separated out was crystallized from benzine. The compound was found to contain sulfur. It melted at 107–108". A mixed melting point with *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid showed no appreciable change in melting point. Other experiments were carried out varying the concentrations of the reactants and the solvents, but in no case was appreciable racemization observed.

Action of Zinc Chloride.—0.61 g. of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid was dissolved in ether and the solution accurately made up to a volume of 25 cc.; $\alpha_{\rm D}^{20}$ in a 2-dm. tube was −0.73. The solution was cooled to 0° and to it was added an ether solution of 0.50 g. of zinc chloride previously cooled to 0°. The deep violet solution was poured into ice water and the colorless ether layer removed. This was washed twice with distilled water and dried. The aqueous layer was extracted with ether and the ether solution was washed and dried with anhydrous sodium sulfate. The two solutions were united and concentrated to 20 cc. The volume was then made up to 25 cc. and the rotatory power determined, $\alpha_{\rm D}^{20}$ in a 2-dm. tube, −0.70". The solution was evaporated and treated as described in the experiments on the ferric chloride

---

[21] Phenylbiphenyl-a-naphthylcarbinol crystallizes from ether with ether of crystallization. This compound melts at 115–116°.

double salt. A mixed melting point determination with *l*-phenylbiphenyl-α-naphthylmethylthioglycolicacid showed no change in melting point.

Other experiments were carried out varying the amount of zinc chloride, but in no case was racemization observed.

Conclusions

Certain derivatives of triarylcarbinols containing an asymmetric carbon atom have been prepared. Phenylbiphenyl-a-naphthylmethylthioglycolic acid has been resolved into a pure levo form, $[\alpha]^{20}_{\mathrm{D}}$ $-13.63°$, and a mixed dextro isomer $[\alpha]^{20}_{\mathrm{D}}$ $+10.13°$. Experiments with this substance show that it forms halochromic compounds. Concentrated sulfuric acid, perchloric acid and mercuric chloride unite with it to form deep violet halochromic compounds which on pouring into ice water yield the carbinol in its optically inactive form. Titanium tetrachloride produces a deep violet halochromic salt which on decomposition with water yields the racemic phenylbiphenyl-a-naphthylmethylthioglycolic acid. However, the double salts with ferric chloride and zinc chloride on hydrolysis give *l*-phenylbiphenyl-a-naphthylmethylthioglycolic acid with no racemization.

A discussion of these facts is given with special reference to the quinonoid theory and carbonium ion theory of formulation for the explanation of color.

SOME CHLORINE DERIVATIVES OF BENZYLPHENOLS. I. DICHLORO DERIVATIVES OF ORTHO AND PARA BENZYLPHENOLS

BY R. C. HUSTON AND E. F. ELDRIDGE

RECEIVED MARCH 18, 1931 PUBLISHED JUNE 8, 1931

This paper is the first of a series dealing with the chlorination and the chlorine derivatives of the benzylated phenols. Only a comparatively few of these compounds have been reported.

A chlorobenzyl phenol[1] was made by treating benzylphenol with sulfuryl chloride. The investigator reported that the chlorine probably entered the ring in the ortho position, giving the formula $C_6H_5CH_2C_6H_3ClOH$, but gave no proof of structure. Beilstein reports its formula as C_6H_5-$CHClC_6H_4OH$ with the chlorine on the CH_2 group. Richter's Lexicon shows the substitution in the meta position.

Sentinis prepared a benzyl chlorophenyl ether[2] by passing chlorine into an alcoholic solution of the ether to which some mercuric oxide had been added as a catalyst. This was later shown by Baw[3] to be benzyl *p*-chlorophenyl ether.

---

[1] Peratoner and Vitaei, *Gazz. chim. ital.*, *28*, 197 (1898).

[2] Sentinis, *Ann.*, 161, 345 (1872).

[3] Baw, *Quart. J. Indian Chem. Soc.*, 3, 101 (1926).

Benzyl 2,4 dichlorophenyl ether[4] and benzyl 2,4,6-trichlorophenyl ether were prepared by treating the respective chlorophenol in alcohol with benzyl chloride and sodium ethoxide. The bromine derivatives were prepared in the same manner.

Benzyl pentachlorophenyl ether,[5] $C_6H_5CH_2OC_6Cl_5$, was made by warming the silver salt of pentachlorophenol with benzyl iodide.

Baw[3] prepared benzyl 2-chlorophenyl and benzyl 2,4-dichlorophenyl ethers by treating the appropriate phenols with benzyl chloride and aniline.

The work on which we wish to report here was limited to those derivatives containing two chlorine atoms. The dichloro compounds of both the ortho and para benzylphenol were prepared.

The latter, 3,5-dichloro-4-hydroxydiphenylmethane, was first made by the aluminum chloride condensation of benzyl alcohol and 2,6-dichlorophenol. The structure of this compound was proved by preparing the same compound by direct chlorination of *p*-benzylphenol in chloroform using the quantitative amounts of chlorine. Needle shaped crystals were obtained. The aluminum chloride condensation, in this case, proved to be of considerable interest as we were able to isolate from the oil obtained from the condensation 2,6-dichlorophenyl benzyl ether. This is the first time that an ether has been isolated from an aluminum chloride condensation and opens a considerable field for speculation as to the mechanism of the reaction. In order to identify this ether it was later prepared by treating 2,6-dichlorophenol and benzyl chloride with metallic sodium in methyl alcohol. The boiling point at 15 mm. was 194–195°, very near that of the phenol.

The preparation of 3,5-dichloro-2-hydroxydiphenylmethane was effected in two ways: first, by the Claisen reaction in which 2,4-dichlorophenol and benzyl chloride were treated with sodium in toluene and, second, by direct chlorination of o-benzylphenol in chloroform with the calculated amount of chlorine. The same compound was obtained in each case.

The ether, 2,4-dichlorophenyl benzyl ether,[3,4] was isolated from the Claisen reaction mixture by extraction with petroleum ether. This same compound was later prepared by the action of sodium on 2,4-dichlorophenol and benzyl chloride in methyl alcohol.

An attempt to substitute more than two chlorines into the ortho and para benzylphenols proved unsuccessful. Both benzyl phenols were treated with three molecular equivalents of chlorine and then with a large excess, but no compounds containing more than two atoms of chlorine were obtained. Apparently chlorine does not easily substitute in the benzyl group.

The benzoic, benzene sulfonic and toluene sulfonic esters of each of the

---

[5] Biltz and Giese, *Ber.*, 37, 4020 (1904).

dichlorobenzyl phenols were prepared. These all proved to be crystalline substances and served to further characterize the phenols.

Experimental

Benzyl Alcohol, 2,6-Dichlorophenol and Aluminum Chloride.—Fifty grams of benzyl alcohol and 225 g. of 2,6-dichlorophenol were suspended in 250 cc. of petroleum ether. The suspension was mechanically stirred while 30 g. of aluminum chloride was added at intervals over one hour. The phenol is only slightly soluble in the ether. Stirring was continued for thirty minutes after the aluminum chloride had been added and the mixture allowed to stand overnight. At no time during the reaction did the temperature exceed 32°. The suspension was decomposed with ice and hydrochloric acid and the petroleum ether withdrawn. The water mixture was extracted with ethyl ether. (Drying with potassium carbonate was attempted in the first condensation, but later omitted as distillation of the dried mixture gave a large amount of charred material.) The solvents were distilled, the residues combined and then fractionated.

The first fractions consisted of unchanged benzyl alcohol and 2.6-dichlorophenol. Twenty-three grams of a yellow oil was obtained between 195 and 205" at 15 mm. The material from six similar condensations was combined and purified by further distillation. The boiling point at 15 mm. after three distillations was 194–196".

A determination of the chlorine content of the oil by the Parr bomb method showed a percentage of chlorine in two samples of 27.7 and 28.1. Since the theoretical amount of chlorine in 3,5-dichloro-4-hydroxydiphenylmethane is 28%, it was at first thought that the oil was that compound. Subsequent results showed that this was not entirely true.

The benzoyl derivative prepared by the pyridine method melted at 98.5–99°.

Chlorination of *p*-Benzylphenol.—Ten grams of *p*-benzylphenol suspended in chloroform was treated with two equivalents of chlorine.[6] The solvent was distilled and a yellow oil obtained which was fractionated. All but a small amount came over between 190 and 205° at 15 mm. This solidified on standing and was recrystallized from petroleum ether; m. p. 58–58.5°.

Anal. Subs., 0.1840, 0.1889: cc. of 0.1 N $AgNO_3$, 14.38, 14.95. Calcd. for $C_{13}H_{10}OCl_2$: Cl, 28.0. Found: Cl, 27.8, 28.1.

Crystals of this compound seeded in the oil prepared by the aluminum chloride condensation dissolved. The benzoyl derivative in this case gave a melting point of 98.5–99°, which was identical with that prepared from the oil.

The oil from the aluminum chloride condensation was then treated with a water solution of potassium hydroxide. An oil remained undissolved. This was withdrawn and the solution acidified with hydrochloric acid. A crystalline compound was obtained which when purified proved to be identical with the compound obtained by direct chlorination of p-benzylphenol.

Benzyl 2,6-Dichlorophenyl Ether.—Six and one-half grams of metallic sodium was allowed to react with 100 cc. of methyl alcohol. The solution was cooled and 45 g. of 2,6-dichlorophenol added. This mixture was heated on the oil-bath at 150° for thirty minutes, cooled and 35 g. of benzyl chloride added. The entire mixture was allowed to stand overnight and then heated on the oil-bath for five hours. After cooling, the oil was extracted with petroleum ether, the ether removed and the residue distilled.

A very small amount of benzyl chloride came over at 90 to 190° at 15 mm. Practically all of the remaining oil distilled between 190 and 196°. Refractionation produced a yellow oil with a boiling point of 194–196° at 15 mm. This oil solidified after standing

---

[6] Houben, "Methods of Organic Chemistry," Vol. 2, p. 799.

in the ice box for three months. A crystal of the ether so prepared was seeded in the oily residue obtained from the aluminum chloride condensation. The oil solidified immediately. The melting point of both compounds was identical, 39.5–40°.

Anal. Subs., 0.2418, 0.1930: cc. of 0.1 N $AgNO_3$, 19.05, 15.1. Calcd. for $C_{13}H_{10}OCl_2$: Cl, 28.0. Found: Cl, 27.9, 27.7.

3,5-Dichloro-2-hydroxydiphenylmethane.—Sodium (11.5 g.) was suspended in 130 cc. of toluene and 81.5 g. of 2,4-dichlorophenol added. The mixture was heated on the oil-bath at 150° for thirty minutes, during which time the white sodium salt was produced. The mixture was cooled and 63.3 g. of benzyl chioride added. After standing overnight it was heated for five hours on the oil-bath (160°), cooled and treated with 250 cc. of methyl alcoholic potassium hydroxide. The solution was extracted with petroleum ether. The remaining alcoholic solution was then neutralized with hydrochloric acid and the phenol extracted with ethyl ether. After removing the ether, the residue was fractionated. The fraction between 140 and 210° at 15 mm. solidified in the receiver and yielded, after recrystallization from petroleum ether, 30 g. of pure dichlorobenzyl phenol, m. p. 77.0–77.5°.

Anal. Subs., 0.2000, 0.1895: cc. of 0.1 N $AgNO_3$, 15.6, 14.82. Calcd. for $C_{13}H_{10}OCl_2$: Cl, 28.0. Found: Cl, 27.6, 27.7.

The same compound was prepared by direct chlorination of *o*-benzylphenol. The chlorination was carried out as before using calculated amounts of potassium permanganate to produce the chlorine. The dark colored oil was fractionated and the fraction between 190–200" at 15 mm. was purified by recrystallization from high test gasoline.

Benzyl 2,4-Dichlorophenyl Ether.—This compound was prepared by treating sodium 2,4-dichlorophenylate in methyl alcohol with the equivalent amount of benzyl chloride. The crystals obtained were purified from petroleum ether. The petroleum ether extract from the previous preparation of 3,5-dichloro-2-hydroxydiphenylmethane was also purified in a similar manner. The compounds[4] were prisms with identical melting points (59.0–59.5°).

Attempt to Produce the **Trichlorobenzylphenols.**—Both the para and ortho benzylphenols were subjected to the calculated amount of chlorine for the substitution of three chlorines and later to an excess of the gas. The compounds in each case were fractionated and purified by recrystallization. Upon analysis each sample showed but two chlorine atoms and gave melting points which proved them to be the dichlorobenzylphenols previously prepared.

Esters

The benzoyl, benzene sulfonyl and the toluene sulfonyl derivatives of both dichlorobenzylphenols were prepared by the pyridine method.

Summary

1. The dichloro derivatives of both ortho and para benzylphenol and their ethers were prepared by direct chlorination and by condensation of the chlorinated phenols with benzyl alcohol.

2. The aluminum chloride condensation of 2,6-dichlorophenol and benzyl alcohol gave the ether as well as the benzylated phenol.

3. No evidence was obtained of the substitution by direct chlorination of more than two chlorines in either para or ortho benzylphenol.

4. The benzoyl, benzene sulfonyl and toluene sulfonyl derivatives of each dichlorobenzylphenol were prepared.

TOXICAROL. II. SOME ACETYL DERIVATIVES OF TOXICAROL

BY E. P. CLARK

RECEIVED MARCH 19, 1931 PUBLISHED JUNE 8, 1931

Evidence has been presented to show that toxicarol is an hydroxy-dimethoxy compound, $C_{23}H_{22}O_7$.[1] The presence in the molecule of at least one hydroxyl group was demonstrated by the formation of a monobenzoyl derivative, but as the nature of four of the seven oxygen atoms was unknown, the existence of other hydroxyl groups was not excluded.

It has now been shown that a diacetyl derivative of toxicarol may be obtained, but because of the reactions which it and toxicarol undergo, it cannot be stated definitely that a second hydroxyl group exists in toxicarol per se. In fact, evidence is more in accord with the idea that the second acetyl group is introduced as a result of some reaction brought about by the reagents involved in the acetylation process.

An attempt to elucidate this point is in progress, but since the information upon the subject now available is interesting and will eventually contribute to the solution of the structure of the molecule, it is presented herewith.

---

[1] Clark, THIS JOURNAL, 52, 2461 (1930).

When treated with boiling acetic anhydride and sodium acetate, toxicarol yields a diacetyl derivative, $C_{27}H_{26}O_9$. This material upon catalytic hydrogenation gives two products, dihydrodiacetyltoxicarol, $C_{27}H_{28}O_9$, and monoacetyldihydrodesoxytoxicarol, $C_{25}H_{28}O_7$. The latter substance may be readily deacetylated, giving a good yield of dihydrodesoxytoxicarol, $C_{23}H_{26}O_6$, but by the methods tried it cannot be further acetylated to a diacetyl derivative.

Catalytic reduction of toxicarol under the conditions which produced the desoxy compound from the acetyl derivative resulted in the formation of only dihydrotoxicarol, $C_{23}H_{24}O_7$.

Acetylation of dihydrotoxicarol with boiling acetic anhydride and sodium acetate gave two products, depending upon the duration of the reaction. When the components were allowed to react for ten minutes, only a monoacetyldihydrotoxicarol, $C_{25}H_{26}O_8$, was obtained, whereas if the reaction continued for two hours the entire product was diacetyldihydrotoxicarol, identical with the diacetyl derivative obtained by reducing diacetyltoxicarol.

Oxidation of toxicarol with potassium ferricyanide resulted in the loss of two hydrogen atoms, giving dehydrotoxicarol, $C_{23}H_{20}O_7$. Dihydrotoxicarol treated in the same manner gave dehydrodihydrotoxicarol, $C_{23}H_{22}O_7$. Dehydrotoxicarol was readily acetylated with acetic anhydride and sodium acetate, but under all the conditions tried only a monoacetyl derivative was obtained.

Reduction of dehydro or acetyldehydrotoxicarol gave, respectively, dihydrotoxicarol and monoacetyldihydrotoxicarol. The latter substance was the same as the acetyl derivative obtained by mild acetylation of dihydrotoxicarol.

In the process of reducing these dehydro derivatives not only was the double bond demonstrated by the catalytic hydrogenation reduced, but the structure which gave rise to the dehydro formation was regenerated. This is in sharp contrast to the corresponding dehydro derivatives of rotenone[2] and deguelin,[3] which do not reduce to the corresponding parent substance.

Dehydrotoxicarol may also be obtained by oxidizing toxicarol in an absolute alcoholic potassium acetate solution with iodine. Four atoms of iodine are readily consumed and a beautiful yellow iodo compound separates. This is undoubtedly iododehydrotoxicarol, but analysis of the compound was not satisfactory. This failure was probably due to the retention of an indefinite quantity of solvent which could not be removed under the condition to which the material was subjected. The melting point of the compound varied over a range of 30° depending upon the

---

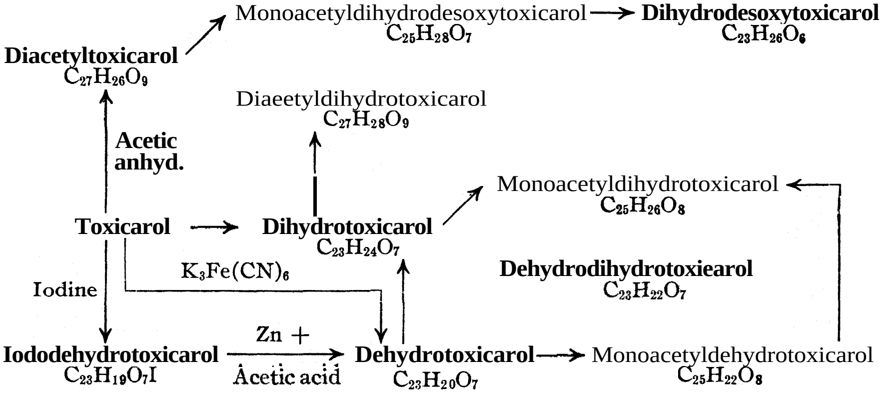
[2] LaForge and Smith, THIS JOURNAL, 52, 1094 (1930).

[3] Clark, unpublished data.

solvent used for its recrystallization, but all samples readily lost their iodine when treated with zinc dust and boiling acetic acid. Upon cooling the reaction mixture, dehydrotoxicarol separated in a relatively pure condition.

The reactions which have been discussed are represented diagrammatically in the chart.

REACTIONS OF TOXICAROL AND SOME OR ITS DERIVATIVES



In connection with the behavior of the compounds under consideration, the following facts are pertinent. Because toxicarol gives a deep green color reaction with ferric chloride, which the benzoyl derivative does not, it is concluded that the hydroxyl group which was benzoylated is phenolic. Likewise the green color is produced by dehydrotoxicarol but not by acetyldehydrotoxicarol. It would therefore be expected that dihydrodesoxytoxicarol would also give the phenolic test, but it does not.

Some work upon the oxidation of toxicarol has been under way, but it has not progressed far enough to be reported upon at this time. It may be stated, however, that when toxicarol was treated with an acetic acid solution of chromic acid, the reaction was very slow, and after twenty-four hours all that could be isolated was approximately 50% of the unchanged starting material. Diacetyltoxicarol, on the other hand, is oxidized at once, and in some experiments as many as four products have been isolated, none of which was starting material.

It therefore seems likely that in the formation of diacetyltoxicarol a new structure is developed, and although a diacetyl derivative is indicative of two hydroxyl groups, it does not seem justifiable at present to conclude that the second hydroxyl group is present in toxicarol itself.

Experimental

Diacetyltoxicarol.—A mixture of 10 g. of toxicarol, 2.5 g. of anhydrous sodium acetate and 40 cc. of acetic anhydride was boiled for thirty minutes under a reflux condenser. The resulting solution was cooled in an ice-bath, then diluted with 100 cc. of acetic acid, and allowed to crystallize. The acetyltoxicarol which separated was removed from the mother liquor by filtration and was washed on the filter first with acetic acid, then with water, and finally with methanol. The yield of crude material, whose melting point was 227–229°, was 6 g.

The mother liquors were poured into 800 cc. of water, causing a further quantity of material to separate. Salt added to the mixture caused flocculation of the precipitate, which was separated by filtration. After the precipitate was air dried it was dissolved in ether and allowed to crystallize. One and six-tenths grams of crude diacetyltoxicarol with a melting point of 195–197° was obtained. This material was recrystallized from its chloroform solution by adding five volumes of ethanol. It then melted at 226°.

The crude diacetyltoxicarol (m. p. 226–229') was recrystallized by dissolving 1 g. of the substance in 25 cc. of boiling acetic acid and adding 25 cc. of boiling water. Crystallization from the 50% acid began at once and was soon completed. Two such recrystallizations gave a pure product which melted at 233° and became clear at 236°. It consisted of thin irregularly shaped plates. In parallel polarized light (crossed nicols) the plates extinguished sharply and brilliant polarization colors were common. In convergent polarized light (crossed nicols) partial biaxial interference figures were shown only rarely: η_α, 1.500 (very common); η_β, indeterminate; η_γ, >1.740.[4]

Anal. Calcd. for $C_{27}H_{26}O_9$: C, 65.58; H, 5.30; OCH_3 (2), 12.6; acetyl (2), 17.4. Found: C, 65.71; H, 5.41; OCH_3, 12.7; acetyl, 17.2.

Reduction of Diacetyltoxicarol (Diacetyldihydrotoxicarol).—Three grams of diacetyltoxicarol dissolved in 200 cc. of hot acetic acid was reduced at atmospheric pressure and approximately 75° with hydrogen and the platinum catalyst of Voorhees and Adams.[5] After the catalyst was removed, the solution was heated to boiling and two volumes of boiling water was added. Crystallization began at once and was completed when the solution reached room temperature. The yield was 2 g. and the melting point of the crystals was 235°. It was recrystallized by dissolving the crude material in a small volume of boiling chloroform, adding approximately ten volumes of boiling methanol and maintaining the solution in a state of vigorous boiling until crystallization began. The material which separated consisted of colorless boat-shaped crystals which melted at 238° and became clear at 240°. In parallel polarized light (crossed nicols) the crystals exhibited deep purple, green and red colors: η_α, 1.480 lengthwise (common); η_β, indeterminate, and η_γ, >1.740, although many of the crystals matched a liquid of this index or showed pale blue or orange margins in white light (crosswise).

Anal. Calcd. for $C_{27}H_{28}O_9$: C, 65.31; H, 5.69; OCH_3 (2), 12.5. Found: C, 64.99; H, 5.82; OCH_3, 12.5.

Monoacetyldihydrodesoxytoxicarol.—The acetic acid mother liquors from the foregoing experiment were concentrated to a sirup under reduced pressure, and the residue was dissolved from the flask with a small quantity of boiling methanol. The solution was set aside and allowed to crystallize. The product which separated had a melting point of 155°, and the yield was usually one-third of the starting material. It was recrystallized by adding five volumes of boiling methanol to its solution in boiling chloroform and maintaining the solution in a state of vigorous boiling until the chloroform was removed. Upon cooling, the solution deposited pure colorless needles and rectangular rods whose melting point was 156°.

In parallel polarized light (crossed nicols) the material had inclined extinction and

---

[5] Voorhees and Adams, THIS JOURNAL, 44, 1397 (1922).

negative elongation. In convergent polarized light (crossed nicols) the substance exhibited partial biaxial interference figures, often showing one optic axis up: , 1.547; η_β, 1.633; η_γ, >1.740; all ±0.003.

Anal. Calcd. for $C_{25}H_{28}O_7$: C, 68.17; H, 6.41; OCH_3 (2), 14.1. Found: C. 68.09; H, 6.47; OCH_3, 14.3.

When a relatively large quantity of fresh catalyst was used (1 g. of platinum dioxide for 10 g. of diacetyltoxicarol), no diacetyldihydrotoxicarol was obtained. Under these conditions, in the first crop of crystals 2.4 g. of monoacetyldihydrodesoxytoxicarol was obtained from 5 g. of diacetyltoxicarol.

Dihydrodesoxytoxicarol.—The acetyl derivative of dihydrodesoxytoxicarol was dissolved in a boiling 2.5% methyl alcoholic solution of sodium methylate. The liquid was then immediately made acid with acetic acid and set aside to crystallize. In a short time the deacetylated product separated as colorless rods. Upon recrystallization from 50% ethanol the product was pure and melted at 188". In this state it consisted of fine colorless needles having parallel extinction and negative elongation (parallel polarized light), η_α, 1.567 (lengthwise); η_β, 1.625 (crosswise); and η_γ, 1.680 (crosswise); all ±0.003. It gave no color test with ferric chloride.

Anal. Calcd. for $C_{23}H_{26}O_6$: C, 69.32; H, 6.58; OCH_3 (2) 15.6. Found: C, 69.29; H, 6.66; OCH_3, 15.6.

Dihydrotoxicarol.—Five grams of toxicarol was reduced with hydrogen as outlined under the reduction of diacetyltoxicarol. Approximately 90% of the solvent was removed by vacuum distillation, and the residue was washed from the flask with five volumes of methanol. Crystallization began at once, yielding 3.4 g. of dihydrotoxicarol melting at 205".

The crude material was recrystallized from a boiling chloroform solution by the addition of five volumes of methanol. It separated as thin hexagonal plates and occasional rods which melted at 206" and became clear at 209°. Macroscopically the preparation had a slight greenish tinge, but microscopically the crystals were colorless. In parallel polarized light (crossed nicols) most of the plates exhibited first order white, and when the stage was rotated many of the plates did not extinguish sharply. In convergent polarized light (crossed nicols) such plates showed partial biaxial interference figures frequently with one axis up: ,? 1.575; η_β, 1.627; η_γ, 1.658 (all ±0.003).

Anal. Calcd. for $C_{23}H_{24}O_7$: C, 66.97; H, 5.87; OCH_3 (2), 15.1. Found: C, 67.08; H, 5.89; OCH_3, 15.1.

Monoacetyldihydrotoxicarol.—A mixture of 0.25 g. of dry sodium acetate. 1 g. of dihydrotoxicarol and 4 cc. of acetic anhydride was boiled for ten minutes. The excess of acetic anhydride was decomposed by the cautious addition of methanol, after which eight volumes more of methanol were added. One gram of monoacetyldihydrotoxicarol with a melting point of 202° separated. It was twice recrystallized from its saturated boiling butanol solution by adding two volumes of methanol. Thus obtained it consisted of colorless prisms which began to sinter at 200° and melted at 207°. In parallel polarized light (crossed nicols) it exhibited negative elongation and straight extinction. In convergent polarized light (crossed nicols) only partial biaxial interference figures were shown: η_α, 1.583 (not common); η_β, indeterminate; η_γ, 1.655 (common crosswise). An intermediate index η_ι, 1.615, frequently occurs lengthwise on the rods (all ±0.003).

Anal. Calcd. for $C_{25}H_{26}O_8$: C, 66.06; H, 5.77; OCH_3 (2), 13.7. Found: C, 66.03; H, 5.79; OCH_3, 13.7.

Diacetyldihydrotoxicarol.—The diacetyldihydrotoxicarol was obtained by the method just given for the monoacetyl derivative except that the reaction mixture was refluxed for two hours. The solution was then cooled, diluted with an equal volume of acetic acid and allowed to crystallize. The diacetyl compound which separated melted at 235–236°. It was recrystallized by the procedure given for the same product obtained by reducing diacetyltoxicarol.

The material had the same melting point as the former product and when mixed with it there was no depression of the melting point. It also had the optical properties characteristic of the diacetyl derivative obtained by reducing diacetyltoxicarol.

Anal. Found: C, 65.32; H, 5.67; OCH_3, 12.5.

Oxidation of Toxicarol with Potassium Ferricyanide: Dehydrotoxicarol.—Five grams of toxicarol dissolved in 500 cc. of boiling ethanol was treated with 75 cc. of a hot aqueous solution of 9 g. of potassium ferricyanide and 2.8 g. of potassium hydroxide. The mixture was allowed to stand until the following day and then quickly diluted with 1500 cc. of water. Dehydrotoxicarol separated as brownish-yellow crystals, and the residual organic material, dispersed in the milky mother liquor, was carefully decanted. The crystals were then washed with water by decantation, transferred to a filter and finally washed with methanol. One and one-tenth grams of dehydrotoxicarol with a melting point of 223° was obtained.

The material was recrystallized by adding five volumes of hot methanol to its solution in chloroform. This procedure gave a product which melted at 230–231°. For analysis the compound was again recrystallized from hot cyclohexanol. In this operation a yield of 85% was obtained. The material separated as yellow rods and needles whose melting point was 234°. The crystals exhibited parallel extinction and negative elongation: η_α, 1.460 (lengthwise); η_β, 1.685 (crosswise); and η_γ, >1.740 (both ±0.003).

Anal. Calcd. for $C_{23}H_{20}O_7$: C, 67.63; H, 4.94; OCH_3 (2), 15.2. Found: C, 67.47; H, 4.97; OCH_3, 15.3.

Monoacetyldehydrotoxicarol.—The acetylation of dehydrotoxicarol was performed in the usual way with sodium acetate and acetic anhydride. The reaction mixture was refluxed for thirty minutes, then diluted with two volumes of acetic acid and allowed to crystallize. The yield was 1.6 g. from 2 g. of starting material. The crude product was recrystallized from a boiling chloroform solution upon the addition of five volumes of methanol. It separated as long light cream-colored rods and needles which melted at 231–232". The extinction was inclined and the elongation was negative: η_α, 1.563; η_β, indeterminate; η_γ, >1.740.

Anal. Calcd. for $C_{25}H_{22}O_8$: C, 66.65; H, 4.93; OCH_3 (2), 13.8. Found: C, 66.47; H, 5.05; OCH_3, 13.8.

Reduction of Dehydrotoxicarol.—Dehydrotoxicarol was reduced by the procedure given for the preparation of dihydrotoxicarol. One and six-tenths grams of dihydrotoxicarol was obtained from 2.6 g. of dehydrotoxicarol. After recrystallization the product melted at 209°. It caused no melting-point depression when mixed with dihydrotoxicarol and possessed the same optical properties that are characteristic of dihydrotoxicarol.

Reduction of Monoacetyldehydrotoxicarol.—Four and thirty-five hundredths grams of monoacetyldehydrotoxicarol was reduced in the usual manner and the resulting solution concentrated to a sirup under reduced pressure. The residue was dissolved from the flask with 25 cc. of hot methanol and allowed to crystallize. The yield was 3.5 g. of monoacetyldiiydrotoxicarol which melted at 206°. When it was recrystallized as outlined before it melted at 207° and caused no depression of the melting point when mixed with the preparation previously described. The optical properties were also identical with those characteristic of monoacetyldihydrotoxicarol.

Oxidation of Toxicarol with Iodine in an Alcoholic Solution of Potassium Acetate.—

Five grams of toxicarol and 7.5 g. of potassium acetate were dissolved in 250 cc. of boiling absolute ethanol and treated portion-wise with 100 cc. of an absolute ethanolic solution of 6 g. of iodine. The reaction mixture was allowed to stand for a day, after which the crystalline iodo compound was removed by filtration. The yield was usually 1.6 g. The product melted with decomposition at various temperatures from 198 to 204°. The crude material when recrystallized from various solvents melted with decomposition over a wide temperature range. The solvents used and the melting points of the crystals obtained from them are as follows: acetic acid, 206°; benzene and ether, 222°; pyridine and butanol, 225°; chloroform and ether, 214°; chloroform and butanol, 215°. However, various preparations obtained from the same solvents frequently showed considerable difference in the melting point. In all cases the material separated as fine yellow needles and rods.

The filtrate from the original crystals was treated with 1500 cc. of water. The precipitate formed was separated, dried, dissolved in 15 cc. of boiling acetic acid and allowed to crystallize for a day. Usually there separated 2.5 g. of iodo compound which melted at 204–205°.

Anal.[6] Calcd. for $C_{23}H_{19}O_7I$: C, 51.69; H, 3.58; I, 23.76; OCH_3 (2), 11.62. Found: C, 49.00; H, 3.53; I, 22.88; OCH_3, 11.5.

Dehydrotoxicarol from the Iodo Compound.—A mixture of 4 g. of iododehydrotoxicarol, 8 g. of zinc dust and 60 cc. of acetic acid was boiled for forty-five minutes. The clear yellow solution which resulted was decanted from the zinc and allowed to crystallize. After the crystals were removed from the mother liquors, washed with acetic acid, then water and finally methanol, 3.4 g. of crude dehydrotoxicarol was obtained. After it was recrystallized as outlined before, it melted at 235–236°. When mixed with dehydrotoxicarol prepared by the ferricyanide oxidation of toxicarol, there was no depression of the melting point. It also possessed the optical properties of dehydrotoxicarol.

Dehydrodihydrotoxicarol.—One gram of dihydrotoxicarol was treated with an alkaline potassium ferricyanide solution as outlined for the preparation of dehydrotoxicarol. There was obtained 0.11 g. of dehydrodihydrotoxicarol which melted at 254°. It was recrystallized from boiling acetic acid, from which it separated as long yellow rods whose melting point was 260°. The substance apparently is monoclinic. In parallel polarized light (crossed nicols) the extinction is usually inclined, although occasionally rods are found having straight extinction (crystals elongated parallel to the *b* axis). In convergent polarized light (crossed nicols) partial biaxial interference figures are common, frequently showing one optic axis up: η_α, 1.500; η_β, 1.680; η_γ, >1.740 (both ±0.003).

Anal. Calcd. for $C_{23}H_{22}O_7$: C, 67.30; H, 5.41; OCH_3 (2), 15.1. Found: C, 67.05; H, 5.45; OCH_3, 14.9.

Summary

1. Acetylation of toxicarol yields a diacetyl derivative which upon catalytic reduction is changed to diacetyldihydrotoxicarol and monoacetyldihydrodesoxytoxicarol.

2. Catalytic reduction of toxicarol, under the conditions used to reduce diacetyltoxicarol, yields only dihydrotoxicarol. This substance may be acetylated in such a way as to introduce either one or two acetyl groups.

---

[6] The sample upon which carbon and hydrogen were determined was recrystallized from acetic acid. That upon which halogen and methoxyl were determined was obtained from chloroform and ether, melting point 210°.

