The Normal Density of Ammonia

BY GERHARD DIETRICHSON, LOUIS J. BIRCHER AND JOHN J. O'BRIEN

Introduction

The accompanying tabulation gives a summary of previous work in determining the density of ammonia at 0° and one atmosphere.

Blanchard and Pickering[1] in their review of the literature pertaining to gas densities conclude, in the case of ammonia, with the following statement: "The weight of a normal liter chosen is therefore 0.7710 with an uncertainty of two or three units in the last decimal place." This is exclusive of the results obtained by Leduc and of the most recent by Moles and Batuecas. In discussing the earlier work Moles and Batuecas[2] also state that they recalculated the data of Guye and Pintza, Perman and Davies and Scheuer. The resulting densities are shown in the column at the right.

The weight of a normal liter has also been calculated from the "compressibility" of ammonia, $(\partial(pv)/\partial p)_T$, using the equations

$$p_0v_0/p_1v_1 = 1 + \bar{\lambda} \qquad d_n = m/v_1 = \frac{M(1 + \bar{\lambda})}{RT_0}$$
$$p_0v_0 = m/M\,RT_0$$

where $\bar{\lambda}$ is understood to be a mean value defined as $\bar{\lambda} = \int_0^{1\text{ atm.}} \lambda\, dp$.[1] Beattie and Lawrence[3] using their own p-v-T data and the Beattie-Bridgeman equation of state

$$pv = RT + \beta/v + \gamma/v^2 + \delta/v^3$$

to obtain the p_1v_1 product, derive the value, 0.7706 g./l. On the other hand, the same form of equation applied to the data of Meyers and Jessup leads to a normal density of 0.7715 g./l.

The foregoing discloses considerable uncertainty as to the true normal density. In view of the elaborate precautions taken by the investigators in purifying ammonia from various sources, it seems certain that the irregularities are not traceable to impurities. It appears accordingly that the discrepancies must be attributed mainly to the experimental procedure adopted. All of the work up to the present has been done by either the

[a] Reported by Blanchard and Pickering.

"balloon" or the "volumeter" method. Neither of these would avoid definitely the adsorption effect expected with ammonia.

Professor F. G. Keyes proposed to the authors a number of years ago a modification of a method originally proposed and used by Maass and Russell[4] in determining the density of acetylene, methyl ether and hydrobromic acid and later by Cooper and Maass[5] in determining the density of carbon dioxide. The suggested modification provides a means of estimating quantitatively the adsorption effect on the container walls. The principle involved is that of measuring the temperature and pressure of the gas in a relatively large bulb of known volume, condensing it in a small bulb that can be sealed off and then weighing in the liquid form or under high pressure. This method obviously makes it possible to work with comparatively large amounts of material and only involves the weighing of very small bulbs with a corresponding decrease in total mass and surface area. It was assumed that the adsorption effect could be eliminated by bringing the gas down to varying final bulb pressures during the condensation process. According to the adsorption law, $q = ap^{1/n}$, the total amount adsorbed tends to approach a constant saturation value at relatively low pressures provided a true adsorption effect is involved.[6] The condensed liquid should, therefore, as the residual pressure is made progressively larger, represent material drawn from the gas phase only. By means of an approximate equation of state it is possible to calculate with exactness the small weight of gas corresponding to the residual pressure, exclusive of the adsorbed layer. This in turn when added to the weight of the gas that has been condensed would give the mass corresponding to the initial pressure. According to this procedure it becomes a matter, therefore, of determining the limiting minimum density with increasing residual pressures.

As the work progressed it was found that the method outlined above did not apparently serve to eliminate completely the adsorption effect. The authors feel, however, that this was finally accomplished by subjecting the ice-bath bulb to a thorough baking and pumping previous to the density determinations and by observing special care in removing the last traces of ammonia in the line before each condensation. The details as to this will be described more fully in a later section.

The present work was undertaken with the idea of obtaining density data at one, two-thirds and one-third of an atmosphere, also for corre-

(6) Keyes [Keyes and Brownlee, "Thermodynamic Properties of Ammonia," John Wiley and Sons, New York, 1916. p. 21] has called attention to the fact that ammonia very likely absorbs in the adsorbed water layer rather than adsorbing to any extent. The amount of ammonia on the walls of the globe would therefore not be related to the pressure by the above formula but more in accordance with Henry's law. In any event, however, the method will indicate the part played by the walls in retaining gas. The final outcome of our work indicates that ammonia does not adsorb on water freed surfaces.

sponding pressures at higher temperatures. At this time only the results at one atmosphere and 0° are being reported. The preliminary densities at the lower pressures and 0° were used to obtain an equation of state needed in the computation of the residual amount of gas in the bulb.

Experimental Method

The experimental work carried out divides itself into two distinct parts. The general arrangement of the apparatus for the first part, experiments Nos. 1–66, is shown in Fig. 1. That for the second, experiments Nos. 67–119, was similar except that the ice-bath and five-liter Pyrex bulb which it contained were replaced by the ice-bath and one-liter Jena glass bulb shown in Fig. 2. In making a determination the ice-bath, provided with a stirrer, was filled with chipped ice and distilled water. Following that the evacuated bulb was filled with ammonia from the storage bulb, C, to very nearly the desired pressure, i. e., one, two-thirds or one-third of an atmosphere, allowance being made for the corrections to be applied. Upon closing stopcock No. 16 the line was pumped down to that point. It developed that this operation required much more time than was at first anticipated. After allowing for temperature equilibrium to be established, ordinarily about three hours, the initial pressure was read. The ammonia was then condensed into bulb G with liquid air to varying final pressures, 0.0 to 40 mm. A total of twelve to fifteen hours was allowed for the condensation in the case of a zero residual pressure. Stopcock No. 16 was always closed during the final pressure readings. The

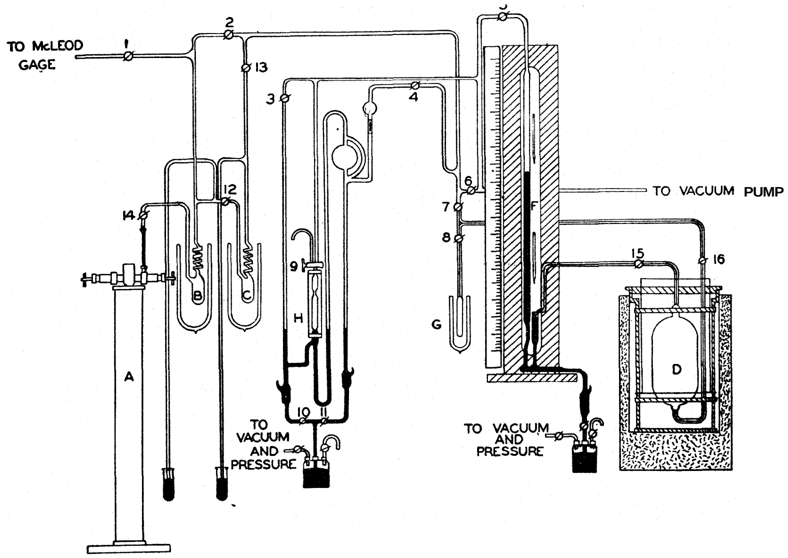

Fig. 1.—General arrangement of apparatus for gas density determinations.

last step consisted in sealing off the capillary extension of the bulb G while the latter was still immersed in liquid air. Necessarily before doing this the ammonia in the line down to stopcock No. 16 (5 l. bulb) and No. 17 (1 l. bulb) was condensed. During the early stages of the work a Toepler pump was used in testing for uncondensed ammonia after sealing off the bulb. This was subsequently found to be unnecessary. The details of weighing the bulbs, closed and open, will be discussed in a later section.

Purification of Ammonia

Synthetic anhydrous ammonia was used throughout the work, that for experiments Nos. 37–119 having been kindly donated by the Barrett Company through the courtesy of Doctor J. M. Braham. The steel cylinder, A, containing freshly cut sodium, was partially filled with the liquid and allowed to stand for several days. The system having been previously evacuated, ammonia was condensed in B by means of liquid air and subjected to several fractionations, the end portions being always discarded. Furthermore, at the end of each distillation the solidified ammonia was pumped until the pressure became less than 0.001 mm. The portion remaining was stored in C, the bulb being kept immersed in liquid air.

As far as could be observed there was no occasion to question this method of purification. Water and non-condensing gases should, on the basis of McKelvey and Taylor's[7] work, be the principal impurities and the treatment described above ought to eliminate completely these or any other foreign substances likely to be present. That such was the case seems evident from the following considerations. It was noted on the one hand in making as many as fifteen successive density determinations from a given portion in the storage bulb, with practically all of the ammonia being used, that no differences in the results could be detected. This obviously would indicate that the material was uniform, *i. e.*, there were no lighter and heavier fractions. Also, it was found that there was no indication of a permanent pressure developing in the bulb used for measuring the volume of the gas, in spite of the fact that the bulb was not pumped between successive determinations in a

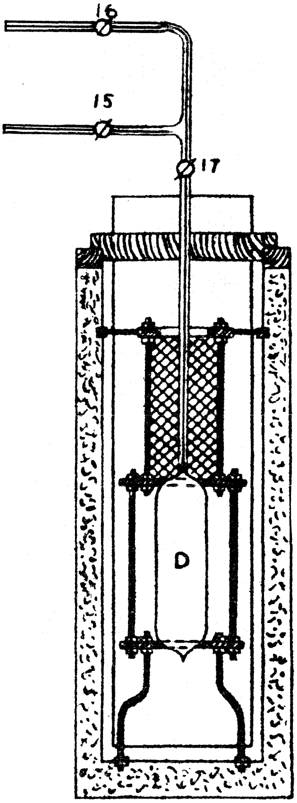

Fig. 2.—One-liter bulb and ice-bath.

---

given series. Non-condensing gases, especially hydrogen, must therefore have been absent.

Details of Procedure

(a) Volume.—As explained in the preceding section, two different bulbs were used for the volume measurements. The calibration of the five-liter Pyrex bulb was carried out by first filling it, at the ice-point temperature, with recently boiled, distilled water to fixed marks on the connecting capillaries. The water was weighed by draining it off into glass-stoppered flasks, the usual air buoyancy and calibration corrections being applied. That adhering to the walls was subsequently pumped out and collected in a liquid air trap that could be disconnected and weighed. Four independent determinations of the bulb volume were made before use and a second series of three a year and a half later. The deviation in all of these determinations was not greater than one part in **50,000.** The "stretch" of the bulb was determined and found to be **0.480** ml. per atmosphere. After connecting the calibrated bulb to the manometer and loading apparatus the volume of the exposed parts was **2.27** ml. Allowance was made for the temperature difference of the latter in estimating the effective volume of the bulb when filled with ammonia. The total volume included that of the bulb and the capillaries, through the bore of stopcock No. **16** (Fig. **1)** and to a fixed mercury level in the short arm of the manometer

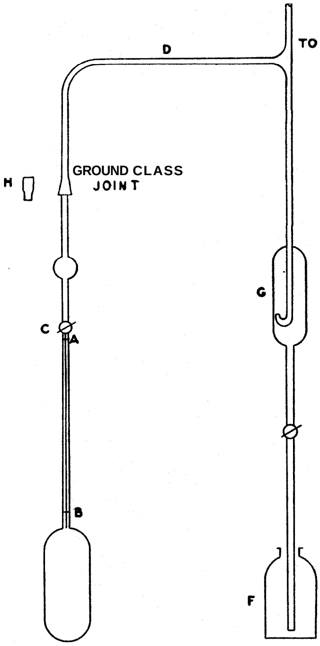

Fig. 3a.—One-liter bulb as set up for calibration.

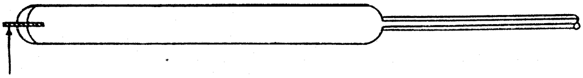
The one-liter bulb was annealed in a tube furnace at 300° before being calibrated. It was then set up as shown, exclusive of the ice-bath, in Fig. **3a.** Before introducing water the bulb was evacuated and weighed with the ground-glass cap, H. Special precautions were taken to exclude air while the bulb was being filled with water. The reservoir above the stopcock served to allow for expansion upon removal from the ice-bath. Before being weighed the bulb and its contents were brought to room temperature. The net volume of the bulb and connecting capillary, including the bore of the stopcock plug, as obtained in five determinations was **1030.56** (±0.01) ml The "dead space" was in this case only **0.3** ml. with a correspondingly smaller correction for the exposed portion. The "stretch" of the bulb was found to be **0.087** ml. per atmosphere.



Platinum tube
Outside diameter **1.00** mm., wall thickness **0.05** mm.

Fig. 3b. —Condensing bulb.

(b) Temperature.—No direct measurements of the ice-bath temperatures were made. However, baths made up in a similar manner, with chipped ice and distilled water, have been tested very thoroughly in this Laboratory by J. M. **Gaines,** Jr., by means of platinum resistance thermometers and found to be constant within **0.003"** ***or*** **0.000** (±0.003) °C.

(c) Pressure.—The same manometer was used throughout all of the work. A great deal of time was devoted to improving the conditions under which the readings were made, especially as regards temperature control and illumination. In the following paragraph there is given a description of the manometer in its final form.

The glass tube of the mercury manometer, F (Fig. 1), had an internal diameter of 17 mm. and was placed in a heavy cast bronze case provided with a plate glass front and a frosted glass back. The sides were covered with felt. The bronze case was placed on a large slate slab, and a cabinet, the interior of which was painted black, built around it. The door on the front of the cabinet was provided with slots through which the observations could be made. Two different cathetometers, both of them Geneva instruments, were available for measuring the pressures. The first of these which was used in experiments Nos. 1–26 carried a silver scale on the column. The second cathetometer was one that had been made with a special device for clamping the telescopes rigidly in position and proved to be a very satisfactory instrument. This cathetometer did not have an attached metal scale, the readings being made on a glass standard meter bar that was set up at the left of the brass case. The scale on the meter bar was ruled in millimeters with a diamond chip by the Société Gknevoise d'Instruments de Physique. It was calibrated at Berne, Switzerland.

In Fig. 4 is shown the construction of the short arm of the manometer as suggested by F. G. Keyes. The fine glass tip served as a fixed mark to which the mercury level was brought while making readings. The mercury surface was illuminated with diffused light coming through the frosted plate glass and a slit in a semicircular brass plate surrounding the rear half of the glass tube. The electric light bulb could be moved up and down by means of an overhead pulley. It was found possible in this way to illuminate the mercury surface so as to get a sharply defined meniscus. The long arm of the manometer was provided with a movable brass plate and a lighting arrangement similar to the one just described. In the case of the glass scale the best results were obtained by illumination from the rear. The lights for this purpose were supported from the same bars that carried the bulbs for the mercury columns. After having made the necessary initial adjustments it was therefore possible to swing the cathetometer telescope directly from the mercury meniscus at any level to the illuminated glass scale. In doing this the spirit levels on the telescopes were always checked.

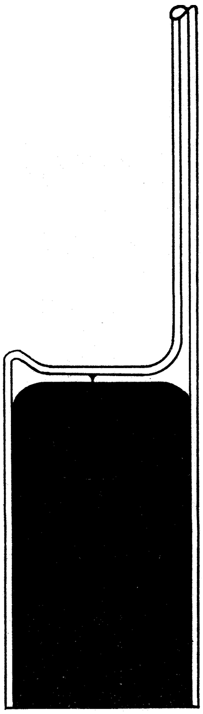


Fig. 4.—Short arm of manometer.

The temperature within the brass case was determined by means of two calibrated thermometers that could be read to **0.01°**. Ordinarily the temperature variations were considerably less than 0.1° during a given set of readings.

The vernier box of each telescope carried a circular head with a scale divided into one hundred divisions that could be estimated to tenths. When the cathetometer was at a distance of twenty-four inches from the manometer and the glass scale one millimeter on the latter corresponded to about a hundred and forty divisions. The following procedure was adopted in making observations. Five settings on the meniscus were first made in succession and the mean of these calculated. The telescopes were then swung over to the glass scale and two settings made on each of the millimeter divisions within which the meniscus level fell. By interpolation the fractional part of a millimeter was computed to the third place. Ordinarily eighteen sets of these observations were made on each mercury column, corresponding therefore to as many independent

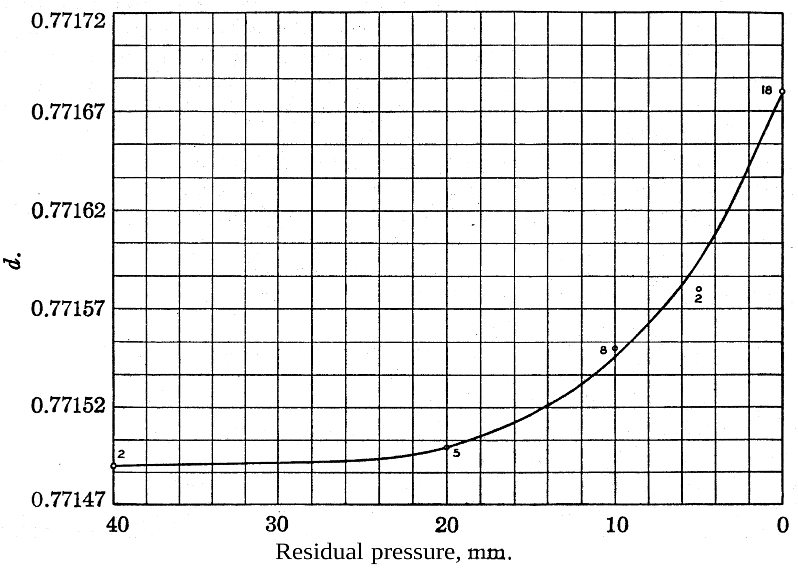

Fig. 5.

pressure determinations. The thermometers were read at the beginning and end of each set of three observations and a correction applied to the mean of these. As a precaution to guard against any lag the mercury columns were lowered at these same intervals and new settings made. By way of illustrating the degree of reproducibility the resultant six mean values for the last experiment, No. **119,** as obtained in pairs by three observers, are tabulated, temperature corrections having been applied.

Meniscus corr.	**$0.006**
Level corr.	**$0.030**
Gravity corr.	**−0.207**
Final corr. press.	760.077 (±0.01)

A correction for the difference in **curvature** of the two mercury surfaces was made by using the equation developed by Lohnstein.[8]

Since the short arm of the manometer and the one-liter bulb were not at the same level, there was a positive correction at one **atmosphere of 0.03 mm.**

The gravity correction was made by taking g_s = **980.665** cm./sec.^{2} and g_1 = **980.398** cm./sec.^{2}, the constant of gravity in Room **4-458** at M. I. T. The value **980.665 cm./sec.^{2}** is that adopted by the "International Critical Tables" and by Blanchard and Pickering in their review of the literature relating to gas densities.

(d) Mass.—As in the case of the pressures, much time was devoted to developing

---

[8] Lohnstein, *Ann. Physik*, **33**, 296 (1910).

the technique of obtaining the weight of the ammonia. For that reason the procedure will be discussed in some detail.

(1) Condensing Bulbs.—Necessarily an important step in connection with the weighing was that of devising a form of bulb that could be opened without any loss of glass. In experiments Nos. **1–79,100, 102, 104, 106, 108** and **110** the Pyrex bulb was of the simple form illustrated in Fig. 1. This type was opened by first freezing the ammonia with liquid air in the capillary end. Upon removal from the liquid air a cloth was wrapped around the cooled portion and a fine flame applied at the other end. In view of the high vacuum existing the glass caved in upon melting and in doing so the particles of blown glass were carried along into the bulb. Following this the capillary end was again immersed in liquid air and the ammonia allowed to evaporate as the liquid air gradually disappeared. There was a tendency for the bulbs to crack unless they were handled in this manner. Before weighing the empty bulb it was put in a tube that could be evacuated in order to replace the remaining ammonia vapors with air.

The above type of bulb proved in the end not to be entirely satisfactory. In some unexplained way they did apparently undergo slight changes in mass while being opened They were accordingly abandoned in favor of a modification proposed by F. G. Keyes and illustrated in Fig. 3b. It had previously been found by Keyes and Kraus that platinum tubes of a high degree of purity and sufficiently thin walled could be sealed directly into Pyrex glass in such a way as to hold a vacuum at liquid air temperatures on the one hand and also to stand the vapor pressure of liquid ammonia at room temperature, approximately ten atmospheres. The outer end of the platinum tube was closed by welding with a fine flame The bulbs were opened by puncturing the platinum tube with a small needle. Density data obtained with these bulbs showed, when other disturbing factors had been eliminated, a high degree of consistency.

(2) Balances and Methods of Weighing.—Considerable difficulty was experienced in determining the weight of the bulbs with the degree of accuracy desired, *i.* e., 0.01 mg.[9] However, with the right kind of a balance and with due regard to the necessary air buoyancy correction involved this was definitely accomplished.

Four different balances were used, the last being a special fifty gram load, semi-micro balance with a sensitivity (displacement of the rest-point) of approximately thirteen scale divisions. The notched beam was divided into a hundred divisions and carried a one milligram rider. Both the substitution and the transposition methods were used in making the weighings. The latter seemed on the whole to give more consistent results. The weights, Class M, had been calibrated by the Bureau of Standards. A counterpoise in the form of an open bulb was always placed on the scale pan with the weights. The size of this was such that its mass would be a little less than that of the empty bulb being weighed. The scale pans were fitted with aluminum wire supports by means of which the bulbs could be kept in a vertical position. This was necessary especially in weighing the sealed bulbs with their liquid contents. The rest points were determined by taking three readings to the right and two to the left. In all cases the weight to the nearest milligram was obtained by placing the proper fractional weights on the pan. With the first three balances the fractional part of a milligram was in turn computed from the rest-point, no rider being required. In the case of the special semi-micro balance referred to above the rider was used for the tenths and the rest-points for hundredths of a milligram. No-load rest-points were obviously not needed in either the substitution or the transposition method.

The procedure adopted consisted in making a total of sixteen weighings, usually only four on any one day. In doing this the temperature within the balance case, the barometric pressure and the humidity were recorded at regular intervals. An elaborate

---

(9) The authors are indebted to Mr. A. T. Pienkowsky of the Bureau of Standards for valuable suggestions in connection with the weighing.

set of tables was made up to simplify the work involved in obtaining the air densities. Since 1 cc. of air under ordinary conditions weighs approximately 1.2 mg. it was necessary to know the net volume displaced to within 0.01 cc. in making the air buoyancy correction. The volumes of the sealed bulbs were determined by means of hydrostatic weighings, whereas those of the open bulbs and the weights were calculated from the known densities of Pyrex glass, platinum, bronze and aluminum.

The following tabulation serves as an illustration of the degree of reproducibility obtained in making a series of weighings. The values given represent the mean, experiment No. 119, of each set of four weighings, after having been reduced to vacuum.

	Closed bulb	Open bulb
	2.243679	1.448758
	2.243673	1.448751
	2.243674	1.448747
	2.243677	1.448736
Av.	2.243676	1.448748
Calibration corr.	+0.000054	+0.000069
Final corr. wt.	2.243730 (±0.00001)	1.448817 (±0.00001)

(3) Residual Gas.—The equation of state used in calculating the weight of the residual ammonia, in those experiments where the final pressure was not zero, was obtained by assuming first the general equation

$$pv = RT_0 + (RT_0\alpha)p + (RT_0\beta)p^2$$

This was in turn put in the form

$$(pv)_1 = A + Bp_1 + Cp_1^2$$
$$(pv)_2 = A + Bp_2 + Cp_2^2$$
$$(pv)_3 = A + Bp_3 + Cp_3^2$$

In evaluating the constants the following approximate values were taken for the density of ammonia

1 atm.	0.77160 g./l.
$^2/_3$ atm.	0.51189 g./l.
$^1/_3$ atm.	0.25470 g./l.

By means of these densities the pv products per gram at the different pressures were calculated and a final equation of state for 0° obtained

$$pv = 1316.19 - 21.675p + 1.485p^2$$

p being expressed in atmospheres and v in cc. For the purpose of calculation the equation was put in the form

$$\text{wt. of residual ammonia} = \frac{\text{vol. of bulb}}{(1316.19/p) + 1.485p - 21.675}$$

Experimental Data and Discussion of Results

Altogether 119 density determinations were made, 88 at one atmosphere and 23 at lower pressures. The remaining eight were lost.

In Table I are presented the results with the five-liter Pyrex bulb at one atmosphere. It is to be noted that the density decreased from an average of 0.77168 at the lowest residual pressure to an average of 0.77149 at the highest. As will readily be seen from the accompanying curve, the latter seemed to represent a definitely limiting value. By way of confirmation it was decided to make a number of determinations with a bulb that had been baked and evacuated in order to remove the last traces of adsorbed water. It was thought that this would result in the complete elimination of any adsorption effects with ammonia and thus constant density data should be obtained regardless of the residual pressure. This proved in the end to be the case. However, before obtaining consistent results it became necessary to devise a new type of condensation bulb and also to observe additional precautions in avoiding adsorption effects in the line.

48	.0	164		51	40.0	144	.77149
49	.0	168	0.77168				

In Table II will be found a summary of the results with the one-liter bulb. Experiments 67–79 were made with the first form of condensation bulb. The mean density values for the different residual pressures agreed very well. Nevertheless, the differences between individual determinations were greater than the accuracy of the measurements involved would lead one to expect. This led to some questioning of the method of opening the bulbs and it was accordingly decided to try the kind illustrated in Fig. 3b. The first two experiments, Nos. 80–81, agreed remarkably well. However, the next series, Nos. 82–92, was far less satisfactory. In the first place the densities were higher and furthermore they varied considerably. Five additional experiments, Nos. 94–98, all at zero residual pressure, were likewise such as to leave one in doubt.

[a] **Indicates stages at which the bulb was baked.** [b] **The remaining experiments with the exception of Nos.** 100, 102, 104, 106, 108 **and** 110 **were made with the type of condensation bulb shown in Fig.** 3b.

In view of the above discrepancies it seemed advisable to obtain some comparative data with the two types of condensation bulbs. In the next series, therefore, Nos. 99–110, they were alternated. As in the case of the other series, the same sample of ammonia was used throughout. After having made the first experiment, No. 99, there were reasons for believing that the variable results might be due to slight traces of adsorbed ammonia in the line that had not been removed by evacuating before the condensation process was started. Up to this point the pumping had been continued for comparatively short periods, ordinarily about an hour, or at least until a McLeod gage gave no indication of any pressure. Beginning with No. 100 the line was pumped somewhat longer with consequent lower densities and also a much higher degree of consistency, *i. e.*, with the new style of bulb. The six determinations, Nos. 100, 102, 104, 106, 108 and 110, made with the first type showed conclusively that the weight of the glass could not have remained constant.

In the next five experiments the line was pumped even longer than in the preceding series, six to eight hours. The results showed a still further decrease in density. In order to determine if the limit of the adsorption effect had been reached, two additional experiments, Nos. 116–117, were made in which dry air was admitted from time to time while the line was being evacuated over a period of fifteen hours. Also, as a further check, in the next two experiments Nos. 118–119, the ammonia was removed by condensing it with liquid air in a second bulb that could be shut off with a stopcock during the subsequent condensation from the one-liter bulb. Since the maximum deviation of the four determinations was slightly less than four parts in seventy-five thousand, it was concluded that the adsorption effect had finally been eliminated and the average of these was accepted as the density of ammonia at 0°.

The authors realize that in selecting the last four values for determining the final mean density of ammonia no weight is given to the previous determinations. The gradual development of the method with consequent elimination of disturbing factors would seem, however, fully to justify this procedure.

Acknowledgment.—The authors wish to express their appreciation to Professor F. G. Keyes at whose suggestion this research was undertaken. His continued interest and helpfulness contributed much to the progress of the work. They are also greatly indebted to C. W. Orleman, Charles Rubin and Stanley L. Witcher, who assisted in the work with the one-liter bulb, especially in developing the technique of weighing.

Summary

A precision method for the determination of gas densities has been developed. An important feature of it is that it makes possible the definite elimination of adsorption effects. Also, the method readily lends itself to use over a wide range of temperatures.

On the basis of the data presented, the normal density of ammonia is considered to be 0.77126 (±0.00001)

The Density of Ammonia at Reduced Pressures and its Relation to the Atomic Weight of Nitrogen, the Gas Constant, R, and the Limiting Molal Volume, V_0

BY GERHARD DIETRICHSON, C. W. ORLEMAN AND CHARLES RUBIN

Introduction

Density determinations at reduced pressures are of particular importance because of the various computations that are thus made possible. The only previous work recorded, in the case of ammonia, is that by Moles and Batuecas.[1] Using the same method employed in determining the normal density,[2] they obtained the values

$^2/_3$ atm..	**0.511815** g./l.
$^1/_2$ atm..	**,382925** g./l.
$^1/_3$ atm.	.254607 g./l.

On the basis of these densities, combined with the previously determined normal density of 0.77169, they found the molecular weight of ammonia to be 17.032 and the atomic weight of nitrogen to be 14.009.

Procedure

The present work was carried out along precisely the same lines as that by Dietrichson, Bircher and O'Brien[3] in determining the normal density of ammonia. A number of preliminary experiments had been made by them at each of the pressures, two-thirds and one-third of one atmosphere, using the five-liter Pyrex bulb for measuring the volume of the gas. The latest results have all been obtained with the one-liter Jena glass bulb. In connection with these determinations it is desired to emphasize once more the precautions observed in eliminating the adsorbed ammonia in the line. This was accomplished in two ways. In some cases it was removed by evacuating over a period of fifteen hours, the pumping being interrupted from time to time and dry air admitted. Figure 1 shows the arrangement that was used in other instances. In these cases the adsorbed ammonia was first condensed in bulb **A.** Stopcock No. 1 was then closed during the subsequent condensation from the one-liter bulb. The condensing bulbs were similar to those used in the previous work. Also, the ammonia was subjected to the same purification process. Allowance was made in all of these experiments for the change in volume of the five-liter and the one-liter bulbs with pressure.

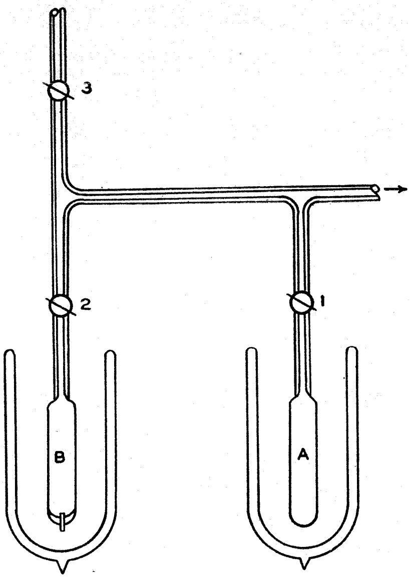
Experimental Data

Nine determinations were made at two-thirds of an atmosphere using the five-liter bulb and six with the one-liter bulb. Table I contains these results. The corresponding numbers at one-third of an atmosphere, as shown in Table II, were fourteen and four.



To one-liter **bulb** and short arm of manometer.

had been baked before being used. Experiments Nos. 120–125 are divided into three groups of two each. In Nos. 120–121 the adsorbed ammonia in the line was pumped out under conditions as previously described. In Nos. 122–123 it was condensed in bulb A. Finally in Nos. 124–125 the residual pressure instead of being zero was about 40.0 mm., the absorbed ammonia in the line being removed by pumping. It is significant that the six density values obtained under these varying conditions agree to within slightly less than five parts in fifty thousand. The close agreement between the first four and the last two determinations also seemed to prove conclusively that the absorption effect in the one-liter bulb, as well as in the line, had been eliminated completely. The density at two-thirds of an atmosphere was accordingly considered to be 0.51161 (±0.00001).

Four density determinations at one-third of an atmosphere, Nos. 126–129, corresponding to Nos. 120–123 at two-thirds, resulted in a mean value of 0.25458 (±0.00001).

Discussion of Results

In the paper by Dietrichson, Bircher and O'Brien it was pointed out that the density of ammonia could be calculated by means of an equation of the form

$$d_n = \frac{m}{v_1} = \frac{M(1 + \bar{\lambda})}{RT_0}$$

Correspondingly, by using experimentally determined densities, it is possible to compute molecular weights and from these in turn atomic weights. Obviously in doing this it is necessary to assign values to R, T_0 and λ. Molecular and atomic weights obtained in this manner will therefore be significant only in so far as these constants, or quantities equivalent to them, are accurately known.

The limitations involved in the above method of determining atomic weights, which was originally proposed by Guye, have been admirably set forth in a paper by Baxter[4] entitled "The Significance of the Density of Hydrogen Bromide with Reference to the Atomic Weight of Bromine." Attention is called especially to the uncertainty with regard to λ which he defines by the equation $p_0v_0/p_1v_1 = 1 + \lambda$, *i. e.*, the ratio of the pressure–volume product at zero pressure to that at one atmosphere, and computed from density data at different pressures. As Baxter states, however, various procedures have been adopted in extrapolating for the p_0v_0 products with consequent variations in λ. The two that are discussed are referred to as a "method of secondary differences" and an "algebraic method." In effect these are the same mathematically in that both assume a quadratic rather than a linear relation.

In his own subsequent determinations of the density of oxygen, nitrogen and the rare gases, Baxter[5] obtains the pv/p_1v_1 ratios at two or three pressures below one atmosphere and then, by using the method of first differences, extrapolates each of these to zero pressure for $p_0v_0/p_1v_1 = 1 + \lambda'$.[6] Moles in his papers on ammonia follows essentially the same procedure except that he finds d/p, or $1/pv$, for each pressure and applies the method of first differences to these values in order to get a limiting density, d_0/p_0 or $1/p_0v_0$. Using his notation, the equation is written in the form, $L_0/L_{\text{Lim.}} = 1 + \lambda''$, which corresponds to

$$\frac{1/p_1v_1}{1/p_0v_0} = \frac{d_1/p_1}{d_0/p_0} = \frac{L_0}{L_{\text{Lim.}}} = 1 + \lambda''$$

In this equation p_1, v_1 and d_1 represent the values of these quantities at one atmosphere and p_0, v_0 and d_0 the limiting values at zero pressure. Moles, as does Baxter, calculates a separate λ to correspond to each pressure at which density determinations have been made and takes the mean as his final value, As will be illustrated in Table III, treatment of the same set of density data by these two operations does not give identical results. That is what one would expect if the pressure–volume product, pv or d/p, is a quadratic rather than a linear function of the pressure.

The situation with regard to the method of differences as applied to determining the value of λ can possibly best be illustrated by means of curves, Fig. 2, showing the variations of pv and of d/p with p for ammonia. If plotted on a sufficiently large scale it is found that, in general, there is a curvature. It necessarily follows that extrapolation to zero pressure

At. wt. N	14.0066	14.0138

becomes increasingly uncertain the greater this effect. In the case of ammonia the curvature is quite pronounced, especially with the data as reported in this paper.

The authors feel that the coefficient of deviation from Boyle's law should be defined as $\left(\frac{1}{pv}\right)_{p\rightarrow 0}\left[\frac{\partial(pv)}{\partial p}\right]_T = A'''$. An evaluation of λ when so defined naturally necessitates an equation of state in terms of p and v. Using the method of least squares, the densities being weighted in proportion to pressures, the following equation per gram of ammonia at 0° was developed.

$$pv = 1315.403 - 17.767p - 1.054p^2$$

For purposes of comparison a similar equation was developed for Moles and Batuecas' data on ammonia. Table III presents a summary of the various computations involved. The value for v_0 as obtained by Baxter and Starkweather in their work on oxygen was used throughout.

$$v_0 = RT_0 = \frac{M(1 + \lambda)}{d_n} = \frac{32 \times 1.00092}{1.42897} = 22.4144$$

It will be noted that the atomic weight of nitrogen, that of hydrogen being assumed to be 1.0078, was found to show considerable variation. It appears therefore that the gas density method for the determination of atomic weights cannot at present be considered as reliable as that based on gravimetric analyses, not because of insufficient accuracy as regards the gas densities, but rather because of uncertainties in connection with λ, R and T_0 (also $v_0 = RT_0$). This conclusion is in accordance with that stated by Baxter in his paper on hydrogen bromide.[4]

In view of the above considerations it seems therefore more profitable at present to use density data for the purpose of determining more accurately the value of R, the gas constant and v_0, the limiting mold volume at 0°. This can be done by considering that the constant, a, in the linear or quadratic equation is equivalent to RT_0/M. In other words, $pv = RT_0/M + bp$ or $pv = RT_0/M + bp + cp^2$. An evaluation of R and v_0 requires accordingly the constant, a, as obtained from the equation of

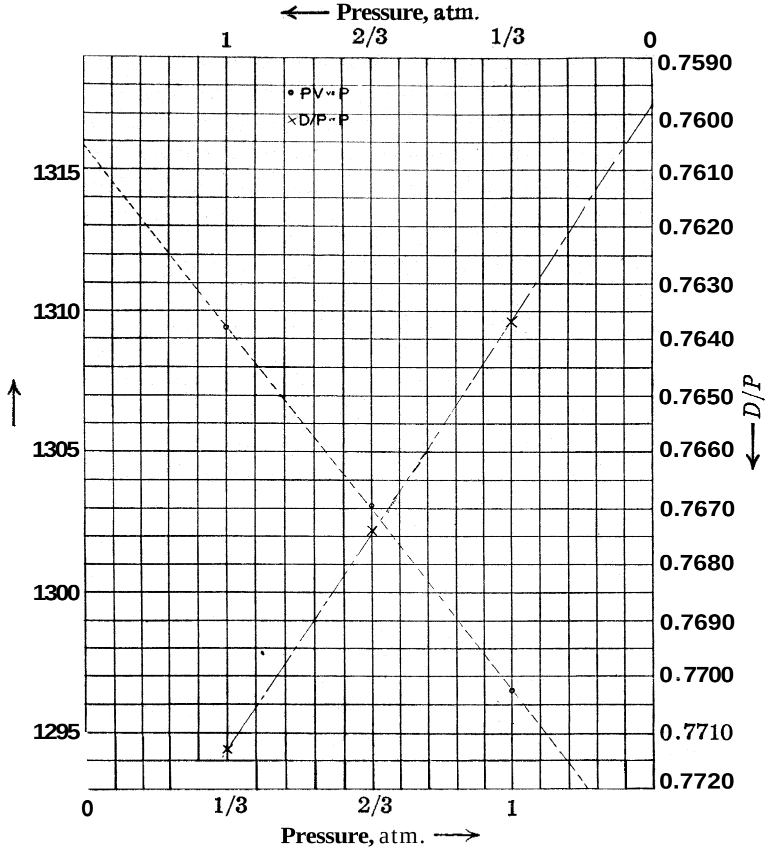

Fig. 2.

state and assumed values for T_0 and the atomic weights involved. Table IV presents a summary of the calculations that were made with the two forms of equation. The constants, a, b and c, were in each case determined as previously explained, *i. e.*, by using the method of least squares, the densities being weighted in proportion to the pressures. The following tabulation indicates the number of density determinations involved.

Pressures in atm.	1	$^2/_3$	$^1/_2$	$^1/_3$
NH_3 (D. B. and O. and D. O. and R.)	4	6		4
NH_3 (M. and B.)	39	17	18	23

A comparison of R and v_0 fails to show agreement in the case of either form of equation. In view of the known curvature of ammonia in plotting pv or d/p against p one would expect the best results with the second power equation. However, it must be kept in mind that a determination of these constants by the equation of state method involves again a more or less uncertain extrapolation. In other words, it is assumed that the curvature between zero and one-third of an atmosphere will be the same as that between one-third and one atmosphere. Density data at still lower pressures would obviously be helpful in settling this question. Also, additional data on other gases are needed. Among these carbon dioxide is of particular interest since the atomic weight of carbon has been determined with such accuracy and, furthermore, the proportion of carbon to oxygen is small. Density determinations of carbon dioxide by the method described in this and the preceding paper are now under way.

The value of R given in the "International Critical Tables," 82.06 cc. atm., is that derived by Keyes[7] on the basis of equations of state involving the densities of hydrogen, nitrogen, oxygen and carbon dioxide. The accuracy, however, is probably not greater than one part in two thousand. About the same time Henning[8] reported a value of 82.04 (±0.03).

In connection with the above, attention may be called to the fact that the second derivative of the equation derived from the authors' data is -2.108, the curvature therefore being convex upward in the range from zero to one atmosphere. This is in agreement with the compressibility isotherms at 25 and 50° as reported by Meyers and Jessup,[9] who obtained data extending into the low pressure region.

TABLE IV

THE GAS CONSTANT, *R*. AND THE LIMITING MOLAL VOLUME, v_0

$pv = a + bp \quad a = RT_0/M \quad T_0 = 273.16\,°\mathrm{K}.$

	a	b	M	R	$v_0 = RT_0$
NH_3 (D. B. and O. and D. O. and R.)	1316.484	-20.066	17.0312	82.081	22,421.3
NH_3 (M. and B.)	1315.940	-20.177	17.0312	82.047	22,412.0

$pv = a + bp + cp^2 \quad a = RT_0/M \quad T = 273.16\,°\mathrm{K}.$

	a	b	c	M	R	$v_0 = RT_0$
NH_3 (D. B. and O. and D. O. and R.)	1315.403	-17.767	-1.054	17.0312	82.015	22,403.2
NH_3 (M. and B.)	1316.025	-20.452	$+0.192$	17.0312	82.053	22,413.6

The equations for these are as follows

$$pv_{25°} = 1436.16 - 14.700p - 0.220p^2$$
$$pv_{50°} = 1552.86 - 10.314p - 0.193p^2$$

The densities obtained by Moles and Batuecas result in a curvature in the opposite direction.

Summary

1. The density of ammonia at two-thirds and one-third of an atmosphere has been determined and found to be 0.51161 (±0.00001) and 0.25458 (±0.00001).

2. The gas density method for the determination of atomic weights has been discussed.

3. The gas constant, R, and the limiting molal volume, v_0, have been computed by means of linear and quadratic equations of state developed on the basis of density data for ammonia as determined by the authors and by Moles and Batuecas.

Properties of Electrolytic Solutions. I. Conductance as Influenced by the Dielectric Constant of the Solvent Medium[1]

BY CHARLES A. KRAUS AND RAYMOND M. FUOSS[2]

I. Introduction

While solutions of electrolytes in solvents of high and of intermediate dielectric constant have been studied extensively, similar solutions in solvents of very low dielectric constant have not been investigated systematically. We know only that such solutions generally are poor conductors and that the equivalent conductance falls rapidly with decreasing concentration.

In addition to a number of isolated observations on the conductance of solutions in benzene,[3] and several series of measurements relating to the conductance of complex compounds in various solvents at relatively high concentrations,[4] the literature includes two important papers by Walden and his co-workers, who investigated[K] the conductance of a variety of *salts* in benzene, ether, carbon tetrachloride and similar solvents. According to Walden's measurements, the equivalent conductance of solu-

tions of quaternary ammonium salts in benzene falls off sharply with increasing concentration over the concentration range studied, namely, 0.1–0.03 N. In solvents of somewhat higher dielectric constant, the conductance passes through a minimum at moderate concentration and thereafter increases.

It is uncertain whether or not the equivalent conductance of electrolytes in benzene and similar solvents continues to fall indefinitely as the concentration decreases; the laws governing the conductance phenomenon in solvents of low dielectric constant are yet to be established. While the influence of the dielectric constant on conductance is satisfactorily accounted for by the interionic attraction theory in solvents of high dielectric constant, it is not known to what extent interionic forces are primarily concerned in solvents of low dielectric constant. Nor is it known to what extent a mass action effect may he involved. The present investigation was undertaken in order to obtain experimental information bearing on these auestions.

Benzene and dioxane $\left(\overline{\mathrm{CH_2CH_2OCH_2CH_2O}}\right)$ were chosen as solvents of very low dielectric constant. Solvents of any desired higher dielectric constant were obtained by adding solvents of high dielectric constant in proper proportion. For this purpose, water and ethylene dichloride were used. The conductance phenomenon has thus been studied in mixtures of dioxane and water over a dielectric constant range from **2.2** to 79 and in mixtures of ethylene dichloride with dioxane and with benzene over the range from 2.2 to **10.4.**

Tetraisoamylammonium nitrate and thiocyanate and tri-isoamylammonium picrate were employed as electrolytes; the first two are strong electrolytes, while the last is a relatively weak electrolyte. The conductances in the various pure and mixed solvents were determined over the (approximate) concentration range **0.00001–0.2** *N*, which was sufficient to establish the general characteristics of the conductance curves.

Because of the very low conductance of the more dilute solutions in solvents of low dielectric constant, the resistances were measured by means of a direct current galvanometric method. While the precision of this method is only approximately 1%, the results obtained with it are reliable within this limit as was shown by checking against results obtained by the usual alternating current method.

II. Materials

Tetraisoamylammonium Salts.—The iodide is best prepared as follows. An equivalent mixture of tri-isoamylamine and isoamyl iodide is introduced into a long tube which is then heated near the top to about 150°. As crystals of the salt form, they fall to the cooler region at the bottom, thus avoiding much of the decomposition which occurs if the salt is heated to higher temperature for an appreciable length of time. The product is washed with petroleum ether, and treated with potassium hydroxide in alcoholic solution to decompose any tertiary salt that may have formed during the heating. The salt is then precipitated by pouring the solution into water. After washing and drying, and rewashing with petroleum ether, a product is obtained which melts at 115°. This material, after several recrystallizations from a mixture of *anhydrous* ethyl acetate and petroleum ether, yielded a product melting at 136°

Anal. Subs., 0.3499, 0.4051, 0.4530: AgI, 0.1933, 0.2240, 0.2498 Calcd. for $(C_6H_{11})_4NI$: I, 29.85. Found: 29.87, 29.88, 29.81, av., 29.86.

Tetraisoamylammonium nitrate was prepared by treating the iodide with an exact equivalent of silver nitrate in alcoholic solution After filtering out the silver iodide, the solution was allowed to evaporate at room temperature, and the product was recrystallized from *a* mixture of anhydrous ethyl acetate and petroleum ether.

Tetraisoamylammonium thiocyanate was prepared by dissolving the nitrate in *absolute* alcohol and adding an exact equivalent of an analyzed solution of potassium thiocyanate in absolute alcohol. After filtering and evaporating the solution, the salt was recrystallized from anhydrous ethyl acetate and petroleum ether.

Anal. Subs., 0.8857, 0.5031: AgSCN, 0.4158, 0.2350. Calcd. for $(C_5H_{11})NSCN$: SCN, 16.29. Found: 16.42, 16.34.

In the first analysis, the silver nitrate was dissolved in water; in the second, the precipitation and first washing were carried out with alcohol. Since tetraisoamylammonium thiocyanate is only sparingly soluble in water, co-precipitation of the quaternary salt apparently occurred

It may be mentioned that the iodide is only sparingly soluble in water, the bromide may be recrystallized from water, while the chloride is extremely soluble and is very hygroscopic.

Tri-isoamylammonium picrate was prepared by adding a saturated hot alcoholic solution of picric acid to a slight excess of tri-isoamylamine. The crude product, which crystallizes from the alcohol almost completely on cooling, was recrystallized from ethylene dichloride and petroleum ether.

Dioxane was purified according to Vingee's method.[6] The technical product was cooked with caustic soda, dried over barium oxide, and subsequently distilled fractionally from sodium–lead alloy (NaPb). The middle fraction (about 90% of the total) was dissolved in liquid ammonia and treated with metallic sodium to remove various reducible impurities.[7] After boiling off the ammonia, the dioxane was redistilled and stored over sodium–lead alloy in a still from which it could be distilled directly into the conductance cells; m. p. 11.7°.

Benzene.—Thiophene-free benzene was washed with concentrated sulfuric acid, water, dilute potassium hydroxide solution and water. After drying, it was fractionally crystallized and stored in a still similar to the one used for dioxane; m. p. 5.43°.

Ethylene dichloride was distilled from phosphorus pentoxide. The middle fraction was stored over phosphorus pentoxide in one of the supply stills; b. p. 82.4° at 747 mm.

III. Apparatus and Method

Electrical Equipment.—Resistances up to 100,000 ohms were measured by the alternating current method. The apparatus was of the conventional type, comprising a drum wound bridge, a Vreeland oscillator, a set of Curtis resistance coils up to 100,000 ohms, condensers for balancing out capacity effects, a two-stage amplifier and telephones.

Higher resistances were measured by a direct current method, which essentially

---

(6) Vingee, Thesis, Brown University, 1931.

(7) According to a later procedure of Vingee, the impurities are removed by boiling the dioxane with metallic sodium, after previous treatment with sodium hydroxide and desiccation with barium oxide This procedure is much more convenient than the treatment in ammonia.

amounted to using a galvanometer as ammeter, and computing the cell resistance by Ohm's law from the current so determined and the voltage applied to the conductance cells. Two galvanometers were used. The first (G_1) had a resistance of 15.6 ohms and a sensitivity of 3 X 10^{-8} amp./cm., the second (G_2) had a resistance of 913 ohms and a sensitivity of 4 X 10^{-10} amp./cm. The galvanometers were mounted on Julius suspensions, and covered with copper shields having windows opposite the mirrors. The sensitivity of the galvanometers was determined at frequent intervals during each experiment. By means of a suitable resistance in series and shunt with the galvanometers, any input current from 10^{-4} to 10^{-8} amperes could be adjusted to give full scale deflection (25 cm.).

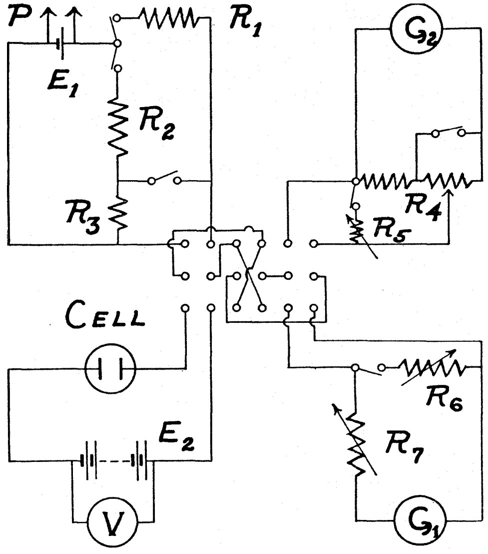

Fig. 1.—Direct current equipment: G_1, 15.6-ohm galvanometer; G_2, 913-ohm galvanometer; R_5, Re, R_7, 0–10,000-ohm variable resistances; R_4, 1–100,000-ohm Ayrton shunt; E_1, 1 5-volt dry cell; P, potentiometer leads; R_1, 1,000,000 ohms; R_2, 10,000 ohms; Ra, 1 ohm; E_2, 150-volt storage battery; V, Weston voltmeter.

The d. c. circuit is shown in Fig. 1. Two 0–10,000 ohm resistances R_6 and R_7 were used to control the sensitivity of galvanometer G_1. An Ayrton shunt R_4 (1–100,000 ohms) was used with the high sensitivity galvanometer G_2; an auxiliary shunt R_5 (0–10,000 ohms) and a shorting switch for half of the Ayrton coil gave intermediate steps between the ten-fold sensitivity changes obtained by R_4 alone. The calibrating circuit included a dry cell El, potentiometer (leads) P and resistances R_1 (1,000,000 ohms), R_2 (10,000 ohms) and R_3 (1 ohm) All resistances were calibrated to 0.1%.

The reversing switch permits the average of right and left swings to be taken and avoids zero point correction as well as permanent distortion of the galvanometer suspension due to repeated full deflection in one direction. The galvanometer deflections could be read to 0.3 mm., but were not reproducible to less than 1 mm. (out of the total deflection of 250 mm.), probably due to stray currents of various kinds in the control resistances. These were reduced to a minimum by keeping the total resistance of the galvanometer circuit as high as conveniently possible. One centimeter deflection on the 913-ohm galvanometer corresponded to a resistance of 4×10^{11} ohms, and a conductance of 5 X 10^{-14} mhos (for a cell with a constant equal to 0.02 and using 150 volts).

The source of current was a battery of 72 lead storage cells which were used when the e. m. f. was on the flat part of the discharge curve. The errors due to internal resistance of the battery and to polarization of the conductance cell (that is, in assuming that the voltage read on the Weston voltmeter V was the e. m. f. producing the current measured on the galvanometers) were determined and found to be less than one per cent., provided at least 150 volts were used. All lead wires were insulated by means of paraffined glass tubes, and the thermostat liquid in which the conductance cell was placed was a good grade of high flash petroleum oil. Practically no error was introduced by faulty insulation; the leakage corresponded to 1–3 mm. on the high sensitivity galvanometer in the most unfavorable cases, and was considered in the corrections.

The results of the alternating and direct current methods of measurement were compared directly for resistances of the order of 100,000 ohms. Lower resistances could not be measured with the d. c. method on account of the relatively high currents, while higher resistances could not be measured with the a. c. method without unbalancing the bridge. Indirect comparisons of the two methods were obtained, however, by measuring the ratio of the cell constants of several cells, first at low resistances (1000–10,000 ohms) by the a. c. method and second at high resistances (1–10 megohms) by the d. c. method. The a. c. and d. c. results agreed within 1% for both direct and indirect comparison.

Conductance Cells and Accessories.—The cells were constructed from Pyrex Erlenmeyer flasks by sealing side bulbs containing electrodes to the bottoms of the flasks. Long (20 X 0.8 cm.) necks with ground-glass stoppers were attached to the flasks in order to minimize the diffusion of moisture into the cells during introduction of solution. The necks were ground to fit the delivery tubes from the various solvent stills. The electrodes were lightly platinized; heavy platinization caused considerable adsorption in dilute solutions, while bright electrodes failed to give steady d. c. resistances. The cells were calibrated by comparing them against each other and against a specially constructed calibration cell whose constant was determined, using Parker's[8] data for 0.1 demal potassium chloride solution. The cell constants are given in Table I.

TABLE I

CELL CONSTANTS

Cell	Determined constant			Average
Calibration	21.626	21.635[a]		21.63
125 cc.	0.17790	0.17780	0.17769	0.1777
250 cc. (first)	.02544	.02552		.02548

500 cc.	.19378	.19369	.19369	.1937

[a] Two separately prepared KCl solutions.

The purified solvents were stored in 3-liter Pyrex flasks, to which were sealed reflux columns and condensers. To the delivery tube of each condenser was sealed a 30-cc. bulb containing electrodes (cell constants 0.02 to 0.03). which permitted control of the specific conductance of the solvent as distilled and before admitting it to the conductance cell. Siphons from the test bulbs were provided with ground-glass joints which fitted the necks of the cells. The best figures for solvent conductance were as follows: dioxane, 5×10^{-15}; benzene, $< 3 \times 10^{-15}$; ethylene dichloride, 3×10^{-10} mhos. In each experiment, the solvent conductance was determined before adding solute and was subtracted from the observed conductance if the correction exceeded 0.5%. The cells were immersed in a thermostat kept at 25.00 ± 0.02°. When room temperature was under 25°, the necks of the cells were kept at about 35° by an electrically heated cap in order to prevent solvent from distilling into the necks. Precautions were taken to keep the glassware dry.

Method.—After making up solutions in different ways and comparing the results in order to locate and avoid any systematic errors in determining concentration, the following method was adopted. Solvent was distilled into one of the larger cells and a small portion of this was pumped by dry air pressure onto a weighed quantity of salt, in the small cell. The amount of solvent in each cell was determined by weighing. After diluting several times, the final solution (A) in the small cell was pumped into a weight buret, and increasing portions of this solution were weighed into the solvent in the first cell. For very dilute solutions, about one gram of solution (A) was weighed

---

(8) Parker and Parker, THIS JOURNAL, 46, 332 (1924).

from a pycnometer into about 60 g. of solvent in a weight buret, and this was, in turn, weighed into the first cell in six to eight portions before starting to weigh in the remainder of solution (A).

Specific gravities were determined by means of a Westphal balance, and normalities were computed from the known weight concentrations.

IV. Results

The experimental results are summarized in Tables 11–XI, where c is concentration in equivalents of solute per liter of solution, and A is equivalent conductance. The values given in these tables were obtained by interpolation (and occasional extrapolation over a small distance) of the actual results on a large-scale log A–log c plot. The round concentrations chosen correspond to approximately equal steps on a log *c* scale, spaced at about the same ratio as the experimental dilution ratio. There are, of course, certain disadvantages in reporting only interpolated values, particularly when the interpolation function is arbitrary and not monotonic, but compact presentation of the large number (about fifty series of conductance measurements) of determinations could not otherwise have been achieved. For discussion and comparison, the conductance curves for the various systems investigated are shown in Figs. 2–5, where the open circles represent the *observed* values.

The conductance values for tetraisoamylammonium nitrate in dioxane are given in Table II and are shown graphically in Fig. 2 where log A is plotted against log c. Nine series of measurements were made in order to test the reproducibility of the results and the reliability of the methods. In the first three series covering the dilute region, the conductance at concentrations below 10^{-4} was somewhat erratic; this appeared to be due to impurities in the solvent, because the solvent conductance was about 4×10^{-13}. After re-treating the dioxane with sodium in liquid ammonia, and refluxing for about twenty hours over sodium–lead alloy, the solvent conductance was reduced to less than 2×10^{-14}. Measurements made in the dilute region with the re-treated dioxane gave consistent results. The conductance curve exhibited an unexpected complexity in structure,

namely, three inflection points in the moderately concentrated region, was obtained for other systems.

Conductance values for tetraisoamylammonium nitrate in various mixtures of dioxane and water are given in Tables III–V. Round concentrations c are given in the first columns and interpolated equivalent conductances A are given in the other columns. The weight percentages of water in the mixed solvents are given at the head of each conductance column. The solvent conductances are given in the last column of Table XII. These mixtures correspond to solvents whose dielectric constants range from 2.2, that of dioxane,[9] to 78.6, that of water.[10] Table III covers the low range of dielectric constant, Table IV the intermediate range, and Table V includes the conductance in water. The conductance data for these mixtures are shown on a log c–log A plot in Fig. **3.** These curves will be discussed below but it may be pointed out here that at a concentration of 10^{-5} N the equivalent conductance changes over a million-fold as the dielectric constant of the solvent changes in the ratio of 2.2 to 78.6. It will be noted that minima appear in the conductance curves for low and intermediate values of the dielectric constant. The values of the minimum conductances and the corresponding concentrations are given in Table VI.

TABLE VI

MINIMUM CONDUCTANCES FOR TETRAISOAMYLAMMONIUM NITRATE IN DIOXANE–WATER MIXTURES

parison of conductance values in different solvents of very low dielectric constant. Interpolated conductance data are given in Table IX for solutions of the thiocyanate: in dioxane, column 2; in benzene, column **3** and in a mixture of benzene and ethylene dichloride, with a dielectric constant of 2.8, column 4.

It was considered desirable, for purposes of comparison, to determine the characteristics of the conductance curve of a weak salt. Accordingly, tri-isoamylammonium picrate was investigated in benzene, in ethylene dichloride and in a mixture of these solvents having a dielectric constant of 3.1. The results are given in Table X.

The temperature coefficient of the conductance of tetraisoamylammonium nitrate in dioxane was determined at several concentrations, over the temperature range 18–35°. The results are summarized in Table XI. The concentration M for each series is given as moles of salt per kilo of solvent, and may be converted to normality by means of the equation

$$d = 1.029 - 0.0248\,M - 0.00105\,(t - 25°)$$

where d is the density, M weight concentration and t the temperature. The temperature coefficients are all positive, and decrease with increasing temperature. They depend markedly on concentration: the average

V. Discussion

The conductance of tetraisoamylammonium nitrate in dioxane is shown graphically in Fig. 2, where the logarithms of equivalent conductance and of concentration are plotted as ordinates and abscissas, respectively. This curve is typical of solutions of strong electrolytes in solvents of very low dielectric constant. The conductivity falls off continuously, although at varying rate, to concentrations well below 10^{-4} N. Indeed, if measurements had been carried only to this concentration, it might have been inferred that the conductance was approaching zero as the limiting value. Actually, however, below 10^{-4} *N*, the rate of decrease diminishes and there is evidence of a minimum in the conductance curve in the neighborhood of 2×10^{-5} *N*. What form the conductance curve may have at concentrations below the minimum point in the solvents of lowest dielectric constant could not be ascertained by the method employed in this investigation. Measurements in solvents of slightly higher dielectric constant, however,

---

[12] For the dielectric constants of the mixtures, we are indebted to Mr. G. S. Hooper, of this Laboratory, who kindly carried through a series of measurements for us.

indicate that, after passing through a minimum point, the conductance increases with decreasing concentration in regular manner.

The curve at higher concentration is quite complex, since it exhibits three inflection points. The decreasing slope of the curve with increasing concentration at high concentrations may be accounted for on the assumption that the ion mobilities are decreasing, owing to the rapidly increasing viscosity of the solutions. Although the viscosities were not measured, it was quite evident that the viscosity of these solutions increases rapidly with increasing concentration. The complex structure of the remainder of the curve remains unaccounted for. Such a structure is seemingly found only in the case of the strongest electrolytes and is not dependent upon the particular solvent employed, so long as the dielectric constant is sufficiently low. Thus, a similar curve is found for tetraisoamylammonium thiocyanate in dioxane (Fig. 4, Curve V) and for the same salt in benzene (Fig. 4, Curve IV). On the other hand, a weaker electrolyte, tri-isoamylammonium picrate, yields a curve in which inflection points are absent (Fig. 5, Curve V).

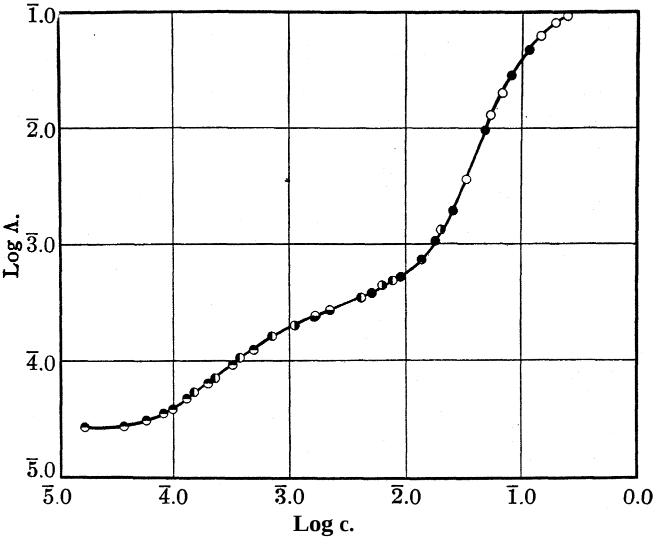

Fig. 2.—Tetraisoamylammonium nitrate in dioxane.

Incidentally, it may be pointed out that conductance values as determined by the alternating and by the direct current method are in excellent agreement. In Fig. 2, the open circles represent points determined by the alternating current method, while the other circles represent points determined by the direct current method. The black circles and the various half-shaded circles represent independent series of direct current measurements in which the methods of carrying out the dilution were varied. As may be seen from the figure, the various determinations are consistent. We may conclude, therefore, that the direct current method yields reliable results and that, even in solvents of dielectric constant as low as 2.2, the conductance curve passes through a minimum at very low concentration.

The influence of the dielectric constant of the solvent medium as well as the influence of specific factors upon the conductance of solutions is of considerable interest. By the methods employed, it was possible to extend the measurements to concentrations sufficiently low to permit determination of the general course of the curve at concentrations below the minimum point. This is well illustrated in Fig. **3** for solutions of tetraisoamylammonium nitrate in varying mixtures of dioxane and water. Dioxane was purposely selected as solvent, since it is completely miscible with water and thus permits of a continuous increase of the dielectric constant of the medium from that of dioxane, 2.2, to that of water 78.6. The composition of various mixtures in weight percentages of water is indicated on the figure.

It will be seen from the figure that, on addition of water to dioxane, the conductance is increased and the complex structure of the curve at higher concentration becomes less pronounced and ultimately disappears. The eccentricities in the conductance curve at higher concentration, while still noticeable at a concentration of 1.24% of water, have disappeared when the concentration of water reaches 4.0%. In the meantime, the minimum point has shifted toward higher concentration, namely, from 2 × 10^{-5}, in pure dioxane (D = 2.2)) to **3** × 10^{-3} N at 4% of water (D = **3.5**). As the dielectric constant of the medium increases with increasing concentration of water, the minimum point shifts more and more toward higher concentration and becomes less and less pronounced in that the approach from the high concentration side becomes less steep. **It** ultimately disappears for a mixture containing 20% of water (D = 12). The form of the conductance

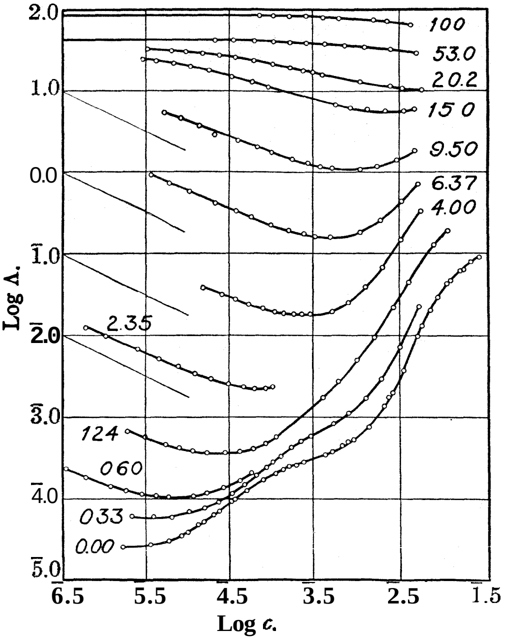

Fig. 3.—Tetraisoamylammonium nitrate in dioxane–water mixtures. (Weight per cent. of water given opposite corresponding curve.)

curve beyond the minimum point (toward lower concentration) remains unchanged as the dielectric constant increases and is practically linear on a logarithmic plot. For mixtures having dielectric constants above 12, the conductance curves are displaced chiefly by an increase of conductance in the more concentrated region and the curves approximate those of strong electrolytes in water.

There is no sharp shift in the conductance curve on the initial addition of water. The controlling factor seems to be the dielectric constant of the medium, for the form of the curves and the value of the conductance at a given concentration is practically the same whether the change in dielectric constant is brought about by the addition of water or of ethylene dichloride.

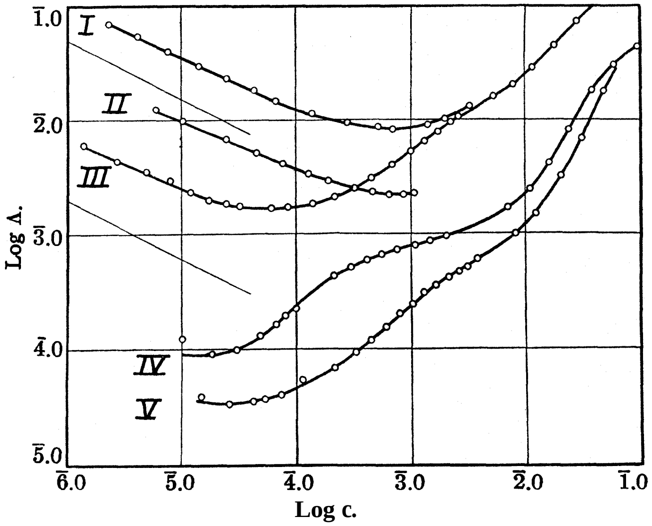

Fig. 4.—I, Tetraisoamylammonium nitrate in dioxane containing 22.9% ethylene dichloride; II, tetraisoamylammonium nitrate in dioxane containing 2.35% water; III, tetraisoamylammonium thiocyanate in benzene containing 13.13% ethylene dichloride; IV, tetraisoamylammonium thiocyanate in benzene; V, tetraisoamylammonium thiocyanate in dioxane.

This is well illustrated in Fig. 4, Curves I and II. The first curve is that of solutions of tetraisoamylammonium nitrate in a mixture of dioxane and ethylene dichloride ($D = 2.45$) and the second in a mixture of dioxane and water ($D = 2.9$). Both curves have a minimum point in the neighborhood of 10^{-3} N and both curves are practically linear and parallel at lower concentrations. The ethylene dichloride mixture is a considerably better conductor than the water mixture, but this is in a large measure due to the much lower viscosity of the former mixture. Curve III, Fig. 4, is for tetraisoamylammonium thiocyanate in an ethylene dichloride–benzene mixture, of dielectric constant 2.8, and it will be noted that the curve approximates that of tetraisoamylammonium nitrate in a dioxane–water mixture, of dielectric constant 2.6 (Curve 1.24, Fig. 3), except for a vertical displacement, presumably due to the difference in solvent viscosities. Curves IV and V, Fig. 4, represent the conductance of tetraisoamylammonium thiocyanate in benzene and dioxane, respectively. The structure of the two curves is much the same and, at low concentrations, the conductance values in the more fluid benzene are the higher. Quite unexpectedly, therefore, specific influences due to the solvent medium are absent, if we leave out of account viscosity effects.

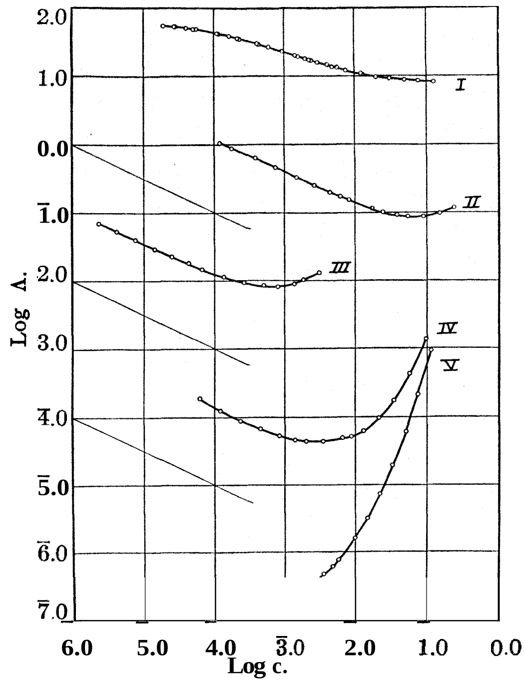

Fig. 5.—I, Tetraisoamylammonium nitrate in ethylene dichloride; II, tri-isoamylammonium picrate in ethylene dichloride; III, tetraisoamylammonium nitrate in dioxane containing 22.9% ethylene dichloride; IV, tri-isoamylammonium picrate in benzene containing 21.2% ethylene dichloride; V, tri-isoamylammonium picrate in benzene.

The conductance curve of tri-isoamylammonium picrate, a weak electrolyte, differs markedly from that of strong electrolytes. This will be evident on comparing Curve V, Fig. 5, for this electrolyte in benzene with Curves IV and V, Fig. 4, for tetraisoamylammonium thiocyanate in benzene and dioxane or with the curve for tetraisoamylammonium nitrate in dioxane, Fig. 2. It will be noted that the conductance of tri-isoamylammonium picrate in benzene is far below that of tetraisoamylammonium thiocyanate in the same solvent at corresponding concentrations. Thus, at 10^{-3} N, the conductance of the first electrolyte in benzene is approximately 2.5×10^{-7}, while that of tetraisoamylammonium thiocyanate is 10^{-3}. As the dielectric constant of the solvent medium is increased by adding ethylene dichloride to benzene, the conductance is largely increased. This is evident on comparing Curve V, Fig. 5, with Curve IV, Fig. 5, where the solvent contains 21% of ethylene dichloride ($D = 3.1$).

The difference in the behavior of a quaternary and a ternary salt at higher dielectric constant is well illustrated by Curves I and II, Fig. 5, for tetraisoamylammonium nitrate and for tri-isoamylammonium picrate, respectively, in ethylene dichloride. Curve III, for tetraisoamylammonium nitrate in a dioxane mixture containing 23% of ethylene dichloride, lies far above Curve IV, for the picrate in benzene containing 21% of ethylene dichloride. The dielectric constants of the solvents are, respectively, 2.45 and 3.1. As in the case of the strong salts, however, the minimum for the tertiary ammonium picrate shifts to higher concentrations with increasing dielectric constant and, at the same time, the slope of the curve, toward higher concentration, decreases. This phenomenon is characteristic of the transition from solvents of low to those of high dielectric constant.

One of the striking results of this investigation, best illustrated in Fig. 3 but also evident from Figs. 4 and 5, is the fact that, at concentrations below the minimum point, the curves as plotted are approximately parallel until the conductance reaches a value in the neighborhood of 1.0. This is illustrated in Fig. 3 by the curves for mixtures containing from 0.60 to 9.50% of water, as well as by Curves II, III and IV of Fig. 5 and Curves I, II and III of Fig. 4. The slope of the curves toward lower concentrations approaches a value of approximately minus 0.5, which is indicated by the straight lines drawn in the figures. Since, in the figures, logarithms of the equivalent conductance are plotted against logarithms of the concentration, it follows that the curves conform approximately to a simple equation $\mathrm{A} = A/C^{1/2}$, where A is constant. One should expect such a relation for a binary electrolyte if the conductance were determined by ionization according to the law of mass action. A theoretical discussion of the foregoing and other results is reserved for a future paper.

Summary

1. The conductances at 25° of the following systems have been determined over the concentration range 0.2–0.00001 N: tetraisoamylammonium nitrate in dioxane, water, ethylene dichloride and various mixtures of ethylene dichloride and of water with dioxane; tetraisoamylammonium thiocyanate in dioxane, benzene and a mixture of benzene and ethylene dichloride; and tri-isoamylammonium picrate in ethylene dichloride, benzene and a mixture of these two solvents.

2. It is shown that, at sufficiently low concentrations, the equivalent conductance increases with dilution, even in solvents of very low dielectric constant.

3. The influence of the dielectric constant on conductance has been determined over the range from dioxane to water and it has been found that, viscosity excepted, specific influences due to the solvents are not conspicuously present.

4. The behavior of strong and weak electrolytes is compared.

The Entropy of Polyatomic Molecules and the Symmetry Number

BY JOSEPH E. MAYER, STEPHEN BRUNAUER AND MARIA GOEPPERT MAYER

Introduction

The calculation of the entropy of organic gases from molecular structure data promises considerable aid to the physical chemistry of organic compounds. Vapor pressure data and heats of vaporization are usually available and accurate estimations of the entropies of the gases may be used easily to calculate the entropies of the solid and liquid states. With heats of combustion these data can be used to calculate free energies and to estimate equilibria.

Calculations of the specific heats and entropies of diatomic molecules from spectral data have long been made, and have yielded results of great accuracy.[1]

More recently Villars and Schultze,[2] Villars,[3] Giauque and his students,[4,5] and Sterne[6] have used similar methods to calculate the entropies of some polyatomic molecules.

The method depends on the empirical fact that the energy of the single molecule may be fairly accurately accounted for as the sum of several independent terms. These terms are the translational energy, the energy due to rotation with constant moments of inertia, and the energies of one or more harmonic vibrational degrees of freedom. In the language of the quantum mechanics this condition is that the correct function necessary to represent any state of the molecule at low energies ($\epsilon/kT \sim 1$) be given to a good approximation as a product of independent functions of the various coordinates, and, further, that the potential energy be a sum of squares of the vibrational coordinates. If the above conditions hold, the entropy may be separated into additive terms due to translation, rotation, vibration, nuclear spin and to electron degeneracy. It is assumed that the lowest electron excitation has a high energy compared to kT and contributes nothing to entropy or specific heat. It is also convenient to make use of the fact that, with the possible exception of hydrogen, the moments of inertia of all actual molecules are so large that the entropy of rotation is given accurately by the classical equation at temperatures of about 200–300°K.

---

[5] MacDougall, ibid., 38, 2074 (1931).

[6] Sterne, *Phys. Rev.*, 39, 993 (1932).

The fundamental equations for the more general case are given by Giauque.[7] If the above conditions hold the molar entropy of a diatomic gas of unlike atoms may be expressed as

$$S = R\left[\ln \frac{V}{N}\left(\frac{2\pi mkT}{h^2}\right)^{3/2} e^{5/2}\left(\frac{8\pi^2IkT}{h^2}\right) e\, p_e p_n + \frac{h\nu/kT}{e^{h\nu/kT} - 1} - \ln\left(1 - e^{-h\nu/kT}\right)\right] \tag{1}$$

where R is the gas constant, V is molar volume, N is Avogadro's number, m is $m_1 + m_2$, the mass per molecule, k $= R/N$, the Boltzmann constant, h is Planck's constant, e = 2.7183, base of natural logarithms, $I = \mu r^2$ $[\mu = m_1m_2/(m_1 + m_2)]$, the moment of inertia, ν is the frequency of vibration, p_e is the degeneracy of the lowest electronic level, p_n is the degeneracy due to nuclear spin

$$p_n = (2s_1 + 1)(2s_2 + 1)$$

where s_1 and s_2 are the spins of atoms 1 and 2. We express the entropy divided by R at temperature T of the harmonic vibrator of frequency ν as

$$S_{\mathrm{Ein}}(\nu, T) = \frac{h\nu/kT}{e^{h\nu/kT} - 1} - \ln\left(1 - e^{-h\nu/kT}\right) \tag{2}$$

which, when $h\nu/kT$ is equal to about four or greater, becomes approximately

$$S_{\mathrm{Ein}}(\nu, T) \cong (h\nu/kT + 1)e^{-h\nu/kT} \tag{3}$$

Equation (1) can then be written for 1 atm. pressure

$$S = R\left[0.769 + \frac{7}{2}\ln T + \frac{3}{2}\ln W + \ln A' + \ln p_e + \ln p_n + S_{\mathrm{Ein}}(\nu, T)\right] \tag{4}$$

where W is molecular weight and $A' = I \times 10^{38}$.

The nuclear spin entropy $R \ln p_n$ may in practice be omitted. Gibson and Heitler[8] have shown that it does not alter in any reaction involving diatomic molecules, and it is usually assumed that this is also true for polyatomic molecules. The results of this paper prove that this is actually the case.

If the two atoms of the diatomic molecule are identical. or if we deal with a polyatomic molecule with two or more identical atoms, a new difficulty arises. Certain rotation states may not occur, or may occur only for molecules with a definite nuclear spin. Essentially the same problem has been handled with the methods of the classical statistics by Ehrenfest and Trkal.[9] They showed that $R \ln a$ must be subtracted from any entropy equation like the above, in which a, the symmetry number, represents the number of permutations of like atoms which can be carried out by changes in the coordinates of rotation alone (nuclear spin neglected). That is, a is the number of ways in which the molecule can be rotated and still look identical. The argument is essentially the same as that which

---

[7] Giauque, This Journal, 52,4808 (1931).

[8] Gibson and Heitler, *Z. Physik*, 49, 465 (1928).

[9] Ehrenfest and Trkal, *Proc.* Sect. *Sci. Amsterdam*, 23, 169 (1920).

justified the division of the total phase space of a gas of N identical molecules by N!, the number of permutations which left the system unchanged.

Hund[10] has discussed the quantum mechanical method by which one can determine the allowed rotational states for a molecule of definite nuclear spin type. **Elert**[11] has applied **Hund's** method to methane, and Villars and Schultze,[2] and Villars[3] have used the results of Hund and Elert to make detailed calculations of the entropies of methane and ammonia. Giauque[4] has correctly pointed out that at room temperatures the entropies of these gases must be given by the usual formulas with terms for classical rotational entropies minus R ln a.

There exists, however, no proof consistent with the formal quantum mechanical derivation of statistics which shows that such a procedure may be universally applied. This is proved here for all molecules with one a'-fold axis and a perpendicular plane of symmetry or lower symmetry. Since probably the only molecules of higher symmetry are tetrahedral (methane like), and it follows from the work of Elert that the symmetry number may be used for these, the procedure can be used generally.

In addition the quantum mechanical solution is given for a symmetric top with two rigid bodies of equal moments of inertia independently rotating about the unique axis. This probably represents the best zeroth order approximation for the ethane molecule, in which it seems likely that there is nearly free rotation about the C–C bond. The equation for the energy levels is derived. The classical entropy of rotation of a gas composed of such molecules is calculated.

The Symmetry Number

We wish first to consider a system composed of N independent similar particles, that is, a system the energy function of which has no terms containing the coordinates or momenta of more than one particle. The functions Ψ giving the state of the system may be expressed as products $\Pi_{i=1}^{i=N}\ \psi_k(i)$. $\psi_k(i)$ is then a function of the coordinates (i) (including spin) of the i'th particle, k represents the value of all of the quantum numbers of the i'th particle. For any single function Ψ_l in which k for each particle is given, we shall introduce the integers λ_k giving the number of particles in the completely defined quantum state k. There will be $N!/\Pi_k\lambda_k!$ different functions having the same values of the λ_k's obtainable from each other by carrying out all of the permutations of particles which have different values of k. All these functions will be solutions to the original differential equations which, with the spin and boundary conditions, determined our system. They will be orthogonal to each other and we will assume them to be normalized. Therefore, any linear combination of these functions will be a solution.

---

[10] Hund, *Z. Physik*, 43, 788; 43, 805 (1927).

[11] Elert, *ibid.*, 51, 6 (1928).

There is one other condition which any function expressing the state of the system must fulfil to be acceptable. If the particles contain an odd number of fundamental units, protons, electrons and probably neutrons, that is, if the particles have half integer spins, the function must be completely antisymmetric. This means that it must become multiplied by minus one by a single transposition of two particles, that is, a transposition of two identical groups of electrons and protons. If the particles contain an even number of units, have zero or integer spins, the function must be completely symmetric, it must be unchanged by a transposition. (A function antisymmetric in transpositions of electrons, protons (and neutrons) would be symmetric in the transposition of two identical groups of an even number of such units, for example, two carbon nuclei.)

There is only one linear combination of all the $N!/\Pi_k\lambda_k!$ functions having the same λ_k values which is perfectly symmetric and normalized, namely, the sum of all the functions. There is only one linear combination which is antisymmetric, the sum of all N possible permutations, the even permutations taken with positive, the odd with negative signs. This antisymmetric function will be identically zero if any λ_k is greater than 1. These two cases of symmetric and antisymmetric functions correspond to the Bose–Einstein and Fermi–Dirac statistics, respectively. In each case a single state is defined by the integers λ_k, and in the second case only values 1 or 0 are allowed.

We are interested in a molecule composed of several atoms of which a certain number may be identical. Since in this case the potential energy is not independent of the relative positions of the atoms (indeed it depends only on the relative positions), we cannot make even an approximate solution in terms of products of functions of the atomic coordinates. We can, however, transform to such coordinates that, to a good approximation, the complete function Ψ of the molecule may be expressed as a product of functions of these coordinates. These coordinates which have no interaction terms are the familiar natural coordinates of translation, rotation and the classical normal coordinates of vibration, as well as the coordinates of nuclear spin which remain untransformed.

The nuclear position coordinates and the natural coordinates must be connected by transformation equations such that the values of one set completely define all the values of the other set. We will find in general that there are several values of the relative positions of the atoms which will have identical minimum values of the potential energy. These will correspond to what will be called here different "optical isomers," according to the terminology of Hund. It is to be understood that among these optical isomers may occur members that differ only in the permutation of identical atoms and will not differ in light rotating power. These positions of minimum energy will all correspond to the same zero value of all the vibrational coordinates. It is necessary, then, to add an extra coordinate to our natural system, the value of which tells us in what optically isomeric form our system is. This coordinate i, by definition, may take only a finite number of discrete values a, b, ... n, corresponding to the n isomers. The eigenfunctions of this coordinate will be $\psi_c(i) = \delta(ci)$, $\delta(ci) = 1$ when $i = c$, $\delta(ci) = 0$ when $i \neq c$, in which c designates the Isomeric state of the molecule.

The complete function Ψ of the molecule may be expressed as a product of the type

$$\Psi = \psi\,(\text{electron}) \times \psi\,(\text{isomer}) \times \psi\,(\text{vibration}) \times \psi\,(\text{rotation}) \times \psi\,(\text{nuclear spin}) \times \psi\,(\text{translation})$$

We shall assume that the function ψ (electron) has been completely solved, and that it is symmetrical to transpositions of identical nuclei, which is usually the case with stable chemical compounds. The following argument is made simpler by this assumption, although the conclusions are independent of it. ψ (translation) depends only on the coordinates of the center of gravity which are unaffected by transpositions of like nuclei and it is therefore perfectly symmetrical. The normal coordinates of vibration may be so selected that they are either unaffected, or change sign, when two like nuclei are transposed. The lowest energy eigenfunction of a harmonic oscillator is symmetric to a change of sign of the coordinate, as are all states with even quantum numbers. In the lowest vibrational energy level ψ (vibration) is then symmetrical. As in the case of ψ (electron) the conclusions we draw will also hold for higher non-symmetric vibration states, but the language of the discussion is simplified if we deal only with the symmetrical case.

The product of the three symmetrical functions ψ (electron) $\times$ ψ (vibration) $\times$ ψ (translation) will be symmetrical and therefore the complete function ψ will have the symmetry character of the remaining product, (or linear combination of the product), ψ (isomer) $\times$ ψ (rotation) $\times$ ψ (nuclear spin). This product must be antisymmetrical to transposition of atoms with half integer spins, and symmetrical to transpositions of atoms with integer or zero spins.

The symmetry number a of a molecule is defined as the number of permutations of identical particles in the molecule which can be carried out by changes in the coordinates of rotation and spin alone.

The Unsymmetrical Molecule.--If a = 1 the rotational coordinates will be unaffected by permutations and the rotational function ψ (rotation) will be perfectly symmetrical. If the molecule contains only N like atoms there will be N isomer functions. If the molecule contains several of each of two kinds of atoms or in general more kinds of atoms, there may exist physically distinguishable (light rotating) isomers of the same potential energy. We may then arbitrarily use two coordinates, one of which defines the physically indistinguishable optical isomer resulting from permutation of the like atoms, the other defines the physically distinguishable isomeric state. The complete isomer function will then be a product of functions of each of these two coordinates. The functions of the coördinate of distinguishable isomers, which do not contain the coordinate of the like atom permutations, will be symmetric to these permutations, and may be omitted from the discussion. The number of the other isomer functions will be N!

Not only simple products of isomer and spin functions will be solutions of the problem. Linear combinations of the isomer functions multiplied by linear combinations of the spin functions will also be solutions, and any linear combinations of permutations of these products. We seek the number of such orthogonal functions which fulfil the conditions of perfect symmetry (/antisymmetry). The *exact* solution of the complete function Ψ is not a product of functions of the different coordinates, since there are actually small interaction terms. Nevertheless, the true Ψ may be determined by the method of perturbations from such a product. It will have the same symmetry character as the product, provided we use the correct zeroth order function of the many possible linear combinations which satisfy the degenerate problem. For any physical perturbation, since it must be symmetrical in identical particles, the correct linear combinations of isomer and spin functions are a complete set of representatives of all the possible symmetry characters.

Using the group theory Wigner[12] has discussed this general problem, **Hund**[13] has recapitulated the discussion and the results without the use of the group theory.

A function of N identical particles is said to belong to the symmetry character $S(\lambda_1 + \lambda_2 + \ldots + \lambda_j + \ldots + \lambda_n)$ with $\Sigma_j \lambda_j = N$ and $\lambda_j \geq \lambda_{j+1}$ if it cannot be made by permutation and linear combination symmetric in more than X_1 particles, and by permutation of the remaining $N - \lambda_1$ particles symmetric in more than λ_2 particles, etc. A *representative* of this symmetry character is symmetric in one group of λ_1 particles, and in another of λ_2 particles, etc.

Any function of symmetry character $\tau = S(\lambda_1 + \lambda_2 + \ldots + \lambda_j + \ldots + \lambda_n)$ has a degeneracy n_τ where $n_\tau = N! \, \Pi_{j>l}(\lambda_l - \lambda_j + j - l)/\Pi_j(\lambda_j + n - j)!$ If the system has no degeneracy besides that due to the identity of the particles, there are n_τ different functions of character τ each having a degeneracy n_τ making in all n_τ^2 orthogonal functions, with $\Sigma_\tau n_\tau^2 = N!$

To every symmetry character τ there corresponds another character τ^* called the reciprocal character[14] and $n_{\tau^*} = n_\tau$. The degeneracy of a

---

[12] Wigner, *Z. Physik*, 40, 492 (1926); 40, 883 (1927).

[13] Hund, *ibid.*, 43, 788 (1927); 43, 805 (1927).

[14] **The definition of the reciprocal character is given by Hund.**[13]

product of functions of character τ and τ' is $n_\tau \times n_{\tau'}$. A symmetric (/antisymmetric) function can only be formed by permutation and linear combination from the product of two functions of characters τ and τ' if $\tau' = \tau (/\tau' = \tau^*)$, and then only the fraction $1/n_\tau^2$ of all the linear combinations leads to a symmetric (/antisymmetric) function.

Spin functions are generally degenerate because there are only $2s + 1$ possible functions per particle. The number of functions of character τ is not in general n_τ and may be zero, although the degeneracy of each existing function must be n_τ.

If the molecule is composed of N identical atoms of spin s there will be $(2s + 1)^N$ spin functions, from which linear combinations may be formed that can be classified into non-combining groups of different symmetry character. The $N!$ orthogonal isomer functions may also be formed into non-combining groups of different character, n_τ^2 functions of the character τ. Only products of isomer and spin functions belonging to the same (/reciprocal) character, may by permutation and linear combination lead to functions completely symmetric (/antisymmetric) to transpositions of identical atoms. From the product of n_τ spin functions of character τ with all the n_τ^2 isomer functions of character τ $(/\tau^*)$ only the fraction $1/n_\tau^2$ or n_s completely symmetric (/antisymmetric) functions can be formed. If we sum the symmetric (/antisymmetric) products over all the different nuclear spin symmetry characters, we obtain as many functions as the total number of nuclear spin functions, $(2s + 1)^N$.

The conclusion is that a molecule of symmetry number $\sigma = 1$, composed of N identical atoms of spin s will have $(2s + 1)^N$ orthogonal functions representing $(2s + 1)^N$ degenerate states for every value of the usual quantum numbers of the molecule. To the simple entropy expression for such a molecule must be added $RN \ln (2s + 1)$, or $R \ln (2s + 1)$ nuclear spin entropy for every atom of spin s.

Had the molecule contained other unlike atoms i, j of spin s_i, s_j the preceding argument could have followed in detail for each of the $\Pi_i(2s_i + 1)$ spin states of these atoms. To the entropy should then be added $R \ln (2s_i + 1)$ for every atom of spin s_i.

Had the number of unlike atoms been greater than 3 there may have been a number I of physically distinguishable isomers and the argument would lead to an additional entropy $R \ln I$.

If the molecule contained an additional N_k identical atoms k of spin s_k a similar grouping of functions with respect to the isomers obtained by permuting the atoms k, for every one of the preceding functions, would lead to an additional $RN_k \ln (2s_k + 1)$ in the entropy.

The total nuclear spin entropy $R \ln (2s_i + 1)$ for every atom of spin s_i is the same expression as that in monatomic and diatomic gases, and as will later be shown in symmetrical polyatomic molecules. This entropy will cancel in all chemical reactions and need not be included in any practical values. The entropy due to the **I** physically distinguishable isomers, R **ln I,** will not cancel, and must always be included.

Those isomers that are not physically distinguishable, that is, the isomers corresponding to different permutations of identical atoms, occur in the complete function of the molecule in the form of linear combinations. Due to the symmetry demands of the Pauli principle no molecule can be said to be composed of only one isomeric type. On those isomers which are physically distinguishable there are no such limitations. As far as present knowledge goes we may write a molecular function which contains only one isomer. Professor G. N. Lewis has suggested to one of us that even in the exact solution the different isomer functions may not combine. This certainly appears reasonable to the prejudice of the chemist, for otherwise not only would the two states have slightly differing energies, but a gas of one isomer cooled to such a temperature that excitation in a given time had low probability, would in finite time be transformed 100% into the other isomer! The mathematical reason for this probable intrinsic degeneracy is, however, not obvious.

The Symmetric Molecule.—In order to investigate the case of a molecule a > 1, ψ (rotation) must be considered. Only molecules having no higher symmetry than a σ'-fold axis of symmetry, and with or without a plane of symmetry perpendicular to this axis will be considered. For these cases a $= 2\sigma'$ or a = a', respectively. Since probably tetrahedral molecules are the only actual cases of a > 1 not falling into these classes the case is quite general. There will be $N!/\sigma$ different isomer functions, and a rotational functions, which latter we shall show differ only by a phase factor. All such molecules will either be symmetric top types, or sufficiently close to it to allow symmetric top eigenfunctions to be used as a first approximation. Higher approximations will show the same number of states, and the same symmetry characters as the zeroth

The rotational eigenfunctions of the symmetrical top problem have been solved in the usual Eulerian angles, θ, ψ and φ.[15,16]

The form of equation here used is given by Hund. The solutions may be written

$$\psi\ \textbf{(rotation)} = \begin{cases} v_{j,m,\lambda}\left(\sin\dfrac{\theta}{2}\right) e^{\pm i(m\psi + \lambda\varphi)} \\ \\ v_{j,m,\lambda}\left(\cos\dfrac{\theta}{2}\right) e^{\pm i(m\psi - \lambda\varphi)} \end{cases} \tag{5}$$

where $j \geq m \geq 0, j \geq \lambda \geq 0$

$$v_{j,m,\lambda}\left(\sin\frac{\theta}{2}\right) = \cos^s\frac{\theta}{2}\sin^d\frac{\theta}{2}\,F\left(\frac{s+d}{2} - j, 1+s+d,\ 1+d, \sin^2\frac{\theta}{2}\right)$$

---

[15] Dennison, *Phys. Rev.*, 28, 318 (1926).

[16] Reiche, Z. *Physik*, 39, 444 (1926).

and $s = m + X$, $d = |m - \lambda|$. F is the Jacobi polynomial. The energy, if C is the moment of inertia about the unique axis and A is the moment about the other two axes, has the form

$$E = \frac{h^2}{8\pi^2}\left[\frac{1}{A}j(j+1) + \left(\frac{1}{C} - \frac{1}{A}\right)\lambda^2\right] \tag{6}$$

Of the permutations of identical atoms σ' lead only to a different phase of rotation about the axis of symmetry, the unique axis of the top, differences which in the natural coordinates correspond only to shift of the type in which φ changes to $\varphi + q2\pi/\sigma'$ where q is an integer. The only change in the complete function of the natural coordinates, without the spin coordinates, is multiplication by a complex number, (exp.)$i\lambda q2\pi/\sigma'$.

If the molecule has a plane of symmetry perpendicular to the unique axis the function is further degenerate. States differing in the substitution of cos $(\theta/2)$ for sin $(\theta/2)$ and simultaneously $-\varphi$ for φ will have identical energies even in the presence of a magnetic field, and even if the top is not perfectly symmetric. We may then rewrite and form the linear combinations

$$\psi\ (\text{rotation}) = \begin{cases} \left[v_{j,m,\lambda}\left(\sin\frac{\theta}{2}\right)e^{\pm i\lambda\varphi} + v_{j,m,\lambda}\left(\cos\frac{\theta}{2}\right)e^{\mp i\lambda\varphi}\right]e^{\pm im\psi} \\ \left[v_{j,m,\lambda}\left(\sin\frac{\theta}{2}\right)e^{\pm i\lambda\varphi} - v_{j,m,\lambda}\left(\cos\frac{\theta}{2}\right)e^{\mp i\lambda\varphi}\right]e^{\pm im\psi} \end{cases} \tag{7}$$

An end to end transformation of the unique axis corresponds to the following changes: θ to $\pi - \theta$, ψ to $\pi + \psi$, and φ to $-\varphi$. The first of the equations is multiplied by (exp.) $\pm im\pi$ by this change, the second by $-$(exp.) $\pm im\pi$, that is, since m is an integer, by ± 1 and ∓ 1.

The molecule of symmetry nhmber σ greater than one has then no longer N orthogonal products of isomer and rotation functions corresponding to the N! permutations. The permutations fall into $N!/\sigma$ groups, each containing σ permutations: the isomer times rotation functions for any of one group can be obtained from any of the other of that group by multiplication by a (complex) factor. There are only $N!/\sigma$ orthogonal functions for every value of the usual quantum numbers. The question is, can every symmetry character be formed out of these $N!/\sigma$ orthogonal functions as the quantum numbers change their values, and, if so, what will be the number of functions of the various symmetry characters?

We may write in a purely formal manner a complete set of orthogonal representatives of the symmetry characters as linear combinations of the various permutations. For each of these permutations must now be substituted the appropriate product of an isomer function and a rotational phase factor. The permutations belonging to each isomer may be grouped and the phases factored out as a sum, which, for instance, in the perfectly symmetrical case will have the form $\Sigma_{q=0}^{q=\sigma'-1}$(exp.)$i\lambda q2\pi/\sigma'$. The complete function may then be multiplied by a complex factor containing λ, such as (exp.) $-i\lambda q 2\pi/\sigma'$, if necessary, to assure that at least one of the phase factors contains 1 in the sum (in the symmetrical case the term with $q = 0$ is already 1). These functions are assuredly orthogonal and are representatives of various symmetry characters. Any one may, however, be identically equal to zero for any given value of the quantum numbers m and λ. The zero value will evidence itself by the fact that each of the phase factors, functions of m and X, will be zero. For every value of m and λ (and for each function of (7) and each j) there will be only $N!/\sigma$ functions which are other than zero.

The sum of all of the phase factors over all values of A between $a + 1$ and $a + \sigma'$ inclusive, and if the molecule contains a plane of symmetry, over an even and an odd value of m, may now be made for each function. Since at least one phase factor contains 1 the sum will not be zero because $\Sigma_{\lambda=a+1}^{\lambda=a+\sigma'}(\text{exp.})\lambda 2\pi i q/\sigma' = 0$, unless $q = 0$ or $q = \sigma'$. Every function exists at least once in these values of the quantum numbers m and A. Since the total number of orthogonal functions which can exist is a X $N!/\sigma$ $= N!$, and this is the number of all of our functions, every function exists exactly once. Over a range of σ' consecutive values of λ and two adjacent values of m the same functions exist, and the same number of them, as exist for every quantum state of a completely unsymmetric molecule.

Within the range of the quantum number λ between $a + 1$ and a + a' (and for two consecutive values of m if the molecule has a plane of symmetry) there are n_τ^2 isomer times rotation functions of character τ. We may then proceed as for the case when a $= 1$ to multiply each of these functions with the spin functions of the same (/reciprocal) symmetry character, and find $(2s + 1)^N$ completely symmetric (/antisymmetric) linear combinations of the products. We obtain for the above a rotation states just as many acceptable orthogonal normalized functions as were previously obtained for every single rotation state of the unsymmetric molecule.

The result allows us to make the following statement. For temperatures high enough that (exp.)$\delta\epsilon/kT$ is about equal to 1, where $\delta\epsilon$ is the energy difference between states having values of λ differing by a', the molar entropy of a molecule having a symmetry number a is R ln a less than the entropy of the same molecule were it entirely non-symmetrical.

It is also a corollary that every nuclear spin state exists in the same proportion as in a non-symmetrical molecule, and the entropy due to nuclear spin will be R ln $(2s + 1)$ for every atom of spin s.

The Ethane Like Top

It appears to be probable that single valence bonds show no potential energy changes in rotation. The opposite rotation of the two CH_3 groups in ethane about the C–C axis, for instance, would cause potential energy changes only due to the varying distances between hydrogen atoms. This effect cannot be very great. It seems reasonable to choose as the zeroth approximation for such a molecule the solutions for absolutely free rotation. Probably the states most numerously present in the gas at 200–300°K. will be given fairly accurately by functions obtained on the basis of this assumption. A3 model for the problem is then chosen a symmetrical top with two equal moments of inertia A about two perpendicular axes x' and y', and consisting of two similar rigid bodies of equal moments of inertia C. Each of the bodies can be independently rotated about the unique axis of the top z'. z' is then the axis of the C–C bond in ethane.

If p and q are the angular velocities about x' and y', and r_1 and r_2 the angular velocities of the bodies 1 and 2, respectively, about z', the kinetic energy will be

$$T = \frac{1}{2}\,[A(p^2 + q^2) + C(r_1^2 + r_2^2)]$$

Angles similar to the Eulerian angles are introduced. θ is the angle between the fixed z axis in space and z', + the angle between the nodal line of the xy and $x'y'$ planes and the fixed x axis, φ_1 and φ_2 the angles between the nodal line and two fixed axes in the two rigid bodies 1 and 2, respectively. Defining p_θ, p_ψ, p_{φ_1} and p_{φ_2} as the momenta conjugate to the respective coordinates, the equation for the kinetic energy may be written

$$T = \frac{1}{2}\left[\frac{p_{\theta}^2}{A} + \left(\frac{A}{C} + \cot^2\theta\right)\frac{p_{\varphi_1}^2 + p_{\varphi_2}^2}{A} + 2\cot^2\theta\,\frac{p_{\varphi_1}p_{\varphi_2}}{A} + \right.$$
$$\left.\frac{p_\psi{}^2}{\sin^2\theta\ A} \quad \frac{2\cos\theta\ p_\psi}{\sin^2\theta\ A}(\mathrm{PI} + p_{\varphi_2})\right] \qquad (8)$$

Transformation by the usual method yields the Schrodinger equation for ψ (rotation), which is here written U. The equation is

$$\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\,\frac{\partial U}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2 U}{\partial\psi^2} + \left(\frac{A}{C} + \cot^2\theta\right)\left(\frac{\partial^2 U}{\partial\varphi_1^2} + \frac{\partial^2 U}{\partial\varphi_2^2}\right) +$$
$$2\cot^*\theta\,\frac{\partial^2 U}{\partial\varphi_1\partial\varphi_2} - \frac{2\cos\theta}{\sin}\left(\frac{\partial^2 U}{\partial\varphi_1\partial\psi} + \frac{\partial^2 U}{\partial\varphi_2\partial\psi}\right) + \frac{8\pi^2 A}{h^2}EU = 0 \qquad (9)$$

when the potential energy V is set equal to zero. Using the following substitution

$$\psi(\text{rotation}) = U = \Theta(\theta)\,e^{i(\lambda_1\varphi_1 + \lambda_2\varphi_2 + m\psi)} \qquad (10)$$

one obtains the differential equation for $\Theta(\theta)$

$$\frac{\partial^2\Theta}{\partial\theta^2} + \cot^*\frac{\partial\Theta}{\partial\theta} - \frac{(m - \lambda\cos\theta)^2}{\sin^2\theta}\Theta + \left[\frac{8\pi^2 A}{h^2}E - \frac{A}{C}(\lambda_1^2 + \lambda_2^2)\right]\Theta = 0 \qquad (11)$$

in which $A = \lambda_1 + \lambda_2$, and λ_1 and λ_2 are integers. This is the same **equation** that was obtained in the solution of the simple symmetrical top problem, and yields functions such as are given in equation *(5)*.

The solution of the problem may then be written

$$\psi\ \textbf{(rotation)} = \left\{ \begin{array}{l} v_{j,m,\lambda}\left(\sin\frac{\theta}{2}\right) e^{\pm i(\lambda_1\varphi_1 + \lambda_2\varphi_2 + m\psi)} \\ \\ v_{j,m,\lambda}\left(\cos\frac{\theta}{2}\right) e^{\pm i(\lambda_1\varphi_1 + \lambda_2\varphi_2 - m\psi)} \end{array} \right. \tag{12}$$

with $j \geq \lambda = \lambda_1 + \lambda_2 \geq 0$; $j \geq m \geq 0$. The meaning of the function $v_{j,m,\lambda}$ is given under equation (5). The equation for the energy is

$$E = \frac{h^2}{8\pi^2}\left[\frac{1}{A}j(j+1) + \left(\frac{1}{C} - \frac{1}{A}\right)\lambda^2 - \frac{2\lambda_1\lambda_2}{C}\right] \tag{13}$$

Although the equation is most easily solved in the coordinates φ_1 and φ_2 it would appear natural to transform to coördinates $\varphi = (\varphi_1 + \varphi_2)/2$ and $\varphi' = (\varphi_1 - \varphi_2)/2$, the "average" angle φ, and the angular displacement φ' of one CH_3 group from this average angle The displacement of the other group is of course equal to $-\varphi'$. In all higher approximations the potential energy will depend only on φ'. The equations then become

$$\psi\ \textbf{(rotation)} = \left\{ \begin{array}{l} v_{j,m,\lambda}\left(\sin\frac{\theta}{2}\right) e^{\pm i(\lambda\varphi + m\psi + \lambda'\varphi')} \\ \\ v_{j,m,\lambda}\left(\cos\frac{\theta}{2}\right) e^{\pm i(\lambda\varphi - m\psi + \lambda'\varphi')} \end{array} \right. \tag{14}$$

with $\lambda = \lambda_1 + \lambda_2$ and $\lambda' = \lambda_1 - \lambda_2$. The quantum numbers must obey the relations $j \geq \lambda \geq 0$; $j \geq m \geq 0$; $\lambda' = \lambda \pm 2n$, where n is an integer, that is, λ and λ' are both odd, or both even. The energy expressed in terms of the new quantum numbers becomes

$$E = \frac{h^2}{8\pi^2}\left[\frac{1}{A}j(j+1) + \left(\frac{1}{2C} - \frac{1}{A}\right)\lambda^2 + \frac{(\lambda')^2}{2C}\right] \tag{15}$$

While this paper was being prepared for publication, there has appeared an article by Nielson[17] in which the ethane-like molecule is handled in a much more elaborate manner. His equations, when the potential energy of rotation within the molecule is set equal to zero, reduce to equation (14).

The entropy of a mole of such rotators may be calculated for high temperatures, in which case it becomes identical to the entropy of a mole of similar classical rotators with appropriate constants. The condition for the temperature is that $h^2/8\pi^2CkT$ and $h^2/8\pi^2AkT$ shall both be considerably smaller than 1. Actually values of about one fourth suffice for this condition. The equation for the entropy is

$$S_{\text{rotation}} = R\left[\ln 64\pi^5\left(\frac{kT}{h^2}\right)^2 AC + 2\right] \tag{16}$$

For ethane, could the two CH_3 groups not rotate separately around the C–C bond, the symmetry number would be 6; with free rotation, however, 18 permutations of the identical atoms can be carried out by changes in the angle coordinates. It is obvious further that the argument of the previous section applies as well to rotations of the angle φ' as to rotations

---

[17] Nielson, *Phys. Rev.*, 40, 445 (1932).

of φ, and that the entropy will be reduced by subtraction of R In σ, with a = 18.

The Entropy Equations

Equations (1) or (4) give the entropy of a diatomic molecule of two unlike atoms at temperatures above about 200°K. but not high enough to produce any appreciable electronic excitation. Ordinarily one can safely use the equations up to 1000°K.

A diatomic molecule of two identical atoms will have the symmetry number a = 2 and to equation (1) or (4) must be added $-\text{R} \ln \text{a} = -\text{R} \ln 2$.

A linear polyatomic molecule will have an entropy given by an equation that differs from (1) or (4) only in that there will be more terms $S_{\text{Ein}}(\nu, T)$. In a triatomic linear molecule there are four vibrational degrees of freedom and four terms $S_{\text{Ein}}(\nu, \text{T})$, two of the frequencies usually the two lowest, those due to bending, will in most cases be identical. This means that spectroscopically only one (degenerate) frequency will be found, but two entropy terms must be used for this frequency. The symmetry number may be 1 or 2.

For non-linear rigid polyatomic molecules the entropy of rotation will be greater due to the greater number of degrees of freedom. There will also be at least three frequencies of vibration. In general if there are N atoms in the molecule, one must account for $3N-6$ vibrational degrees of freedom. Some observed frequencies may be degenerate, the assignment of the number of degrees of freedom to any frequency is a problem which may be solved by mathematical[18] or by mechanical[19] means.

The equation for the entropy of a rigid non-linear polyatomic molecule is

$$S = R\left[\ln \frac{V}{N}\left(\frac{2\pi mkT}{h^2}\right)^{3/2} e^{5/2}\left(\frac{8\pi^{7/3}(ABC)^{1/3}kT}{h^2}\right)^{3/2} e^{3/2}\, p_e p_n \cdot \frac{1}{\sigma} I + \sum_{i=1}^{i=3N-6} S_{\text{Ein}}(\nu_i, T)\right] \quad (17)$$

in which **I** is the number of physically distinguishable optical isomers, and with A, B and C the three moments of inertia. The explanation of the other symbols is given under equation (1). This may be written, at 1 atm. pressure

$$S = R\left[2.307 + 4 \ln T + 3/2 \ln \text{W} + 1/2 \ln A'B'C' + \ln p_e p_n I/\sigma + \sum_{i=1}^{i=3N-6} S_{\text{Ein}}(\nu_i, T)\right] \quad (18)$$

in which $A' = \text{A} \times 10^{38}$, $B' = B \times 10^{38}$ and $C' = C \times 10^{38}$.

If two of the moments of inertia A and B are equal the molecule is a

---

[18] See for instance Mulliken, *Rev. Modern* Phys., 2, 60, 506 (1930); 3, 90 (1931).

[19] Kettering, Shutts and Andrews, *Phys. Rev.*. 36, 531 (1930).

symmetrical top and the equations (17) or (18) may still be used with this substitution.

A molecule of the ethane type will have 3N—7 vibrational degrees of freedom. The equation for the entropy may be written

$$S = R\left[\ln \frac{V}{N}\left(\frac{2\pi mkT}{h^2}\right)^{3/2} e^{5/2}\left(\frac{8\pi^{5/2}(AC)^{1/2}kT}{h^2}\right)^2 e^2\, p_e p_n \frac{1}{\sigma} I + \sum_{i=1}^{i=3N-7} S_{\mathrm{Ein}}(\nu_i, T)\right] \tag{19}$$

which reduces at 1 atm. pressure to

$$S = R\left[3.841 + 9/2 \ln T + 3/2 \ln W + \ln A'C' + \ln p_e p_n I/\sigma + \sum_{i=1}^{i=3N-7} S_{\mathrm{Ein}}(\nu_i, T)\right] \tag{20}$$

with $A' = A \times 10^{38}$, $C' = C \times 10^{38}$.

Accuracy

The accuracy with which the universal physical constants that enter the entropy equations are known is undoubtedly far greater than any practical use of the entropy demands. The molecular weight also introduces no error. The uncertainty in the use of these equations lies partly in the assumptions of their derivation and partly in the accuracy with which the moments of inertia and the frequencies are known.

The assumption that the moments of inertia in all states existing in appreciable quantities remain constant can be roughly tested by calculation of the stretching force constant from the frequencies. In most cases the average change in the moment of inertia up to 1000°K. is less than 8%, introducing about 0.1 Entropy Unit (cal. deg.^{-1}) error per rotational degree of freedom at this temperature. Failure of the vibrations to be linear harmonic probably introduces even less error. The assumption that ethane-like molecules rotate freely about the C–C bond is much more questionable. Ebert[20] and Wagner[21] have discussed the question of how "free" the rotation really is in ethane, basing their discussion largely on the specific heat measurements of Heuse[22] which were carried out in 1913–1914. The specific heat values appear to agree with those of a fully excited vibrator, rather than with the lower specific heat of a free rotator; it may be questioned, however, whether data of that date are sufficiently accurate to decide the question.

Although the calculations, if carried out for the constrained rotating oscillator, would use a = 6 and correspondingly three times as many isomer functions as here used, the phase space would be constrained to one-third of the total angle 2π, instead of the full rotational angle, and the

entropy based on such an assumption would approach, with decreasing potential energy, that of the free rotator of equation (20). We believe that for ethane itself, at least, the entropy will be given fairly well by equation (20). More accurate measurements of the specific heat and entropy appear to be the only experimental method of decision.

The moments of inertia of some molecules can be obtained from spectroscopic data. Usually no values so obtained are available, but the spacing of the atoms can frequently be accurately estimated from x-ray data for the molecule in question or for some similar compound. With the usual assumptions for the geometrical structure these data probably allow calculations of the moments of inertia for the simpler organic compounds to within at least 10%, introducing 0.1 Entropy Unit error per rotational degree of freedom. The total entropy of one vibrational degree of freedom with frequency 200 cm.^{-1} at 300°K. is 2.16 E. U., and for 1100 cm.^{-1} at 300°K. it is only 0.03 E. U. An error of 10% in the value of the frequency introduces an error of 0.2 E. U. in the first case and no appreciable error in the second. Much more important is the correct assignment to each frequency of the number of degrees of freedom, and the certainty with which one can assume that all frequencies are known. Much progress has been made in the interpretation of the lower, and less numerous, frequencies[19] which are due to the mutual vibrations of the heavier atoms. In many cases one can feel quite confident that the interpretation is correct. Fortunately the less certain frequencies due to the motion of the hydrogen atoms appear to be all above 1100 cm.^{-1} and introduce less than 0.03 E. U. at 300°K. per degree of freedom

It appears not unreasonable to expect that we can calculate the entropies of many of the simpler organic compounds to within 0.5 cal. deg.^{-1}. This would introduce barely 30% error in an equilibrium constant prediction.

The Entropy of Some Simple Molecules

Ethane.—The moment of inertia C of the CH_3 group about the C–C bond will be equal to the moment of inertia of methane, if the tetrahedral angle for the hydrogen bonds is approximately maintained in ethane. The moment of inertia of methane is known from its band spectra.[23] x-Ray data show that the C–C distance in aliphatic hydrocarbons has a constant value, and this with the C–H distance calculated from the moment of inertia of methane gives the other moment A of the ethane molecule

The Raman line at 990 cm.^{-1} is undoubtedly due to the mutual vibration of the two methyl groups, and will have one degree of freedom. The assignment of the other frequencies, 4 at 1200 cm.^{-1} and 6 at 1460 cm.^{-1} both due to hydrogen "bending" is pure guess, especially since no line at 1200 is observed, but the total entropy which these contribute is so low (0.2 E. U.) that the assignment is unimportant.

---

[23] Moorhead, *Phys. Rev.*, 39, 83 (1932).

The following constants are then used for ethane in equation (20) to calculate the entropy at 1 atm. pressure, 298°K.: W = 30; C' = moment of inertia of methane, $C \times 10^{38} = 0.0517$; A', calculated from C–C distance 1.55 Å. and C–H distance 1.08 Å., is 0.417; $h = 2^6 = 64$; $p_e = 1$; $\sigma = 18$; ν_1, 1 degree of freedom 990 cm.$^{-1}$; ν_2, 4 degrees of freedom 1200 cm.$^{-1}$; ν_3, 6 degrees of freedom 1460 cm.$^{-1}$; total vibrational entropy at 298°K. = 0.26 E. U. For ethane gas, 298°K., 1 atm., the total absolute molar entropy $S = 63.8$ cal. deg.$^{-1}$, of which R ln 64 = 8.3 due to nuclear spin may be neglected, leaving for the practical entropy $S_p = 55.5$.

Acetylene.—A band in the infra-red spectrum of acetylene[24] at 730 cm.$^{-1}$ may possibly contribute 4 degrees of freedom and 0.5 E. U. at 298°K. It seems more probable that this band is not a fundamental and that the lowest fundamental, contributing 4 degrees of freedom due to hydrogen "bending," is at 1330 cm.$^{-1}$. The following entropy may be as much as 0.5 E. U. too low because of this assumption The constants used in equation (4) with 4 of the total 7 frequencies contributing an appreciable entropy are: W = 26; $A' = 0.23$;[25] $p_e = 1$; $p_n = 2^2 = 4$; a = 2; ν_1, 4 degrees of freedom, 1330 cm.$^{-1}$ contributing 0.1 E. U. at 298°K. For acetylene gas, 1 atm., 298°K. the total absolute entropy, $S = 49.9$ cal. deg.$^{-1}$, of which 2.7 E. U. are due to nuclear spin, leaving a practical entropy $S_p = 47.2$ E. U.

Benzene.—Andrews[19] has obtained excellent agreement between the Raman lines of benzene and his models, which enables us to assign the number of degrees of freedom to the frequencies with considerable certainty. x-Ray data on hexamethylbenzene and graphite,[26] and electron diffraction data on gaseous benzene,[27] allow us to estimate the C–C distance accurately. The C–H distance, which is unimportant in the moments of inertia, is assumed to be that of methane. The following constants are substituted in equation (18): W = 78; $A' = B'$, calculated from C–C = 1.42 Å. and C–H = 1.08 Å., is 1.508; $C' = 3.016$; $p_e = 1$; $p_n = 64$; $\sigma = 6$

ν_1, 2 degrees of freedom = 360 cm.$^{-1}$
ν_2, 1 degree of freedom = 605 cm.$^{-1}$
ν_3, 2 degrees of freedom = 805 cm.$^{-1}$
ν_4, 6 degrees of freedom = 990 cm.$^{-1}$
ν_5, 1 degree of freedom = 1170 cm.$^{-1}$
ν_6, 12 degrees of freedom = 1590 cm.$^{-1}$

other frequencies too high to contribute to the entropy. The total vibrational entropy at 298°K. is 3.8 E. U. For benzene gas, 1 atm., 298°K., the total absolute entropy $S = 73.4$ cal. deg.$^{-1}$, of which R ln 64 = 8.3

[24] Levin and Meyer, J. Opt. *Soc.* Am., 16, 137 (1928).

[25] From infra-red measurements.[24]

[26] Ewald and Hermann, "Strukturbericht," 1913–1928.

[27] Wierl, Ann. *Physik*, 8, 521 (1931).

E. U. are due to nuclear spin, leaving a practical entropy, S_p = 65.1 cal. deg.$^{-1}$.

The experimental entropy of the liquid at 298°K. is 41.9 E. U. and the entropy[28] of vaporization at the equilibrium vapor pressure at this temperature, 94 mm., is 27.5 E. U. To the sum of these must be added −4.3 E. U. to convert to 1 atm., making the experimental entropy of benzene gas at 1 atm., 298°K., 65.1 E. U.