3. Oxidation of toxicarol with ferricyanide yields dehydrotoxicarol involving the loss of two hydrogen atoms from the mother substance.

4. Dehydrotoxicarol is also formed by the oxidation of toxicarol with iodine in an alcoholic potassium acetate solution. In this reaction an intermediate iododehydrotoxicarol is formed which can be dehalogenated with zinc dust and acetic acid.

5. Reduction of dehydrotoxicarol or its acetyl derivative not only results in the reduction of the double bond, demonstrated by the dihydro formation, but it also regenerates the structure responsible for the dehydro formation.

6. It seems possible that the second acetyl group introduced into toxicarol is the result of some reaction brought about by the reagents involved in the acetylation process.

ROTENONE. XII. SOME NEW DERIVATIVES OF ROTENOL

BY H. L. HALLER AND F. B. LAFORGE

RECEIVED MARCH 21, 1931 PUBLISHED JUNE 8, 1931

When rotenone ($C_{23}H_{22}O_6$) is refluxed with zinc and alkali in alcohol solution, two products are obtained, derritol, which is soluble in alkali, and rotenol, which is alkali insoluble. Rotenol is a white compound which possesses two hydrogen atoms more than rotenone, and Butenandt[1] assumes that it is formed by the reduction of the carbonyl group to a secondary alcohol group because, unlike rotenone, it does not yield an oxime and because it liberates one mole of methane with the Grignard reagent. The presence of an hydroxyl group in rotenol has not been satisfactorily demonstrated, however, as all attempts to obtain acyl derivatives have failed, and we have lately found several new facts which contradict the assumption that it is an alcohol.

In the course of our work on the structure of rotenone it has been found that rotenol readily yields isotubaic acid on alkali fusion[2] and that dihydrorotenolic acid is readily cleaved with alkaline hydrogen peroxide, forming netoric acid[3] ($C_{12}H_{14}O_5$), which contains the original methoxyl groups.

Both these reaations are best explained by the assumption of cleavage at a carbonyl group, as is generally assumed for other derivatives of rotenone. An attempt was made, therefore, to determine whether or not rotenol possesses a ketone group or whether this group has been reduced as suggested by Butenandt.

---

[1] Butenandt, Ann., 464, 253 (1928).

[2] Haller and LaForge, THIS JOURNAL, 52, 4505 (1930).

[3] Smith and LaForge, *ibid.*, 52, 4595 (1930).

We have, in fact, confirmed the observations of Butenandt in that we have been unable to form an oxime from rotenol and have not been successful in preparing an acetyl derivative. On the other hand, we have found in one important reaction an indication of the presence of a ketone group.

With Clemmensen's reagent (amalgamated zinc) isorotenol ($C_{23}H_{24}O_6$) yields a compound having the empirical formula $C_{23}H_{26}O_5$, thus indicating the reduction of a carbonyl group. Rotenol and dihydrorotenol on the other hand are not reduced with this reagent but are recovered unchanged. Rotenol, however, can be isomerized to isorotenol identical with the isorotenol obtained from isorotenone, and there is no reason to assume that the carbonyl group is involved in the process of isomerization.

As it has been shown that rotenone contains two asymmetric centers, one of which disappears when rotenone and its derivatives are isomerized with sulfuric acid to isorotenone and its derivatives, and the other in the formation of the dehydro derivatives, it would be expected that isorotenol would be optically active, especially as a new asymmetric center would be formed in the conversion of the carbonyl group to the secondary alcohol group. The fact that isorotenol is optically inactive whereas rotenol is optically active is an additional argument against its supposed alcoholic nature.

On oxidation with ferricyanide and alkali, rotenol and dihydrorotenol yield dehydro derivatives isomeric with rotenone and dihydrorotenone. Unlike all the other dehydro derivatives of rotenone, which are yellow, dehydrorotenol and dehydrodihydrorotenol are white. Molecular weight determination shows that dehydrorotenol is not a dimolecular compound. It does not yield an oxime nor an acetyl derivative. On catalytic hydrogenation dehydrorotenol yields a mixture of a dihydro compound which is identical with the dehydro derivative obtained from dihydrorotenol and an acid which has been termed dehydrodihydrorotenolic acid. This acid is quite stable to alkali and is not cleaved in alkaline solution with hydrogen peroxide as are most of the rotenonic acid derivatives. With zinc and alkali, dehydrorotenol does not add water as do other dehydro derivatives of rotenone but is reduced quantitatively to rotenol.

Dihydrorotenol also yields a dehydro derivative. This substance, dehydrodihydrorotenol, is not reduced with catalytic hydrogen, but on boiling with zinc and alkali in alcohol solution it is quantitatively reduced to dihydrorotenol.

On boiling with zinc and alkali in alcohol solution, dihydrorotenonic acid yields dihydrorotenolic acid. There is no evidence that dihydroderritolic acid is formed, as might be expected from the analogy in the case of rotenone itself.

Experimental

Dehydrodihydrorotenol.—One-half gram of dihydrorotenol was dissolved in 25 cc. of 95% alcohol and 0.9 g. of potassium ferricyanide, and 0.135 *g*. of potassium hydroxide in 7.5 cc. of water was added to the hot solution. The reaction mixture was allowed to stand overnight and then diluted with about 400 cc. of water. The precipitated substance was filtered off, washed with water and dried. Recrystallized from 95% alcohol, it melted at 171°.

Anal. Subs., 0.0870, 0.0912: CO_2, 0.2220, 0.2325; H_2O, 0.0472, 0.0499. 0.1770 subs. in 12.3 g. benzene; AT = 0.191°. Calcd. for $C_{23}H_{24}O_6$: C, 69.69; H, 6.06; mol. wt., 396. Found: C, 69.59, 69.62; H, 6.07, 6.12; mol. wt., 376.7.

Dehydrodihydrorotenol did not yield an oxime when refluxed with hydroxylamine hydrochloride and sodium acetate in absolute alcohol. When boiled with acetic anhydride and sodium acetate it was recovered unchanged.

Dehydrorotenol.—Dehydrorotenol was obtained when rotenol was treated with alkali and potassium ferricyanide in the same manner that was described for the preparation of dehydrodihydrorotenol. It was purified by crystallization from 95% alcohol. It melted at 124°.

Anal. Subs., 0.0936: CO_2, 0.2402; H_2O, 0.0465. Calcd. for $C_{23}H_{22}O_6$: C, 70.03; H, 5.63. Found: C, 69.99; H, 5.56.

Reduction of Dehydrorotenol with Catalytic Hydrogen.—1.86 g. of dehydrorotenol dissolved in 25 cc. of ethyl acetate was added to 25 cc. of ethyl acetate containing about 0.3 g. of platinum oxide catalyst, previously saturated with hydrogen, and the solution was shaken in an atmosphere of hydrogen. About 200 cc. of hydrogen was absorbed in two or three minutes, after which absorption practically ceased. The solution was decanted from the catalyst, most of the ethyl acetate was distilled off, and the concentrated solution was dissolved in ether. The ether solution was extracted with 5% sodium hydroxide, then with water. It was dried over sodium sulfate. After the ether was removed the remaining product was crystallized from 95% alcohol. It melted at 171°. When mixed with an equal quantity of dehydrodihydrorotenol, no depression in melting point was noted.

The aqueous alkaline extract was acidified with dilute sulfuric acid and extracted with ether. The ether extract was washed with water and dried over sodium sulfate. The ether was removed, and the substance was crystallized from 95% alcohol. It melted at 206°. It was named dehydrodihydrorotenolic acid.

Anal. Subs., 0.0839: CO_2, 0.2129; H_2O, 0.0474. *Titration.* Subs., 0.0328: 0.85 cc. of $N/10$ KOH. Calcd. for $C_{23}H_{26}O_6$: C, 69.31; H, 6.58. Found: C, 69.21; H, 6.32. Acid number calcd., 398; found, 386.

The potassium and sodium salts of dehydrodihydrorotenolic acid are relatively quite insoluble in dilute alkaline solution. In an attempt to oxidize this acid in alkaline solution with hydrogen peroxide by the procedure usually employed, only the unchanged material was recovered. Unchanged starting material was also obtained when the acid was treated with alkaline permanganate, although some oxidation took place.

The acid was also found to be stable on prolonged boiling in strong alcoholic potash solution.

Mixed Anhydride of Dehydrodihydrorotenolic Acid and Acetic Acid.—One-half gram of dehydrodihydrorotenolic acid was refluxed with 20 cc. of acetic anhydride and 1 g. of anhydrous sodium acetate for two hours. The solution was poured into water, the precipitate was filtered off, washed with water and dried. It was then recrystallized from 95% alcohol. It melted at 136°.

Anal. Subs., 0.0770: CO_2, 0.1919; H_2O, 0.0428. Calcd. for $C_{25}H_{28}O_7$: C, 68.15; H, 6.41. Found: C, 67.97; H, 6.22.

The substance is insoluble in cold dilute alkali and is quite stable in boiling methyl alcohol. When it is decomposed with cold alcoholic alkali, dehydrodihydrorotenolic acid can be recovered.

Reduction of **Dehydrodihydrorotenol** to **Dihydrorotenol.**—Five-tenths of a gram of dehydrodihydrorotenol was refluxed for two hours with 20 cc. of 95% alcohol, 5 cc. of 40% potassium hydroxide, and 2 g. of zinc. The hot solution was then filtered into ice cold dilute sulfuric acid. The precipitate was filtered off, washed with water and dissolved in ether. The ether solution was washed with water and dried over sodium sulfate. After the removal of the ether the substance was crystallized from 95% alcohol. It crystallized in fine needles which melted at 131–132°. The yield was 0.5 g. When mixed with an equal quantity of dihydrorotenol, the melting point was 129°. It was further identified as dihydrorotenol by an optical examination of the crystals.

Anal. Subs., 0.0785: CO_2, 0.1994; H_2O, 0.0462. Calcd. for $C_{23}H_{26}O_6$: C, 69.31; H, 6.58. Found: C, 69.28; H, 6.59.

Reduction of Dehydrorotenol to **Rotenol.**—The procedure employed was the same as that described above for the reduction of dehydrodihydrorotenol. The product obtained was recrystallized from 95% alcohol. It melted at 120° and was identified as rotenol.

Desoxyisorotenol.—Two grams of isorotenol dissolved in 80 cc. of glacial acetic acid was added to 12 g. of amalgamated zinc followed by 10 cc. of concentrated hydrochloric acid. The reaction mixture was then refluxed for two hours. The hot solution was decanted from the zinc and slowly poured into 500 cc. of water. After cooling, the precipitate was filtered off, washed with water and dissolved in ether. The ethereal solution was washed with water and dried over sodium sulfate. On removal of most of the ether the substance readily crystallized. It was recrystallized from 95% alcohol. It melted at 149°. It does not give a color with ferric chloride.

Anal. Subs., 0.0825: CO_2, 0.2189; H_2O, 0.0525. Calcd. for $C_{23}H_{26}O_5$: C, 72.25; H, 6.86. Found: C, 72.35; H, 7.07.

Isorotenol from **Rotenol.**—Three grams of rotenol (melting point 119°) was dissolved in a solution of 36 cc. of glacial acetic acid and 9 cc. of concentrated sulfuric acid. The solution was heated to 100° for five minutes, cooled and poured into 600 cc. of water. A little sodium sulfate was added, and the precipitate was filtered off and washed twice with water. The precipitate was dissolved in ether, and was washed twice with 5% potassium carbonate solution and then with water. After it was dried over sodium sulfate, the ether was removed, when the substance crystallized. The yield was 2.2 g. After repeated crystallization from 95% alcohol, it was obtained pure. It melted at 131°. It gave the same color in alcohol solution with ferric chloride as does isorotenol prepared from isorotenone. It was further identified as isorotenol by an optical examination of the crystals.

Reduction of **Dihydrorotenonic** Acid **with** Zinc and Alkali.—Two grams of dihydrorotenonic acid was refluxed for four hours in a solution of 60 cc. of 95% alcohol and 20 cc. of 15% potassium hydroxide to which had been added 4 g. of zinc. The hot solution was decanted from the zinc and filtered into cold dilute sulfuric acid. The precipitate was filtered off, washed with water, and dissolved in ether. The ethereal solution was washed with water and dried over sodium sulfate. On removal of the ether the substance readily crystallized. It was recrystallized from methyl alcohol and melted at about 90°. It was identified as dihydrorotenolic acid.

When 45% potassium hydroxide was employed, dihydrorotenonic acid also yielded dihydrorotenolic acid. There was no indication of the formation of dihydroderritolic acid.

Summary

Rotenol and dihydrorotenol on oxidation with alkaline ferricyanide yield dehydro derivatives.

Dehydrorotenol is reduced with catalytic hydrogen to a mixture of dehydrodihydrorotenol and dehydrodihydrorotenolic acid.

Dehydrodihydrorotenolic acid is not cleaved with alkaline hydrogen peroxide.

With zinc and alkali dehydrorotenol and dehydrodihydrorotenol are reduced quantitatively to rotenol and dihydrorotenol.

Isorotenol ($C_{23}H_{24}O_6$) on reduction with Clemmensen reagent (amalgamated zinc) yields a compound of formula $C_{23}H_{26}O_5$, indicating the reduction of a carbonyl group.

Dihydrorotenonic acid is reduced with zinc and alkali to dihydrorotenolic acid.

THE MUTAROTATION OF THE ALCOHOLATE AND ALDEHYDROL OF ALDEHYDO-GALACTOSE PENTAACETATE

BY M. L. WOLFROM

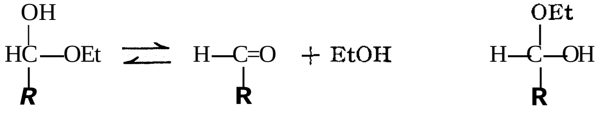
RECEIVED MARCH 23, 1931 PUBLISHED JUNE 8, 1931

The open chain or aldehydo sugar acetates synthesized in this Laboratory show mutarotation in alcohol but not in such non-hydroxylated solvents as acetylene tetrachloride. The mutarotation in alcohol is indicative of chemical combination of some kind between the solvent and the carbonyl group of the sugar acetate. In the case of galactose,[1] well-defined crystalline compounds with ethanol and water were isolated. At the time of the isolation of these two compounds, we were interested only in determining their initial rotation in chloroform and the U. S. P. grade of this solvent was used. The rotations were thus determined in chloroform containing an appreciable amount of ethanol. In both cases mutarotation curves which passed through a minimum were obtained. The unusual nature of these mutarotation curves has been pointed out to us by Professor T. M. Lowry and we have accordingly repeated the experiments using alcohol-free chloroform. In this solvent we find a minimum only in the curve for the ethanol compound (Fig. 1). Data for two experiments with the ethanol compound are given in Table I. The actual speeds for the two experiments are widely different but values identical within the limits of experimental error are obtained for the minimum and final rotations. This variation in speed is probably due to the catalytic effect of hydrogen chloride produced by the slight photochemical decomposition of the alcohol-free chloroform used, the amount of acidity present being apparently different in the two cases.

---

[1] M. L. Wolfrom, THIS JOURNAL, 52, 2464 (1930).

The nature of the mutarotation curve for the ethanol compound indicates a rapid initial reaction followed by a slower one and is also indicative of the presence of three substances with differing rotations. This can be adequately explained on the basis of structural theory as follows



$$\underset{(A)}{\mathrm{HC(OH)(R)}\text{—OEt}} \rightleftarrows \underset{(B)}{\mathrm{H—C(R)=O}} + \mathrm{EtOH} \qquad \underset{(C)}{\mathrm{H—C(OEt)(R)—OH}}$$

(A) (B) (C)

The fact that the free aldehyde form (B, $[\alpha]_D$ $-25°$) and the known ethanol compound (A, $[\alpha]_D$ $+1.5°$) have widely differing rotations in chloroform is proof that the ethanol is constitutionally combined and is not present as alcohol of crystallization. In the hemi-acetal structure (A) the aldehydo carbon atom becomes asymmetric and can exist in two forms, (A) and (C). From the nature of the mutarotation curve the form (C) must be more dextro-rotatory than **(A).** Experiments to find conditions for the isolation of the second form (C) are now in progress in this Laboratory.

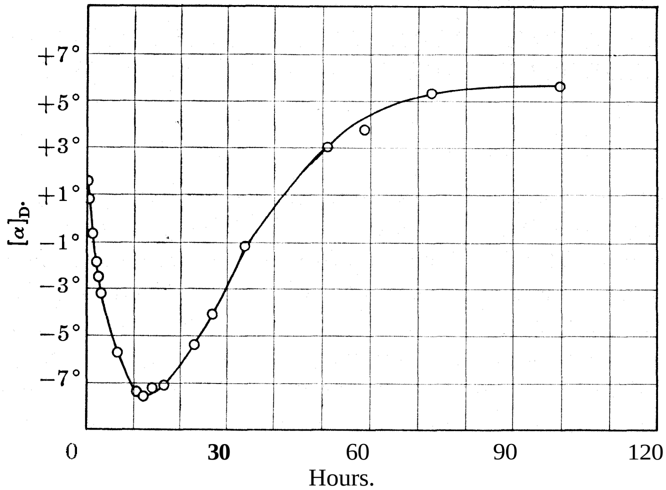


Fig. 1.—Mutarotation of the ethyl **hemi-acetal** of aldehydo-galactose pentaacetate in chloroform, Expt. 1.

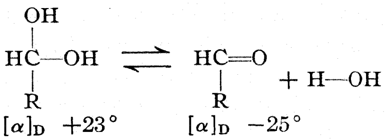
The mutarotation curve obtained for aldehydo-galactose pentaacetate aldehydrol in ethanol-free chloroform is shown in Fig. 2. This is now a smooth exponential curve and differs widely in form from that obtained for the ethanol compound. In the case of the aldehydrol, the aldehydo carbon atom is not asymmetric and only one form is possible. The nature of the mutarotation is indicated by the following simple reaction



$$\underset{[\alpha]_{\mathrm{D}}\ +23^\circ}{\begin{array}{c}\mathrm{OH}\\ |\\ \mathrm{HC{-}OH}\\ |\\ \mathrm{R}\end{array}} \rightleftharpoons \underset{[\alpha]_{\mathrm{D}}\ -25^\circ}{\begin{array}{c}\mathrm{HC{=}O}\\ |\\ \mathrm{R}\end{array}} + \mathrm{H{-}OH}$$

As the rotations of both the forms indicated above are known, the data obtained may be analyzed mathematically. The data of Table II show that the reaction is a simple monomolecular decomposition, as would be predicted on the basis of an aldehydrol structure for the hydrate. The value obtained for the final rotation indicates that the change to the free aldehyde form ($[\alpha]_D$ −25°) is nearly complete. When a 4% chloroform solution of the aldehydrol was used the solution became turbid in about thirty minutes due to the separation of water.

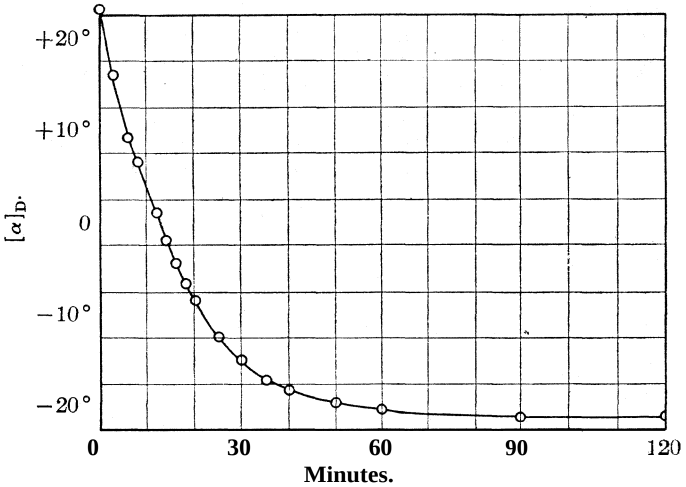


Fig. 2.—Mutarotation of the aldehydrol of aldehydo-galactose pentaacetate in chloroform.

It may be stated that the material from the equilibrated chloroform solutions of both the aldehydrol and ethyl hemi-acetal can be recovered unchanged in good yield by recrystallization from the appropriate solvents. The rotation of the free form of aldehydo-galactose pentaacetate is stable in pure chloroform solution. This is also true of the aldehydo-acetates of d-glucose[2] and of *l*-arabinose[3] recently isolated in this Laboratory. These facts show that the chloroform mutarotation of the aldehydrol and ethyl hemiacetal of aldehydo-galactose pentaacetate is not in the nature of a profound structural change involving an acetyl shift to a ring form. It is believed that the pure chloroform mutarotation of these compounds offers good evidence of their constitutional structure.

[2] M. L. Wolfrom, This Journal, 51,2188 (1929).

M. L. Wolfrom and Mildred R. Newlin, *ibid.*, 52,3619 (1930).

On the basis of the more accurate initial rotation data now reported, the specific rotation in chloroform solution of aldehydo-d-galactose pentaacetate aldehydrol is +23° and that for the ethyl hemi-acetal is +1.5°. The values previously obtained were +19.5 and −0.5°, respectively.

Summary

1. The rotation changes of the aldehydrol and ethyl hemiacetal of aldehydo-d-galactose pentaacetate have been determined in alcohol-free chloroform solution.
2. The nature of the rotation changes observed is presented as evidence for the constitutional nature of these compounds.
3. New values for the rotations of these substances in chloroform have been determined.
4. Polarimetric evidence is given for the existence of two isomeric forms of aldehydo-galactose pentaacetate ethyl hemi-acetal.

THE ROTATORY DISPERSION OF SEVERAL ALDEHYDO SUGAR ACETATES

BY M. L. WOLFROM AND WALLACE R. BRODE

RECEIVED MARCH 23, 1931 PUBLISHED JUNE 8, 1931

Rotatory dispersion work in the sugar series has not been carried on to any great extent. Lowry and Richards[1] have made a very accurate study of the dispersion of sucrose in water solution and have found it to be normal and simple. In the sugar acetate series, very complete data have been obtained by Levene and Bencowitz[2] for the ring pentaacetates of *a*- and p-mannose and of *a*- and β-glucose in a number of solvents, including chloroform. In all these cases they have found the dispersion in the visible region of the spectrum to be normal and simple. Wagner-Jauregg[3] has reported

the dispersions of a number of sugars in water solution and of some methylated sugars in chloroform. He has found them to be simple in every case except that of β-pentamethylglucose in chloroform, which was stated to be complex.

Optical rotations at 5892 Å. have been previously recorded for the open chain or aldehydo acetates of *d*-glucose,[4] d-galactose[5] and l-arabinose[6] in chloroform solution. We have now measured the complete optical dispersion of these substances in the visible region. This was done with the object of determining whether these compounds which are known to possess a free aldehyde group would show any unusual optical rotatory properties. The data obtained are given in Table I and an analysis of the figures obtained has been made by the graphic method. When the reciprocals of the molecular rotations are plotted against the square of the wave lengths a straight line is obtained in the case of the aldehydo-acetates of galactose and arabinose (Fig. 1). On this basis, these dispersions are then normal and simple. In the case of aldehydo-d-glucose pentaacetate, a smooth curve without a maximum or minimum is obtained when the rotations are plotted against the wave length. When the reciprocal of the molecular rotation is plotted against the square of the wave

length (Fig. I) a deviation from a straight line appears in the violet region. The dispersion is then apparently normal and complex. The rotations for the glucose acetate are low and consequently we do not wish to place much emphasis upon this deviation, as it may represent experimental error. However, since these substances possess a carbonyl group, they would be expected to show absorption in the ultraviolet with a consequent possible effect upon the rotatory dispersion in this region of the spectrum.

In the data herein reported, a Schmidt and Haensch polarimeter with spectrometer attachment was used. The spectrometer was calibrated by a method similar to that of Bencowitz.[7] A calibration was first made against the mercury arc. This was then verified by readings on a quartz plate calibrated by the National Bureau of Standards for two lines, using the data of Lowry and Coode-Adams[8] for the dispersion of quartz. The solvent used in determining the dispersion data was alcohol-free chloroform, in which the rotations of these acetates are stable. After dispersion readings were completed, the first reading taken was always checked.

TABLE I

ROTATORY DISPERSION IN CHLOROFORM SOLUTION OF THE ALDEHYDO-ACETATES OF d-GLUCOSE, d-GALACTOSE AND l-ARABINOSE (l, 4-DM.)

423	−3.24	−20.25	−14.1	−88.2	−27.4	−171

Summary

1. The rotatory dispersion in the visible region has been determined for the aldehydo acetates of d-glucose, d-galactose and I-arabinose in chloroform solution.
2. All these substances show normal dispersion. A graphic analysis of the data shows that the dispersion of aldehydo-glucose pentaacetate is apparently complex and that the others are apparently simple.

THE DECARBOXYLATION OF d-GALACTURONIC ACID WITH SPECIAL REFERENCE TO THE HYPOTHETICAL FORMATION OF 1-ARABINOSE[1]

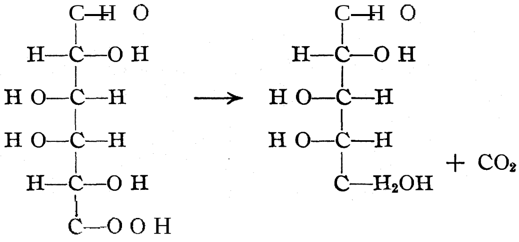
BY C. M. CONRAD

RECEIVED MARCH 24, 1931 PUBLISHED JUNE 8, 1931

Introduction

1-Arabinose has long been considered to be a component in the molecular structure of pectins.[2] Recently, several investigators[3] have cast doubt on this belief. They think that 1-arabinose may arise during dilute acid hydrolysis of pectin by decarboxylation of d-galacturonic acid.

When d-galacturonic acid is heated with 12% hydrochloric acid it decomposes into carbon dioxide and furfural.[4] Theoretically, *l*-arabinose should be formed momentarily, thus



d-Galacturonic acid *l*-Arabinose

McKinnis[5] predicted that in dilute mineral acids decarboxylation would occur and that the arabinose produced would not be decomposed. Link and Niemann[6] have shown that d-galacturonic acid (also d-glucuronic acid) actually is decarboxylated with dilute mineral acids. However, it has not been determined whether arabinose occurs among the reaction products.

Proof that arabinose or other pentoses are produced from uronic acids during the hydrolysis of plant materials would be of considerable importance with respect to carbohydrate chemistry. First, it would discredit the occurrence of arabinose, as such, in pectins. Second, it would render more

or less uncertain the occurrence of the pentoses reported in many gums, mucilages and hemicelluloses. The pentoses assumed to have been hydrolytic products could have been decarboxylation products of a complex uronide. Therefore, it is important to determine, if possible, whether arabinose is formed as a decarboxylation product of galacturonic acid in dilute mineral acids.

Experimental Part

In order to test the production of arabinose by decarboxylation it is necessary to work with galacturonic acid or with its arabinose-free derivatives. For this purpose barium galacturonate, and Ehrlich's[4] tetra acid "a" were chosen.

Preparation of Materials.—Barium galacturonate was prepared from lemon pectin,[7] according to the procedure of Link and Dickson.[8] On a dry weight basis the product yielded *16.50%* carbon dioxide when boiled with 12% hydrochloric acid and contained *25.15%* of barium. The theoretical values are *16.81* and 26.3%, respectively.

Tetra acid "a" was prepared from lemon pectin according to Ehrlich's[4] directions. One part of pectin is heated at 80° with *10* parts of 5% hydrochloric acid for six hours. The grayish white precipitate which forms is washed exhaustively, first with 1% hydrochloric acid, then with water, 95% alcohol, and finally ether. The material is sucked as dry as possible on the Büchner funnel and spread out to dry in the air. The material thus prepared contained *13.61%* moisture, 0.61% ash and yielded 24.55% carbon dioxide on the dry ash-free basis. Ehrlich found for the tetra acid "a" of sugar beets, 0.19% ash and *an* average of *24.81%* of carbon dioxide.

Apparatus.—The apparatus used to measure the extent of decarboxylation has been described previously by Conrad.[9]

Selection of 4% Sulfuric **Acid** for Decarboxylation.—Sulfuric acid has been used more than any other mineral acid for hydrolysis and isolation of sugars. This is because of the ease with which it can be removed from thr hydrolytic products. In the case of **gums,** mucilages and hemicelluloses a 4% concentration is more often employed.[10] This concentration does not appear to be very injurious to the liberated arabinose if the heating is not longer than eight to ten hours.[11] By preliminary experiments it was found that within this time sufficient decarboxylation could be obtained to detect arabinose if it is produced.

Method for the Determination of Arabinose.—Since the recovery of arabinose in crystalline condition is usually attended by much loss, it was thought preferable to obtain it as the diphenylhydrazone compound according to the method of Neuberg and Wohlgemuth.[12] Instead of using the free base, as these investigators did, the hydrochloride salt was used. This was purified by once recrystallizing the commercial prepa-

ration from 95% alcohol containing a little hydrochloric acid. It was used in 50% alcoholic solution, either with 1.5 parts of sodium acetate, or after addition of almost the calculated quantity of N sodium hydroxide.

In a few cases α-benzylphenylhydrazine hydrochloride was employed in parallel tests with the diphenylhydrazine hydrochloride. It was always used with 1.5 parts of sodium acetate in 75% alcohol.

Results

Failure to Obtain Arabinose from **Galacturonic** Acid.—When barium galacturonate is treated with 4% sulfuric acid the barium is at once precipitated as the sulfate, and the concentration of sulfuric acid is slightly reduced. The liberated galacturonic acid, on heating, yields carbon dioxide and other decomposition products. Among these, arabinose was sought in a number of experiments of which the following is a typical example.

Five grams of barium galacturonate in an Erlenmeyer flask was covered with 100 cc. of 4% sulfuric acid and gently boiled for five hours on the sand-bath. At the end of this period the evolved carbon dioxide was found to be 0.1633 g., or theoretically equivalent to 0.5565 g. of arabinose. The solution was removed from the apparatus, cooled, and treated with a very slight excess of barium hydroxide solution. The excess of alkali was immediately neutralized with a stream of carbon dioxide, and the mixture heated on the steam-bath for about an hour to enlarge the barium sulfate particles. After standing overnight the mixture was warmed with animal charcoal and filtered through a thin layer of infusorial earth. The clear filtrate was evaporated to dryness at 25-mm. pressure in a water-bath heated to 55°. The residue was dissolved in 10 cc. of water and the residual barium galacturonate precipitated with 190 cc. of 95% alcohol. The salt was flocculated by heating somewhat and separated by means of a hardened paper on a suction filter. The filtrate was clarified once again with animal charcoal and divided into two equal parts. These were evaporated to dryness, separately. To one was added 15 cc. of 50% alcoholic solution containing 0.259 g. of diphenylhydrazine hydrochloride and 0.4 g. of sodium acetate. The mixture was heated under the reflux condenser for thirty minutes and set aside. To the other portion was added 2 cc. of 75% alcoholic solution of 0.277 g. of benzylphenylhydrazine hydrochloride and 0.415 g. of sodium acetate. It was heated under the reflux condenser for twenty minutes. In both cases a dark resinous substance separated immediately on cooling. After standing for seven days no hydrazone crystals could be seen in either test. The gums dissolved completely in cold 50% aqueous pyridine and could therefore contain no hydrazone.

In a control experiment 0.4 g. of arabinose was dissolved in a mixture of 5 g. of barium galacturonate in 100 cc. of 4% sulfuric acid. The mixture was not heated, the object being only to determine how much of the arabinose would be lost due to adsorption, transfers and the like. Although the solution was not colored, animal charcoal and infusorial earth were used exactly as in the previous experiment. The final residue was not divided. It was treated with 36 cc. of an alcoholic solution containing 0.62 g. of diphenylhydrazine hydrochloride and 0.93 g. of sodium acetate. The mixture was refluxed as before and there was obtained 0.5256 g. of beautiful *l*-arabinose diphenylhydrazone, equivalent to 0.249 g. of arabinose. This is 62.3% of the amount originally added.

In a second control experiment it was sought to determine whether certain decomposition products of galacturonic acid might prevent the separation of the hydrazones. The 5 g. of barium galacturonate was boiled for five hours on the sand-bath. A quantity of arabinose, 0.556 g., equivalent to that calculated to have been produced in the principal experiment was divided into two equal portions. One portion was added at the beginning of the heating period, the other when it was half through. There was collected 0.1805 g. of carbon dioxide theoretically equivalent to 0.615 g. of additional arabinose. On removing the sulfuric acid, clarifying, concentrating, removing the remaining barium galacturonate and dividing the final alcoholic solution into two equal parts, there was finally obtained from one portion 0.3401 g. of *l*-arabinose diphenylhydrazone. Allowing for the division of alcoholic solution this accounts for 58% of the added *l*-arabinose. After purifying once from 95% alcohol and twice from 50% aqueous pyridine the hydrazone melted at 202.5° (uncorr.). From the other portion there were obtained crystals which after twice recrystallizing from 75% alcohol melted at 173–174° (uncorr.). Van der Haar[13] gives corrected values of 204 and 174°, respectively, for the diphenylhydrazone and a-benzylphenylhydrazone of *l*-arabinose. It is therefore evident that the decomposition products of galacturonic acid do not prevent the separation of these hydrazones.

Failure to Obtain Arabinose from Ehrlich's Tetra Acid "A."—According to Ehrlich and Schubert[4] tetra acid "a" is a polymer containing four units of galacturonic acid. It contains no pentose units. On heating with acids it is hydrolyzed into galacturonic acid which in turn undergoes decarboxylation.

In repeated trials arabinose was sought in the decarboxylation products from tetra acid "a." The following is a typical experiment. A 5-g. sample of tetra acid "a" in 100 cc. of 4% sulfuric acid was boiled gently for nine hours. There was collected 0.1309 g. of carbon dioxide equivalent to 0.446 g. of arabinose. The sulfuric acid was precipitated with barium hydroxide and the mixture heated for an hour on the steam-bath. It was filtered through paper pulp and the filtrate clarified with bone charcoal. The almost colorless filtrate was evaporated at 25–35-mm. pressure to about 10 cc. Barium galacturonate was precipitated with five volumes of 95% alcohol, and removed by filtration. The clear filtrate was evaporated to 2–3 cc. Some material which had separated was again removed by adding 95% alcohol and filtering. The clear filtrate was evaporated completely to dryness. The residue was extracted three times with 10, 10 and 6 cc. of hot 95% alcohol. The combined extracts were filtered and evaporated to about 2 cc. In testing for arabinose no diphenylhydrazone could be obtained, although a dark resinous substance separated.