The value of a = 6 for benzene was calculated by Deitz[29] from measurements of the vapor pressure. The less structure sensitive methods of x-ray and electron diffraction have hitherto always indicated plane structure for the carbon atoms, which would lead one to assume a = 12. An undetected transition in the solid state of benzene below the lowest temperatures of the specific heat determinations could only lead to a lower value of a. The excellent constancy of the a as calculated by Mr. Deitz over a wide range of temperatures (from 100°K. to 298°K. a varied from 5.4 to 6.9) indicates, we believe, conclusively, that all twelve atoms of benzene do not lie in one plane.

Summary

It has been shown that any molecule will have among the additive terms in the entropy expression: $-R$ ln a, with a the symmetry number; R $\ln(2s_i + 1)$ for every atom i of spin s_i; R ln I, with I the number of distinguishable optical isomers present in the gas.

The quantum mechanical wave functions and the energy values of an ethane-like molecule have been calculated under the assumption of free independent rotation of the two CH_3 groups about the C–C bond. The entropy of this type of molecule has also been calculated.

Convenient expressions have been given for the molal entropy of diatomic, rigid linear and non-linear polyatomic, and ethane-like molecules.

The data necessary for the entropy evaluations have been reviewed, and the accuracy which can be expected has been briefly discussed. It appears probable that for many of the simpler organic gases the entropy can be calculated with present data to within 0.5 E. U. (cal deg.$^{-1}$).

The practical molar entropies (neglecting nuclear spin which cancels in all chemical reactions), of ethane, acetylene and benzene gases at 1 atm., 298°K., have been calculated to be 55.5, 47.2 and 65.1 E. U., respectively.

Line Spectrum of Samarium Ion in Crystals and its Variation with the Temperature

BY SIMON FREED AND J. G. HARWELL

The magnetic behavior of Sm^{+++}[1] and the absorption spectra[2] showed that there was an equilibrium distribution of the ions between different electronic configurations. The present work was instituted with the view of obtaining quantitative data concerning the differences in energy between the various configurations. These differences may be looked upon as originating through the action of the electric fields about Sm^{+++} in the lattice. They are a measure of their symmetry and intensity. Recently, Miss Amelia Frank[3] obtained rough agreement with the magnetic susceptibility at higher temperatures by taking into account the presence of the activated state $^6H_{7/2}$, presumably about 1000 cm.$^{-1}$ higher in energy than the basic state $^6H_{5/2}$. The agreement is rather surprising since both the basic state, $^6H_{5/2}$ and active state, $^6H_{7/2}$ are largely decomposed into sublevels of wide separation by the electric fields of the lattice. The specific heat of Sm^{+++}[4] at low temperature has given a measure of the separations between the basic electronic levels. It appeared that energy of about 160 cm.$^{-1}$ (450 cal./mole) had to be supplied to activate a mole of Sm^{+++} in the sulfate. Even greater intervals may have resulted in the decomposition of the $^6H_{5/2}$ term, but they must be so great that relatively few ions exist in the upper level.

The present work is mainly concerned with the effect of the electric fields upon the state $^6H_{5/2}$, that is, with levels which are sufficiently occupied at ordinary temperatures to have their presence recorded in the absorption spectrum. They are identified by the change in the relative intensity of the lines as the temperature changes, more especially by those instances when a line increases in intensity apparently at the expense of a neighboring line. When this line is of higher frequency than the one whose intensity is decreasing, there is considerable probability that the lines arise at two levels slightly different in energy and end in a common energy level. And the recurrence of the same interval in different regions of the spectrum practically establishes the existence and separation of the lower energy levels.

The experimental method has been described[6] in another connection. A hydrogen discharge tube served as the source of the continuous radiation

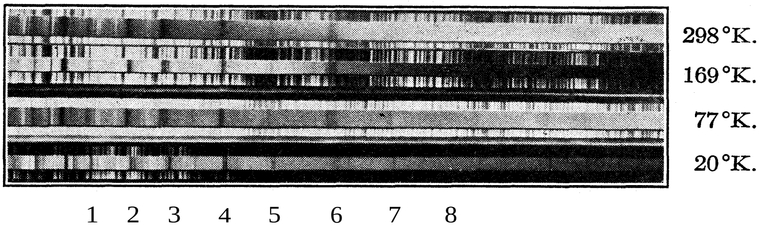
and the spectra extended from 4200 to about 2200 Å. A Hilger spectrograph of the type E2 was employed. The radiation was passed parallel to the optic axis of the hexagonal crystal[6] $Sm(C_2H_5SO_4)_3 \cdot 9H_2O$ which was about 0.5 mm. thick. For the purpose of lowering the temperature of the crystal, liquid hydrogen (20°K.), liquid nitrogen (77°K.), and liquid ethylene (169°K.) were used, all boiling at atmospheric pressure. The average absolute error in the measurement of the lines is about 5 cm.$^{-1}$. Some of the lines were faint or diffuse and there has been listed next to each line in the table the number of times it was measured and the reproducibility of the measurement. The recorded intensities are visual estimates and should be trusted only as a measure of relative intensity within a restricted region of the spectrum and in spectra originating at the same temperature.



Absorption spectrum of Sm^{+++} in $Sm(C_2H_5SO_4)_3 \cdot 9H_2O$.

The group of lines assigned to energy levels have undergone such changes in intensity that the increase or decrease in intensity of one line with respect to another could be told at a glance on an enlargement of the spectrogram.

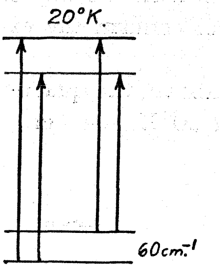
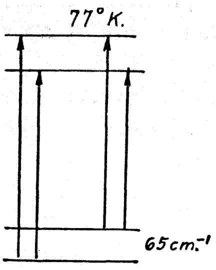
For convenience, the groups have been numbered on the reproductions of the spectra. Below each diagram is given a list of the frequencies derived from the energy levels and these are compared with the observed frequencies for each group of lines. All the deviations are well within the errors of measurement. Groups 4, 7, 8 and 10 under low dispersion appear as doublets having the same energy difference at each temperature. Under higher dispersion, each line is found to be doubled and with the data in hand it is impossible to prove rigorously whether the "fine-structure" energy level belongs to the basic term system or not. More data, we are informed, will be available soon in a more extensive paper by Spedding and Bear from Berkeley? If the "fine-structure" level is assigned to the basic multiplet, it becomes possible to include the quartet 5 and also the sextet: *3* and 6. This arrangement of levels has a considerable degree of probability and by its aid all the multiplets in which marked intensity changes occur can be interrelated.

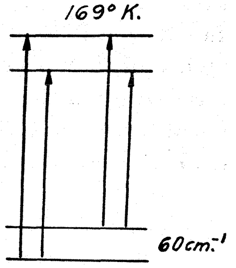
---

[7] Spedding and Bear, *Phys. Rev.*, in press.

Below is a typical example of an energy level pattern which the quartets 4, 7, 8 and 10 accord with and also the basic separations which are valid for all of them. The intensities too agree with these assignments.







Group	Temp., °K.	Separation of upper level, cm.⁻¹	Calcd. line, cm.⁻¹	Observed line, cm.⁻¹	Deviation. cm.⁻¹
4	20	12		29,008 **(accepted)**	
			28,996	28,996 ± 3	0
			28,948	28,949 ± 1	1
			28,936	28,936 ± 1	0
	77	12		29,010 **(accepted)**	
			28,998	28,996 ± ?	2
			28,945	28,945 ± 3	0
			28,933	28,936 ± ?	3
	169			29,016 **(accepted)**	
			28,956	28,955 ± 0	1
7	20	12		32,721 **(accepted)**	
			32,708 **too faint**		
	77			32,723 ± 1 **(accepted)**	
			32,658	32,655 ± 2	3
	169			32,728 ± 1 **(accepted)**	
			32,668	32,666 ± 1	2
8	20	23		35,857 **(accepted)**	
			35,834	35,834	
	77	12		35,846 ± 2 **(accepted)**	
			35,834	35,833 ± 0	1
			35,781	35,777 ± 3	4
	169			35,838 ± 0	
			35,778	35,777 ± 0	1
10	20			42,321 ± **(accepted)**	
			42,261	42,260 ± 2	1
	77			42,319 ± 1 **(accepted)**	
			42.254	42,251 ± 1	3

Some of the lines which one would normally expect from these levels were too faint to be measured. At higher temperatures, some of the lines were so diffuse that the average between two unresolved lines is given.

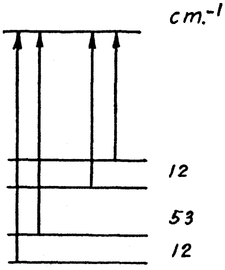
There can be no doubt concerning the existence of an interval of 60 cm.$^{-1}$ (at 20°K., 65 cm.$^{-1}$ at 77°K. and 60 cm.$^{-1}$ at 169°K.) between two energy levels in the basic multiplet. Also, there is little doubt but that this interval can be related to the influence of the electric fields of the lattice upon $^6H_{5/2}$. It may be predicted at this point that a close study of the specific heat measurements at low temperatures will confirm the existence of this interval.

Based upon the same pattern of levels as those given above, the quartet 5 will have the following basic intervals: 60 cm.$^{-1}$ at 20°K., 54 cm.$^{-1}$ at 77°K. and 43 cm.$^{-1}$ at 169°K.

Group	Temp., °K.	Calcd. line, cm.$^{-1}$	Obs. line, cm.$^{-1}$	Deviation
5	20		30,115 ± 2 *(accepted)*	
		30,130	30,133 ± ?	3
		30,070	30,071 ± 2	1
		30,055	30,058 ± 1	3
	77		30,121 ± 2 *(accepted)*	0
		30,007	30,067 ± 1	
	169		30,118 ± 1	
		30,075	30,072 ± 2	3

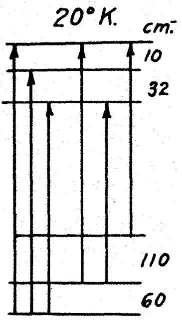
Now it is clear that if the 12 cm.$^{-1}$ interval (the "fine-structure" interval) is inserted in the basic multiplet of *4*, 7, *8*, 10, the group 5 fits into the same scheme as groups *4*, *7*, *8*, *10* and we shall see later the sextets *3* and 6 will also be associated with the same levels. As an example we shall give the energy levels of group *4* and *5* at 77°K., employing the same basic multiplet for both.

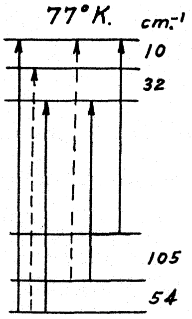
Quartets 4 and 5
77° K.

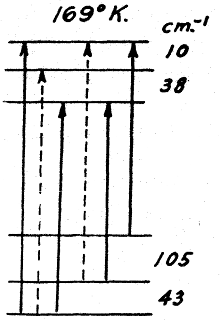


The fact that the "fine structure" interval is of the same magnitude in all groups (with the possible exception of *8*) is evidence for including it in the basic multiplet. Its inclusion results naturally in any attempt to superpose the levels of the groups for the purpose of obtaining all the components into which $^6H_{5/2}$ has been split. It must be stated again that more data are necessary for this purpose, especially spectra at the temperature of liquid helium.

Since the spectrum of Sm^{+++} consists of rather isolated groups, one would expect the lines to originate and end at neighboring levels. The intensities justify this point of view as the components of greater frequency always become more intense as the temperature is reduced. The sextets *3* and 6 contain the same energy interval as the quartet *5* and the intensities of corresponding lines behave in the same way with regard to temperature. We shall therefore associate *3* and 6 with the same basic states as 5. Below is the energy level pattern of *3* based upon that of 5.







Temp., °K.	Calcd. line, cm.$^{-1}$	Obs. line, cm.$^{-1}$	Deviation, cm.$^{-1}$
20		27,639 ± 1 (accepted)	
	27,629	27,629 ± 1	0
	27,597	27,597 ± 0	0
	27,579	27,585 ± 6	6
	27,537	27,537 ± 0	0
	27,469	27,469 ± 1	0
77		27,637 ± 1 (accepted)	
	27,595	27,595 ± 2	0
	27,543	27,540 ± 1	1
	27,478	27,478 ± 1	0
169		27,639 ± 0	
	27,591	27,591 ± 1	0
	27,548	27,549 ± 0	0
	27,491	27,491 ± 0	0

The sextet 6 follows a similar pattern, its first interval being identical at each temperature with that of *3* but the over-all separation of the basic multiplet is slightly different. This difference can probably be ascribed to another "fine structure" interval in the basic term system.

The lines which have been studied here because of the variation in their intensities constitute about one-half the prominent lines of the spectrum.

A part of this experimental work was done by one of us (S. F.) during his stay in the laboratory of Professor de Haas, Leyden, Holland, while he was a fellow of the John Simon Guggenheim Memorial Foundation.

Summary

The absorption spectra of Sm^{+++} in the hexagonal crystal $Sm(C_2H_5SO_4)_3\cdot 9H_2O$ were taken parallel to the optic axis at 20, 77 and 169°K. Absorption lines are listed in the region of the spectrum between 4200 Å. and 2200 A.

This paper is principally concerned with the various electronic configurations in the basic multiplet, especially as they result from the interaction of Sm^{+++} and the electric fields of the lattice. In consequence, all the lines whose relative intensities vary with the temperature have been studied in terms of energy level diagrams.

The Photodissociation of Hydrogen Peroxide in the Presence of Hydrogen and Carbon Monoxide and the Recombination of OH Radicals

BY GUENTHER VON ELBE[1]

The ultraviolet absorption spectrum of hydrogen peroxide in the gas phase has been determined by Urey, Dawsey and Rice.[2] The authors conclude that for every absorbed light quantum two hydroxyl radicals are formed according to the equation

$$H_2O_2 + h\nu = 2OH \qquad (1)$$

Hydroxyl radicals are also involved in Bonhoeffer and Haber's scheme of the hydrogen and carbon monoxide combustion[a]

$$H + O_2 + H_2 = H_2O + OH \qquad (2)$$

$$OH + H_2 = H_2O + H \qquad (3)$$

$$\text{or } OH + CO = CO_2 + H, \qquad (4)$$

This scheme has been discussed by Frankenburger and Klinkhardt[4] who carried out experiments on the action of photochemically generated hydrogen atoms in hydrogen and oxygen mixtures. They propose that reaction (2) should be followed either by (3) or by

$$OH + OH + M = H_2O_2 + M \qquad (5)$$

and that reaction (3) should require an activation energy of not less than 14,000 cal. An activation energy of that order would keep the rate of (3) sufficiently small until about 400° to make (5) the predominant reaction. The formation of chains would thus be prevented until about that temperature, which is consistent with the observed behavior of hydrogen–oxygen mixtures.

In the present work, mixtures of hydrogen peroxide vapor with hydrogen or carbon monoxide were exposed to the light of a condensed zinc spark. A small but distinct reaction was observed in both cases, suggesting the occurrence of reaction (1) and (3) or (1) and (4). In view of Frankenburger and Klinkhardt's work, most of these experiments were made with hydrogen. If OH was formed, according to (1), these experiments should allow one to test the reaction scheme proposed by these authors. In the

first place, the observed rates of hydrogen consumption should correspond to an activation energy of not less than 14,000 cal. This is indeed the case,[5] but this fact alone is not sufficient for the test. The purpose may be achieved by varying the experimental conditions which influence the rate of hydrogen consumption. If the reaction scheme is right, one should be able to predict changes of this rate. If the observed changes do not check with those theoretically predicted within a reasonable limit, the scheme certainly would appear rather doubtful.

Experiments and Results

The apparatus consisted of a closed flow system filled with either hydrogen or carbon monoxide. The details will appear from the figure. The small bubbler within the thermostat contained a 95% hydrogen peroxide solution which was prepared as in the method of Rice, Reiff and Kilpatrick.[6] The liquid was sufficiently shielded against direct or stray radiation from the zinc spark. Oxygen within the system could be removed by passing the gas flow through a pyrogallol solution.

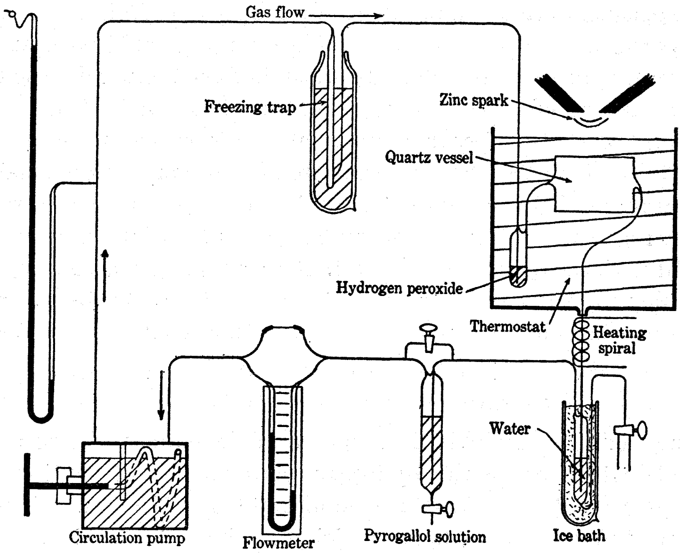

Fig. 1.—Apparatus for measuring photochemical reactions of hydrogen peroxide in the gas phase.

The data obtained are given in Table I. The first column shows the time for which the mixtures were exposed to ultraviolet light. The next three columns give the actual pressure changes effected by illumination. In some experiments, the oxygen was allowed to accumulate and afterward removed by pyrogallol. The fifth column contains the partial pressure of hydrogen peroxide in the mixture. It is calculated from the amount of hydrogen peroxide evaporated and the volume of hydrogen passing in a

(6) Rice, Reiff and Kilpatrick, *ibid.*, 48,3019 (1926).

given time. The latter is given in the next column. The hydrogen peroxide was caught in a water trap, except for the small amount which was used in the reaction. This amount was so small, indeed, that it did not appreciably change the hydrogen peroxide partial pressure. At the end of the run the contents of the ice water trap were removed and titrated with 0.1 *N* potassium permanganate. The seventh column shows the temperature of the thermostat. The last two columns show the number of hydrogen molecules disappearing and oxygen molecules formed during the illumination per sec. per cc. Since the reaction took place in the quartz vessel only, these last values were obtained by dividing the total number of molecules disappearing or formed per second by the volume of the quartz vessel which was 86 cc. The total amount of hydrogen and oxygen disappearing per sec. was obtained from the observed rate of pressure change, as given by the first four columns, the temperature and the total volume of the apparatus, namely, 218 cc.

The experiments can roughly be divided into two groups: those at 40° and a hydrogen peroxide pressure of 4 to 5 mm., and those at 28° and about 2 mm. hydrogen peroxide. It was not advisable to raise the temperature much above 40°, because the decomposition of hydrogen peroxide in the liquid phase then became appreciable. It was also not advisable to go lower than about 28°, because the rate of reaction was too small.

The number of light quanta entering the vessel per sec. was estimated in the following way. Mixtures of hydrogen and hydrogen bromide were passed through the quartz vessel, while the zinc spark was running, and the free bromine formed was measured. According to E. Warburg, for each hv absorbed one bromine is formed.[7] The results are shown as follows

H Br partial pressure (mm. Hg)	52	98	118
$h\nu$ absorbed per sec. $\times 10^{-16}$	4.4	4.7	5.2

For the hydrogen bromide decomposition the same two line groups are responsible which cause the hydrogen peroxide decomposition, namely, the groups around 2070 Å. and around 2530 Å. However, they are absorbed at different percentages which can be calculated for hydrogen bromide from Warburg's data, and for hydrogen peroxide vapor from the work of Urey, Dawsey and Rice,[2] the length of the light path being, in the present case, 5 cm. In the above table, the apparent depending of the number of *hv* absorbed upon the hydrogen peroxide pressure may be attributed to changing absorption in the 2530 group. A calculation on this basis shows that the number of light quanta entering the vessel per sec. is 3.2×10^{16} in the 2070 group, and 2.4×10^{16} in the 2530 group. If the vessel is filled with hydrogen peroxide vapor at 5 mm., the first group will be absorbed to 26%, the other to 7%. The total absorption will amount to 1.0×10^{16} hv per sec. This yields 23×10^{13} OH radicals per sec. per cc.

Discussion

As mentioned before. reactions **(3)** and **(5)** provide a scheme for the reactions subsequent to the OH formation. If this scheme is true the disappearance of hydrogen would then be accounted for by (3), while a certain excess of OH should disappear unnoticed according to (5). The formation of oxygen requires some special consideration. One might consider the reactions

$$OH + OH = H_2O + O \qquad (6)$$
$$H_2O_2 + O = H_2O + O_2 \qquad (7)$$
$$O + O + M = O_2 + M \qquad (8)$$

of which **(6)** has been proposed by Bonhoeffer and Pearson.[8] This reaction **(6)** cannot be applied to the present experiment without interfering with Frankenburger and Klinkhardt's scheme. No way is left in their scheme for an appreciable consumption of OH according to (6), which means that collisions of OH among themselves must be largely ineffective, so ineffective that three-body collisions according to *(5)* dominate. This is perfectly consistent with the experimental facts of Bonhoeffer and Pearson.[5] Also in the present experiments reaction **(6)** cannot play a role if Frankenburger and Klinkhardt's scheme is true, because the hydrogen concentration and temperature were about the same as in their experiments and the relation between the number of two-body and three-body collisions must be the same as in their experiments.

Another reaction in which oxygen may be formed is

$$OH + OH + H_2O_2 = 2H_2O + O_2 \qquad (9)$$

But this reaction, however plausible, would not fit in the scheme either, because three-body collisions would occur much more frequently with hydrogen molecules than with hydrogen peroxide molecules since the concentration of the former is higher by the order of 10^2. Thus, reaction **(5)** would suppress reaction (9) completely.

As far as the author can see, **all** oxygen forming reactions are now disposed of[9] save those in which OH remains unaffected as, for example

$$OH + H_2O_2 = H_2O + O + OH \qquad (10)$$

This reaction, which would be analogous to the conversion of para to normal hydrogen by hydrogen atoms, would be endothermic, but there is an excess of energy of the dissociating light quanta, forming rather "hot" OH radicals. Another possibility might be

$$OH + H_2O_2 + H_2O_2 = 2H_2O + O_2 + OH \qquad (11)$$

The point is that by applying the Frankenburger–Klinkhardt scheme the oxygen formation in the present experiments must be considered as due to a kind of catalytic decomposition of hydrogen peroxide and not involving the disappearance of OH radicals. If the Frankenburger–Klinkhardt scheme holds, these radicals can only disappear according to **(3)** and **(5).**

---

(8) Bonhoeffer and Pearson, *Z. physik. Chem.*, **14B**, 1 (1931).

(9) Compare the discussion of this subject in Bonhoeffer and Pearson's paper.

The rate of OH formation according to (1) per sec. per cc. can be symbolized by $+\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(1)}$, of OH disappearance according to (3) and (5) by $-\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(3)}$ and $-\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(5)}$. Then for the stationary state

$$\frac{+\,\mathrm{d}[\mathrm{OH}]}{\mathrm{d}t}_{(1)} = \frac{-\,\mathrm{d}[\mathrm{OH}]}{\mathrm{d}t}_{(3)} + \frac{-\,\mathrm{d}[\mathrm{OH}]}{\mathrm{d}t}_{(a)} \qquad (12)$$

$+\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(1)}$ equals twice the amount of $h\nu$ absorbed per sec. per cc. and is, therefore, determined by the hydrogen peroxide concentration and the light intensity. $-\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(3)}$ equals the number of hydrogen molecules disappearing per sec. per cc., or the number of successful binary collisions $\mathrm{OH} + \mathrm{H}_2$, given by the equation

$$\frac{-\,\mathrm{d}[\mathrm{OH}]}{\mathrm{d}t} = Ze^{-Q/RT} = 2N_{\mathrm{H}_2}\, N_{\mathrm{OH}}\, \sigma_{1,2}^2 \sqrt{2\pi RT\,\frac{M_1 + M_2}{M_1\,.\,M_2}} \qquad (13)$$

N_{H_2} = number of H_2 per cc. = 22.1×10^{18} for $p_{\mathrm{H}_2} = 71$ cm., $t = 40$°C.
N_{OH} = number of OH per cc.
$\sigma_{1,2} = 2.3 \times 10^{-8}$ [4]
$R = 8.313 \times 10^7$

$-\mathrm{d}[\mathrm{OH}]/\mathrm{d}t_{(5)}$, the rate of recombination of OH to hydrogen peroxide, cannot be observed directly. It equals the number of ternary collisions (5) per sec. per cc., and is estimated by Frankenburger and Klinkhardt in the usual way (for atmospheric pressure) as 10^{-4} times the number of binary collisions $\mathrm{OH} + \mathrm{OH}$. The value is $2.77 \times 10^{-15}\, N_{\mathrm{OH}}^2$ binary collisions per sec. per cc. This (their) value can, therefore, be used here because the hydrogen concentration is about the same and the temperature dependency so small as to be negligible in this rough calculation.

For the following calculations an accuracy of a factor ten is quite sufficient for this value of the number of ternary collisions.

Equation (12) becomes

$$\frac{+\,\mathrm{d}[\mathrm{OH}]}{\mathrm{d}t} = 7 \times 10^9\, e^{-Q/RT}\, N_{\mathrm{OH}} + 2.77 \times 10^{-15}\, N_{\mathrm{OH}}^2 \qquad (14)$$

and

$$7 \times 10^9\, e^{-Q/RT}\, N_{\mathrm{OH}} = -\,\mathrm{d}[\mathrm{H}_2]/\mathrm{d}t \qquad (15)$$

Taking experiment No. 9 as a specific example and assuming that 23×10^{13} OH are formed per sec. per cc., one obtains from (14)

$$23 \times 10^{13} = 7 \times 10^9\, e^{-Q/313\,R}\, N_{\mathrm{OH}} + 2 \times 2.77 \times 10^{-15}\, N_{\mathrm{OH}}^2$$

and from (15)

$$7 \times 10^9\, e^{-Q/313\,R}\, N_{\mathrm{OH}} = 6.8 \times 10^{13}$$

After elimination of N_{OH}, Q turns out to be 14,780 cal.

Now, if in experiment No. 9, the partial pressure of hydrogen peroxide were 2 mm. instead of 5.1 mm., the light absorption would be only 4.5×10^{13} $h\nu$ per sec. per cc. corresponding to 9×10^{13} OH formed per sec. per cc. If at the same time a temperature of 28° is assumed, instead of 40.5°, equations (14) and (15) change to

$$9 \times 10^{13} = 6.9 \times 10^9\, e^{-14{,}780/301\,R}\, N_{\mathrm{OH}} + 2 \times 2.77 \times 10^{-15}\, N_{\mathrm{HO}}^2$$

and

$$6.9 \times 10^9 e^{-14,780/301\,R} N_{OH} = -\,d[H_2]/dt$$

After elimination of N_{OH} and employing the value of Q derived above one obtains for the number of hydrogen molecules disappearing per sec. per cc. the value 1.87 X 10^{13}.

This value, which should be right for 28° and 2 mm. water pressure, is less than one-third of the value 6.8 × 10^{13} found experimentally for 40° and 5.1 mm. hydrogen peroxide pressure. This large difference holds not only for the above specific example but for all corresponding experiments in Table I. Furthermore, the result is only slightly dependent on assumptions concerning the three-body collision frequency and on errors in the assumed rate of OH formation. The three-body collision frequency might be wrong even by a factor ten without an appreciable change in the above result. The rate of OH formation might have been overestimated, but even if in the above example a value of 7.7 × 10^{13} instead of 23 X 10^{13} is taken—which would just be reconcilable with a value of 14,000 cal. for *Q*—the hydrogen consumption would be altered only to 2.5 X 10^{13} molecules per sec. per cc. It appears, therefore, that for the present experiments, if a change of the hydrogen peroxide pressure from 5 mm. to 2 mm. and of the temperature from 40 to 28° is made, the rate of hydrogen disappearance should decrease to one-third or less, if the proposed reaction scheme holds. This is obviously not in agreement with the facts. The above specific example, experiment No. 9, may properly be compared with experiment No. 13, because they were run one immediately after the other, thus, ensuring similar conditions. In No. 13 a rate of 4.2 X 10^{13} hydrogen disappearing was found, which corresponds to a decrease to two-thirds rather than one-third of the rate of No. 9. But besides this specific case, the decrease in the rate generally in all the experiments corresponds to certainly not more than a half, the mean value in group one being 7.2 X 10^{13} H_2 per cc. per sec. and in group two 3.6 × 10^{13} H_2 per cc. per sec.

From the above it can be concluded that the scheme consisting of reactions (1), (3) and (5) should be discarded. In the opinion of the author, the experiments and calculations are sufficiently accurate to justify this statement. On the other hand, it seems to be difficult to ascertain what has to be eliminated.

From the work of Urey, Dawsey and Rice it seems to be fairly well established that $H_2O_2 + h\nu = 2OH$. If this cannot be disputed, objections may be raised only against the occurrence of reaction (3) and (5). The reaction (3), ($OH + H_2 = H_2O + H$), however, seems to be most plausible for explaining the actually observed disappearance of hydrogen. It seems, therefore, that the reaction which is most probably at fault is reaction (5), $OH + OH + H_2 = H_2O_2 + H_2$. However, no other facts are published in the literature which might lead to objections against reaction *(5)* except this process of elimination. As already pointed out by von Elbe and Lewis[5] the paper of Bonhoeffer and Pearson does not contain any experimental material contradictory to Frankenburger and Klinkhardt's conclusions.

With reaction (5) discarded, an explanation for the formation of hydrogen peroxide is still to be sought. Marshall[10] some time ago proposed the intermediate formation of HO_2. While there is no experimental evidence for this, there is certainly no evidence against it.

In the present experiments the following scheme can be proposed

$$H_2O_2 + h\nu = 2OH \qquad (1)$$
$$OH + H_2 = H_2O + H \qquad (3)$$
$$OH + OH + H_2O_2 = 2H_2O + O_2 \qquad (9)$$

Perhaps this is a plausible scheme, as a rough calculation indicates. If for ternary collisions (9) a similar expression is used as for ternary collisions (5) previously, it follows that Q for reaction **(3)** equals 16,000–17,000 cal., and that the rates of hydrogen consumption and oxygen formation in both groups of experiments change by about one-half. It is hoped, however, that further experiments will allow more definite conclusions to be drawn on the subject.

Summary

3. Mixtures of hydrogen peroxide vapor and hydrogen or carbon monoxide were exposed to the light of a zinc spark. The kinetics of the reaction between the assumed product of dissociation—namely, OH—and hydrogen or carbon monoxide was studied at different partial pressures and temperatures.

2. The results do not sustain the reaction scheme of Frankenburger and Klinkhardt involving the recombination of two OH to hydrogen peroxide. However, there are no facts available which disturb the Bonhoeffer–Haber mechanism for the formation of water from hydrogen and oxygen.

A Study of the Catalytic Properties of Bright Platinum and Iridium Deposits in the Activation of Hydrogen[1]

BY LOUIS P. HAMMETT AND ARTHUR E. LORCH

While there are many reasons for believing that quality of surface is at least as important as quantity of surface in determining the activity of a contact catalyst,[2] it has been in practice extremely difficult to separate these variables, and indeed to standardize conditions so that catalysts of reproducible properties may be obtained. The prospect of so doing was, however, considerably advanced by the discovery[3] that smooth bright surfaces of the platinum metals, surfaces therefore of an area as definite as may be hoped for on a solid metal, may be obtained which are very effective for the catalytic activation of hydrogen. The present study is concerned with the determination and investigation of those factors which affect the catalytic properties of electro-deposited platinum and iridium and especially the decrease in activity which occurs when such catalysts are exposed to the activated substance hydrogen.[3]

Measurement of Activity.—Catalytic activity was determined by measuring the specific rate of the electrochemical reaction

$$H_2 \rightleftharpoons 2H^+ + 2e$$

by determination of the polarization of an electrode carrying the catalyst. By means of the apparatus shown in Fig. 1 current–potential curves were obtained, the potential E being measured by a Leeds and Northrup Type K potentiometer, and the current by determination of the potential drop across a known resistance in the circuit. The slope of these curves at the point of zero current, in amperes per volt, and for a gross area of 1 sq. cm. at 25° is reported as the catalytic activity. Since there is no discontinuity of slope at the equilibrium potential, it is immaterial whether the slope be determined by experiments in which hydrogen is oxidized (ΔE and I positive), as is the case with most of the results here reported, or by experiments in which hydrogen ion is reduced.

Our interest being principally in the comparison under identical conditions of electrodes of different preparation, we designed the apparatus to hold *as* many as ten electrodes closely and equivalently grouped around the salt bridge outlet, and used only the gentle stirring furnished by the hydrogen stream at a rate of two or three bubbles a second. The gain

---

[1] This article is based upon part of the dissertation submitted by Arthur E. Lorch to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, May, 1932.

in comparability of results more than compensates for the loss in precision of the measurement of absolute activity which is implied by the omission of a capillary extension of the salt bridge and by the greater effect of concentration polarization. Values of activity greater than 0.01 ampere per volt/sq. cm. are reproducible to 5 or 10%, and might be increased by very efficient stirring as much as several thousand per cent. To such figures only slight significance can be attached. Below about 0.005 the values are reproducible to about 1% and are altered only a few per cent. by increase in stirring rate.

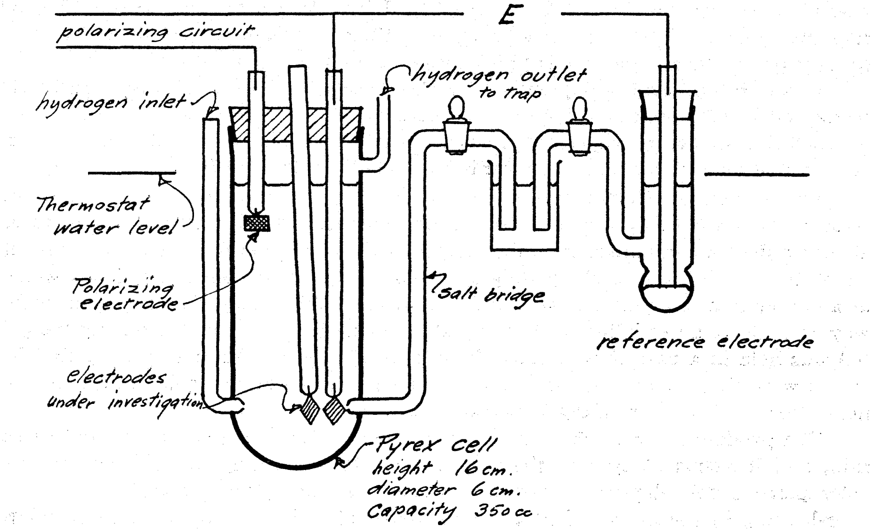

Fig. 1.

Materials.—Hydrogen was prepared by electrolysis of 30% sulfuric acid which was tested and found free from arsenic. The cathode consisted of a large copper sheet and the anode of a lead rod, the material for the latter having been specially freed from arsenic by fusion with lead chloride. The use of sulfuric acid as electrolyte eliminates the nuisance of fine spray, as when alkali is used, and in addition makes possible the continuous service of the generator for many months without appreciable solution of the electrodes. With the low currents used (0.05 to 0.5 ampere per sq. dm.) little if any reduction of sulfate ion occurs. In the purification we have especially guarded against traces of hydrogen sulfide, of sulfur dioxide, of arsine, and of lead hydride[4] as well as against oxygen. In the hydrogen line were placed long columns of cotton and soda lime, heated copper gauze, calcium chloride or "hydralo," and a coil immersed in liquid air. Rubber deteriorates in a hydrogen atmosphere, and emits foul-smelling products which we found to poison the catalysts. The stopper in our cell was a cork well soaked in paraffin wax, capped over with wax and painted with shellac when in place. Only one rubber connection was used in the hydrogen line, and in this a fresh piece of tubing was used in each experiment, and was protected from the hydrogen.

[4] Paneth and Nörring, *Ber.*, 53, 1693 (1920).

Water was twice distilled through a tin condenser and was stored in non-sol bottles. Hydrochloric acid was distilled in Pyrex glass.

Chloroplatinic acid was prepared by dissolving the metal in aqua regia followed by two precipitations with ammonium chloride, the precipitate being ignited each time and redissolved in aqua regia. The final solution was freed from nitrates by ten to fifteen evaporations to dryness with hydrochloric acid on a steam-bath.

Chloroplatinous acid was prepared by heating chloroplatinic acid at about 300° for one hour, and dissolving the residue in hydrochloric acid to give a solution about one molar in hydrochloric acid and with 1 to 5% of chloroplatinous acid.

"Iridium tetrachloride" from two different sources was used with equivalent results. The most likely composition for the substance usually sold as iridium tetrachloride seems to be about $IrCl_{3.8}\cdot 1.6HCl\cdot 4.5H_2O$.[5] At least it is essentially quadrivalent iridium. Tests on a small sample by the methods of Noyes[6] showed that the proportion of other noble metals present was certainly less than 3%.

Chloroiridous acid was prepared by the method of Délépine,[5] the tetrachloride being boiled with dilute alcohol in acid solution until metallic iridium began to form. The solution was then evaporated to dryness, and the residue dissolved in hydrochloric acid to give a solution about one molar in hydrochloric acid and with 1 to 3% of H_3IrCl_6.

Preparation of Electrodes.—A gold foil 0.65 cm. square free from etching and scratches was used as the base for the electro-deposit. It was found necessary to cut all electrodes for comparison from the same piece of foil in order to ensure approximately equal areas as a base for the plating operation. The square piece of foil was welded at a comer to a fine platinum wire and this was sealed into soft glass tubing in such a way as to leave a negligible amount of platinum exposed. During the sealing the gold foil was held in a pair of tweezers to keep it from melting. Prior to plating the electrodes were thoroughly cleaned (a few minutes in warm chromic acid) to ensure even deposition. This is especially important when using low current densities.

The production of bright deposits from chloroplatinic acid is difficult and uncertain, and it seems likely that the favorable results previously found[3] with purified chloroplatinic acid depended upon the presence of chloroplatinous acid produced by over-heating in the evaporation of the chloroplatinic acid. In the absence of chloroplatinous acid we now find that high current densities lead to grayish or spongy deposits and low current densities lead to no deposit.

A plating bath of chloroplatinous acid, on the other hand, gives brilliant deposits over a wide range of current densities. Since we have found that the presence of small amounts of oxidized material during the plating greatly affects the activity of both platinum and iridium catalysts, and since it decreases the current efficiency, we have used a U-shaped plating cell in which anode and cathode compartments were separated by a plug of filter paper. When working with low current densities we have excluded oxygen by bubbling nitrogen through the cathode compartments and by providing the gas outlet with a trap.

The current efficiency of the deposition of platinum was determined as follows. A piece of gold foil was carefully cleaned, heated to redness, weighed, then very loosely welded to a platinum wire which was sealed into a glass tube. The gold foil was cleaned again and half immersed in the plating bath so that no metal could be deposited near the platinum wire. The plating current was accurately measured at short time intervals by means of a potentiometer and known resistance. The finished deposit was

[6] Noyes, "A System of Qualitative Analysis for the Rare Elements," The Macmillan Co., New York, 1927.

washed thoroughly and the gold foil was pulled away from the platinum wire. A blank experiment showed that with the proper technique this could be done without any measurable loss in the weight of the gold foil. After careful washing the gold foil and platinum deposit were heated to red heat and then weighed again. Weights, balance and current measuring devices (resistance and potentiometer circuit) were very carefully checked to ensure the reliability of the results. These are given in Table I.

TABLE I

Wt. of Pt deposit, mg.	Time of plating	Average current, ma.	Plating efficiency of current on basis $Pt^{++} \longrightarrow Pt$, per cent.
20.93	**6** hrs. **0** min.	**0.900**	**106.7**
16.43	**7** 0	.590	**109.5**
24.90	**12** 6	.537	**105 5**

The experimental errors connected with these determinations are estimated as less than one per cent. We can explain these results either by assuming that a tremendous amount of adsorption takes place on the platinum or by assuming the existence of monovalent platinum in the solution. It seems most likely that the latter is the correct assumption. The existence of monovalent platinum has been suggested by several investigators,[7] but is not generally accepted.

Chloroiridic acid solutions give bright deposits over a wide range of current densities, but the current efficiency is low, and we have not been able to obtain reproducible catalytic activities.

Chloroiridous acid solutions give bright deposits at current densities from **0.05** to **50** milliamperes per square centimeter when the solution is stirred. We have not measured directly the current efficiency but the assumption that the thickness of a layer of iridium required to just conceal the color of the gold base is the same as that of a platinum deposit of the same covering power leads to values between **90** and 100%. The conclusion that the efficiency is high and constant is supported by the reproducibility of the catalytic properties of the deposits.

Reproducibility of Catalytic Activity and Life.—In Fig. 2 we have the results of a test of the reproducibility of the preparation of bright iridium catalysts from chloroiridous acid solutions. The six catalysts in question were prepared in the order of their numbers at a current density of 0.418 milliampere per square centimeter over a period of twenty-five minutes. After washing they were introduced into 0.1 molar hydrochloric acid in the cell of Fig. 1, which was placed in a thermostat at 25°, the hydrogen current was started, and the activity was determined from time to time. In the figure the logarithm of the activity is plotted against time. It will be noted that with the exception of number 1, the catalysts are very nearly identical in their activity-life curves. The deviating behavior of number 1, a type of behavior which we have consistently found with the first electrode or two prepared from a fresh solution, is probably to be ascribed to the presence in the solution of quadrivalent iridium, which we have found to give catalysts of slower decay.

[7] Lea, ***Z. anorg. Chem.*, 8, 121** **(1895);** Sonstadt, *Proc. Chem. Soc.*, ***14, 25*** **(1898);** Wohler and Streicher, ***Ber.***, 46, **1.591** ***(1913);*** Wohler and Balz, Z. ***anorg.*** *allgem. Chem.*, ***149, 353*** **(1925).**

In Fig. 3 are given the results of a similar test with platinum, the catalysts being bright platinum plated in the order of their numbers from chloroplatinous acid solution for thirty minutes at a current density of 0.80 milliampere per square centimeter. The reproducibility of properties, while not so good as with iridium, is still excellent for a contact catalyst.

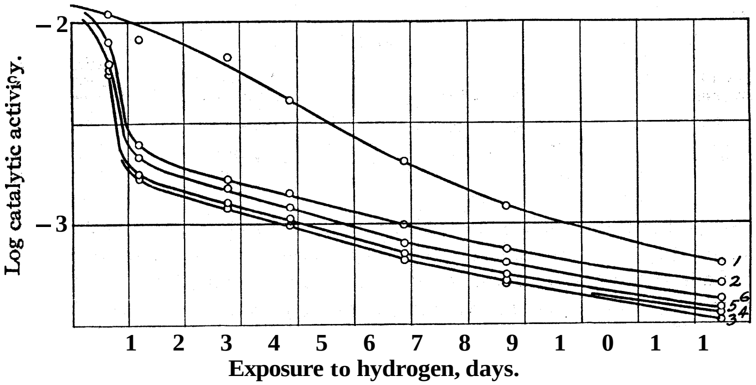

Fig. 2.

We have found that differences in temperature during the plating of as much as 10° have a negligible effect upon catalytic properties.

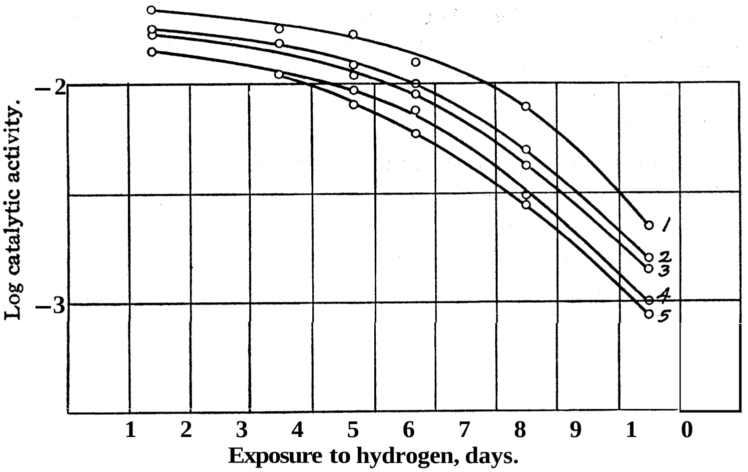

Fig. 3.

The Nature of the Decay in Catalytic Activity.—The decay in activity in a hydrogen atmosphere may be explained in terms of (1) reversion of active and unstable atoms or atomic groupings on the surface to less active states, a process inhibited by the presence of adsorbed oxygen, and accelerated by hydrogen only because of the removal of this inhibition; (2) a relation between the activation of hydrogen and the exhaustion of the catalyst; (3) a poisoning of the catalyst occurring only when the protecting layer of oxygen is removed by hydrogen.

We reject the third explanation on the basis of the following considerations. The very carefully purified hydrogen used in these experiments produces a decay qualitatively identical with that produced in earlier work by commercial tank hydrogen and by hydrogen made in the laboratory by electrolysis of sodium hydroxide solutions with nickel electrodes. The omission of the liquid-air trap in our hydrogen train produced no measurable change in the rate of decay. The known poison, hydrogen sulfide, is reversible in its effect, the activity increasing when the poison is removed; and the decrease in activity produced by saturated hydrogen sulfide solution is less than that produced on long aging in the presence only of the purest hydrogen, water, and hydrochloric acid. In further experiments a number of tubes containing hydrogen were sealed with two platinum electrodes apiece. The electrodes were variously exposed in these tubes. Some were immersed in 0.1 *N* hydrochloric acid, some in pure water, some in water which had never been in contact with glass. The tube in this latter case had been coated with paraffin and the water had been distilled through a tin condenser directly into the tube. Some electrodes were kept entirely out of the solution, being suspended above it in the hydrogen atmosphere. In all these cases the rate of decay of the catalysts was the same, within the limits of experimental error. These limits, it must be admitted, are somewhat wider than those prevailing in other sections of the work, since measurements can only be obtained on the catalysts by transferring them to a cell, a process which causes them to be reactivated to some extent by the air.

Either of the other explanations implies that the decay in activity which takes place at elevated temperatures under any conditions[8] is related to that which we observe at room temperature. This suggests that there should be a difference in the rate of this so-called sintering at elevated temperatures according to the environment, that hydrogen should have a catalytic effect upon the sintering. Such an effect is shown by the experiments described in Table II. In these, eight platinum catalysts prepared so as to be as nearly identical in properties as possible were heated in a Pyrex tube under various conditions, and were then transferred to the cell of Fig. 1. After a lapse of three days in hydrogen in the cell to allow the effects of the temporary activation by the air during the transfer to wear off, the activities were determined. Similar experiments at other temperatures confirm the conclusion that hydrogen does indeed accelerate the decay in activity over a wide range of temperatures.

Effect of Thickness of Deposit and of Rate of Plating.—Figure 4 shows the life curves of five iridium catalysts of different thickness. These were plated for varying times at the same current density (0.27 ma./sq. cm.) from the same solution of chloroiridous acid in the order of the numbers attached to the curves. The average thickness of the deposit calculated on the basis of 100% current efficiency is given in the figure. Figure 5

[a] Due to a miscalculation the figures for thickness given in the thesis upon which this article is based were in error by a constant factor of 0.7.

contains the results of similar experiments with platinum catalysts obtained from a solution of chloroplatinous acid at a current density of 0.141 ma./sq. cm. Similar results have been obtained in other experiments, and we conclude that for electrodeposited platinum and iridium catalysts of equal gross area the catalytic life is greater the thicker the deposit.

The decay curve for an ordinary platinum foil activated by anodic oxygen evolution for five minutes is included in Fig. 5, and shows a very rapid decay rate. This is further confirmation because such an activation should produce only a very thin active layer.

In Table III are given the results of an experiment designed to test the effect of rate of deposition upon the properties of iridium catalysts. The catalysts were all prepared from the same 3% chloroiridous acid solution in the order of the numbers, and it was attempted to make them all of the same thickness by varying the rate of deposition in inverse proportion to the time of plating. The first three were plated at the same rate and the agreement of properties between 2 and 3 shows that the bath had reached a steady condition. The thickness calculated on the basis of constant 100% current efficiency is given and, as a check, the value calculated from the time required to just conceal the color of the gold base. The agreement is excellent except in the case of the two electrodes plated at the highest current densities, and we have discarded the results on these. The accepted results are plotted in Fig. 6, from which it is clear that the best iridium catalysts are those plated at the lowest rate.

Figure 6 also contains the life curve of a catalyst prepared from an iridium tetrachloride solution, and estimated from the time required to conceal the gold base to be somewhat less in thickness than the other catalysts included in the figure. Because of the low current efficiency prevailing in such solutions, this required a current of 0.26 ma./sq. cm. for five and one quarter hours. The characteristically long life may be due to a specific effect of the oxidized iridium as a source of the deposit or possibly to the very slow rate of deposition.

With platinum the difference in properties arising from variation in rate of deposition is certainly smaller than with iridium, and it is difficult to be certain whether any such effect exists, especially in view of the poorer reproducibility of platinum catalysts.

Both the effect of thickness of deposit and the effect of rate of deposition are not obvious conclusions from usual theories of contact catalysis. All of the catalysts for which we have here given results appeared perfectly smooth and lustrous to the naked eye or under magnification of 750 diameters. Nevertheless the quantity of metal required to conceal the color of the gold base corresponds to a thickness of from 1 to 2.5×10^{-6} cm. or about 40 to 100 atomic layers. This suggests that crystal growth starts from centers scattered over the surface of the gold and proceeds laterally as well as upward until adjacent crystals touch. The surface of the deposit might then be expected to have a saw-tooth cross section with a tooth height of some 80 to 200 atom diameters. Since, however, an increase in thickness beyond that required to obscure the base results in increased catalytic life, it must be supposed that fissures or pores much deeper than the average depth of the saw-teeth exist, and have a very marked effect upon catalytic properties.

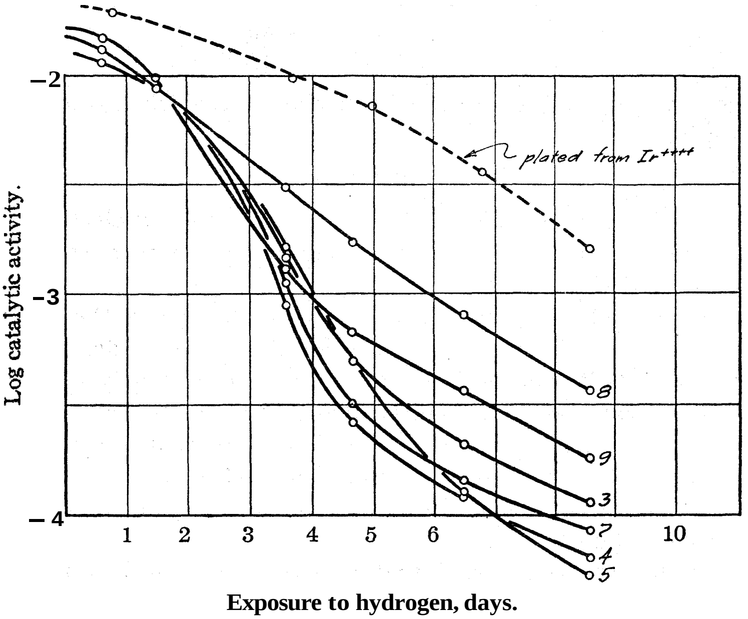

Fig. 6.

All of the curves show an initial rapid decay whose rate is very nearly the same in all cases. This initial decay is therefore independent of the thickness of the deposit and is to be attributed to the loss in activity of that part of the catalyst in which all these catalysts are identical, the ordinary or external surface. It is only after this, which furnishes most of the initial activity, has decayed that the properties of that part of the catalyst which depend upon thickness become significant. Furthermore, the differences in slope of the later parts of the curves in Figs. 4 and 5 indicate that thicker deposits lead to inner surfaces (of the fissures or pores) whose specific rate of decay is smaller, whereas the parallelism (on the semilogarithmic plot) of the later part of the curves in Fig. 6 suggests that differences in rate of deposition result in differences in activity of the inner surface but not in the fractional loss of activity in unit time.

In other words, the external surface, which is the most exposed to hydrogen, decays most rapidly, and of the inner surfaces, those present in the thicker deposits, and therefore least accessible to the hydrogen, decay at the lowest rate. This experimental conclusion may also be derived as a corollary from Tanner's recent theory of contact catalysis,[9] according to which activation depends upon the existence of local excesses in temperature at the active points. It follows that contact with and consequent activation of the reactant should tend to produce decay of the catalyst and that those areas which are most exposed to hydrogen and on which the reversible reaction

$$2H^+ + 2e \rightleftharpoons H_2$$
$$\text{or} \qquad 2H \rightleftharpoons H_2$$

proceeds at the greatest rate should be those on which loss of activity is most rapid.

Summary

Methods have been perfected for the preparation by electrodeposition of platinum and iridium catalysts of reproducible properties for the activation of hydrogen.

The loss in activity which such catalysts undergo in the presence of hydrogen at room temperature has been shown to be dependent upon the hydrogen itself and not upon poisons, and to be closely related to the so-called sintering which takes place at higher temperatures.

The dependence of decay upon thickness of deposit and upon rate of deposition has been investigated, and the conclusion reached that these apparently smooth solid deposits have an inner surface of great importance for their catalytic behavior.

Indications have been found that it is the actual activation of hydrogen which is responsible for the decay, and the relation of this conclusion to Tanner's theory of contact catalysis has been pointed out.

The Photo-oxidation of Gaseous Hydrogen Iodide

BY JOHN R. BATES AND GEORGE I. LAVIN

In studies[1] of the reaction of hydrogen atoms with oxygen molecules it has been assumed that the first process consists of an associative reaction between these atoms and oxygen molecules.

$$H + O_2 \longrightarrow HO_2 \qquad (1)$$

The molecule HO_2 then reacts with a hydrogen molecule if a subsequent collision with hydrogen occurs within the lifetime of HO_2 and has sufficient energy.

The straight bimolecular process

$$H + O_2 \longrightarrow OH + O - 13.5\ \text{cal.} \qquad (1a)$$

has been ruled out as improbable, due to the high activation energy necessary. If we accept the values for the heat of formation[2] of OH and O_2 of 104 cal. and 117.5 cal., respectively, the reaction is endothermic 13.5 cal. Only one collision in at least 5×10^{10} would be effective at 0°. However, the value of 104 cal. for OH is not as definite as might be desired, and it is well to note that this mechanism does not agree with the experimental evidence obtained from quantum yield studies of the reaction.

The value of the quantum yield of hydrogen peroxide formation in the sensitized reaction is of the order of 1.2–2.5 as given by the work of Marshall[3] and of Frankenburger and Klinkhardt.[4] Reaction (1a) would give rise to a maximum of but one hydrogen peroxide molecule per quantum, since oxygen atoms are known[5] not to react with hydrogen molecules.

For a considerable time it was assumed that the quasi molecules such as HO_2 could only exist for about 10^{-13} to 10^{-14} seconds. More recently it has been suggested by Kassel[6] and demonstrated experimentally by Pease[7] in the hydrogenation of ethylene that these molecules may have greater lifetimes, especially in cases where the molecule is polyatomic. It seemed, therefore, desirable to see if it was not possible to learn something concerning the lifetime of HO_2 in the reaction of hydrogen atoms with oxygen.

Since hydrogen iodide is known to decompose into atoms[8] on the absorption of a quantum of light it appeared feasible to study the oxidation of hydrogen atoms by the method used in the case of methyl groups[9] and to

obtain from the kinetics of the hydrogen iodide photo-oxidation valuable data concerning the reaction of hydrogen atoms and oxygen molecules.

Experimental

The apparatus was similar to that of Bates and Spence.[9] The same mercury arc and reaction vessel was used, but since hydrogen iodide is corrosive a quartz spiral manometer was substituted for the mercury manometer. Very satisfactory yields of hydrogen iodide[10] were obtained by passing hydrogen over iodine and then over a platinum catalyst. The hydrogen iodide was distilled in *vacuo*, and a pure white product, free from iodine, was obtained. The final product was distilled into a tube which was immersed in liquid air. Oxygen was taken from a tank, dried and stored in a large glass bulb. Since, according to Bodenstein and verified by the present work, hydrogen iodide does not appreciably attack pure vaseline, this was used to lubricate the stopcocks shutting the reaction vessel from the rest of the system,

The quartz reaction vessel was kept at a temperature of 0°. The vessel was connected to the rest of the apparatus by a ground joint so that it could be removed and the reaction products studied.

Experimental Results

A series of runs showed that with oxygen present the pressure decrease was greater than could be obtained by the decomposition of hydrogen iodide alone. In the straight decomposition process **a** decrease equal to half the original hydrogen iodide present is to be expected:

$$2HI \longrightarrow H_2 + I_2$$

In Table I it can be seen that with oxygen present the pressure decrease observed $(-\Delta P_{\text{obs.}})$ is considerably greater than $-\Delta P$ obtained by dividing the original hydrogen iodide pressure by two.

Reaction Products

Iodine.—By titrating with $N/10$ thiosulfate it was possible to show that practically all of the iodine originally present in the hydrogen iodide could be recovered as free iodine. The titrations of iodine are given by $-\Delta HI$ in Table II.

Hydrogen Peroxide.—Since all of the mechanisms postulated for the reaction of hydrogen atoms with oxygen involve the formation of hydrogen peroxide efforts were made to identify it in the products. **A** liquid product, which could be seen in the reaction vessel after a run, was washed out in water and the excess iodine removed with silver nitrate. Such **a** liquid gave very slight tests for peroxide. **A** blank run on iodine dissolved in water gave no such test. It is not surprising that hydrogen peroxide should not appear in large quantities, since Abel[11] has shown that liquid

hydrogen peroxide is decomposed in the presence of hydrogen iodide, yielding water and oxygen. The hydrogen iodide acting as a catalyst is not removed by the reaction. Knowing little of the conditions in the liquid phase in our reaction system, we were forced to the assumption that those processes occurring in the liquid phase were without effect upon the gas reactions, an assumption which is perhaps approximate, but which is borne out by the results.

Hydrogen.—Since both decomposition and oxidation were taking place simultaneously, it became necessary to determine the hydrogen formed during the course of the reaction. Accordingly gas analyses were carried out upon the gaseous products resulting from various initial concentrations of reactants. In most cases the hydrogen to oxygen ratio was determined by explosion and by absorption of oxygen by pyrogallol. These data are shown in Table II. Also recorded in the same table are the initial concentrations, the final total pressure and the final pressure of hydrogen calculated from the final total pressure and the gas analyses.

Influence of Oxygen on the Reaction Rate.—The variations of rate of decrease in pressure with varying oxygen pressures were studied, keeping the hydrogen iodide pressure constant. These results are represented in Table III, column 2.

TABLE III

Discussion of Results

If we assume that the reaction of hydrogen atoms with oxygen takes place through the formation of the molecule HO_2, *as* seems most probable, we may write the steps of the reaction as follows

$$HI + h\nu \longrightarrow H + I \quad I(1 - e^{-\alpha HI}) = A \qquad (1)$$
$$H + HI \longrightarrow H_2 + I \qquad K_1 \qquad (2)$$
$$H + O_2 \longrightarrow HO_2 \qquad K_2 \qquad (3)$$
$$HO_2 + HI \longrightarrow H_2O_2 + I \qquad K_3 \qquad (4)$$
$$HO_2 \longrightarrow H + O_2 \qquad K_4 \qquad (5)$$

At stationary concentrations

$$\frac{d[H]}{dt} - - \frac{d[H]}{dt} \text{ and } \frac{d[HO_2]}{dt} = \frac{d[HO_2]}{dt}, \text{ or}$$

$$[HO_2]K_4 + A = [HI[HI]K_1 + [H][O_2]K_2, \text{ and} \qquad (I)$$
$$[H][O_2]K_2 = [HO_2][HI]K_3 + [HO_2]K_4 \qquad (II)$$

Equations I and II can be solved simultaneously to give the stationary concentrations of HO_2 and H in terms of [HI], $[O_2]$, A, K_1, K_2, K_3 and K_4.

The rate at which hydrogen is produced according to (2) is

$$\frac{\mathrm{d}[\mathrm{H}_2]}{\mathrm{d}t} = [\mathrm{H}][\mathrm{HI}]K_1 \qquad \text{(III)}$$

while the total rate of hydrogen iodide decomposition may be represented

$$-\frac{\mathrm{d}[\mathrm{HI}]}{\mathrm{d}t} = 2[\mathrm{H}][\mathrm{HI}]K_1 + 2[\mathrm{HO}_2][\mathrm{HI}]K_3 \qquad \text{(IV)}$$

Dividing III by IV we obtain

$$-\frac{\mathrm{d}[\mathrm{Ha}]}{\mathrm{d}[\mathrm{HI}]} = 1/2\ \frac{[\mathrm{H}][\mathrm{HI}]K_1}{[\mathrm{H}][\mathrm{HI}]K_1 + [\mathrm{HO}_2][\mathrm{HI}]K_3} \qquad \text{(V)}$$

Substituting the values of [H] and $[HO_2]$ obtained from I and II we obtain

$$[\mathrm{H}_2] = -\ 1/2 \int_{\mathrm{HI}_0}^{\mathrm{HI}_E} \frac{([\mathrm{HI}]K_3K_1 + K_1K_4)\mathrm{d}[\mathrm{HI}]}{[\mathrm{HI}]K_3K_1 + [\mathrm{O}_2]K_2K_3 + K_1K_4} \qquad \text{(VI)}$$

where HI_0 and HI_E are the initial and final pressures of hydrogen iodide. If $[O_2] = 0$, we arrive at the expression

$$[\mathrm{H}_2] = 1/2 \int_{\mathrm{HI}_E}^{\mathrm{HI}_0} \mathrm{d}\,[\mathrm{HI}], \text{ or } [\mathrm{H}_2] = \frac{\text{HI decomposed}}{2} \qquad \text{(VII)}$$

which is true for straight photochemical decomposition. The same expression is deduced if $K_4 >> K_1$, K_2 and K_3, which would indicate that, if K_4 is very much greater than the other constants, no oxidation of the hydrogen atoms will occur.

If, on the other hand, we can neglect K_4 in comparison with the other constants we obtain

$$\mathrm{d}[\mathrm{H}_2] = 1/2 \int_{\mathrm{HI}_E}^{\mathrm{HI}_0} \frac{[\mathrm{HI}]K_1}{[\mathrm{HI}]K_1 + [\mathrm{O}_2]K_2}\ \mathrm{d}[\mathrm{HI}] \qquad \text{(VIII)}$$

Integrating, and taking the limits

$$\frac{1}{K} = \frac{1}{\mathrm{HI}_0 - \mathrm{HI}_E - 2\mathrm{H}_2} \ln \frac{K + \mathrm{HI}_0}{K + \mathrm{HI}_E} \qquad \text{(IX)}$$

where $K = (K_2/K_1)[O_2]$.

It appears immediately that K_4 is not sufficiently greater than the other constants to make VII hold. If this were true, we should expect no influence of oxygen on the decomposition of hydrogen iodide, and hydrogen and iodine would be the sole products, which is definitely disproved by the data of Table II.

Equation VI cannot be used in its present form to express the results because of the large number of undetermined constants it contains. It seemed, therefore, most convenient first to attempt to fit the experimental results to IX and then to observe any deviations which might occur in the constancy of K_2/K_1, which would indicate the relative magnitude of K_4 and the other constants. HI_0 is the initial pressure of hydrogen iodide, while

$HI_0 - HI_E$ is given by the iodine titration. whence values for both of these can be obtained. $[H_2]$ can be obtained in two ways, The analysis of the hydrogen and oxygen resulting from the reaction, together with the final total pressures of these gases, gives $[H_2]$ directly. If we assume that the oxidation product of the reaction is water it is possible to obtain the amount of hydrogen present after reaction from the total decrease in pressure and the iodine titration. If γ is the fraction of the hydrogen iodide reacting to give water, $1 - \gamma$ produces hydrogen. If, then, we write the two over-all reactions:

$$2HI \longrightarrow H_2 + I_2, \text{ and}$$
$$4HI + O_2 \longrightarrow 2H_2O + I_2$$

it can readily be seen that the following equation holds

$$\frac{(1 - \gamma)(HI_0 - HI_E)}{2} + 5/4\,(HI_0 - HI_E)\gamma = -\Delta P + 4.6 \text{ mm.}$$

where 4.6 mm. is the vapor pressure of water at 0°. After solving this for γ, $[H_2]$ is obtained from the expression

$$H_2 = \frac{2}{(1 - \gamma)(HI_0 - HI_E)}$$

The values for H_2 obtained from these two sources are found in Table II, columns 7 and 8, labeled H_2 G.A. and $H_2\Delta P$, respectively. Fairly good agreement is obtained between the two values in any one experiment, indicating that water is the final product of the oxidation reaction.

We now have all the values necessary for a determination of K and K_2/K_1 from equation IX. This equation is easiest solved by a method of trial and error. We put $1/K = Y = 1/(HI_0 - HI_E - 2H_2)\ln(K + HI_0)/(K + HI_E)$, and then plot the hyperbola $Y = 1/K$, which is independent of the various experimental values. The point at which $Y = 1/(HI_0 - HI_E - 2H_2)\ln(K + HI_0)/(K + HI_E)$ intersects the hyperbola is the desired solution of K. The values of K are given in Table II. From these, and the initial oxygen concentrations, K_2/K_1 are obtained and given in columns 12 and 14. These values agree among themselves within the limits of these experiments and indicate that we are justified in neglecting K_4 and using equation X to express our results.

It can be seen that the rate of the reaction, that is, $-\mathrm{d}P/\mathrm{d}t$, will be given by

$$-\frac{dP}{dt} = \frac{dH_2}{dt} + 2.5\,\frac{dH_2O_2}{dt} \tag{X}$$

Eliminating [H] and $[HO_2]$ and substituting we have

$$-\frac{dP}{dt} = \frac{A([HI] + 2.5[O_2]K_2/K_1)}{[HI] + [O_2]\,K_2/K_1} \tag{XI}$$

The value of A is found by placing $[O_2] = 0$ and is the rate of decomposition of hydrogen iodide. It is to be pointed out that since it was impossible to maintain a constant (from day to day) light intensity it was always necessary to make parallel experiments with hydrogen iodide alone and then with oxygen. In this way the variation of the light source was minimized and the necessary modification of A obtained.

We are now in a position, having evaluated K_2/K_1, to calculate $-dP/dt$ assuming K_4 to be small, and to compare the value so obtained to the experimental value. In Table III the values of A are obtained from the corresponding runs with hydrogen iodide alone; in column 4 the ratio, calculated from equation XI, and using the A values given in column 2. In the last two columns these values are corrected to an A value of 0.76, thus showing the rise in absolute rate as the oxygen increased. The corrected experimental values agree with the calculated within 20% and are a further proof that our mechanism is correct.

It becomes of great interest to see what restrictions neglecting K_4 in equation VII places upon the magnitude of this quantity. Suppose K_1, K_2 and K_3 are bimolecular constants expressed in millimeters pressure of mercury reacting per second per millimeter pressure of reactants. One atom at one millimeter pressure makes $\sim 10^7$ collisions per second, so that the total number of bimolecular collisions at 1 mm. pressure of reactants is equal to $\sim 10^7 \times 10^{16} = \sim 10^{23}$ per cc./sec. at 1 mm. pressure of the gases. Thus our constants K_1, K_2, K_3 are $\gtrsim 10^{23}/10^{16} = 10^7$ mm./sec. per mm. of reactants. Their true value will be smaller than this figure by a factor giving the efficiency of collisions, which will depend upon activation energy, and steric factors. They cannot, which is of importance for our considerations, exceed this order of magnitude.

If, using $K_1 = K_2 = K_3 = 10^7$, we substitute a value of $K_4 = 10^{13}$, which gives an accepted value for the life of a quasi-molecule equal to 10^{-13} sec., and also substitute for [HI] 50 mm. and [O_2], 200 mm., we find that the amount of oxidation would be of the order of 2 parts in 100,000. The value of $-d[H_2]/d[HI]$ would differ from 0.5 by only 0.02%, indicating that hydrogen would be the sole detectable product. This shows us immediately that such a value for K_4 is much too high, since at these concentrations we observe considerable oxidation (Table I).

Before going further it would perhaps be well if we could arrive at more carefully estimated values for our k's. Bonhoeffer and Farkas[8] have observed that the relative efficiencies of the reaction of hydrogen atoms with hydrogen iodide and iodine are in the ratio 1:100. This means that K_1 must be less than 10^5. Our results show that K_2, on this basis, would be $\sim 10^4$. These values in the expression $([HI]K_1K_3 + K_1K_4)/([HI]K_1K_3 + [O_2]K_3K_2 + K_1K_4)$ give the values shown in Table IV, using $[O_2] = 200$ throughout and the values of $K_3[HI]$ and K_4 indicated. The fraction under $K_4 = 0$ are those which agree with our experiments, and deviations from these values for various K_4 values can be read from the table.

TABLE IV

$O_2 = 200$ mm.

$K_4 =$		0	10^7	10^8	10^9	10^{10}
$K_3 = 10^7$	HI = 50	0.715	0.72	0.75	0.884	0.981
	HI = 10	.333	.354	.500	.925	.990
$K_3 = 10^6$	HI = 50	.715	.75	.884	.981	
	HI = 10	.333	.500	.925	.990	

It can easily be seen that in the most unfavorable circumstances, shown by the top row that K_4 is certainly $\leqq 10^9$. There the deviation from experiment is $(0.884 - 0.715)/0.715 = 23.6\%$. In addition, since our results represent an integration over pressures of hydrogen iodide from 50 to $\sim$3 mm., we can safely say that the value of K_4 is probably 10^8.

The usually accepted values for the lifetime of such a quasi-molecule are of the order of 10^{-13} to 10^{-14} seconds, which give rise to a decomposition reaction constant of 10^{13} to 10^{14}. These values are, then, 10^4 to 10^6 greater than we find in our experiments, and indicate, as suggested by Kassel, that the lifetimes involved in polyatomic quasi molecules are considerably greater than usually accepted. This is of great interest in all cases in which a so-called three-body process is involved, since, when the lifetime increases above a definite value, the reaction loses its three-body characteristics and becomes essentially a straight bimolecular reaction. It also should be recognized that the reverse process of unimolecular decomposition involves considerations which may be affected by this longer lifetime.

It is of interest to discover the significance of these high values of the lifetime of HO_2 in the light of Kassel's considerations. This molecule has a heat of formation from a hydrogen atom and an oxygen molecule of 69 large calories if we take half of the energy of formation of hydrogen peroxide:

$$2H + O_2 \longrightarrow H_2O_2 + 138 \text{ Cal}$$

Further, having three atoms, its "s" value is three. Using these data we find that for $K_4 = 10^9$, n, the number of vibration levels, must be $\sim$50. For $K_4 = 10^8$, $n \sim 100$. These give us average vibrational quanta of 500 cm.$^{-1}$ and 250 cm.$^{-1}$, respectively, provided 0.1 of the energy continuum is to be filled. *A priori,* these are not at all impossible values. It must be remembered that these are only average values. The most fully worked out example of the relation of such an average value to the fundamental frequency of a molecule is given by the upper electronic level involved in the visible iodine absorption bands. Here 59 vibration levels are known within an energy interval of 4400 cm.$^{-1}$,[12] giving a maximum average separation of 75 cm.$^{-1}$. The fundamental frequency of this state is 127.5 cm.$^{-1}$. Remembering that the value 75 cm.$^{-1}$ is obtained by using only the number of measured levels, which is smaller than the actual number,

---

(12) Ruark and Urey, "Atoms, Molecules and Quanta," The McGraw-Hill Book Co., New York, 1930, pp. 395, 400, 402. The value 4400 is ohtained by subtracting the energy of the electronic jump from that of the convergence limit.

e can readily see that the average separation is considerably smaller than he fundamental frequency. An examination of band spectra data will eveal that this must be fairly universal. In attempting to compare the alues of 500 and 250 cm.$^{-1}$ with those of the HO_2 molecule, the nearest ossible approach are the fundamental frequencies of hydrogen peroxide,[13] 75 and 903 cm.$^{-1}$. These are not incompatible with the 500 cm.$^{-1}$ average alue, but perhaps high for the 350 cm.$^{-1}$ average.

A consideration of the possibility of the reaction

$$H + O_2 \longrightarrow OH + O \qquad \text{(a)}$$

ccurring in the light of these data yields an interesting fact which makes this process seem unlikely. As we have said, the ratio of the K_b and K_c n the reactions

$$H + I_2 \longrightarrow HI + I \quad K_b \qquad \text{(b)}$$
$$H + HI \longrightarrow H_2 + I \quad K_c \qquad \text{(c)}$$

is 100, $K_b/K_c = 100$. Now reaction (b) is supposed to involve little or no activation energy.[14] Hence, reaction (a) would take place in about 1 in every 1000 collisions, which indicates an activation energy of 3.8 cal. If this were true, the heats of formation of O_2 and OH could not differ by more than this amount, while the difference in the accepted values is 13.5 cal., a discrepancy of 10 large calories.

Since this mechanism seems an unlikely one according to the accepted values for the heats of linkage involved, we are led to the formation of the HO_2 complex as the only plausible explanation of the reaction. In addition to other evidence already discussed earlier in this work, the formation of high percentages (90%) of hydrogen peroxide in the mercury sensitized hydrogen–oxygen reaction also points to the HO_2 intermediate. This reaction has been the subject of intensive work in this Laboratory which will be presented shortly in THIS JOURNAL. The long life ascribed by us to the HO_2 molecule is naturally contingent upon its intermediate formation being the correct mechanism for the reaction studied.

The authors wish to thank Professor Hugh S. Taylor for his many constructive criticisms.

Summary

1. The kinetics of the photo-oxidation of gaseous hydrogen iodide have been studied.

2. The result of the application of simple reaction kinetic theory to the experimental results leads to the conclusion that the quasi molecule HO_2 can have a life of 10^{-8} to 10^{-9} seconds, which is many orders of magnitude larger than that usually ascribed to such complexes.

A Potentiometric Titration Method for Fluorine

BY NELSON ALLEN[1] AND N. HOWELL FURMAN

Introduction

A potentiometric titration of fluorine requires an indicator electrode for fluoride ions or for the substance that is reacting with the fluoride. Since no electrodes are available for the fluoride ion an electrode must be selected which changes its potential with the concentration, or activity, of the ions of the reagent. The fluoride may be precipitated or caused to form a complex ion such as $FeF_6^{\equiv}$ or $AlF_6^{\equiv}$. Treadwell and Kohl[2] were the first to propose a potentiometric method for fluorine, their procedure being based on the formation of $FeF_6^{\equiv}$, a volumetric method which had been previously investigated by Greeff[3] using potassium thiocyanate as a color indicator. Later these two authors made use of aluminum chloride for the titration,[4] the aluminum ions decomposing the iron cryolite complex, and Treadwell and Bernasconi applied the method to the determination of aluminum and magnesium in the presence of each other.[5] In the papers of Treadwell and Kohl the conductimetric titration of pure fluoride solutions with aluminum ions was reported.

The insoluble fluorides are few in number and the precipitation titrations are limited to the formation of the fluorides of the alkaline earths, thorium and the rare earths. Most of the volumetric methods are based on the precipitation of calcium fluoride, although one useful and interesting method involves the titration of chloride secured from lead chlorofluoride.[6] Potentiometric methods depending purely on the precipitation of an insoluble fluoride are still further limited because of the lack of suitable indicator electrodes, and thus far no such methods have been advanced.

Kurtenacker and Jurenka[7] titrated fluoride with cerous nitrate using methyl red as an indicator and their work indicates that cerous fluoride is quite insoluble and very stable. Batchelder and V. Meloche[8] did further work on the titration using methyl red and their work corroborates the statement anent the insolubility of cerous fluoride. The stability of the precipitate is shown by the results secured by Batchelder and V. Meloche using their indirect method for fluorine in which an excess of cerous nitrate is added and the excess determined by potassium permanganate using the method of Lenher and C. Meloche.[9] Thus precipitation of fluoride as

cerous fluoride seems particularly suited for a potentiometric method provided some electrode can be obtained to serve as an indicator for cerous ions.

Development and Theory of Method.—Unfortunately a cerous–ceric combination cannot be used as an indicator since ceric fluoride is only slightly soluble also, but still more soluble than the cerous salt. A suitable electrode for cerous cerium has been found in an application of the ferri–ferrocyanide electrode.[10]

Cerous cerium has been determined by oxidation with potassium ferricyanide by Tomiček,[11] by precipitation as $Ce_4[Fe(CN)_6]_3$ by Treadwell and Chervet[12] and by precipitation as $CeKFe(CN)_6$ by Atanasiu.[13] Atanasiu performed the titration at 65° in a solution containing 30% ethyl alcohol. A repetition of this work checked his results and it was found possible to determine fluoride indirectly by adding an excess of cerous nitrate and determining the excess potentiometrically with potassium ferrocyanide. However, a direct method was desired and the insoluble $CeKFe(CN)_6$ was used to furnish an indicator electrode for cerous ions in the following manner. Kolthoff[14] employed a mixture of potassium ferricyanide and lead ferrocyanide in contact with a platinum electrode as an indicator for lead ions in the potentiometric titration of sulfate with lead nitrate. We have found that a ferricyanide–cerous potassium ferrocyanide mixture acts as a good indicator for cerous ions. The potential of a ferri–ferrocyanide mixture in contact with platinum at 25° is represented by

$$E = e_0 + 0.0591 \log \frac{[Fe(CN)_6^{\equiv}]}{[Fe(CN)_6^{--}]}$$

If the ferrocyanide ions are furnished only by a saturated solution of cerous potassium ferrocyanide, then for the saturated solution

$$[Ce^{+++}]\cdot[K^+]\cdot[Fe(CN)_6^{--}] = \textbf{Solubility product of } CeKFe(CN)_6$$

and

$$[Fe(CN)_6^{--}] = \frac{k}{[Ce^{+++}]\cdot[K^+]}$$

The potential of the electrode becomes

$$E = e_0 + 0.0591 \log \frac{[Fe(CN)_6^{\equiv}]\cdot[Ce^{+++}]\cdot[K^+]}{k}$$

and if $[Fe(CN)_6^{\equiv}]$ and $[K^+]$ are constant, dilution of the solution during titration being disregarded

$$E = e_0' + 0.0591 \log [Ce^{+++}]$$

The electrode potential is thus shown to be directly proportional to the logarithm of the molar concentration of the cerous ion. Actually such a

simple relation does not apply due to the dependence of the potential of the ferri–ferrocyanide electrode upon the salt concentration of the solution. For large quantities of fluoride or in the presence of large amounts of foreign salts no breaks in potential were obtained at the equivalence point.

Experimental

Apparatus and Materials.—The indicator electrode was a spiral of bright platinum wire and the reference electrode was a saturated calomel cell of the type recommended by Müller and by Kolthoff and Furman.[15] This cell was connected by a long salt bridge of saturated potassium nitrate with the solution to be titrated, a long bridge being necessary because all titrations were performed at 70". The potentiometer was a Leeds and Northrup Potentiometric Unit, No. 4908. Titrations were made in open beakers using motor stirring and holding the temperature to within 1° of 70° with a small Bunsen flame.

Standard solutions of sodium fluoride of normalities 0.1000, 0.0100 and 0.0050 were prepared by the method used by Hawley[16] and by Allen and Furman.[17] Various amounts were measured out from calibrated pipets.

The cerous nitrate used was a C. P. product which was recrystallized once from water. The cerium content of the solution prepared was determined by oxidizing measured portions to the ceric state with ammonium persulfate using silver nitrate as a catalyst[18] and titrating back with ferrous sulfate which had been checked against standard potassium permanganate. Other analyses were made by evaporating down definite volumes of the solution and igniting the residue to constant weight; the cerium content of the ignited residue was then determined as above. Such analyses gave an average of 97.82% ceric oxide in the residue. The original cerous nitrate contained as impurities nitrates of the other rare earths but as Batchelder and Meloche[19] have pointed out such impurities may be disregarded and the normality of the solution calculated from the weight of the ignited residue, assuming it to be pure ceric oxide. In the present case this method was used since the other rare earth nitrates would change the normality of the solution to fluorine only by about 0.1%.

The potassium ferricyanide was used as an approximately 0.1 molar solution of a C. P. salt free from ferrocyanide. The cerous potassium ferrocyanide was precipitated by mixing equivalent volumes of cerous nitrate and potassium ferrocyanide and the precipitate was washed repeatedly with distilled water by decantation. This substance was used as a suspension in water. It is possible that the precipitate contained some $Ce_4[Fe(CN)_6]_3$, but this would not affect the results in any way.

Outline of the Method.—Some preliminary work had shown that cerous fluoride was precipitated in a gelatinous state and that it adsorbed excess cerous ions to a high degree; no gravimetric determination of fluorine as cerous fluoride could be made. This finding checks the results of Batchelder and Meloche.[8] On the other hand, at 70° and in a solution containing 50% ethyl alcohol by volume good results were secured by the potentiometric titration method. Other temperatures were tried but 70° gave the best results. This is about the same temperature that Atanasiu[13] used in his work. In accordance with the experience of Kolthoff with the sulfate titration, steady potentials were obtained only with 50% alcohol, other concentrations gave erratic readings. The procedure for the titrations recorded in Table I follows. The volumes of sodium fluoride

used were measured out by pipets and diluted with water and 95% ethyl alcohol so that the final volume contained 50% alcohol. The total volume of the solution titrated was 70–80 ml. for Titrations 1–22, 50 ml. for 23–34 and 25–30 ml. for 3544. Three to five drops of 0.1 *M* potassium ferricyanide (about 0.25 ml.) and about 10 mg. of the cerous potassium ferrocyanide suspension were then added. The exact amount of the ferrocyanide used may vary somewhat but it should be cut down for the smaller quantities of fluorine. The amount of ferricyanide must be kept fairly constant at the value given. The solution was then heated to 70° and the titration performed at that temperature, not deviating more than one degree. With a 50-ml. buret, volume increments of 0.05 ml. were used near the equivalence point and with the micro-buret the increment was 0.02 ml. The equivalence point was located by computing the difference quotients in the usual manner. With volume increments of 0.05 ml. the break in potential at the equivalence point ranged from about 20 millivolts for the larger amounts of fluorine to about 90 mv. for the smaller quantities. Volume increments of 0.02 ml. used in the case of the micro-buret gave breaks of 30-40 millivolts. The potential curve for Titration No. 40 is given in Fig. 1, and is typical of the course of the potential during every titration.

40–44	2.02	.19	0.476	.0216	.20	+ .01	+ .01

Discussion of Results.—The amount of fluorine that may be titrated by the method ranges from about 0.1 mg. to 50 mg. With a quantity greater than this upper value no break in potential is observed. This is undoubtedly due to the effect of a high salt concentration on the ferri–ferrocyanide potential, but the volume of the solution must not be too large as the method is a precipitation titration and depends on the separation of the cerous fluoride. 0.1 mg. is the lower limit set by the volumes that must be taken. In order to titrate an amount of fluorine smaller than this a more dilute solution of cerous nitrate would have to be used and then the dilution would be so great that the break in potential would not be observed at the equivalence point.

Cerous fluoride is less soluble than cerous potassium ferrocyanide so with large amounts of fluorine all of the ferrocyanide goes into solution as shown by the equation

$$3F^- + CeKFe(CN)_6 \longrightarrow CeF_3 + K^+ + Fe(CN)_6^{---}$$

As cerous nitrate is run in the excess fluoride is first precipitated and when this reaction is completed the ferrocyanide begins to reprecipitate. There is of course no indication of the completion of the cerous fluoride precipitation but since an amount of cerium equivalent to the fluoride precipitated in the beginning will be required for the ferrocyanide the correct equivalence point is shown by the break in the ferri–ferrocyanide potential. With small amounts of fluorine perhaps all of it is precipitated and the method then becomes simply a titration of ferrocyanide with cerous cerium.

The gelatinous nature of cerous fluoride and the presence of cerous potassium ferrocyanide cause poisoning of the platinum electrode. After several titrations the electrode responds very sluggishly and the magnitude of the potential breaks decreases rapidly, hence the electrode must be cleaned often by standing in cleaning solution, then washing with distilled water and igniting.

Interfering Substances.—Ions which give precipitates with cerous cerium must be absent, thus excluding hydroxide, carbonate, phosphate, etc. The solution cannot be acid, as the cerous potassium ferrocyanide is readily soluble in dilute acids. Large amounts of salts completely obscure the potential break but with only small amounts present the titration may be performed. In some experiments with 19 mg. of fluorine good results were secured in the presence of 0.5 g. of sodium chloride. Successful titrations were also made in the presence of 0.5 g, of potassium chloride, of sodium nitrate and potassium nitrate; 0.5 g. of sodium sulfate, however, completely obscured the potential break; in the presence of about 0.2 g. the determination could be made. The breaks in potential with solutions containing foreign salts are not as large as with solutions of pure fluorides. A solution of sodium fluoride containing 19 mg. of fluorine and 50 mg. of sodium silicate and another one with 32 mg. of sodium borate were neutral-

:ed to phenolphthalein and titrated. Potential breaks were secured but hey came at too large a volume of cerous nitrate.

The method was applied to the determination of the percentage of uorine in the Bureau of Standards sample of fluorspar, No. 79. The uorine was extracted by the Berzelius method using a double fusion as utlined In a previous paper.[17] Since the titration works well only with mall amounts of fluorine and foreign salts must be present in small concentrations, it was necessary to resort to the use of aliquot parts of the preared solutions of fluoride. The analyses are recorded in Table II.

TABLE II

DETERMINATION OF FLUORINE IN FLUORSPAR

Using micro-buret, $Ce(NO_3)_3$ 0.1080 *N*

Sample, g.	Tot. vol., ml.	Vol. for titr., ml.	Vol. $Ce(NO_3)_3$ A	B	C	% F A	B	C	Av. % F
0.2427	249.92	10.06	2.244	2.234	2.224	47.13	46.92	46.71	46.92
.3075	249.92	10.06	2.796	2.816		46.35	46.68		46.52
.3648	249.85	10.06	3.309	3.319	3.299	46.23	46.37	46.09	46.23

Average of all titrations, 46.56%. Bureau of Standards value, 46.20%.

The potential breaks at the end-points ranged from 15 to 25 millivolts for .02 ml. of reagent. The results run slightly high; this may be due to the oreign salts present or to a slight amount of carbonate which might not lave been removed. Considering the small samples involved in the taking f aliquots and the relatively high concentrations of sodium and potassium itrates in the solutions, the results exhibit a fair degree of accuracy.

Acknowledgment.—This work was done with the aid of a fellowship grant in analytical chemistry from the J. T. Baker Chemical Company of Phillipsburg, New Jersey. Gratitude is here expressed for this support.

Summary

A potentiometric titration method for fluorine involving the precipitation of cerous fluoride has been developed through a new application of the ferri–ferrocyanide electrode.

The method gives good results for amounts of fluorine ranging from 0.1 mg. to 50 mg. Small amounts of foreign salts may be present but large amounts mask the equivalence point. Ions which precipitate cerous cerium must be absent. Fluorspar has been analyzed by the method.

The Temperature Coefficient of the Photosensitized Hydrogen–Oxygen Reaction

BY HUGH S. TAYLOR AND DONOVAN J. SALLEY

The mechanism of the hydrogen–oxygen reaction at high temperatures has been the subject of considerable discussion recently. All of th schemes postulated for the reaction involve a chain, with either excite molecules or free atoms and radicals as propagating agents. One of th general characteristics of a chain reaction is that there exists a temperature region in which its reaction velocity does not obey the Arrheniu equation d ln $k/dT = E/RT^2$, but increases more rapidly with temperature than this law demands. Such a reaction is said to possess an ant Arrhenius temperature coefficient. This behavior arises from the fac that there will be superposed on the ordinary temperature effect, whic causes an increase in the number of reactions initiated, an additiona temperature effect due to increase in the length of each chain starte As a result of these two influences, the change of reaction velocity wit temperature cannot be expressed by a simple law.

The temperature coefficient of the direct photochemical hydrogen oxygen reaction has been measured by Andrejeff[1] and by Coehn an Grote[2] These investigators found that the value of k_{t+10}/k_t was onl 1.04–1.06 in the range 130–240°. Consequently, increase in temperatur did not result in marked increase in chain length in this temperature range Kistiakowsky[3] showed for the same reaction that, whereas the temperature coefficient was 1.05 at room temperatures, it increased to 1.25 a temperatures above 500°. Kistiakowsky concluded that over a considerable temperature range only short chains existed, but that above 500°, quite long chains were propagated in the illuminated gas mixture

More recently Farkas, Haber and Harteck[4,5] have determined the chain lengths in hydrogen–oxygen mixtures sensitized to light by ammonia Their work indicated that water formation proceeded by a chain, the length of which increased exponentially with temperature, as expressed by the empirical equation $l_t = 3\,e^{0.023(t-200)}$, where l_t is the chain length at the temperature t°C.[5] This gives at about 400° a chain of about 350 molecules of water for each hydrogen atom produced by light from the ammonia. Furthermore, explosions occurred at temperatures about 420' and oxygen–hydrogen pressures above 300 mm. These results would

indicate that the chains were lengthening rapidly as the temperature increased, becoming very long at comparatively low temperatures. To explain their findings, these authors used the Bonhoeffer–Haber mechanism of water formation,[4,5,6,7] which postulates chain propagation by means of hydrogen atoms and hydroxyl radicals. To explain the explosions, it was suggested in addition that chain branching could occur through a reaction producing two hydroxyl radicals.

Now, the results obtained in ammonia–hydrogen–oxygen mixtures are at variance with those of the direct photochemical reaction as measured by Kistiakowsky. The initial difference between the two reactions would seem to lie in the fact that following light absorption, hydrogen atoms are produced in the former whereas oxygen atoms are formed in the latter. The oxygen atoms must, however, react with the hydrogen by the step[8]

$$O + H_2 = OH + H \qquad (1)$$

Although reaction step (1) has a small activation energy, it should be completely efficient at about 400°. Therefore, if the Haber mechanism bc correct, both the OH radical and the H atom could initiate a chain. Consequently, it is to be expected that chain lengths in both the direct photochemical and the ammonia sensitized reaction should be about the same at comparable temperatures. This does not appear to be the case.

Hydrogen atoms can be produced at high temperatures from the action of excited mercury on molecular hydrogen. At ordinary temperatures, Marshall[9] has determined the chain length in the mercury sensitized hydrogen–oxygen reaction, finding an average value of 2.5 molecules per quantum. He also determined the temperature coefficient of the reaction to be 1.04 over a limited temperature range. In view of the discrepancy of the direct photochemical and the ammonia sensitized hydrogen–oxygen reaction, and because of the suitable character of the mercury sensitized reaction, a comparison of the temperature coefficients of the mercury sensitized and the ammonia sensitized reactions is of importance. The anti-Arrhenius behavior of the temperature coefficients should indicate the temperature at which long chains are set up in the reaction mixtures.

The Mercury Sensitized Reaction.—The experiments on the mercury sensitized hydrogen–oxygen reaction were carried out in a circulatory system, in order that the gases could be kept saturated with the mercury contained in a glass spiral saturator. The reaction vessel proper was of quartz, 10 cm. long, 1.8 cm. diameter, and 0.5 mm. wall thickness. It was kept at the desired temperatures by an electric furnace. The source of illumination was a water cooled Cooper–Hewitt mercury arc.

Starting in every case with a 2:1 $H_2:O_2$ mixture at 600 mm. total pressure, reaction rates were measured at various temperatures from 280 to 535°, and with mercury pressures of 0.0004, 0.0035, and 0.020 mm. Each individual reaction showed an induction period of one or two minutes, but thereafter progressed at a constant speed, measured by the slope of the straight line portion of the time–dp curves. In order to check the temperature coefficient from time to time, the light intensity of one series

of runs was taken as a standard, and other series (made with the same mercury pressure) were correlated with this standard.

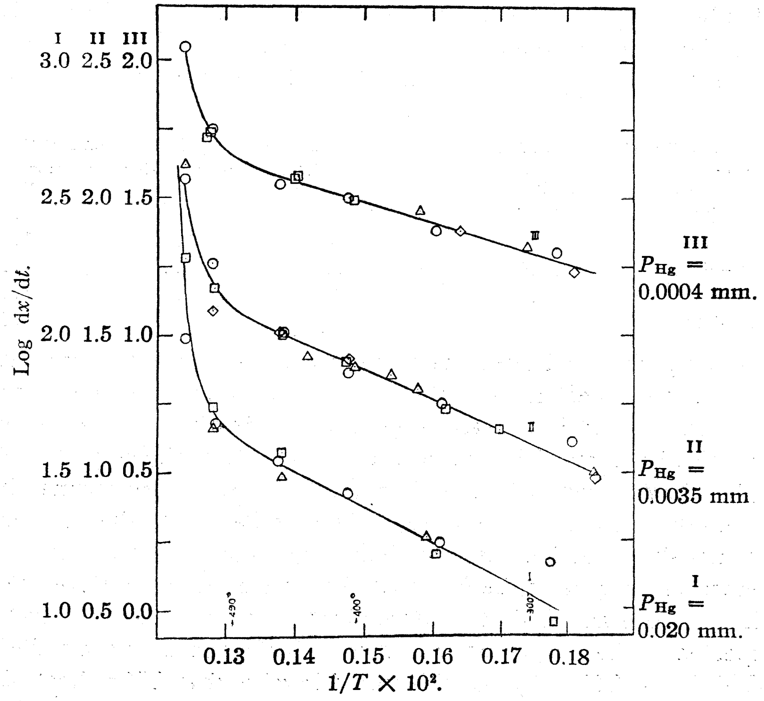

Fig. 1.—Variation of log dx/dt with $1/T$.

A reaction in the dark appeared at temperatures above 490° and amounted in some instances to as much as 25% of the total rate with light. The dark reaction velocity was subtracted from the total velocity in order to obtain the true light velocity.

The data are summarized in Table I, and represented graphically on a log dx/dt–$1/T$ plot, Fig. 1. (The figures under dx/dt were obtained by dividing the values under dp/dt by the ratio I/I_0.)

Discussion

A study of the data presented in the table and the figure reveals the fact that the temperature coefficient of the mercury sensitized hydrogen–oxygen reaction is anti-Arrhenius in character only above 490°. At lower temperatures, the temperature coefficient is small, and follows the Arrhenius law more or less closely. The value of the "constant" E of the Arrhenius equation, calculated from the slope of the curves of Fig. 1, increases from about 3000–5000 calories in the low temperature range to greater than 25,000 calories at high temperatures. The conclusion can, therefore, be drawn that below 490°, the length of the reaction chains does not change sensibly, but that at higher temperatures, the length of the chains increases very rapidly with increasing temperature.

This same conclusion was reached by Kistiakowsky[3] in regard to the direct photochemical reaction. For purposes of comparison with his results, the averaged temperature coefficients, k_{t+10}/k_t have been calculated for the photo-sensitized reaction, and are tabulated in Table II

TABLE II

TEMPERATURE COEFFICIENT OF HYDROGEN–OXYGEN PHOTOREACTION

Temperature interval, °C.	Photochem. reaction	Mercury photosensitized reaction P_{Hg}, 0.0004	0.0035	0.020
300–400	1.07	1.12	1.09	1.05
400–490	1.13	1.08	1.07	1.05
490–505	1.25	..	..	..
490–510	..	1.17	1.14	1.13
510–530	..	1.37	1.39	1.31

This comparison indicates that a very close agreement exists between the temperature coefficients of the photochemical and the mercury sensitized reactions, and it is reasonable to conclude that the two reactions are practically identical in this respect. Now, Kistiakowsky[3] has shown that the chains produced in both reactions were of approximately the same length at room temperatures. The similarity of the temperature coefficients shows further that the chain lengths are about the same at all temperatures, in spite of the fact that the oxygen atoms initiate the reaction in one case and hydrogen atoms in the other. Such a result is to be expected if the oxygen atoms produce hydrogen atoms by the reaction $O + H_2 = OH + H$, and this would involve that OH radicals do not participate in the chain at least below 490°.

It appears from these results that the mercury sensitized hydrogen–oxygen reaction does not show the characteristics reported by Farkas, Haber and Harteck for the ammonia sensitized reaction. In order to make a direct comparison of the two reactions, a study of the ammonia sensitized reaction was undertaken, using the same apparatus as described above for the mercury sensitized reaction.

The Ammonia Sensitized Reaction.—The ammonia used in the experiments on the ammonia sensitized hydrogen–oxygen reaction was supplied by solutions of ammonium hydroxide contained in a small efficient bubbler cooled in an ice-bath. This method of supplying the ammonia insured a constant partial pressure of both ammonia and water vapor during a run. The source of illumination was a Cooper Hewitt mercury arc, operated as a hot arc on 8 amperes and 80 volts.

Before presenting the main results and general discussion, one or two observations of interest should be reported.

The **Dark** Reaction.—When the experiments in this investigation were first commenced, no dark reaction was observable before illumination of the reaction mixture. However, after some fifty separate runs, a slow dark reaction could be detected preceding the light reaction, even at temperatures as low as 300°. When no experiments had been made for several days, on recommencing the runs this dark reaction would not appear for the first few experiments, but, thereafter, would be noticeable in the fresh gas mixtures.

A dark reaction was always observed after every light reaction. For the first minute or two after cutting off the light, the rate of this dark reaction was about 50% of the light rate, but then fell to a very small value. That a dark reaction persisted for a considerable time, however, was shown by permitting a mixture, in which reaction had been initiated previously by light, to stand for several hours in the dark. During this interval a pressure decrease occurred.

The Effect of Mercury.—Since mercury served as the valves and piston of the circulating pump, no attempt was made to remove the mercury vapor from the gases for these experiments with ammonia as a sensitizer. That no sensitization by mercury was taking place was shown by the fact that no reaction occurred in the absence of ammonia when the arc was operated hot. Moreover, the rate of the ammonia sensitized reaction was not affected by varying the partial pressures of mercury from 0.0004 to 0.020 mm. Although this determination was made only for the one partial pressure of ammonia of 14.5 mm., it has been assumed that the presence of mercury has no effect on the reaction rates at other ammonia concentrations.

The Effect of Temperature and of Ammonia Pressure.—Reaction rates for ammonia–oxygen–hydrogen mixtures sensitized to light were measured over a temperature range from 275–450°, and with partial pressure of ammonia from 1.3 mm. up to 97.5 mm. In every case the partial pressures of hydrogen and of oxygen in the system were 400 mm. and 200 mm., respectively. The pressure of water was at all times less than 5 mm.

The graph of an individual reaction indicated that an induction period of one or two minutes existed, after which the reaction proceeded smoothly at a constant speed, measurable by the slope of the straight line portion of the time–d*p* curve. The reaction rates were quite reproducible, checking within ±4%. Every effort was made to keep the light intensity and other conditions constant during the whole series of experiments, in order that the rates measured at various pressures of ammonia and at various temperatures could be compared directly. That constancy of conditions actually prevailed over a long time was indicated by checking the runs at a given partial pressure of ammonia (14.4 mm.) at intervals during the investigation. The complete data are collected in Table III, showing the reaction rate observed at each temperature and ammonia pressure. Most of the rate values recorded are the mean of two or more duplicate runs. (The values listed under d*x*/d*t* were obtained by dividing the figures under d*p*/d*t* by the ratio of 1/10.)

[a] These abnormally low values for which we have no explanation have been omitted in the graphical representation and in the conclusions drawn from these latter.

The Temperature Coefficient.—A plot of the data of Table III on a log dx/dt–$1/T$ graph, Fig. 2, shows that the reaction velocity of the ammonia sensitized hydrogen–oxygen reaction increases *from 300° upward* more rapidly with temperature than the Arrhenius equation requires. Although this effect is observed with all concentrations of the sensitizer, it is more pronounced when lower partial pressures are employed. The curve obtained with 2.5 mm. of ammonia is particularly striking in this respect.

No explosions were obtained at temperatures up to 435–440°, although the reaction rate was becoming so fast at these temperatures that it seemed likely that explosions might have occurred a few degrees higher.

The Effect of Ammonia Concentration.—The dependence of reaction rate on the concentration of ammonia is indicated in Fig. 3, in which dx/dt is plotted against the partial pressure of ammonia, at three different temperatures. The rate values used in constructing this graph were those read off for the desired temperatures from a graph of the temperature coefficients plotted from all the data of Table III.

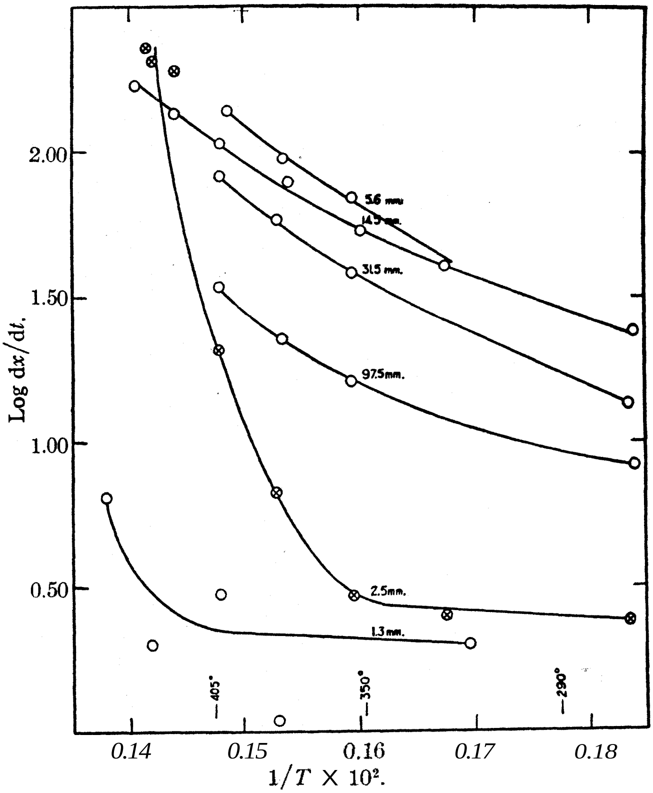

Fig. 2.—Variation of log dx/dt with $1/T$.

The curves indicate the remarkable dependence of reaction rate on the ammonia concentration. For any given temperature, there exists a concentration of ammonia at which the reaction rate is a maximum. The interpretation of this fact is that at concentrations of ammonia less than that required to give the maximum rate, the chain propagating influence of ammonia is effective, while at concentrations greater than the optimum, a chain breaking effect of ammonia becomes predominant.

The Chain Length.—In order to estimate the length of the chains occurring in the reaction, the rate of photodecomposition of ammonia was measured. Since this reaction is slow, and since the total volume of the system used for the ammonia sensitized hydrogen-oxygen reaction was large (280 cc.), a direct determination of the ammonia decomposition rate by following pressure change could not be made in that apparatus. Therefore, using the same reaction vessel and furnace, a small static system of total volume of 48 cc. was constructed in which to measure ammonia decomposition. The arrangement of arc, furnace and reaction vessel was the same in this apparatus as in the ammonia sensitized reaction, so that the conditions under which reaction took place were comparable in both cases. The same arc, operating at the identical voltage and amperage, was employed. Tank ammonia, purified by fractional distillation at low temperatures, was used in these experiments.

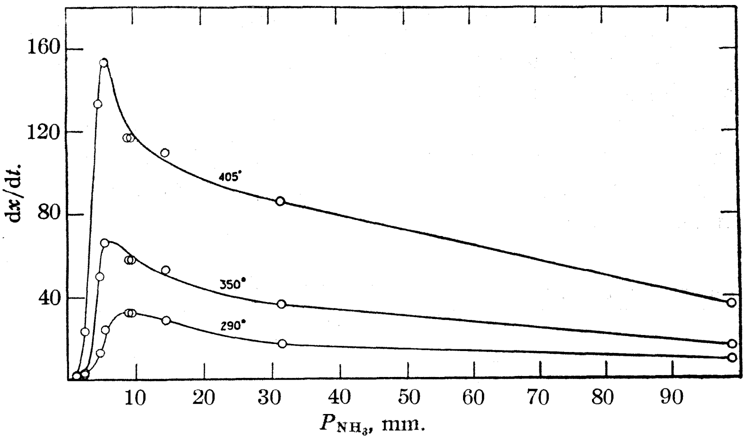

Fig. 3.—Dependence of reaction rate on ammonia pressure.

The rate of the photodecomposition was measured at temperatures from 300 to 450°, and at ammonia pressures from 10 to 100 mm. by following the pressure increase with a constant volume mercury manometer. It was found that the reaction rate fell off as the reaction progressed; consequently the pressure increase occurring in the first two minutes was taken as a measure of the rate of reaction. Also, practically no temperature coefficient was observed for the photodecomposition rate.[10] Consequently, in obtaining the dependence of rate on initial ammonia concentration, the rates observed at the several temperatures were all plotted against the pressure of ammonia. The smooth average curve drawn through all the combined data was of the form $dx/dt \propto I_{abs} = (1 - e^{-\alpha[NH_3]})$, indicating that the decomposition rate was directly proportional to the ammonia pressure in the low concentration range, and independent of the ammonia pressure at higher concentrations. Complete

absorption was achieved only at fairly high pressures of ammonia, for we were probably dealing only with the weak 2260 Å. ammonia absorption band.

A calculation was then made of the number of moles of ammonia decomposed in unit time in the photodecomposition of ammonia, and compared with the number of moles of water produced in the ammonia sensitized hydrogen-oxygen reaction. The ratio moles of water formed in unit time to moles of ammonia decomposed in unit time should be a measure of the length of the chain existing in the hydrogen–oxygen mixture at a given temperature, assuming that only the hydrogen atoms produced by light from the ammonia are effective in starting chains.[11]

The final figures are collected in Table IV. The first column gives the pressure of ammonia; the second the average number of moles of ammonia decomposed in unit time at any temperature from 290 to 430°; the third, the number of moles of water formed in unit time at 290° in the ammonia sensitized reaction; and the fourth, the ratio of the moles of water formed to the moles of ammonia decomposed. The remaining columns of the table give the corresponding data for the temperatures of 350 and 405°, respectively.

Discussion

A comparison of the results of our experiments on the mercury sensitized and the ammonia sensitized hydrogen–oxygen reactions indicates that the temperature coefficients of the two do not behave in the same manner, but are in fact quite divergent. However, our findings on the temperature sensitivity of ammonia–hydrogen–oxygen mixtures are essen-

---

[11] If the true quantum yield of the ammonia photodecomposition at these temperatures is 0.5, as reported by Kistiakowsky and Wiig, the true chain lengths in the ammonia sensitized reaction should be just one-half of the values reported for the ratio moles water formed to moles ammonia decomposed.

tially in agreement with those of Farkas, Haber and Harteck. This is shown by the following comparative data.

	Farkas, Haber and Harteck	Present work
Total pressure, mm.	500	600
Ratio, $H_2:O_2$	2:1	2:1
Pressure of NH_3, mm.	3	2.5
Molecules water formed per second at 290°	$a \times 10^{17}$	5.5×10^{15}
Molecules water formed per second at 405°	2.5×10^{18}	4.5×10^{16}
Ratio $\dfrac{\text{Molecules per sec. at } 405°}{\text{Molecules per sec. at } 290°}$	8.3	8.2

Our Table IV indicates that the so-called "chain length" is not constant at a given temperature, as it should be, but varies with the concentration of the sensitizer. This is very clearly brought out in Fig. 4, where the ratio moles water formed to moles ammonia decomposed, is plotted against the ammonia pressure. On the low pressure side of the maximum the ratio is dependent almost exactly on the square of the ammonia pressure, while on the high pressure side, the values are inversely proportional to the 1.3 power of the ammonia pressure. The fact that the "chain length" is not constant even at the lower pressures of ammonia, where its inhibiting effect does not enter, indicates the strong influence of the ammonia on the course of the reaction.

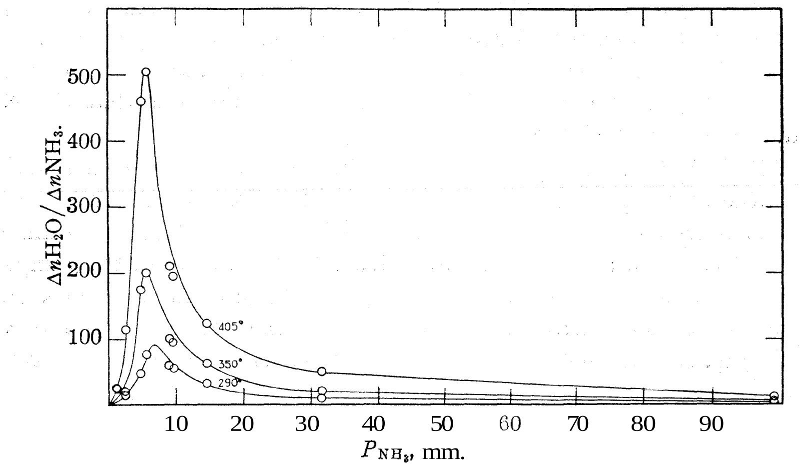

Fig. 4.—Dependence of the ratio, moles of water formed to moles of ammonia decomposed, on the ammonia pressure.

From the facts brought out above, it seems clear that sensitization of hydrogen-oxygen mixtures by ammonia is not simply a case of initiation of reaction by hydrogen atoms. On the contrary, the reaction mechanism must be much more complicated. We suggest as possibilities that NH_2 radicals, and intermediate oxidation products of these, are helping to propagate long chains. It was pointed out some time ago[12] that with oxygen as one of the reactants in the system, there is always the possibility that primary interaction of oxygen with ammonia might influence the course of any reaction in which ammonia was used as a sensitizer. In work with other sensitizers, hydrogen sulfide, hydrogen bromide, etc., for the hydrogen–oxygen reaction, Farkas, Haber and Harteck[13] find that the sensitizer not only produces hydrogen atoms but also enters into oxidation reactions. In preliminary experiments on the photochemical oxidation of ammonia, we find that the rate of removal of ammonia when oxygen is present is three or four times as fast as the photochemical decomposition of ammonia under the same conditions when oxygen is absent. This implies that the photochemical oxidation of ammonia is a chain reaction which may be involved in the mechanism of the ammonia sensitized hydrogen-oxygen reaction. It is known that nitrogen dioxide has an enormous accelerating influence on the explosibility of hydrogen–oxygen mixtures, but evidence indicates that its action may be due to a wall effect. While the possibility of its intervention in the ammonia sensitized reaction cannot be excluded, we incline to the view that the NH_2 fragments are primarily responsible.

As the result of the investigation of the ammonia sensitized reaction, the source of the divergence between it and the mercury sensitized reaction has been located. The appearance of long chains in the ammonia sensitized reaction at temperatures at least 100° lower than the temperature at which they appear in the mercury sensitized or direct photochemical reaction is accounted for by the fact that the ammonia itself powerfully influences the course of the reaction, whereas the mercury has no similar effect.

Since, as is apparent from the preceding considerations, the ammonia and its decomposition products are important factors in determining the length of chain at a given temperature, it is evident that the results obtained from the sensitization experiments with ammonia cannot be used to determine the efficiencies of postulated reactions in the hydrogen–oxygen reaction chain. This has been done by Frankenburger and Klinkhardt, who used the chain length in the ammonia sensitized reaction as a function of temperature as a measure of the activation energy of the reaction $OH + H_2 = H_2O + H$. Had this been correct, the mercury sensitized reaction would have shown a similar temperature variation in the same temperature range. No such is observed. Furthermore, the ammonia concentration markedly affects the temperature variation. No significance attaches, therefore, to the value of 12,000 calories deduced thus for the activation energy, and the arguments based by Frankenburger and Klink-

hardt on this value are correspondingly weakened. This conclusion has been independently reached by Haber and Oppenheimer,[14] who note marked differences between the ammonia sensitized reaction and that initiated by atomic hydrogen from a tungsten arc. While we agree with their conclusion, we believe that their observations with the tungsten arc must be similarly suspect since they show abnormal sensitivity with temperature when compared with our mercury-sensitized and the photochemical reaction. We suspect a reaction accelerated by tungsten dust from the atomic hydrogen arc as the cause of Haber and Oppenheimer's results.

Summary

1. The temperature coefficients of the mercury sensitized and the ammonia sensitized hydrogen–oxygen reactions have been measured at high temperatures.

2. The temperature coefficient of the ammonia sensitized reaction is anti-Arrhenius at temperatures above 300° while that of the mercury sensitized reaction is anti-Arrhenius only above 490°, indicating that a marked increase in chain length occurs at a much lower temperature in the case of ammonia–hydrogen–oxygen mixtures.

3. The temperature coefficients of the mercury sensitized and the direct photochemical reactions of hydrogen and oxygen are shown to be comparable over the whole temperature range. It is suggested that the chain mechanism of the reaction is the same whether initiated by atomic oxygen or atomic hydrogen.

4. The rate of reaction in mixtures of hydrogen and oxygen sensitized by ammonia is markedly dependent on the concentration of ammonia. At low concentrations, a chain propagating influence of ammonia is effective; at high concentrations, a chain breaking effect of ammonia becomes predominant.

5. Sensitization of hydrogen–oxygen mixtures by ammonia is not simply a case of initiation of reaction by hydrogen atoms. It is suggested that NH_2 radicals and intermediate oxidation products of these help to propagate the chains.

6. The cause of the divergence of the ammonia sensitized from the mercury sensitized reaction of hydrogen and oxygen is ascribed to the powerful influence of ammonia on the course of the reaction.

The Production of Hydrogen Peroxide in the Mercury Sensitized Hydrogen–Oxygen Reaction

BY J. R. BATES AND D. J. SALLEY

In spite of a large number of investigations there still seems to exist considerable doubt as to the mechanism whereby oxygen reacts with hydrogen atoms produced by different methods.[1] Still more striking is the fact that there is no agreement among the various workers as to the primary products of the reaction. Bates and Taylor[2] reported that in the mercury sensitized reaction, which is generally conceded to go through the intermediate stage of atomic hydrogen, they were able to show hydrogen peroxide to be the sole product. This fact was in complete agreement with the mechanism originally suggested by Taylor and Marshall, which may be written

$$\begin{array}{lr} Hg' + H_2 \longrightarrow Hg + 2H & (1) \\ H + O_2 \longrightarrow HO_2 & (2) \\ HO_2 + H_2 \longrightarrow H_2O_2 + H & (3) \\ H + H \longrightarrow H_2 & (4) \end{array}$$

This mechanism has chain characteristics and, therefore, can have a quantum yield of hydrogen peroxide of any magnitude, depending upon the relative efficiency of the processes involving oxidation compared with the recombination of hydrogen atoms. Thus if (2) and (3) are relatively rapid and (4) is slow, we might have chains much greater than unity, while if the reverse were true, yields of unity or less might be expected.

Another possible mechanism was postulated by Bonhoeffer and Haber[3]

$$\begin{array}{lr} H + O_2 \longrightarrow HO_2 & (2) \\ HO_2 + H_2 \longrightarrow H_2O + OH & (3a) \\ OH + H_2 \longrightarrow H_2O + H & (4a) \\ OH + OH \longrightarrow H_2O_2 & (5a) \end{array}$$

We see that the initial process is the formation according to (3a) of water and an hydroxyl group. The latter may react according to (4a), giving water and hydrogen atom, again a chain process. If, however, the latter process required a large activation, it would occur so seldom as to allow practically all of the hydroxyls to form hydrogen peroxide according to (5a). If the latter condition exists, the quantum yield of hydrogen peroxide formation is unity, and, what is most important, there are formed

simultaneously at least two molecules of water. There must appear, therefore, at least **51.4** weight per cent. of water in the products. This mechanism has received general recognition, in spite of the work of Bates and Taylor already cited, and of Bonhoeffer and Boehm,[4] who found **75%** of hydrogen peroxide in the products of the reaction of molecular oxygen with hydrogen atoms produced by a discharge.

Another possible point of divergence is the quantum yield of hydrogen peroxide. If this were of a magnitude greater than unity the Haber mechanism would be ruled out. **A** yield, however, of unity or less would be entirely inconclusive. Marshall's measurements of the quantum yield[4a] gave a value of 6.6. More recently Frankenburger and Klinkhardt have redetermined this magnitude and find a value near unity, which they advance as strong proof of the Haber mechanism. Since, however, they find that in fifteen out of twenty-three experiments recorded the value was somewhat greater than unity, these authors have introduced an alternative reaction to (3a)

$$HO_2 + H_2O \longrightarrow H_2O_2 + OH \qquad (6a)$$

This would lead to a quantum yield of three, and they then explain their high values by suggesting that both (3a) and (6a) take place, giving a value intermediate between 1 and **3.** This supposition rules out the later work of Marshall[5] as a basis for distinguishing between the two mechanisms, because he used moist gases in obtaining **100%** hydrogen peroxide formation.

It immediately appears that considerably more importance is to be attached to the early work, which showed hydrogen peroxide as the sole product in dry gases, than was supposed at that time. This work has, therefore, been repeated with great care with a view to settling this point and thereby differentiating between the two postulated mechanisms. The great frequency with which the Haber mechanism has been introduced into various reaction kinetics during the past years makes this simple yet crucial experiment seem of great importance![6]

The effect of water vapor on the production of hydrogen peroxide ha. also been studied in an effort to test the validity of reaction (6a).

Experimental

Tank hydrogen and tank oxygen were used without purification, since the possible impurities, nitrogen, etc., have been shown by Marshall to be without effect on the reaction.

Monograph No. 57, p. 121.

In all the experiments a flow system was used. The rate of flow was measured by flowmeters previously calibrated against a standard gasometer. The gases, before entering the reaction zone, were separately bubbled through wash bottles containing mercury, and, after the streams of hydrogen and oxygen were united, they were once more bubbled through mercury to ensure saturation and complete mixing. The gas mixture was then either dried over phosphorus pentoxide, or else passed through a medium which regulated the water vapor pressure to a desired amount. On leaving the illuminated zone, the gases were led into a trap or traps immersed in liquid air. Quartz to Pyrex seals and ungreased ground glass joints were used to prevent as much as possible any decomposition of the peroxide which might occur from contact with rubber or other foreign materials.