In a control experiment 5 g. of tetra acid "a" was heated with 100 cc. of 4% sulfuric acid in a boiling water-bath (instead of the sand-bath) for fifteen and one-half hours. Only 0.0620 g. of carbon dioxide equivalent to 0.2114 g. of arabinose was obtained and no diphenylhydrazone could be recovered. Again, 15 g. of tetra acid "a" was heated with 500 cc. of 1% sulfuric acid in the autoclave at 25-lb. pressure for one hour. In this case it was impossible to measure the amount of carbon dioxide formed. After removal of the sulfuric acid and concentration as before no *l*-arabinose diphenylhydrazone could be obtained. On the other hand, the light colored sirupy residue which remained reacted with the diphenylhydrazine to give a dark colored resinous mass.

Identification of Arabinose in the Hydrolytic Products of Apple and Lemon Pectins.—McKinnis,[5] in a study of apple pulp, concluded that apple pectin contains no arabinose. In view of the results obtained above with galacturonic acid and tetra acid "a" it was of interest to subject

---

[13] Van der Haar, "Anleitung zum Nachweis, zur Trennung und Bestimmung der Monosaccharide und Aldehydsauren," Gebrüder Borntraeger, Berlin, 1920.

pectins to the same conditions of experimentation and determine whether arabinose is to be found among the products.

The apple pectin[14] used was prepared from "Certo" by alcoholic precipitation and thorough washing with additional alcohol. It contained 74.3% of galacturonic acid on the dry, ash-free basis. The lemon pectin was the same as that used for the preparation of barium galacturonate and tetra acid "a."

Ten grams of pure apple pectin was mixed with 200 cc. of 4% sulfuric acid in a 500-cc. Florence flask and heated on the steam-bath for a short time until dissolved. The flask was removed to the sand-bath and the solution boiled very gently for five hours. During this period 0.0688 g. of carbon dioxide theoretically equivalent to 0.2350 g. of arabinose was produced. After cooling somewhat the acids were neutralized with barium hydroxide solution. The mixture was digested on the steam-bath for a time and set aside overnight. Next morning the supernatant liquid was poured off and the residue filtered on a hardened paper in a Buchner funnel. The decanted liquid and filtrate were combined, stirred with animal charcoal, and filtered by means of suction through a thin layer of infusorial earth on a hardened paper. The clear, practically colorless filtrate was evaporated at 20-mm. pressure in a water-bath at 50° to about 200 cc. Some white substance, probably mineral, was filtered off after first adding some animal charcoal. The filtrate was now evaporated to dryness. The residue was dissolved in 10 cc. of water and barium galacturonate precipitated by addition of 190 cc. of 95% alcohol. The precipitate was flocculated by gentle heating and filtered off on a hardened paper. The clear filtrate was again evaporated to a stiff sirup under reduced pressure. The sirup was dissolved in 33 cc. of water and treated with a solution of 1.55 *g.* of diphenylhydrazine hydrochloride and 6.50 cc. of *N* sodium hydroxide in 50 cc. of 95% alcohol. The mixture was heated under a reflux condenser for thirty minutes and set aside. After two days there had separated *l*-arabinose diphenylhydrazone which, when dried and weighed, amounted to 1.151 g. This is equivalent to 0.5465 g. of arabinose or over twice the amount that could be calculated from the carbon dioxide obtained. After twice recrystallizing from 50% aqueous pyridine, the hydrazone melted, on rapid heating, at 204.2° (corr.). Van der Haar[15] gives 204° as the melting point.

Using practically the same procedure there was obtained from lemon pectin 0.0668 g. of carbon dioxide equivalent to 0.2280 g. of arabinose. However, only 0.1892 g. of arabinose in the form of the diphenylhydrazone was isolated. In this case all the arabinose found could have been produced by decarboxylation. Nevertheless, from results obtained above, its generation through decarboxylation is unlikely. The hydrazone melted at 204° (corr.).

Discussion of Results

The results of the foregoing experiments render it very doubtful that *l*-arabinose arises as an intermediate product in the decarboxylation of galacturonic acid by mineral acids. Instead there are formed one or more sirupy substances which readily react with diphenylhydrazine and α-benzylphenylhydrazine to give dark resinous products.

There is another argument which militates against the theory that

---

[14] This was kindly furnished by the Pectin Sales *Co.,* since incorporated as the General Food Sales Co., of Fairport, N. Y.

[15] Van der Haar, Ref. 13, p. 178.

arabinose arises from galacturonic acid. As is well known, arabinose, when distilled with 12% hydrochloric acid, gives 70–80% of the theoretical quantity of furfural. Galacturonic acid, distilled under these conditions, loses practically the theoretical quantity of carbon dioxide.[4,16] If, in this process, arabinose is first formed and gives rise to furfural, we should expect to recover 70–80% of the theoretical amount of furfural. However, Ehrlich and Schubert[4] obtained only 41.1–42.6%[17] under these conditions and McKinnis,[5] working with digalacturonic acid, obtained only 33.3% of the theoretical yield of furfural. These results, therefore, suggest that some substance other than arabinose is formed at the intermediate stage and that this substance does not decompose into furfural as completely as arabinose does.

If d-galacturonic acid on decarboxylation with mineral acids does not give arabinose, we may well ask what is the intermediate substance. This must remain for further investigation to disclose. In the meantime we must conclude that the recovery of arabinose from the hydrolytic products of plant materials is indicative of the occurrence of arabinose as such and not of galacturonic acid.

Summary and Conclusions

1. A test was made of the theory that *l*-arabinose arises in acid decomposition of d-galacturonic acid as an intermediate product in the formation of furfural. Galacturonic acid in the form of its barium salt was decarboxylated with 4% sulfuric acid but no arabinose could be recovered.
2. Ehrlich's tetra acid "a," a polymer of d-galacturonic acid, was also studied but in no case could arabinose be recovered from the decarboxylation products.
3. Carefully conducted controls showed that added arabinose could always be recovered.
4. 1-Arabinose was found in the hydrolytic products of both apple and lemon pectins. In the case of apple pectin over twice the amount of arabinose that could have been due to decarboxylation was found.
5. The arabinose recovered from the hydrolytic products of plant substances comes from arabinose units in the substances and not from decarboxylation of galacturonic acid.

EXPERIMENTS ON THE ISOLATION OF THE ANTINEURITIC VITAMIN

BY ATHERTON SEIDELL AND VICTOR BIRCKNER

RECEIVED MARCH 26, 1931 PUBLISHED JUNE 8, 1931

In all methods used for the isolation of the antineuritic vitamin the losses of active material are so great that only meager amounts of the final concentrate are obtained. In many cases the quantities have not been sufficient even for preliminary chemical study.

Each advance in the purification of the active fraction demonstrates more clearly the minuteness of the dose of antineuritic vitamin capable of exerting a definite physiological effect. The most active preparations so far made are probably still far from chemical purity. Even the crystals isolated by Jansen and Donath[1] seem to owe their activity to admixed vitamin. This presumption is based on the fact that fractions active in distinctly smaller doses than the Jansen and Donath crystals[2] have been obtained by the procedure described in this and in previous publications[2,3] from this Laboratory.

The necessity for obtaining larger amounts of the most highly active fractions is apparent. Existing methods need to be improved both in the reduction of losses which occur at the several stages and in their application on an increasingly large scale. The experiments here recounted were made with this purpose in view.

For convenience of discussion the procedure may be subdivided into the following steps: (1) preparation of the "activated solid"; (2) extraction and concentration of the vitamin solution; (3) benzoylation and acetone precipitation of the salts; (4) extraction and acetone precipitation of the vitamin concentrate.

Preparation of the "Activated Solid."—This step of the process was first described some fifteen years ago[4] and since then various modifications of it have been introduced. The one to be described now was the result of efforts to prepare the product on a larger scale than had previously been possible. For the opportunity and equipment to do this grateful thanks are extended to M. H. Penau, Technical Director of Les Établissements Byla, located at Gentilly (Seine) near Paris, France.

[2] The results of tests of a sample of the Jansen and Donath crystals given in a previous publication [Seidell and Smith, *Pub. Health Repts.*, *45*, 3191–3200 (1930)] show the minimum curative dose for rats to be 0.04 mg., whereas repeated tests of the most active sample obtained in the present series of experiments showed it to be active in 0.03 mg. doses.

[3] Seidell, *J. Biol. Chem.*, 82, 633–640 (1929).

[4] Seidell, *Pub. Health Repts.*, *31*, 364 (1916).

One hundred and sixty kilograms of pressed brewer's yeast (equal to approximately 45 kg. of dry yeast) was added quickly to about 300 liters of rapidly stirred water heated to about 80°. The mixture, after cooling somewhat, was filtered through a large filter press. To the clear filtrate 15 kg. of fuller's earth was added and the mixture mechanically stirred for one hour. It was then allowed to stand for two hours for subsidence of the fuller's earth which had now become "activated solid." A sample of the mixture which stood in a glass cylinder showed that the supernatant liquid contained a considerable amount of material in suspension. Since this suspended colloidal matter might clog the filter press and would certainly contaminate the activated solid, it was decided to remove it by decantation. The necessities of the case, therefore, led to a modification of the procedure which subsequent experiments have shown to be of decided advantage. The final concentrate resulting from this experiment, when tested on pigeons and on rats by the Smith method,[5] was found to be considerably more active than any previously made from activated solid which had been separated from the yeast solution by means of a Sharples supercentrifuge. It is believed that this simple modification effects the removal of organic constituents which interfere with subsequent steps of the process. The supernatant liquid, therefore, should be decanted from the activated solid and this latter washed with slightly acidified (1.0 cc. of concd. hydrochloric acid per liter) water one or more times.

If the extraction of the activated solid is not to be made immediately it should be filtered or separated with a Sharples supercentrifuge and thoroughly dried or else simply immersed in about 20% alcohol to prevent decomposition of its adsorbed organic matter by organisms.

Although heating yeast in water to about 80° is a very simple and effective way of liberating the vitamins from the cells, an experiment was made in one case with the use of a liquefying agent for obtaining an aqueous solution of the vitamin.

To 7.0-kg. portions of pressed brewer's yeast there was added 700 cc. of a mixture prepared according to Pirie[6] in the ratio of 80 cc. of 81% ethyl alcohol, 20 cc. of concentrated sulfuric acid and 100 cc. of ether. The yeast rapidly liquefied and, after dilution with about three times its volume of cold water, was passed through the Sharples supercentrifuge. To the nearly clear effluent 500 g. of fuller's earth was added and the resulting activated solid after decantation of the supernatant liquid was washed twice by decantation with acidified water.

The combined activated solid thus prepared when used for the remaining steps of the process yielded an aqueous extract which contained an amount of dissolved solids greater than was present in the extracts from activated solid made by the heating method. This excess of solids was also found to interfere with subsequent steps of the process, resulting in a low yield of poor quality final concentrate. .

Extraction and Concentration of the Vitamin Solution.[7]—As pointed out in previous papers the extraction of the activated solid is made by agitating it violently in approximately 0.4 to 0.5 normal sodium hydroxide solution for about five minutes and separating the alkaline liquid from the

solid as quickly as possible by means of a Sharples supercentrifuge. The extract must be acidified quickly with sulfuric acid and adjusted to approximately *P_H* 3.0. In all cases just at this turning point a light, fluffy precipitate separates and serves as an indication that acidity has been reached. In one case a quantity of this precipitate was separated and tested for antineuritic vitamin. Its activity was found to be very little greater than the dry yeast from which it came. Since the amount of the precipitate was small the actual loss of vitamin was insignificant.

When the slightly acid extract is distilled under diminished pressure to about one-tenth its volume, a rather large amount of a brownish product separates. This is removed best by deposition in a large cup centrifuge and the nearly clear supernatant solution decanted. This, after seeding with sodium sulfate decahydrate, is kept in a cool place for crystallization of the large excess of this salt which is present.

The brown precipitate mentioned above has been found by Doctor M. I. Smith, in rat experiments,[8] to be very rich in the thermostable growth factor (B_2 or G) required as a supplement to the antineuritic vitamin for normal growth.[9] Dried samples of it are usually about five times as active as dried yeast. This product therefore furnishes a convenient source of the thermostable factor B_2 and by very simple means, designed to eliminate the sodium sulfate present, it can be concentrated to an activity of more than ten times that of the yeast from which it was derived.

The concentrated solution from which the excess of sodium sulfate decahydrate crystallizes should be treated with about an equal volume of methyl or ethyl alcohol in order to precipitate more of the inorganic salts and the organic impurities which are present.

It is a question as to just how far this alcohol precipitation should be continued. Of course, vitamin is lost if the alcoholic concentration is raised too high. Much material which interferes with subsequent purification of the vitamin is, however, eliminated and a much better final product may be obtained by sacrificing some of the vitamin at this point.

The clear approximately 50% alcoholic solution resulting from the above treatment usually contains about 30 g. of dissolved solids per liter, of which about 30% are inorganic salts. Some typical results obtained up to this point in the procedure are shown in the accompanying table (I).

It will be noted that the estimated quantity of dry yeast used per 5.0 kg. of activated solid, as shown in Table I, varied from 20.5 to **30** kg. This was due to the difficulty of estimating closely the amount of dry yeast corresponding to given amounts of fresh or even pressed yeast. There was also considerable variation in the amount of the thermostable growth vitamin (B_2) rich precipitate which separates during the distillation of the

aqueous extract of the activated solid. This is due not only to a variation in the quantity of this insoluble material but also to the presence of variable amounts of sodium sulfate and other salts which separate together with it.

The volume of the alcoholic antineuritic (B_1) vitamin solution depends upon the degree to which the concentration by distillation has been carried and this cannot be accurately controlled in the large enamel lined vacuum distilling apparatus which was used.

The extent of the recovery of the antineuritic vitamin itself is not shown in the table, but estimates from experiments on pigeons made with certain of the fractions indicated that between 5 and 20% of the original vitamin of the yeast is present in the alcoholic solution. There is consequently a loss of 80 to 95% of the antineuritic vitamin up to this point. Some of this loss may be ascribed to variations in the vitamin content of different samples of brewer's yeast but, of course, the larger part is simply due to the imperfections of the fractionation procedure. In this connection it should be pointed out that the actual yield is not such an important matter as the quality of the final product obtained. Accumulated experience seems to show that the quality and yield of the final concentrate obtained by the subsequent steps of the process vary inversely with the percentage of the original vitamin present at the 50% alcoholic solution stage. The most active concentrate which has so far been made was obtained from an alcoholic solution in which there was only about 5% of the antineuritic vitamin of the yeast from which it was prepared. Apparently the removal of inactive constituents can be effected only with simultaneous considerable losses of the active compound, especially in the earlier stages of the process.

Benzoylation and Acetone Precipitation of the Salts.—The 5 to 12 liter quantities of alcoholic vitamin solution obtained by the procedure described above were usually divided into three equal portions and these separately distilled down and benzoylated. In the case of Experiments 23, 24 and 25 it was observed that the final products obtained from the three fractions of each of these solutions differed considerably in activity even though the benzoylation and acetone precipitations were conducted as nearly alike as possible. In an attempt to ascertain the effects of slight variations of reagents and technique upon the character of the final product, a series of experiments was made with the alcoholic solutions obtained in Experiments 27–31. Each of these was divided into three equal portions which were separately distilled to small volumes. They were each centrifuged to remove slight amounts of insoluble material, and the clear supernatant solutions diluted with water to the volumes shown in Table II. The quantities of sodium carbonate and benzoyl chloride recorded in the table were quickly added and the mixtures stirred with a thermometer. The highest temperature reached during the reaction was noted and about an hour allowed for the mixtures to cool. They were then extracted with chloroform and the resulting aqueous layers poured slowly into 10–15 times their volume of acetone. The weights of the precipitated salts and their nitrogen contents are recorded in the table.

Extraction and Acetone Precipitation of the Vitamin Concentrate.—The vitamin salts were extracted by rotating for twenty-four hours with a mixture of three volumes of normal propyl alcohol and one volume of concentrated hydrochloric acid, using about 3 cc. of this mixture per 1.0 g. of salts. The extract was separated by centrifugation and the residue extracted a second time in the same manner. The two extracts were distilled under diminished pressure to about 50 cc. This concentrated liquid was centrifuged to remove a small amount of salts which separate during the distillation. The clear solution was then added dropwise to about 1600 cc. of acetone. The resulting precipitate was separated by centrifugation and dissolved in about 15 cc. of methyl alcohol and this added dropwise to about 800 cc. of acetone. The precipitate is now white and in a voluminous flaky condition. It is centrifuged and then washed with acetone by centrifugation and finally dried in a vacuum. The quantities obtained in the several experiments are shown in Table II.

The activities of the 16 precipitates made in this manner were determined by Dr. M. I. Smith, using his rat method.[5] The activities of the alcoholic vitamin solutions of Experiments 28–31 were also determined in the same manner and found to correspond, respectively, to 116, 83, 55 and 87 thousand vitamin units, or minimum curative doses.

Discussion

An examination of the results in Table II shows that unaccountable variations in the yield and quality of the final acetone precipitate frequently occur. In the case of Experiment 28(a) the yield of vitamin was only about 11%, while in the case of Experiment 31(a) it was about 70%. The only intentional difference in the two cases was that the proportion of

Of the figures in parentheses the first in each experiment shows the ratio of solution to organic solids; the second shows the ratio of sodium carbonate to organic solids, and the third the ratio of benzoyl chloride to sodium carbonate.

sodium carbonate used in the benzoylation was slightly higher in the first case than in the second. A similar diminution with increase of sodium carbonate is noted in Expt. 30(c) but in this case the quality of the final precipitate was not affected but only the quantity obtained. It is apparent that the exact ratio of reagents to organic solids in the solution being benzoylated must be very carefully controlled in order to get the best results. The optimum ratios appear to be approximately seven times as much aqueous solution as there are organic solids, 1.8 times as much sodium carbonate as organic solids and 1.8 times as much benzoyl chloride as sodium carbonate.

The experiments have definitely demonstrated the advantage of higher temperatures for the reaction. In the cases of experiments 28(b) and (c) and 29(a) the mixtures were immersed in ice water to prevent a rise in temperature, and in each case the activity and yield of the final precipitate was of a low order. The effect of higher temperatures than result spontaneously during the reaction has not as yet been studied.

The results in the table also show that the lower the percentage of nitrogen in the precipitated vitamin salts, the higher the activity of the final acetone precipitated vitamin. Attention should therefore be directed continually toward conducting the benzoylation in such a manner that as little nitrogenous material as possible remains in the acetone precipitated salts.

It is noteworthy that the samples of final acetone precipitated vitamin except those from solutions cooled during the benzoylation vary in activity, as measured by minimum curative dose, from 0.03 mg. to 0.3 mg. It will be noted that in general the more active samples have the lower nitrogen content. There is, however, no close parallelism between nitrogen content and activity. Hence, considerable amounts of non-vitamin nitrogenous compounds are probably still present even in the more active samples.

In conclusion, attention is directed to the fact that the procedure here described does not involve the use of any of the precipitating agents which form so important a part of most other methods for the concentration of the antineuritic vitamin. Even without the use of platinum precipitation, a concentrate distinctly more active than the crystals made with such extraordinary expenditure of effort by Jansen and Donath has been obtained. Furthermore, fairly large quantities may be prepared. Under favorable conditions about 1.0 g. of a product approximately equal in activity to the Jansen and Donath crystals should be obtained from each 10 kg. of dried brewer's yeast. It is hoped that with further intensive study this yield can be increased; also, that it will be possible to prepare considerably larger amounts of the product curative in 0.03-mg. doses which has, so far, been obtained only once.

Summary

The procedure involving adsorption of the antineuritic vitamin upon fuller's earth and subsequent extraction, benzoylation and acetone precipitation has yielded, without the use of any precipitating agents, final products the most active of which was curative in 0.03-mg. doses, by the Smith rat method. This is an activity about one-fourth greater than that of the jansen and Donath crystals. It is more than twice as great on the nitrogen basis. Products of somewhat lower activity were obtained in considerably larger yields. Apparently small variations of conditions at certain stages of the process may affect greatly the quantity and quality of the final product. Especial attention has been given to the effect of variation of ratio of the benzoylating reagents and of the temperature of the reaction upon the quality and yield of the final concentrate.

NEW ALKAMINES IN THE TETRAHYDRONAPHTHALENE SERIES[1]

BY ERICH MOSETTIG AND ALFRED BURGER

RECEIVED MARCH 27, 1931 PUBLISHED JUNE 8, 1931

In the classic investigations of partially hydrogenated naphthalene derivatives carried out by Bamberger[2] over forty years ago, the fact was established that alicyclic β-tetrahydronaphthylamine and its derivatives exert to a considerable degree a specific pharmacological action. After studying a number of compounds, Bamberger stated the rule that this property is exhibited only when the substituted nucleus is hydrogenated, and only when the basic substituent occupies the 8-position. In more recent years, this observation was confirmed through the investigations of von Braun[3] on alicyclic amino alcohol derivatives of tetrahydronaphthalene. He was able to show that only compounds of type I have pharma-

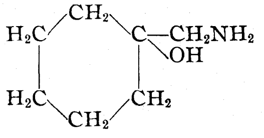
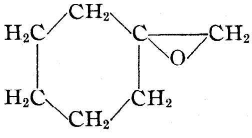
cological properties resembling those of alicyclic β-tetrahydronaphthylamine, whereas derivatives of type II are comparatively inactive. The P-position of the basic group in these cases is likewise the deciding factor.

In an earlier paper[4] we described attempts to synthesize hydroaromatic alkamines of type III which had their starting point in the oxide IV,



III



IV

but which as practicable synthetic methods were unsuccessful, since the reaction of diazomethane on cyclohexanone, used for the preparation of IV, ran chiefly to ring enlargement, giving cycloheptanone and cyclooctanone. At that time the surmise was made that the corresponding naphthalene derivatives, *a*- and β-ketotetrahydronaphthalene, because of the linkage of the hydrogenated ring to an aromatic nucleus, would show far less tendency to undergo ring enlargement.

Of the isomeric ketotetrahydronaphthalenes, only β-tetralone can be induced to react with diazomethane; a-tetralone is indifferent toward this reagent. This is in general accord with the observations of von Braun and others[3] on the remarkable differences in the activity of the two tetralones. We need mention here only the relative instability of β-tetralone, and the unexplained blue color which results when this compound is exposed to atmospheric oxygen in the presence of alkali.[5] The behavior of the two ketones toward sodium bisulfite differs also; only the @-isomergives a bisulfite compound. We believe that'an analogy for this is to be found in the case of mixed aliphatic–aromatic ketones. Whereas ketones of the type $ArCOCH_3$ do not, in general, give bisulfite addition products, benzyl methyl ketones, the so-called @-ketonesof the type $ArCH_2COCH_3$, in most cases do so. In a recent investigation of ketones of this type[6] the conclusion was drawn that if a ketone forms a bisulfite compound it may be expected to react with diazomethane. The behavior of a- and β-tetralone toward diazomethane and sodium bisulfite gives additional support to this conclusion.

When carefully purified β-tetralone is acted upon by diazomethane in ether–methanol mixture, a product containing an additional $-CH_2-$ group and showing none of the properties of a ketone results. It is characterized as an ethylene oxide derivative by its facile conversion to amino alcohols. Arndt, Meerwein and Mosettig (for a bibliography, see the paper

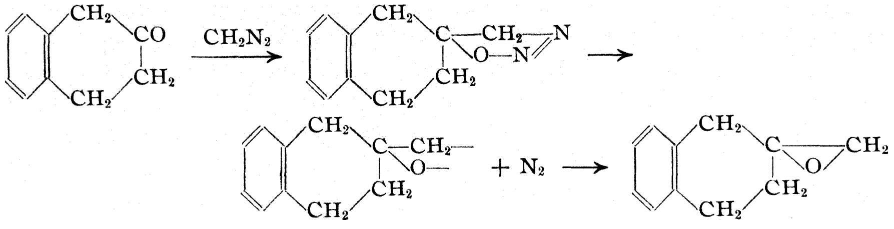
---

[4] Mosettig and Burger, THIS JOURNAL, 52, **3456** (1930).

[5] We have found that this color appears also in the presence of ammonia and amines, as dimethylamine, diethylamine or piperidine.

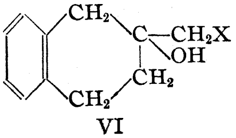
[6] Mosettig and Jovanovif. ***Monatsh..*** 53 and 54. 427 (1929).

of Mosettig and Burger, Ref. 4) have investigated thoroughly in recent years the reaction of diazomethane with carbonyl compounds, and according to their formulation the reaction under discussion may be represented as



V

where Formula V depicts the oxide obtained as the end-product. Reasoning from analogy and from the general rule that addition of amines to ethylene oxides results in an hydroxyl group on the carbon atom carrying the least hydrogen, we believe that the amino alcohols formed by addition of amines to V must have the formula VI.

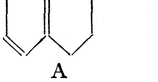


VI

$X = -N(CH_3)_2, -N(C_2H_5)_2, -NC_5H_{10}$

The oxide (V) derived from 8-tetralone could not be purified for analysis, and the dimethylamino-, diethylamino- and piperidino alcohols from it, which do not crystallize, were characterized and analyzed as the well-crystallized hydrochlorides, perchlorates and platinichlorides. It is possible that isomers of these amino alcohols, formed by addition of the amines to the oxide in the alternative way, are present in the reaction mixture, and the formation of homologs, from a theoretically possible homologous oxide, is not excluded. The mother liquors from the crystalline salts of all of these amino alcohols yielded oily fractions in considerable quantity, but in only one case (that of the dimethylamino alcohol) could a second amino alcohol be isolated in the form of well-defined salts.

In addition to the oxide (V), the reaction of diazomethane with β-tetralone gives about a 30% yield of a yellow oil which has the properties of neither a ketone nor an ethylene oxide. The substance is free from nitrogen and is monomolecular, but analytical values, which do not correspond to any plausible empirical formula, are not significant, since in spite of the narrow boiling range observed we cannot be sure that only one compound is present. The oil has an agreeable odor, recalling that of 8-naphthol methyl ether. The methoxyl determination and hydrogenation experiments were negative, which together with the high boiling point, 137–139° (1 mm.), excludes the possibility that the indifferent compound is the methyl ether



A

of the enolic form of 8-tetralone, b. p. 136° (15 mm.) (A), which has been prepared by von Braun.[7] We are at present able to make no conjecture as to the nature of the indifferent by-product.

The reaction of diazoethane with β-tetralone proceeds much more vigorously than that of diazomethane, but yields nevertheless more than half of the p-tetralone unchanged. The rest of the reaction mixture consists of a high-boiling, rather unstable, strongly colored oil, which could not be purified. The crude reaction mixture, which was believed to contain an ethylene oxide type, was treated with piperidine in an unsuccessful attempt to isolate amino alcohols. In this experiment the interesting observation was made that β-tetralone forms an addition product with piperidine on gentle warming. The addition compound is unstable and decomposes slowly on standing into its components, p-tetralone and piperidine. The decomposition, which also takes place in dilute hydrochloric acid solution, is accelerated by heating.

a-Tetralone does not give such an addition product with piperidine.

The new alicyclic alkamines from tetrahydronaphthalene described in this paper have been prepared preliminary to an extension of the synthetic method to analogous compounds involving higher ring systems. According to Bamberger's rule mentioned above, the amino alcohols prepared from p-tetralone should have a marked pharmacological action. The pharmacological report on these substances will be published (C. W. Edmunds and N. B. Eddy) from the Medical School of the University of Michigan.

Experimental Part

β-Tetralone (1,2,3,4-Tetrahydro-2-ketonaphthalene) and Diazomethane.—β-Tetralone was prepared by heating the methiodide of 1-dimethylamino-2-hydroxy-1,2,3,4-tetrahydronaphthalene according to the directions of von Braun.[8] The product obtained gave a semicarbazone which melted at 194–195° on rapid heating, 189–191° on slow heating (v. Braun gives m. p. 190–191°).

The p-tetralone, which cannot be kept unchanged for any length of time, was converted to the bisulfite compound, which was washed with ether and kept in a glass-stoppered bottle The free ketone was liberated from the bisulfite compound with sulfuric acid, just before using.

Twenty-five grams of β-tetralone was prepared by decomposition of the bisulfite compound and distilled in a vacuum, b. p. 142° (15 mm.). It was added to a solution of 15.2 g. of diazomethane (i.e., a little over two molecular equivalents) in 660 cc. of ether at —5". After addition of 200 cc. of absolute methyl alcohol, the mixture was allowed to stand at room temperature and soon began to evolve nitrogen vigorously. After the solution had stood for thirty-six hours, the ether was removed on a steam-bath and the methyl alcohol was distilled off under reduced pressure at 25–30'. The residue was purified by distillation in a vacuum. It boiled between 123–140° at 1 mm. pressure, the main portion distilling at 137–138°. The distillate consisted of 24 g. of a yellow oil The residue from the distillation was a reddish-brown resinous tar.

---

[7] Von Braun and Weissbach, Ber., 63, 3055 (1930).

[8] Von Braun. Braunsdorf and Kirschbaum, *ibid.*, 55, 3659 (1922).

In another run with 74 g. of β-tetralone and 47 g. of diazomethane in 2560 cc. of ether and 500 cc. of methyl alcohol, 68 g. of the yellow distillate was obtained, of which 63 g. boiled from 135–145° at 6 mm. pressure. In this case relatively more of the non-distillable resinous substance remained in the flask.

The yellow oil gave neither a semicarbazone nor a bisulfite compound. It showed a more or less pronounced color reaction when treated with a dilute solution of alkali or strong amines. The solution turned blue although no β-tetralone could be shown to be present in the mixture. The oxide (V) formed about two-thirds of this oil, from which it could be removed by treating with amines as described below. The indifferent part (35 to 36% of the whole weight of the oil) was purified by repeated distillation. The final distillate was a yellow oil of b. p. 137–139° (1 mm.).

Amino Alcohols from the Oxide V

General Preparative Method.—These amino alcohols were prepared by heating the crude oxide with 10% more than the calculated amount of the amines (dimethylamine, diethylamine, piperidine, respectively) and the same weight of water in a sealed tube at 95–100° for five hours. The reaction mixtures were taken up in ether and washed with water to remove most of the unchanged amine. The amino alcohols were extracted with dilute hydrochloric acid from the ethereal solution, precipitated with alkali and taken up again in ether. The ethereal solution was dried and the solvent evaporated. The residues distilled in a vacuum as almost colorless oils. The original ethereal layer contained the indifferent oil mentioned above.

The oily amino alcohols were dissolved in a little ether and an ethereal solution of perchloric acid was added in small portions. An oil precipitated out which soon crystallized. The addition of perchloric acid was continued until the precipitated salt began to separate as a viscous mass. It was collected on a filter and recrystallized from alcohol-ether. The yield was about half of that expected. These perchlorates were decomposed with a solution of sodium hydroxide, and the free alkamines were taken up in ether. The dried ethereal solution was treated with ethereal hydrochloric acid and the crystalline hydrochloride recrystallized from a mixture of alcohol and ether.

The procedure outlined above was used to obtain pure dimethyl- and diethylamino alcohols, but in the case of the piperidino alcohol it was found advisable to precipitate the hydrochloride first with ethereal hydrogen chloride, interrupting the precipitation as soon as the hydrochloride no longer separated well crystallized. The mother liquors resulting from the perchlorate precipitations described above yielded a further precipitate of an oily perchlorate with more ethereal perchloric acid.[9] Only in the case of the dimethylamino alcohol could this second precipitated fraction be obtained crystalline, and from it other well-crystallized salts of the unidentified (apparently homologous) dimethylamino alcohol, which is listed second in the table, could be prepared.

β-Tetralone and Piperidine.—Four grams of β-tetralone and a solution of 3.2 g. of piperidine in an equal amount of water was heated in a sealed tube to 100° for four hours. The reaction mixture was shaken with ether and the latter washed with water until the aqueous extracts were but faintly blue. The ethereal layer was then rapidly extracted with dilute hydrochloric acid twice. This absolutely clear acid solution becomes turbid after some time. When the acid solution was warmed to 30°, 3 g. of an oil separated

---

[9] The piperidino alcohol hydrochloride mother liquors were made alkaline, extracted with ether, and the extract treated with perchloric acid.

[a] The same yields were obtained when the dimethylamino alcohols were prepared by heating the oxide with a benzene solution of dimethylamine. [b] All hydrochlorides were analyzed by direct precipitation with silver nitrate. [c] All perchlorates were analyzed by the method of Hofmann, *Ber.*, 43, 1080 (1910), fusion with sodium carbonate and determination of halogen. [d] The hydrochloride of the diethylamino alcohol crystallizes from a mixture of ordinary alcohol and ether with one molecule of water of crystallization, which is given off at 92°. The halogen analysis was carried out after drying the substance at 90–95° in a vacuum.

out which was extracted into ether and was identified as pure 8-tetralone (semicarbazone, m. p. 189–190°). The acid solution contained only piperidine.

It was not possible to distil the unstable supposed addition compound under the same conditions as the piperidino alcohols described above, and no analysis could be carried out because of the rapid decomposition which took place even at ordinary temperatures. On distillation the addition compound decomposed into the components, β-tetralone and piperidine.

Summary

A series of new alkamines derived from tetrahydronaphthalene has been prepared for pharmacological study.

The alkamines of Formula  $C_{10}H_{10}\langle^{CH_2X}_{OH}$ (X = $-N(CH_3)_2$, $-N(C_2H_5)_2$, $-NC_5H_{10}$) are formed through addition of secondary amines, as dimethylamine, diethylamine or piperidine, to the ethylene oxide type of compound $\underline{C_{10}H_{10}CH_2O}$ which results from the action of diazomethane on β-tetralone.

THE CLEAVAGE OF BETA DIKETONES. I. CLEAVAGE BY ORGANIC MAGNESIUM COMPOUNDS

BY E. P. KOHLER AND J. L. E. ERICKSON

RECEIVED MARCH 28, 1931 PUBLISHED JUNE 8, 1931

In a recent communication from this Laboratory,[1] it was reported that organic magnesium compounds effect a very characteristic cleavage of α-oxido ketones. We have observed a somewhat similar cleavage of β-diketones. In a study of the relative activity of the three carbonyl groups of diphenylpropane trione, we added this substance to phenyl magnesium bromide in the usual manner and obtained benzoin and triphenyl carbinol. Manifestly, these products are due to cleavage, and from the formation of triphenyl carbinol it is evident that this cleavage is anterior to the final decomposition of the magnesium derivatives with acids.

From general considerations as well as from the results published by Neufville and v. Pechmann,[2] it appears probable that the central carbonyl group in the triketone is much the most active of the three. If this is really the case, then the primary reaction between the triketone and phenyl magnesium bromide would be expected to yield phenyl dibenzoyl carbinol, a very interesting disubstitution product of a β-diketone. In the hope of discovering some means of confining the process to this first stage, we decided to make a more careful examination of the action of organic magnesium compounds on other β-diketones.

Surprisingly few β-diketones have heretofore been treated with Grignard reagents. Zelinsky[3] added acetylacetone to methyl magnesium iodide and observed a vigorous reaction, but he obtained only a very small quantity of a product, of which he states, merely, that it boiled at 101–102° under 15 mm., and that its composition corresponded approximately to $C_7H_{16}O_2$. Zerewitinoff[4] announced later that the diketone liberates one mole of methane from a solution of methyl magnesium iodide in isoamyl ether; he made no attempt to isolate any products.

More definite results were reported by Smedley,[5] who added dimethyl dibenzoylmethane to methyl magnesium iodide. She concluded that the reagent combined with each of the carbonyl groups, and that the final product was the ditertiary alcohol which would be expected as the result of such a process—$C_6H_5(CH_3)COHC(CH_3)_2C(OH)(CH_3)C_6H_5$. There is no evidence in support of these conclusions.

The only other open chained β-diketone that has been treated with a

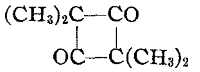
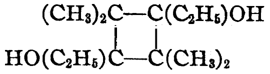
Grignard reagent is dibenzoyl methane. Vorlander, Osterburg and Meye[6] added this diketone to phenyl magnesium bromide and proved, conclusively, that when the resulting magnesium compound was acidified, the product was β-hydroxy-β,β-diphenyl propiophenone. They, therefore, wrote the equation

$$C_6H_5COCH_2COC_6H_5 + C_6H_5MgBr \longrightarrow (C_6H_5)_2C(OMgX)CH_2COC_6H_5$$

In addition to these open chained compounds one cyclic 8-diketone of an unusual type has been examined. Wedekind and Miller[7] added tetramethyl cyclobutanedione to an excess of ethyl magnesium bromide and obtained, in almost the calculated quantity, the corresponding ditertiary alcohol





If one were to judge from these meager reports one would have to conclude that the reaction between 8-diketones and organic magnesium compounds is relatively simple and uniform—far more uniform than would be expected from the varied results that have been obtained from β-ketonic esters. In reality it is neither simple nor uniform, as may be seen from the following list of diketones and the final products which we obtained from them.

I	$C_6H_5COCH_2COC_6H_5$	$(C_6H_5)_2C(OH)CH_2COC_6H_5$
II	$CH_3COCH_2COCH_3$[a]	$(CH_3)_2C(OH)CH_2COCH_3$
III	$C_6H_5COCH(C_6H_5)COC_6H_5$	$C_6H_5COCH_2C_6H_5 + (C_6H_5)_3COH$
IV	$C_6H_5COCH(CH_3)COC_6H_5$	$C_6H_5COCH_2CH_3 + (C_6H_5)_3COH$
V	$CH_3COC(CH_3)_2COCH_3$	$CH_3COCH(CH_3)_2 + (C_6H_5)_2(CH_3)COH$
Va	$CH_3COC(CH_3)_2COCH_3$[b]	$CH_3COCH(CH_3)_2 + CH_3COC_6H_2(CH_3)_3$
VI	$C_6H_5COC(CH_3)_2COC_6H_5$	$C_6H_5COCH(CH_3)_2 + (C_6H_5)_3COH$
VII	$C_6H_5COCHBrCOC_6H_5$	$C_6H_5COCH_2COC_6H_5$
VIII	$C_6H_5COCBr_2COC_6H_5$	$(C_6H_5)_2COHCHBrCOC_6H_5$
IX	$C_6H_5COCOCOC_6H_5$	$C_6H_5COCHOHC_6H_5 + (C_6H_5)_3COH$

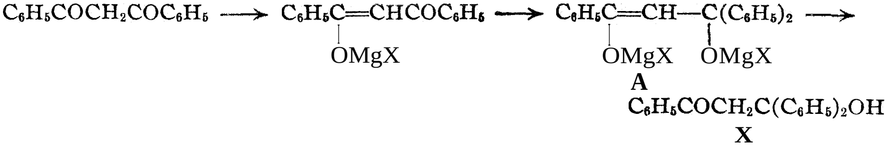
[a] With methyl magnesium iodide. [b] With mesityl magnesium iodide.

An examination of this list shows that relatively normal products are obtained from those compounds only which are largely or entirely enolic. Even in the case of these substances the reaction is not quite as simple as it was formulated by Vorlander and his collaborators, because quantitative determinations show that they react with two moles of reagent and liberate a mole of gas. When they are added to but one equivalent of reagent, half of the material is recovered unchanged, and when, inversely, one equivalent of reagent is added to the substance, **all** of the latter is recovered. The reaction with phenyl magnesium bromide must therefore be represented as follows

---

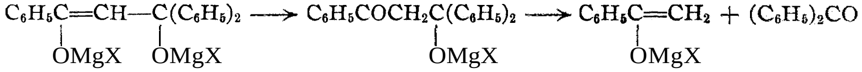
[6] **Vorländer,** Osterburg and **Meye, Ber.,** 56, 1136 **(1923).**

[7] Wedekind and Miller, *ibid.,* 44,3285 (1911).



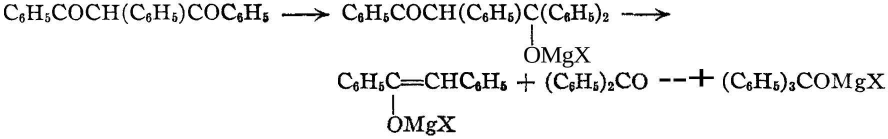
$$C_6H_5COCH_2COC_6H_5 \longrightarrow \underset{\displaystyle OMgX}{C_6H_5C}{=}CHCOC_6H_5 \longrightarrow \underset{\underset{\displaystyle \mathbf{A}}{}}{\underset{\displaystyle OMgX}{C_6H_5C}{=}CH{-}\underset{\displaystyle OMgX}{C}(C_6H_5)_2} \longrightarrow \underset{\displaystyle \mathbf{X}}{C_6H_5COCH_2C(C_6H_5)_2OH}$$

In the case of these highly enolized β-diketones the outcome is quite definite it is not possible to add more than one equivalent of the reagent, and no cleavage occurs anterior to the decomposition of the resulting magnesium derivatives with acids. It is necessary, however, to exercise great care in acidifying these magnesium derivatives, because they can pass into intermediate monomagnesium compounds that undergo cleavage with ease



$$\underset{\displaystyle OMgX}{C_6H_5C}{=}CH{-}\underset{\displaystyle OMgX}{C}(C_6H_5)_2 \longrightarrow C_6H_5COCH_2\underset{\displaystyle OMgX}{C}(C_6H_5)_2 \longrightarrow \underset{\displaystyle OMgX}{C_6H_5C}{=}CH_2 + (C_6H_5)_2CO$$

The situation is quite different in the case of the mono- and disubstitution products of these simple diketones. The monosubstitution products are too little enoliied or too feebly acidic to form copper derivatives with copper acetate; they liberate only traces of gas from methyl magnesium iodide; they nevertheless consume two equivalents of the reagent.[8] Here the first step is the addition of the reagent to one of the carbonyl groups. The resulting magnesium derivative is unstable and it decomposes in a manner that is essentially the same as that of the magnesium compounds which are formed from α-oxido ketones. The entire process, then, must be represented as follows



$$C_6H_5COCH(C_6H_5)COC_6H_5 \longrightarrow C_6H_5COCH(C_6H_5)\underset{\displaystyle OMgX}{C}(C_6H_5)_2 \longrightarrow \underset{\displaystyle OMgX}{C_6H_5C}{=}CHC_6H_5 + (C_6H_5)_2CO \longrightarrow (C_6H_5)_3COMgX$$

The extent of this kind of cleavage, and the ease with which it takes place, naturally vary with the stability of the first magnesium derivative. From the products which have been obtained with dialkyl acetacetic esters,[9] it is reasonable to infer that cleavage is less likely to occur with alkyl than with phenyl magnesium halides, and our experiments with β-hydroxy-β,β-diphenyl propiophenone show that it also takes place less readily with compounds that have less highly branched chains. These experiments with the hydroxy ketone are of special interest because in contrast with the dibenzoyl methane from which it is obtained, it can form the type of magnesium derivative that may cleave

$$C_6H_5COCH_2C{-}(C_6H_5)_2OH \longrightarrow C_6H_5COCH_2C(C_6H_5)_2OMgX$$

[9] Slavjanoff, J. *Russ. Phys.-Chem. Soc.*, 39,140 (1907).

According to Vorlander and Meye,[10] the hydroxy ketone does not react with phenyl magnesium bromide; but they must have been deceived by the similarity in the melting points of the hydroxy ketone and that of one of the products of the reaction. In reality the substances react with great ease. One of the products is triphenyl carbinol, which shows that the magnesium compound B undergoes the usual cleavage; but in addition to this there is formed an equal quantity of the dihydroxyl compound, $(C_6H_5)_2COHCH_2COH(C_6H_5)_2$ (XI).

At times it is possible to avoid cleavage almost entirely by operating at a sufficiently low temperature. Thus by proceeding in the reverse of the usual manner, adding phenyl magnesium bromide cautiously to phenyl dibenzoyl methane while the temperature was kept below -10° and acidifying without delay, it was possible to secure a fair yield of tetraphenyl propenone—the dehydration product of the corresponding tertiary alcohol.

$$C_6H_5COCH(C_6H_5)C(C_6H_5)_2OMgX \longrightarrow C_6H_5COCH(C_6H_5)C(C_6H_5)_2OH \longrightarrow C_6H_5COC(C_6H_5){=}C(C_6H_5)_2$$

XII

As would be expected from the foregoing analysis, 8-diketones which have two substituents in the methylene group behave precisely like those which have but one. Smedley's conclusions are not in agreement with this view, but we are convinced that she was misled by her results. She subjected her product to distillation under diminished pressure and analyzed a fraction boiling at 120–125° under 55 mm. This is manifestly far too low a boiling point for the ditertiary alcohol $C_6H_5(CH_3)COHC(CH_3)_2C(OH)(CH_3)C_6H_5$. According to our interpretation, this reaction would be expected to yield the cleavage products dimethyl acetophenone and phenyl methyl carbinol. Since these substances have approximately the boiling point given by Smedley, it seems likely that she analyzed a mixture that happened to have the same composition as the ditertiary alcohol. We treated the same diketone with phenyl magnesium bromide and obtained only cleavage products.

The bromine substitution products are exceptions. They undergo the peculiar reaction of α bromo ketones which was reported many years ago by Kohler and Johnstin,[11] and which has since been observed by others.[12] The mechanism of this reaction will be considered in a later paper.

In the light of the foregoing results it is not difficult to follow the course of the reaction between phenylmagnesium bromide and diphenyl propanetrione. The most active carbonyl group combines with a molecule of the

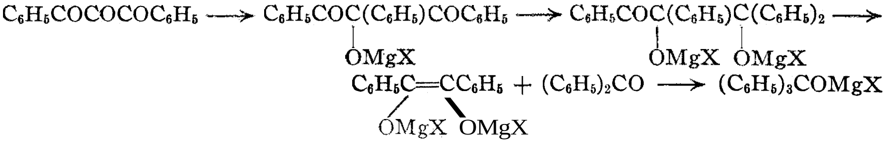
reagent and the addition product behaves like any other disubstituted β-diketone



$$C_6H_5COCOCOC_6H_5 \longrightarrow C_6H_5CO\underset{OMgX}{C}(C_6H_5)COC_6H_5 \longrightarrow C_6H_5CO\underset{OMgX}{C}(C_6H_5)\underset{OMgX}{C}(C_6H_5)_2 \longrightarrow$$

$$C_6H_5\underset{OMgX}{C}{=}\underset{OMgX}{C}C_6H_5 + (C_6H_5)_2CO \longrightarrow (C_6H_5)_3COMgX$$

In *a* preliminary attempt to isolate the carbinol corresponding to the intermediate magnesium compound the reagent was added to the triketone at a low temperature and the resulting magnesium derivative was decomposed immediately. The product was a crystalline solid which had the composition of phenyl dibenzoyl carbinol XIII, but which proved to be the benzoate of benzoin XIV.

Experimental Part

Since many of the diketones on the list were examined by the same general procedure, it is not necessary to describe the experiments with each of these substances in detail. Experimental details will be given, therefore, only in those cases in which a special procedure was adopted or in which the reaction resulted in the formation of compounds which were not known heretofore.

The general method of procedure was to add either the diketone itself or its ethereal solution to a large excess of the Grignard reagent, warm for a few minutes to complete the reaction, decompose the magnesium derivatives either with ice and dilute acid or ice and ammonium chloride, and separate the products by whatever method seemed best.

Dibenzoyl Methane, I.—Since Vorländer and Meye's equation[e] accounts neither for the gas evolved when the diketone reacts with methyl magnesium iodide, nor for the fact that, unlike its alkyl substitution products, it is not cleaved by Grignard reagents, it was necessary to reexamine the behavior of this substance toward Grignard reagents. The true course of the reaction was established by means of three experiments with phenyl magnesium bromide.

In the first experiment the reagent was added gradually to a slight excess of the diketone, the mixture was boiled for an hour, then decomposed with iced acid in the usual manner. Of the 10 g. of diketone used all but 0.35 g. was recovered. After removing the last of the diketone in the form of its copper derivative, there remained a few drops of oil, but no triphenyl carbinol could be detected in this residue. The first step in the reaction, therefore, is the formation of the magnesium bromide derivative of the enol, and even Prolonged boiling does not result in cleavage at this stage.

In the second experiment the operation was reversed, the diketone being added to an excess of reagent. On prolonged boiling this mixture gradually deposited a gray crystalline magnesium derivative. This was collected, washed with ether, and decomposed with iced acid; it gave mainly β,β-diphenyl-β-hydroxy propiophenone (X), the substance previously obtained in the same manner by Vorländer and Meye. Some more of this hydroxyl compound was also obtained on acidifying the filtrate from the solid magnesium compound, making a total yield of 82%. The oily residue from the hydroxy ketone was composed of acetophenone—which was removed by oxidation—and benzophenone, which was separated by distillation with steam. These are decomposition products of the unstable hydroxy ketone. Since no triphenyl carbinol could be detected, there was no cleavage during the Grignard reaction.

In the last experiment **20** g. of the hydroxy ketone X was added to a solution of phenyl magnesium bromide which had been prepared from **7.0** g, of magnesium. The solid ketone was added at a rate that kept the liquid boiling gently and the mixture was boiled for fifteen minutes after all the solid had been added. The magnesium derivatives were decomposed with iced acid, and the ethereal layer washed and dried in the usual manner. After concentration, and dilution with petroleum ether, it first deposited several crops of triphenyl carbinol **(9.2 g.)** and then **7.4** g. of a different product melting at **121–123°.**

The lower melting product was purified by recrystallization from ether and petroleum ether from which it separated in flat prisms.

Anal. Calcd. for $C_{27}H_{24}O_2$: C, **85.3;** H, **6.3.** Found: C, **85.9;** H, **6.2.**

In the machine the substance consumed approximately two moles of methyl magnesium iodide and liberated two moles of methane; it is therefore a dihydroxyl compound. A similar substance was obtained by Berberianu[13] by the action of phenyl magnesium bromide on β-hydroxy-β,β-diphenyl propionic ester. After recrystallization from alcohol our product, like Berberianu's, melts at **104°,** loses alcohol at the melting point, then resolidifies and melts again at a higher temperature.

Oxidation.—To a solution of **1** g. of the substance in glacial acetic acid was added a solution of **1** g. of chromic acid in an equal weight of water. The mixture was warmed on a steam-bath for an hour, then diluted with water, neutralized and distilled with steam. From the distillate ether extracted **0.93** g. of pure benzophenone instead of **0.96** g. calculated on the assumption that the substance is tetraphenyl propanediol (XI).

Acetylacetone. 11.—Our general procedure probably differed from that of Zelinsky[3] only in the care with which we acidified. We dribbled our magnesium compound into a mixture of ice and concentrated hydrochloric acid which was stirred vigorously and then maintained at a temperature of about $-20°$. The product was isolated by distillation under diminished pressure, and identified as diacetone alcohol by its boiling point, its composition and its conversion into mesityl oxide. The yield was 92%.

Phenyl Dibenzoyl Methane, 111.—The products obtained by the usual procedure were desoxybenzoin and triphenyl carbinol. These substances were separated by crystallization from mixtures of ether and petroleum ether and identified by comparison with authentic samples. In an "inverse Grignard reaction" an ethereal solution of phenyl magnesium bromide prepared from **0.6** g. of magnesium was added gradually to a suspension of **3.0** g. of the diketone in ether which was kept at $-10°$ by means of a freezing mixture. When the resulting solution was added to iced acid it deposited a very sparingly. soluble crystalline solid. After washing with alcohol and ether, the solid melted sharply at **150°.** It was identified as tetraphenyl propenone (XII) by comparison with a sample on hand. The yield was **67%.**

Methyl **Dibenzoylmethane, IV.—The** ethereal solution of the products was concentrated, then gradually diluted with petroleum ether until it deposited nearly all of the triphenyl carbinol. The residue on distillation yielded an oil boiling at 210–215°. When this oil was treated with semicarbazide it formed the semicarbazone of propiophenone melting at **177–178".**

---

[13] **Berberianu, *Chem. Abstracts,*** 8, **1423 (1914)**

Dimethyl Acetylacetone, V.—Combes' method of preparing dimethyl acetylacetone by heating the sodium derivative of acetylacetone with methyl iodide in a sealed tube to 130°[14] is not very satisfactory. Better yields and a purer product were obtained in the following manner. To a boiling solution of 20 g. of acetylacetone and 71 g. of methyl iodide in absolute methyl alcohol was added, slowly, a solution of sodium methylate containing 9.2 g. of sodium. The solution was stirred continuously during the addition of the methylate and boiled for half an hour after all had been added. Most of the methyl alcohol was then removed by distillation under diminished pressure, and enough water was added to the residue to dissolve the sodium iodide. The aqueous solution was thoroughly extracted with ether, the ethereal solution dried over calcium chloride and evaporated.

The residue was an oil which when it was distilled under diminished pressure boiled at 69" under 12 mm. and gave a distillate that immediately solidified, giving a mass of colorless crystals melting at 21°, and having an odor resembling that of camphor. The yield was 50%.

Action of Phenyl Magnesium Bromide.—The etheral solution of the product, which was obtained in the usual manner, was dried and evaporated until almost free from ether. The residue, on dilution with a small quantity of petroleum ether, deposited a crystalline solid which melted at 81°. When this was mixed with a sample of diphenyl methyl carbinol prepared by the action of phenyl magnesium bromide on acetophenone it caused no depression of the melting point. The yield was almost quantitative.

Action of Mesityl Magnesium Bromide.—In order to prove definitely that the cleavage of the diketones occurs at the same stage as that of the oxides, dimethyl acetylacetone was also treated with mesityl magnesium bromide. The product, isolated by fractional distillation under diminished pressure, was an oil which distilled at 110–111° under 10 mm.; yield, 6 g. from 10 g. of the diketone.

For the purpose of identification 2 cc. of a 10% solution of sodium methylate was added to a methyl alcoholic solution of 0.7 g. of the oil and 0.8 g. of m-nitrobenzaldehyde. The solution was boiled for a few minutes, then diluted with enough water to produce a slight turbidity and set aside. It deposited a golden-yellow solid which, after recrystallization, melted at 82°. For comparison a sample of m-nitro benzal acetomesitylene was prepared in the same manner from acetomesitylene. The two preparations, and a mixture of both, melted at the same temperature.

Anal. Calcd. for $C_{18}H_{17}O_3N$: C, 73.2; H, 5.8. Found: C, 73.5; H, 6.0.

Dimethyl Dibenzoyl Methane, VI.—Since Smedley had reported that this diketone adds methyl magnesium iodide to form a product similar to that which is obtained from dibenzoyl methane itself, we carried out the reaction with phenyl magnesium bromide at −10°, and decomposed the resulting magnesium compounds with especial care. But when the concentrated ethereal solution of the products was cautiously diluted with petroleum ether, it deposited almost the calculated quantity of triphenyl carbinol. The mother liquor, on distillation, yielded an oil that boiled between 210–220°, and formed an oxime which melted at 59-60'—the melting point of the isobutyrophenone oxime.

Wieland and Bloch's[15] method for the preparation of diphenyl triketone, using dibenzoyl methane and nitrogen tetroxide was tried but abandoned in favor of the older method of Neufville and v. Pechmann,[16] which gave better yields and a purer product. This method involves the following steps

---

[14] Combes and Combes, *Bull. soc. chim.*, [3] 7, 783 (1892).

[15] Wieland and Bloch, *Ber.*, 37, 1524 (1904).

[16] Neufville and v. Pechmann, *ibid.*, 23, 3379 (1890).

$$C_6H_5COCH_2COC_6H_5 \longrightarrow \underset{A}{C_6H_5COCHBrCOC_6H_5} \longrightarrow \underset{B}{C_6H_5COCH(OCOCH_3)C_6H_5} \longrightarrow$$

$$\underset{C}{C_6H_5COCBr(OCOCH_3)C_6H_5} \longrightarrow \underset{IX}{C_6H_5COCOCOC_6H_5}$$

The bromination of dibenzoyl methane was conducted essentially as described by v. Pechmann. The yield was 236 g. of bromo compound from 224 g. of the diketone, equivalent to 78%. For the purpose of preparing the acetate, 106 g. of the bromo ketone was added to a solution of 49 g. of freshly fused potassium acetate in 400 cc. of glacial acetic acid. The mixture was boiled for forty-five minutes, after which time the transformation was found to be complete. To the clear liquid enough water to produce turbidity was added while the solution was stirred continually and allowed to cool. It first deposited an oil which in a short time solidified to a brown mass, then colorless needles which filled the liquid. The solid was collected, washed, and recrystallized from methyl alcohol. It was then obtained in snow white crystal melting at 94". The yield was 78.5 g. or 79%.

Bromo Dibenzoyl **Carbinol** Acetate, C.—The bromination of the acetate was carried out in a manner similar to that of dibenzoyl methane. It is important to cool the solution well, to add the bromine very slowly, and to stir constantly to avoid local rise in temperature. To a solution of 77 g. of the acetate in 400 g. of chloroform was added in the course of three hours 44 g. of bromine. A stream of dry air was then passed through the solution to remove the hydrogen bromide as completely as possible.

The bromo compound may be isolated by allowing the solution to evaporate, washing the residue with alcohol and recrystallizing it from chloroform and petroleum ether; but for the purpose of making the triketone it was more convenient to operate directly with the chloroform solution as it is left after the bromination. This solution was concentrated, then transferred to a Claisen distilling flask and freed from chloroform by distillation. The flask was then heated at about 120° until the bromo acetate had decomposed and all of the acetyl bromide had distilled. The residue, which was almost pure triketone, was then distilled under diminished pressure. It was collected as a brown oil which promptly solidified to a golden-yellow crystalline mass.

The average yield of pure, redistilled triketone, boiling at 179–181° under 4 mm., was 50 g. from 77 g. of the acetate. The triketone may be recrystallized from boiling petroleum ether which has been distilled from phosphorus pentoxide. It separates in golden-yellow needles melting at 69–70". As it is extremely hydroscopic and in the air rapidly becomes coated with the white hydrate, it must be kept in a vacuum desiccator or in sealed tubes.

Reaction **with Phenyl** Magnesium Bromide.—An ethereal solution of phenyl magnesium **bromide** was prepared in the usual manner from 11.8 g. of magnesium. Meanwhile diphenyl triketone was distilled into a cylindrical dropping funnel provided with a side tube by means of which it could be connected with the distilling flask while the apparatus was exhausted through the top of the funnel. After collecting 14.5 g. of the triketone in this receiver, ether was distilled into it from the Grignard solution. In this manner it was possible to secure a solution in perfectly dry ether and in an apparatus that was convenient for the next step in the operation.

From the modified dropping funnel the ethereal solution of the triketone was added to the solution of phenyl magnesium bromide in the course of half an hour. Each drop produced a slight yellow precipitate which immediately redissolved. The mixture was boiled for an hour, then cooled and decomposed with ice and ammonium chloride. The ethereal layer was dried and concentrated. It gradually deposited crystals which melted at 131° and which were identified as benzoin by analysis and by a mixed melting point.

The mother liquor was evaporated to small volume and diluted with petroleum ether—it deposited a second crop of crystals which after recrystallization melted at 159° and which were identified as triphenyl carbinol. The yield of pure triphenyl carbinol was **9.8** g. or 62%. The same products were obtained when the magnesium derivatives were decomposed with iced acid.

Action of One Mole of Phenyl Magnesium Bromide. Inverse **Grignard** Reaction.—A solution of phenyl magnesium containing **1.82** g. of magnesium was added. gradually, to an ethereal solution of **14.30** g. of diphenyi triketone which was stirred rapidly throughout the operation. As each drop was added an insolubie magnesium compound was precipitated as a yellow solid. The mixture was decomposed with ammoniacal ammonium chloride and the ethereal solution was washed and dried in the usual manner. It yielded a colorless crystalline compound which melted at **123–124°.**

Anal. Calcd. for $C_{21}H_{16}O_3$: C, 79.7; H, 5.1. Found: C, **79.8;** H, **5.1.**

The substance has the composition of phenyl dibenzoyl carbinol but when it was treated with excess of phenyl magnesium bromide it yielded products that were quite different from those which had been obtained from the triketone. Thus **0.95** g. of the substance was added to an ethereal solution of the bromide made from **0.48** g. of magnesium. The mixture was boiled for fifteen minutes and then decomposed with iced acid. The ethereal layer deposited colorless needles which melted at 164° and which were ultimately identified as triphenyl ethylene glycol by analysis and by comparison with a sample of the glycol that was prepared from benzoin by the method of Acree.[17]

The formation of triphenyl ethylene glycol suggested that our product might be the benzoate of benzoin. This substance was therefore prepared by benzoylating benzoin and a comparison showed that the two products are identical. In order to ascertain whether the benzoate is formed during the Grignard reaction or is the result of a rearrangement of the carbinol by the base used in decomposing the magnesium derivative, the experiment was repeated, but this time the mixture was treated with ice and dilute hydrochloric acid. The result was an oil which after many fractional recrystallizations was separated into benzoic acid and the same benzoin benzoate.

Summary

1. β-Diketones that have no substituents in the methylene group react with two equivalents of phenyl magnesium bromide. The product is a dimagnesium compound which on hydrolysis yields a β-hydroxy ketone.

2. β-Diketones that have one or more substituents in the methylene group likewise react with two equivalents of phenyl magnesium bromide but the result in this case is a mixture of two magnesium compounds, because the process involves a cleavage which is similar to that of oxido ketones.

THE ACETOACETIC ESTER CONDENSATION. III. THE ROLE OF SODIUM IN THE CONDENSATION

BY JOHN M. SNELL AND S. M. McELVAIN

RECEIVED MARCH 30, 1931 PUBLISHED JUNE 8, 1931

Since the discovery,[1] in 1863, that acetoacetic ester is formed by the action of metallic sodium on ethyl acetate, periodic discussions of the role of the metal in the condensation have appeared in the literature. One group of investigators[2] has advanced the idea that sodium is not the direct cause of the condensation but serves only to generate sodium ethoxide, the active condensing agent, from traces of alcohol in the ester or from other side reactions. Another group[3] has maintained that when sodium reacts with the ester it is the metal itself which is directly responsible for the condensation. The main objections to the formulation of sodium ethoxide as the active condensing agent have arisen from the observation that sodium produces higher yields of acetoacetic ester than does sodium ethoxide,[3b,d] and that ethyl acetate from which all alcohol has been carefully removed reacts with sodium just as readily as does ordinary ethyl acetate.[3e]

A previous study[4] of the reaction of sodium with various aliphatic esters has shown that ethyl acetate and ethyl propionate are unique among this type of ester in that they are not converted by sodium into the corresponding acyloins when they are reacted with the metal in the presence of an excess of the ester. Rather, they undergo the acetoacetic ester condensation. Consequently, a study of the role of sodium in the acetoacetic ester condensation of this type of ester must necessarily be restricted to the use of ethyl acetate or ethyl propionate if complications resulting from acyloin formation are to be avoided.

This paper is a report of a study of the reaction of ethyl acetate with sodium in which a careful determination of the amounts of the reaction products, acetoacetic ester, alcohol and hydrogen, has been made. The amounts of these reaction products were determined in the reaction mixture as directly obtained from the reaction of sodium and the ester as well as after the condensation had been driven to completion as far as possible by

the removal of the alcohol produced in the reaction. Similar determinations were made with sodium ethoxide as the condensing agent under comparable reaction conditions. The results which were obtained appear to be strong evidence in favor of Claisen's original postulate that sodium is not the active condensing agent in the acetoacetic ester condensation.

Experimental Procedure and Results

In a 1-liter 3-necked flask fitted with a mercury seal stirrer, a condenser for downward distillation and a coil reflux condenser 20 cm. in length, 11.5 g. (0.5 mole) of sodium was finely powdered by heating under boiling xylene with vigorous stirring. The xylene, after cooling, was removed from the powdered sodium by decantation and the latter washed with dry ether. After pouring off this wash ether the sodium was covered with a considerable excess (2.3 moles) of carefully purified ethyl acetate.[5] The delivery end of the condenser for downward distillation was fitted with a distilling flask as a receiver. By plugging or leaving open the side arm of this receiver the ester in the reaction flask could be caused to reflux from the coil condenser or to distil into the receiver. From the top of the coil reflux condenser a tube was led to the bottom of a tower filled with porous chips which had been soaked previously in concentrated sulfuric acid. From the top of the tower a tube was led to a flask for the collection of the hydrogen evolved in the reaction.

The reaction flask was then heated in an oil-bath with stirring until the ester boiled gently. The reaction appeared to proceed quite slowly for about twenty minutes, but after this time it became so vigorous that it was necessary to remove the heating bath from the reaction flask and to cool the latter periodically with a wet towel. This more vigorous reaction continued for approximately another twenty minutes, after which time the sodium had completely disappeared and the reaction mixture was homogeneous. It was during this latter twenty minutes' reaction period that practically all of the hydrogen was evolved from the reaction. This hydrogen was collected and its volume measured.

The reaction mixture was then subjected to distillation through the other condenser attached to the reaction flask. As the ethyl acetate was removed by the distillation, pure ethyl acetate was added through the reflux condenser to the reaction mixture and the distillation allowed to proceed slowly until the distillate showed the same refractive index as that of the pure ester. As the alcohol produced in the reaction was carried out by the ethyl acetate, the reaction mixture lost its homogeneity and a voluminous salt-like precipitate, which could not be taken into solution by the pure ester, settled out.

After all of the alcohol had been removed the reaction mixture, which still had considerable excess ethyl acetate present, was treated with the calculated quantity of 35% sulfuric acid[6] to react with all of the sodium originally put into the reaction. The ester layer was then decanted from the solid $Na_2SO_4 \cdot 10H_2O$ and this salt washed with a fresh portion of ester. The combined ester portions were then washed with a solution of potassium carbonate and, after drying with solid potassium carbonate, fractionated. The ethyl acetoacetate fraction, which boiled at 70–75° (10 mm.), was collected and weighed.

Determination of Alcohol in the Distillate.—The amount of alcohol which was present in the distillate from the reaction of sodium ethoxide with various aliphatic esters has been determined from the refractive index of the distillate.[6] This method did

---

[5] McElvain, This Journal, 51,3128 (1929).

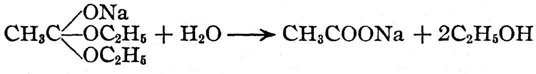
[6] Cf. Snell and McElvain, *ibid.*, 53,752 (1931).

not seem to be suitable when metallic sodium was used as the condensing agent on account of the presence in the distillate of small but unknown amounts of those liquids, xylene and ether, which were used in the preparation of the powdered sodium. For this reason the following procedure for the determination of the alcohol was adopted.

An accurately weighed aliquot (approximately 1 g.) of the distillate was heated at 100° in a sealed tube with approximately 0.6 g. of phthalic anhydride for four hours. The tube was then cooled and opened and the contents poured into a 125-cc. Erlenmeyer flask and the ethyl acetate evaporated off by heating for a few minutes on a steam-bath. The reaction tube was then washed out thoroughly with hot water and these washings added to the residue in the flask from which the ester had been evaporated. The contents of the flask, amounting to about 50 cc., was heated to boiling for about two minutes until the residue completely dissolved and then titrated with $N/5$ sodium hydroxide using phenolphthalein as an indicator. The titration was carried out as rapidly as possible and stopped when the entire solution showed the characteristic pink color of the indicator for thirty seconds. From the difference between the alkali used for this titration and the alkali equivalent of the phthalic anhydride used in the determination the amount of alcohol in the aliquot was determined. Three test solutions of alcohol in ethyl acetate containing 5.52, 10.50 and 14.25% of alcohol by weight were found by the above procedure to contain 4.51, 9.98 and 13.50% of alcohol, respectively.