Two methods of illumination were employed. In the first, an ordinary vertical arc of the Cooper–Hewitt type was immersed in a water-bath maintained at 14°. Surrounding this, and also under water, was a quartz spiral of 4.5 cm. diameter, made of 140 cm. of 5-mm. bore quartz tubing. The arc burned at 6 amperes and 21 volts. The second method of illumination made use of the special type of mercury arc described in detail by Bates and Taylor.[2] The reaction tube is surrounded by the arc, and the gases flow through in a straight line. In our set-up, the reaction tube was of quartz, 8 mm. in bore and 40 cm. long.

Procedure

In making a run, the arc was first started and allowed to come to a constant condition. The gases were turned on, and their rates of flow adjusted to the desired values; they were not permitted to flow through the reaction zone until a moment before a run was started, in order to avoid as much as possible the formation and deposition of mercuric oxide at the outlet from the reaction zone, since it was found that an accumulation of this yellow oxide materially reduced the yield of hydrogen peroxide. When all was ready, the gases were passed through the reaction zone for one minute, and the trap, previously weighed and now immersed in liquid air, was attached by the ground glass joint to the outlet. In order that frost should not form at the outlet and later melt and run back into the trap, the off-gases were led out through a length of rubber tube attached to the trap. After the reaction had been permitted to proceed for the desired time (usually ten minutes), the trap was removed from the liquid air, warmed up to room temperature and weighed. The reaction products were then rinsed out with distilled water, and titrated for hydrogen peroxide with 0.1 *N* potassium permanganate. The operations of weighing and titration were carried out as expeditiously as possible in order to minimize the amount of peroxide decomposed during the time. From the total weight of the product, and the amount of hydrogen peroxide as determined in the titration, the percentage yield of the hydrogen peroxide could be calculated.

Experimental Results

Dry Gases.—It has been stated previously that the gases were dried in the experiments by passing them over phosphorus pentoxide. In order to indicate the efficiency of this process several blank runs were made at various times during the investigation, and in no instance was any weighable moisture frozen out in the traps.

The results with the quartz spiral and small mercury lamp are recorded in Table I, experiments 1 to 7. Various rates of flow and different ratios of hydrogen to oxygen were tried. It was observed that mercury oxide was deposited on the last coil of the spiral and that it considerably decreased the peroxide yield from any subsequent run. Consequently, the practice was adopted for the later experiments of cleaning out the spiral with dilute nitric acid before each test. The data show that in all except the first two experiments, the weight per cent. of hydrogen peroxide in the product was greater than the 50% yield to be expected according to Frankenburger. In one instance it was as high as 75%.

Using the special type of mercury arc, more experiments were carried out with dry gases. A rate of flow of about 135 liters per hour and an eight to one hydrogen to oxygen mixture gave the best results. Here as with the other set-up an accumulation of mercury oxide at the outlet of the reaction zone cut down the peroxide yield. The results are shown in Table I, experiments 12 to 21.

Experiments 1 **to** 7 **with quartz spiral; experiments** 12 **to** 21 with **special arc.**

They indicate that again more than **50%** by weight of peroxide could be obtained, and that in fact a yield of over **80%** was found in two cases.

It seemed possible that in the freezing-out process hydrogen peroxide might be trapped more easily than water, thereby leading to high peroxide yields. It was not expected that a preferential condensation of the peroxide could be occurring by reason of a difference in vapor pressure of the two substances for at liquid air temperatures the vapor pressures of both must be negligibly small. Nevertheless, a purely mechanical separation might be effected, for while the peroxide might be trapped out completely, the water might be caught only partially, since it is known that water tends to be carried through a liquid air trap in the form of a mist or "snowstorm."

Consequently, a second trap (Trap No. 2) of the ordinary type was attached in series with the first (Trap No. 1) by means of a ground glass joint, and more experiments were made. These showed that a considerable quantity of the product was carried through the first trap and caught in the second. But what is more to the point, the water was as readily trapped out as the peroxide, for the percentage of the latter was the same in both traps. Table II, experiments 2 to **23,** contains a **résumé** of these results. In this set of experiments, peroxide yields as high as 88% were obtained, while the average of seven tests was 82.5%.

Inasmuch as all the product might not be caught even in two traps, the second was replaced by another trap of *a* different type. This consisted of a series of five U-tubes made from a single long length of 6-mm. Pyrex tubing. The bends were made sharply so that all five could be put into one Dewar flask containing the liquid air. This multiple trap was attached to the first by a ground glass joint, so that in reality there were six traps in series. During a run, the top bends of the multiple trap were kept warm by a blast of hot air. Thus any "snowstorm" of water or peroxide must have been melted during its passage from one U to the next, thereby ensuring a more complete condensation of the product.

In accordance with expectations, experiments showed that a large portion of the total amount of the substance was frozen out in this multiple trap. Liquid was condensed in progressively smaller amounts on each down tube of the successive U's. On the fourth down tube, the amount condensed **was** just visible, while on the last, little or no product was observable. The conclusion was reached that with this device essentially complete recovery of the product was accomplished. As in the previous work with the double trap the percentage of hydrogen peroxide **was** the same in the multiple as

Double trap, runs 2 to 23; multiple trap. runs 29 to 41.

in the first trap, indicating again that the peroxide was not preferentially condensed. The data are tabulated in Table II, experiments 29 to 41.

The results of all the preceding experiments with dry gases demonstrate conclusively that 85% by weight of hydrogen peroxide can be obtained easily in the condensable product from the mercury sensitized hydrogen–oxygen reaction.

Moist Gases.—In the first experiments to determine how moisture in the gases influences the hydrogen peroxide yields, only the total amount of peroxide appearing in the product was ascertained. Alternate runs were made, using first dry and then moist gases, in order to bracket and check the results. To regulate the moisture in the gases, they were by-passed either through a long tube containing granular calcium chloride, or through a trap containing cracked ice, the trap itself being maintained in an ice-bath. These two environments ensured a partial pressure of water in the gases of about 0.4 mm. and 4 mm., respectively. When using ice to maintain the water vapor pressure, the ice trap was put in the gas train before the mercury saturators in order that the mercury pressure in the gases might not be altered.

The observations obtained using the special type of mercury arc as a source of illumination are recorded in Table III, experiments 18a to 18f indicating the results with 0.4 mm. of water, experiments 19a to 20c with 4 mm. of water.

TABLE III

RUNS WITH MOIST GASES AND SPECIAL ARC

No	Condition of gases	Rate of flow liters/hr. O_2	H_2	Ratio H_2/O_2	Time of run. min.	H_2O_2, mg.

20c	Dry	12	130	11:1	10	8.7
Gases dried over phosphorus pentoxide. Gases wet over ice.						

As examination of the results apparently indicates that when the lower pressure of water was used, the peroxide yield was very slightly increased over that obtained with *dry* gases. However, but little trust is to be placed in this conclusion, since the magnitude of the observed differences between the yields with wet and dry gases may be within the experimental error. Certainly with the higher concentration of water, no differences between the wet and dry runs are to be found, since the amounts of peroxide procured in the alternate runs agree well within the experimental deviation.

A number of runs, in which two traps were placed in series to catch the products, were conducted using moist gases. In these experiments, only calcium chloride was used as a means for regulating the moisture content of the gas mixture. The amount of water which could be recovered from the moist gases was ascertained by making several blank runs. Such a determination was accomplished by weighing the water caught in the two traps, and also by observing the increase in weight of a small phosphorus pentoxide tube attached directly to the outlet from the reaction zone. The phosphorus pentoxide tube caught about 1 mg. more moisture than the total amount found in the two traps. This was not surprising in view of the fact, already shown, that two traps cannot catch all the product. The amount of water recovered was about that to be expected if 0.3 to 0.4 mm. partial pressure of water existed in the gases. The results given in Table IV, experiments 12 to 22, are to be compared with those of Table II, experiments 1 to 23, for the runs with the moist gases were alternated with those of the dry gases recorded in that table. In Table IV, the amounts of moisture collected in the blank runs are also recorded, experiments 4 to 24.

These results indicate very definitely that with 0.4 mm. of water vapor in the gases, the total hydrogen peroxide yield is not altered to an observable extent. Moreover, since the ratio H_2O_2 in No. 1/H_2O_2 in No. 2, is the same whether the gases be originally wet or dry, it is apparent that the presence of water does not affect the relative amounts of hydrogen peroxide caught in the two traps. This conclusion is also warranted by the fact that the percentage yields of hydrogen peroxide recorded in Table IV are identical for both traps.

Finally, the work was repeated using the multiple trap. Here again, a study of the data of Table IV, experiments 36 to 43, together with those of Table II, experiments 29 to 41, shows that moisture in the gases does not increase the yield of hydrogen peroxide nor alter the relative amounts of product caught in the respective traps.

Using ice as the medium to supply the moisture some experiments were carried out with the quartz spiral set-up. Alternate runs with wet and dry gases were made, only the total amount of hydrogen peroxide formed being determined. It appeared that with this particular experimental arrangement, the total amount of peroxide was actually reduced more than 40% by the presence of 4 mm. of water in the gases. We have no explanation for this result, but present it as further evidence that hydrogen peroxide is decomposed during the course of the reaction.

Discussion of Results

It is quite obvious that the original Haber mechanism is not capable of accounting for percentage yields of hydrogen peroxide of the order of 85%. Thus we can rule this out as giving a complete description of the processes occurring in the reaction. It should be emphasized that the values of the percentage composition of peroxide in the products are minimum values. All experimental errors would tend to decrease it. For example, in weigh; ing the trap in which the products are condensed after drying at room temperature or above, then immersing it in liquid air and again weighing after allowing it to warm up and drying with a towel, it would perhaps be expected that the weight in the latter case might be higher than the former due to condensation of moisture from the atmosphere. This would result in an apparent increased total weight of products and consequently a smaller observed percentage of peroxide.

Any objection to these results based upon the supposition that the peroxide is caught preferentially and water allowed to go through the trap is ruled out by the facts that the same percentage of peroxide is found in subsequent traps as in the first and also that in moist gases the water is caught as well or better than peroxide.

It is to be observed that, since we have been able to show the products of the reaction to consist of from 85–100% hydrogen peroxide, as compared with the smaller percentage reported by Frankenburger and Klinkhardt, their quantum yield must have been higher than their calculations show. Most or all of the water reported by these authors in their products must result from subsequent decomposition of peroxide. This would mean that their quantum yield of peroxide is in reality at least **3** molecules per quantum. These authors did not report the water formed in their individual experiments. If, therefore, the two to one ratio of water to hydrogen peroxide, which they claim to be present in some runs, persisted in all their runs, then in reality they were obtaining average values of **3.6** and maximum values up to **6** molecules per quantum. Such values would be in good agreement with those reported by Marshall. Furthermore, mercury is known to bring about decomposition of hydrogen peroxide? Indeed, we have actual proof that this occurs to some extent. When the products in the trap are first observed mercury appears as a black deposit. After warming and weighing this can be seen to have changed to the characteristic yellow of mercuric oxide. Due to these facts, together with the possibility of decomposition in the reaction zone, of which there is evidence in the appearance of mercuric oxide, the authors are inclined to the view that hydrogen peroxide is the sole primary product of the reaction.

However, the suggestion of Frankenburger and Klinkhardt that the reaction

---

(7) Elder and Rideal, *Trans. Faraday Soc.*, **23**, 550 (1927).

$$HO_2 + H_2O \longrightarrow H_2O_2 + OH \qquad (6a)$$

might play a part in the reaction must be considered in some detail in order to see if this process will account for the high peroxide yields, even in dry gases. This suggestion may be formulated

$$K_1 \quad HO_2 + H_2 \longrightarrow H_2O + OH \qquad (3a)$$
$$K_2 \quad HO_2 + H_2O \longrightarrow H_2O_2 + OH \qquad (6a)$$

Reaction (3a) gives rise to one molecule of water and one-half molecule of peroxide; reaction (6a) to three-halves molecules of peroxide. We may then write

$$d\,\frac{[H_2O_2]}{dt} = \frac{[HO_2]\,[H_2]}{2}K_1 + \frac{3[HO_2]\,[H_2O]}{2}K_2$$

$$d\,\frac{[H_2O]}{dt} = [HO_2]\,[H_2]\,K_1 - [HO_2]\,[H_2O]\,K_2$$

dividing, we obtain

$$\frac{d[H_2O_2]}{d[H_2O]} = 1/2\,\frac{([H_2]\,K_1 + 3[H_2O]\,K_2)}{[H_2]\,K_1 - [H_2O]K_2}$$

$$2[H_2O_2] = \int_{[H_2O_0]}^{[H_2O_E]} \frac{[H_2]\,K_1 + 3[H_2O]\,K_2}{[H_2]\,K_1 - [H_2O]\,K_2}\,d[H_2O]$$

where $[H_2O_0]$ is the initial water concentration, and $[H_2O_E]$ the final. Integrating, and taking the limits, we obtain

$$2[H_2O_2] + 3([H_2O_E] - [H_2O_0]) = 4K\ln\frac{K - [H_2O_0]}{K - [H_2O_E]} \qquad (A)$$

where $K = K_1[H_2]/K_2$, and $[H_2]$ is considered constant.

If now we take the average values for $[H_2O_2]$, $[H_2O]$, and $[H_2]$ as found from the data in Table II, runs 2–23, and express them in mm., we find $[H_2O_0] = 0$, $[H_2O_E] = 0.122$ mm., $[H_2O_2] = 0.359$ mm., $[H_2] = 675$ mm. These substituted in equation (A) give $K = 0.144$, or $K_2/K_1 = 4700$, which means that HO_2 would react at least 4700 times as fast with H_2O as with H_2, or that the activation energy of reaction (3a) would be some 5.0 Cal. greater than reaction (6a), which is not at all an impossible result, in spite of the fact that process (3a) is some 80 cal. more exothermic than (6a).

However, if we now take the data from Table IV (runs 12–22) in which moist gases were studied and find the pressures of the reactants and resultants, we find $[H_2O_0] = 0.360$ mm., $[H_2O_E] = 0.482$ mm., and $[H_2O_2] = 0.371$ mm. as the average values. These give a $K = 0.76$, over five times the value determined in the dry gases, a difference which is much larger than the experimental error, and indicates that water has no effect on the reaction. The above data used in the calculations of K_2/K_1 are those of our results which present the most favorable case for the Frankenburger mechanism. However, only about 75% of the total product was caught using the double trap, so the value of the partial pressure of H_2O_2 and H_2O used in the above calculations should be increased some 25%. This does not change to any great extent the value of K_2/K_1 calculated for the dry gases, but makes the discrepancy between the constants in the dry and moist gases even more marked. This is shown by taking the data from Table II, runs 31-41, and Table III, runs 36 to 43, where, for the dry gases $[H_2O_2] = 0.465$ mm., $[H_2O_0] = 0$, $[H_2O_E] = 0.164$, whence $K = 0.195$; for the moist gases, $[H_2O_2] = 0.405$ mm., $[H_2O_0] = 0.360$ mm., $[H_2O_E] = 0.665$, where $K = 1.75$. Thus K for the wet gases is some 9 times greater than K for the dry, which is somewhat greater than that obtained above. This can also be indicated from the fact that the amounts of hydrogen peroxide and water produced in the moist gases are practically the same as those in dry gases, in spite of the increase in water concentration, thus 0.371 mm. as against 0.359 mm., and 0.482—0.360 = 0.122 mm. According to the value of K obtained from the dry gases, we should expect, if this were the true mechanism, that the water concentrations should have actually decreased in the moist gases experiments. This can be seen from the fact that at equilibrium

$$[H_2]\,K_1 = [H_2O]\,K_2$$
$$[H_2O] = [K_1]\,[H_2]/K_2 = K = 0.144$$

Therefore, starting with $[H_2O_0] = 0.360$, we should expect $[H_2O_E]$ to lie between 0.360 and 0.143, instead of being greater than 0.360. Thus we can find no support for the Haber mechanism as modified by Frankenburger and Klinkhardt.

The mechanism of Marshall and Taylor has been criticized by Frankenburger and Klinkhardt for two reasons. First, they object because it postulates the necessity of an association reaction

$$H + O_2 \longrightarrow HO_2 \qquad (2)$$

But this actually has no basis, since the other mechanisms have the same assumption. The three-body reaction is in reality two consecutive bimolecular reactions, with the additional requirement that collision of the quasi-molecular association with its next reaction partner must come within its life-time, whatever that may be. The second criticism is that, if we assume that the two hydrogen atoms which add to oxygen each result in 69 cal. of energy, the reaction

$$HO_2 + H_2 \longrightarrow H_2O_2 + H - 31 \qquad (3)$$

would be 31 calories endothermic. On the same basis the reaction

$$HO_2 + H_2O \longrightarrow H_2O_2 + OH - 42 \qquad (6a)$$

would be 42 calories endothermic.

A further objection that reaction (3) would never take place, because the hydrogen atom would react with the hydrogen peroxide to give the more exothermic result

$$HO_2 + H_2 \longrightarrow H_2O + OH + 33 \qquad (3a)$$

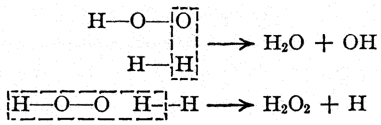
or

$$H + O_2 + H_2 \longrightarrow H_2O + OH + 112$$

instead of

$$H + O_2 + H_2 \longrightarrow H_2O_2 + H + 38$$

is not justified. Reaction (3a) most probably requires a higher activation energy than reaction (3), because in general the activation energies of processes involving a mutual interchange of partners and the breaking of two bonds are greater than those of simple replacement



$$\mathrm{H{-}O{-}O} + \mathrm{H{-}H} \longrightarrow H_2O + OH$$

$$\mathrm{H{-}O{-}O\ \ H{-}H} \longrightarrow H_2O_2 + H$$

The calculation of the activation energy of the reaction $OH + H_2 \longrightarrow H_2O + H$ from Frankenburger and Klinkhardt's data, used by them to support the validity of their assumptions, is of no value for two reasons. First, we have shown that it is possible to obtain very high peroxide percentages which would invalidate their results and second the value of this energy obtained from the data of Farkas, Haber and Harteck, and with which they found agreement, is now recognized as not being characteristic of this process at all.[8] The present authors see no necessary connection between reactions in the gas phase and the cathodic formation of hydrogen peroxide at a rate of one mole per mole of hydrogen ions liberated, which Frankenburger and Klinkhardt advance as support for their mechanism. However, even granting a correspondence between the cathodic and gas phase reactions, we can see no discrepancies between this equivalence and the mechanism postulated on page 110.

The original mechanism of Taylor and Marshall meets with none of these difficulties and the authors are inclined to believe it to be the true one. Since this reaction scheme has chain characteristics, why are the quantum yields of both Marshall, and Frankenburger and Klinkhardt so low? This difficulty can be met by a slightly modified mechanism. The heat of formation of hydrogen peroxide from $H + H + O_2$ is 138 kilocalories. Assuming that this energy is divided equally between the two steps *(2)* and (3), the complex HO_2 is endowed with 69 calories at the instant of its formation. It is, therefore, an activated molecule, and may have an appreciable life. If its first collision after formation is with a hydrogen molecule, the reaction to give H_2O_2 and H can easily take place, since the internal energy of the complex can overcome the endothermicity of the reaction step.

A series of possible processes could be

$$H + O_2 \longrightarrow HO_2' \qquad (2b)$$

$$HO_2' + Hz \longrightarrow H_2O_2 + H \qquad (3b)$$

$$HO_2' + O_2 \longrightarrow HO_2 + O_2' \qquad (6)$$

$$\text{or } HO_2' + O_2 \longrightarrow H + 202 \qquad (7)$$

$$\text{or } HO_2' \longrightarrow H + O_2 \qquad (8)$$

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2 \qquad (9)$$

$$H + H \longrightarrow H_2 \qquad (4)$$

---

(8) Haber and Oppenheimer, Z. *physik.* Chem., **16B**, 443 (1932); unpublished work in this Laboratory; see Taylor and Salley, THIS JOURNAL, **55**, 96 (1933).

Such a mechanism involving activated complexes can explain the shortness of the chains at room temperature. Steps (6) and (8) indicate how the complex might be deactivated or disrupted; either process tends to give (9) and (4) more chance to take place. Step (9) might very possibly occur predominantly as a wall reaction, since this reaction is neither exothermic nor endothermic, but may require an activation energy. Any part of the reaction which goes through step (9) gives rise to one molecule of peroxide per quantum. If hydrogen atoms recombine according to (4) there is no yield of peroxide. Both of these reactions would, therefore, tend to lower the observed quantum yield.

These considerations have been based on the assumption of Frankenburger and Klinkhardt, that both hydrogen atoms adding to oxygen give the same energy. If, however, as is possible, the second hydrogen gives rise to a greater energy liberation, the endothermicity of reaction (3) is decreased. If the first hydrogen-oxygen bond were 38 cal. and the second 100 cal., reaction (3) would have no heat of reaction. This reaction would then occur on every collision if there were no activation energy involved. Considerations of this type, however, will lead us nowhere with our present lack of knowledge of the relative magnitude of these hydrogen–oxygen linkages.

It must not be forgotten that in the mercury sensitized reaction, mercury hydride, HgH, may be playing a role. A possible mechanism would be as follows

$$Hg' + H_2 \longrightarrow HgH + H \qquad (1a)$$
$$HgH + O_2 \longrightarrow HgO + OH \qquad (11)$$
$$H + O_2 \longrightarrow HO_2 \qquad (2)$$
$$HO_2 + H_2 \longrightarrow H_2O + OH \qquad (3a)$$
$$OH + OH \longrightarrow H_2O_2 \qquad (5a)$$
$$H + H \longrightarrow H_2 \qquad (4)$$

For every quantum of light absorbed, one hydrogen peroxide molecule and one water molecule would be formed, leading to a yield of 65% by weight of peroxide. However, even this is lower than the observed 85% yield, and so cannot account completely for the observed results. If some hydrogen atoms recombined, the peroxide percentage might be increased. This, however, would give rise to a quantum yield even less than unity. Further, mercury atoms are known to absorb many quanta of light in passing through the reaction zone, which would be improbable if mercuric oxide were formed in the process. For several reasons, then, we can eliminate such a mechanism.

The authors wish to thank Professor Hugh S. Taylor for his interest and valuable assistance in this work.

Summary

1. The yield of hydrogen peroxide from the mercury sensitized hydrogen–oxygen reaction is greater than 85%. The water formed is ascribed in

the main to secondary peroxide decomposition. It is concluded that hydrogen peroxide is the sole product of the reaction significant as regards reaction mechanism.

2. The yield of hydrogen peroxide is unaltered by the presence of water vapor in the gases. As a consequence, the reaction step $H + O_2 + H_2O = H_2O_2 + OR$ cannot be of any importance.

3. The Haber mechanism for the reaction of hydrogen atoms with oxygen molecules does not represent the only course of the reaction at ordinary temperatures. Peroxide formation must occur not only by combination of OH radicals but also by some other reaction.

4. Possible reaction mechanisms consistent with the results have been discussed.

Effect of Particle Size upon Intensity in x-Ray Spectroscopic Analysis

BY GORDON R. FONDA

In a limited number of elements,[1] a lower intensity of the La doublet has been observed when the element was in the form of a metallic powder rather than in that of a polished metallic plate or even in that of an oxide. It persisted whether the crystal in the spectroscope was sodium chloride or aluminum oxide. No such difference was observed for the $K\alpha$ doublet. As such irregularities are liable to introduce serious errors in applications of x-ray spectroscopy to quantitative analysis, the subject has been studied further. The conclusion is that they are a consequence of too large particle size which brings about an abnormal absorption of the x-radiation emitted, particularly when it is in the longer wave length range. It is for this reason that it was first noticed in L radiation. The effect has been found to be present likewise in K radiation, though to a much less extent. It occurs under the experimental condition which generally holds—namely, that the emitted x-ray beam be examined at a different angle from that made by the exciting beam of electrons.

x-Radiation is excited throughout a certain depth of material, depending on the penetration of the electrons, and consequently encounters in its emission a corresponding amount of absorption by the material itself. If there are any irregular protrusions in the surface which lie in the path of the beam which is under observation, then the radiation is subjected to additional absorption as it passes through them. Such an effect should

---

[1] Fonda, THIS JOURNAL, 54, 115 (1932).

be presented, for instance, by the surface of a powdered material whose particles are of sufficient size. It can be well demonstrated by examination of the intensity from a grid formed by winding wires closely together with their turns touching. Such a grid was used as a target above the window of the cathode ray tube, placed vertically and operated as before from a regulated dc. circuit at 0.2 ma. and 86 kv. It was held at an angle of 20° to the axis of the tube and the intensity of the α doublet in the radiation given off in a horizontal direction was measured with a Seemann spectroscope placed horizontally. The surface of the crystal in the spectroscope lay in a vertical plane. Measurements were first made with the grid so placed that the turns of wire lay in the axis of the spectroscope, a condition comparable to that of a smooth plate in that the surface irregularities formed by the grid wires were not interposed in the path of the x-ray beam. The intensity was, in fact, found to be the same as for a smooth plate within the limit of error.

The grid was then placed with the turns of wire normal to the axis of the spectroscope. Here the conditions are altogether different as compared with the plate. The x-radiation excited on the side of a grid wire turned away from the spectroscope must pass first through the wire itself and a portion of that formed on the side toward the spectroscope must pass through the adjoining wire. This represents a greater thickness of material than the radiation from a smooth plate is subjected to and the absorption will be correspondingly greater. The loss in intensity will become less only as the size of the wire is decreased, thus lessening the additional absorption, or as x-radiation is chosen of shorter wave length for which the absorption coefficient is consequently lower.

Experiments were made with grids of molybdenum, copper and tungsten. The results are given in Table I. As the interest lies in the intensity from the grid when placed normal to the axis of observation, the value of this term is expressed as the ratio which its intensity bears to that measured when the grid was parallel to the direction of observation. There are geometrical reasons for the increase in the intensity ratio observed for the grid with the larger tungsten wire.

TABLE I

EFFECT OF GRID POSITION ON INTENSITY OF X-RADIATION

	Mo-Ka	Cu-Ka	W-*La*
Wave length x-radiation, Å.	0.708	1.537	1.473
Absorption coeff.	200	540	2700
Intensity ratio—51 μ wire diam.	0.93	0.67	0.41
Intensity ratio—127 μ wire diam.	0.78	..	0.53

These results are in accord with the conclusion that surface irregularities of whatever origin will lead to a loss in intensity by their interposition in the path of the beam. Such a loss was observed, for instance, in the L radiation of tungsten from a plate which had been roughened by sand blasting or even by etching. It is to be expected likewise from powdered material, in which its effect should increase with particle size and should be more pronounced for L radiation than for K because of the longer wave length of the former and the resulting higher values for the absorption coefficient.

These expectations are supported by examinations of several materials in the powdered form. In all the sample was held at a 20° angle to the axis of the tube. This is important because otherwise the relative value of the absorption factors is changed and a still different order of the intensities will be found in the case of those substances which are affected by these factors. The particle size was determined for each sample in terms of the diameter by examination with the microscope. One hundred or more particles of each lot were measured and a distribution curve plotted. The average diameter was found always to coincide with the peak representing optimum distribution and is therefore the value employed in the tables for the sake of brevity. All of the oxides experimented with had been prepared by chemical precipitation and are consequently so fine in size that no abnormal absorption effects could arise with them. They were frequently used as standards for calibration.

The first group of substances examined included metal powders whose intensities were compared with those from the corresponding oxides in mixtures with a comparison element. The results in terms of normal intensity as unity are given in Table II.

In the case of tungsten some direct intensity measurements also were made. In them the intensity from powder whose particles were of $1\ \mu$ size was found to be the same as that from a polished plate. Larger size particles gave reduced intensities. All the sizes investigated gave reproducible intensities denoting that even for the largest size a sufficient number of particles was involved to maintain the same average orientation under different distribution. For still larger sizes it is to be presumed that the intensity would become irregular depending upon the chance

TABLE II

INTENSITY FROM METAL POWDER AS DEPENDENT ON DIAMETER AND ABSORPTION COEFFICIENT

			Intensity for particle sizes of					
Metal	Radiation, Å.	Abs. coeff.	$28\ \mu$	$12\ \mu$	$8\ \mu$	$4\ \mu$	$2\ \mu$	$1\ \mu$
Sn	Kα-0.489	93					1.00	
Mo	Kα-0.708	200				1.00		
Cu	Kff-1.537	540			1.00			
Co	Ka-1.785	560				1.00		
Fe	Kα-1.932	590					1.00	
Pb	La-1.172	1380		0.70				
W	La-1.473	2710	0.41			0.60		1.00
Sn	La-3.592	ca. 14000					0.60	

orientation of those particles which were within the area subjected to cathode ray bombardment.

The second group comprised some crystalline sulfides whose brittleness allowed them to be ground up and graded by screening into different sizes. Intensity measurements were made directly under comparable conditions and Table III gives a comparison in terms of the intensity from the smooth face of a large, single crystal as unity.

TABLE III

EFFECT OF PARTICLE SIZE ON INTENSITY OF SULFIDES

Substance	Radiation, Å.	Abs. coeff.	Intensity at particle sizes of 520 μ	310 μ	220 μ	160 μ	51 μ	4 μ	2 μ
FeS	Ka-1.932	550	0.32	0.52	0.64	0.76	0.76	1.00	1.00
PbS	La-1.172	1380	.50	.32	.48	.48	.50	0.74	0.80

This serves to demonstrate that the effect may become equally pronounced in the case of K radiation if the particles are of sufficient size. As the average particle size of powders that have been ground for analysis is generally below 4 μ, it is apparent that irregularities are not apt to be encountered in K radiation but only in L. This was demonstrated further by the examination of some carbides. Columbium carbide at an average diameter of 5 μ gave an intensity of the Kα doublet at 0.744 Å. that was normal for its columbium content. Tungsten carbide, however, at an average size of 2 μ gave an intensity of its La doublet at 1.473 Å. that was only 81% normal.

Finally a more complex case was examined of a tantalite containing a small percentage of columbium. A definite analysis was obtained by fusing the ore first and finally obtaining by a precipitation method a pure mixture of tantalum and columbium oxides which was complete and which proved from gravimetric measurements to comprise 66.4% of the ore. Spectroscopic analysis of the oxide, which was so finely divided as to be capable of avoiding error due to particle size, gave values of 93.8% Ta_2O_5 and 7.1% Cb_2O_5 corresponding to a content in the original ore of 62.3% Ta_2O_5 and 4.7% Cb_2O_5. From these values it was possible to calculate what the normal intensity of tantalum and columbium radiation should be from the ore Table IV gives values for the observed intensity as determined from spectroscopic analysis of the ore at different particle sizes in terms of the normal intensity. In the case of tantalum, correction is made for the small absorption due to the presence of iron and manganese.

TABLE IV

EFFECT OF PARTICLE SIZE ON INTENSITY MEASUREMENTS FROM A TANTALITE ORE

Particle size	Percentage of normal intensity Ta-La, %	Cb-Kα, %
9.5 μ	44.1	62.0
4.2	86.6	...
2 5	98.6	100.0

Conclusion

The intensity of a diffracted x-ray beam has been found to be decreased by surface irregularities of the target in proportion to their magnitude and to the coefficient of absorption of the target material for the wave length involved. This effect was studied for grids of various size and powdered particles of metals and compounds of various diameter. For accuracy in quantitative chemical analysis based on x-ray spectroscopy attention must therefore be given to the fineness of the powdered samples, more especially when La radiation is involved.

Sodium-Lead Alloys. The Structure of the Compound Known as Na_4Pb

BY CHARLES W. STILLWELL AND WALTER K. ROBINSON

A number of recent investigations have shown that when copper, silver or gold is alloyed with cadmium, zinc, tin or aluminum, the same types of crystal structures often occur in each binary alloy even though the empirical formulas of the compounds differ. The type structure of any specific compound seems to depend upon the ratio between the number of atoms and the number of valence electrons in the molecule.[1]

The behavior of binary alloys of these three metals is fairly consistent and it is of considerable interest to know whether similar relations hold for alloys in which the first group metal is an alkali metal. The only x-ray study of such alloys which has been reported is that for the lead rich end of the sodium–lead system, up to 32 atomic per cent. of sodium.[2] An extension of the data for this system is therefore desirable. The present paper presents an analysis of the crystal structure of the compound usually designated as Na_4Pb.

Experimental Part

The alloy was prepared by melting together in an iron crucible the theoretical quantities of sodium and lead, making due allowance for the evaporation of some sodium. Cooling curves showed the initial break at the melting point of the compound Na_4Pb indicated in the equilibrium diagram.[3] The alloy was annealed for sixty hours at 280–300° in an atmosphere of argon.

A Mueller tube and CuK_α radiation were used for obtaining the diffraction patterns. The camera was essentially the Debye–Scherrer type tipped on edge so that it rested on the curved surface instead of on the base of the cylinder. With this arrangement the specimen may be mounted at the center of curvature and kept covered with mineral oil

to prevent oxidation during the exposure. The x-ray beam is thus diffracted from the surface of a single piece of the alloy and good patterns may be obtained in a relatively short time. There are several obvious sources of error in this type of camera, but repeated calibration with pure metals has demonstrated that the maximum error in the determination of the interplanar spacings is 0.5%, and in general the error is somewhat less.

Complete diffraction data for the compound are listed in Table I. The values in column II are average values from four different films made from four different specimens of the alloy.

				Av.	13.27 ± 0.035 Å.

Discussion

The analysis indicates a face-centered cubic lattice in which $a_0 = 13.27 \pm 0.035$ Å. The error indicated is 0.5%, the maximum error established by the calibration of the camera. It is evident that most of the values for a_0 are well within this limit.

The structure of this phase suggests that it is analogous to the y-phase of the copper, silver and gold alloys. Of these, Cu_5Zn_8, Cu_9Al_4 and $Cu_{31}Sn_8$ are typical examples. These are similar in that they have cubic structures with large unit cells and in each the ratio of valence electrons to atoms is as 21:13. They differ in detail. Thus Cu_5Zn_8 is body-centered cubic and contains 52 atoms in the unit cell;[4] Cu_9Al_4 is simple cubic and contains 52–49 atoms per unit cell;[5] $Cu_{31}Sn_8$ is face-centered cubic, containing 416 atoms per unit cell.[6] In order that the number of molecules in a unit cell may be a whole number, Bernal[7] assigns the formula $Cu_{41}Sn_{11}$ to this copper–tin phase.

If it is assumed, as it was for the y-phase of the copper–tin system, that the more exact formula for the compound Na_4Pb is $Na_{31}Pb_8$, then the 21:13 value for the ratio of valence electrons to atoms is satisfied. The density of $Na_{31}Pb_8$ has been determined as 3.31 at 25° and from this value the number of atoms in the unit cell has been calculated as 77.2. This is sufficiently close to 78 to indicate that there are two molecules in the unit cell.

Another check is furnished by the data of Zintl.[2] He has reported a face-centered cubic structure (Na_2Pb_5 and Na_4Pb_9), containing four atoms in the unit cell in which $a_0 = 4.872 - 4.883$ Å. The side of the unit cell of $Na_{31}Pb_8$ is about 2.72 times as long as the above and the volume of $Na_{31}Pb_8$ is therefore twenty times that of the smaller cell. From these figures the number of atoms in the unit cell of $Na_{31}Pb_8$ has been calculated as 80, which agrees significantly with the value 77.2 determined from the density.

We are grateful to Dr. G. Calingaert of the Ethyl Gasoline Corporation, who prepared the alloys for this study, and to Dr. G. L. Clark of this Department, who suggested a study of sodium–lead alloys.

Summary

Diffraction data for the compound usually designated as Na_4Pb have been analyzed. The analysis indicates that the structure of this compound is face-centered cubic, with $a_0 = 13.27 \pm 0.035$ Å. There are 78 atoms in the unit cell. It is apparently analogous to the familiar y-phase of copper, silver and gold alloys and its more exact formula is therefore $Na_{31}Pb_8$.

Atomic Chlorine and its Reaction with Hydrogen[1]

BY W. H. RODEBUSH AND W. C. KLINGELHOEFER, JR.

One of the most promising methods of studying the mechanism of gaseous reactions is the introduction of the various atomic species into the reaction mixture. The classical example of such a study is the work of Bonhoeffer on atomic hydrogen.[2] The most satisfactory method for the production of gaseous atoms is by the high frequency electrodeless discharge. If it is desired to pass the atoms into a reaction chamber, a too high frequency is disadvantageous because the discharge will travel along the tube and affect the reaction. The catalytic effects of walls, water, metals, etc., have been clearly demonstrated in the case of hydrogen atoms but it has been proved in this Laboratory that each species of atom is a law unto itself so far as these effects are concerned.

The Production of Chlorine Atoms.—The thermal and photochemical dissociations of the chlorine molecule have been demonstrated by a number of observers but no one has produced any considerable amount of atoms by this method. The first attempt to produce chlorine atoms in this Laboratory was made with a discharge between cooled copper electrodes in a long tube of the Wood type. The electrodes were not attacked and the discharge could be maintained over a considerable range of pressure but the gas was not dissociated. This type of apparatus was discarded in favor of the electrodeless discharge.

Experimental

Dissociation of Chlorine.—The apparatus is shown in Fig. 1. It consisted of a supply of chlorine, A, a bulb for the electrodeless discharge, E, a diffusion gage, H, liquid air trap, mercury vapor pump and oil pump. The chlorine, prepared from concentrated hydrochloric acid and potassium permanganate, was washed with water, dried by sulfuric acid and liquefied in a bulb of about 30 cc. capacity by a mixture of dry ice and acetone. Moisture was kept out of the vent tube by means of a U-tube kept in the cold bath. The chlorine bulb was connected to the apparatus through a capillary which controlled the flow. The bulb was held at a temperature of −80°.

The discharge was produced in a 200-cc. Pyrex bulb. The energizing circuit was connected as shown. A 2.5 k. v. a., 25,000 volt Thordarson transformer was used. The condenser D consisted of 14 plates, about 20 by 23 cm., separated by about 5 mm. of window glass, the whole being immersed in insulating oil. The spark gap, F, of about 1 cm. width, had zinc electrodes about 3 cm. in diameter. The gap was mounted in a sound-proof box fitted with an air connection for cooling the electrodes and regulating the voltage drop. The coil, which was fitted closely to the bulb, was made in two parts of five turns each. It was carefully grounded near the center in order to reduce the stray discharge into the remainder of the apparatus. When this was properly done no discharge could be seen in a dark room at more than about 5 cm. distance from the bulb.

(2) *Bonhoeffer, Z. physik. Chem., 113,* **199** **(1924).**

All of the connections in the high frequency circuit were made with 3-mm. copper tubing. The current in the primary of the transformer was usually about 15 amperes and was regulated by a series resistance, B, and the air flow at the spark gap to give the best glow discharge.

The diffusion gage H was used to detect the atoms produced. It was similar to the gage described by Wrede.[3] It consisted of an orifice 0.1 mm. in diameter and gages for measuring the total and differential pressures. The orifice was made in a thin glass film sealed on the end of a 5-mm. tube which extended into the gas stream at a point about 7 cm. from the discharge bulb. The film was made by blowing out a glass bubble until it was thin enough to show colors. It was sealed to the tube by heating the latter and sticking it into the glass bubble. The hole in the film was made by placing it between two needle points between which a spark was passed by means of an induction coil. The size of the hole was controlled by the energy of the spark. The gages were of 5-mm. tubing and were filled with a heavy paraffin oil which was found to be unaffected by the chlorine. Gage J measured the total pressure; I, the pressure difference across the orifice. A cathetometer sensitive to 0.01 mm. was used to read the oil levels. The gage was compared to a McLeod gage using hydrogen in a static system. A 1-mm. differential on the oil gage corresponded to 0.06 mm. of mercury. Thus a pressure difference of 0.0006 mm. of mercury could be detected. The diffusion gage required about two minutes to come to equilibrium after small pressure changes.

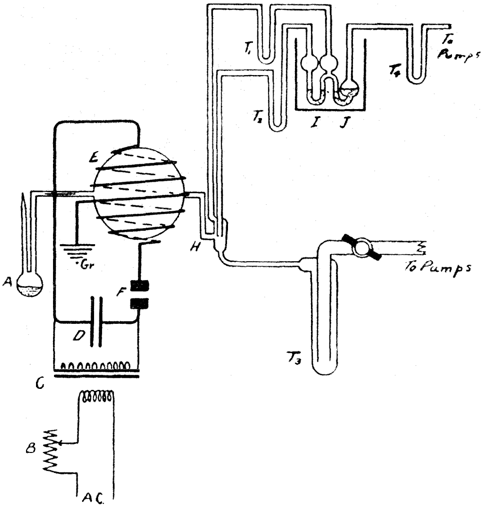

Fig. 1.

The gages were kept in a bath of oil to reduce temperature variations. Oil vapors were kept out of the rest of the apparatus by means of the traps T_1 and T_2 which were kept in a carbon dioxide–acetone mixture. At first the orifice chamber was cooled by an air blast, later it was placed in a thermostat.

The glow discharge was obtained from very low pressures up to about 1 mm. At the lower pressures the glow spread throughout the bulb and was of a bright greenish-blue color. The discharge would not start itself at a pressure above about 0.6 mm., but once started, it continued to operate until an upper limit was reached at about 1 mm. At the higher pressures the discharge took on a ring form.

The degree of dissociation measured by the diffusion gage increased with the chlorine flow. In the range of 5 to 10 cc. per minute generally used here this change was small. With chlorine pressures between 0.2 and 0.7 mm., the degree of dissociation varied between about 0.08 and 0.18, tending to decrease at the higher pressures. When the temperature of the orifice chamber and leads was varied from −80 to 100° the dissociation increased from 0.04 to 0.09. This change was probably due to the more rapid motion of the gas at the higher temperature.

After a few hours of operation the discharge bulb became coated with a white

---

(3) Wrede, *Z. Physik*, 64, 51 (1929).

deposit. After a longer time the connecting tubes showed a similar deposit. When the bulb was cooled by a blast of air less of this material formed. It was found to sublime slowly when heated to redness in air. It was insoluble in water and the common acids. The degree of dissociation did not change greatly with time, showing that the deposit had little activity for the recombination of chlorine atoms.

Properties of **Atomic** Chlorine.—To obtain some information concerning the catalytic activity of materials for the combination of the atoms, the method which Bonhoeffer[2] used with atomic hydrogen was chosen. The method consists of coating the materials on the bulb of a thermometer placed in the active gas and observing the temperature rise. The apparatus was similar to that used above, except that the Wrede gage was replaced by a tube to contain the thermometer. The bulb of the thermometer was directly in the gas stream about 7 cm. from the discharge bulb. The materials were either placed directly on the bulb or on a thin glass cap which fitted closely over it. The apparatus was cooled by an air blast. The results are shown in Table I.

TABLE I

CATALYTIC ACTIVITY IN CHLORINE RECOMBINATION

Material	Maximum temperature, °C.	Material	Maximum temperature, °C
Pyrex glass	30	NaCl, fused	34
Ag foil	115+	KCl, fused	70
Cu foil	115+	AgCl, fused	91
Al foil	82	$CaCl_2$, fused	66
Ni wire	120	$CoCl_2$, evap.	72
Platinized glass	35	Gas carbon	115+

The silver and copper were rapidly attacked, forming an adherent layer of chloride. The aluminum and nickel showed no sign of attack. Sodium chloride, potassium chloride and platinum were erratic in behavior, some samples heated rapidly, others not at all. Their activity was always lost after running for some time.

The pressure difference produced at the diffusion gage and the heating effect produced with some materials showed conclusively that we produced chlorine atoms and not more complex molecules. Since chlorine attacks silica at high temperatures to produce silicon tetrachloride it is not surprising that the atoms attack glass at moderate temperatures. The products would of course be different. The deposit observed could not have been one of the normal chlorides of silicon or boron since these are quite volatile.

The fact that the atoms can pass through a tube at a temperature much below the normal boiling point for the liquid is very unusual. Hydrogen, oxygen and nitrogen atoms are all condensed when passed into a liquid air trap, This difference in behavior may be due to the fact that these latter gases need a certain water content to prevent recombination while chlorine does not. If water had been required with chlorine the study of its reaction with hydrogen would have been made difficult if not impossible.

The data obtained with catalysts for the recombination showed which materials should be avoided in order to reduce recombination, and which may be used to aid recombination. Thus silver was chosen for use in the diffusion gage and for stopping the reaction. Silver, copper, nickel, carbon and similar materials were carefully excluded from the rest of the apparatus.

The recombination on glass, sodium chloride, potassium chloride and platinum was small, but the method was not sensitive enough to distinguish between them in activity. The initial activity observed with platinum, sodium chloride and potassium chloride may have been due to impurities which later volatilized. The low activity of platinum and sodium chloride agrees with the results of Senftleben and Polanyi.[4]

Silver should be a good material for detecting chlorine atoms in a molecular ray or elsewhere. Their action on a thin mirror surface was particularly noticeable. The mirror remained bright on the glass side for several days when exposed to dry chlorine, but immediately turned white and translucent when treated with atomic chlorine.

In view of the great catalytic activity of copper it seems remarkable that Jost and Sweitzer[6] were able to pass activated chlorine through a copper capillary while Bodenstein and Taylor[a] and others were unable to pass it through glass capillaries at somewhat smaller velocities.

The Reaction of Chlorine Atoms with Hydrogen.—The apparatus used is shown in Fig. 2. It consisted of a chlorine supply, A, a hydrogen leak, F, the discharge bulb, B, Wrede gage, C, with oil manometers G and H, reaction tube, D, and the sampling train of liquid air traps T_6 to T_{11}. Traps T_6, T_7 and T_{12} were made with ground joints.

The chlorine bulb was kept in a large Dewar half filled with ethyl acetate at its melting point. A metal tube was provided for cooling with liquid air. The mixture was thoroughly agitated by a screw stirrer. A toluene thermometer was used to observe the temperature, which could be kept between -83.5 and $-84.0°$. Mixtures of carbon dioxide with alcohol or acetone were found unsatisfactory as they became several degrees cooler when chlorine was used, due to the heat absorbed by vaporization.

The hydrogen was taken from a commercial cylinder. It was bubbled through water into a gas buret which was used to measure the rate of flow. The flow was regulated by the capillary leak, F. Moisture was removed by trap T^1 which was immersed in liquid air.

The discharge bulb and coil circuit were of the same type as described above. The arrangement of the reaction tube and diffusion gage was changed with the different experiments and will be described later. They

were placed in a small thermostat which was controlled to 0.1°. A catalyst of silver foil was used in the gage for the recombination of chlorine atoms.

The connection used to lead the chlorine into the reaction tube was adjusted to the chlorine flow to prevent the diffusion of hydrogen back into it. When the total pressure was about 0.4 mm. and the tube was small enough to cause a pressure drop of about 0.1 mm. between the discharge bulb and the reaction tube no diffusion took place. This was shown by the fact that the spectrum of the discharge was not changed when the hydrogen flow was started The degree of dissociation also remained the same. Since the discharge could not be maintained at a pressure much above 1 mm. and the diffusion gage required a pressure of 0.5 mm. or less, the method was applicable only within the pressure range of 0.3 to 0.5 mm.

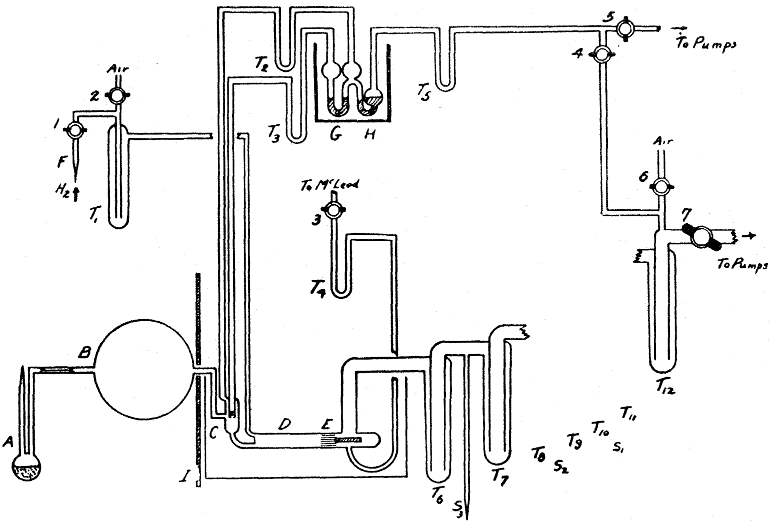

Fig. 2.

No sealing wax was used in the construction of the apparatus and the reaction mixture was protected from stopcock grease by liquid air traps.

Samples of the products were taken by placing Dewar flasks of liquid air on the sampling traps. The time of sampling, which was usually five or ten minutes, was terminated by placing liquid air on the next trap to the left. Conditions could then be changed and another sample taken.

When all the samples were taken, the discharge was turned off, and the pumps and hydrogen shut off. The samples were swept out one at a time through the sampling tubes after removing the liquid air from the corresponding traps. The chlorine and hydrogen chloride were absorbed in 200 cc. of 5% potassium iodide solution. Several tests showed that this procedure removed all of the chlorine and hydrogen chloride from the trap. The air flowing from both sides prevented the diffusion of the chlorine or hydrogen chloride into the other traps which were still cooled with liquid air.

The samples were analyzed by titrating with 0.20 *N* sodium thiosulfate without an indicator, then with 0.10 *N* potassium hydroxide using methyl orange indicator. All of the solutions were made from conductivity water which was also used in rinsing. Numerous blank runs were made to check the neutrality of the solutions and of the chlorine.

Extent of Reaction.—A reaction bulb of about 35 cc. volume was used. The diffusion gage was sealed directly into one side of the reaction bulb. It was connected to the discharge bulb by 7 cm. of 4 mm. tubing bent twice at right angles. The dissociation was measured at the beginning of each run before the hydrogen flow was started. The reaction was probably not confined to the reaction bulb, but also took place in the connecting tubes to the sampling traps which were at room temperature. The results are shown in Table II, the temperature given is that of the thermostat. The pressure was 0.4 mm. and the hydrogen flow 17.5 cc. per minute.

TABLE II

EXTENT OF REACTION WITH HYDROGEN

Temp., °C.	Cl_2, cc./min.	Dissociation	Cl_2 reacting, %
0	7.0	0.20	52
36	10.4	.20	97
99	8.8	.20	96
0	7.5	.07	24
25	7.9	.07	83
50	8.4	.07	99

It was observed that when the reaction bulb was not placed in the thermostat it became hot. The reaction then ran nearly to completion even with a very low degree of dissociation.

When there was an excess of chlorine, the hydrogen was sometimes completely used up, as shown by the very slow pressure increase when the pumps were shut off. The results were the same when the room was darkened to prevent the occurrence of a photochemical reaction. Blank tests with hydrogen and chlorine, but with the discharge off, showed no hydrogen chloride formation in either a darkened or a light room.

No reaction was observed when the current was not great enough to form a glow in the discharge bulb. With this arrangement a weak static discharge took place in the connecting tubes, but no dissociation could be detected by the gage.

Effect of Oxygen.—The same apparatus was used except that a bulb which had been silvered inside was placed after the reaction bulb. That it stopped the reaction beyond this point was shown by the fact that the silver was attacked only at the inlet. The hydrogen flow was 6.7 cc. per minute and a flow of 0.08 cc. per minute of oxygen was added to it by means of a capillary leak. The chlorine flow was about 9 cc. per minute. Its dissociation was measured before and after each run; the average was about 0.04. Samples were taken with the oxygen flow on and then with it turned off.

The average yields, expressed as percentage of the chlorine reacting, were: with oxygen 21% at 0° and 38% at 25°; without oxygen 25% at 0° and 36% at 25°.

Effect of Surface.—The effect of surface was studied using an empty Pyrex bulb of about 60 cc. volume, and the same bulb filled with short lengths of 4-mm. Pyrex tubing. The surface to volume ratio was changed from 2 to 10. The apparatus was thoroughly cleaned with hot $CrO_3 \cdot H_2SO_4$ The diffusion gage was arranged as in Fig. 2 and the chlorine was mixed with the hydrogen just at the inlet to the bulb. The dissociation was measured for each sample and was about 0.10.

The yields, calculated as the molecules of hydrogen chloride formed per chlorine atom introduced, were 3.1 and 5.0 at 0 and 25° for the packed bulb, and 2.8 and 3.8 at 0 and 25" for the empty bulb.

Rate of Reaction.—The apparatus is shown in Fig. 2. The light of the discharge was screened off by the shield I. The connecting tube from B to C was a 6 cm. length of 6 mm. tubing, that from C to D was a 1.5 cm. length of 4 mm. tubing. The reaction tube D was about 1.3 cm. wide and 8 cm. long and was calibrated from the inlet side. The system was made quite small in order to keep the amount of reaction small and the partial pressures of chlorine atoms and hydrogen nearly constant.

The reaction was stopped at the desired time by a roll of silver foil about 1 cm. wide shown at E. It caused all the atoms to recombine. A glass covered iron armature fastened to the silver foil made it possible to move it by means of a magnet and hence to vary the time of reaction.

The pressure of the reacting mixture was measured by a McLeod gage with a ratio of 875 to 1. The dissociation was measured twice for each sample and the readings were averaged. The time required for the chlorine to pass from the discharge bulb to the reaction tube was about 0.015 second.

Results.—When the silver foil was placed about 2 mm. from the inlet end of the reaction tube, the amount of reaction was very small. This showed that the foil was very effective in stopping the reaction and that no hydrogen was diffusing into the chlorine leads.

The data for a typical run are given below

Reaction volume	10 cc.
Hydrogen flow	6.3 cc. per minute
Pressure	0.340 mm. of mercury
Time of sampling	10 minutes
Reaction temperature	0.0°
Temperature of chlorine	−83.5°
Total pressure at diffusion gage	7.00 mm. of oil

Differential pressure across orifice	0.40 mm. of oil
Degree of dissociation of chlorine	0.11
Thiosulfate titration	36.5 cc. of 0 20 N
Potassium hydroxide titration	9.1 cc. per minute
Chlorine flow	9 1 cc. per minute
Per cent. of chlorine reacted	10.2
Hydrogen chloride formed per Cl atom introduced	0.92
Time of reaction	0.016 seconds
Number of collisions per Cl atom	30 X 10^3
Probability for reaction	1 5 X 10^{-5}

The last two entries were calculated by the kinetic theory. The number of collisions, Z, which a molecule of type I (Cl) makes with molecules of type II (H_2) per second is

$$2N_2\left(\frac{d_1+d_2}{2}\right)^2\sqrt{\frac{m_1+m_2}{m_1m_2}}\sqrt{2\pi kT}$$

N_2 is the number of type II molecules in volume V, d_1 and d_2 are the collision diameters, and m_1 and m_2 are the corresponding masses. The diameter of the chlorine atom is not known. The value given for argon ($d = 2.97 \times 10^{-8}$)[7] was used. The value for hydrogen ($d = 2.39 \times 10^{-8}$) was taken from the same source.

The average number of collisions, Z', which a chlorine atom experienced while in the reaction tube is

$$Z' = Z\, nV_R/N_T$$

Where n is the total number of molecules per cc. in the reaction tube of volume V_R, and N_T is the total number of molecules entering the tube per second.

It was assumed that the reactions involved were

$$Cl + H_2 = HCl + H \qquad (I)$$
$$H + Cl_2 = HCl + Cl \qquad (II)$$

and that the rate of (II) was greater than the rate of (I). Thus each chlorine atom which reacted would form 2HCl. The ratio of HCl formed to the Cl introduced was found by dividing the fraction of chlorine which reacted by the degree of dissociation.

The probability, W, of a chlorine atom reacting with a hydrogen molecule on collision is

$$W = (HCl/Cl)/2Z'$$

The results of the other rate measurements are shown in Table III. The temperature is in degrees centigrade, pressure in mm. of mercury, and reaction volume in cc. The values in the columns headed H_2 and Cl_2 are the corresponding rates of flow in cc. at N. T. P. per minute. The degree of dissociation of the chlorine (a) is given in column 6. Column 8 gives the yield of HCI per chlorine atom calculated from the dissociation

---

(7) "Treatise on Physical Chemistry," 2d ed., D. Van Nostrand Co., New York, 1931, p. 249.

and the amount of HCl formed. Column 9 gives the number of collisions (Z') one chlorine atom had with hydrogen molecules in passing through the reaction tube. The probability (W) of a chlorine atom reacting with hydrogen on collision is given in column 10.

TABLE III

RATE OF REACTION OF ATOMIC CHLORINE WITH HYDROGEN

Test	T	P	V	H_2	a	Cl_2	HCl/Cl	$Z' \times 10^{-3}$	$W \times 10^5$
I	0.0	0.30	9.3	6.6	0 049	9.8	0.57	21	1.4
2	.0	.30	9.3	6.6	042	10.1	.62	21	1.5

23	.0	.31	5.0	6.4	.070	10.7	.15	11	.7

The reaction tube was cleaned after test 12. A new reaction tube, orifice chamber and discharge bulb was placed in the apparatus before test 17.

Following these tests a glass plate was placed before the silver catalyst. The clearance around the edge of the plate was about 0.5 mm. and its presence caused a pressure drop of about 0.2 mm. It should have prevented a lowering of the concentration of atomic chlorine by diffusion to the catalyst. The yield was somewhat higher, but since the pressure was uncertain, the collisions could not be calculated.

A run was also made in which the hydrogen was saturated with water vapor at room temperature. There was slightly less reaction than with the dried gas. A maximum value for the water in the chlorine may be calculated from the vapor pressures. The vapor pressures of chlorine and ice at −80° are 58.7 mm. and 0.0004 mm., respectively. At the operating pressure this would give a partial pressure of water vapor of about 10^{-6} mm. Since the chlorine was dried before being liquefied this figure is probably much too high.

The saturated hydrogen contained about 3% water vapor. This would give a partial pressure of water vapor of about 0.003 mm. in the reaction tube, at least 3000 times that in the dry gases.

Discussion of the Chlorine–Hydrogen Reaction.—The reaction of chlorine with hydrogen has been the subject of so many studies that complete references cannot be given here.[8] The original mechanism proposed by Nernst is a chain involving two steps

$$Cl + H_2 = HCl + H \qquad (I)$$

$$H + Cl_2 = HCl + Cl \qquad (II)$$

It has been generally accepted that (2) takes place and that it is a rapid reaction Bodenstein has estimated a reaction probability of 10^{-3} per collision for (2). Most of the discussion has centered around (1). The question concerning this step in the reaction apparently was raised by the work of Coehn and Jung,[9] who claimed that a trace of water was necessary for the photochemical reaction. It seemed necessary to introduce water into the reaction mechanism somewhere and various proposals were made which involved replacing (1) by various complicated mechanisms.

The experiments reported above prove conclusively that the reaction

$$Cl + H_2 = HCl + H$$

does take place, at least at low pressures.