The amount of alcohol in the distillates usually amounted to about 10%. All of the determinations of alcohol were made in triplicate. The average deviation from the mean was of the order of 0.05 to 0.10%. It should be pointed out that the alcohol values as determined represented minimum values as is shown by results obtained on samples of ethyl acetate containing known amounts of alcohol. This error is due, no doubt, to a slight amount of hydrolysis of the ethyl acid phthalate during the titration of the excess phthalic anhydride.

The amounts of the products of the reaction of ethyl acetate with sodium and sodium ethoxide are tabulated below. In Runs 1 and 2 the ester (2.3 moles) was allowed to react with 11.5 g. (0.5 atom) of sodium and the alcohol formed in the reaction was removed as described above. In Run 3 the same procedure was followed except that 34 g. (0.5 mole) of sodium ethoxide was used as the condensing agent instead of 0.5 atom of sodium. In Run 4 the same quantities of reactants were used and the reaction was allowed to continue only to the point at which all of the sodium had disappeared. This point was reached in about forty minutes after the ester had reached the boiling temperature. The reaction was stopped by adding a slight excess of dry hydrogen chloride dissolved in ethyl acetate to the reaction mixture. This alteration in the isolation procedure was made in order that the formation of alcohol by the reaction



$$CH_3C\begin{cases}ONa\\OC_2H_5\\OC_2H_5\end{cases} + H_2O \longrightarrow CH_3COONa + 2C_2H_5OH$$

which has been shown to take place when the reaction mixture is decomposed with 35% sulfuric acid, might be prevented. The ethyl acetate and alcohol were then distilled through a fractionating column from the reaction flask, and the amount of alcohol present in the distillate was determined by phthalic anhydride. The residue in the reaction flask was treated with water, to dissolve the sodium chloride, and ether to dissolve the acetoacetic ester. The ether layer after drying was fractionated. Run 5 was made under the same conditions as to time of reaction and method of decomposition of the reaction mixture as Run 4 except that sodium ethoxide was the condensing agent instead of metallic sodium.

The last column in the table shows the amount of residue which remained after the distillation of the acetoacetic ester.

Yields of Products from the Reaction of Ethyl Acetate with Sodium and Sodium Ethoxide

[c] Calculated on the basis of $1NaOC_2H_5$ producing $2C_2H_5OH$, the ratio expected from the acetoacetic ester condensation when $NaOC_2H_5$ is the condensing agent. [d] Reaction allowed to proceed for forty minutes. No alcohol removed from the reaction mixture and the latter decomposed with dry hydrogen chloride.

Discussion of the Experimental Results

The most striking feature of the results that are summarized in the above table is the relative amounts of alcohol and acetoacetic ester which are obtained when sodium reacts with ethyl acetate. When the alcohol is removed from the reaction (Runs 1 and 2), the ratio of alcohol to acetoacetic ester is about 1.7 to 1 and in the case (Run 4) where the alcohol is not removed the ratio is about 2 to 1. Obviously the simple equation

$$2CH_3COOC_2H_5 + Na = CH_3CONaCHCOOC_2H_5 + C_2H_5OH + H$$

which is often used to express the course of the reaction is inadequate, for according to this equation the ratio of alcohol to keto ester is 1 to 1. The alcohol in excess of that which is produced by the acetoacetic ester condensation must be formed by the reduction of some of the excess ethyl acetate. The low yield of hydrogen (about 16% of the theory) supports such a conclusion.[7] The sodium equivalent of the hydrogen that is given off from the reaction is obviously lost for reduction, but from the remainder of the sodium the amount of alcohol produced by reduction can be estimated if it be assumed that it is derived from ethyl acetate. Thus in Run 1, since a 16% yield of hydrogen is obtained, only 84% of the sodium that was used in the reaction is available for reduction. Therefore 0.42 mole of alcohol per atom of sodium should have been formed through reduction. There is left 1.30–0.42 = 0.88 mole of alcohol per atom of sodium which is due to the acetoacetic ester condensation. This yield (88%) of alcohol is quite comparable to the yield **(93%)** of alcohol obtained when sodium ethoxide was the condensing agent (Run **3**). Similarly it is seen from Run 4

---

[7] Von Meyer and Friessner [*J. prakt. Chem.*, **65**, 528 (1902)] reported a **33%** yield of hydrogen from the action of sodium on ethyl acetate and concluded that the missing hydrogen, by reduction, induced side reactions that lowered the yield of acetoacetic ester. The lower yields of hydrogen obtained in the present work were due, no doubt, to the fact that very finely divided sodium was used in the reaction.

that approximately 0.42 mole of alcohol per atom of sodium is produced by reduction, leaving 0.96 − 0.42 = 0.54 mole of alcohol per atom of sodium which may be attributed to the acetoacetic ester condensation. This yield (54%) of alcohol parallels quite closely the yield (49%) of acetoacetic ester in this particular run. Obviously, the method of determination of the amounts of acetoacetic ester formed in these reactions is not as accurate[8] as the method used for the alcohol determination, so it is not surprising that the yields of the latter compound are generally somewhat higher than those of the former.

The manner in which the reduction of the ester takes place is of considerable interest. If it is assumed that "nascent hydrogen" can cause such a reduction, then there can be no argument against the contention that sodium is the direct cause of the acetoacetic ester condensation when ethyl acetate is reacted with the metal, for the sodium could in some manner condense the ester with the liberation of "nascent hydrogen" which would reduce more of the ester, thus

$$8CH_3COOC_2H_5 + 4Na \longrightarrow 4CH_3CONaCHCOOC_2H_5 + 4C_2H_5OH + 4H \qquad (1)$$
$$CH_3COOC_2H_5 + 4H \longrightarrow 2C_2H_5OH$$

Such a formulation, however, does not seem probable in view of some recent work on the mechanism of sodium reductions. Willstatter, Seitz and Bumm[9] have demonstrated that the mechanism of the reduction of phthalic acid by sodium amalgam in aqueous solution does not proceed with the "nascent hydrogen" but rather it involves the primary addition of the alkali metal to the carbon to carbon double bond followed by the hydrolysis of the organo-alkali compound. More recently, Wooster and Smith[10] showed that a similar mechanism was followed in the reduction of naphthalene by sodium or potassium in liquid ammonia. If sodium assumes such a role in the reduction of a carbon to carbon double bond it would seem safe to conclude that it functions similarly in the reduction of the carbon to oxygen double bond of an ester. As a matter of fact, the formation of an acyloin by the action of sodium on an ester is a reduction that follows such a mechanism.[4]

On the basis of such a conclusion it is difficult to see how sodium can be directly responsible for the acetoacetic ester condensation. It would seem more in accord with the experimental facts to postulate the condensation as taking place through the agency of sodium ethoxide resulting from the

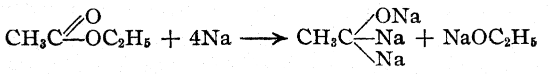
---

[8] The residue left after the distillation of the acetoacetic ester represents a considerable loss in the yield of the keto ester, since it undoubtedly results from the self-condensation of some of the acetoacetic ester during distillation into β-(β′-ketobutyryloxy)-aotonate and dehydroacetic acid [*cf.* Adkins and Connor, THIS JOURNAL, 52, 5193 (1930)].

[9] Willstatter, Seitz and Bumm, *Ber.*, 61, 871 (1928).

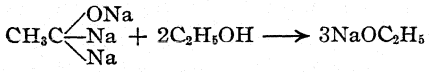
[10] Wooster and Smith, THIS JOURNAL, 53, 179 (1931).

reduction of the ethyl acetate by metallic sodium. The steps in the condensation could be represented as follows



$$\mathrm{CH_3C}\begin{smallmatrix}/\!\!/\mathrm{O}\\ -\mathrm{OC_2H_5}\end{smallmatrix} + \mathrm{4Na} \longrightarrow \mathrm{CH_3C}\begin{smallmatrix}/\mathrm{ONa}\\ -\mathrm{Na}\\ \backslash\mathrm{Na}\end{smallmatrix} + \mathrm{NaOC_2H_5} \qquad (2)$$

$$\mathrm{2CH_3COOC_2H_5 + NaOC_2H_5 \longrightarrow CH_3CONaCHCOOC_2H_5 + 2C_2H_5OH} \qquad (3)$$



$$\mathrm{CH_3C}\begin{smallmatrix}/\mathrm{ONa}\\ -\mathrm{Na}\\ \backslash\mathrm{Na}\end{smallmatrix} + \mathrm{2C_2H_5OH \longrightarrow 3NaOC_2H_5} \qquad (4)$$

$$\mathrm{6CH_3COOC_2H_5 + 3NaOC_2H_5 \longrightarrow 3CH_3CONaCHCOOC_2H_5 + 6C_2H_5OH} \qquad (5)$$

At present there is no experimental evidence for reactions (2) and (4). They simply represent the reduction of the ester through the intermediate formation of an organo-sodium compound followed by alcoholysis in accordance with the suggestion of Willstatter, Seitz and Bumm.[9] It may be that (2) represents the sum of two or more previously occurring reactions.[11]

The sum of (2), (3), (4) and (5) would be the same as the sum of the reactions shown above in (1), *viz.*

$$\mathrm{9CH_3COOC_2H_5 + 4Na \longrightarrow 4CH_3CONaCHCOOC_2H_5 + 6C_2H_5OH} \qquad (6)$$

The hydrogen which is given off in the reaction would result from the following reaction

$$\mathrm{2C_2H_5OH + 2Na \longrightarrow 2C_2H_5ONa + H_2} \qquad (7)$$

It is seen from reaction (6) that **1.5** moles of alcohol are produced in the reaction for each mole of acetoacetic ester. As pointed out above the acetoacetic ester condensation went to the extent of 88% on the basis of the alcohol yields and about 75% on the basis of the keto ester yields in Runs **1** and **2.** If, however, the residue obtained in these runs after the distillation of the acetoacetic ester is considered as derived from acetoacetic ester (cf. footnote ref. 8), the yield of keto ester would be raised to about 0.85 mole per atom of sodium[12] (85%). Thus the ratio of alcohol to keto ester obtained from the reaction mixture would be 1.30/0.85 = **1.53** to 1, which compares quite closely to the ratio established by reaction (6).

In the above discussion an attempt has been made to show that a semi-quantitative consideration of the reaction products in the light of the most probable mechanism of sodium reductions leads to the conclusion that

---

[11] It is quite probable that such a reduction mechanism could be tested experimentally if it were possible to find an acetate, $\mathrm{CH_3COOR}$, of such a nature that RONa did not cause the acetoacetic ester condensation of it. Work along this line is now in progress in this Laboratory.

[12] The question might well arise as to why it is not possible to raise the yield of keto ester even higher if the alcohol produced in the condensation is removed. **A** very probable reason why this is not possible is that as the alcohol is removed from the reaction mixture the sodium salt of acetoacetic ester precipitates and in so doing carries with it some of the active condensing agent, sodium ethoxide, possibly as the addition product,

$\mathrm{CH_3CONaCHC}\begin{smallmatrix}/\mathrm{ONa}\\ -\mathrm{OEt}\\ \backslash\mathrm{OEt}\end{smallmatrix}$.

sodium is not directly responsible for the acetoacetic ester condensation, but serves only to generate sodium ethoxide, which is the active condensing agent. In further support of this contention another important observation should be emphasized, *viz.*, that sodium ethoxide produces practically the same amount of condensation (Runs **3** and 5) and just as readily (Run 5) as does metallic sodium. This observation is not in agreement with the findings of some of the earlier investigators of the reaction, but it is in accord with the results recently reported by Kutz and Adkins.[13]

Summary

A study of the reaction of sodium and ethyl acetate has been made in which the amounts of the reaction products, acetoacetic ester, alcohol and hydrogen have been determined. The amount of alcohol found in the reaction mixture is approximately the sum of that produced by the acetoacetic ester condensation and that resulting from the reduction of the ester by the sodium used in the reaction. It has also been shown that sodium ethoxide brings about the condensation just as readily and completely as does metallic sodium. These results lead to the conclusion that the role of sodium in the acetoacetic ester condensation is to generate, by reduction of the ester, sodium ethoxide, which is the real condensing agent.

A QUANTITATIVE STUDY OF THE INFLUENCE OF ACETATE AND OF PHOSPHATE UPON THE ACTIVITY OF THE AMYLASE OF ASPERGILLUS ORYZAE

BY M. L. CALDWELL AND M. G. TYLER

RECEIVED APRIL 1, 1931 PUBLISHED JUNE 8, 1931

Recent work[1] has emphasized anew the importance of maintaining the optimal hydrogen-ion activity in studies of enzyme action and has also shown that this is not necessarily a fixed value, but may and often does differ with changes in the environmental conditions under which the enzyme acts. Important among the factors which have been found to influence enzyme action is the kind and concentration of electrolyte present. The experiments reported briefly here were undertaken to establish quantitatively the relations of acetate and of phosphate to the saccharogenic activity (formation of reducing sugar, chiefly maltose)[2] of the amylase

of *Aspergillus oryzae* and to the hydrogen-ion activities which favor its action.

Experimental

The general plan of this work was: first, to establish the optimal hydrogen-ion activities for the enzyme in the presence of each of several different concentrations of acetate or of phosphate: by a series of parallel measurements of the activity in starch systems in which the hydrogen-ion activities differed at close intervals but in which the concentration of acetate or of phosphate was kept constant and all other conditions were strictly comparable; second, to make direct comparisons of the activity of the enzyme in the presence of the different concentrations of each buffer when the systems were in each case adjusted to the optimal hydrogen-ion activity as previously determined; and, third, to compare the activity of the enzyme in the absence of either buffer, with its activity in the presence of the most suitable concentration of phosphate or of acetate, each solution being adjusted to the most favorable hydrogen-ion activity. In these parallel experiments the control systems containing neither acetate nor phosphate were adjusted to closely graded hydrogen-ion activities by the use of graded concentrations of sodium hydroxide.

All reagents were carefully purified. Merck's soluble potato starch according to Lintner was used. It was repeatedly washed with distilled and finally with redistilled water, air dried, and moisture determined. The salts, sodium acetate and the mono- and disodium phosphates, which were of the best commercial chemically pure grade, were recrystallized twice from distilled and once from redistilled water. They were then air dried and moisture determined. Redistilled water was used for all solutions. The preparation of the amylase was obtained from a commercial product[3] by the method of Sherman and Tanberg.[4] Fresh portions of this preparation were weighed out for each experiment but the concentration was kept constant throughout the work. The activity of the enzyme (the formation of reducing sugar, chiefly maltose,[2] from starch) was determined under accurately controlled constant conditions by a slight modification of the gravimetric copper-reduction method previously described.[5] The enzyme acted for thirty minutes at 40 ± 0.02° upon 2% starch containing the concentrations of acetate or phosphate under consideration. When one concentration of a buffer at different hydrogen-ion activities was being studied, the total concentration of acetate or of phosphate was kept constant but the proportions of equimolar acetic acid and sodium acetate or of equimolar mono- and disodium phosphates were changed, the proportions depending upon previous electrometric titrations of similar starchacetate or starch–phosphate systems. The hydrogen-ion activities of all solutions were verified by electrometric measurements with a saturated calomel electrode and a hydrogen electrode of the type described by Wilson and Kern."

Results

Interrelation of Hydrogen-Ion Activity, Concentration of Acetate or of Phosphate and Activity of the Amylase of Aspergillus **Oryzae.**—The average of several determinations of the influence of hydrogen-ion activity upon the amylase activity of this enzyme in the presence of each of several concentrations of acetate or of phosphate gave the following results: the maximum enzymic activity occurs under the observed conditions at hydrogen-ion activities of *P*H 5.3 to 5.5, ***P*H** 4.9 to 5.5, ***P*H** 4.7 to 5.3 and PH 4.8 to 5.2 in the presence of 0.01, 0.03, 0.06 and 0 10 M sodium acetate, respectively; and at hydrogen-ion activities of ***P*H** 5.3 to 5.5, *P*H 5.0 to 5.3, ***P*H** 4.9 to 5.1 and ***P*H** 4.7 to 5.2 in the presence of 0.01, 0.03, 0.06 and 0.10 M phosphate, respectively. In both series of experiments there is a tendency for the maximum activity of the amylase to occur in slightly more acid solutions as the concentration of acetate or of phosphate is increased from 0.01 to 0.10 M. Similar results have also been noted with pancreatic and malt amylases.[1,7]

Influence of the Concentration of Acetate or of Phosphate upon **the** Activity of the Amylase of Aspergillus **Oryzae.**—When the activities of the amylase in the presence of each of the four concentrations of acetate, with each system adjusted to the optimal hydrogen-ion activity as previously determined, were compared, it was found that there was a consistent but very small decrease in the activity of the enzyme as the concentration of acetate was increased from 0.01 to 0.10 M. Thus, the average amylase activity expressed in terms of reducing power calculated to maltose[2] was found, in twelve strictly comparable determinations, to be 211, 209, 207, 206 mg. of maltose in the presence of 0.01, 0.03, 0.06 and 0.10 M acetate, respectively.

Similar experiments with the four concentrations of phosphate under optimal conditions of hydrogen-ion activity for each system showed that there was no measurable difference in the activity of the amylase as the phosphate concentration was increased from 0.01 to 0.10 M. Thus, the average amylase activity expressed in terms of reducing power calculated to maltose was found in six strictly comparable determinations to be 213, 212, 213, 213 mg. of maltose in the presence of 0.01, 0.03, 0.06 and 0.10 M phosphate, respectively.

A Comparison of the Saccharogenic Activity of the Amylase of **Aspergillus** Oryzae in the Absence and in the Presence of Acetate or **Phosphate.**—In view of the results discussed above a concentration of 0.01 M acetate and of 0.01 M phosphate was chosen for the comparison of their influence upon the activity of the enzyme. The amylase acted simultaneously upon 2% starch alone, 2% starch containing 0.01 M acetate at the optimal hydrogen-ion activity of ***P*H** 5.5, 2% starch containing

---

[7] Sherman, Caldwell and Dale, THIS JOURNAL, 49,2596 (1927).

0.01 M phosphate at the optimal hydrogen-ion activity of P_H 5.3, and upon a series of 2% starch systems to which graded concentrations of sodium hydroxide had been added, resulting in a series of hydrogen-ion activities from P_H 4.4 to 5.5, the optimal amylase activity under these conditions occurring at about P_H 5.1. It was found that under these conditions the activity of the amylase was the same in the presence of 0.01 *M* acetate as in the presence of 0.01 *M* phosphate, that this was consistently higher than its activity in the unbuffered unadjusted aqueous starch systems and slightly lower than the highest activities obtained in the unbuffered systems in which the hydrogen-ion activities were adjusted by the use of sodium hydroxide instead of by acetate or phosphate buffers. The average values of several parallel determinations under these conditions in which the activity of the amylase is expressed in terms of reducing power calculated to maltose, were 196, 203, 203,207 mg. of maltose, respectively, for the unadjusted unbuffered starch, 0.01 *M* acetate, 0.01 *M* phosphate starch systems and for the average of the highest activities in the systems adjusted only with sodium hydroxide. In the latter unbuffered systems, however, the results were very irregular, probably due to the impossibility of obtaining quantitatively reproducible hydrogen-ion activities.

These results show that if the most favorable conditions for each case are maintained, the saccharogenic activity of the amylase of *Aspergillus oryzae* is the same in the presence of 0.01 *M* acetate or of 0.01 *M* phosphate. While the activity of the enzyme is slightly lower in the presence of these buffers than that which may be obtained in their absence, the differences are very small and may, in our opinion, be considered negligible, as they would be more than offset in usual measurements of amylase activity by the advantage of having well buffered systems so necessary for reproducible and comparable results. For this reason also, acetate is preferable to phosphate for use in the measurements of activity of the amylase of *Aspergillus oryzae*, as it is a much more efficient buffer at the hydrogen-ion activities at which this amylase is most active.

Summary

The optimal hydrogen-ion activities for the action of the amylase of *Aspergillus oryzae* in the presence of different concentrations of acetate or phosphate have been quantitatively established, and found to be dependent both upon the kind and concentration of the buffer used.

The highest amylase activity of this enzyme in the presence of either of these buffers occurs in systems of slightly lower hydrogen-ion activity as the concentration of either is increased from 0.01 to 0.10 *M* (measurements at 40° for thirty minutes in presence of 2% starch).

Increasing the concentration of acetate from 0.01 to 0.10 *M* causes a slight decrease in the activity of the amylase. The decrease in activity

of the amylase in the presence of 0.01 M acetate is negligible and is more than offset by the increase in reproducibility of results over those obtained in unbuffered systems.

Changes in the concentration of phosphate from 0.01 to 0.10 M do not influence the activity of the enzyme if the hydrogen-ion activities of the systems are suitably adjusted.

If the hydrogen-ion activities of the systems are suitably adjusted, the activity of this amylase is the same in the presence of 0.01 M acetate or of 0.01 M phosphate.

In measurements of the activity of the amylase of *Aspergillus oryzae*, acetate is preferable to phosphate because of its more efficient buffer effect in the region of hydrogen-ion activities which are optimal for the action of this amylase.

In measurements of thirty minutes at 40° with 2% starch containing 0.01 M acetate, the amylase of *Aspergillus oryzae* is most active saccharogenically at hydrogen-ion activities of P_H 5.3 to P_H 5.5.

THE "YELLOW COMPOUNDS" RESULTING FROM THE DECOMPOSITION OF ROTENONE IN SOLUTION

BY HOWARD A. JONES AND H. L. HALLER

RECEIVED APRIL 1, 1931 PUBLISHED JUNE 8, 1931

The literature on *Deguelia* (Derris) contains numerous references to "yellow compounds" which are obtained in the process of isolating the active insecticidal principles, or which result from the treatment of rotenone ($C_{23}H_{22}O_6$, m. p. 163°), the most important constituent, with various reagents.[1]

Greshoff's[2] derrid, described as an amorphous material melting at 61°, and decomposing at 160°, was probably a mixture of rotenone and certain yellow materials. The same investigator later reported the melting point of pure derrid as 204°.[3]

Van Sillevoldt[4] obtained from the roots of *Deguelia elliptica* a pale yellow substance melting at 73° which he also called derrid. This, on treatment with an alcoholic solution of hydrogen chloride, gave yellow needles

---

[1] Clark, *Science*, 71, 396 (1930), has isolated a yellow crystalline material, toxicarol, from the root of Deguelia *sp.* and it is possible that other yellow compounds are associated with rotenone in this root. This paper, however, deals primarily with such yellow compounds as result from the decomposition of rotenone in solution.

[2] Greshoff, *Ber.*, 23, 3537 (1890).

melting at 214°, which he called anhydroderrid. He stated that this material was also present in crude derrid.

Power,[5] on treatment of the resin from the chloroform extraction of stems of *Deguelia trifoliata* (*Derris uliginosa*), obtained a material identical with the anhydroderrid of Van Sillevoldt.

In the course of a chemical investigation of the constituents of *Deguelia elliptica* root, Tattersfield and Roach[6] obtained, in addition to rotenone: three yellow crystalline compounds. These materials were formed on fractionation of the alcoholic extracts of the root. One of these compounds corresponded to the anhydroderrid of Van Sillevoldt, another melted at 222–224°, and the third decomposed at 280°. They crystallized in the form of long, yellow needles and were only slightly soluble in organic solvents. These investigators were unable to obtain anhydroderrid from derris extract which had been freed of rotenone. They concluded that all three yellow compounds were secondary products of the extraction process.

Butenandt,[7] by treatment of rotenone with mild oxidizing agents, obtained a yellow crystalline compound melting at 218°, which he called dehydrorotenone and which he showed has the empirical formula $C_{23}H_{20}O_6$. LaForge and Smith[8] obtained a melting point of 225° for this compound.

Takei[9] obtained, on oxidation of rotenone with chromium trioxide in glacial acetic acid, a yellow compound melting at 298°. This he named rotenonone. Butenandt[7] also prepared this compound and assigned to it the formula $C_{23}H_{20}O_7$; whereas LaForge and Smith[8] assigned it the formula $C_{23}H_{18}O_7$. The latter investigators have shown that rotenonone can be obtained from dehydrorotenone and that dehydrorotenone precedes the formation of rotenonone from rotenone. Butenandt has suggested that dehydrorotenone and rotenonone are possibly the "yellow compounds" which are so frequently mentioned in the literature as accompanying rotenone. These two compounds are practically non-toxic to fish and insects.

During an investigation of the solubility of rotenone it was noted that solutions of rotenone in certain organic solvents changed, on standing, from colorless to various depths of yellow.[10] This change does not occur with equal rapidity in all solvents. Thus at room temperature pyridine solutions become deep amber in color within a few days, chloroform and ethylene dichloride solutions exhibit this change more slowly, in acetone and diacetone alcohol the change takes place only very slowly and in benzene and alcohol the change is almost imperceptible. This alteration in

color is accompanied by a change in the optical rotation of the solution, the rates of the two changes being roughly proportional. The solutions also lose their toxicity to fish and insects.[11]

Pyridine solutions of rotenone on standing for several days deposited long, yellow, needle-like crystals. Solutions in acetone, amylene dichloride, chloroform, diacetone alcohol and other solvents gave similar yellow crystals. However, the crystals did not separate spontaneously from these solvents, as was the case with the pyridine solutions, but only after long standing and final boiling and evaporation of the solutions to a small volume.

The present investigation has proved conclusively that the changes occurring in solution are a result of the oxidation of the rotenone by air. Thus the change is accelerated by greater exposure to air, but when rotenone is dissolved in pyridine through which nitrogen has been passed and the solution kept in an atmosphere of nitrogen, no color change takes place and no deposition of crystals is to be observed even on long standing The change is not influenced by differences in light intensity.

A chemical examination of the yellow crystalline product of the decomposition has shown it to be a mixture of dehydrorotenone and rotenonone,' both oxidation products of rotenone. The proportion of the two materials in the product deposited seems to depend upon several factors, chief of which are temperature, access of air and the length of time the solution is allowed to stand. The first product deposited seems to be dehydrorotenone, and as the decomposition progresses rotenonone is formed. These crystalline materials are only the initial products of the decomposition. The reaction continues beyond the formation of these two compounds, resulting in a complex mixture of other oxidation products of rotenone.

A sample of the yellow crystalline material removed from a pyridine solution of rotenone soon after the deposition of crystals began was found to melt at about 225°. This same material in chloroform solution had an optical rotation of $[\alpha]^{20}_{\mathrm{D}}$ $-43°$. Butenandt and Hildebrandt[12] obtained $[\alpha]^{18}_{\mathrm{D}}$ $-40.5°$ for dehydrorotenone in chloroform solution. Samples of yellow crystalline material separating at early stages from other pyridine solutions had melting points ranging from 220 to 240°. Probably rotenonone was present in some of these samples.

That rotenonone is present in increasing amounts in the mixture separating from pyridine solutions after longer standing or on more severe treatment (increased temperature or bubbling of air through the solution) was also established. Thus a sample of crystalline material, separated from a pyridine solution which had been allowed to stand over a long period of time, melted at about 280°. Several recrystallizations of this material

---

[11] Davidson and Jones, *J. Econ. Entomol.*, *24*, 257 (1931).

[12] Butenandt and Hildebrandt. *Ann.*, 477, 246 (1930).

from acetic acid (no doubt causing further decomposition) raised the melting point to 298°. When mixed with an equal quantity of pure rotenonone it caused no depression of the melting point. Another sample of yellow material separating from a pyridine solution was recrystallized twice from ethyl acetate. Its melting point was found to be about 290°. The minimum and the intermediate indices of refraction[13] of both these samples were identical with those of pure rotenone. The maximum index was higher than that of the readily available reference liquids.

The yellow crystalline material separating from a pyridine solution of rotenone was found to be non-toxic to goldfish.[14] Both dehydrorotenone and rotenonone are practically non-toxic to fish.

The needle-like, yellow crystals obtained from amylene dichloride and diaeetone alcohol solutions of rotenone also appeared to be mixtures of dehydrorotenone and rotenonone.

The yellow material melting at 222–224° obtained by Tattersfield and Roach as a result of boiling alcohol solutions of rotenone was no doubt principally dehydrorotenone and the material decomposing at 280° was probably largely rotenonone.

It was also found that dihydrorotenone (in which the double bond in the side chain has been reduced) behaves similarly to rotenone in pyridine solution, as does isorotenone (in which the double bond has migrated). The pyridine solutions of these materials become deep yellow in color and needle-like, yellow crystals separate, which in the case of dihydrorotenone are no doubt a mixture of dehydrodihydrorotenone and dihydrorotenonone, and in the case of isorotenone probably consist of dehydroisorotenone and isorotenonone

Gimlette,[15] describing work done by Durham, states that crystals of rotenone are altered and reddened by exposure to light. The material in this case was no doubt impure or perhaps contained solvent of crystallization. A sample of pure, crystalline rotenone exposed to ordinary light conditions in this Laboratory showed no change in color after standing for more than a year. No change was observed in melting point, specific optical rotation or toxicity against fish and insects.

Conclusions

1. Rotenone in solution in various organic solvents decomposes, the rate of this decomposition depending on the solvent, temperature, access of air and other factors.

2. This change is an air oxidation of the rotenone, the initial products

of the decomposition being the yellow, crystalline compounds dehydrorotenone and rotenonone.

3. Similar changes are undergone by dihydrorotenone and isorotenone in pyridine solution, analogous compounds no doubt being formed.

4. Dry, crystalline rotenone undergoes no change on long standing.

STUDIES ON LEVULINIC ACID. I. ITS PREPARATION FROM CARBOHYDRATES BY DIGESTION WITH HYDROCHLORIC ACID UNDER PRESSURE[1]

BY RALPH W. THOMAS AND H. A. SCHUETTE

RECEIVED APRIL 2, 1931 PUBLISHED JUNE 8, 1931

Priority of discovery of the fact that dilute mineral acids acting upon hexoses or any carbohydrate yielding them on hydrolysis cause the formation, among other substances, of levulinic acid must be accorded to Mulder[2] in that the compound which he isolated from such a reaction mixture and described as glucinic acid was later found by Grote and Tollens[3,4] to be identical with the substance which they obtained from inulin under similar conditions.[4] It is to the latter investigators that the common name for this keto acid is due.

The traditional equation for the formation of this acid

$$C_{12}H_{22}O_{11} = 2CH_3COCH_2CH_2COOH + 2HCOOH + H_2O$$

by no means represents a complete picture. Subsidiary reactions take place to such an extent that the best yields[5] of levulinic acid which have been reported as a direct result of studied attempts so to guide the course of this reaction that a greater conversion of carbohydrate might be rapidly

---

[1] This paper, and others already published by R. W. Thomas on the general theme of the sugars as chemical raw materials [THIS JOURNAL, 52, 2028, 3010 (1930)], forms part of a thesis presented to the Graduate Faculty of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1931.

[2] Mulder, *J. prakt. Chem.*, 21, 219 (1840).

[3] Grote and Tollens, *Ber.*, 7, 1375 (1874).

[4] Mulder's discovery has been many times verified. Since his day the following carbohydrates have been made to yield this acid: starch [Grote and Tollens, *Ber.*, 7, 1379 (1874)]; dextrose, levulose [Grote, Kehrer and Tollens, *Ann.*, 206, 228 (1881)]; lactose [Rodewald and Tollens, *ibid.*, 206, 231 (1881)]; galactose [Kent and Tollens, *ibid.*, 227, 228 (1885)]; raffinose [Rischbiet and Tollens, *ibid.*, 232, 193 (1886)]; sorbose [Wehmer and Tollens, ibid., 243, 320 (1888)]; Smith and Tollens, *Ber.*, 33, 1286 (1900); and mannose [Fischer and Hirschberger, *ibid.*, 22, 370 (1889)].

[5] (a) McKenzie, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1929, Vol. IX, p. 50; (b) Sah and Ma, THIS JOURNAL, 52, 4880 (1930).

and conveniently brought about are approximately 23% of the theoretical when sugars serve as raw material, starch yielding lesser amounts. Berthelot and André,[6] in studying the decomposition of dextrose by phosphoric acid, and Ost and Brodtkorb,[7] in following the action of dilute sulfuric acid upon this sugar at temperatures up to 145°, in a sense pointed out a way for the development of an improved procedure for the preparation of levulinic acid, This fact has apparently been overlooked until now although it is true that the statement''' has been recently made, without supporting data, that the action will proceed rapidly if the temperature of the solution be raised to 110°.

The best current practice for preparing levulinic acid consists in digesting sucrose or dextrose with dilute hydrochloric acid (1 + 4)'' or (1 + 1)[5b] for ten to forty-eight hours on a boiling water-bath, filtering off the humus material, either fractionating the filtrate[5]".' or concentrating it and finally extracting the acid with a suitable solvent. An alternative procedure[5a] is to evaporate the reaction mixture to dryness before extracting the acid. These methods, however, are uneconomical in that they are time-consuming and productive of even at best but comparatively low yields, and for this reason were not well suited for the preparation of levulinic acid in the quantity needed for carrying out an investigation under way[8] in this Laboratory on sucrose as a chemical raw material. The hope that a study of the effect of altering the acid concentration and time and temperature of digestion might lead to improvements in the technique of preparing this acid, to the end that the process would be shortened and the yields increased, was realized in so far as the latter have been increased by approximately 100% over those obtainable by heretofore existing methods. How these objectives have been reached is herein communicated.

Experimental

Materials.—Commercially pure (99.85%) sucrose, levulose (moisture, 3.1%, $[\alpha]^{25}_{D}$ −79.0°), dextrose (moisture, 6.9%, $[\alpha]^{25}_{D}$ +49.5°), and ordinary domestic corn starch were used in this study.

Procedure.—The carbohydrate in question was treated with dilute hydrochloric acid in a two-liter beaker, the whole transferred to a four-liter copper autoclave containing water and digested for varying periods of time and at various temperatures as indicated in the accompanying tables. The reaction mixture[3] was then evaporated to dry-

---

[6] Berthelot and André [Compt. rend., 123, 567 (1896)] heated dextrose and phosphoric acid in sealed tubes kept at 100° for 168 and 648 hours, respectively. On measuring quantitatively the products of reaction they found 37 10% of levulinic acid in the first case and 39.88% in the second.

[7] Ost and Brodtkorb, *Chem.-Ztg.*, 35, 1126 (1911).

[8] Schuette and co-workers, THIS JOURNAL, 48, 3163 (1926); 52, 2028, 3010 (1930).

[9] It was found that ether removed practically nothing from the humus material formed in the reaction and, since its presence gave to the dried residue a porous character which proved an aid to extraction, it was not filtered off.

ness on a steam-bath and the levulinic acid extracted from it with diethyl ether. The latter operation required approximately forty-eight hours when carried out in a continuous extractor. After recovery of the ether the residual oily liquid was distilled, the fraction boiling at 120–130° (4.5 mm.), collected and redistilled. The final product boiled at 106–108° (2 mm.), n^{40} 1.4342, average deviation for all runs being $+0.0004$. This latter value, which is new, was obtained on a product twice recrystallized and one which did not turn yellow after liquefaction and standing in the light for several years. It was used as a criterion of purity for each batch of levulinic acid made.

All yields recorded herein represent the mean of duplicate runs. They were found to be easily reproducible within two to three per cent.

Results and Discussion

Table I shows the effect of the temperature of digestion on the amount of sucrose converted to levulinic acid. The advantage of carrying out this reaction at high temperatures is clearly shown, the yields steadily increasing to 162°, which was the maximum obtainable with the apparatus available for this study. If per cent. yield is plotted against temperature, a curve is obtained which, although rising, begins to flatten out at the higher temperatures, thus indicating that above 162° there would result a relatively smaller increase in yield per degree rise in temperature.

TABLE I

EFFECT OF TEMPERATURE OF DIGESTION ON CONVERSION OF SUCROSE TO LEVULINIC ACID

Sucrose, g.	HCl, (1 + 5) cc.	Digestion data Time, hrs.	Temp., °C.	Pressure, atm.	Levulinic acid Yield g.	%
250	600	1	120	2.0	30.5	10.2
250	600	1	130	3.6	53.6	31.6
250	600	1	145	4.3	58.2	34.3
250	600	1	162	7.0	72.5	42.7

In Table II are set down the data pertinent to the effect that time of digestion was found to exert upon the amounts of sucrose, dextrose, levulose and starch converted to levulinic acid. It appears that equilibrium is practically reached in one hour at a temperature of 162°, longer periods of digestion producing no appreciably larger yields. The same holds true at a temperature of 145°.

Continuing the digestion of levulose, dextrose or starch with hydrochloric acid for periods longer than one hour actually resulted in decreased yields of levulinic acid, the effect decreasing in the order named. These results were not entirely unexpected, however, because of the sensitiveness of the hexose sugars to heat and continued action of the mineral acid.

That the yields of levulinic acid depend to some extent upon the concentration of the hydrochloric acid used is shown in Table III, in which the data as recorded were obtained by using always the same volume of acid solution (600 cc.), its strength being so adjusted as to give the value indicated in the second column. Hydrochloric acid diluted in the proportion

TABLE II

EFFECT OF TIME OF DIGESTION ON CONVERSION OF SUCROSE, DEXTROSE, LEVUMSE AND STARCH TO LEVULINIC ACID

Carbohydrate, g.	HCl (1 + 5), cc.	Digestion data			Levulinic acid Yield	
		Time, hrs.	Temp., °C.	Pressure, atm.	g.	%
			Sucrose			
250	600	1	162	7.0	72.5	42.7
250	600	2	162	7.0	73.6	43.4
250	600	5	162	7.0	72.7	42.9
250	600	1	145	4.3	58.2	34.3
250	600	2	145	4.3	61.5	36.2
250	600	5	145	4.3	55.0	32.4
			Dextrose			
250	600	1	162	7.0	61.0	37.8
250	600	2	162	7.0	53.0	32.9
			Levulose			
200	480	1	162	7.0	50.2	39.0
200	480	2	162	7.0	37.5	29.1
			Starch			
250	600	1	162	7.0	65.4	36.5
250	600	2	162	7.0	60.2	33.6

of one volume to five of water (6.5%) is of ample strength, a greater concentration being not only unnecessary but undesirable in that it was found to complicate the purification of the final product.

TABLE III

EFFECT OF CONCENTRATION OF HYDROCHLORIC ACID UPON CONVERSION OF SUCROSE TO LEVULINIC ACID

Sucrose, g.	Concentration of HCl, %	Digestion data			Levulinic acid Yield	
		Time. hrs.	Temp.. °C.	Pressure, atm.	g.	%
250	3.5	1	162	7.0	59.0	34.8
250	6.5	1	162	7.0	72.0	42.4
250	10.7	1	162	7.0	70.0	41.3
250	4.2	1	145	4.3	62.0	36.5
250	6.5	1	145	4.3	60.0	35.4
250	10.7	1	145	4.3	63.0	37.1

Not much further need be said about these data except that they clearly show that a readjustment of the experimental conditions heretofore recommended is desirable not only because, by the use of high temperatures, economies as to time and materials are effected but also that the course of the fundamental reaction involved in the preparation of levulinic acid from hexoses is hereby directed away from its empirical feature to a closer approach to stoichiometrical conditions. The large increase in yields of acid so obtained points to these conclusions.

In the light of the information gained by this study the following procedure appears to warrant recommendation as a modified practical method for preparing levulinic acid.

Dissolve sucrose in dilute hydrochloric acid solution (1 + 5) in the proportion of 250 g. (0.73 mole) to 600 cc. of acid. Heat the mixture, contained in a beaker, for one hour in an autoclave after the temperature has reached 162°. If the beaker be surrounded by water, which is a very necessary condition here, the total pressure will rise to approximately seven atmospheres at this temperature. Break up the cake of humus material which has formed in the reaction mixture and transfer the whole to an evaporating dish, taking it to dryness on a steam-bath. Extract the dry residue with diethyl ether until the levulinic acid is completely removed. Drive off the ether by distillation at atmospheric pressure and then fractionally distil the residual oily liquid in *vacuo,* collecting for redistillation (106–108°, 2 mm.) that fraction boiling at 120–130° (4.5 mm.); yield, 42%.

Equally satisfactory yields may be obtained by filtering the reaction mixture, washing the humus material well with water and fractionally distilling the combined filtrates. While this latter procedure materially shortens the process, it has a disadvantage in that a tarry residue is left in the distillation flask which is very difficult to remove. Proceeding according to this modification, levulinic acid may be prepared in yields exceeding 40% in a period of five to six hours.

If a product of high degree of purity is desired, the acid may be crystallized in an ice-bath. To that end stir the liquefied acid to induce the formation of small crystals, remove them from the mother liquor by centrifugal force, and wash the crystalline mass several times with small portions of cold diethyl ether, which is in turn removed by centrifuging. Remove the last trace of ether by evaporation at room temperature and reclaim the acid in the washings by distillation. A product prepared in this way (n^{40}, 1.4342) may be kept in the liquid state without the appearance of the slightly yellow tint that is characteristic of the fractionally distilled acid.

Summary

As the result of a study of the action of dilute hydrochloric acid on certain carbohydrates, during the course of which the three variables concentration of acid, time and temperature of digestion were altered, there has been developed a modification of existing procedures for preparing levulinic acid to the end that a larger conversion of carbohydrate to this acid is now possible than by heretofore existing methods. The recommended procedure is to digest sucrose under pressure for one hour with dilute hydrochloric acid at 162° in the presence of water vapor. Details of a method leading to the preparation of a very pure product are given.

REDUCTION PRODUCTS OF NAPHTHACENEQUINONE

BY LOUIS F. FIESER

RECEIVED APRIL 3, 1931 PUBLISHED JUNE 8, 1931

Naphthacenequinone is the most interesting of those few anthraquinones which fail to give the characteristic red vat when treated with hyposulfite and alkali in the usual manner. The failure of the Liebermann reaction cannot be attributed to steric interference, as in the case of the poly-α-substituted anthraquinones,[1] and the substance is simpler in structure than its benzologue, *lin.*-dibenzanthraquinone, which presents the same anomaly.[2] It is not generally known that naphthacenequinone belongs to this exceptional class of substances, for although the discoverers[3] made the highly interesting observation that the quinone forms an eosin-red solution on reduction in glacial acetic acid solution, they did not study the alkaline reduction, and the compound has received no attention since the time of their work. Further study perhaps has been delayed by the statement of Mills and Mills[2] that naphthacenequinone reacts in the usual manner with zinc and alkali. This unfortunate statement is probably an incorrect quotation from the paper of Gabriel and Leupold, for there is no indication that the English investigators studied the compound themselves. That there is this error in the very meager literature of the subject, became apparent to the present author in the course of an attempt to measure the reduction potential of naphthacenequinone. This attempt met with no success, and the failure appeared to be due to the unusual instability of the immediate reduction product.

Before any extensive study of the unusual behavior of naphthacenequinone could be conveniently undertaken, it was necessary to find a more suitable method of preparation than those which involve the very unsatisfactory hydrogen iodide–phosphorus reduction of hydroxy-[4] or dihydroxynaphthacenequinone.[3] Such a method was found in the dehydrogenation of 2,3-tetralanthraquinone with bromine. Pure naphthacenequinone can be obtained in 80% yield by this method in the course of a few hours. It is of interest that the hydrocarbon, naphthacene, results from the zinc-dust distillation of 2,3-tetralanthraquinone.

The reduction of naphthacenequinone has been studied under a variety of conditions, and the main results are summarized in the accompanying chart. Boiled in glacial acetic acid solution with tin, the quinone, I, first gives a deep red solution of the hydroquinone, II, and the latter substance

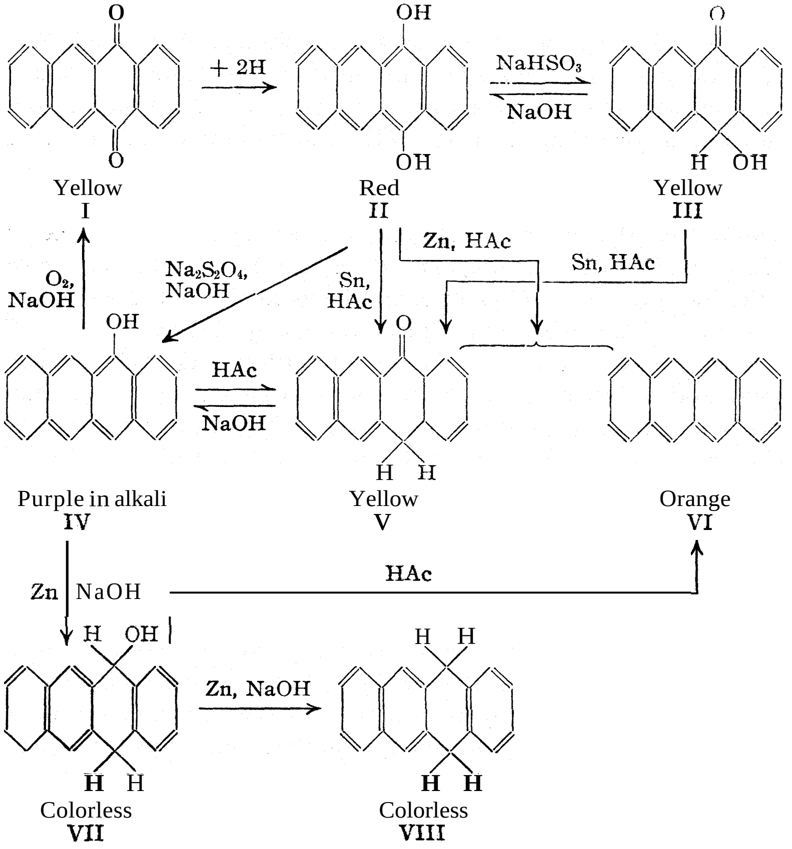
[4] Deichler and Weizmann, *ibid.*, **36**, 547 (1903).

is then slowly converted into 2,3-benz-9-anthrone, V, and the reaction stops at this point. With the more active metal zinc, a mixture of the anthrone and naphthacene, VI, is obtained and, since the anthrone cannot be converted into naphthacene under similar conditions, it is concluded that the hydrocarbon is produced by the direct reduction of the hydroquinone. In order to prepare the diacetate of the hydroquinone in good yield, it is necessary to modify the standard method of reductive acetylation by substituting tin for zinc. Otherwise the product is contaminated with the anthrone and the hydrocarbon.



Crystalline naphthacenequinone may be boiled indefinitely with alkaline hyposulfite solution without developing the red color characteristic for most anthraquinones. When it is prepared in a finely divided condition by pouring a solution in concentrated sulfuric acid into boiling water, the quinone rapidly dissolves in alkaline hyposulfite solution and the latter acquires a deep green color. The usual red vat is obtained only by the use of alcohol as the solvent. When hyposulfite solution and a rather large quantity of alkali are added to a suspension of the quinone in boiling alcohol, the material dissolves in a few minutes to give a deep red solution of naphthacene hydroquinone, II. The color then slowly changes to an intense purple for which the anthranol, IV, is responsible. On acidification, the substance ketonizes and is obtained in the form of the anthrone.

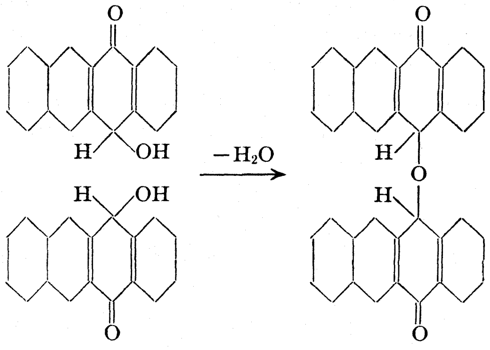
While the anthrone, V, is a very stable substance, the enol form, IV, is sensitive to both oxidation and reduction. The purple solution in alcoholic alkali oxidizes readily in the air to give naphthacenequinone. It is not attacked by hyposulfite, but it is easily reduced by zinc in the presence of alcoholic alkali to the dihydro-anthranol, VII, which in turn is converted by the same reagent into dihydronaphthacene, VIII. The dihydroanthranol, VII, very easily loses the elements of water with the formation of naphthacene, VI. The dehydration takes place instantly in a boiling alcoholic solution on adding a trace of a mineral acid, and it is likely to occur in the process of crystallizing the compound from alcohol or ligroin unless a trace of a basic substance such as pyridine is added to stabilize it.

Naphthacenehydroquinone (II) is unstable in solution not only because it is easily reduced by the reagents ordinarily used to produce it, but also because it easily undergoes two other reactions, na'mely, disproportionation and ketonization. In a solution of the substance prepared by the hydrolysis of its diacetate, in order to eliminate the possibility of reduction, the hydroquinone undergoes mutual oxidation and reduction with the formation of the quinone and the anthrone. The reaction is quite rapid in an alcoholic solution which is either strongly acidic or weakly alkaline; it is very slow in a strongly alkaline medium. The striking color changes accompanying the disproportionation are described in the Experimental Part.

Under conditions which are not easily specified, naphthacenehydroquinone ketonizes and passes into 2,3-benz-9-hydroxyanthrone, III. The keto form may be obtained quantitatively from the quinone by adding hyposulfite solution and a certain small quantity of alkali to *a* boiling alcoholic suspension of the quinone. The deep red solution of naphthacenehydroquinone which first results suddenly changes within a few minutes to brown and then to a pale pink and the solution is now found to contain the hydroxyanthrone as the sole product. With more alkali present, the substance remains in the enolic form until it is slowly converted by reduction into the anthranol. The keto form can be enolized by the action of pyridine or, more slowly, by alcoholic alkali. Although the equilibrium appears to favor the keto form in neutral or acid solution, the quantitative ketonization of the hydroquinone bas not been accomplished except in the course of the preparative method described. When working in the absence of reducing agents, the disproportionation reaction appears to be more rapid than the ketonization.

The failure of naphthacenequinone to form a red vat in an aqueous medium is probably due in large part to the great instability of naphthacenehydroquinone.

One other reduction product, and one of an unusual type, was isolated by H. D. Newman in the course of some preliminary experiments described in the Experimental Part. It was later found that the same compound may be produced in quantity by the oxidation of 2,3-benz-9-anthranol, IV, in alcoholic alkaline solution by the action of sulfur. The substance has the molecular formula $C_{36}H_{22}O_3$. It yields naphthacenequinone on oxidation and 2,3-benz-9-anthrone on acid reduction, and it corresponds in the state of oxidation to naphthacenehydroquinone. The substance is obviously composed of two C_{18} residues, but an adequate basis for a choice between several possible formulas was only furnished by the results of a quantitative study of the action of the Grignard reagent. This showed that the compound has no active hydrogen atoms, but that it adds this reagent. From these facts it was concluded that the substance has the structure of di-(2,3-benz-9-anthronyl)-ether, X. If this formula is correct,



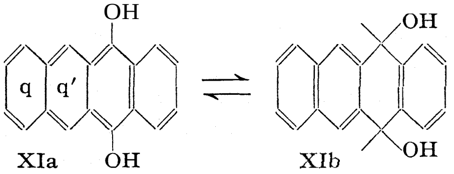
IX X

it should be possible to obtain the compound by the dehydration of two molecules of 2,3-benz-9-hydroxyanthrone, IX, and this was indeed found to be the case. The conversion is easily brought about by the action of acetic anhydride and a trace of sulfuric acid. The ether structure is thus confirmed, and the compound represents a type which is probably novel in the anthraquinone series.

The Theoretical Significance of the Results.—When the various naphthacene derivatives here described are compared with the corresponding derivatives of anthracene, it becomes apparent that there is a marked difference between the two series. Naphthacenehydroquinone, II, is more easily reduced than is anthrahydroquinone, and it has a much greater tendency to ketonize. This statement applies equally well to 2,3-benz-9-anthranol (IV); it readily forms a dihydride on reduction, and the ketonization takes place with such facility that the isomerization can only be reversed by the action of alcoholic alkali. Pyridine and aqueous alkali, reagents which readily enolize anthrone, are without effect on 2,3-benz-9-anthrone, V In each of the instances cited it is seen that the naphthacene derivatives possess an enhanced tendency to react in such a way as to produce derivatives of dihydronaphthacene. A further example of the greater stability of the dihydride structure in the naphthacene as compared with the anthracene series is that, while dihydroanthranol becomes dehydrated in alkaline solution to give anthracene, its 2,3-benz-derivative (VII) does not lose water under similar conditions, but retains the dihydride structure and is easily reduced to dihydronaphthacene.

The disproportionation of naphthacenehydroquinone is a reaction-which may be classed with those already cited. While anthrahydroquinone reacts in a similar manner only on prolonged boiling in an alcoholic solution containing hydrochloric acid,[5] naphthacenehydroquinone is completely decomposed in a few minutes even in a weakly alkaline solution. Here again a substance having a completely aromatic structure appears to be peculiarly unstable and it undergoes mutual oxidation and reduction to form products which, in their most stable condition, possess the dihydride structure.

The ortho quinonoid structure for anthracene and its benzologues furnishes the simplest explanation of the facts observed. As compared with anthrahydroquinone, naphthacenehydroquinone, XIa, has, in place of a single ortho quinonoid ring, two rings which are quinonoid. The combined system presented by rings q and q' is similar to that of the unknown 2,3-naphthoquinone, and the lack of stability of this substance shows that such a system is one of great strain or of great reactivity. This furnishes an adequate interpretation of the pronounced tendency of the compound in question to pass into substances having the dihydride structure either by ketonization, reduction or disproportionation, for the condition of strain in the molecule is thereby relieved. The striking colors of those naphthacene derivatives which have the completely aromatic



XIa XIb

---

[5] K. H. Meyer, *Ann.,* **379,** 61 (1911).

structure may also be attributed to the quinonoid grouping, though the relationship of the different substances is not clear (see chart).

One may also regard naphthacene as a substance having a conjugated system of six double bonds and with consequent enhanced reactivity[6] at the meso carbon atoms, which are at the ends of this long system. Regarded thus as a condensed derivative of o-phenylenedodeca-hexa-ene, the orange hydrocarbon corresponds well in color with diphenyl-dodeca-hexa-ene, which is brown-orange.' There is also a rough correlation between the aromatic and aliphatic compounds having systems of eight conjugated double bonds with phenyl groups at the two ends, for Clar and John[s] have described *lin.*-dibenzanthracene as a blue hydrocarbon, while Kuhn and Winterstein[7] have found diphenyl-hexadeca-octa-ene to be bluish copper-red.

Since the o-quinonoid formula and the poly-ene formula are one and the same, the two points of view regarding the anthracene hydrocarbons are in no way antagonistic, but they rather supplement each other.

Clar and John[8] have recently advanced evidence to show that their blue *lin.*-dibenz-anthracene has the properties of a bivalent radical. According to their views, naphthacenehydroquinone in solution should consist of an equilibrium mixture containing the radical XIb. Naphthacene itself can hardly be formulated as a bivalent radical, for it is not attacked by moist oxygen in high-boiling solvents in the manner characteristic of the pentacyclic hydrocarbon. There is reason to believe, however, that the hydroxyl or metal-oxyl groups of naphthacenehydroquinone would promote radical dissociation at the meso carbon atoms. The red color of acid solutions of the substance is unusual among the anthrahydroquinones, and the suggestion that the color is due to the presence of a certain quantity of the bivalent radical is an attractive one. The reactions by which the compound stabilizes itself also find a ready explanation in terms of this hypothesis.

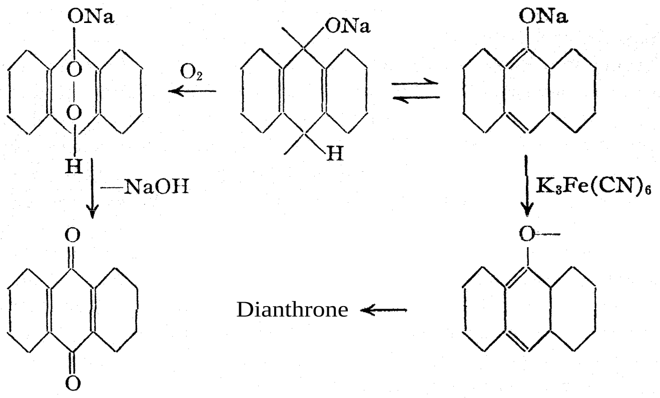
It may be pointed out in this connection that the assumption of free radicals furnishes the basis for a comprehensive interpretation of the alkaline oxidation of anthrahydroquinones and anthranols. It is generally agreed that the oxidation of sodium anthranolate to dianthrone by reagents other than oxygen proceeds through the intermediate formation of a univalent oxygen radical. The reaction with molecular oxygen must follow a different course, for the product is anthraquinone and not dianthrone. If the solution consists of an equilibrium mixture containing the trivalent carbon radical, this could form a peroxide which, by loss of sodium hydroxide, would yield anthraquinone. The reactions may be formulated as follows

---

[6] Wittig and Wiemer, Ann., 483, 144 (1930).

[7] Kuhn and Winterstein, *Helv. Chim. Acta*, 11, 87 (1928).

[8] Clar and John, *Ber.*, 63, 2967 (1930).



Applied to the action of oxygen on anthrahydroquinone in alkaline solution, the same mechanism may serve to account for the great speed of the reaction,[9] and it agrees well with the facts. The peroxide in this case would yield anthraquinone by the elimination not of sodium hydroxide but of sodium peroxide, and it is well known that this is one of the reaction products.

It must be recognized that the results presented in this paper neither confirm nor contradict the interesting hypothesis that anthracene derivatives partially isomerize to substances with trivalent meso carbon atoms and that the isomerization increases with the number of linear rings. Since any isomerization to radicals must be the result of a strained condition within the molecule for which the ortho quinonoid structure may be considered responsible, the ortho quinonoid theory may be extended to include the possibility of radical formation, and it is thus both the sounder and the more fundamental of the two views.

Experimental Part

2,3-Tetralanthraquinone.—As a result of the preparation of large quantities of this material, the following procedure can be recommended as representing some improvement of Schroeter's procedure for the preparation of *o*-[tetroyl-2]-benzoic acid.[10] A mixture of 250 g. of phthalic anhydride, 350 g. of tetralin, 1200 cc. of benzene and 400 g. of aluminum chloride was stirred and heated at the boiling point for three hours. After cooling, the benzene layer was decanted from the addition product and discarded. The addition product was decomposed by adding ice and 400 cc. of concentrated hydrochloric acid, and then treated with steam until most of the adhering benzene and tetralin was removed. After removal of the aqueous solution, the product was treated with a solution of 150 g. of sodium carbonate monohydrate and digested with steam until all but a small residue had dissolved and the remaining tetralin was evaporated. The solution yielded 459 g. (97%) of good product on acidification.

In the condensation to the tetralanthraquinones, it was found expedient to use two

[10] Schroeter, *Ber.*, 54, 2242 (1921).

to three times the quantity of sulfuric acid employed by Schroeter, though there was no improvement in the yield.

Naphthacenequinone.—A boiling solution of 50 g. of *lin.*-tetralanthraquinone in 350 cc. of glacial acetic acid was treated with 65 g. of bromine in the course of one-half hour. Most of the solvent was removed by distillation and the thick sirup which remained was washed out while still hot into a distilling flask with sealed-on receiver. The remaining solvent was distilled off, and the heating was continued cautiously in order to promote the evolution of hydrogen bromide. The reaction should be carried out as slowly as possible, for it easily becomes too vigorous. As the formation of naphthacenequinone reached completion, the contents of the flask suddenly solidified. The product was then distilled under diminished pressure with the use of an oil pump, and then redistilled. The crude product (44 g.) is best crystallized from tetxachloroethane, which has marked solvent power for the polycyclic quinones and hydrocarbons. A single crystallization gave 37 g. of the pure quinone, while a further 3-g. portion was recovered from the mother liquor; yield (pure), 81%.

Naphthacenequinone forms yellow needles from tetrachloroethane, very long yellow or orange-yellow needles from glacial acetic acid. The purest samples melted at 285°. Gabriel and Leupold[3] have described the characteristic color tests with concentrated sulfuric acid and with glacial acetic acid and zinc dust

2,3-Benz-9-anthrone (5-Oxo-naphthacene), V.—The best method of preparing the anthrone from naphthacenequinoneis by reduction with tin in glacial acetic acid solution. Zinc is too energetic in its action and invariably leads to the production of some naphthacene. It is of interest that the hydrocarbon produced by reduction with zinc and acetic acid does not come from 2,3-benz-9-anthrone, for this substance, though easily reduced when in the anthranol condition (alkaline solution), is not affected by prolonged boiling in glacial acetic acid solution with zinc and hydrochloric acid. It thus must result above from the reduction of benz-anthrahydroquinone.

Four grams of naphthacenequinone was suspended in 100 cc. of glacial acetic acid and boiled under the reflux with 8 g. of granular tin. The quinone slowly dissolved with the formation of a deep red solution; the color faded to a pale yellow-brown in about one hour, when the reduction was complete. The solution was filtered, treated with 10 cc. of concentrated hydrochloric acid, concentrated to half its volume, and allowed to cool. The anthrone separated in nearly pure condition (3.5 g.).

A second satisfactory method of preparing 2,3-benz-9-anthrone is by reduction in alkaline solution with sodium hydrosulfite. This will be described below.

The anthrone is readily soluble in glacial acetic acid or benzene and moderately soluble in alcohol. It forms yellow needles melting at about 196°, the temperature being dependent upon the rate of heating.

Anal. Calcd. for $C_{18}H_{12}O$: C, 88.49; H, 4.96. Found: C, 88.21; H, 5.16.

The solution of the anthrone in concentrated sulfuric acid is bright red. The compound is not soluble in aqueous alkali, but dissolves readily in alcoholic sodium hydroxide solution. The solution is intensely purple; when shaken with air it rapidly loses this color and naphthacenequinone precipitates. The anthrone is not enolized by pyridine, for the material was recovered unchanged after boiling a pyridine solution with acetic anhydride.

Naphthacenehydroquinone Diacetate **(9,10-Diacetoxy-2,3-benz-anthracene).**—Liebermann's method of reductive acetylation with zinc dust, sodium acetate and acetic anhydride gave a very poor yield in the present case owing to the great ease of reduction of naphthacenehydroquinone. The desired product was invariably contaminated with the anthrone and with naphthacene. A satisfactory preparation was found in the substitution of granular tin for zinc and proceeding in the usual manner. A pure product was thus easily obtained in good yield. The substance crystallizes well from glacial acetic acid, forming orange needles melting at 269°. Dilute solutions of the substance are yellow with a green fluorescence. The hydrolysis of the diacetate will be described below.

Anal. Calcd. for $C_{22}H_{16}O_4$: C, 76.72; H, 4.60. Found: C, 76.33; H, 4.98.

2,3-Benz-9-hydroxyanthrone (5-Hydroxy-12-oxo-5,12-dihydronaphthacene), III.—This compound was first obtained by adding successive portions of sodium hyposulfite solution to *a* boiling alcoholic suspension of naphthacenequinone. Each addition of reagent caused the solution to take on a red color which, however, disappeared suddenly in the course of a few minutes (ketonization of the hydroquinone); but even after several hours the reduction of the quinone was not complete. It was then found that the presence of a limited quantity of alkali materially assists in the reduction and in the formation of the desired compound. With a still larger quantity of alkali present the reduction does not stop at the hydroxyanthrone stage but converts this into the anthranol. The hydroxyanthrone also may be reduced with tin in glacial acetic acid solution, forming the anthrone.

To a suspension of 6 g. of naphthacenequinone in 400 cc. of boiling alcohol, there was added a concentrated aqueous solution of 12 g. of sodium hyposulfite and 10 cc. of 6 N sodium hydroxide. The quinone rapidly dissolved, giving a deep red solution having the appearance characteristic of an anthraquinone vat. After about two minutes, the color suddenly changed to a dark greenish-brown and then as suddenly cleared to a pale pink, with the separation of inorganic salts. The inorganic material, together with a small amount of unreacted quinone, was removed by filtering the hot solution and the latter was poured into an equal volume of water to precipitate the reaction product. The material was pale pink in color and very nearly pure. The yield depends somewhat upon the character of the starting material. If a crystalline sample of the quinone is used, about 10% of it is recovered unchanged. When the naphthacenequinone is prepared in finely divided condition by pouring a sulfuric acid solution of the substance into boiling water, the conversion is quantitative.

When the above procedure was altered only to the extent of using twice the specified quantity of alkali the course of the reduction was entirely different. The red, vat color persisted for about one-half hour, when a change to reddish-purple became apparent. After one hour the solution had the purple color characteristic of the anthranol salt, and it showed no further change on prolonged reaction. On acidifying and diluting the solution, 2,3-benz-9-anthrone was obtained in excellent yield. Reduction in an alcoholic medium in the presence of a large amount of sodium carbonate also led to the formation of the anthrone. When in a finely divided condition, naphthacenequinone may be reduced with hyposulfite and alkali in an aqueous medium. The solution first becomes deep green; the color then suddenly fades and a mixture of the anthrone and the hydroxyanthrone separates.

2,3-Benz-9-hydroxyanthrone dissolves readily in benzene or glacial acetic acid; it is moderately soluble in alcohol and sparingly soluble in ligroin. It forms excellent, long, hair-fine, yellow needles and decomposes at about 230°. A characteristic test for the compound is furnished by the deep red color which it imparts to alcoholic sodium hydroxide solution (see below). It is insoluble in aqueous alkali.

Anal. Calcd. for $C_{18}H_{12}O_2$: C, 83.05; H, 4.65. Found: C, 82.55; H, 4.57.

This benz-hydroxyanthrone enolizes readily in boiling pyridine solution and the solution rapidly acquires the deep red color characteristic of naphthacenehydroquinone. The color fades on shaking with the air and naphthacenequinone crystallizes from the solution. When heated with a mixture of equal parts of pyridine and acetic anhydride, the benz-hydroxyanthrone is converted largely into naphthacenehydroquinone diacetate,

m. p. 269°, though a part of the naphthacenehydroquinone becomes oxidized to the quinone before it can be acetylated.

2,3-Benz-9,10-dihydro-anthranol (5-Hydroxy-5,12-dihydronaphthacene), VII.—This compound has been obtained as the first product of the reduction of 2,3-benz-9-anthrone in alcoholic alkaline solution with zinc dust, but it is most readily prepared directly from naphthacenequinone. The velocity of reduction increases very rapidly with an increase in the concentration of alkali. Under the conditions of the experiment 2,3-benz-9,10-dihydro-anthranol is in turn easily reduced to dihydronaphthacene, and the formation of a small amount of this material could not be avoided. The best yields were obtained in the following manner.

A suspension of 1 g. of naphthacenequinone in 100 cc. of alcohol and 10 cc. of 25% sodium hydroxide was boiled with 5 g. of zinc dust for one hour. The quinone rapidly dissolved to give a deep red solution; this became deep green within a few minutes and then the color slowly faded. At the end of the time specified the solution was pale greenish-yellow. It was cooled and the residue, consisting chiefly of zinc, was washed with water, dried and extracted with benzene. The benzene extract contained dihydronaphthacene (0.2 g.). The 2,3-benz-9,10-dihydro-anthranol was precipitated with water from the alcoholic solution. In order to remove a trace of zinc hydroxide and dihydronaphthacene, the crude product was dissolved in alcohol containing one drop of sodium hydroxide; the solution was cooled well, filtered and the product was precipitated with water. The material cannot be further purified by crystallization from pure solvents such as alcohol or ligroin because it is partially converted by the boiling solvents into naphthacene. A trace of an alkaline reagent, however, prevents this dehydration. The substance thus crystallizes well from benzene–ligroin containing a drop of pyridine. The solvent completely removes an otherwise persistent yellow color, and the compound forms colorless silken needles which form cottony clusters of great beauty.

Anal. Calcd. for $C_{18}H_{14}O$: C, 87.77; H, 5.73. Found: C, 87.40; H, 5.75.

The benz-dihydro-anthranol has no melting point but decomposes even on very gentle heating with the formation of naphthacene. The dehydration occurs slowly on boiling an alcoholic solution of the substance, and it is completed within a few seconds if a trace of mineral acid is added. This is a good way of preparing pure naphthacene.

Dihydronaphthacene, **VIII.**—A good method of preparing this substance consists in reducing naphthacenequinone with zinc dust and alcoholic alkali in exactly the manner described above, with the exception that the heating is continued for six hours. Water is added to the now pale yellow solution and the product is extracted from the zinc with benzene. The purified material was yellow and melted at 207°. Like Gabriel and Leupold,[3] I was unable to remove the colored impurity.