The completeness of the reaction, when allowed to run in a fairly large volume, shows that a chain reaction takes place. The chains are short, due to the large number of chlorine atoms introduced compared to the total reacting mixture. This fact also accounts for the lack of any effect of light on the yields The number of atoms which could be formed by light absorption under the experimental conditions would be very small compared to the number present.

The negligible effect of additional surface of Pyrex glass was due to its small activity for recombination of chlorine atoms. Since hydrogen atoms recombine rapidly on dry glass surfaces, this effect shows that either the hydrogen atoms react very rapidly with chlorine or that their recombination is prevented by a layer of chlorine adsorbed on the glass.

The absence of an appreciable retardation of the reaction by oxygen was due to the shortness of the chains. Photochemical work has shown that the effect of oxygen is very great when the chains are long, but small when the chains are short.

The largest source of error in measuring the rate of reaction was the recombination of the atoms on the walls. A clean glass surface was only slightly active, but the activity increased with the time of operation. This is shown in Table III by tests 9 to 14. The probability of reaction decreased from about 3.5×10^{-5} to about 2.3×10^{-5}. A similar decrease

---

(9) Coehn and Jung, *Z. physik Chem.*, 110, 705 (1924)

is shown by tests 17 to 23. When the reaction tube was kept at 0° all the time the discharge was on, this change was slow. This indicates that some of the material which sublimed from the discharge bulb may have deposited on the walls and increased the atom recombination.

At the lower temperature less of this material could have reached the reaction bulb because of better condensation in the lead tubes.

Another possibility of error was the diffusion of the atoms to the silver catalyst. This would lower the concentration of chlorine atoms in the reacting mixture and make the probability of reaction too low. The experiment with the glass plate for preventing diffusion showed that this effect was not very large. Tests 5 to 12 show that the amount of reaction was nearly proportional to the reaction volume. If the diffusion had been rapid, the amount of reaction should have increased more rapidly than the reaction.

The error in determining the degree of dissociation was about 5%. The rates of flow were known to about 2%. Titration errors of 5% are probable in the amount of hydrogen chloride formed. The total error for all measurements was about 10%.

Allowing for the decrease of reaction with time, the most reasonable values for the probability of reaction on collision are 1.4×10^{-5} at 0° and 3.3×10^{-5} at 25°. The reaction was carried out under conditions in which practically the only moisture present was that coming from the glass, thus approaching the conditions of dryness obtained in the experiments of Coehn and Jung.[9] The fact that no difference in the reaction was observed when moisture was present throws grave doubt upon their results and makes it unnecessary to speculate upon a mechanism involving the water molecule. This is in agreement with recent work by Bodenstein,[10] who has been unable to confirm the previous work upon the necessity of moisture to the reaction

Reaction Probability Calculated from the Results of Other Workers.—The photochemical rate of reaction experiment as ordinarily carried out at high pressures with constant illumination upon mixtures of hydrogen and chlorine is a measurement of average chain length only. Since the chain involves at least two alternating mechanisms and the average chain length depends upon the competition of these mechanisms with others, such measurements do not give direct information of reaction probability, heat of activation or any other fundamental property of the reaction. By making a sufficient number of assumptions, however, a figure may be arrived at and calculations have been made by several. The figures obtained vary from 10^{-3} to 10^{-6} for the mechanism (I). The value arrived at by Bodenstein[10] 10^{-4} is in approximate agreement with our result.

It must not be forgotten that in our calculation we assumed mechanism

---

(10) Private communication.

(II) to be rapid so that two molecules of hydrogen chloride will be formed for each atom of chlorine. If this assumption were not true, the order of magnitude of the reaction probability would be unchanged.

The Heat of Activation of the Reaction.—$Cl + H_2 = HCl + H$ (I). It was assumed formerly that an exothermic reaction of the type of (I) required no heat of activation. This assumption is certainly not correct. The above reaction is probably exothermic but so long as the heat of reaction is less than the heat of activation it is not of great importance what the sign of the former is. We shall assume that reaction may take place only when the relative velocity in collision exceeds a certain critical value. This is equivalent to assuming that the activation energy is entirely in the form of kinetic energy of translation. Even when the critical energy is exceeded it is not likely that a collision will always result in reaction. Hence we introduce a "steric" factor. The reaction probability f is therefore given by an expression of the form[11]

$$f = K\left(\frac{1 + E_0}{RT}\right) e^{-E_0/RT}$$

where K the steric factor is presumably independent of temperature. From the ratio of the reaction probabilities at two temperatures we may calculate the value for the activation energy E_0. The average values obtained for the reaction probabilities at 0 and 25° give a value for E_0 of 6100 cal. The steric factor corresponding to this activation energy is 0.08, but because of the uncertainty of the experimental results only the order of magnitude may be established. The value of E_0, on the other hand, would not vary by more than 1000–2000 calories for the different reasonable combinations of individual results at the two temperatures.

It is interesting to compare these results with estimates that have been made by others as to the heat of activation. Rollefson and Lindquist[12] were led by a study of the photochemical reaction of iodine monochloride and hydrogen to postulate that only Cl atoms in the $^2P_{\frac{1}{2}}$ state react with molecular hydrogen. The $^2P_{\frac{1}{2}}$ state has an energy of about 2500 calories greater than the normal state. It would therefore be necessary to postulate an additional critical energy of collision of about 3500 calories to bring about reaction. On account of the large number of collisions which a chlorine atom undergoes on the average before it reacts with a hydrogen molecule, it seems probable that statistical equilibrium would be established between the $^2P_{\frac{1}{2}}$ and $^2P_{\frac{3}{2}}$ states so that the same results should be obtained regardless of the original state of the chlorine atom. In Rollefson and Lindquist's experiments apparently the chlorine atoms reacted with something else much more readily than with hydrogen. Their postulate

---

[11] Ref. 7, p. 987. The expression given above assumes the total energy of collision to be available for reaction. This is probably not a proper assumption but the value obtained for the heat of activation would not be greatly different in any case. The question will be discussed by one of the authors elsewhere.

[12] Rollefson and Lindquist, THIS JOURNAL, 52, 2793 (1930).

that only the $^2P_{\frac{1}{2}}$ state reacts with hydrogen is therefore not required by the evidence.

Eyring[13] has calculated the heat of activation of reaction (I) from wave mechanics and obtains a value for E_0 between 14,000 and 25,000 calories according to the assumptions. The agreement is perhaps as good as is to be anticipated.

The authors wish to express their appreciation to Professor Bodenstein for his courtesy in communicating to them his recent experimental results.

Summary

The technique of preparing chlorine atoms has been developed. The conditions favoring recombination of chlorine atoms are not the same as for hydrogen atoms.

When chlorine atoms are introduced into a hydrogen–chlorine mixture at low pressure a chain reaction is started which will run, under favorable conditions, until one of the gases is used up. Oxygen and water are without effect on this reaction and the simple mechanism proposed by Nernst is adequate to account for it.

The reaction probability for the reaction $Cl + H_2 = HCl + H$ (I) has been estimated to be 1.4×10^{-5} per collision at 0° and 3.3×10^{-5} at 25°. From the temperature coefficient a heat of activation of 6100 ± 1000 calories is estimated.

The Photochemical Oxidation of Phosgene

BY G. K. ROLLEFSON AND C. W. MONTGOMERY

The direct photochemical oxidation of phosgene has never been reported in the literature. It was thought possible that the reaction might take place upon insolation with light of $\lambda < 2700$ Å., since Henri[1] had found evidence of predissociation of phosgene beginning in this region. The primary act of absorption is believed[2,3] to lead to the process

$$COCl_2 + h\nu \longrightarrow COCl + Cl$$

in which the intermediate compound COCl is formed. This same intermediate has been postulated in the mechanisms of Bodenstein, Lenher and Wagner[4] and Lenher and Rollefson[5] for the photochemical formation of phosgene.

[1] Henri, *Proc. Roy. Soc.*, (London) **A128**, 178 (1930).

[5] Lenher and Rollefson, THIS JOURNAL. **52**, 500 (1930).

The direct oxidation has been found to take place upon irradiation with ultraviolet light. Since there can be but little question as to the direct formation of $COCl$ in the primary process, a study of the reaction must be chiefly concerned with the subsequent processes involving the intermediate. Thus an entirely new point of attack on the mechanism of phosgene photochemical reactions is afforded.

Experimental

The reaction vessels employed were of clear fused quartz, one a spherical bulb of about 200 cc. volume, the other a cylindrical absorption cell 20 cm. long and 2 cm. in diameter. The cylindrical vessel was mounted on end and illuminated from a source parallel to the longitudinal axis The source of illumination was the full light of the quartz mercury arc. Two Cooper-Hewitt quartz arcs were used, the earlier work being done with a 110-volt arc while later a 220-volt arc giving greater intensity in the ultraviolet was used. As the arc was run quite close to the reaction vessel, it was found necessary to cool the latter during the work at room temperature. This was done by allowing water to flow smoothly over the surface of the vessel. The temperature of the water never varied more than 2° over a run. For the work at 90 and 200°, a small electric oven having a long narrow quartz window was used. Temperature was kept constant at 90 * 2° and 200 * 3° by varying a slide wire resistance in series with the oven.

The phosgene (Kahlhaum) was distilled directly into the line from a glass bomb after freezing the liquid by means of liquid air. The phosgene was then distilled through three reservoir traps in the line, the gas being allowed to bubble through the liquid. Finally, approximately the first and last thirds were pumped off, the middle third being collected in a reservoir trap which was always kept immersed in a Dewar filled with ice water The liquid phosgene remained perfectly clear, showing no trace of discoloration. When the gas was needed, the liquid in the reservoir was allowed to vaporize into a three-liter bulb from which small amounts could be drawn. The chlorine was prepared by heating anhydrous cupric chloride in the manner previously described.[6,7] Oxygen was prepared electrolytically from potassium hydroxide solution, freed from hydrogen by passing over hot copper oxide, and dried in a storage tube containing magnesium perchlorate.

The course of the reaction was followed by measuring the pressure increase with time. For the low pressure work a sulfuric acid (sp. gr. 1.84) manometer was used and later, with higher pressures, mercury was used as the manometer liquid, protected by 3 or 4 cm. of sulfuric acid. Readings were taken with the arc off at intervals of fifteen to sixty minutes depending on the speed of the reaction. In several of the runs, in order to check the pressure readings, the oxygen was measured by freezing out the other gases (phosgene, carbon dioxide and chlorine) with liquid air.

Results

In Fig. 1 log ($COCl_2$) is plotted against time for several runs. The straight lines obtained indicate that the rate of reaction is proportional to the first power of the phosgene concentration.

The effect of incident light intensity was investigated by using various wire screens which had been previously calibrated by means of a thermopile. The results summarized in Fig. 2 show that the rate is proportional

---

(6) **Rollefson, THIS JOURNAL, 51, 770 (1929).**

(7) **Loeb, *Phys. Rev.*, 35, 184 (1930).**

to the first power of the incident intensity. The intensity with no screen is taken as unity.

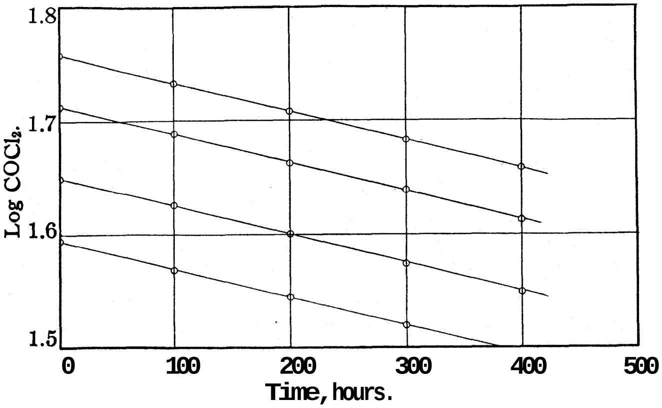

Fig. 1.

At higher oxygen pressures, the rate was found to be independent of the oxygen concentration, while at lower pressures, the rate gradually fell off with decreasing oxygen. This suggested that the rate of reaction might be a function of the chlorine-oxygen ratio rather than of the oxygen concentration itself. In Fig. 3 the rate is plotted against the function $1/(1 + k'(Cl_2/O_2))$ for the temperature, 90°. In each case such a value of k' was taken as would yield a straight line through the origin.

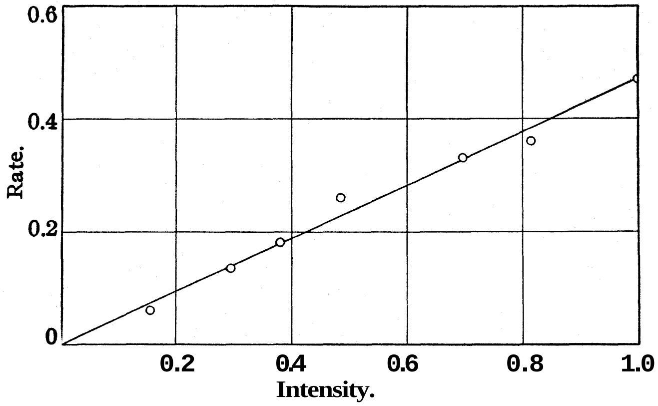

Fig. 2.

As has been pointed out[8] k' should be a definite function of the temperature. The reaction was therefore studied at three temperatures: 20, 90 and 200°. The values of K' found corresponding to these temperatures are as follows

---

(8) Rollefson, This Journal. 55, 148 (1933).

Temp., °C.	20	90	200
K'	0.17	0.38	1.00

As an example of the data, the following values of the rate and the Cl_2/O_2 ratio may be given. These points are those obtained at 90° and are represented graphically in Fig. 3.

Rate	0.545	0.475	0.389	0.335	0.139
Cl_2/O_2	0.134	0.565	1.28	2.18	9.89
$1/[1 + 0.4(Cl_2/O_2)]$	0.95	0.81	0.66	0.53	0.22

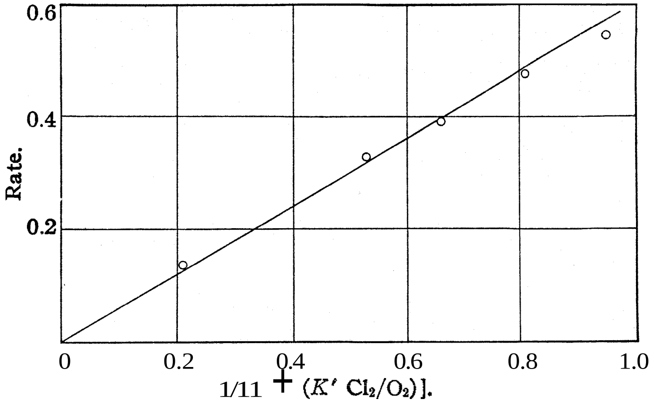

Fig. 3.

Discussion

The data presented above indicate that the rate law for the oxidation of phosgene may be expressed by the equation

$$\frac{d\,(CO_2)}{d\,t} = \frac{k\,I_0\,(COCl_2)\,(O_2)}{(O_2) + k'\,(Cl_2)}$$

or, showing more clearly the dependence on the chlorine-oxygen ratio

$$\frac{d\,(CO_2)}{d\,t} = \frac{k\,I_0\,(COCl_2)}{1 + k'\left(\frac{Cl_2}{O_2}\right)}$$

This rate law may be very simply derived from the following rate mechanism

$$\begin{array}{lll}
COCl_2 + h\nu & \longrightarrow COCl + Cl & (1) \\
COCl + O_2 & \longrightarrow CO_2 + ClO & (2) \\
COCl_2 + ClO & \longrightarrow CO_2 + Cl_2 + Cl & (3) \\
COCl + Cl_2 & \longrightarrow COCl_2 + Cl & (4) \\
Cl + W & \longrightarrow {}^1/_2Cl_2 + W \left.\right\} & (5a) \\
Cl + Cl & \longrightarrow Cl_2 & (5b)
\end{array}$$

Assuming that the rate of change of (COCl) and (ClO) is negligibly small compared to their rates of formation and reaction, we may write

$$\frac{d\,(\mathrm{COCl})}{d\,t} = I_{\mathrm{abs.}} - k_2\,(\mathrm{COCl})(\mathrm{O_2}) - k_4\,(\mathrm{COCl})(\mathrm{Cl_2}) = 0 \qquad (\mathrm{I})$$

$$\frac{d\,(\mathrm{ClO})}{d\,t} = k_2\,(\mathrm{COCl})(\mathrm{O_2}) - k_3\,(\mathrm{ClO})\,(\mathrm{COCl_2}) = 0 \qquad (\mathrm{II})$$

The rate of oxidation is given by

$$\frac{d\,(\mathrm{CO_2})}{d\,t} = k_2\,(\mathrm{COCl})(\mathrm{O_2}) + k_3\,(\mathrm{ClO})\,(\mathrm{COCl_2}) \qquad (\mathrm{III})$$

According to II we may write

$$k_3\,(\mathrm{ClO})(\mathrm{COCl_2}) = k_2\,(\mathrm{COCl})(\mathrm{O_2})$$

Substituting this expression in III, we obtain

$$\frac{d\,(\mathrm{CO_2})}{d\,t} = 2\,k_2\,(\mathrm{COCl})\,(\mathrm{O_2}) \qquad (\mathrm{IV})$$

From I we have

$$k_2\,(\mathrm{COCl})\,(\mathrm{O_2}) + k_4\,(\mathrm{COCl})\,(\mathrm{Cl_2}) = I_{\mathrm{abs.}}$$

$$\mathrm{COCl}\,(k_2\mathrm{O_2} + k_4\mathrm{Cl_2}) = I_{\mathrm{abs.}}$$

$$(\mathrm{COCl}) = \frac{I_{\mathrm{abs.}}}{k_2\mathrm{O_2} + k_4\mathrm{Cl_2}} \qquad (\mathrm{V})$$

Substituting V in IV gives us

$$\frac{d\,(\mathrm{CO_2})}{d\,t} = \frac{2\,k_2\,(\mathrm{O_2})\,I_{\mathrm{abs.}}}{k_2\mathrm{O_2} + k_4\mathrm{Cl_2}} \qquad (\mathrm{VI})$$

Since the total amount of light absorbed is small, we may write

$$I_{\mathrm{abs.}} = I_0\,(\mathrm{COCl_2})$$

which reduces VI to the expression already obtained experimentally

$$\frac{d\,(\mathrm{CO_2})}{d\,t} = \frac{2\,I_0\,(\mathrm{COCl_2})\,(\mathrm{O_2})}{(\mathrm{O_2}) + (k_4/k_2)\,(\mathrm{Cl_2})} = \frac{kI_0\,(\mathrm{COCl_2})\,(\mathrm{O_2})}{(\mathrm{O_2}) + k'\,(\mathrm{Cl_2})}$$

As (Cl) does not enter the derivation explicitly, it is immaterial which process (5a or b) leads to recombination. The rate mechanism is seen to lead to a quantum yield of 2, a point which is to be tested experimentally in the near future.[9]

The manner in which oxygen and chlorine enter the rate law brings out once more the close analogy between a purely chemical process in which two reactants ($\mathrm{Cl_2}$ and $\mathrm{O_2}$) are in competition for a chemical intermediate (COCl) and the process of quenching of fluorescence. This similarity which holds even to the form of the mathematical expressions involved may be seen clearly in this case. Here, although we do not have fluorescence, we may say that the COCl molecule has a definite life period with respect to its reaction with chlorine. If, however, we start with a definite chlorine pressure and vary the oxygen pressure, the number of COCl molecules formed which react with chlorine will decrease as the oxygen pressure

---

(9) Experimental evidence obtained from a comparison with the phosgene sensitized formation of carbon dioxide which is very similar to the chlorine sensitized reaction indicates that the quantum yield cannot be greater than 10 and is probably of the order of magnitude of 2 or 3. This phosgene sensitized reaction is being investigated in this Laboratory and the results will be published in the near future.

increases in much the same manner that the intensity of fluorescence decreases with increasing amount of foreign gas present.

k' has been shown to be equal to the ratio k_4/k_2 and may thus be interpreted as a measure of the relative reactivity of chlorine and oxygen with COCl. These two reactions (2 and 4) also appear in the mechanism proposed by Lenher and Rollefson.[5] In some recent work, Rollefson[8] has studied the relative amounts of carbon dioxide and phosgene produced by these two processes in the chlorine sensitized oxidation of carbon monoxide. In both this reaction and the direct oxidation, the same intermediate COCl is reached, though by entirely different processes. Likewise, in both reactions, COCl is believed to react in the same manner with oxygen and chlorine. This parallelism between the two systems is emphasized by the plot in Fig. 2 of Rollefson's paper which shows that the relative efficiencies of oxygen and chlorine are the same for both reactions at all temperatures. While it is possible that different intermediates might give the same ratio at one temperature, it is extremely improbable that the temperature coefficients would also be the same. Therefore we believe that the experiments presented here constitute a definite proof of the existence of COCl as an intermediate in the reactions discussed.

Summary

The direct photochemical oxidation of phosgene has been studied and the following rate law has been determined for the reaction

$$\frac{d(CO_2)}{dt} = \frac{k I_0 (COCl_2)(O_2)}{(O_2) + k'(Cl_2)}$$

A mechanism has been suggested for the reaction and the results have been correlated with the work of Lenher and Rollefson on the photochemical formation of phosgene and the chlorine sensitized oxidation of carbon monoxide.

The Photochemistry of Mixtures of Chlorine, Oxygen and Carbon Monoxide

BY G. K. ROLLEFSON

When mixtures of carbon monoxide, chlorine, and oxygen are illuminated with light which is absorbed by the chlorine, part of the carbon monoxide is changed to phosgene and part to carbon dioxide. At relatively high pressures of oxygen, carbon dioxide formation occurs almost exclusively, whereas at low oxygen pressures the phosgene formation is predominant. The action of oxygen in this system has been attributed to a reaction with the intermediate COCl.[1,2] According to the mechanism of Lenher and Rollefson the COCl molecule may react either with chlorine or oxygen, the relative amounts of the two being determined by the specific rate constants for the reactions and the relative pressures of the two gases. In the original mechanism of Bodenstein, Lenher and Wagner it was postulated that only the oxygen reacted with the COCl and the latter compound was assumed to be in equilibrium with carbon monoxide and chlorine in the absence of oxygen but not in the presence of oxygen. Recent work from Bodenstein's laboratory[3] indicates that they now accept the view held by Lenher and Rollefson that COCl reacts with both oxygen and chlorine, but they still retain the assumption of equilibrium in the absence of oxygen and a non-equilibrium state in the presence of oxygen. In order to have such conditions it is necessary that the rates of formation and decomposition of COCl be fast compared to the rate of reaction of COCl with chlorine and comparable with the rate of oxidation of COCl. It is the purpose of this paper to present experimental results which show that the specific rates for the reactions of COCl with chlorine and oxygen are of the same order of magnitude and therefore the postulates of Bodenstein and his students are invalid.

The experimental procedure for determining the relative efficiency of reaction of chlorine and oxygen with COCl is suggested by a comparison with the most simple system of this type which we can find, namely, the quenching of fluorescence by the addition of gases. In that case we may represent the processes involved by the equations

$$A^* = A + h\nu$$
$$A^* + M = A + M + \text{kinetic energy or } A + M^* + \text{kinetic energy}$$

That is, we have the activated molecules, A, returning to the normal state with the emission of light or being deactivated by collision with some molecule M. The relative-amounts of these two processes are well known from

(3) Schumacher and Stieger, *ibid.*, B13, 157 (1931).

results in the literature. In the present case we do not have any fluorescence, but we may speak of the COCl molecule as having a certain life period with respect to its reaction with chlorine. Now if we take a definite pressure of chlorine and vary the pressure of the oxygen, the fraction of the total number of COCl molecules formed that react with chlorine will decrease as the oxygen pressure increases, much as the intensity of fluorescence is decreased by the addition of a foreign gas. To express this behavior in terms of chemical equations, let us consider the reactions

$$COCl + Cl_2 = COCl_2 + Cl \qquad (1)$$

$$COCl + O_2 = CO_2 + ClO \qquad (2)$$

The rates of these reactions are given by

$$-\frac{d\,(Cl_2)}{d\,t} = k_1\,(COCl)\,(Cl_2)$$

$$-\frac{d\,(O_2)}{d\,t} = k_2\,(COCl)\,(O_2)$$

The fraction of the phosgene molecules reacting with oxygen is

$$\frac{\dfrac{d\,(O_2)}{d\,t}}{\dfrac{d\,(O_2)}{d\,t} + \dfrac{d\,(Cl_2)}{d\,t}} = \frac{k_2\,(COCl)\,(O_2)}{k_1\,(COCl)\,(Cl_2) + k_2\,(COCl)\,(O_2)} = \frac{1}{1 + \dfrac{k_1}{k_2}\dfrac{(Cl_2)}{(O_2)}}$$

According to this equation the number of moles of oxygen reacting according to (2) will be equal to the number of moles of chlorine reacting according to (1) when $k_1(Cl_2)$ is equal to $k_2(O_2)$. Therefore if we determine the ratio of the pressures of chlorine and oxygen for which equal numbers of moles of these two gases react, we will have the ratio of the rate constants.

The experimental technique involved is extremely simple, consisting of illuminating mixtures of chlorine, oxygen and carbon monoxide and determining the extent of the two reactions from the pressure change at room temperature and also after freezing out the condensable gases with liquid air. In order to show how this is done, consider the two reactions

$$2\,CO + O_2 = 2\,CO_2$$

$$CO + Cl_2 = COCl_2$$

Let Δp_1 be the pressure change due to the first reaction and Δp_2 be that due to the second. The total pressure change is $\Delta p = \Delta p_1 + \Delta p_2$. One other equation involving Δp_1 and Δp_2 will suffice for the determination of these two quantities. To obtain this consider the changes in the sum of the carbon monoxide and O_2 pressures which we shall represent by $\Delta(CO + O_2)$.

$$\Delta(CO + O_2) = 3\Delta p_1 + \Delta p_2$$

Combining this with our previous equation

$$\Delta p_1 = {}^1/_2[\Delta(CO + O_2) - \Delta p]$$

$$\Delta p_2 = \Delta p - \Delta p_1$$

Since carbon dioxide, chlorine and phosgene all have very low vapor pressures at liquid air temperatures the pressure measured when the reaction vessel is immersed in liquid air is that of the carbon monoxide and oxygen. The value of $\Delta(CO + O_2)$ may be obtained by immersing the reaction vessel in liquid air before and after a period of illumination, reading the change in pressure, and calculating the value of $\Delta(CO + O_2)$ at room temperature by means of an experimentally determined factor. This factor varies slightly with temperature of the liquid air but was usually about **3.2.**

In Fig. 1 the values of $\Delta O_2/(\Delta O_2 + \Delta Cl_2)$ obtained at 20° are plotted against the values of Cl_2/O_2. From this curve we find that the number of moles of chlorine and oxygen reacting are equal when the chlorine pressure is 5.0 times that of the oxygen. In order to be certain that the relative amounts of the two reactions are a function solely of Cl_2/O_2, the partial pressures of the reactants were varied between the following limits (pressures in cm. of sulfuric acid): carbon monoxide from 10 to 25, chlorine from 18 to 57, oxygen from 2.7 to 42. Regardless of the pressures used the points fall on the curve within the limits shown by the graph, thereby justifying the assumption that the relative amounts of chlorine and oxygen reacting are a function solely of the ratio of these two gases.

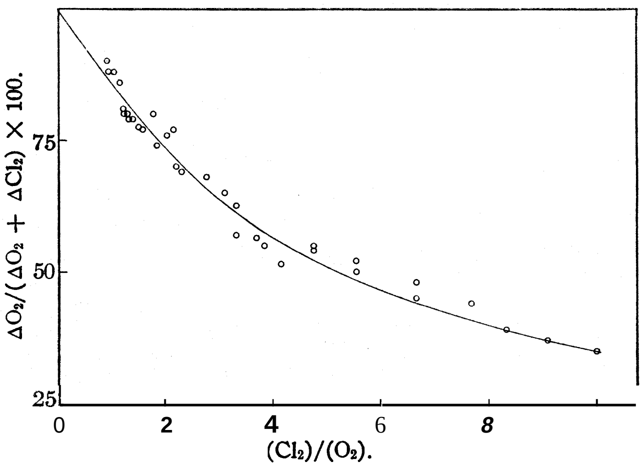

Fig. 1.

If we carry out experiments of the same type at different temperatures the division between reactions (1) and (2) should vary, as the heats of activation for the two reactions would normally be expected to be different. Such experiments have been carried out at 89 and 130°. The results fall on the same type of curve as those at 20° but the values of Cl_2/O_2 for which the rates of (1) and (2) are equal are 2.0 and 1.25, respectively. Such a trend shows that reaction (1) has a higher temperature coefficient and therefore a higher heat of activation than reaction (2). The difference between the heats of activation may be calculated from a consideration of the relationship existing between the rate constant and temperature,

$k = se^{-Q/RT}$, where s is a factor involving the number of collisions and possibly some steric factor, and Q is the heat of activation. If we let the subscripts 1 and 2 refer to the reactions (1) and (2) we have

$$\frac{k_1}{k_2} = \frac{s_1}{s_2} e^{-(Q_1 - Q_2)/RT}$$

Taking the logarithms of both sides

$$\ln \frac{k_1}{k_2} = \ln \frac{s_1}{s_2} - \frac{Q_1 - Q_2}{RT}$$

Therefore if we plot the logarithms of the experimentally determined values for k_1/k_2 against the reciprocal of the absolute temperature a straight line should be obtained. The slope of this line is $-(Q_1 - Q_2)/R$ and the intercept on the $\ln(k_1/k_2)$ axis is $\ln(s_1/s_2)$.) Figure 2 shows such a plot of the data reported in this paper combined with that obtained by Rollefson and Montgomery[4] using phosgene as a source of COCl. From the graph we find that $Q_1 - Q_2 = 2880$ cal. and $\ln(s_1/s_2) = 3.16$ or $s_1/s_2 = 24$. These figures are taken from the line which represents the combined results of the two researches; if the line is drawn through the points obtained by the method reported in this paper a slightly higher result, 3200 cal., is obtained for $Q_1 - Q_2$ and 38 for s_1/s_2. Due to the approximate methods of calculation used in obtaining k_1/k_2 in the work of Rollefson and Montgomery the higher values given above are favored. Probably the best values **are** 3000 ± 200 cal. for $Q_1 - Q_2$ and 30 ± 5 for s_1/s_2.

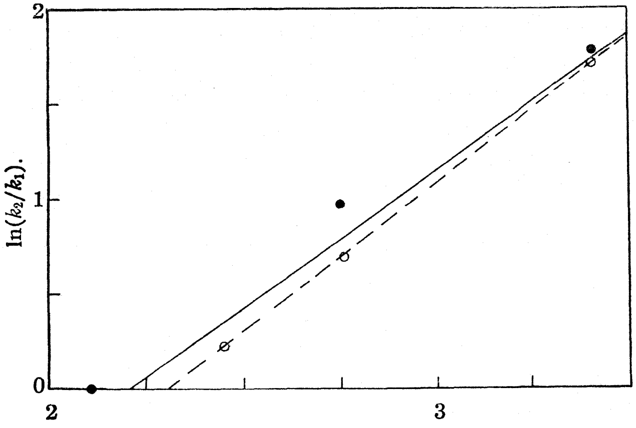

Fig. 2.

The interpretation of the difference in the two heats of activation must await an explanation of the nature of such activation. The s values, however, have been interpreted as collision numbers modified by a "steric" factor. In the case we are concerned with the difference in the number of

---

(4) Rollefson and Montgomery, THIS JOURNAL, 55, 142 (1933)

collisions of COCl with oxygen and with chlorine cannot be very great. Using the data for molecular diameters obtained from viscosity measurements it may be calculated that if the same pressures of the two gases were used there would be 1.45 times as many collisions with chlorine as with oxygen. After allowing for this effect we have a factor of approximately twenty for the so-called "steric" effects. This does not mean that there are twenty times as many geometrical arrangements of COCl and Cl_2 which lead to reaction as there are of COCl and O_2, but rather the probability of a rearrangement to give the products is twenty times as great in the former case as in the latter. This difference in probabilities may be due in part to geometrical considerations but must depend also on such factors as changes in electron spins and electron distribution.

From the facts which have been presented we have a definite mechanism to account for the diminishing effect of oxygen as the temperature is raised. That COCl is an intermediate step in the formation both of carbon dioxide and phosgene seems very definitely established by the identity of the ratio of the rate constants obtained by the two methods of attack. Furthermore, the results indicate that CO_2 formation should not disappear entirely as the temperature is raised but should be small except in the presence of relatively high pressures of oxygen. From the magnitude of the ratios observed we see that at equal pressures of oxygen and chlorine the rates of reaction with COCl never differ by more than a factor of approximately five in the temperature range from 20 to 200°. This means that we can never consider either reaction as negligible compared to the other under comparable conditions and therefore Bodenstein's postulate that COCl is present in its equilibrium concentration in the phosgene reaction and not in the sensitized carbon dioxide formation must be considered extremely questionable. A more quantitative discussion of the magnitude of the rates of the individual steps in the mechanism must await the development of the mechanism for the chlorine sensitized photochemical formation of carbon dioxide.

Summary

An experimental investigation has been made of the relative amounts of carbon dioxide and phosgene formed when mixtures of carbon monoxide, chlorine and oxygen are illuminated with light absorbed by the chlorine. It has been shown that the relative amount of the two reactions is a function solely of the ratio of chlorine to oxygen provided the temperature is kept constant. If the temperature is varied the logarithm of the ratio is a linear function of the reciprocal of the absolute temperature. These facts have been shown to be in accord with the assumption that the carbon dioxide and phosgene are formed by the reaction of an intermediate compound COCl with oxygen and chlorine, respectively.

Heat Capacity Curves of the Simpler Gases. I. Heat Capacity, Entropy and Free Energy of Gaseous Nitric Oxide from Near Zero Absolute to 5000°K.[1]

BY HERRICK L. JOHNSTON AND ALAN T. CHAPMAN

In carrying out various types of thermodynamic calculations, an accurate and assured knowledge of the heat capacities of the substances involved is often essential. Frequently, at least one of the constituents in such considerations is a gas and, due to inherent experimental difficulties, the literature is generally lacking in reliable values for the specific heats of gases.[2] The latter observation is particularly true for data taken either at very high or at very low temperatures. Yet, frequently, it is in these more extreme temperature regions that a more exact knowledge of the heat capacity curves assumes greatest interest and importance.

Moreover, until quite recently no adequate quantitative theory had been proposed to account for the heat capacities of molecules containing more than one atom. The most useful guide had been the principle of the Equipartition of Energy, enunciated by Boltzmann.[3] This principle was derived by application of statistical methods to a classical energy distribution among the various degrees of freedom associated with the translational, rotational and vibrational motions of the molecules. For monatomic gases the Equipartition Principle yields correct specific heats,[4] but its inadequacy to account correctly for the magnitudes, as well as the variations, in the specific heats of more complex gases constituted one of the original arguments in favor of quantum theory.

The approach to a correct solution of the more general problem was made, independently, by Kemble[5] and by Reiche.[6] These authors attempted to calculate the rotational portion of the heat capacity of hydrogen on the basis of what was then known concerning rotational quantization in molecules. By considering the diatomic molecule as a rigid rotator, Reiche obtained the well-known equation for C_R, the molar rotational heat capacity, which takes the form[7]

$$C_R = \sigma^2 R \frac{d^2 \ln Q}{d\sigma^2} \tag{1}$$

---

[1] Presented March 31, 1931, as part of the Symposium on "Applications of Quantum Theory to Chemistry," Indianapolis Meeting of the American Chemical Society.

[2] The low temperature measurements on hydrogen, made by Cornish and Eastman [THIS JOURNAL, 50, 627 (1928)] are a noteworthy exception.

[3] Boltzmann. *Sitzb. Akad. Wiss. Wien.*, 58 (1861).

[4] Except at high temperatures, where all monatomic gases will rise above the equipartition value due to electronic excitation.

[5] Kemble, *Phys. Rev.*, 11, 156 (1918).

[6] Reiche, *Ann. Physik*, 58, 657 (1919).

[7] Here R is the molar gas constant; T, the absolute temperature; k, the gas constant per molecule: I, the moment of inertia; p_m the statistical weight of the rotational state possessing the quantum number "m": and the summation is over all values of "m" from m_{minimum} to ∞.

$$\text{where } \mathbf{a} = \frac{h^2}{8\pi^2 IkT} \text{ and } Q = \Sigma_m p_m e^{-m^2\sigma}$$

There existed, at that time, considerable uncertainty both with respect to the proper choice of statistical weights and with respect to the value of "m" for the lower limit of the summation. These uncertainties have since been removed both through the recent advances in the wave mechanics and through progress in the empirical analysis and interpretation of molecular spectra. But working prior to these more recent developments, Reiche was limited by the dilemma of several alternative solutions for equation (1), which depended on the choice of values for "p_m" and "m." Out of some five alternatives, one solution yielded a specific heat curve whose shape was in rough agreement with the experimental curve for hydrogen. As we now know, the agreement would have been much improved had account been taken of the, then unsuspected, dual nature of molecular hydrogen.[8]

Urey[9] applied Reiche's treatment to the rotational heat capacities of several diatomic and a few polyatomic molecules. This treatment still involved the assumed condition of rigid rotators but represented an improvement through introduction of moments of inertia obtained from the molecular spectra.

The use of quantum energies obtained directly from spectroscopic measurements was introduced by Hicks and Mitchell[10] who, at the suggestion of Tolman, dropped the assumption of rigid molecules and obtained an equation for the heat capacity of gaseous hydrogen chloride in terms of the relative energies of the individual rotation and vibration states. These were secured accurately from analysis of the fine structure of the vibration-rotation bands. This meant that the heat capacity problem became one of summing up a series of terms rather than of integrating a general expression. The former of these procedures has by far the advantage since it takes account of actually perturbing effects present in the energy terms which the more approximate equation does not give and cannot predict. Although not specifically considered in the paper of Hicks and Mitchell, their equation can be extended to cover such not uncommon influences as multiplet electronic states, missing or non-combining rotation levels, excitation of higher electronic terms, etc., by a more general choice of limits for the summations.

At that time there was still some uncertainty as to the assignment of statistical weights (also referred to as "*a priori*" probabilities) and Hicks and Mitchell, unfortunately, made an incorrect assignment which led to

error in their calculations. The first correct calculation of the heat capacity of a gas other than monatomic was made by Hutchisson[11] who recalculated the heat capacity of hydrogen chloride, with correct statistical weights, from 1 to 600°K. More recently, Giauque[12] has followed this correct method in computing the heat capacity of hydrogen from near zero absolute to room temperature.

Very reliable spectroscopic data are now available for substantially all of the common diatomic gases and for several of the unstable but important diatomic molecules which appear at intermediate stages in chemical reactions. In most instances the available data for diatomic molecules are so accurate that the heat capacities, for instance, can be calculated to several thousand degrees with uncertainties of only a few hundredths of a calorie per mole per degree. We do not feel that the same claims can be made, as yet, for the calculations pertaining to any tri- or polyatomic molecule. However, for a number of the simpler tri- and polyatomic molecules data from infra-red spectra in conjunction with Raman spectra permit fairly reliable approximate values to be calculated over temperatures at which the molecules are picking up their vibrational energy and, in a more limited number of cases, their rotational energy.

The present paper is the first of a series in which we plan to compute the heat capacity curves, over comparatively wide ranges of temperature, for the common diatomic gases and for certain of the comparatively unstable diatomic molecules, such as OH. For several of the gases we will include computations of entropy[13] and of free energy.[14] In conjunction with stellar spectra, the computations at the higher temperatures should be of some assistance in the study of the physical conditions at the surfaces of certain of the stars.

The series will include more approximate calculations for certain of the tri- and polyatomic gases for which comparatively reliable data are available. We will hope to recalculate the latter when the status of the spectroscopic data warrants the more exact treatment.

The Heat **Capacity** Equation.—Three simply related quantities, independently summed, appear in the equation for heat capacity. For the sake of simplicity we will refer to these respective quantities as *A*, B and C. They are defined by the relationships:

$$A = p_i e^{-\epsilon_i/kT}; \quad B = \epsilon_i p_i e^{-\epsilon_i/kT} \quad C = \epsilon_i^2 P_i e^{-\epsilon_i/kT}$$

Here "ϵ_i" is the discrete energy, per molecule, for an individual quantum state; "P_i" the corresponding statistical weight; "*e*" the base of the natural system of logarithms and "*k*" and " T have the meanings previously assigned.

---

(11) **Hutchisson,** THIS JOURNAL, *60,* 1895 (1928).

(12) **Giauque,** ibid., *52,* 4816 (1930).

(13) **Giauque and Wiebe, ibid.,** *50,* 101 (1928).

(14) **Giauque,** *ibid.,* **52,** 4808 (1930).

In terms of these symbols the heat capacity equation takes the form

$$C_V^\circ = 3/2\,R + \frac{R}{k^2T^2}\left[\frac{\Sigma C}{\Sigma A} - \left(\frac{\Sigma B}{\Sigma A}\right)^2\right] \tag{2}$$

where the sums are to be taken over *all* possible quantum states, including electronic or nuclear levels, which the molecule in question may assume. This equation gives the molar heat capacities, at constant volume, arising from all sources excepting molecular dissociation or gas imperfection.

The derivation of this important equation, in moderately simple steps, is repeated by Giauque.[14] We wish here to emphasize the essential simplicity and rigor of the underlying derivation. In using equation (2) one is essentially performing the following steps: (1) counting the numbers of molecules present in *each* discrete quantum state by application of the Maxwell–Boltzmann distribution law; (2) obtaining the *total energy content* of *each* quantum level by multiplying the number of molecules in each by their appropriate energies; (3) summing over *all* quantum levels to get the *total energy* per *mole* of gas; (4) repeating the calculation for a temperature slightly higher and (5) from this computing the increase in total molar energy per unit increase in temperature. Steps (4) and (5) are, of course, actually combined in equation (2) which is the solution of a differential equation.

The Equations for Entropy and Free Energy.—The expression for entropy takes the form

$$\begin{aligned} S^\circ - S_0^\circ = {} & 3/2\,R \ln T + R \ln V + 3/2\,R \ln M + S' \\ & + R\left[\ln \Sigma A + \frac{1}{kT}\frac{\Sigma B}{\Sigma A}\right] \end{aligned} \tag{3}$$

"S_0°" is the entropy of the gas at the absolute zero and is to be taken as identically zero if the sums in the last term are taken over *all* existent quantum states of the molecule in question.[8b,15] The first four terms to the right of the equation sign represent the entropy contribution arising from translational freedom[16] and the last bracketed term, the entropy arising from internal degrees of freedom. "V" and "M" signify molal volume and molecular weight, respectively, and "S'" is a term composed of universal constants[17] and has the value of -11.057 calories per degree per mole.

The free energy equation takes the form

$$(F^\circ - E_0^\circ)/T = 5/2\,R - S_T - R \ln \Sigma A \tag{4}$$

Here "S_T" represents the translational contribution to entropy given by the first four terms to the right of the equation sign in equation (3) and "E_0°" represents the molal internal energy of the gas at the absolute zero. It is indeterminate but the ΔE_0° appropriate to a given reaction may be

determined from thermochemical data or, in some cases, from spectroscopic data.

Like equation (2), equations **(3)** and (4) assume the gas to be in the hypothetical perfect state. This is indicated by the small circles above and to the right of the respective symbols. Suitable corrections for gas imperfection may be applied when desirable.

Spectroscopic Interpretation of Nitric Oxide.—The β band system of nitric oxide was discovered and photographed by E. P. Lewis.[18] The fact that the bands occur in absorption shows that the ground level is the normal state of the molecule. A careful analysis of these bands was made by Jenkins, Barton and Mulliken,[19] who photographed and analyzed some two thousand lines in thirty-six bands, under high dispersion. This work was extended recently by Schmid, Koenig and Farkas,[20] who added some thousand more lines and twenty-two more bands. The thorough work of the latter authors confirms in every detail the earlier analysis and energy assignments by Jenkins, Barton and Mulliken.

A summary of the analysis of the bands, so far as it relates to quantum assignments, has been published previously.[15] We repeat here only those facts essential to the calculations by the use of equations (2), **(3)** and (4).

The ground state of nitric oxide is a normal $^2\Pi$ state with a doublet separation of 124.4 cm.$^{-1}$ (354 calories per mole). The **A** type doubling of the rotational levels is so small that it cannot be evaluated accurately and does not affect the specific heat values, except at some small fraction of a degree absolute. Jenkins, Barton and Mulliken find that the vibrational energies, in the normal state, are quite accurately reproduced by the formulas

For the $^2\Pi_{1/2}$ **state,** $\tilde{\nu} = 1892\ 119\,v - 14.4243\,v^2 + 0.04021\,v^a - 0.001351\,v^4$ **(5a)**
For the $^2\Pi_{3/2}$ **state,** $\tilde{\nu} = 1891.976\,v - 14.4543\,v^2 + 0.04229\,v^3 - 0.001423\,v^4$ **(5b)**

where $\tilde{\nu}$ refers to the energy (in wave number units) in excess of the "zero point" energy held in the "v" $= 0$ state. The same authors find that the energies of the various rotation states for the $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ forms of nitric oxide are satisfactorily reproduced by the formula

$$F(J) = \text{Const.} + A(J + 1/2) + B(J + 1/2)^2 + C(J + 1/2)^3 + D(J + 1/2)^4 \qquad (6)$$

where $F(J)$ is the energy, in cm.$^{-1}$, of the rotational level characterized by a particular value of the quantum number J; the constant term represents vibrational and electronic energy; and A, B, C and D are constants whose numerical values are given in Table I.

The arrangement and spacings of the energy levels in nitric oxide, calculated from equations 5 and 6, is shown diagrammatically in Fig. 1.[21] The separations of rotational levels in (b) and of the normal doublet levels in (c) are greatly exaggerated.

$^2\Pi_{3/2}$	.0070	(1.7239 − 0.018660)	.010	− .871
	± .0121	±0.0015	± .069	± .135

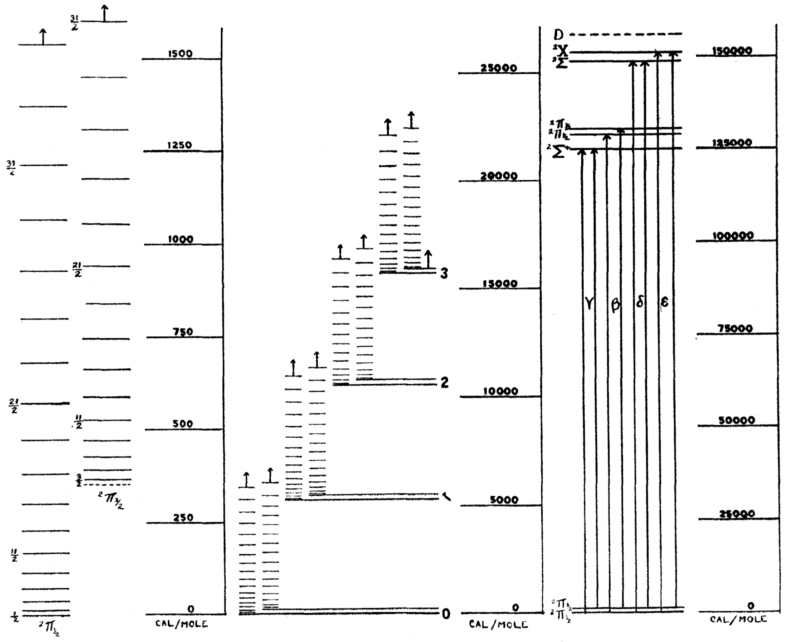
Statistical weights appropriate to the various energy states are given by the expression

$$p_i = (2J + 1)(2i_1 + 1)(2i_2 + 1) \tag{7}$$

where J is the rotational quantum number associated with the state in question and the i's represent nuclear spins. For nitric oxide, with a nuclear spin of one for nitrogen and zero for oxygen this equation reduces to

$$p_i = 3(2J + 1) \tag{7a}$$

The earlier uncertainty in respect to statistical weights has been entirely removed by the developments of the wave mechanics and the above relationship is now definitely established. The mystery formerly attached to the significance of this important quantity has also been removed. The solution of the wave equation leads to the result that for each discrete value of J associated with a particular electronic state there exist (2J + 1)



(a) Rotation levels. (b) Vibration–rotation levels. (c) Electronic levels and transitions.

Fig. 1.—Energy level diagram of NO.

$(2i_1 + 1)(2i_2 + 1)$ "eigen values" which satisfy the equation. These can be interpreted, physically, as $(2J + 1)(2i_1 + 1)(2i_2 + 1)$ different states, nearly alike in energy and all having the same electronic, vibrational and rotational quantum numbers. While the physical meaning here ascribed to statistical weights is non-essential to the immediate solutions, which depend simply on correct numerical values of p_i, this interpretation is essential to a clear conception of entropy in gases.[14]

The Heat Capacities.—Molar heat capacities of nitric oxide from 0.5 to 5000°K. were computed by the use of equation (2) and are recorded in Table II. This table is in terms of the 15° calorie and applies to nitric oxide in the hypothetical ideal gaseous condition. The tabulations represent heat capacities at constant pressure and were obtained from C_v by the addition of R calories.

5.0	6.912	200	7.292	1125	8.273		

The relative energies of the various vibrational and rotational states of the molecule were calculated from equations (5a, b) and (6), and the energy of the $^2\Pi_{3/2}$ state for which v = 0 and J = 3/2 was taken to be 129.55 cm.$^{-1}$ higher than that of the $^2\Pi_{1/2}$ state for which v = 0 and J = 1/2. This corresponds to an electronic coupling energy of 124.4 cm.$^{-1}$ computed from the band origins. Statistical weights were computed by equation (7a). All natural physical constants employed in the calculations were taken from the "International Critical Tables."[22] The molecular weight was taken to be 30.008.[23]

Approximations Used in Obtaining the Higher Vibration Sums.—It was found possible to avoid much of the labor incident to the higher vibration sums, without introducing appreciable inaccuracy, by the use of certain corrected approximations. As shown in Table I the rotational energies are influenced by the vibrational frequencies, so that the spacings between successive rotational levels are slightly less for states with high values of

---

(23) "Thirty-Sixth Annual Report of the Committee on Atomic Weights," THIS JOURNAL, **52**, 857 (1930).

the vibrational quantum number than for the lower vibrational states. However, these effects are comparatively small and, as a first approximation, can be neglected. This is equivalent to making the assumption that B_{v+1} is approximately equal to B_v, or that for every rotational level in the vibration state with quantum number v there lies a corresponding rotational level in the state with quantum number (v + 1) whose energy is exactly $(\tilde{\nu}_{v+1} - \tilde{\nu}_v)$ higher than the energy in the lower vibrational level. On the basis of this assumption it can easily be shown that the sums for the (v + 1) level are related to those of the v level by the following equations, in which the symbol "ϵ_v" is used to replace the vibrational energy increment $(\tilde{\nu}_{v+1} - \nu_v)$

$$\Sigma_{v+1}A = e^{-\epsilon_v/kT}\,\Sigma_v A \tag{8a}$$

$$\Sigma_{v+1}B = e^{-\epsilon_v/kT}\,\Sigma_v B + \epsilon_v\Sigma_{v+1}A \tag{8b}$$

$$\Sigma_{v+1}C = e^{-\epsilon_v/kT}\,\Sigma_v C + \epsilon_v(2\Sigma_{v+1}B - \epsilon_v\Sigma_{v+1}A) \tag{8c}$$

Table III illustrates the application of these approximation equations to the computations at 2000°K. The columns headed "summed" give the values obtained by actual summing for the first five vibration states. The columns headed "calculated" give sums which were computed by equations (8a, b and c). The differences, in percentage, are listed in the columns headed "% correction." The near constancy in these corrections as a function of the vibration follows from the nearly linear dependence of the B constant (Table I) on the vibrational quantum number. The starred sums were computed by applying the appropriate percentage corrections to sums calculated by equations (8a, b, c). These correction factors were obtained by graphical extrapolations of the corrections evaluated empirically for the lower vibration states.

The percentage corrections necessary to the calculations by equations (8a, b, c) were also studied as a function of temperature. The results are shown in Table IV which compared the "summed" and "calculated" values for the v = 1 vibration level at four widely different temperatures

TABLE IV

THE VIBRATION SUMS FOR THE (v = 1) LEVEL OF NITRIC OXIDE AS A FUNCTION OF THE TEMPERATURE

	ΣA		% Correction	$\left(\frac{1}{2.30259\,kT}\right)\Sigma B$		% Correction	$\left(\frac{1}{2.30259\,kT}\right)^2\Sigma C$		% Correction
T, °K.	*Summed*	*Calcd.*		Summed	Calcd.		Summed	Calcd.	
1000	52.04	51.48	1.06	85.24	84.32	1.08	149.59	147.96	1.09
2000	417.20	412.68	1.08	433.52	428.79	1.09	530.37	524.53	1.10
3000	996.71	985.86	1.09	837.38	828.15	1.10	895.58	885.54	1.12
4000	1680.16	1661.71	1.10	1245.76	1231.83	1.12	1249.82	1235.52	1.14

It is evident that the correction factors do not greatly change as functions either of the vibration or of the temperature. Accordingly, for all of the higher temperatures the rotation levels were summed only for the (V = 0) levels of the two separate electronic states and the sums for the higher vibration levels were computed by equations (8a, b, c) in conjunction with the correction factors obtained by joint interpolation and extrapolation of the factors in Tables III and IV. At 1000, 2000, 3000 and 4000° the summed values for vibration states which appear in Tables III and IV were employed. In view of the rapid decrease of the sums as a function of the vibrational quantum number (cf. Table III) it is apparent that no appreciable error was introduced by this treatment.

Analysis and Interpretation of the Heat Capacity Curve.—The results are shown graphically in Figs. 2 and 3, in which open circles are used to plot spectroscopic values and dark circles mark the less reliable experimental values obtained by a calorimetric method,[24] and by a velocity of sound method.[25] These curves represent heat capacity in excess of that associated with translation and refer, in general, to heat capacity arising from rotation, from vibration and from electronic excitation.

Figure 2 includes the temperature interval from about 1°K. to approximately 5°K. over which gaseous nitric oxide takes up its rotational specific heat. There also appears, at a little higher temperature, an inflection which leads to a sharp maximum at about 75°K. This interesting maximum, predicted by Witmer,[26] shows clearly in Fig. 3 and results from the absorption of the coupling energy which separates the $^2\Pi$ electronic levels of the molecule. This behavior, which relates to a component of the specific heat never considered in the Equipartition treatment, is typical of gases which, like nitric oxide, possess a multiple normal electronic state. The temperature at which the maximum occurs and the extent of the interval over which the effect persists depends principally on the spacing of

the component levels. Figure **3** also shows the vibrational contribution to the heat capacity curve, which becomes effective at about 300°K.

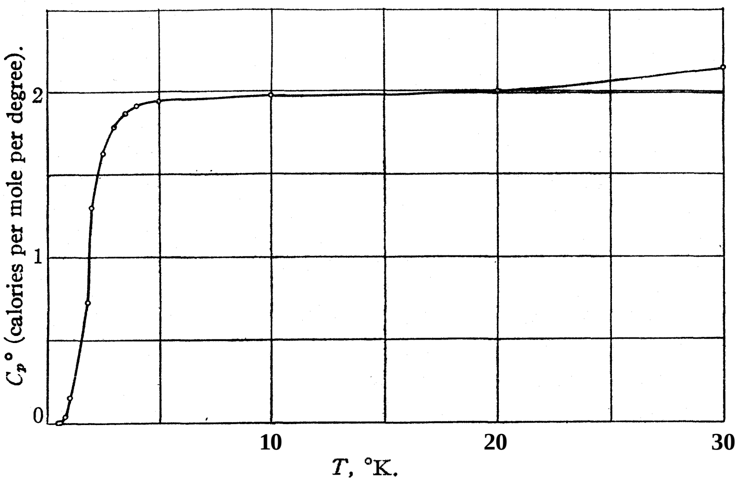

Fig. 2.—Heat capacity of gaseous nitric oxide (in excess of that due to translation).

In order to analyze in more detail the separate behavior of these several components of the total specific heat we have computed heat capacities with

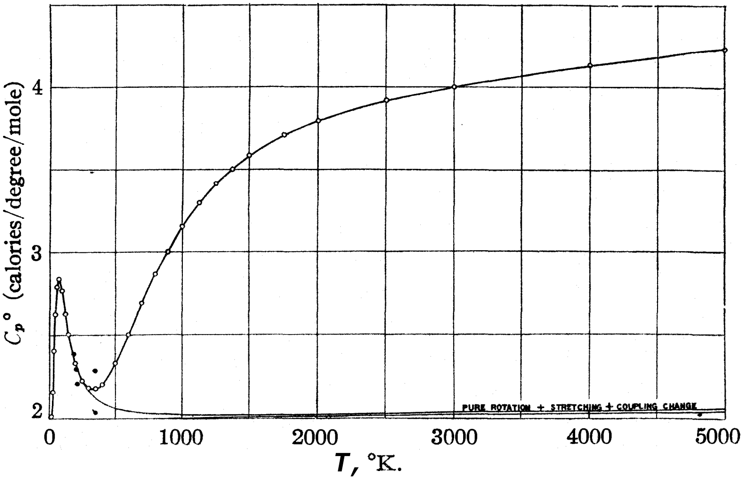

Fig. 3.—Heat capacity of gaseous nitric oxide (in excess of that due to translation): O, spectroscopic; ●, calorimetric (Heuse); $\overset{|}{\bullet}$, velocity of sound (Partington and Shilling).

certain groups of levels purposely omitted from the sums. By summing only the rotational series of the $(v = 0)$ vibration state of the $^2\Pi_{1/2}$ molecules we obtained a hypothetical pure rotation curve from which are excluded effects due to absorption of energy by either vibration or electronic excitation. This curve, which is identical with the total curve to about 15°K. and is within 0.01 calorie of rotational equipartition at 20°K., rises very gradually to a value which exceeds R by 0.05 calorie at 5000°K. This small added specific heat represents energy absorbed by centrifugal stretching at high speeds of molecular rotation. Although small in the case of nitric oxide, it typifies an effect present in all gases to a greater or less degree. Kemble and Van Vleck[27] have shown that, in hydrogen at 1350°K., the specific heat due to molecular stretching exceeds that arising from vibration. Another curve was computed by summing only the ($v = 0$) rotation series of both electronic states. This, as well as the pure rotation curve, is shown at the bottom of Fig. **3.** The differences between these curves represent specific heat arising from energy absorbed by molecules which pass from the $^2\Pi_{1/2}$ to the $^2\Pi_{3/2}$ levels while the differences between the total curve and the (Rotation + Stretching + Coupling) curve represent vibrational specific heat. At 5000°K. this equals 2.18 calories, which exceeds vibrational equipartition by 0.19 calorie, and is still rising. This results from the anharmonic character of the molecular vibration and is typical of all actual molecules. Anharmonic oscillation of a vibrator, like stretching of a rotator, adds potential energy with a consequent gain in the capacity to absorb heat. This influence has been considered previously in connection with the vibrational heat capacity of solids.[28]

A simple physical explanation of the heat capacity curve of nitric oxide can be given in terms of quantum theory by reference to the energy level diagrams of Fig. 1. At the absolute zero all of the molecules exist, under equilibrium conditions, in their state of lowest energy. This is the $^2\Pi_{1/2}$ level with $v = 0$ and $J = 1/2$ and is shown as the bottom level in the diagrams of Fig. 1 (a and b). Although the molecules perform internal oscillations due to retention of "zero point" vibrational energy, they are at rest with respect to translational motion. The immediate effect of a small increase in temperature is the appearance of kinetic energy associated with translational motion. This, in all probability, is not attained fully excited but rises rapidly to the equipartition value of 3/2 RT per mole at some small, undetermined fraction of a degree absolute. The gas thus acquires a molar translational specific heat, C_v, of 2.98 calories per degree, which corresponds to that of a monatomic gas and is represented by the base line of Fig. 2. At about 1°K. appreciable numbers of molecules begin to rise from the ($J = 1/2$) level to higher rotational levels in the same series, with consequent absorption of rotational energy. At 1°K. about 0.1 of 1% of all the molecules are in rotational levels above that for which $J = 1/2$. At 5°K. approximately 20% have reached the ($J = 3/2$) level, nearly 2% are

---

in the (J = 5/2) level and smaller numbers have attained higher rotational states. This redistribution toward rotational levels of higher energy continues above 5°K. with a nearly uniform rate of energy absorption.

Table V shows the temperature distribution of molecules between the levels associated with the $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ isomeric forms. At 20°K. less than 1 molecule in 25,000 possesses sufficient energy to attain the lowest $^2\pi_{3/2}$ level. The absorption of the 124 cm.$^{-1}$ (353 calories per mole) coupling energy which accompanies the redistribution produces the electronic component of the specific heat.

TABLE V

PERCENTAGES OF MOLECULES IN THE $^2\Pi_{1/2}$ ELECTRONIC STATE

T, °K.	%	T, °K.	%	T, °K.	%	T, °K.	%

At room temperature only 1 molecule in 10,000 has gained vibrational energy in excess of that which it possessed at the absolute zero.(29) Above

---

(29) Table XII of Ref. 14 is in error in so far as it applies to vibration states higher in energy than those for which $v = 0$ (there identified by "n" = 1/2) through an inadvertent error in the value used for the vibrational energy. This necessitates a correction in $S_{298.1}$, which should read 50.35 E. U., as given in this paper. The error to which we refer in no wise affects the comparison of calorimetric and spectroscopic entropies at 121.36°K., or the important conclusions with respect to the use of the Third Law of Thermodynamics. A typographical error also occurred on p. 3211 where brackets were omitted from the equation for S_{E+V+R}.

room temperature appreciable numbers of molecules acquire frequencies corresponding to higher overtones, with attendant increase in the rate of energy absorption.

The Entropy of Nitric Oxide.—Table VII gives the entropy of nitric oxide calculated by equation (3) for temperatures ranging from 1 to 5000°K. These values refer to the hypothetical ideal gaseous state at a pressure of 1 atmosphere and are expressed in calories per mole per degree.

TABLE VII

ENTROPY OF NITRIC OXIDE IN THE IDEAL GASEOUS STATE AT 1 ATMOSPHERE PRESSURE

(Nuclear Spin Entropy Not Included)

T, °K.	$S°$	T, °K.	$S°$	T, °K.	$S°$	T, °K.	$S°$
1	10.617	75	40.028	400	52.449	1250	61.234
5	20.672	100	42.267	500	54.062	1500	62.780
10	25.477	125	43.978	600	55.408	1750	64.111
20	30.295	150	45.350	700	56.573	2000	65.275
30	33.145	200	47.473	800	57.607	2500	67.248
40	35.227	250	49.088	900	58.474	3000	68.877
50	36.896	298.1	50.350	1000	59.392	4000	71.481
62.5	38.609	350	51.494	1125	60.356	5000	73.526

In obtaining these values we have subtracted the multiplicity of 3 arising from the one unit of nuclear spin associated with the nitrogen nucleus. Hence, in order to obtain the total absolute entropy of nitric oxide the values in the above table must all be increased by $R \ln 3 (= 2.18)$ entropy units. However, it is probable that for nitrogen, as for iodine,[30] this entropy is carried by the nitrogen atom into its various chemical combinations and so cancels out[31] when one computes the entropy *change* which occurs in a reaction. For that reason we do not include it in the table, which gives the values that should be employed in thermodynamic calculations involving nitric oxide gas. It is, of course, understood that these entropies are to be combined with entropies which likewise omit the nuclear spin entropy arising from the presence of nitrogen atoms. In all probability the nuclear spin entropy of nitrogen will be absent from the entropies obtained calorimetrically for nitrogen compounds.

The usual method of getting the entropy of a chemical substance is by graphical or analytical integration of $\int_{T'}^{T} C_p \, d \ln T$, in which the lower limit of integration represents a temperature so low that the heat capacity approaches zero asymptotically and so can be extrapolated to a negligible value with little error in the resulting area under the curve. Giauque and Johnston[5b] and Johnston and Giauque[15] have pointed out that reliable calorimetric information, alone, is sometimes insufficient to give the correct value of the entropy for use in thermodynamic calculations. An interesting illustration of this, which shows clearly the reason for the point in

(30) Giauque, THIS JOURNAL, 53, 507 (1931).

(31) Gibson and Heitler, *Z. Physik*, 49, 465 (1928).

question, is provided in the computations for gaseous nitric oxide. We believe that the heat capacities which we have calculated represent the values which would be approached by accurate calorimetric determinations corrected for gaseous imperfection, and that if 100% accurate calorimetric measurements could be made on the hypothetical perfect gas down to, say, 1°K., the curves which we have shown would be reproduced. Such a curve could easily be extrapolated to a negligibly low value below 1°K. Yet if data so obtained were plotted against the natural logarithm of the temperature, the correct entropy values of Table VII would not be obtained. We show this in Table VIII which was obtained by graphical integration of the values recorded in Table II. It will be observed that the graphical values lie under the exact equation (3) values by R ln 4 (=2.76) entropy units.

TABLE VIII

"INCORRECT" ENTROPY OBTAINED GRAPHICALLY FROM THE HEAT CAPACITY CURVE

T, °K.	"$S°$"	T, °K.	"$S°$"	T, °K.	"$S°$"	T, °K.	"$S°$"
1	7.87	20	27.54	298.1	47.58	2000	62.52
5	17.91	50	34.14	500	51.30	3000	66.12
10	22.73	100	39.51	1000	56.62		

The explanation, in this case, is quite simple. Up to the present we have referred to the lowest level of nitric oxide as the ($J = 1/2$) level of the ($v = 0$) vibration state of the $^2\Pi_{1/2}$ molecule, and have represented this level by a single horizontal line in Fig. 1 (a and b). In reality this level itself consists of four very close component levels (we still exclude the influence of nuclear spin) among which the molecules are evenly divided at 1°K., and even down to somewhat lower temperature. This multiplicity is in consequence of two factors: (1) the double statistical weight of the ($J = 1/2$) rotational level by equation (7) which means, physically, two distinct quantum states of the molecule and (2), the doubling of the electronic level. This multiplicity did not contribute to the heat capacity curve above 1°K. because its effect was spent below this temperature, in much the same way that the $^2\Pi$ coupling energy had practically spent its effect below 500°K. At some temperature below 1°K., probably at a few hundredths of a degree absolute, there should exist a very narrow, but possibly quite high, specific heat maximum which represents the equilibrium transformation between the two Λ types of the molecules. The area under the C_v vs. T curve, through this maximum, represents the small energy of transformation of half a mole of the lower energy modification into the higher energy form. In nitric oxide, this Λ coupling energy is too small for evaluation although sufficiently large to permit spectroscopic resolution of the doublets which comprise the higher rotation lines. The double weight of the ($J = 1/2$) level must also lead to a narrow maximum at a still lower temperature, due to the slight energy difference which must arise between the two rotational forms as a result of the perturbing influence of weak fields, such as the magnetic field of the earth. It is omission of these effects, necessary to the complete heat capacity curve, that led to the incorrect values in Table VIII. The proper correction may readily be applied when there is recognition, as in this case, of the existence of the equimolar, four component mixture whose entropy of mixing is $R \ln 4$ as given by the Second Law of Thermodynamics.

Free Energy Values and the Degree of Dissociation.—In Table IX we give values of $-(F^\circ - E_0^\circ)/T$ for gaseous nitric oxide at a pressure of one atmosphere. Underscored values were calculated by equation (4). The remainder were interpolated by a graphical method.

1050	52.244	2800	59.995		

This table will find eventual application in a large number of reactions involving gaseous nitric oxide. Immediate application can be made to the equilibria involved in the decomposition of the gas into its elements. The more important of these equilibria is that between the gas and molecular nitrogen and molecular oxygen, which forms the basis of the Birkeland–Eyde process for the fixation of atmospheric nitrogen. This equilibrium will be discussed by Giauque and Clayton in a paper soon to appear in THIS JOURNAL. A less important, but nevertheless interesting, equilibrium is that between molecular nitric oxide and nitrogen and oxygen atoms. Consider the reaction NO = N + O.

For this reaction

$$\frac{\Delta F^\circ}{T} = \frac{F^\circ(\mathrm{O})}{T} + \frac{F^\circ(\mathrm{N})}{T} - \frac{F^\circ(\mathrm{NO})}{T}$$

$$= \left(\frac{F^\circ - E_0^\circ}{T}\right)_{\mathrm{O}} + \left(\frac{F^\circ - E_0^\circ}{T}\right)_{\mathrm{N}} - \left(\frac{F - E_0^\circ}{T}\right)_{\mathrm{NO}} + \frac{\Delta E_0^\circ}{T}$$

The term in $(F^\circ - E_0^\circ)/T$ for NO, is taken from Table IX; the corresponding term for atomic oxygen is taken from the table prepared by Johnston and Walker;[32] and that for atomic nitrogen is calculated by equation (4) with ΣA put equal to

$$4 + 10e\,\frac{-54{,}640}{RT} + 6\,e\,\frac{-82{,}070}{RT}$$

The statistical weights and the energies appropriate to the latter expression are derived from consideration of the spectrum of the neutral nitrogen atom, which has been worked out by Compton and Boyce.[33] ΔE_0° is the heat of dissociation at the absolute zero and is identical with the spectroscopic "heat of dissociation" into normal atoms. This quantity is not known for nitric oxide with any high degree of accuracy. Hence we can calculate, at present, only the order of magnitude of the dissociation. Taking ΔE_0° to be 142,000 calories per mole, which Mulliken[34] estimates as correct to within 5000 to 15,000 calories, we obtain the figures in Table X.

TABLE X

APPROXIMATE VALUES OF THE DISSOCIATION OF NITRIC OXIDE INTO ATOMS AT A TOTAL PRESSURE OF 1 ATMOSPHERE

T, °K.	ΔF°	K	α
2000	88,468	2.15×10^{-10}	1.47×10^{-5}
3000	58,842	5.16×10^{-5}	7.18×10^{-3}
4000	29,668	2.39×10^{-2}	0.153
5000	19,820	0.136	0.346

The equilibrium constant K was obtained from the thermodynamic relationship $AF^0 = -RT \ln K$ and the degree of dissociation, α, was computed from the relationship $\alpha = \sqrt{K/(K + P)}$, with P put equal to 1. Although we must regard these figures as correct only in the order of magnitude, they serve to indicate the relatively high stability of nitric oxide with respect to dissociation into atoms. The instability which attaches to nitric oxide at moderate temperatures exists in virtue of the unusually high stability of the nitrogen molecule, favoring dissociation in that direction, and is not due to any intrinsic instability of the NO molecule.

Evaluation of the Limits of Error.—Except for small uncertainties in the physical constants employed, which influence the final figures to an almost negligible degree (this uncertainty may influence the values in Tables VII and IX by as much as 0.01 calorie; the influence on heat capacities would be only about one-tenth of this), the extent to which values in the preceding tables may be in error is determined by the accuracy of the spectroscopic data or, more properly, of the equations for the vibrational and rotational energies (Equations (5a, b), 6). Below 1000°K. substantially all of the terms needed in accurately evaluating the several sums lie within the range of energies covered by spectroscopic observations which the energy equations accurately reproduced. Even at 5000°K. the several higher vibration levels which made appreciable contributions to the sums were almost entirely represented in the observed bands. Thus only 0.07% of ΣA, 0.37% of ΣB and 1.21% of ΣC were contributed by vibration levels which represented extrapolations of energies by the accurate equations (5a, b). A considerably larger fraction of the rotational sums was contributed, at the higher temperatures, by rotational terms whose energies lay beyond the spectroscopic observations. This is illustrated in Table XI which shows: (1) the total number of rotational terms summed in the $^2\Pi_{1/2}$ ($v = 0$) vibrational level, and (2) the number of those terms, starting with the ($J = 1/2$) term, which contributed 90% of the totals to the respective sums. The actual spectroscopic data covered the first 32 rotational terms. It was thus necessary, at these higher temperatures, to employ equation (6) to compute the energies of many rotational terms which represent an extrapolation beyond those observed experimentally. However, this does not constitute a serious source of error since the equation of Jenkins, Barton and Mulliken will certainly give the first several extrapolated energies with considerable accuracy and since the higher extrapolations, which may be relatively inaccurate for purposes of spectroscopy,[35] involve terms with energies so large that the same degree of accuracy is not essential in their evaluation. Indeed, for an equation which will faithfully reproduce the first thirty-two terms in the rotational series, the increase in the error on passing from term to term in the high rotational extrapolations will probably be more than offset by the dwind-

ling importance of the successive terms. Accordingly, we believe that we can make a fair estimate of the extent to which the calculated data are in error by considering the probable errors assigned to the constants in their rotational energy equation, by Jenkins, Barton and Mulliken. These were given in Table I. In computing the error which may exist in the values in our tables we assumed the case most unfavorable to ourselves, namely, that the probable errors to the several constants in equation (6) were all present at full value and of such sign that they were all additive. This is a rather extreme assumption and the tables are probably somewhat more accurate than indicated by the errors which we compute.

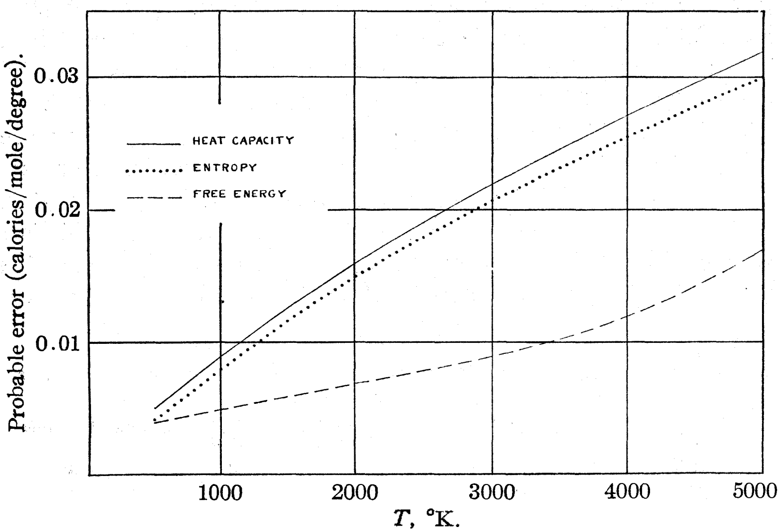

Fig. 4.—Probable errors in the spectroscopic values of C_p°, of S° and of $((F^\circ - E_0^\circ)/T)$ for nitric oxide.

In making the actual computations of the probable error we employed a method which is an extended form of that used by Hutchisson.[11] This depends on the recognition that a certain percentage error in ϵ_i is equivalent to the same percentage error (of opposite sign) in T, since T appears under ϵ_i in all of the equations which we employ in evaluating the sums. By plotting the respective sums against T, on a large-scale graph, it is thus possible to estimate the needful corrections for a small correction in ϵ_i. For hydrogen chloride at low temperatures Hutchisson needed to consider the probable error only in the B constant of the rotational energy equation and so could assume a constant percentage error to apply to all of the energy terms which make up a given sum. With nitric oxide at high temperatures the influence of the different rotational constants produced a variable effect on the energies of the various rotational terms. It was thus necessary to use a weighted average for the percentage probable error of the temperature term for the sums. We accomplished this by dividing the rotational terms into successive groups of ten; computing the average percentage error in the energies of the ten terms composing a group; and computing a weighted mean by considering separately the proportional contributions of the several decimal groups to Σ's A, B and C in turn. The heat capacity, entropy and free energy were then recalculated from these "corrected" sums and the divergences were noted. This procedure was followed for temperatures of 500, 1000, 1500, 2000, 2500, 3000, 4000 and 5000°. The results are shown graphically in Fig. 4 in which separate curves are drawn to represent the probable errors in the various tables. It is noteworthy that even at 5000°K. the probable errors in none of these quantities exceed 0.03 calorie while at 500°K. the errors do not exceed 0.005 calorie.

We wish to acknowledge a grant from the National Research Council, which has been applied to the purchase of an electric computing machine to aid in the subsequent investigations in this series.

Summary

The importance of accurate values for gaseous specific heats has been stressed and attention has been called to the present unreliability of experimental values.

Equations based on quantum theory, which permit accurate calculation of heat capacity, entropy and "free energy," have been discussed.

The heat capacity of nitric oxide in the ideal gaseous state has been calculated for the temperature range 0.5 to 5000°K. The heat capacity curve shows a sharp rise between approximately 1 and 5°K., which represents the attainment of rotational equipartition; a maximum at about 75°K., which results from excitation to the upper level of the normal $^2\Pi$ electronic state of the molecule; and a vibrational component which starts at about 300°K. and attains the equipartition value at about 3000°K. At high temperatures the rotational component of the specific heat exceeds the equipartition value, due to centrifugal stretching of the molecule, and the vibrational component exceeds R calories, due to the anharmonic character of the oscillations.

Tables are included which show the temperature distributions of nitric oxide molecules between the electronic levels of the normal doublet and between the various vibrational levels.

The entropy has been calculated and tabulated for temperatures from 1 to 5000°K. The fact that heat capacity data alone are sometimes insufficient to give the full entropy is reaffirmed.

The "free energy," as represented by the quantity $-(F^\circ - E_0^\circ)/T$ has been calculated from 75 to 5000°K. and tabulated in a fashion that permits easy interpolation.

Approximate values are given for the degree of dissociation into atoms, at one thousand degree intervals. The approximate character of the computations results from present uncertainty in the heat of dissociation. The computations show that nitric oxide is intrinsically stable with respect to dissociation into its atoms at moderate temperatures.

Certain corrected approximations which permit reliable computations of the higher vibrational sums with a considerable saving in labor are discussed.

The probable errors of the heat capacity, entropy and "free energy" calculations are determined. For each of the three quantities they amount to only about 0.03 calorie per mole per degree at 5000°K. and to less than 0.005 calorie per mole per degree at 500°K.

Heat Capacity Curves of the Simpler Gases. II. Heat Capacity, Entropy and Free Energy of Gaseous Oxygen from Near Zero Absolute to 5000°K.[1]

BY HERRICK L. JOHNSTON AND MARGERY K. WALKER

The chemical importance of oxygen lends particular interest to the evaluation of its heat capacity, entropy and free energy. From a theoretical standpoint the heat capacity curve possesses added interest due to the multiple nature of the normal electronic level, the absence of alternate rotational states and the comparatively low energy of some of the excited electronic levels. The more than usual reliability of the spectroscopic data on molecular oxygen, both in point of interpretation and in point of accurate wave length determinations, permits the attainment of high accuracy in the calculations.

In this paper we present the results of heat capacity, entropy and free energy calculations to a maximum temperature of 5000°K. The calculations were carried out in the manner described in the previous paper.[2] The reader is referred to that paper for the meanings of symbols which we here employ without redefinition.

Spectroscopic Interpretation of Molecular Oxygen.—Two band systems are prominent in the spectrum of molecular oxygen. These are the Schumann–Runge system, which occurs in the ultraviolet and has been extensively photographed both in emission[3] and in absorption,[4] and the

"atmospheric absorption" system,[5] so called because of its prominence among the Fraunhofer lines which have been identified as arising from absorption of solar radiation by the earth's atmosphere. This system lies in the near infra-red. The fact that both systems make their appearance by absorption in cold gas shows that their common ground state is the normal level of the molecule.

These experimental data were successfully analyzed and interpreted through the efforts of Ossenbrüggen[6] and of Mulliken.[7] The structure assigned to the oxygen molecule by Mulliken accorded also with the magnetic behavior of molecular oxygen[8] and was subsequently confirmed by the identification and analysis of nearly a hundred faint lines which had their origin in oxygen molecules containing the isotopic atoms O^{18} and O^{17}.[9]

A summary of the analyses of the atmospheric bands, in so far as it relates to quantum assignments, has been published previously.[10] We repeat here only those facts essential to the calculations in the present paper.

The ground state of the oxygen molecule is a $^3\Sigma$ state whose three components are termed, by Mulliken, the F_1, F_2 and F_3 coupling states, respectively. The coupling energy of the F_2 form exceeds that of the other components by about 2 cm.$^{-1}$ (6 calories per mole). One equation serves equally well to represent the vibrational levels of all three forms. In the calculations included in the present paper we have adopted the vibrational formula

$$\tilde{\nu} = 1565.37v - 11.37v^2 \qquad (1)^{11}$$

which was derived by Birge and Sponer[12] from a careful analysis of the extensive data on the Schumann–Runge bands.[3,4a,b,c,d,e] $\tilde{\nu}$ here refers to the vibrational energy (in wave number units) in excess of the "zero point" vibrational energy retained by the molecules in their lowest level, ($v = 0$).

Equations for the rotational energies of molecular oxygen have been given by Dieke and Babcock,[5e] by Ossenbrüggen[6] and by Mecke and Wurms.[13] Expressed in the modern notation, these all take the form

(11) Recent very accurate measurements of the (1,1) absorption band of atmospheric oxygen [Babcock, Phys. *Rev.*, **35**, 125 (1930) and also Ref. 5g] give 1556.31 cm.$^{-1}$ and 1556.41 cm.$^{-1}$, respectively, for the relative energy of the $v = 1$ vibrational level. These values are to be preferred to the value 1554.0 cm.$^{-1}$ obtained by the use of equation (1) but recalculation of certain of our heat capacity, entropy and free energy values on the basis of the more accurate energy produced no change in the third decimal, even for quite high temperatures, at which the vibrational levels become relatively more effective.

(13) Mecke and Wurms, *Z.* Physik, **61**, 37 (1930).

$$F(K) = B[K(K+1)] - D[K^2(K+1)^2] \qquad (2)$$

where $F(K)$ is the energy, in cm.$^{-1}$, of the rotational level characterized by a particular value of the rotational quantum number K, and B and D are numerical constants. Values given for the numerical constants appropriate to the ($v = 0$) vibrational level of normal ▪▪ oxygen are summarized in Table I.

TABLE I

ROTATIONAL ENERGY CONSTANTS OF THE (v = 0) VIBRATIONAL LEVEL OF THE NORMAL $^3\Sigma$ STATE OF MOLECULAR OXYGEN

Authors	B	D
Dieke and Babcock	1.438	6.31×10^{-6}
Ossenbriiggen	1.4380	4.9×10^{-6}
Mecke and Wurms	1.4375	4.77×10^{-6}

Giauque and Johnston[8] found that the "D" constant of Dieke and Babcock was in error since, for high rotational quantum numbers, the equation given by the latter authors failed to reproduce, with sufficient accuracy, the data from which it was derived. A better value of this constant can be obtained by making use of a theoretical relationship which relates it to the value of "B" and to the vibrational constants.[14] By this method we obtain $D = 4.86 \times 10^{-6}$. With this correction the equation of Dieke and Babcock becomes substantially identical with that of Ossenbruggen, and of Mecke and Wurms, and is in good agreement with the experimental values for the rotational energies. In the calculations included in the present paper we have employed the rotational energy formula

$$F(K) = (1.438 - 0.01596v)\,K(K+1) - 0.00000486K^2(K+1)^2 \qquad (2a)$$

which includes a correction term ($0.01596v$,), for the variation of "B" with the vibrational quantum number v, as found by Mecke and Baumann.[5g] Since only the alternate rotational levels are present in the oxygen molecule,[5e,f,g,6,7,9,15] only odd values of K are to be used with equation (2a).

Equation (2a) yields, accurately, the rotational energies of those molecules which possess the F_2 form of electronic coupling in the normal $^3\Sigma$ state. The energy of an isomeric F_1 or F_3 molecule is approximately 2 cm.$^{-1}$ less than that of an F_2 molecule with the same rotational quantum number K. This difference in electronic coupling energy between the isomeric forms of the multiplet normal level is responsible for the appearance of doublets in the spectrum of molecular oxygen. Measurement of the widths of these doublets provides a means of obtaining the energy levels of the F_1 and F_3 molecular species.

Making use of the data of Dieke and Babcock,[5e] supplemented by the more recent data of Babcock,[9,16] we have computed the energies of mole-

cules in the F_1 and F_3 states relative to molecules in the F_2 state for rotational quantum numbers to "K" = 25. The results are represented graphically in Fig. 1, which includes data from the isotopic O^{16}–O^{18} molecule as well as from the ordinary O^{16}–O^{16} molecule. This use is permitted since the electronic isotope effect is small and is quite negligible for the 2 cm.$^{-1}$ difference in electronic energy of coupling involved in these calculations. The inclusion of data pertaining to the isotopic molecule yields coupling energies appropriate to even as well as to odd rotational levels since alternate levels are missing only for the symmetrical O^{16}–O^{16} molecule. In obtaining Fig. 1 we have used all the spectrum lines which yielded the appropriate combinations, without regard to their relative reliability. In obtaining Fig. 2 we have excluded all calculations which involved a line marked in the tables of Dieke and Babcock, or of Babcock, as "double"

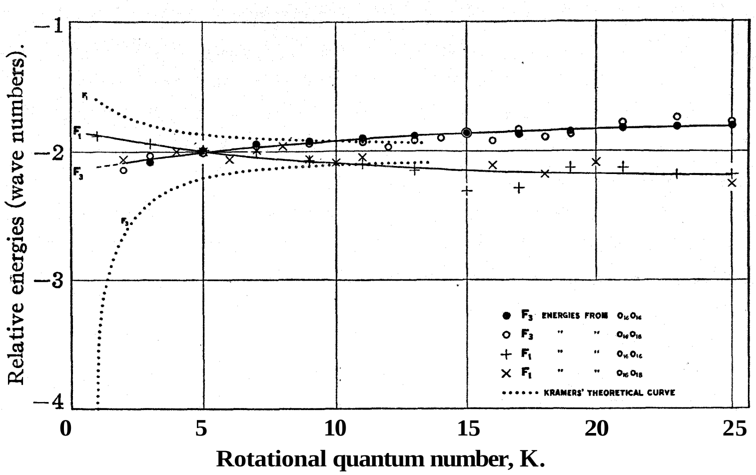

Fig. 1.—Energies of the F_1 and F_3 rotational levels of normal oxygen related to the F_2 levels.

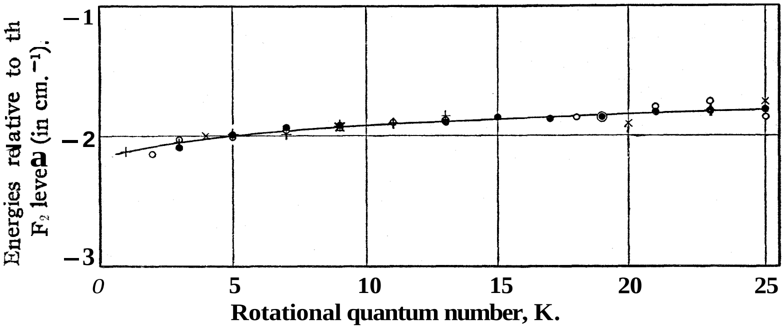

Fig. 2.—Interpolation curve for obtaining smoothed values of the coupling energies.

or as "used in more than one series" resulting from coincidence or near coincidence of lines with others of the oxygen spectrum or with lines of the solar spectrum. We have also taken advantage of the relationship, first noted by Mulliken,[7] that the experimental curves for the energies of the F_1 and F_3 levels, relative to the F_2, are symmetrical around 2 cm.$^{-1}$. We have rotated the F_1 energy values around this coordinate as an axis and so obtained a common curve utilizing the data from both the P doublets and the R doublets of the spectrum. The curves through the experimental data in Fig. 1 were constructed by symmetrical transposition of the curve obtained in Fig. 2.

The non-appearance in the spectrum of the line corresponding to the $(J = 0) \longrightarrow (J = 0)$ transition precludes the direct experimental evaluation of the relative energy of the F_3 level with $K = 1$. For the present calculations we have taken the energy of this level to be 2.13 cm.$^{-1}$ beneath that of the corresponding F_2 level. We obtained this value by direct extrapolation of the F_3 curve of Fig. 1. However, we wish to call attention to the possibility of an error introduced by this extrapolation. Kramers[17] has derived a wave mechanical formula which gives the separations to be expected among these multiplet levels, as a function of the rotational quantum number. His equation does not give very good quantitative agreement with the experimental values, as is apparent in Fig. 1, which includes curves derived from Kramers' equation. This lack of agreement (in a quantitative sense) is attributable in part to failure to carry the laborious mathematical analyses beyond the second approximation and, in part, to the introduction of certain simplifying assumptions regarding the nature of the molecule which fail to make allowance for actual perturbing influences which do exist. Professor Mulliken[18] has called our attention to the fact that probably Kramers' formula will apply to the one level we are here considering. This results from the fact that the perturbations referred to above are produced by an interaction between levels with the same J value. The level in question is unique in standing alone in its J value $(J = 0)$ and so escapes the perturbation. Should this analysis be correct we should take the energy of this level as 4.0, rather than as 2.13 cm.$^{-1}$ below the corresponding F_2 level. However, there is still some uncertainty on this one point of analysis and in the absence of either a direct experimental value or of an unquestioned theoretical derivation, we choose to employ the value extrapolated from adjacent rotational levels, and yielded by the symmetry of the F_1 and F_3 curves. An error of 2 cm.$^{-1}$, which is the uncertainty involved in the relative energy of this one level, produces an altogether negligible effect on the calculated heat capacities, entropies and free energies above 10°K. But below 10°K. a 2 cm.$^{-1}$ error in this

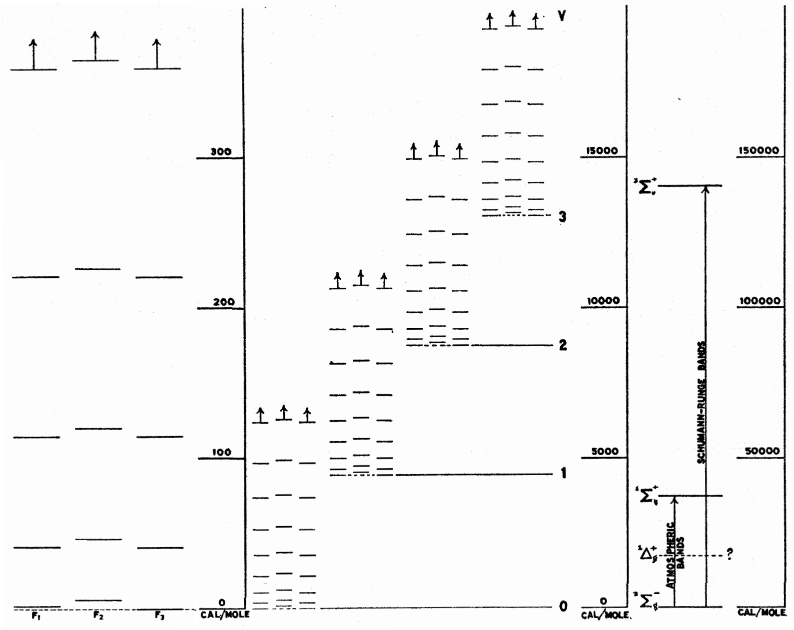
one level would appreciably influence the quantitative relationships—although not the qualitative character—of the interesting inflections in the heat capacity curve, which is reproduced in Fig. 4.

The arrangement and spacings of the energy levels in oxygen are shown diagrammatically in Fig. 3. The separations of rotational levels in (b) are greatly exaggerated.



(a) Rotation levels. (b) Vibration–rotation levels. (c) Electronic levels and transitions.

Fig. 3.—Energy level diagram of O_2.

Statistical weights appropriate to the various energy states are given by the expression

$$p_i = (2J + 1) \tag{3}$$

where $J = (K + 1)$, (K) and $(K - 1)$ for the F_1, F_2 and F_3 forms, respectively. The terms in i drop out[19] since oxygen is without nuclear spin.

The Heat Capacities.—Molar heat capacities of gaseous oxygen from 0.020 to 5000°K. have been calculated with the aid of equation (2) from the previous paper.[2] Table II summarizes the results of the calculations for the interesting temperature interval below 10°K. The tabulations refer to the hypothetical ideal gaseous state, at constant volume, and do not include the 2.980 calories per mole per degree associated with the translational motion of the molecules. The heat capacity curve, shown in Fig. 4, was constructed from the values included in Table II. The two maxima

which occur below 2°K.—one extending to a height of nearly three calories—are electronic heat capacity curves and result from the absorption of energy by molecules which undergo transition from the F_3 to the F_1 and F_2 forms of coupling. They are analogous to the prominent maximum which occurs in the specific heat curve of nitric oxide at about 75°K.[2] Their occurrence at a much lower temperature, in oxygen, is due to the much smaller coupling energy in molecular oxygen as compared with nitric oxide. The steep rise between 2 and 10°K. represents the growth of the rotational specific heat.

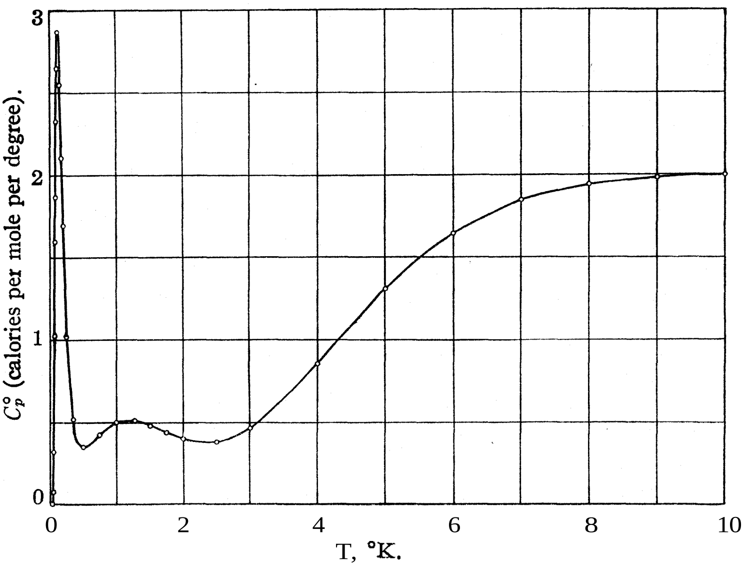

Fig. 4.—Heat capacity of gaseous oxygen (in excess of that due to translation).

The heat capacities at higher temperatures are tabulated in Table III and the results are shown graphically in Fig. 5.

values are included only for the sake of comparison since the spectroscopic values are the more reliable. The recent work of Henry[20] with a special type of flow calorimeter is in excellent agreement with the spectroscopic curve. The results obtained by the velocity of sound method,[22a,b] are obviously subject to some serious source of systematic error not detected by the investigators. We have omitted from the graph certain older[24] calorimetric measurements because of the crowded condition of the drawing.

It is noticeable that the heat capacity rises considerably above the classical $9/2R$ calories per mole per degree which, on the basis of the Equipartition Principle, is the limiting value for the heat capacity of a diatomic gas. This behavior, typical of other diatomic gases as well,[2] is a consequence of three factors which remove the gas from that condition hypothesized in the derivation of the Equipartition Principle. These factors are: (1) a variable moment of inertia, (2) the anharmonic character of the molecular vibration and (3) energy absorption by a change in electronic structure. In an effort to separate, more or less arbitrarily, the influences of these several factors, we have constructed the curves which are marked with special notations. Thus the curve marked "Pure Rotation + Stretching" was constructed by limiting our consideration to those quantum states which comprise the rotational levels of normal $^3\Sigma$ oxygen in its lowest, ($v = 0$), vibrational level. This yields a hypothetical rotational specific heat curve which, at 5000°K., exceeds rotational equipartition by some 0.06 calorie. This is directly a consequence of the "D" term in equation (2) and is attributable, physically, to energy absorption by the molecular stretching under the influence of centrifugal force, at high speeds of rotation. The curve marked "Rotation + Vibration + Stretching" was obtained by including all of the vibrational levels of normal $^3\Sigma$ oxygen.[25] Thus the difference between this and the previous curve represents the vibrational specific heat. For oxygen, the vibrational component attains its equipartition allotment at about 2500°K. and at 5000°K. exceeds this limit by about 0.30 calorie.

The inclusion of the $^1\Sigma$ electronic term, whose contribution to the specific heat becomes appreciable at about 2500°K., yields the complete specific heats, which are listed in Table III and are used to construct the heavy curve in Fig. 5. Although the numbers of molecules converted to the diamagnetic $^1\Sigma$ form are inconsiderable (*cf.* Table V) below 5000°K. the excitation energy is so large (37,000 calories per mole) in comparison with the other ways of internal energy absorption that the specific heat contribution is significant at the higher temperatures, and attains 0.25 calorie per mole per degree at 5000°K.

The distributions are calculated on the basis of the Maxwell–Boltzmann law of energy partition.[26]

By reference to these tables the changes which occur in the body of gas during the process of heat absorption are easily visualized. Below 0.02°K. substantially *all* molecules of oxygen are in a single quantum state—the F_3 form with the rotational quantum number $(K = 1)$—and the heat capacity is identical with that of a monatomic gas. Above 0.02°K. molecules attain to quantum states possessing higher energies and the energy absorbed in the process results in the appearance of specific heat associated with internal degrees of freedom. The first of these absorption processes corresponds to the transformation of molecules from the F_3 to the F_1 form of coupling without change in the rotational quantum number, and produces the first sharp maximum at about 0.12°K., where the ***rate*** of this transformation is greatest. The second, considerably broader, maximum at a little above 1°K., results from a similar transformation of a portion of the molecules to the F_2 coupling state, still without change in the rotational quantum number. Between 2 and 10°K. the specific heat, in excess of that due to translation, is due principally to excitation of molecules to the $(K = 3)$ rotational levels. As Table IV makes plain, the near attainment of rotational equipartition does not require a large distribution of molecules among the higher rotational levels. In oxygen, at 10°K., 76% of the molecules still remain in the $(K = 1)$ levels and less than 1% have attained the third set of rotational levels (with $K = 5$). Table V indicates the character of the absorption processes responsible for the specific heat components which enter at the higher temperatures.

The Entropy of Oxygen.—Table VI gives the entropy of oxygen for temperatures ranging from 1 to 5000°K. These values refer to the hypothetical ideal gaseous state at a pressure of 1 atmosphere and are expressed in calories per mole per degree.

TABLE VI

ENTROPY OF OXYGEN IN THE IDEAL GASEOUS STATE AT ONE ATMOSPHERE PRESSURE

(26) At very low temperatures an actual gas will obey the Bose–Einstein statistics rather than the Boltzmann statistics. However, this need concern us no more than the recognition that actual gases are subject to Van der Waals forces. Were we attempting to compare experimental data on the actual gas with our calculated values, it would be necessary to make corrections both for Van der Waals' imperfection and for quantum degeneracy, since our calculations apply to the hypothetical ideal gaseous state which, by definition, excludes both of these forms of imperfection. However, in this paper, we desire to know the results in terms of just such an ideal gas since the "standard state" of thermodynamic usage is customarily defined in terms of such a gas. For a further discussion of this point see Giauque, THIS JOURNAL, 52,4810 (1930).

The Free Energy.—In Table VII we give values of $-(F^\circ - E_0^\circ)/T$ for gaseous oxygen at a pressure of one atmosphere. Underscored values were calculated from the spectroscopic data. The remainder were interpolated by a graphical method.

TABLE VII

Evaluation of the Limits of Error.—Below 1000°K., substantially all of the terms needed to evaluate the several sums employed in the present calculations lie within the range of energies covered by spectroscopic observations which the energy equations accurately reproduce. Even at 5000°K. the several higher vibration levels which make appreciable contributions to the sums are almost entirely represented in the observed bands. Thus only 0.15% of ΣA (cf. Ref. 2 for the significance of symbols), 0.7% of ΣB and 2.1% of ΣC were contributed by vibration levels whose energies were extrapolated by the accurate equation (1). As in nitric oxide, a considerably larger fraction of the rotational sums was contributed, at the higher temperatures, by rotation terms whose energies lay beyond

---

[27] A few of these values differ slightly (by the order of 0.01 or 0.02 unit) from a preliminary table furnished to Clayton and Giauque and used by them in their calculation of the CO equilibria [Clayton and Giauque, THIS JOURNAL, **54**, 2610 (1932)]. Since the small effect which these changes would produce in their calculations lies well within other sources of error no corrections need be applied to their tables.

the spectroscopic observations. This is illustrated in Table VIII which shows: (1) the total number of rotational terms summed in the normal vibration level of the $^3\Sigma$, F_1 series, and (2) the number of these terms, starting with (K = 1), which contributed 90% of the totals of the respective sums. The actual spectroscopic data covered the first 13 rotational terms

TABLE VIII

THE NUMBERS OF ROTATIONAL TERMS WHICH CONTRIBUTED APPRECIABLY TO THE ROTATIONAL SUMS OF THE $^3\Sigma$, F_1 (v = 0) STATE

T, °K.	Total (all sums)	Terms contributing 90% of the respective sums		
		ΣA	ΣB	ΣC
1000	54	16	23	27
2000	67	23	31	36
3000	85	40	50	59

(to K = 25). It was thus necessary, at these higher temperatures, to employ equation (2a) to compute the energies of many rotational terms which lie beyond those observed experimentally. However, this does not constitute a serious source of error for equation (2a) reproduces the experimental data, both for ordinary oxygen and for the isotopic displacements, with an accuracy which approximates 0.01 cm.$^{-1}$ on the average[28] and the equation should extrapolate with considerable accuracy for several rotation terms beyond those which enter into the observed data. In order to set a reasonable limit to the inaccuracy which might enter through this extrapolation we have recalculated, at representative temperatures, the heat capacity, entropy and free energy on the supposition of a ± 50% error in the D constant of equation (2a). The changes thus produced are recorded in Table IX.

TABLE IX

ERRORS INTRODUCED BY A 50% ERROR IN THE CONSTANT OF THE QUADRATIC TERM IN EQUATION (2a)

T, °K.	C_p°	S°	$-\frac{F^\circ - E_0^\circ}{T}$
2000	0.000	0.004	0.002
3000	.000	.004	.003
5000	.000	.004	.003

A similar recalculation on the basis of a reasonable limit to the inaccuracy of the B constant of Table I produced changes much smaller than these. If we make some allowance for small inaccuracies in the B constants of the higher vibrational levels, in the vibrational frequencies and in the physical constants which are employed, it would appear that 0.02 or 0.03 calorie per mole per degree would cover the uncertainties in either heat capacities, entropies or free energies, even at 5000°K.

However, this statement must be modified to admit two sources of uncertainty, operative in the extreme regions of temperature, which involve

---

(28) Birge, *Nature*, 134, 13 (1929).

neither the energy equations nor the physical constants used in the computations. The possibility of an error in the energy of the first F_3 rotational level, which would influence the magnitudes of the calculated values below 10°K., has already been discussed. The other source of uncertainty arises from the not unlikely possibility of the existence of a metastable $^1\Delta$ electronic term intermediate between the $^3\Sigma$ and $^1\Sigma$ states which are involved in the atmospheric bands (cf. Fig. 3). This level has been predicted, on theoretical grounds, by Mulliken[29] and by Hückel,[30] who estimates that the level lies about midway between the $^3\Sigma$ and $^1\Sigma$ terms. As this state has never been confirmed experimentally, we are unable to know certainly of its existence, or to evaluate accurately the contribution it would make to the results of the present calculations. However, we can estimate the approximate influence on the heat capacity curve at high temperatures should the term exist with the approximate energy hypothesized by Hückel. The effect would be to add what we might term a $^1\Delta$ component to the heat capacity curve. Such a component would become effective at about 1250°K., and at 2500°K. would have attained the approximately 0.25 calorie which the $^1\Sigma$ component attains at 5000°K. The $^1\Delta$ contribution would continue to rise above this value and would ultimately attain a maximum, followed by a gradual decline, in much the same manner as exhibited by the electronic coupling energy contributions which appear in the curve below 3°K. For either the $^1\Delta$ or $^1\Sigma$ levels, however, the maximum would not appear until very high temperatures were reached. The presence of the $^1\Delta$ term would also produce an increase in the numerical values of Tables VI and VII, at high temperatures, but the influence would be relatively less than for the heat capacity.

Between about 10 and 1200°K. the values recorded in Tables III, VI and VII should be fully as reliable as previous considerations have indicated. That is, an accuracy of ±0.01 calorie per mole per degree, or better, should apply to any of these quantities, on the basis of the "International Critical Tables" values for the physical constants employed in the calculations.

It is improbable that, in addition to the $^1\Sigma$ state and the hypothetical $^1\Delta$ state, there can exist other electronic terms with excitation energies sufficiently low to influence our calculations. Should the existence of a $^1\Delta$ term be verified experimentally and its excitation energy be determined, together with its accompanying vibrational and rotational constants, it will be a small matter to amend our present calculations to include the contributions of this term. It is our intention to do this should the necessity arise. In conclusion, we wish to emphasize the fact that the future discovery of any quantum states which may now be unknowingly omitted

---

(30) Hückel, *Z. Physik*, **60**, 442 (1930).

from our interpretation may lead to an ***increase*** of the numerical values of the accompanying tables, but that no such future discovery can lead to a ***decrease*** of these figures.

We wish to acknowledge a grant from the Graduate Council of the Ohio State University, which provided research assistance that has greatly aided us in this investigation. The completion of the calculations was also greatly facilitated through the use of an electric computing machine obtained by a grant from the National Research Council.

Summary

The spectroscopic interpretation of the oxygen molecule has been briefly summarized.

The heat capacity of molecular oxygen in the ideal gaseous state has been calculated for the temperature range 0.02 to 5000°K. The heat capacity curve shows two maxima below 2°K. These are due to transformations between closely related electronic forms of the normal molecule. The rotational component of the specific heat appears a little below 3°K. and attains rotational equipartition at about 10°K. The vibrational component makes its appearance at about 200°K., and passes the equipartition value at about 2500°K. At high temperatures the rotational component of the specific heat exceeds the equipartition value due to centrifugal stretching of the molecule and the vibrational component exceeds R calories due to the anharmonic character of the oscillations. At about 2500°K. an additional electronic component of the specific heat makes its appearance. This arises from the excitation of molecules into the $^1\Sigma$ electronic term of the "atmospheric" bands.

Tables are included which show the temperature distributions of oxygen molecules among the various rotational, vibrational and electronic levels.

The entropy has been calculated and tabulated for temperatures from 1 to 5000°K.

The "free energy," as represented by the quantity $-(F^\circ - E_0^\circ)/T$ has been evaluated from 75 to 5000°K., and tabulated in a fashion that permits easy interpolation.

The probable errors of the heat capacity, entropy and "free energy" calculations have been determined. Also the possible influences of a small error in the coupling energy of the lowest F_3 rotational state and of the existence of a $^1\mathrm{A}$ electronic state have been discussed. These uncertainties affect the calculations only at very low and at very high temperatures. Between 10 and 1200°K. the calculations are regarded as accurate to within ±0.01 calorie per mole per degree.

The Dissociation of Oxygen to 5000°K. The Free Energy of Atomic Oxygen[1]

BY HERRICK L. JOHNSTON AND MARGERY K. WALKER

Knowledge of the extent to which the common gases are thermally dissociated can be of value in the interpretation of phenomena which relate to reaction kinetics, specific heats, gaseous conduction, etc. Direct measurement of the dissociation of the more stable gases is quite difficult due, at low temperatures, to the small magnitude of the effect and, at high temperatures, to numerous experimental difficulties. A new and highly accurate point of approach is now available for several gases, as a result of the recent developments in the fields of molecular and atomic spectra. The first extensive and accurate calculation of a gaseous dissociation, based entirely on spectroscopic data, was made by Giauque,[2] who calculated the dissociation of hydrogen for various temperatures between room temperature and 5000°K. The earlier experimental results of Langmuir[3] and of Langmuir and Mackay[4] were found to be in very satisfactory accord with the more accurate values derived from the spectroscopic data. The present paper presents the results of similar calculations for the dissociation of molecular oxygen between room temperature and 5000°K.

Thermodynamic Relationships.—The calculations make use of the relationships

$$\begin{aligned} -R \ln K &= AF^{\circ}/T \\ &= 2\left(\frac{F^{\circ} - E_0^{\circ}}{T}\right)_{O} - \left(\frac{F^{\circ} - E_0^{\circ}}{T}\right)_{O_2} + \frac{\Delta E_0^{\circ}}{T} \end{aligned} \qquad (1)$$

Here R is the molar gas constant, in calories; T, the absolute temperature; ln K, the natural logarithm of the dissociation constant; AF°, the free energy change which accompanies the dissociation of one mole of molecular oxygen in the hypothetical ideal gaseous state, at one atmosphere, into monatomic oxygen in the perfect gaseous state, at one atmosphere; the parenthetical quantities are the molal "free energies" of atomic and molecular oxygen, respectively; and ΔE_0° is the molecular heat of dissociation at the absolute zero. It, like the parenthetical terms, can be evaluated, in this instance, entirely from trustworthy spectroscopic data. In making the computations in the above equation the molal "free energies" for molecular oxygen are taken from Table VII of the previous paper.[5] The "free energies" of atomic oxygen are computed by us and are given in

(4) Langmuir and Mackay, *ibid.*, 36, 1708 (1914).

(5) Johnston and Walker, *ibid.*, 66, 172 (1933).

Table II of the present paper, and the dissociation energy of oxygen, whose reliability is discussed in **a** later paragraph is taken to be 5.09 (±0.03) volts (equal to 117,350 (±700) calories per mole.)

The Free **Energy** of Atomic **Oxygen.**—Following equation (4) of a previous paper[6] the mold "free energy" of atomic oxygen in the hypothetical ideal gaseous state is given by the expression

$$\left(\frac{F^\circ - E^\circ_0}{T}\right) = 5/2R - 3/2R \ln T - R \ln \frac{RT}{P}$$
$$- 3/2\ R \ln 16 + 11.057 - R \ln \Sigma A \qquad (2)$$

Before we can evaluate the last term in this equation we must know the nature of the more stable quantum levels of atomic oxygen, their statistical weights and their relative energies.

The normal, or valence, level of the neutral oxygen atom is an inverted ^3P term?

The existence of metastable $^1D_2$ and $^1S_0$ terms, corresponding to considerably higher energies, has also been established[8] from the line spectra of neutral oxygen. Still other electronic states are known but we need not consider these because their energies are so great, compared to the normal ^3P term, that their influence in the present calculations is entirely negligible. Nor is there likelihood of the occurrence of unidentified levels of sufficiently low energy to influence our calculations, because the observed ^3P, ^1D and ^1S levels are in accord with the well-established theoretical relationships which connect the spectroscopic terms with the position of the element in the Periodic Table.[9]

The relative energies of these various atomic levels of oxygen are given in Table I, together with their respective statistical weights.

TABLE I

RELATIVE ENERGIES AND STATISTICAL WEIGHTS OF THE MORE STABLE QUANTUM STATES OF THE NEUTRAL OXYGEN ATOM

	Relative energies		
Term	Volts	Calories per mole	Statistical weight
$^3P_2$	0.000	*0*	*5*
	.020	*449.4*	3
$^3P_0$	.028	*644.5*	*1*
$^1D_2$	*1.957*	*45,096*	*5*
$^1S_0$	*4.168*	*96,039*	*1*

From this table ΣA, of equation (2), was evaluated by the relationship

$$\Sigma A = 5 + 3e^{-449.4/RT} + 1e^{-644.5/RT} + 5e^{-45,096/RT} + 1e^{-96,039/RT} \qquad (3)$$

This then permitted the evaluation of the molal "free energies" of mon-

This table is of use not alone in the immediate calculations but in equilibrium computations for any reaction in which monatomic oxygen is involved.

The Heat of Dissociation of Molecular Oxygen.—Birge and Sponer[10] obtained a value of 0.81 volt for the energy required to dissociate an excited $^3\Sigma_u^+$ oxygen molecule into atoms. Assuming that this dissociation was into normal atoms, Birge and Sponer thus obtained the value 7.05 volts for the dissociation of a normal molecule into normal atoms. A later theoretical treatment by Wigner and Witmer[11] showed that $^3\Sigma_u^+$ oxygen must dissociate into one normal atom and one excited atom in a $^1D_2$ level. The subsequent identification and measurement of this level[8b,c] led to the value of 5.09 (±0.03) volts for the dissociation of a normal oxygen molecule into normal atoms.[12]

This value is confirmed by a variety of independent determinations by other methods.[13]

Even those values which differ from the spectroscopic value by eight or ten thousand calories constitute confirmations of the latter more accurate determination. This is a consequence of the fact that the only possible source of error in the spectroscopic value (beyond the very small error involved in the wave length measurements themselves) is associated with the point at which Birge and Sponer made their erroneous assumption—the nature of the dissociation products of the excited $^3\Sigma$ oxygen. If, for the sake of argument, we exclude the conclusions of Wigner and Witmer[11] one of the following alternatives would have to be accepted: dissociation into two normal atoms (the assumption of Birge and Sponer), dissociation into two $^1D_2$ atoms, or dissociation into one $^1D_2$ atom and one $^1S_0$ atom. These respective alternatives would lead to the following alternative heats of dissociation: 163,000 calories, 72,000 calories, 21,000 calories. Within each alternative the value would be accurate to within about 1000 calories. The several independent lines of investigation do not support any of these alternatives. So we may regard the heat of dissociation of normal oxygen molecules into normal oxygen atoms as fixed at 117,350 calories ± about 700 calories.

Since the spectroscopic energies correspond to molecular and atomic states whose term values are independent of temperature, the heat of dissociation from spectroscopic data is identical with the heat of dissociation at the absolute zero and so is identical with the ΔE_0° of our equation (1).

Equilibrium Constants and the Degree of Dissociation.—By means of equation (1) we have calculated equilibrium constants of the reaction $O_2 = 2O$. We have also calculated percentage dissociations for a total pressure of one atmosphere. These were calculated by the relationship

$$100\alpha = 100\sqrt{K/(K+4P)} \tag{4}$$

where P is the total pressure and 100α is the percentage dissociation. The results are tabulated in Table III. The limits of error are computed on the basis of an uncertainty of ±0.03 volt in the energy of dissociation.

4800	32.7 ± 2.3	94.4 ± 0.4
4900	42.7 ± 3	95.6 ± 0.3
5000	55.4 ± 4	96.6 ± 0.2

This uncertainty, although small, entirely masks the small errors which may exist in the $-(F^\circ - E_0^\circ)/T$ values which are involved. A modification of this statement must be made for the five or ten highest temperatures in order to allow for the not improbable existence of a $^1\Delta$ molecular level.[14] We have estimated the possible effect that would be produced by the existence of the $^1\Delta$ level, by recalculating equation (1) for a few representative temperatures with the molecular "free energies" modified by inclusion of the contributions that would result from a singlet level about half way between the normal $^3\Sigma$ and the excited $^1\Sigma$ levels of molecular oxygen. The results of this recalculation are given in Table IV.

TABLE IV

DISSOCIATION CONSTANTS AND PERCENTAGE DISSOCIATIONS RECALCULATED WITH THE INCLUSION OF A HYPOTHETICAL $^1\Delta$ LEVEL IN MOLECULAR OXYGEN

T. °K.	K	Percentage dissociation
2000	5.14×10^{-7}	3.6×10^{-2}
2500	2.34×10^{-4}	0.77
3000	1.40×10^{-2}	5.92
4000	2.37	61.0
5000	52.6	96.4

The comparatively large specific heat contribution which the $^1\Delta$ term would make at high temperatures[5] is a result of the large quantity of energy absorbed by the few molecules which attain the $^1\Delta$ level. The contribution of the hypothetical $^1\Delta$ term to the "free energy," and hence to equilibria, is less significant because, in the latter case, the magnitudes of the energy play no part, except as they influence the statistical distributions.

The literature contains no reference to any direct determinations of the thermal dissociation of gaseous oxygen. From consideration of the energy losses of a tungsten filament in air, Langmuir made the observation[8a,b] that in the neighborhood of 2400°K. oxygen must be either largely dissociated into atoms or associated into ozone. From a consideration of the phenomena which occur in an electric arc in air, Karrer[15] concluded that oxygen must be partly dissociated at the temperature of the arc. Jenckel[16] measured the heat losses of a glowing Nernst filament in oxygen, as well as in nitrogen, and attempted to interpret his results in terms of dissociation of the oxygen. The latter quantity was computed from thermochemical data by means of an approximation formula. Jenckel's experimental results are not suitable for direct evaluation of the degree of dissociation.

The dissociation constants and percentage dissociations calculated in the present paper should be reliable, within the limits set in Table III, for use in all problems which involve the dissociation of oxygen.

---

The completion of these calculations has been greatly aided by the use of an electric computing machine provided by a grant of the National Research Council. We also wish to acknowledge a grant from the Graduate Council of The Ohio State University, which provided research assistance.

Summary

Accurate values for the dissociation constants of molecular oxygen have been calculated for the temperature interval 298.1 to 5000°K. The calculations are based upon a thermodynamic treatment of reliable spectroscopic data.

Accurate values of the percentage dissociation at a total pressure of one atmosphere have also been calculated between 298.1 and 5000°K. The dissociation attains 1% at a temperature between 2500 and 2600°K. and, at 5000°K., the molecules are dissociated to the extent of 96.6 ± 0.2%.

The "free energy" of monatomic oxygen, as represented by the quantity $-((F^{\circ} - E_0^{\circ})/T)$, has been evaluated from 298.1 to 5000°K., and tabulated in a fashion which permits easy interpolation.

The possible inaccuracy introduced through the omission of a probable 'A electronic state of molecular oxygen has been discussed. At 5000°K. the uncertainty thus introduced cannot change the calculated percentage dissociation by more than about 0.2 of one per cent. Below 4000°K. the influence of the hypothetical $^1\Delta$ level is practically negligible. It is pointed out that the influence of a hypothetical $^1\Delta$ level cannot appreciably modify the values of the molecular free energy function for use in other equilibria which involve molecular oxygen.