Naphthacene.—This hydrocarbon was obtained both from 2,3-benz-9,10-dihydro-anthranol and by the zinc dust distillation of 2,3-tetralanthraquinone. The zinc serves to hydrogenate one part of the molecule, while it dehydrogenates another part.

One gram of 2,3-tetral-anthraquinone was dissolved in benzene in a small distilling flask and treated with 50 g. of zinc dust. After evaporation of the benzene, a further 25 g. of zinc dust was added and the flask was strongly heated. The distillate (0.5 g.) crystallized from tetrachloroethane, forming orange plates melting at 331°; it was identical with naphthacene.

Di-(2,3-benz-9-anthronyl) Ether, X.—This compound first made its appearance when a mixture of naphthacenequinone and naphthanthraquinone was being separated by vatting the latter compound with alkaline hyposulfite solution. Naphthacenequinone does not vat in the usual way, but as a result of the repeated treatment with hyposulfite, a small portion of the material was converted into the new ether. The substance concentrated in the mother liquors from the crystallization of the naphthacenequinone from glacial acetic acid. It was later found that the substance is produced in good yield when a very weakly alkaline solution of 2,3-benz-9-anthrone in alcohol is boiled for about one week in an atmosphere of nitrogen in a three-necked flask carrying rubber stoppers. The observation that the anthrone solution is perfectly stable when boiled in an all-glass apparatus led me to suspect that the observed reaction is an oxidation brought about by the sulfur in the stoppers. This was confirmed by experiment, and a suitable method of preparation thus became available.

Three grams of 2,3-benz-9-anthrone was dissolved in 450 cc. of alcohol, the solution was swept free of oxygen, and 1 g. of sulfur was added. A few drops of alkali were added to produce a purple solution, and more was added later to maintain a weakly alkaline solution. Crystals of the ether soon began to deposit on the walls of the flask and the reaction was complete in about three hours. The product was collected from the hot solution, which was very dark in color, and smelled of hydrogen sulfide. The material so prepared was very nearly pure; yield, 2 g.

The ether is very sparingly soluble in alcohol or benzene. It is very soluble in chloroform, but dissolves quite slowly. It may be purified by dissolving in chloroform, concentrating the solution and precipitating the product with petroleum ether. Good crystals are formed from glacial acetic acid, though the substance dissolves very slowly in this solvent and crystallizes only after considerable concentration. Thus naphthacenequinone, which crystallizes first from a mixture with the ether, can be dissolved out of such a mixture with glacial acetic acid, without dissolving the ether. The latter substance also crystallizes well from pyridine, in which it is very soluble. The ether forms small, salmon-colored plates melting at 295°. Crystals from chloroform are colorless, but acquire the above color on drying. A characteristic property of the ether is its color in concentrated sulfuric acid. The cold solution is bright red; on standing, or on gentle heating, it changes to an intense, pure blue.

Anal. Calcd. for $C_{36}H_{22}O_3$: C, 86.03; H, 4.42. Found: C, 86.03, 86.22; H, 4.79, 4.50. *Mol. Weight.* Calcd.: 502.2. Found (Rast): 498,496.

In the modified Zerewitinoff "machine" of Kohler[11] the substance showed no active hydrogen atoms, but added well over one mole of Grignard reagent in five minutes, even though it did not completely dissolve. The ether is converted quantitatively into naphthacenequinone by chromic acid, or into 2,3-benz-9-anthrone by tin and glacial acetic acid.

The relationship of the ether to 2,3-benz-9-hydroxyanthrone was established by the following experiment. To a suspension of 0.6 g. of the latter compound in 5 cc. of acetic anhydride a drop of concentrated sulfuric acid was added. The material rapidly dissolved to give a dark brown solution and crystals of the ether soon began to separate. After heating for one-half hour on the steam-bath, the product was collected and purified. It formed the characteristic salmon-colored plates melting at 295°, and was identical with the material prepared previously.

The Properties **of Naphthacenehydroquinone (II).**—This substance is the primary reduction product of naphthacenequinone in acid or alcoholic alkaline medium, and it imparts a red color to the solvent in either case. The solution in alcoholic alkali is deep blood-red; the alcoholic or glacial acetic acid solution is only slightly brighter. The action of zinc dust and acetic acid on naphthacenequinone produces only an eosin-red solution, because the hydroquinone is reduced further nearly as rapidly as it is formed, but by the substitution of tin for zinc a solution can be obtained which approaches in intensity the usual anthraquinone vat color. Because of its sensitivity to further reduction, solutions of the hydroquinone are best prepared from its diacetate or from its ketonic modification, though in neither case is it possible to prepare an unquestionably

---

[11] Kohler and collaborators, THIS JOURNAL, 49,3181 (1927); 51,3736 (1930).

pure solution, for the substance very readily undergoes a disproportionation. The reaction is best described by quoting a few experiments.

A suspension of 0.5 g. of naphthacenehydroquinone diacetate in 150 cc. of alcohol was boiled in an all-glass apparatus in an atmosphere of nitrogen and then cooled to room temperature, when only a part of the material remained in solution (yellow). On adding 15 cc. of 6 N sodium hydroxide the solution became deep green. In a few seconds this changed to blue and this as rapidly changed to reddish-purple. On warming, the solution became deep red. These striking color changes are interpreted as follows. The blue solution probably contains the monoacetate, which is a derivative of 2,3-benz-9-anthranol and which might well exhibit a similar color. The final red color is without doubt due to the presence of the hydroquinone salt or ion. The green and purple solutions thus represent mixtures of the diacetate and monoacetate and of the monoacetate and the hydroquinone. The red color was not permanent but changed in the course of three to four days (at the boiling point) to the intense purple characteristic of solutions of the anthranol. When this solution was acidified, it became pale yellow at once and it was found to contain naphthacenequinone and the corresponding anthrone. The experiment shows that disproportionation of the hydroquinone takes place slowly in strongly alkaline solution.

In another experiment the diacetate was hydrolyzed in exactly the same manner, but as soon as the solution reached the pure red stage (five minutes) it was acidified with an excess of hydrochloric acid. The color changed from the deep, vat red to a less intense, bright red. This rapidly faded and in fifteen minutes it had become pure yellow. The alcoholic solution was found to contain about equal parts of naphthacenequinone and the anthrone. This shows that the disproportionation of the hydroquinone takes place much more rapidly in acid than in alkaline solution. The fading of the red solution of the hydroquinone as the result of the disproportionation was less rapid in the presence of acetic acid.

When a much smaller amount of alkali (1–2 cc.) was used to hydrolyze the diacetate (0.5 g.) in alcoholic suspension, the solution became green, then blue and finally purple, and the red color characteristic of the anthrahydroquinone was never reached. The acidified solution was only faintly pink and it contained the usual products of oxidation and reduction. The conclusion drawn from this observation is that the disproportionation occurs as rapidly in a weakly alkaline solution as in the presence of acids. The anthrahydroquinone disappears about as rapidly as it is produced by hydrolysis.

The benz-anthrahydroquinone may also be produced in solution by the enolization of 2.3-benz-9-hydroxyanthrone by alcoholic alkali, but the process is so slow that some of the material is probably destroyed by disproportionation during the period required. Thus when a boiling solution of 0.5 g. of the material in 150 cc. of alcohol was treated with 15 cc. of 6 N sodium hydroxide, the solution became deep brown and only acquired the intensely red color after one and one-half hours. On adding hydrochloric acid, the bright red solution which rapidly changes to yellow was again obtained. An observation for which I cannot account is that the addition of a few drops of alkali to an alcoholic solution of the hydroxy-anthrone produces at once a light red solution, while with a large amount of alkali the solution changes from red to brown to red only slowly. The light red solution can hardly contain a large amount of the anthrahydroquinone, because it undergoes disproportionation only after several days.

Summary

A satisfactory method of preparing naphthacenequinone consists in the dehydrogenation of 2,3-tetralanthraquinone with bromine. By choosing suitable reagents and conditions, naphthacenequinone may be converted

in good yield into any one of the following reduction products: the keto form of the hydroquinone, the anthrone, a di-anthronyl ether, the dihydroanthranol, naphthacene or dihydronaphthacene. Naphthacenehydroquinone, known only in solution or in the form of derivatives, is a remarkably unstable substance. It may be reduced with great ease, it ketonizes readily and it also undergoes a disproportionation.

All of the naphthacene derivatives which have a completely aromatic structure show a marked tendency to pass into derivatives of dihydronaphthacene. This is interpreted in terms of the ortho quinonoid structure for anthracene. The theory of bivalent radical formation is also discussed.

THE PREPARATION AND SOME PROPERTIES OF THE CHLOROMANDELIC ACIDS, THEIR METHYL ESTERS AND AMIDES

BY SANFORD S. JENKINS[1]

RECEIVED APRIL 3, 1931 • PUBLISHED JUNE 8, 1931

In connection with another research[2] some derivatives of the chloromandelic acids were desired. Apparently only the ortho[3] and para[4] acids and the para[5] amide have been described heretofore. It was thus decided to prepare the three acids with the corresponding methyl esters and amides.

The method of Karrer,[3] in which o-chloromandelic acid was obtained from the aldehyde through the cyanohydrin, was employed. Certain modifications described in the experimental part, however, greatly increased the yield. For the esterification the method of Fischer and Speier[6] was employed. The amides were obtained by treating alcoholic ether solutions of the esters with anhydrous ammonia. The reactions are

$$ClC_6H_4CHO \xrightarrow{HCN} ClC_6H_4CHOHCN \xrightarrow{H_2O} ClC_6H_4CHOHCOOH \xrightarrow{CH_3OH}$$

$$ClC_6H_4CHOHCOOCH_3 \xrightarrow{NH_3} ClC_6H_4CHOHCONH_2$$

Experimental

Preparation of **the** Chloromandelic Acids.—Into a 500-cc. Claisen flask standing in an ice-bath were placed 100 g. of the chlorobenzaldehyde, 48 g. of 96–98% potassium

cyanide, finely powdered, and 150 cc. of ether. Seventy-five cc. of concentrated hydrochloric acid was added from a dropping funnel during forty-five minutes, while the solution was being rapidly stirred mechanically. The ice-bath was removed after thirty minutes more and the stirring continued for two hours longer at room temperature. Since cyanohydrins, in general, are unstable, no attempt was made to isolate them. The ether solution containing the nitrile was decanted from the potassium chloride directly into 500 cc. of concentrated hydrochloric acid. The acid mixture was heated on a boiling water-bath for five hours with vigorous mechanical stirring. The cooled solution was made slightly alkaline with 30% sodium hydroxide and extracted twice with 150-cc. portions of ether to remove unchanged material. The purified solution of sodium chloromandelate was then treated wth 75 cc. of concentrated hydrochloric acid and again extracted twice with 150-cc. portions of ether. The ether solution was dried over anhydrous sodium sulfate after which the ether was distilled and the crude chloromandelic acid recrystallized from benzene. (See Table II for yields and analytical data.)

The ortho and para chlorobenzaldehydes used in this work were purchased from the Eastman Kodak Company, the former being the practical grade. The *m*-chlorobenzaldehyde was prepared from m-nitrobenzaldehyde according to the method of Erdmann and Schwechten.[7]

Preparation of the Methyl Esters.[6]—Fifty grams of acid, 300 cc. of absolute methyl alcohol and 15 cc. of concentrated sulfuric acid were refluxed for five hours, after which 225 cc. of the alcohol was distilled off. The remaining liquid was made slightly alkaline with 10% sodium carbonate solution and extracted twice with 100-cc. portions of ether. The ether solution was dried over anhydrous sodium sulfate and the ester obtained by distilling off the ether.

The ortho ester was purified by fractionation *in vacuo* since it could not be induced to crystallize. The meta and para esters were obtained pure by crystallization from benzene–petroleum ether (b. p. 30–60°) solution.

Preparation of the Chloromandelamides.—The amides were prepared by dissolving 25 g. of the esters in 50 cc. each of anhydrous ether and absolute alcohol. The solution

---

[7] Erdmann und Schwechten, Ann., 260, 53 (1890).

was cooled to 0° and treated with anhydrous ammonia for ten hours At the expiration of this time most of the amide had crystallized out. The alcohol and ether were evaporated under reduced pressure, after which the amide was pulverized and washed with ether. This treatment gave a product sufficiently pure for most purposes. The pure amides were obtained by recrystallization from benzene.

[a] Karrer reported 18 g. of this acid from 50 g. of o-chlorobenzaldehyde or 28%.

In conclusion the writer wishes to thank Dr. E. Emmet Reid for his interest and valuable suggestions.

Summary

1. A convenient method for the preparation of the monochloromandelic acids has been described.
2. The complete series of acids, methyl esters and amides was obtained and some properties of these compounds are given. Six new compounds were prepared in the course of this work.

THE ACTION OF SODIUM ON CELLULOSE IN LIQUID AMMONIA

BY PHILIP C. SCHERER, JR., AND ROBERT E. HUSSEY

RECEIVED APRIL 8, 1931 PUBLISHED JUNE 8, 1931

The action of sodium hydroxide solutions upon cellulose to form a compound of cellulose which has attained commercial importance in the viscose process has long been known.[1] The constitution of the compound formed in this reaction has never been definitely established although, reasoning from analogy with the ordinary alcohols, it has been assumed to be of a sodium alcoholate type in which the hydrogen atom of one, or possibly more, hydroxyl groups is replaced by sodium. Definite proof of such a compound is, however, lacking and the authors in this research have attempted to supply some evidence of it.

Kraus and his students[2] have shown that when an alcohol is treated with sodium in liquid ammonia, a sodium alcoholate results and an atom of hydrogen is liberated according to the general reaction

$$ROH + Na = RONa + \tfrac{1}{2}H_2$$

In applying this general reaction to cellulose several points were investigated. First, the amount of hydrogen obtainable from a definite amount of sodium reacting with cellulose was carefully determined and was found to agree very closely with the above reaction. Second, the final product was examined and found to possess in full the property of normally prepared soda cellulose, of reacting with carbon bisulfide to form xanthates completely soluble in water or alkali. This reaction is treated in more detail in another paper.[3] Third, it was found that there was no appreciable amount of sodium amide formed as a product of the reaction of the sodium with the solvent. The hydrogen evolved in the experiments, then, could only have come from the reaction of the sodium upon the cellulose. Fourth, it was found that one atom of hydrogen per $C_6H_{10}O_5$ group was rapidly and easily displaced. The succeeding atoms of sodium entered very slowly, due possibly to the formation of a film of rather insoluble soda cellulose about the fibers. This slower rate of reaction might also be due to lesser affinity of the secondary alcohol groups for the sodium or to an overloading of the molecule with such a strongly positive atom as sodium. No matter in what excess nor for how long a time such an excess of sodium was allowed to react upon cellulose, no more than three atoms of sodium per $C_6H_{10}O_5$ group could be introduced into the molecule. This reaffirms

[3] Hussey and Scherer, "Rate of Reaction between Carbon Disulfide and Soda Cellulose."

previous evidence from acetylation and nitration of the presence of only three hydroxyl groups per $C_6H_{10}O_5$ group.

A consideration of the above described results leads to the conclusion that cellulose reacts in liquid ammonia as a typical tribasic alcohol and that, by analogy, the product of its reaction with solutions of caustic soda is probably sodium cellulose alcoholate. The number of hydroxyl groups so converted by sodium hydroxide solution probably depends upon the conditions of the reaction. Soda cellulose prepared by the action of metallic sodium in liquid ammonia is being used in this Laboratory as a material for an investigation of its reactions with other reagents.

Experimental Part

Apparatus.—As indicated in the sketch, the reaction tube consisted of a Pyrex glass test-tube (A), 32 by 300 mm., immersed in a Dewar tube (B) containing liquid ammonia boiling at atmospheric pressure. Tube (C) which passed through the rubber stopper of the reaction tube was a T tube in which the sodium to be added could be suspended by means of the movable rod (D). This tube also served to connect the reaction vessel to either the manometer (F) or the eudiometer (G) through the two-way stopcock (E). The manometer served as a mercury seal to the apparatus and to supply the pressure necessary to condense ammonia in (A). The hydrogen evolved was collected over water in order to remove the gaseous ammonia.

The ammonia was dried by passing over fused potassium hydroxide in the two towers (K) and then through a tube (J) packed with carefully dried Bentonite and the train was kept free of moisture and air by the mercury seals (I).

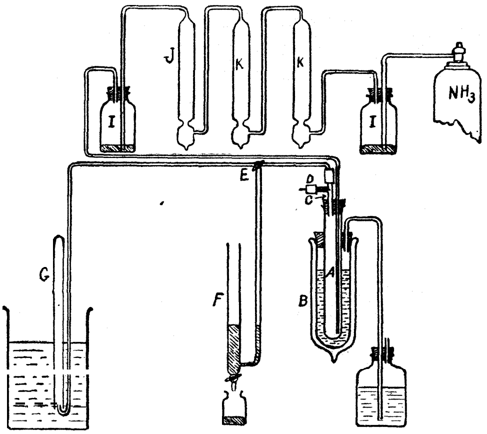

Fig. 1.

Procedure and Materials.—In order to prove the absence of water in the condensed and gaseous ammonia, about 50 cc. of ammonia from the train was condensed in **(A)** and 0.1 g. of freshly cut sodium was suspended in tube (D). After all gases had been blown out by a rapid current of ammonia, the sodium was dropped into the condensed ammonia. Absolutely no hydrogen was collected even after several hours.

The sodium used in the experiments was freshly cut under low boiling petroleum ether, weighed in Nujol, washed carefully in petroleum ether and then introduced into tube (D).

The cellulose used in these experiments was of three types. The first was a standard cellulose prepared from absorbent cotton according to the method described by Corey and Gray.[4] This contained 98.7% alpha cellulose and 0.10% ash.

The wood pulp cellulose was prepared by finely dividing and carefully drying Brown Company alpha pulp containing 94.67% alpha cellulose and 0.136% ash.

---

[4] Corey and Gray, *Ind. Eng. Chem.*, 16, **853** (1924).

The regenerated cellulose used was prepared by finely dividing and carefully drying bleached and desulfurized viscose rayon prepared from Brown Company alpha pulp.

In all the experiments a sample of cellulose, accurately weighed in a weighing bottle, was placed in the reaction tube and about 50 cc. of ammonia condensed on it under a pressure of about 15 cm. of mercury in the manometer. The pressure was released by running mercury from the manometer and, with a rapid stream of ammonia passing, the tube (D) was opened and the weighed sodium suspended therein. The tube was closed and the apparatus was freed of traces of air and petroleum ether by a current of ammonia. By means of the two-way stopcock the apparatus was connected to the eudiometer and the sodium was dropped into the reaction vessel. A vigorous reaction ensued which was timed from the first addition of the sodium to the disappearance of all trace of the characteristic blue color of free sodium. After careful sweeping, the collected gas was measured and analyzed.

The residue in the reaction tube was allowed to settle and was washed several times by condensation of fresh portions of ammonia upon it. The liquid was removed each time by suction and evaporated under reduced pressure. After warming to drive out ammonia, the infinitesimal residue was dissolved in water and was of sufficient alkalinity to turn phenolphthalein. One drop of $N/10$ sulfuric acid was sufficient to turn the solution acid and it was concluded that no sodium amide resulted from the reaction The cellulosic residue, as described in another paper,[1] gave typical xanthates.

Results

The results were compiled into tables for ease of comparison and are given herewith.

EXPERIMENTS WITH STANDARD CELLULOSE

Ratio cellulose/sodium	Cell, g.	Sodium, g.	Time, min.	Atoms of H_2 per atom of sodium

1:2 93	.1358	.0564	150	.925
1:excess	.2532	.2310	240	2.949[a]
			General average	0.990

[a] These values give the atoms of hydrogen replaced per $C_6H_{10}O_5$ group, the general average of which is 2.993 atoms.

Summary

1. The action of metallic sodium on cellulose in liquid ammonia has been studied.

2. One atom of sodium enters the molecule rapidly, whereas the second and third enter very slowly.

3. A maximum of three atoms of sodium per $C_6H_{10}O_5$ group enters the molecule.

4. The reaction corresponds in general to the ordinary alcoholate reaction, ROH + Na = RONa + $\frac{1}{2}H_2$.

3. It is concluded that cellulose acts as an alcohol in liquid ammonia and probably does so in its other reactions in other solvents.

THE IDENTIFICATION OF MESACONIC ACID[1]

BY H. H. MOTTERN AND G. L. KEENAN

RECEIVED APRIL 9, 1931 PUBLISHED JUNE 8, 1931

During an investigation of the occurrence of organic acids in plant material, interest was aroused in the true melting point of mesaconic acid, and also in the preparation and physical and chemical properties of some new derivatives which might prove useful in its identification. Of the derivatives commonly used, the amide is the only one which previously has been reported, but since the hydrazide is the most easily prepared, when the ester is available, it has been the derivative most commonly used in this Laboratory for the identification of naturally occurring organic acids.

---

[1] Food Research Division Contribution No. 103.

Mesaconic acid and two of its derivatives, the hydrazide and *p*-nitrobenzyl mesaconate, being definitely crystalline, readily lend themselves to a microscopical study by the optical immersion method. The optical data given are of considerable importance in the rapid and accurate identification of small amounts of these substances. They have not been reported heretofore.

Experimental

Mesaconic Acid.—Mesaconic acid was prepared from citraconic anhydride by the method of Fittig.[2] Citric acid was distilled at atmospheric pressure and the oily layer obtained in the distillate was separated from the aqueous layer and redistilled; 40 g. of citraconic anhydride thus obtained was dissolved in 80 cc. of water containing 12 cc. of concentrated nitric acid, and the solution was boiled until fumes of nitrogen tetroxide appeared. When the solution had cooled, mesaconic acid crystallized out and was separated from the mother liquor by filtration. The acid was purified by recrystallization from water and was dried at 100°. It melted at 204.5° corrected When sublimated in a Hortvet sublimator it showed no change in melting point. Mesaconic acid obtained from Kahlbaum melted at 204°. The melting point is variously stated in the literature to be from 200.5 to 208°, 202° being the most commonly accepted temperature.

The melting points were taken on two different types of melting point apparatus, including the electrically heated apparatus of Sando.3 Anschiitz and Wheeler total immersion thermometers with Bureau of Standards corrections were used. All determinations were by the capillary method and were taken slowly, as the compound does not show any decomposition at this temperature within the ordinary time of taking a melting point. It is concluded therefore that 204.5" represents the melting point of mesaconic acid more closely than any figure previously reported.

Optical Properties.—Mesaconic acid, sublimed, is colorless and rod-like in habit, usually occurring in laminated, fibrous masses. With crossed nicols (parallel polarized light), the rods show parallel extinction, and the elongation is positive or negative. The double refraction apparently is very strong. The minimum index of refraction (immersion method) is considerably less than $n = 1.445$. The acid is soluble in all the oily mixtures available. The maximum refractive index (γ) was found to be 1.740 (methylene iodide) but occurs infrequently. The most significant refractive index for the substance is that shown when the elongated crystals are oriented with their long axis parallel to the vibration plane of the lower nicol. In this position the rods frequently match a liquid with $n = 1.690$ (apparently the β-value). This liquid is most useful for determinative purposes since the intermediate value occurs so frequently and is always shown lengthwise on the rods. The liquid used for this purpose consisted of a mixture of monochloronaphthalene and methylene iodide in proportions to give the refractive index desired.

A sample of mesaconic acid obtained from Kahlbaum, and one prepared from citric acid showed the same optical constants as the sublimed material.

Diethyl Mesaconate.—Fifteen grams of mesaconic acid prepared as previously described was refluxed for eighteen hours on a steam-bath with 300 cc. of absolute alcohol containing 2% of dry hydrogen chloride. The alcohol was then distilled off and the ester was dissolved in ether and washed in a separatory funnel with dilute sodium hydroxide solution until the wash water remained alkaline, then dried with anhydrous

---

[2] R. Fittig, ***Ann.***, 188, 73 (1877).

[3] C. E. Sando, Ind. ***Eng. Chem., Anal. Ed.*, 3**, 65 (1931).

sodium sulfate. The ether was distilled off and the ester distilled under reduced pressure. The diethyl mesaconate so obtained boiled at 93–95° under 10 mm. pressure. The boiling point under reduced pressure has not been previously reported.

Mesaconic **Hydrazide.**—The hydrazide of mesaconic acid was prepared from the ester as follows. One cc. of 42% hydrazine hydrate in water was added to a solution of 0.7 g. of the ester in 5 cc. of absolute alcohol. After standing overnight the hydrazide crystallized out in the form of clear. glassy rods. It was soluble in water and insoluble in alcohol. On recrystallization from dilute alcohol the hydrazide melted with decomposition at 217–218°, corrected.

Anal. Subs., 0.0982, 0.0969: CO_2, 0 1377, 0.1866; H_2O, 0.0550, 0.0560 Subs., 0.0438, 0.0435: N, 0.0157, 0.0157. Caled. for $C_5H_{10}N_4O_2$: C, 37.96; H, 6.37; N, 35.43. Found: C, 38.25, 38.18; H, 6.27, 6.47; N, 35.85, 36.09.

Optical Properties.—When examined at a magnification of 15 diameters, mesaconic hydrazide, crystallized from dilute alcohol, is seen to consist of clear, glassy rods. For microscopical examination by the immersion method, the substance is pulverized into a fine powder, producing irregular fragments. When examined with crossed nicols (parallel polarized light), most of the fragments extinguish sharply and show colors of first and second order. Occasionally fragments occur which do not extinguish sharply, remaining essentially bright when the stage is rotated, and showing a partial biaxial interference figure with the optic axis up when the material is examined in convergent polarized light (crossed nicols). The refractive indices are: n_α 1.583; n_β 1.610; n_γ 1.680; all ±0.003.

p-Nitrobenzyl Mesaconate.—The p-nitrobenzyl ester of mesaconic acid was prepared by the method of Reid.[4] On recrystallization from dilute alcohol it melted sharply at 134° corrected.

Optical Properties.—p-Nitrobenzyl mesaconate crystallizes in rods and plates. With crossed nicols, the extinction is parallel and the elongation negative. The refractive indices are $n_\alpha = 1.610$, occurring frequently lengthwise on rods; $n_\beta = 1.627$, frequently shown crosswise on rods; $n_\gamma = 1.680$, also shown crosswise on rods but not as common as α and β; all ±0.003. In identifying the substance by the optical immersion method, the ***a***- and ,!?-values are very useful.

Summary

The capillary melting point of mesaconic acid was found to be 204.5". The ethyl ester boiled at 93–95' at 10 mm. The melting point of the hydrazide is 217–218°, and of the p-nitrobenzyl ester, 134". Both the hydrazide and the p-nitrobenzyl ester were found to be satisfactory derivatives for the purpose of identification, but the hydrazide is the more easily prepared, if the ester is available. Optical crystallographic data for the acid and two of the derivatives are given.

MIXED BENZOINS. V. REVERSIBILITY OF THE BENZOIN CONDENSATION AND THE PREPARATION OF MIXED FROM SIMPLE BENZOINS

BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED APRIL 9, 1931 PUBLISHED JUNE 8, 1931

Much work has been done on the benzoin condensation and various suggestions have been advanced as to its mechanism, but it can scarcely be said that the reversibility of the reaction has been demonstrated in an unexceptionable manner. Much of the work is irrelevant as it was carried out under conditions far different from those ordinarily used. For example, the heating of the dry reagents to high temperatures can scarcely be called a benzoin reaction. In most cases where the conditions were comparable, benzaldehyde was estimated by difference, or detected by the odor, a risky procedure where many side-products may be formed. Another factor apparently not recognized by earlier workers is what may be called the eccentricity of the reaction, that is, the occasional rapid and unusually favorable progress of the reaction. An instance is remarked by Adams[1] and the present authors have frequently encountered similar cases. No explanation for this phenomenon can be offered at present.

The best yields recorded for benzoin itself are about 90%, the other 10% being accounted for as unchanged benzaldehyde and side-products such as mandelic acid, benzoic acid, benzyl alcohol, toluylene hydrate, amarine, etc. In the equation $2C_6H_5CHO \longleftrightarrow C_6H_5CHOHCOC_6H_5$ it is evident that the equilibrium lies well over to the right. A means of removing benzaldehyde as generated would enable the right-to-left reaction to be demonstrated clearly. Such a means was found by adding a second aldehyde to the solution of benzoin in aqueous alcoholic potassium cyanide, whereby a mixed benzoin was formed. In a number of cases this mixed benzoin could be isolated and identified.[2] The equation is

$$C_6H_5CHOHCOC_6H_5 + 2XC_6H_4CHO = 2C_6H_5CHOHCOC_6H_4X$$

Specifically, benzoin and *p*-dimethylaminobenzaldehyde, refluxed in aqueous-alcoholic solution, in the presence of potassium cyanide, gave an excellent yield of *p*-dimethylaminobenzoin, proving beyond doubt that the benzoin had broken up into benzaldehyde. Piperoin and furoin were found to behave similarly. In the case of anisoin, no mixed benzoin was

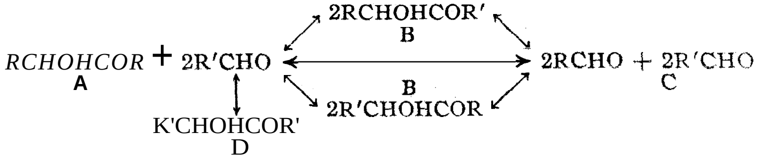
---

[1] Adams, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1921, Vol. I, p. 34.

[2] Hörbye, "Dissertation," Dresden, 1917, seems to have had a similar idea in mind. He heated benzoin with anisaldehyde and anisoin with benzaldehyde (no cyanide was used) and obtained only negative results.

obtained, but a portion of the anisoin was recovered, even after ample refluxing.

Having proved that a benzoin may give rise to the corresponding aldehyde, the scheme shown for the formation and equilibrium of a mixed benzoin follows logically



In previous work, the authors have obtained the mixed benzoin B by going from C to B. In the present work, the benzoin B is obtained by the route A to B. It would be of interest to compare these two routes from a strictly quantitative point of view, but the practical difficulties in the way are formidable.

The above scheme carries several interesting implications. A mixed benzoin, in the presence of aqueous-alcoholic potassium cyanide, should give rise to a mixture containing the two corresponding simple benzoins. In the presence of added aldehydes, further mixed benzoins would be formed. Similarly, a mixture of two simple benzoins should be capable of giving rise to mixed benzoins. There is also a possibility that a given mixed benzoin, in aqueous-alcoholic potassium cyanide solution, might change into its isomer, but this would only be expected in the sense of the less stable isomer changing into the more stable isomer. Work is in progress on some of these possibilities, but it is not to be expected that more than a few instances of each type will be found, on account of experimental difficulties. It is evident that unless one particular product is uncommonly favored by conditions such as yield, solubility, crystallizing tendency, etc., its isolation from a complex reaction mixture would be impossible—at least, provided that it contained no special groups such as $-NMe_2$. The same considerations make it evident why comparatively few mixed benzoins are isolable from the usual condensation mixtures.

Ideally, the same point should be reached (using appropriate molecular proportions) by starting with (a) two aldehydes X and Y, (b) aldehyde X with the benzoin from Y, (c) aldehyde Y with the benzoin from X, (d) the benzoin from X with the benzoin from Y, (e) either of the isomeric mixed benzoins from X and Y. It is improbable that this can be demonstrated for several reasons, such as the formation of side products, the instability of certain aldehydes (*e.* g., furfural), the inability of an aldehyde to form a simple benzoin (*e.* g., *p*-dimethylaminobenzaldehyde) or the impossibility of isolating the simple benzoin (*e.* g., veratroin), and the difference in stability of any two isomeric mixed benzoins.

The method under discussion (the preparation of a mixed from a simple benzoin) does not appear to offer any marked advantages over the older method, starting with two aldehydes. It is also limited by the non-existence of many simple benzoins.

The authors have refrained from discussing the various hypotheses of benzoin formation given in the literature. Lachman[3] gives a review of this field.

Experimental

The experimental conditions were chosen so that the reactions took place under conditions approximating those of the usual benzoin condensation. One mole of the benzoin and two moles of the aldehyde were dissolved hot in the given volume of alcohol and the potassium cyanide added in saturated aqueous solution. The mixture was then boiled under a reflux condenser on the steam-bath, **5** cc. of water being added as soon as boiling commenced. After the elapse of the stated time, the flask was removed and cooled, alcohol or water added as required, and the mixture kept in a cold place. With manipulation and attention, the product crystallizes out in time. A second or third crop may sometimes be obtained by diluting the liquors or by adding further potassium cyanide and again refluxing. The yields are given for unrecrystallized but washed material of good grade. For identification, this was recrystallized and compared with an authentic specimen. Mixed melting point determinations also were made. Experiments carried out with anisoin and different aldehydes resulted in the recovery of part of the anisoin. Mixed benzoins, which were doubtless formed, were not isolated. **A** peculiar product was obtained from anisoin and piperoin. This appears to be a double compound of anisoin and piperoin, since it can be obtained by simply crystallizing anisoin with piperoin from alcohol. Analysis so far has not given concordant results, but the crystalline form, melting point, etc., of the product are distinct from those of the components.

p-Dimethylaminobenzpiperoin, not previously described, may be obtained as given in the table, or, more conveniently, by refluxing for two hours, **6.00** *g*. of piperonal and 5.96 g. of p-dimethylaminobenzaldehyde, dissolved together in **30** cc. alcohol, with **4.0** g. of potassium cyanide (added in saturated aqueous solution). The crystalline mass which separates is filtered off after three days and recrystallized from alcohol. The compound forms a dull-white mass of tiny fern-like crystals. It is moderately soluble in alcohol, soluble in cold acetic acid, cold dilute (1:1) hydrochloric acid, cold acetone and cold chloroform; readily soluble in warm benzene, and soluble in cold concd. sulfuric acid to an intense blackish-crimson solution. The benzoin melts at 132° to a turbid liquid, clear at **136°**.

Anal. Calcd. for $C_{17}H_{17}O_4N$: **C, 68.19; H, 5.73; N, 4.68.** Found: **C, 68.47; H, 5.92; N, 4.77.**

Summary

A general method for demonstrating the reversibility of the benzoin condensation is described, involving the preparation of mixed benzoins from simple benzoins. Some of the consequences of the reversibility are discussed. A new mixed benzoin is described.

STEREOCHEMISTRY OF N,N′-DIPYRRYLS. RESOLUTION OF N,N′,2,5,2′,5′-TETRAMETHYL-3,3′-DICARBOXYDIPYRRYL. XVI[1]

BY CHIN CHANG[2] AND ROGER ADAMS

RECEIVED APRIL 11. 1931 PUBLISHED JUNE 8, 1931

The resolution of N,2-carboxyphenyl-2,5-dimethyl-3-carboxypyrrole[1b] (I) demonstrated that optical isomerism which was possible in properly substituted diphenyls, due presumably to restricted rotation of the rings, may also occur in substituted N-phenylpyrroles. This indicates the probability of optical isomerism in other dicyclic compounds such as in properly substituted dipyrryls. The more important general types of this class of compounds which from analogy to the diphenyls might exhibit isomerism may be represented by the Formulas II, III, IV.

The investigation described in this communication has involved the

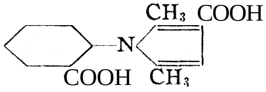
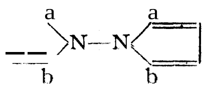
[2] This communication is an abstract of a portion of a thesis submitted by Chin Chang in partial fulfilment of the requirements for the degree of Doctor of Philosophy in chemistry.

preparation and resolution of a N,N′-dipyrryl of type III, namely, N,N′-2,5,2′,5′-tetramethyl-3,3′-dicarboxydipyrryl, the two enantiomorphs of which might be represented by Formulas V and VI.

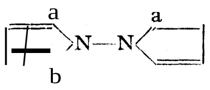
These are written as if the three valences of each nitrogen were in a single plane, upon which assumption the compounds would resemble diphenyl in structure. It is probable, also, that under such conditions restricted rotation in the dipyrryl molecules would conform more or less closely to that of the diphenyl series.



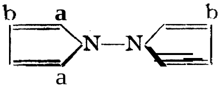
I



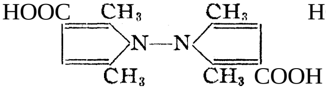
II



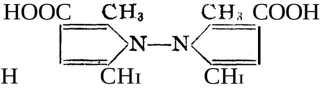
III



IV



V



VI

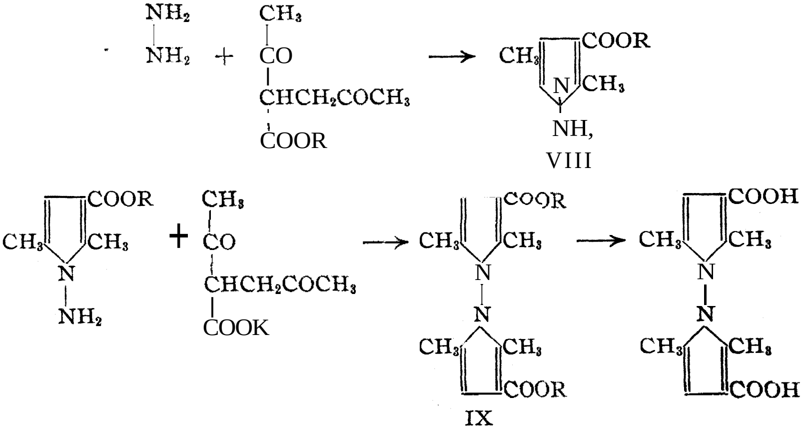
On the other hand, on the assumption of a tetrahedral structure for nitrogen, the geometric structures of the phenylpyrroles and the N,N′-dipyrryls will be quite different from the diphenyls. In the latter compounds there is a single axis for the two rings, but in the phenylpyrroles and the dipyrryls this would not be true. The formula for phenylpyrrole is illustrated by (VII) and a dipyrryl would be of a similar character excepting that the angle between the two pyrrole rings in the molecule would be considerably different from the angle between the benzene and the pyrrole rings in phenylpyrrole. It might well be expected in molecules of these types that other conditions of substitution would affect restricted rotation between the rings. In fact, upon the assumption of a regular tetrahedral structure for the nitrogen atom, it is difficult to see how *ortho* substituted groups in the pyrrole rings of a dipyrryl would interfere with each other at all.

VII

Other possibilities for isomerism may occur in these molecules that do not have a single axis for the two rings. If one ring is unable to rotate on the C–N or the N–N axis to the other side of the second ring, conditions exist which are not possible in the diphenyl series. Whereas in diphenyls the molecules must have restricted rotation between the rings and in addition each ring must be asymmetrically substituted in itself to allow the possibility of mirror images, in a phenylpyrrole or dipyrryl restricted rotation and asymmetry in only one of the rings would be necessary in order to make possible optical activity. Such molecules may readily be produced and some light should thus be thrown on the structures of the phenylpyrroles and dipyrryls from the results of the investigation now under way.

The racemic N,N',2,5,2',5'-tetramethyl-3,3'-dicarboxydipyrryl was readily resolved through the brucine salt arid the two optically active forms (V and VI) obtained in a pure state. They proved to be very resistant to racemization under ordinary conditions. After twenty-four hours of boiling in pyridine no change in rotation occurred. Even after boiling for eighty-four hours in 0.1 *N* sodium hydroxide the racemization was only partial. Insolubility in all ordinary solvents except pyridine limited the study of the ease of racemization.

The compound N,N',2,5,2',5'-tetramethyl-3,3'-dicarboxydipyrryl has already been described by Korschun,[3] who obtained it as a by-product in the condensation of hydrazine with 3-carboxy-2,5-dimethylhexadione in alcohol solution. It was found, however, that it could be produced in quantity more readily by using a slightly different procedure. Hydrazine was first condensed with 3-carboethoxy-2,5-dimethylhexadione in alcohol and acetic acid with the formation of N-amino-2,5-dimethyl-3-carboethoxypyrrole (VIII). This latter substance was then condensed again with 3-carboethoxy-2,5-dimethylhexadione with the formation of the substituted dipyrryl (IX).



Outside of the fact that the dibrucine salt tended to hydrolyze readily in the presence of solvents containing any water, there was nothing unusual to mention in connection with the resolution of this compound into its active forms.

The results of this investigation offer additional evidence that optical isomerism due to restricted rotation between rings may be expected in many, if not in all, heterocyclic and alicyclic types that are semi-aromatic in character where the proper number and kind of groups are substituted in the ortho positions to the linkage between the rings.

[3] Korschun, *Ber.*, **37**, **2183** (1904)

Experimental

N,N′,2,5,2′,5′-Tetramethyl-3,3′-dicarboethoxydipyrryl.—A solution of 15 g. of N-amino-2,5-dimethyl 3-carboethoxypyrrole (Korschun)[3] in 200 cc. of absolute methyl alcohol was heated with 15 g. of 3-carboethoxy-2,5-dimethylhexadione in a 500-cc. flask fitted with a reflux condenser for four hours on a steam-bath. The solvent was then evaporated from the reaction mixture. A thick oily substance was obtained; yield 26 g. (94% of the theoretical).

N,N′,2,5,2′,5′-Tetramethyl-3,3′dicarboxydipyrryl.—A mixture of 26 g. of N,N′,2,5,2′,5′-tetramethyl-3,3′-dicarboethoxydipyrryl with 70 cc. of 10% alcoholic potassium hydroxide was heated for two hours on a steam-bath. Upon acidifying the resulting solution with a little hydrochloric acid, a brownish precipitate was obtained. The product was filtered and washed with water. This was then dissolved in about 400 cc. of absolute methyl alcohol and refluxed for half an hour with 6 g. of decolorizing charcoal. After filtration, sufficient water was added until a precipitate just appeared. Upon standing the dipyrryl separated as a white precipitate which upon drying amounted to 18 g. (84% of the theoretical). It was purified by crystallizing from absolute methyl alcohol until it had a constant melting point of 278–280°.

It is slightly soluble in ethyl acetate, ethyl alcohol, benzene and chloroform and somewhat more soluble in absolute methyl alcohol and acetone.

Anal. Calcd. for $C_{14}H_{16}O_4N_2$: mol. wt., 276; N, 10.11. Found: mol. wt., 279; N, 9.96.

Resolution of **N,N′,2,5,2′,5′-Tetramethyl-3,3′-dicarboxydipyrryl.**—A solution of 20 g. of brucine in 400 cc. of absolute methyl alcohol was heated to its boiling point and 7 g. of powdered N,N′,2,5,2′,5′-tetramethyl-3,3′-dicarboxydipyrryl was added slowly with stirring. After standing for several hours at 0°, the salt which separated was filtered. The first fraction thus obtained which amounted to 12.7 g. was crystallized from absolute methyl alcohol three times until a constant rotation was obtained; melting point 153–157°.

Rotation. d-Salt, 0.1024 g. made up to 25 cc. with pyridine at 20° gave or, —0.60; $l = 2$; $[\alpha]^{20}_{D}$ —73.2.

Anal. Calcd. for $C_{60}H_{68}N_6O_{12}$: N, 7.87. Found: N, 7.76.

The more soluble fraction obtained in solution as a filtrate from the less soluble salt was evaporated part way to dryness and again allowed to cool. Any crystalline material which separated was filtered and consisted of a mixture of the two salts, though primarily of the less soluble. It was necessary to concentrate to dryness before the more soluble salt was obtained. It then separated from the methyl alcohol as a gum which on long standing in a desiccator solidified. It was found impossible to recrystallize this material so that in the crude form a sample was weighed out and a rotation taken. The rotation undoubtedly is not the maximum one for the salt.

Rotation. I-Salt, 0.1550 g. made up to 50 cc. with pyridine at 20° gave a, —0.51; $l = 2$; $[\alpha]^{20}_{D}$ —82.3'.

The I-salt in this crude form melted at 293–304°. It turned dark at 241°.

***d*- and l-N,N′,2,5,2′,5-Tetramethyl-3,3′-dicarboxydipyrryl.**—The active acids were liberated from the individual salts by suspending in water and treating with hydrochloric acid. A suspension of 4 g. of the less soluble salt in 100 cc. of water was treated with 4 cc. of concentrated hydrochloric acid and thoroughly stirred. The solid acid which precipitated was filtered and recrystallized to a constant melting point from absolute methyl alcohol. Melting point, 218–219°.

Rotation. *d*-Acid, 0.1817 g. made up to 25 cc. with pyridine at 20° gave or, +0.40; $l = 2$; $[\alpha]^{20}_{D}$ +27.5.

Anal. Calcd. for $C_{14}H_{16}O_4H_2$: C, 60.87; H, 5.85. Found: C, 61.03; H, 6.10.

The I-acid was obtained in a similar manner from the crude soluble salt. The free acid was recrystallized from absolute methyl alcohol; melting point 220–221°.

Rotation. Z-Acid, 0.1544 g. made up to 25 cc. with pyridine a t 20° gave or, −0.31; $l = 2$; $[\alpha]^{20}_{D}$ −25.1.

Racemization Experiments.—A solution of 0.1817 g. of d-acid made up to 25 cc. with pyridine at 20°, α_D +0.40, $l = 2$, $[\alpha]^{20}_{D}$ +27.5, was refluxed for twenty-four hours. No change in initial rotation was observed.

A solution of 0.1990 g. of d-acid in 50 cc. of 0.1 N sodium hydroxide gave an initial rotation of α_D +0.19; $l = 2$; $[\alpha]^{20}_{D}$ +23.9; upon boiling for eighty-four hours the rotations were as follows: nine hours, α_D +0.14, $l = 2$, $[\alpha]^{20}_{D}$ \$17 6; forty-eight hours, or, +0.12, $l = 2$, $[a]^{20}_{D}$ +15.1; seventy-two hours, a +0.07, $l = 2$, $[\alpha]^{20}_{D}$ +8.8; eighty-four hours, α_D +0.06, $l = 2$, $[\alpha]^{20}_{D}$ +7.5.

Summary

1. N,N′,2,5,2′,5′-Tetramethyl-3,3′-dicarboxydipyrryl has been prepared by condensing N-amino-2,5-dimethyldicarboethoxypyrrole with 3-carboethoxy-2,5-dimethylhexadione.

2. The product was resolved through the brucine salt and the active forms were found to be unusually resistant to racemization.

THE REDUCTION OF AROMATIC NITRO AND NITROSO COMPOUNDS WITH SODIUM ALCOHOLATES. II.

BY F. B. DAINS AND W. O. KENYON

RECEIVED APRIL 15, 1931 PUBLISHED JUNE 8, 1931

The reduction of aromatic nitro compounds with sodium or potassium hydroxide in alcohol solution or with sodium alcoholates has been studied by a number of investigators from the time of Mitscherlich to the present.' Under various conditions there have been obtained amines, azoxybenzene, azobenzene and in the case of *p*-nitrotoluene stilbene derivatives.' In addition, Suter and Dains have found that the reduction of o-halogen nitrobenzenes with sodium propylate or butylate gave an unexpected product, a substituted amino acid.[2]

$$o\text{-ClC}_6\text{H}_4\text{NO}_2 + n\text{-C}_3\text{H}_7\text{ONa} \longrightarrow o\text{-ClC}_6\text{H}_4\text{NHCH(CH}_3\text{)COONa} + \text{H}_2\text{O}$$

[2] Suter and Dains, THIS JOURNAL, 50,2733 (1928).

The present paper is a continuation of their investigation and was undertaken with the following purposes: (1) to study the reducing action in benzene solution of polyhydric alcohols and of ketones which are capable of forming sodium derivatives; (2) to ascertain whether ortho groups other than halogen atoms will cause the formation of amino acids; (3) to compare the action of nitroso compounds as oxidizing agents; (4) to ascertain the amount of halogen removed from the ring.

Experimental

The method outlined by Dains and Suter was used in most cases. When the reduction was complete the separation of products was carried out as outlined in their paper. The benzene layer of the distillate contained the unchanged nitro compounds.

The amine formed was estimated by the method of Francis and Hill.[3] The brominated amine thus formed was used for identification wherever possible.

After separation of azo or azoxy derivatives, acidification with sulfuric acid precipitated the amino acids, organic acids, or phenolic products. These were removed, the filtrate diluted to a definite volume and the halogen removed was estimated by a Volhard titration of an aliquot portion. When soluble organic acids were present which would affect the titration, they were removed by making the solution alkaline, evaporating to dryness and fusing the residue until all carbon was removed. The melt was then dissolved and the halogen estimated.[4]

Table I gives a résumé of the laboratory results and in the later discussion references are made to the particular experiments involved. All melting points are uncorrected.

Discussion

The Effect of Added Amines upon Reduction.—The work of Fry and Cameron and of Fry and Bowman[5] has shown that when pyridine or other organic bases such as aniline are present in the reaction mixture, they increase the reduction of nitrobenzene by sodium methylate.

In benzene solution it was found that nitrobenzene is reduced to only a slight extent (Ia) and the presence of an equimolar amount of aniline has only slight effect on the amount of reduction (Ib).

In the case of *p*-chloronitrobenzene and sodium propylate, Suter has shown that 33% of the nitro compound goes to the *p*,*p*'-dichloroazoxybenzene. A series of reductions (IIIa, b, c, d) in the presence of organic bases gives yields almost twice as great as when no base is added. In

[a] 0.1 Mole of pyridine added to solvent benzene. [b] Aniline. [c] 25 cc. of water as solvent. [d] 40 cc. of water as solvent. [e] Diamine.

(IIIc), 0.1 mole of amine was added to the reaction mixture but only 88% of this could be recovered.

The Action of Glycol and Glycerol.—The reductions using glycerol and sodium in benzene were very slow due to the formation of two layers in the reaction medium. In the case of sodium or sodium hydroxide with glycol and glycerol in an excess of the alcohol (Ie, g, h), the formation of azobenzene is unique and rather surprising. In contrast to this, *p*-chloronitrobenzene with glycol and alkali yields mainly *p,p'*-dichloroazoxybenzene (IIIe). The formation of oxalic and volatile acids is also to be noted.

The Oxidation of Ketones and Ketone Acids.—The sodium salt of acetone is a powerful reducing agent (Ie, d, IIIf) and gives from 36 to 44% amines, but otherwise thick tars. Acetophenone behaves in an analogous manner (VIIId).

With phenyl benzyl ketone (IIIg) there was observed the interesting formation of benzilic as well as benzoic acid. This is due to oxidation of the ketone to benzil, which in part is oxidized to benzoic acid but mainly undergoes rearrangement in the alkaline solution during the steam distillation[6] to benzilic acid.

Ethyl acetoacetate (IIc, IIIh) was not only oxidized by o- and P-chloronitrobenzenes, but was able to replace the chlorine in the ring by hydrogen, since the amine recovered was practically all aniline, which was not the case with benzoylacetic ester (IIIi) or malonic ester (IId, IIIj).

Reactions with 3,4-Dichloronitrobenzene.—The series IVa-h deals with the reduction of the 3,4-dichloronitrobenzene. Three different alcohols were used, the reactions being carried out in various ways and the product, aside from small amounts of the corresponding amine, was tetrachloroazoxybenzene. A typical experiment is as follows.

Preparation of **3,4,3',4'-Tetrachloroazoxybenzene.**—Sodium (4.6 g.) was dissolved in a mixture of benzene (300 cc.) and n-propyl alcohol (45 cc.). To this was added 3,4-dichloronitrobenzene (19.2 g.) dissolved in a little benzene. The mixture was refluxed for two hours.

After distillation, the distillate showed 3.78% of 3,4-dichloroaniline. The residue in the flask gave 10.4 g. of brown material. This was extracted with ether alcohol and recrystallized from carbon disulfide and benzene. The melting point is 137–138°; 61.9% yield.

Anal. Calcd. for $C_{12}H_6ON_2Cl_4$: Cl, 42.2. Pound: Cl, 42.02, 42.08.

The molecular weight in benzene by the freezing point method gives 372; calculated. 336. In no case under the conditions employed was any evidence obtained for the formation of ethers of 4-nitro-3-chlorophenol such as were described by McMaster and McGill[7] as resulting from the interaction of sodium alcoholates on this dichloronitrobenzene.

[6] Klinger, Ber., 19, 1867 (1886).

[7] McMaster and McGill, THIS JOURNAL, 50, 3041 (1928).

The Nitrobenzaldehydes, Acids and Phenols.—*o*-Nitrobenzaldehyde and sodium propylate (XXa) gave only tars, while the *m*-nitrobenzaldehyde (XIXa) was changed almost quantitatively to m-nitrobenzoic acid. Evidently in the alkaline solution it undergoes the Cannizzaro reaction and then the nitrobenzyl alcohol, in turn, with dilute alkali is oxidized to the acid. o-, m- and *p*-nitrobenzoic acids (XVIIIa) gave no reduction products, though the ethyl ester of *p*-nitrobenzoic acid (XXIa) was reduced (86%) to the *p,p'*-azoxybenzoic acid, identified by its properties and analysis of its silver salt. a-Nitrophenol was not reduced but went over into the red sodium salt of the acid form.

Formation of Amino Acids.—Suter and Dains[2] showed that such amino acids resulted from the reduction of o-halogen nitro compounds. Thus far this seems to be an essential condition since no amino acids have been isolated with the following ortho substituents: CH_3, OH, OCH_3, OC_6H_5, C_6H_5, CHO and $NHCOCH_3$ (in IXa, Xa, XIIIa, XIVa, XVa, XXIIa).

Since ethyl alcohol failed to give an amino acid with dichloronitrobenzene, while propyl did, it is evident that a 3-carbon alcohol at least is necessary for this synthesis. The following illustrates, however, the synthesis of such acids.

α-2,5-Dibromoanilinopropionic Acid, $CH_3CH(NHC_6H_3Br_2)COOH$.—Sodium (4.6 g.) is dissolved in a mixture of benzene (250 cc.) and n-propyl alcohol (45 cc.) and 2,5-dibromonitrobenzene (28.1 g.) in 50 cc. of benzene is slowly added. When the violent reaction subsides, the mixture is refluxed on the water-bath for two hours. The amine present (21.65%) is removed by steam distillation and the residue filtered. Acidification precipitated the acid as an oil which later solidified. This crude material was dissolved in alcohol, boiled with norite and the product precipitated by dilution of the hot filtered solution with water. It forms colorless crystals, m. p. 156°, which became brown on contact with air.

Anal. Calcd. for $C_9H_9O_2NBr_2$: Br, 49.49. Found: Br. 49.59, 49.37.

Its constitution was further proved by its synthesis from dibromoaniline and a-bromopropionic acid on refluxing in water solution until the mixture was homogeneous. A mixed melting point showed identity.

In connection with the method of determining the amount of 2,5-dibromoaniline formed (method of Francis and Hill) in the preceding reduction, it was found necessary to synthesize the possible product. When bromine water is added to a dilute sulfuric acid solution of 2,5-dibromoaniline, the 2,4,5,6-tetrabromoaniline is found. The crystals from alcohol melt at 118°.

Anal. Calcd. for $C_6H_3NBr_4$: Br, 78.21. Found: Br, 78.08.

α-2-Chloro-5-methylanilinopropionic Acid.—This was formed in 49.18% yield together with 8.43% of amine from the chloronitrotoluene and sodium propylate in benzene solution. The white crystals from hot water melt at 158°.

Anal. Calcd. for $C_{10}H_{12}O_2NCl$: Cl, 16.57. Found: Cl, 16.64, 16.72.

The same acid was synthesized from a-bromopropionic acid and 3-amino-4-chloro-

In a previous paper[8] it was suggested that the formation of these amino acids may be due to an increased ability of the *o*-nitroso group to add an aldehyde complex and then rearrange. This does not seem to be true of the *p*-nitroso derivatives (XXIIIa, XXIVa, XXVa), since they exhibit strong oxidizing properties, yielding amines and azoxy compounds.

Halogen Removal.—While varying amounts of halogen were removed in many cases, no definite phenols were isolated. This is probably due to the interaction of the intermediate nitroso compounds with such phenols, yielding tarry products.

Summary

1. A study has been made of the action of sodium alcoholates (or tautomeric substances) on nitrobenzene, substituted nitrobenzenes and nitrosobenzenes in anhydrous benzene solution.
2. The products are normally amines or the corresponding azoxy derivatives, though polyhydric alcohols tend to form azo compounds.
3. Sodium derivatives of tautomeric substances are often good reducing agents, being oxidized usually at the inethylene bond.
4. When p-nitrotoluene or its substitution products are used, stilbenes may be formed.
5. No substituting groups other than halogen form a-amino acids.

STEREOCHEMISTRY OF DIPHENYLS. PREPARATION AND PROPERTIES OF 4,4'-DICARBOXY-1,1'-DIANTHRAQUINOYL. XVII[1]

BY W. M. STANLEY AND ROGER ADAMS

RECEIVED APRIL 17, 1931 PUBLISHED JUNE 8, 1931

It was pointed out in a previous paper[2] that it should be possible to resolve a 2,2'-disubstituted diphenyl derivative into optical antipodes, provided the two substituting groups are sufficiently large and assuming that a hydrogen atom may serve as a blocking group. Diphenyl-2,2'-disulfonic acid[3] was investigated but it could not be resolved. In the present investigation 4,4'-dicarboxy-1,1'-dianthraquinoyl (I) and its di-*l*-menthyl ester were synthesized in order to determine whether the CO group in a quinone ring would be a sufficiently large 2-substituted group to cause inter-

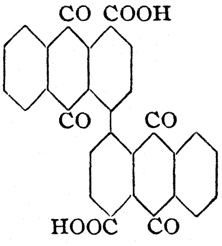
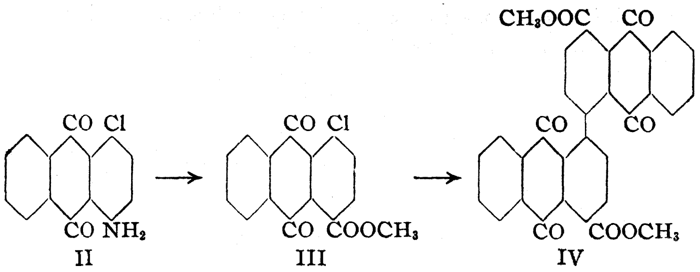
ference with the 2'-hydrogen atom and thus allow resolution into optical isomers. It could not, however, be resolved.



I

If the interference of the C—CO is calculated as an additive value of the C—C and C=O distances (2.45 Å.), an assumption which is hardly warranted, the compound should be resolvable: C—CO, 2.45 Å. + C—H, 0.94 Å. $\longrightarrow$ 3.39 Å. − 2.90 Å. (distance between 2,2′ carbons) $\longrightarrow$ 0.49 Å. On such a basis, the x-ray values do not agree with the facts. However, there are factors in the structure of such a compound as has been described in this investigation which make it somewhat different from the simple diphenyls. The positions of the carbon atoms in the quinone rings are fixed in such a way that the effective interference diameter of each of the C—C and of the C=O groups would probably be modified from that in an ordinary diphenyl. Certainly the values would not be additive. The forces of the C=O group extend probably in a vertical direction from the quinone ring and, therefore, with the fixed position of the carbon atom, a set of conditions is introduced which necessitates a modification of the simple assumption for interfering values which has been used so successfully for the diphenyls with no condensed nuclei.

The 4,4′-dicarboxy-1,1′-dianthraquinoyl was prepared from 1-chloro-4-benzoylaminoanthraquinone by removal of the benzoyl group, diazotization and replacement of the amino group by a cyano group, hydrolysis and esterification of this derivative to give 1-chloro-4-carbomethoxyanthraquinone, condensation of this to 4,4′-dicarbomethoxy-1,1′-dianthraquinoyl and saponification of this to the acid. Due to its extreme insolubility the dimethyl ester was not isolated from the condensation reaction mixture, the uncoupled 1-chloro-4-carbomethoxyanthraquinone being removed by extraction with chloroform and the residual mixture being saponified directly to give 4,4′-dicarboxy-1,1′-dianthraquinoyl. It was impossible to purify the free acid by crystallization due to its slight solubility. Purification was accomplished by crystallization of the disodium salt, repeated treatment with charcoal in alkaline solution, and repeated precipitation of the acid from solutions of the salt by means of dilute mineral acid.



It was found impossible to fractionate the alkaloid salts of 4,4′-dicarboxy-1,1′-dianthraquinoyl due to their insolubility. In one experiment the monoquinine salt of the acid was extracted with three liters of hot *p*-cymene with no indication of resolution. It was also found impossible to render the acid soluble by forming the monoquinine-monosodium salt of the acid since this derivative rearranged to a mixture consisting mainly of the disodium salt and the diquinine salt. The di-*l*-menthyl ester was prepared and fractionated from three different solvents without giving any change in the rotation or melting point.

The authors wish to thank The Jackson Laboratory of E. I. du Pont de Nemours and Co. through Mr. Clark for the 1-chloro-4-benzoylamino-anthraquinone used in this investigation.

Experimental Part

1-Chloro-4-aminoanthraquinone (II).—A solution of 250 g. of technical 1-chloro-4-benzoylaminoanthraquinone in 400 cc. of concentrated sulfuric acid was heated to 80–90° for four hours. The solution was then cooled to 0" and poured slowly onto ice with continual stirring. The red precipitate was removed by filtration, warmed with strong ammonium hydroxide, filtered and washed with dilute ammonium hydroxide until the filtrate gave no precipitate upon acidification. After a final washing with 250 cc. of water, the red precipitate was dried under vacuum at 100°. The yield was 175 g.

1-Chloro-4-cyanoanthraquinone.—A solution of 55 g. of sodium nitrite in 500 cc. of concentrated sulfuric acid was prepared by dusting small portions of thoroughly dried sodium nitrite powder into concentrated sulfuric acid at 0° with continual stirring. The addition required about forty minutes, after which the sulfuric acid was heated to 50–60° to effect complete solution of the sodium nitrite. The solution was then cooled to 0°, and to it was added an ice-cold solution of 175 g. of 1-chloro-4-aminoanthraquinone in 850 cc. of concentrated sulfuric acid. After standing at 0° for fourteen hours, the solution was poured slowly with stirring onto cracked ice. The bright yellow precipitate which formed was quickly removed by filtration with suction, washed with 100 cc. of ice water and immediately taken up in 3 liters of ice water. This mixture was added slowly to a cold solution of 325 g. of cupric sulfate pentahydrate and 365 g. of potassium cyanide in 2 liters of water. This solution was previously prepared by adding a saturated aqueous solution of potassium cyanide to a boiling aqueous solution of cupric sulfate. After the addition of the diazonium salt, the mixture was heated to boiling during three hours and filtered hot. The precipitate was washed with hot 10% aqueous potassium cyanide solution and finally with 8 liters of boiling water. After drying, the precipitate weighed 250 g., so it was heated to boiling with 2 liters of 5% aqueous potassium cyanide, filtered hot, washed with 2 liters of hot 5% aqueous potassium cyanide, then with 4 liters of boiling water and dried. The yield was 155 g. (85%) of a product melting at 265–268°. The melting point after two crystallizations from glacial acetic acid was 271–272°.

Anal. Calcd. for $C_{15}H_6O_2NCl$: Cl, 13.25. Found: Cl, 12.97.

1-Chloro-4-carboxyanthraquinone.—A mixture of 150 g. of 1-chloro-4-cyanoanthraquinone, 300 cc. of water and 900 cc. of concentrated sulfuric acid was heated to boiling (190°), cooled and diluted with 2 liters of water. The precipitate so obtained was removed by filtration, washed with water and then digested and washed with a total of five liters of dilute ammonium hydroxide. The ammoniacal filtrate was acidified and the brown colored acid so obtained was removed and dried. The yield was 135 g. (82%) of a product melting at 220–224° without recrystallization. Heller and Schulke[4] give the melting point of 1-chloro-4-carboxy anthraquinone obtained by the oxidation of I-chloro-4-methylanthraquinone as 228–229° after two crystallizations.

1-Chloro-4-carbomethoxyanthraquinone (ID).—A mixture of 66 g. of 1-chloro-4-carboxyanthraquinone and 2 liters of absolute methyl alcohol was saturated with dry hydrogen chloride (required 580 g.). After refluxing for twenty-four hours, 600 cc. of alcohol was removed by distillation, and the residual mixture was cooled to 0° and filtered. The precipitate was washed with water, then with dilute sodium carbonate solution until acidification of the filtrate gave no precipitate and finally with water. The yield was 60 g. (87.5%) of a product melting at 183–185°. The run was repeated using 34 g. of 1-chloro-4-carboxyanthraquinone and 500 g. of absolute methyl alcohol. The yield was 30 g. (85%). The ester was recrystallized twice from chloroform and gave large rhombic crystals having a melting point of 187.5–188.5°.

Anal. Calcd. for $C_{16}H_9O_4Cl$: Cl, 11.80. Found: Cl, 11.90.

4,4′-Dicarboxy-1,1′-dianthraquinoyl (I).—A mixture of 30 g. of 1-chloro-4-carbomethoxyanthraquinone and 30 g. of copper powder (Kahlbaum's Naturkupfer C) in a Pyrex tube was heated by means of a metal bath slowly to 265° during ten minutes and then at 265° for twenty minutes with occasional stirring. A noticeable reaction took place at about 250° during which the temperature of the mixture went to 300°. The run was repeated using 54 g. of 1-chloro-4-carbomethoxyanthraquinone and 75 g. of copper powder. The two runs were combined, cooled, pulverized and extracted with 500 cc. of hot chloroform, the evaporation of which gave 30 g. of solid material. The reaction mixture was again extracted successively with 300 cc. and with 200 cc. of chloroform, the evaporation of which gave 2.0 g. and 0.5 g., respectively, of solid material, thus indicating the removal of the uncoupled material. The remaining mixture, consisting of copper powder, copper chloride, and 4,4′-dicarbomethoxy-1,1′-dianthraquinoyl, was refluxed with a mixture of 32 g. of potassium hydroxide and 800 cc. of ethyl alcohol for twelve hours. The alcohol was removed by distillation, the residue was heated to boiling with 750 cc. of water and filtered hot. The residue was extracted twice with 500 cc. of hot water, and the combined filtrates acidified with hydrochloric acid. The light brown precipitate of 4,4′-dicarboxy-1,1′-dianthraquinoyl was removed by filtration and dried. The yield was 44 g. of a product melting unsharply from 350–360°. The disodium salt of the acid was crystallized from water and then dissolved in water, boiled with charcoal, filtered and precipitated with hydrochloric acid six successive times. The light cream colored acid so obtained weighed 25 g. and melted sharply at 448° (corr.) on the block. The acid is slightly soluble in pyridine (0.06 g. in 100 g.) and insoluble in all other common solvents.

[4] Heller and Schulke, *Ber.*, 41,3636 (1908)

Di-*l*-menthyl Ester of **4,4′-Dicarboxy-1,1′-dianthraquinoyl.**—A mixture of 5 g. of 4,4′-dicarboxy-1,1′-dianthraquinoyl and 175 g. of thionyl chloride was refluxed for six hours, the acid going slowly into solution. The excess thionyl chloride was carefully removed under vacuum and the yellow residue dried until the odor of thionyl chloride was very faint. A 10-g. portion of Lmenthol was then added and the mixture heated to 150° for six hours, after which 150 cc. of dry benzene was added and the mixture refluxed for six hours. The benzene was removed under vacuum, and the residue steam distilled to remove the excess 1-menthol. The residue was recrystallized from chloroform, giving 6.5 g. (85%) of light yellow product melting at 298–299°. The di-1-menthyl ester is soluble in chloroform, slightly soluble in ether, ethyl acetate and acetone and insoluble in petroleum ether and ethyl alcohol.

Rotation. 0.2206 g. made up to 12 cc. with chloroform at 20° gave a, 0.28; $l = 1$; $[\alpha]_{\mathrm{D}}^{20}$ −15.2°.

Anal. Subs., 3.974 mg.; CO_2, 11.19 mg..; H_2O, 2.27 mg. Calcd. for $C_{50}H_{50}O_8$: C, 77.08; H, 6.47. Found: C, 76.79; H, 6.39.

Fractionation of the ester from chloroform, ether and ethyl acetate did not change the rotation or the melting point.