Spreading of Liquids on Solid Surfaces. The Anomalous Behavior of Fatty Oils and Fatty Acids with Experiments Leading to a Tentative Explanation

BY RONALD BULKLEY AND GEORGE H. S. SNYDER

Introduction

The accepted theories of spreading are supported by ample experimental evidence for the case of one liquid spreading upon the surface of another. For example, the known interfacial and surface tension relations lead to the expectation that fatty oils and fatty acids will possess a more marked spreading tendency on water than will hydrocarbons and well-refined mineral oils. This expectation is realized experimentally.

For the spreading of liquids on solids, however, the current theories are not well substantiated by experimental data. Indeed, for many liquid–solid systems there would appear to be a conspicuous, but heretofore overlooked, disagreement between theory and experiment. While the surface tension of solids and their interfacial tension against liquids cannot be measured, there is, nevertheless, considerable evidence to show that on metals as well as on water the fatty oils and fatty acids should possess a more pronounced spreading tendency than the mineral oils.

It is a matter of common observation that such is not the case. On smooth and clean metal surfaces a drop of olive oil or of oleic acid shows little tendency to flatten or spread, whereas liquid paraffin hydrocarbons and moderately viscous mineral oils spread readily and apparently without limit as long as any liquid substance remains.

It is the purpose of this paper to discuss some of the evidence for the genuine existence of the anomaly, and to suggest a tentative explanation based on experiments which will be described. The experiments are of further interest in that they show for the first time, as far as the authors are aware, the phenomenon of rupture of thin layers of liquid on a solid surface due to the instability created by an underlying adsorbed film of low surface energy. A similar effect for fatty and mixed oils on water is well known.

The Spreading Tendency

As early as 1805 Thomas Young[1] had considered the laws governing the spreading of liquids on solids, and had published his famous equation (1), describing the equilibrium of a drop of liquid on a solid surface.

$$T_m = T_{mo} + T_o \cos \theta \qquad (1)$$

Here the solid is represented by the subscript m, the liquid by o; T_m, T_{mo} and T_o are the surface tensions of the respective surfaces and interfaces, and θ is the angle of contact between the liquid and the solid.

---

(1) Young, *Phil. Trans.*, 95, I, 65 (1805). *See* also "Works," i, p. 432.

In recent years Harkins and Feldman, Osterhof and Bartell and others[2] have formulated various spreading criteria which differ from each other in little except notation. If the tendency to spread be represented by S, then, ignoring the work of viscosity

$$S = T_m - T_{mo} - T_o \qquad (2)$$

for spreading on a solid surface.

The quantities T_m and T_{mo} cannot be measured, and it is consequently impossible to determine the numerical magnitude of the spreading tendency for any given instance of a liquid spreading on a solid surface. It is to be noted, however, that the common fatty oils and fatty acids differ but little in surface tension from mineral oils as a class. If there is any substantial difference, therefore, between the interfacial tensions of the fatty liquids against metals and the mineral oils against metals, that class of liquids which has the lower values of T_{mo} should possess the superior spreading tendency.

Evidence That the Interfacial Tension between Metals and Fatty Liquids Is Less than between Metals and Mineral Oils

(a) Preferential Adsorption.—In accordance with a well-known general principle, surfaces and interfaces tend spontaneously to assume a condition of minimum free surface energy. At an interface between a metal and a mineral oil containing fatty acid in solution, that constituent of the solution which lowers the interfacial tension by the greater amount should, therefore, become more concentrated than in the solution as a whole.

Fatty oils and fatty acids lower the static coefficient of friction between metal surfaces more than do mineral oils of the same viscosity. Moreover, a mineral oil containing only a small percentage of fatty acid lowers the friction almost as much as a straight fatty oil. The explanation generally accepted is that the fatty acids are preferentially adsorbed from their solutions in mineral oils by metallic surfaces. Other experimental evidence of a more direct nature will be presented later which leads to a similar conclusion, namely, that metal surfaces preferentially adsorb the fatty acids from solutions of the latter in mineral oil. On the principle stated above, the fatty acids must, therefore, reduce the surface tension of metals more than do mineral oils.

(b) Interfacial Tension between Oils and Mercury.—Harkins and Ewing, Wells and Southcombe, and Bhatnagar and Garner[3] have presented data showing that the interfacial tension between mercury and fatty liquids is considerably lower than between mercury and hydrocarbons or mineral oils. The differences reported are of the order of 20 to 50 dynes per cm. It is also shown that the addition of small percentages of fatty acid to a

(3) Harkins and Ewing, THIS JOURNAL, 42, 2539 (1920); Wells and Southcombe. J. *Soc. Chem. Ind.*, 39, 51T (1920); Bhatnagar and Garner, *ibid.*, 39, 185T (1920).

mineral oil progressively lowers the interfacial tension between the oil and mercury.

Some rough preliminary measurements made during the course of the present investigation indicate that well-refined lubricating oils of a medium grade may have an interfacial tension against mercury 20 to 40 dynes per cm. higher than olive oil or than the same mineral oils containing 1 to 2% fatty acid.

The significance of these results to the question under discussion is obvious. Most solid metals probably have lower interfacial tensions against fatty oils and fatty acids than against mineral oils as is true for the case of the metal mercury. Moreover, the differences are not likely to be less than about 20 to 50 dynes per cm. As shown in Table I below, the difference between the surface tensions of the fatty liquids and the mineral oils is seldom greater than 2 or 3 dynes per cm. Clearly, on the basis of Equation (2) the fatty oils and fatty acids should manifest the more marked spreading tendency.

TABLE I

PREFERENTIAL WETTING OF POWDERS

o means powder wetted preferentially by oil; w means powder wetted preferentially by water

Test liquid	Viscosity, poises	Surface tension dynes/cm.	Zn	Cu	Fe	G
n-Tetradecane	...	..	w	w	w	..
Kerosene	...	26.2	w	w	w	w
Transformer oil	0.22	29.7	w	w	w	..

Oleic acid	.37	31.5	o	o	o	w

(c) Preferential Wetting of Powdered Materials.—Davis and Curtis[4] have described a simple method of obtaining qualitative information on the relative interfacial tensions of powdered solids against water as compared to their interfacial tensions against organic liquids not miscible with water. The solid particles, completely immersed as a paste in one of the liquids, say liquid o, are brought into intimate contact with the second liquid, *w*, by stirring into the paste a quantity of the second liquid. The particles choose to remain in liquid o if, and only if $T_{mo} < T_{mw}$. If the reverse is

---

[4] Davis and Curtis, Ind. *Eng. Chem., 24, 1137 (1932).*

true, that is, if $T_{mw} < T_{mo}$, then, on the principle of minimum energy, **the** particles will be preferentially wetted by liquid *w*, into which they will pass and remain.

Davis and Curtis applied the test to 15 different powdered solids, and used on each solid eleven fatty oils, two mineral oils and several other organic liquids. They found, with few exceptions, that the fatty oils displaced water from the surface of all the solids and that water in turn always displaced the mineral oils. No powdered metals were tested by Davis and Curtis, but in the present investigation their procedure has been applied to tests on powdered zinc, copper and iron, using the liquids listed in Table I. A powdered glass, G, such as is used in baked enamel coatings was also tested with several of the liquids. The results are given in tabular form below, together with the values for viscosity and surface tension of the liquids used here and in the spreading tests to be described later. The surface tension and the viscosity were determined at room temperature; the former with the du Noüy tensiometer with the aid of the correction factors given by Harkins and Jordan;[5] the latter with the Michell viscometer.

It will be observed that in every instance the fatty oils and the liquids containing the fatty acid displace water from the metal powders, and that water, in turn, displaces the petroleum oils. In other words, the metals are preferentially wetted in the order fatty liquid–water–petroleum oil, or

$$T_{mf} < T_{mw} < T_{mp} \qquad (3)$$

where *f*, w and *p* represent, respectively, fatty liquid, water and petroleum oil. While the tests are only of a qualitative nature, yet, from the interfacial tension measurements of oils against mercury and from the very clean-cut manner in which the oils displace or are displaced by water in the present experiments, it seems safe to state that the difference between T_{mf} and T_{mp} must be considerably greater than the slight differences between the surface tensions of the fatty liquids and the petroleum oils.

It is not possible to say from these experiments which of the two classes of organic liquids shows the lower interfacial tension against glass. The experiments described below indicate, however, that against this solid, also, the fatty materials show a lower interfacial. tension than the mineral oils.

(d) Deflocculation of Pastes.—An interesting experiment consists in mixing 10 or 20 g. of some very finely divided solid such as zinc oxide, powdered glass, powdered zinc, copper or iron into a paste with kerosene and then adding a drop of oleic acid. Only enough of the kerosene should at first be used as will wet the powder completely, yielding a paste so stiff that it can be molded into an upright prism. Considerably more kerosene can now be stirred in without changing the consistency noticeably, but if a single drop of oleic acid is added, the mixture, when stirred, becomes so thin that it will run far out over the plate.

(5) Harkins and Jordan, THIS JOURNAL, **52**, 1751 (1930).

For a similar experiment in which poppy seed oil took the place of oleic acid, Green[6] was able to show by photomicrographs that the pigment in the stiff paste was flocculated, whereas in the thin cream, which resulted from adding a drop of fatty material, the particles were evenly dispersed. The interpretation is that the fatty oil or fatty acid lowers the interfacial tension between solid and liquid to such an extent that no flocculating tendency remains. As long as a high interfacial tension prevails between solid and liquid the fine particles clump together to eliminate as much of the interface as possible.

The evidence of the experiments presented under (a), (b), (c) and (d), above, as well as others, such as heats of wetting, etc., which could be mentioned, is to the effect that the interfacial tension between metals and fatty oils and fatty acids is substantially less than between metals and petroleum oils. On the basis of the accepted theories of spreading, the spreading tendency of the fatty oils and fatty acids should then be correspondingly greater.

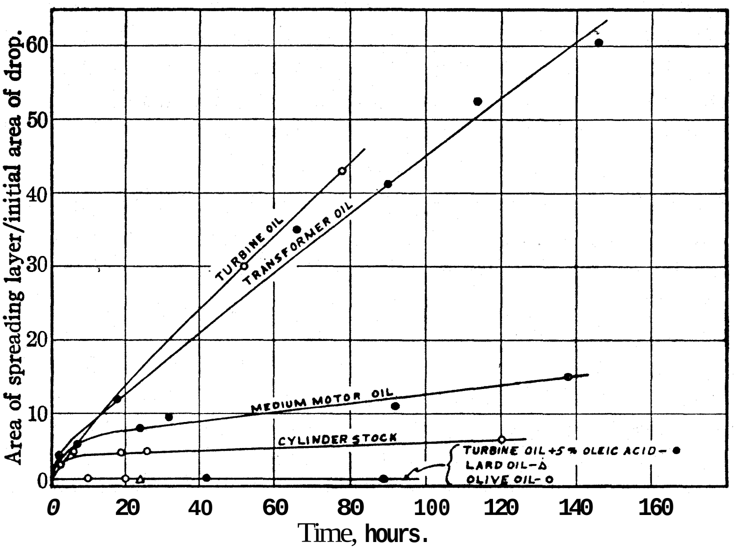

Fig. 1.—Spreading experiments on steel.

Spreading Experiments on Metal Plates

Figure 1 shows characteristic spreading graphs for droplets of various oils on brightly polished steel plates. In these graphs the ordinates represent the amount of spreading defined as the ratio of the area covered by the spreading layer at a chosen time to the initial area covered by the droplet, The initial area cannot be determined with precision, and a high degree of reproducibility is not obtained in duplicate experiments

(6) Green. *Ind. Eng. Chem.*, **15**, 122 (1923).

The test plates were polished to a mirror finish on wet broadcloth using chromium oxide as abrasive. They were kept level during the experiments and were protected from dust by suitable covers. An ample supply of fresh air was provided in all cases.

Figure 2 represents the behavior of several oils on polished surfaces of cadmium. It was not found possible to obtain as bright a polish on this metal as on steel, but, aside from this, the tests on cadmium and on steel were conducted under similar conditions. The shape of the curve for turbine oil is largely hypothetical as only the initial and final areas were measured.

In Fig. 3 the spreading liquid is a thin mineral oil. The non-spreading drop is olive oil. Both drops were initially of nearly the same size and both were put on the plate at the same time, about twenty hours before the picture was taken.

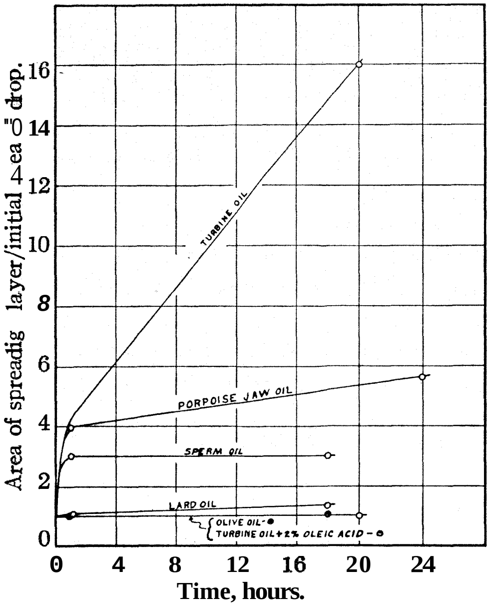

Fig. 2.—Spreading experiments on cadmium.

The behavior of mineral oils on a metal plate can be described by saying that each droplet flattens rapidly into a thin layer which seems to continue to spread indefinitely. In many instances the spreading has been observed to continue long after the layer has become so thin that several orders of color appear With an oil as volatile as kerosene the area covered reaches a maximum in a few hours, after which the layer disappears due to evaporation.

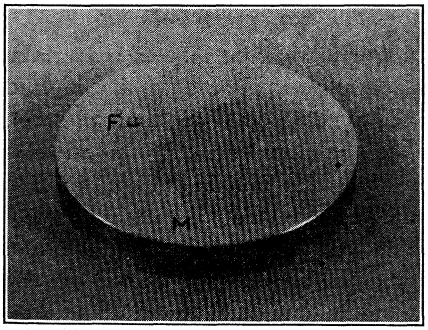

Fig. 3.—Relative spreading of fatty oil (F) and mineral oil (M) on steel plate.

Droplets of lard oil, olive oil and of mineral oils containing 5% or more of oleic acid spread only during the first few minutes after being placed on the plate. The lowest curves on Figs. 1 and 2 are representative. Porpoise jaw and sperm are exceedingly thin oils and have more marked spreading tendencies than other fatty oils. Mineral oils containing only 1 or 2% of fatty acid show about the same behavior as fatty oils on cadmium, but on steel and several other metals their behavior is peculiar and striking, and will be described in a later section.

Cadmium was chosen as one of the test metals because of its close relationship to mercury in the Periodic Table. If cadmium is affected in the same manner and to a similar degree as mercury by fatty and mineral oils, then the interfacial tension between cadmium and the three oils whose curves are shown at the bottom of Fig. 2 must be about 20 to 40 dynes per cm. less than the interfacial tension between cadmium and the turbine oil. The greatest difference in the surface tensions of the oils is 2.2 dynes per cm. By Equation (2), the lard oil, the olive oil and the turbine oil containing fatty acid should thus possess the greater spreading tendency. Experimentally these oils are observed not to spread to an appreciable extent. The spreading of liquids on solids seems, therefore, to be determined in many cases by factors other than the energy requirements.

Behavior of Fatty Acids and of Oils Containing Fatty Acids on Flat Plates

When a drop of oleic acid is placed on a clean polished surface of steel it apparently does not wet the plate at all, but can be rolled about in much the same manner as a drop of mercury.' A film of mineral oil spreading on the plate is halted abuptly at the invisible path along which the oleic acid has passed, thus giving evidence of the deposition of an exceedingly thin film on that part of the plate with which the drop has been in contact. The path of the drop can also be brought out strikingly to the eye merely by breathing on the plate when it is cool. Gentle etching with fumes from inorganic acids will likewise make the path of the drop visible.

The above effects seem to occur for a fairly wide variety of materials. They have been observed in this investigation for oleic acid, for melted capric, palmitic and stearic acids and for melted cetyl alcohol on steel, brass, babbitt, glass and mica. Several of the common fatty oils such as castor, lard and olive manifest a somewhat similar behavior, but to a less marked degree. Cadmium and platinum seem to be wetted in the ordinary sense of the word by all of the liquids mentioned above. This may be due, in part, to the difficulty of getting a sufficiently smooth polish on the surfaces of these metals.

Mineral oils which spread rapidly on ordinary metal surfaces seem to have no spreading tendency when placed on a metal surface which is covered with the invisible fatty acid film. The film thus seems to be similar to the neutralizing surface layer (epilame) described by Woog,[8]

---

(7) This effect was first noticed by one of the authors (*G.* H. S. S.) in September, 1931.

(8) Paul Woog, *Compt. rend.*, 181, 772 (1925). See also "Contribution à l'Étude du Graissage," Delagrave. Paris. 1926.

but its thickness is probably only a small fraction of the thickness of the layers of stearic acid deposited by Woog's patented process. Indeed, there is good reason to believe that the drop of fatty acid leaves behind it only an adsorbed film, which is, therefore, perhaps only a few molecules in thickness. For instance, the surface may be rinsed several times in benzol without removing the film.

The effect of the adsorbed film in reducing the wettability of the metal surface by mineral oils goes further. This was demonstrated by rolling several drops of fatty acid across a plate, and then dipping the lower half of the plate into a beaker of mineral oil. When the plate was withdrawn the clean metal retained a relatively thick layer of oil for an indefinite period, but all the oil ran off those portions which the fatty acid drops had touched.

Another detail of interest was observed when a drop of oleic acid was placed just on the edge of a very shallow pool or layer of motor oil on a polished plate. The plate was level so there was no tendency for the drop to roll by gravity. It moved, nevertheless, of its own accord into and through the layer of oil, mixing with the portion in its path, and leaving behind on the steel only the adsorbed film with no visible trace of liquid (Fig. 4). For experiments in which the layer of mineral oil was very thin, the drop of fatty acid was often observed to traverse the entire width of the pool and then to turn about and recross in the opposite direction, wiping out a continuous path all the way.

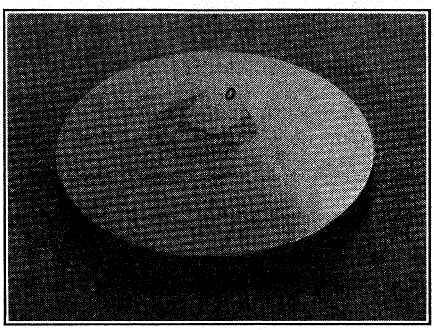

Fig. 4.—Action of a drop of oleic acid when placed at O on the edge of a spreading layer of mineral oil.

One additional group of observations may be described, after which an explanation of these phenomena will be attempted. When a drop of thin mineral oil containing 1 or 2% of oleic acid was placed on a polished steel plate it spread rapidly outward for a few minutes, at which time a hole appeared in the layer near its edge. This hole became elongated, expanding parallel to the circumference of the spreading layer. The main body of the oil pulled inward as the rupture progressed, until at last the oil was completely separated into two portions: a surrounding ring which continued to expand outward at a more rapid rate than the ordinary spreading, and an inner pool which contracted to a relatively small radius and then remained dormant (Figs. 5 and 6). On the metal surface between these two portions no liquid was visible. The surface was found to be covered with an adsorbed film similar in all respects to the one obtained from the pure acid.

On steel and on several other solid surfaces, solutions of various fatty acids in oil were found to behave in a somewhat similar manner. Some combinations were more active than others. Solutions of capric acid and palmitic acid in oil seemed to be more energetic than oleic acid in oil. Stearic acid solutions were almost inert. Fresh mica surfaces were somewhat more active than steel. For the more active combinations such as solutions of palmitic acid on steel or mica, the spreading layer sometimes appeared actually to fly to pieces on the surface, breaking up into numerous drops and droplets which moved rapidly about on the surface (Fig. 7). Each moving portion left in its wake a trail of adsorbed fatty acid on the metal surface.

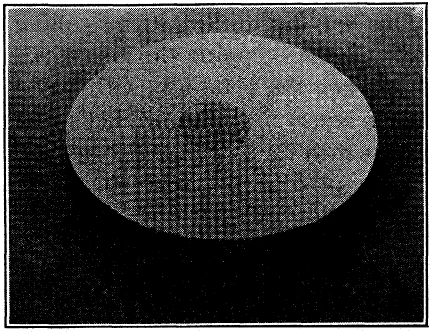

Fig. 5.—Ring commencing to break away (two per cent. of oleic acid in kerosene on steel).

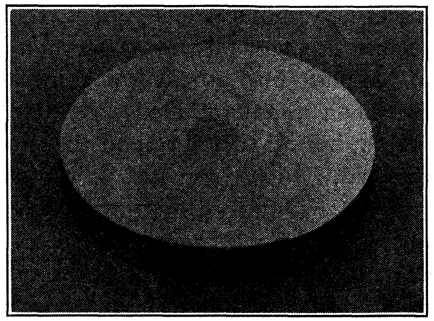

Fig. 6.—Later stage of ring mechanism (same view as Fig. 5 four minutes later).

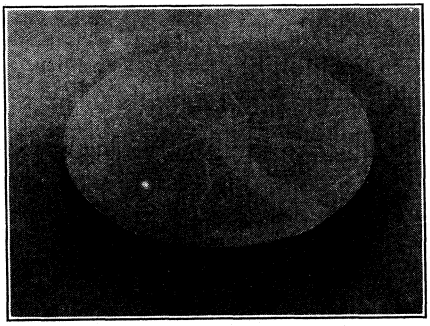

Fig. 7.—Configuration after explosive spreading (two per cent. of palmitic acid in kerosene on steel).

In some instances a drop as a whole was observed to move about. This behavior seems to be a characteristic of castor oil, the only non-compounded oil used, which was found to possess the type of activity mentioned here. On steel, drops of castor oil were observed to move slowly, leaving behind long thin arms of liquid. On fresh mica, the drop as a whole traveled about leaving no visible liquid behind.

The ability of a solid surface to produce the effects mentioned was found to be greatest immediately after the surface had been polished, and to decline rapidly with time of exposure to the laboratory atmosphere. This was evidently due to moisture or oil vapors, for when the surface was kept in a clean dry atmosphere the activity was found to have suffered only slightly after a period of sixteen hours.

The effect of concentration of the fatty acid in the oil was tried. From 0.1% up to saturation—about 2%—solutions of palmitic and capric acid in kerosene showed little change in behavior, except that at the lower concentrations more time was required before rupture occurred and the break started farther in from the edge. With oleic acid, which is more soluble in oils, it was possible to go to higher concentrations, and the results are considered to be of significance in arriving at an explanation of the non-spreading of fatty oils and fatty acids in general.

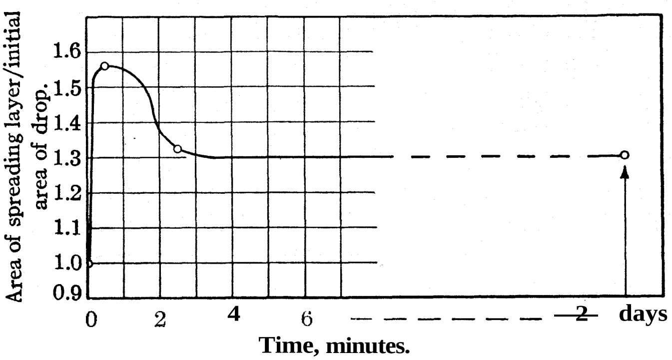

Fig. 8.—Spreading of a high viscosity compounded oil on steel.

At concentrations of oleic acid in kerosene less than one-half of 1% the initial rupture of the spreading layer was considerably delayed, and the ring which detached itself was wide. At 1% the rupture occurred sooner and closer to the edge of the spreading layer. At 2% the time before rupture was still less and the ring which detached itself was thinner than ever. At 5% the break often appeared to be just at the edge, and in several instances no visible ring could be observed to detach itself. In these cases a wave of contraction started at some point in the edge very shortly after the drop was placed, and spread around the periphery, the drop pulling itself inward as the wave progressed and then remaining completely dormant. At 10% no ring was ever seen, but the contraction of the drop immediately after placing was still visible. At higher concentrations this effect also disappeared, probably because it occurred too quickly to be observed.

For oils of higher viscosity, less fatty acid is required to make the rupture occur at or near the edge of the drop. For an oil of cylinder stock grade, 1% of oleic acid may be sufficient to produce a visible contraction of the drop after an initial period of spreading, without the appearance of any visible fringe or ring. Figure 8 is plotted from measurements made on such a drop with a cathetometer.

Relation of the Experimental Results to the Non-Spreading of Fatty Oils and Fatty Acids

Certain similarities exist between the behavior of fatty acids and fatty oils on water and their behavior on metals as described above.

Oleic acid spreads rapidly on the surface of clean water to give a layer of visible thickness, which at once gathers itself back up into a drop. The water is left covered with an adsorbed film which reduces the surface tension to a low value. The regathering of the bulk of the material into a drop comes about as a consequence of the low surface tension of the water when covered with such a film. Oleic acid does not spread of its own accord on a polished plate, but if it is forced to spread into a thin layer by mechanical means it will at once gather itself back up into a drop when the applied force is removed. Moreover, the area with which it has been in contact will remain covered with an adsorbed film.

The surface energy of the metal so covered will be low, as in the case of water. The value will be considerably less than that of clean metal and substantially less than that of metal covered with mineral oil. This was demonstrated for the case of metal powders and mercury in a previous section; the experiments describing the behavior of fatty acids and of oils containing fatty acids on flat plates confirm the essential correctness of this view. For instance, mineral oils will not spread on or readily adhere to the surface of metal covered with the adsorbed film. The fatty acid itself will not wet such a surface as shown by the rolling effect and the gathering into a drop. Again, when a drop of oleic acid travels of its own accord through a thin layer of mineral oil on a polished plate, and removes the oil from the surface, it is believed that the driving power responsible for such behavior is the considerable lowering of the surface energy of the metal which occurs when the mineral oil is replaced by fatty acid.

When mineral oils containing a small amount of fatty acid spread and rupture on solid surfaces the behavior is similar, and the cause of rupture is the same as when the spreading of such liquids takes place on water, The phenomena are well known for spreading on water and mercury; they have been described often, and have been beautifully illustrated by Beilby and by Devaux.[9] Therefore, only a brief discussion of the main features as applied to spreading on solids will be given here.

When a drop of petroleum oil containing some fatty acid is placed on a polished plate, the petroleum portion spreads in its normal manner; the fatty acid is preferentially adsorbed on the solid surface, and lowers the interfacial tension between solid and liquid to such an extent that a condi-

---

(9) Sir George Beilby, "Aggregation and Flow of Solids," Macmillan and Co , London, 1921 Henri Devaux, *Kolloid-Z.*, 68, 129 (19.32).

tion of unstable equilibrium arises. The reason for this instability is comprised in the principles underlying Young's equation (1). It is perhaps sufficient merely to state in words that on an area of low surface energy the stable configuration for a small portion of liquid is not that of an extended film but that of a drop. At a certain minimum thickness of liquid layer, rupture therefore occurs. Any portion of oil in the midst of an area covered with the adsorbed film can only pull itself together into a drop; this is the situation for all the oil when the underlying substance is water or mercury. For spreading on solids, however, not all of the surface has been contaminated when rupture occurs, and the oil in contact with clean metal therefore continues to spread outward.[10]

A mechanism which may be responsible for the non-spreading of fatty oils and fatty acids is suggested by the experiments with kerosene containing varying percentages of oleic acid. For low concentrations the adsorbed film between the oil and metal seems to require more time to become organized completely than for high concentrations. It may be supposed that this film commences to form when the drop first touches the metal, and that it grows outward at a rate which is some direct function of the concentration of fatty acid. At low concentrations, therefore, not only will the rupture be delayed more than for high concentrations, but, when rupture is imminent, the advancing edge of the liquid layer will in general be farther away from the region in which the probability of rupture is the greatest. The break will occur closer and closer to the edge as the concentration is increased, until the ring which spreads outward becomes too thin to be seen. At very great concentrations it may be only of molecular dimensions. In all cases, however, the oil on the inward side of the rupture is pulled further inward by surface tension when rupture occurs, and is prevented from exhibiting any further spreading tendency by the surrounding area of metal of low surface energy.

This has been observed to be the mechanism of the non-spreading of mineral oils containing moderately high concentrations of oleic acid. The same explanation may be assumed for fatty oils and fatty acids if there exists in such liquids a small amount of a less active but spreading ingredient which permits the functioning of the mechanism described. Even for pure fatty acids a similar view can be held by considering the molecules as requiring at least a short time to become oriented on the surface. The ring which would be pictured as detaching itself in such a case would be a ring of unoriented molecules which would rapidly exhaust its substance in covering the metal surface to a very short distance beyond the edge of the drop.

---

(10) The ring or droplets which result from the rupture of the original layer move faster than the ordinary spreading rate, prohably because the forces of surface tension roll the liquid up from the rear as fast as it spreads outward in the front. There is thus always maintained a hydrostatic head many times greater than that which is present in a normally spreading layer of oil.

The situation presented is somewhat curious. It might be said that mineral oils spread mainly because they reduce the surface tension of solids to a low value. With regard to fatty oils, fatty acids and mineral oils containing relatively large amounts of fatty acids, it becomes necessary to state that they fail to spread although they reduce the surface tension considerably more.

The paradox is adequately explained, for the case of the solutions of oil and fatty acid, by the ring mechanism which is easily and directly observed. For pure fatty oils and fatty acids the same mechanism suggests itself as a possible and reasonable explanation, although here other factors may have to be considered, especially for such materials as possess an appreciable vapor pressure. A high concentration of oleic acid vapor effectually prevents the spreading of mineral oils on a steel plate initially clean, presumably by condensing as an adsorbed film and lowering the surface tension of the metal. It seems likely that the condensation of vapor from a drop of oleic acid or fatty oil onto the immediately adjacent surface might similarly prevent the spreading which would be predicted for such a drop from energy considerations alone.

Adam[11] has suggested that the mechanism of spreading of a liquid layer on solids is the evaporation of the spreading material near its edge, followed by recondensation on the solid surface. The question might reasonably be asked as to how one and the same mechanism could produce spreading in the case of mineral oils, and prevent it in the case of fatty liquids. The probability that this situation actually prevails seems not to be great, but its possible existence may be admitted for the time being.

The answer to the above question would then seem to be that in the case of the fatty liquids the surface tension of the metal is reduced to such a low value by the condensed film as to make a liquid layer thereon unstable. If a layer thick enough to have the properties of a liquid should build up for a short distance beyond the drop, this layer would at once contract inward by reason of its own surface tension, and because of the low surface energy of the adjacent metal which, in the meantime, would have become covered with an adsorbed film.

An equally acceptable and perhaps simpler view is that when a liquid spreads, the liquid flows outward as liquid at the margin of the spreading layer, under the strong attractive influence of the solid surface molecules. If this point of view is adopted, the question discussed above does not present itself.

Regardless of what may be the mechanism of spreading, there can be little doubt that, in the case of fatty oils and fatty acids where the expected spreading fails to occur, the reason for the non-spreading is to be found in the fact that the surface energy of the metal surrounding the drop is re-

---

(11) Adam, "The Physics and Chemistry of Surfaces," Oxford. 1930.

duced to such a low level as to make a liquid layer on the metal unstable. This reduction in surface energy is brought about either by the ring mechanism described in this paper, by the condensation of vapors in advance of the spreading layer or, perhaps, by a combination of both. Mineral oils and mineral oil vapors also reduce the surface energy, but not to a sufficient extent to make a thin liquid layer on the metal unstable.

Other Suggested Explanations.—The literature seems to contain no previous mention of the anomaly of the non-spreading of the fatty oils and fatty acids, and there are consequently to be found but few suggestions of a helpful nature as to its cause. Harkins and Feldman[2] are of the opinion that practically all organic liquids should spread readily on all clean metal surfaces because many such liquids spread readily on water, and "since the free surface energy of solids is in general much higher than of liquids, and since in general the interfacial tension is less than that of the surface tension by a greater amount." These authors suggest that cases of non-spreading of liquids on solids are to be explained by the presence of impurities on the surface which lower the free surface energy.

The arguments set forth in the present paper constitute further substantiation of the view of Harkins and Feldman that, on the basis of energy considerations alone, organic liquids should spread on clean solid surfaces. The presence of impurities on the surface, however, seems inadequate to explain the non-spreading of fatty oils and fatty acids. It is difficult to understand, for instance, what the nature of the contaminant could be which would interfere so slightly with the spreading of mineral oils on metal plates and at the same time entirely prevent the spreading of the fatty liquids which are possessed of the superior spreading tendency.

Moreover, platinum can be cleansed of organic contaminants very thoroughly by heating to incandescence, and glass can be brought to a comparable condition of cleanliness with the aid of strong acids. The spreading behavior of mineral oils and of fatty oils and fatty acids on surfaces so cleansed is, nevertheless, qualitatively the same as on the metal surfaces used throughout this investigation. In general the behavior is the same also on surfaces of mica freshly exposed by cleavage.

A test which is generally recognized as a delicate one for detecting minute amounts of contaminants on a solid surface is to see how well the surface retains a film of water. All the experiments described in the present papers were made on surfaces which were clean in the sense that they were capable of being wetted perfectly by water.

Woog's[8] suggestion as to the reason for the non-spreading of fatty oils is more in keeping with the experiments described in this paper, although it seems to have been made on the strength of meager evidence. No consideration is given to the energy relations involved, and there is no mention of the fact of an anomaly. His description of the manner in which drops of mineral oil containing fatty acid spread at first and then contract into drops is similar to some of the effects described in this paper (Fig. 8). If any rings separated from the drops in his experiments he apparently did not observe them. This may account for his failure to suggest any suitable mechanism for the formation of the zone of oriented molecules which he postulates as surrounding the drops.

Trillat and Cuypers[12] have quoted Woog's explanation without substantial modification.

Summary

Several lines of experimental evidence are described in support of the view that the interfacial tension between metals and petroleum oils is substantially greater than between metals and fatty oils or between metals and fatty acids.

The energy requirements for spreading on solids being the same as for spreading on liquids, the fatty oils and fatty acids should spread more readily than mineral oils on metal surfaces.

Experimentally, fatty oils and fatty acids spread little or not at all while mineral oils spread apparently without limit. The non-spreading of the fatty liquids must, therefore, be regarded as anomalous.

The higher fatty acids do not wet polished metal surfaces in the ordinary sense, but roll about freely. They deposit an adsorbed film on the surface which reduces the surface energy to a low value.

Thin layers of mineral oil containing fatty acids rupture spontaneously on metal surfaces. The explanation is the same as when a similiar phenomenon occurs on water, namely, the formation of an underlying film of low surface energy. Thin layers are unstable on areas of low surface energy.

Fatty oils and fatty acids are prevented from spreading on metal surfaces by the great reduction in the surface energy of the metal which is brought about to some distance in advance of the spreading layer by the breaking away of an expanding ring or by the condensation of vapors.

The Systems (I) Diphenyl–Diphenylamine, (II) Diphenyl–Benzophenone and (III) Benzophenone–Diphenylamine[1]

BY H. HOWARD LEE AND J. C. WARNER

This investigation was undertaken for the purpose of determining the freezing point-composition diagrams for the binary systems (I) diphenyl–diphenylamine, (II) diphenyl–benzophenone and (III) benzophenone-diphenylamine. The system benzophenone–diphenylamine was investigated by Giua and Cherchi[2] but their results are evidently in error over a considerable range of composition and we have consequently reinvestigated the entire system. Each of the three compounds contains two phenyl groups. Diphenyl is non-polar but benzophenone and diphenylamine possess electric moments of considerable magnitude. It was therefore considered of interest to compare actual solubilities to ideal solubilities in these systems.

Materials.—The chemicals were Eastman's "Highest Purity" grade. The diphenyl was purified by crystallization from alcohol, washing with ether and drying in an oven at 100°. The diphenylamine and benzophenone were distilled under reduced pressure. In each case recrystallization or redistillation was continued until no further change in melting point was observed. The melting points of the compounds used in the investigation are compared to the "International Critical Tables" values in Table I.

TABLE I

	Melting point, °C.		Heat of fusion,[3]
	Our material	I. C. T.	g. cal./mole
Diphenyl	69.0	69.0	4020
Diphenylamine	52.8	53.0	4260
Benzophenone	47.7	48.5	4290

The agreement in melting points is good except for benzophenone. It seems certain that the "I. C. T." melting point for benzophenone is in error since any number of recrystallizations or redistillations failed to yield a product of melting point higher than 47.7°. Furthermore, none of the seven reported investigations on binary systems with benzophenone[4] as one constituent shows a melting point for pure benzophenone above 47.7°.

Temperatures were measured with 100° thermometers graduated in tenths of a degree. They were compared to a thermometer of the same type which had been calibrated by the Bureau of Standards. Correction for emergent stem was always made when the correction was equal to, or greater than, the experimental error.

Experimental

Weighed samples in test-tubes (15 mm. diameter) were placed in larger test-tubes which were immersed in a water-bath. The melt was allowed to cool with the bath, the temperature difference between the bath and the sample ranging between a few tenths of a degree and several degrees depending upon the particular sample and the temperature at which observations were made. The samples were well agitated during cooling by a glass stirrer which encircled the thermometer stem. When undercooling occurred, the cooling curves were projected back to intersect with the liquid cooling curve to obtain a more accurate primary crystallization temperature. With some samples, particularly those containing high percentages of benzophenone or diphenylamine, undercooling was very marked in spite of vigorous agitation and inoculation. In such cases, the results obtained from cooling curves were checked by thermostating samples to determine the temperature at which the solid phase disappeared.

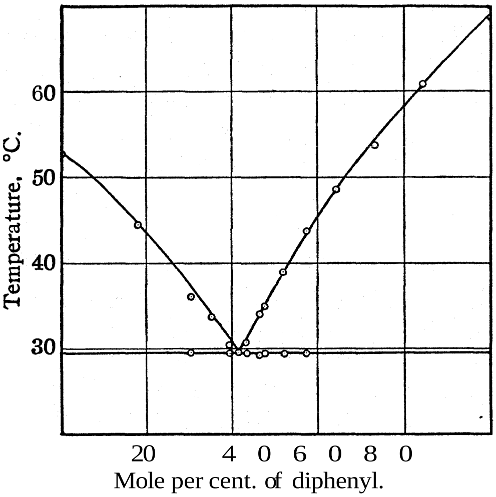

Fig. 1.—Diphenyl–diphenylamine.

(I) **Diphenyl–Diphenylamine.**—The freezing point–composition diagram for this system is shown in Fig. 1. The diagram is based upon the data in Table II.

A sample having the eutectic composition (41.7 mole per cent. diphenyl) indicated by the intersection of the liquidus curves solidified at 29.6'. This is in good agreement with the average final solidification temperature of 29.5'. Assuming ideal solution behavior and constant heats of fusion (see Table I), the calculated eutectic temperature is 26.5' and the eutectic composition is 43.8 mole per cent. diphenyl. The solubility of each constituent in the other is therefore less than the ideal solubility. This should be expected since one component is polar and the other non-polar.

Primary crystals of diphenyl which were separated from the liquid above the eutectic temperature melted sharply at 68.8°. Similarly obtained crystals of diphenylamine melted sharply at 52.8'. Hence there is no appreciable solubility of the constituents in each other in the solid state.

(II) **Diphenyl–Benzophenone.**—The freezing point–composition diagram for this system, constructed from the data given in Table III, is shown in Fig. 2.

This system also shows a simple eutectic. According to the intersection of the liquidus curves, the eutectic composition is 39.3 mole per cent. diphenyl and the eutectic temperature is 25.2°. A sample of this composition solidified at 25.2°. The average of the four final solidification temperatures in Table III is 25.1°. Using the method described under the previous system, we have shown that there is no appreciable solubility of the constituents in each other in the solid state. Assuming ideal solution behavior, we calculate that the eutectic composition should be 41.3 mole per cent. diphenyl and the eutectic temperature should be 23.5°. Here again, due to one constituent being polar and the other non-polar, solubilities are lower than ideal.

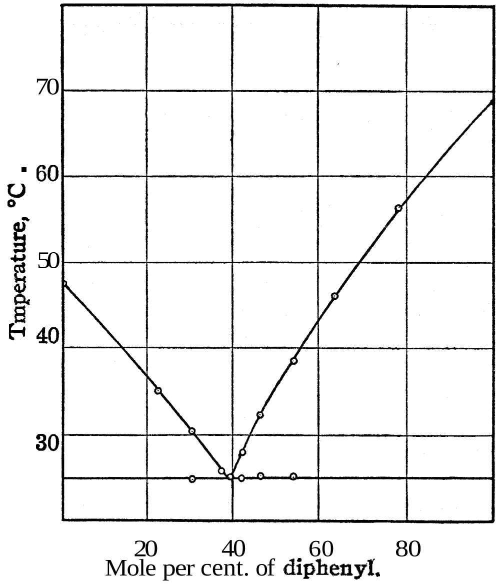

Fig. 2.—Diphenyl-benzophenone.

(III) **Benzophenone–Diphenylamine.**—The unbroken freezing point–composition curve in Fig. 3 is constructed from our data given in Table

IV and the broken curve from our data in Table V. The dots in the figure represent points reported by Giua and Cherchi.[2] The curve shows a compound with equimolecular quantities of diphenylamine and benzophenone and two eutectics; one at **30** mole per cent. benzophenone and at 34.1°; the other at 74.5 mole per cent. benzophenone and at **31.9'.** Due to the marked interaction between these polar compounds, solubilities are much higher than ideal. There is definite evidence that there are two forms of the compound. If a sample consisting of the compound composition is melted and then solidified in an ice–salt bath, crystals of the metastable compound are obtained. These crystals melt sharply at **30.8'.** When this melt is agitated, it solidifies completely, yielding crystals which melt sharply at 40.2°. Although the transition temperature has not been determined, it is definitely below room temperature. **A** sample of the metastable solid

73.6	30.2	

compound was largely converted into stable solid in fifteen hours at room temperature.

In general, on cooling melts containing from **31** to **74** mole per cent. of benzophenone, initial crystallization temperatures which fall on the metastable curve will be obtained unless the samples are carefully inoculated with crystals of the stable compound. Due to the marked tendency of the compound and of benzophenone to undercool, most of the points on the unbroken curve (Fig. **3)** were obtained by thermostating samples for eight to twelve hours to determine the temperature at which the last of the solid phase disappeared. However, a number of points were checked by carefully determining the temperature of initial and final crystallization.

Up to **30** mole per cent. and in the range above **75** mole per cent. benzophenone, the data reported by Giua and Cherchi, based entirely on cooling curves, are in fair agreement with ours. In the region **30** to **75** mole per cent. benzophenone, their curve is somewhat similar to our metastable curve, but most of their points are too low, evidently due to undercooling. It is very difficult to obtain reliable data in the vicinity of the eutectic between metastable compound and benzophenone. This eutectic temperature may be in error by as much as **2** or 3°.

Summary

1. The freezing point–composition diagram for the system diphenyl–diphenylamine shows a simple eutectic at **41.7** mole per cent. diphenyl. The eutectic temperature is **29.5'.**

2. In the diphenyl–benzophenone system, there is likewise a simple eutectic at **39.3** mole per cent. diphenyl with a eutectic temperature of 25.2°.

3. Diphenylamine forms an equimolecular compound with benzophenone. The stable compound has a melting point of **40.2'.** The eutectic between compound and diphenylamine occurs at **30.0** mole per cent. benzophenone and at **34.1'.** The eutectic between compound and benzophenone occurs at 74.5 mole per cent. benzophenone and at 31.9'. Evidence is presented for the existence of a metastable form of the compound with a melting point of 30.8°.

The Kinetics of the Thermal Decomposition of Trichloromethyl Chloroformate

BY H. C. RAMSPERGER AND G. WADDINGTON

Trichloromethyl chloroformate gas is known to decompose at 300° to give two molecules of phosgene[1] as shown by the equation

$$ClCOOCCl_3 = 2COCl_2 \qquad (1)$$

The liquid can be decomposed at room temperature by the addition of various metallic chlorides such as aluminum chloride,[1,2] in which case, however, the reaction is

$$ClCOOCCl_3 = CO_2 + CCl_4 \qquad (2)$$

The rate of the thermal decomposition in the gas phase has been studied by us between 260 and 310° and in the pressure range 4 to 17 mm. with the intention of providing further data on unimolecular reactions.

Preparation of the Compound.—The method of preparation was similar to that of other investigators,[1,2] namely, the photochemical chlorination of methyl formate. A 100-cc. portion of methyl formate was placed in an all-glass apparatus provided with a reflux condenser cooled with ice and salt to prevent loss of the very volatile methyl formate. The flask containing the methyl formate was illuminated by a 500-watt lamp placed just above it. To avoid explosions illumination was commenced before the slow stream of "tank" chlorine was passed in. The temperature was kept at about 30° during the initial stages of the reaction. As the chlorination progressed the chlorine was passed in more rapidly and the temperature was gradually increased until finally it reached about 90°. Chlorination was complete after thirty hours.

A portion of the product was distilled under reduced pressure in a small all-glass apparatus provided with a fractionating column and condenser. The middle fraction of a sample, which boiled between 50.0 and 50.1° under 48 mm. pressure, was collected in a bulb containing calcium chloride. This supply was frozen with a carbon dioxide–ether mixture, sealed onto a high-vacuum line, pumped off and allowed to diffuse over into a second bulb immersed in carbon dioxide–ether, after which the original container was sealed off. The sample (A in Fig. 1) could be partially evaporated into the 500-cc. bulb B, frozen back into A and any non-condensed gas pumped off. Repetition of this process ensured the elimination of dissolved gas.

Apparatus and Experimental Method.—A diagram of the apparatus is shown in Fig. 1. C_1, C_2 and C_3 are stopcocks specially designed to handle corrosive gases; these

have been described in detail elsewhere.[3] D is a mercury boiler, and E the reaction cell, which was heated to the desired temperature by boiling the mercury under a constant pressure, maintained by having a twenty-liter bottle connected with the system and adjusting by hand the small pressure changes due to changes in the room temperature. The cell was sealed to the boiler at F with a cement of litharge and glycerin and this was coated with sealing wax. This joint was cooled by a copper coil carrying a stream of water. This arrangement permitted the cell to be replaced easily by another cell and made it possible to use cells of various kinds of glass. The cells had a volume of about 125 cc., and the external volume in the tubing, stopcock and click gage was about 1.5 cc. No corrections were made for this small outside volume in the calculation of rate constants.

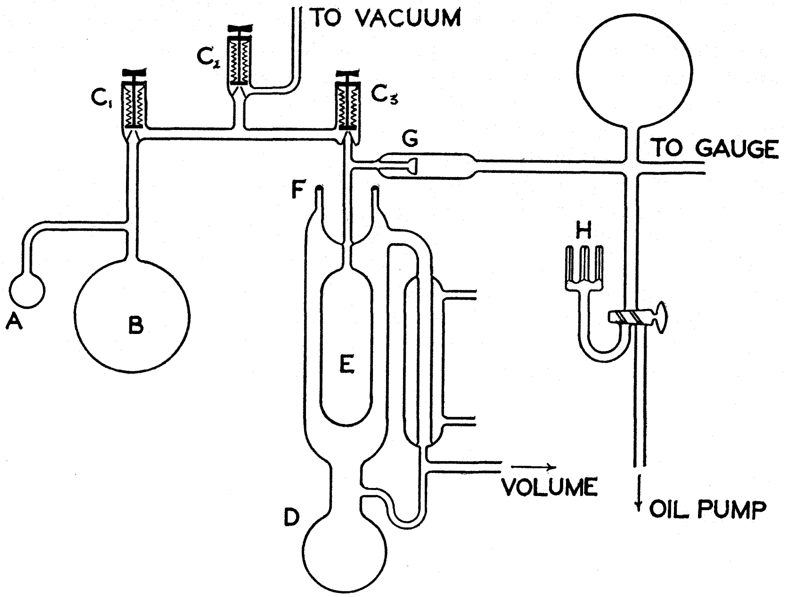

Fig. 1.—Apparatus.

Pressures were measured by means of the click gage G,[4] which was operated by admitting air through the controlled leak H until the click was heard. The pressure in the click system was then measured by means of a McLeod gage designed so as to measure accurately pressures of from 1 to 5 cm. In filling the cell the opening and closing of the stopcock C_3 required only a few seconds. Time measurements were started on closing C_3. Pressure measurements were then made at time intervals chosen so that the pressure increments were approximately equal, and were continued until the reaction was about 80% complete. The final pressures were obtained by allowing the reaction to go to completion; in the runs at lower temperatures time was saved by completing the reaction at a higher temperature and using the gas laws to calculate the final pressure at the lower temperature, it having been shown that the gas laws were obeyed by the reaction products.

Chemical Nature of the Reaction.—According to both equations (1) and (2) the final pressure should be exactly twice the initial pressure. This was verified by admit-

[4] Smith and Taylor, THIS JOURNAL, **46**,1343 (1924).

ting the compound to the cell and measuring its pressure at a low temperature where decomposition was negligibly slow. The temperature was then raised and the reaction carried to completion. The gas laws had been shown to be obeyed by the compound at lower temperatures. In this manner the final-to-initial pressure ratio was found in three experiments to be 1.99, 2.00 and 1.986. To distinguish between reactions (1) and (2) the reaction products, at about 3 cm. pressure, were frozen out in a side-tube with a carbon dioxide–acetone mixture at −79 to −80° The pressures from three experiments were 5.4, 5.6 and 5.0 mm., agreeing quite well with the vapor pressure of phosgene at this temperature, which is about 6 mm., and indicating that there could be no appreciable amount of carbon dioxide, carbon monoxide or chlorine formed. Freezing out with liquid air gave zero pressure in one case and about 0.05 mm. in another experiment, indicating the absence of non-condensable gases such as carbon monoxide. A direct analysis of the reaction product by hydrolyzing with excess standard sodium hydroxide and back-titrating with standard hydrochloric acid using methyl orange indicator gave 98% of the amount of acid required if the product were pure phosgene. Incomplete hydrolysis may account for the slight discrepancy. The evidence is thus quite strong that phosgene is the only product formed.

From the known free energy of formation of phosgene from carbon monoxide and chlorine,[5] it is found at 290° and a partial pressure of 1 cm. of phosgene that phosgene would be about 30% dissociated at equilibrium. It is also known that the rate of decomposition of phosgene at the above temperature is negligible.' Our experiments show definitely that only phosgene is formed; this would suggest that the rupture of the trichloromethyl chloroformate molecule gives two molecules of phosgene as the immediate products. Pure phosgene could not be produced from carbon monoxide and chlorine formed initially and subsequently recombining, for then the equilibrium between phosgene, carbon monoxide and chlorine would be produced.

Experimental Results

First order rate constants were calculated by the interval method using the equation

$$k_1 = \frac{2.303}{t_2 - t_1} \log_{10} \frac{P_{t_1}}{P_{t_2}}$$

where P_{t_1} and P_{t_2} are the partial pressures of trichloromethyl chloroformate at times t_1 and t_2 in seconds. Approximately equal amounts of reaction occurred during these time intervals. We have averaged these interval constants to obtain a rate constant for the run. No more refined statistical procedure used in obtaining an average constant would have made any material difference because of the exceptionally good first order rate constants obtained during the course of each run.

Since it was not possible to obtain a pressure reading until at least one-half minute after the beginning of a run, it was more accurate to calculate the partial pressure from the final pressure, using a factor of exactly two for the final–initial pressure ratio, this being justified by the experiments previously referred to.

Table I gives the complete data for three runs. The first column of figures refers to total observed pressures while the second column gives the partial pressures of trichloromethyl chloroformate.

When no change in the nature of the cell was made or no extra surface was added, the average rate constant was exceptionally reproducible. It was found early in the research that there was some effect of the cell wall on the rate. This is best illustrated by Fig. 2, in which log k is plotted against $1/T$ for two series of runs. Series A was made in a Pyrex cell containing Pyrex tubing, the cell and contents having been treated with a chromic acid cleaning solution, while Series B was carried out in an empty Pyrex cell which had merely been wiped free of dust and flamed very thoroughly.

The curvature exhibited by the plot of Series A runs indicates that in these runs there were two simultaneous reactions differing in energy of activation, while the straight line of Series B shows that the reaction was homogeneous or very nearly so. All Series B runs, particularly those at lower temperatures, have lower rates than those of Series A. The results of Series A are typical of reactions in which in addition to a homogeneous reaction there is present a heterogeneous reaction of lower energy of activation. In Series B the heterogeneous reaction has been practically eliminated. When, however, the surface-to-volume ratio was increased tenfold by adding, to the cell used in Series B, Pyrex tubing which had been wiped clean and flamed, there was an increase of 15 or 20% in the rate at 290". If we assume that the original surface had the same catalytic activity as the added surface, then the wall reaction in Series B runs would amount to only about 2%. This fact, together with the straight line obtained in Fig. 2, is good evidence that these runs are practically homogeneous.

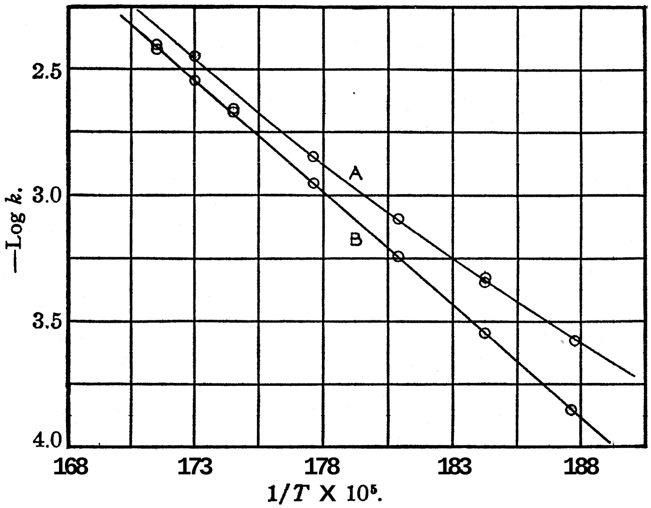

Fig. 2.—Curve A, cell packed with Pyrex tubing; Curve B, cell empty.

Many further unsuccessful attempts, using cells packed with tubing, were made to obtain surfaces free from catalytic activity. More careful flaming of the tubing sometimes gave results similar to those just described but in other cases the rates were faster. Various chemical treatments, such as thorough washing with cleaning solution, hot nitric acid or sodium hydroxide solution, again gave results similar to Series **A.** Treating the cell with hot concentrated hydrochloric acid often gave results which were identical with those of Series B, but with added tubing similarly treated the rates were again 15 to 20% faster. Soft glass or quartz cells gave rates which were 10 to 20% faster than Series B runs, The use of different samples of trichloromethyl chloroformate never altered the rate which had been characteristic of the cell used.

From the slope of the straight line of Fig. 2 the energy of activation is found to be 41,500 cal. per mole. The equation for the rate constant is $k_1 = 1.4 \times 10^{13} \times e^{-41,500/RT}$

Table II gives a summary of Series B runs.

TABLE II

Expt.	Temp., °C.	Initial pressure	Av. $k \times 10^3$	Number of constants	Expt.	Temp., °C.	Initial pressure	Av. $k \times 10^3$	Number of constants
11	260	1.640	0.143	6	9	305	1.333	2.86	4
4	270	1.293	.289	7	10	310	1.564	3.78	3
5	280	1.503	.579	6	12	310	1.472	3.98	3
2	290	1.576	1.11	5					
6	290	0.445	1.08	5	21	270	1.468	0.286	6
3	290	1.609	1.11	5	17	280	1.677	0.593	7
7	300	1.187	2.20	4	19	290	1.594	1.12	5
8	300	1.267	2.15	4	22	290	1.330	1.11	6
13	300	1.513	2.22	4	18	305	1.568	2.98	4
14	300	1.337	2.16	5	20	305	1.413	2.88	4
1	305	1.398	2.84	3					

The average of the average deviations of the rate constants for all runs is only 2.18%. Runs 17 to 22 were made with a new portion of the compound and reproduced the earlier experiments almost perfectly.

The first order constant is evidently independent of the initial pressure over the pressure range investigated. It would have been desirable to obtain data at lower pressures in order to test rather severely the theory of unimolecular reactions, but the catalytic effect of the walls at lower pressures would very probably be greater and would therefore be a serious disturbing factor.

We may calculate a lower limit to the number of oscillators required to agree with theory. An examination of specific heat data at high temperatures of highly chlorinated organic molecules such as carbon tetrachloride shows that these have unusually high specific heats. This would indicate that the oscillators of such molecules are of sufficiently low frequency that we will be justified in considering them as classical oscillators. Doing so, making use of the formulation of the calculation given by Kassel,[6] we then find that with the reasonable assumptions of fourteen oscillators and a diameter of 8×10^{-8} cm., the rate constant at 4 mm. pressure would be about 4% below the high pressure rate. Since the maximum number of oscillators which this molecule could contain is 18, we have here a reaction whose rate at the lowest pressures approaches fairly close to the maximum permitted by theory.

Summary

The thermal decomposition of trichloromethyl chloroformate has been studied over a temperature range of 260 to 310° and a pressure range from 4 to 17 mm. The reaction has been found to be first order and homogeneous save for a slight trace of wall catalysis. The rate constant is given by the expression

$$k_1 = 1.4 \times 10^{13} e^{-14,500/RT}$$

---

[6] Kassel, "Kinetics of Homogeneous Gas Reactions." The Chemical Catalog Co., New York, 1931, p. 103, eq. 24.

The maintenance of the high pressure rate over the pressure range studied can be theoretically accounted for if the molecule is assumed to have a diameter of 8×10^{-8} cm. and to contain 14 classical oscillators.

The possible equilibrium between phosgene, carbon monoxide and chlorine was not found to occur as a result of the reaction, the sole product of the decomposition being phosgene.

The Effect of Gaseous Impurities on the Radiochemical Combination of Carbon Monoxide and Oxygen

BY CHARLES ROSENBLUM

Part of the recent work on the carbon monoxide oxidation under the influence of radon[1] involved a study of the effect of certain gaseous impurities possibly occurring in traces in the reactants as a result of the methods employed for their preparation. These foreign substances were water vapor, formic acid vapor and gaseous nitrogen.

The formic acid was prepared by reduced pressure distillation[2] in the presence of phosphorus pentoxide, and saturation of a $2CO{:}1O_2$ mixture was effected at 21.3°. Another sample of the reaction mixture was saturated with water vapor at 21.5°. A measured volume of tank nitrogen, purified by passing through a train containing, besides a liquid air trap, tubes of fused potassium hydroxide, sublimed phosphorus pentoxide and yellow phosphorus, was added to a third quantity of reactants. The gas mixtures so prepared were confined with radon in small spherical vessels[3] and the progress of the reaction followed manometrically.

Table I shows the reaction in gases wet with water vapor. Here $e^{-\lambda t}$ is the fraction of radon left after time t, E_0 is the initial amount of radon in curies, $P_{2CO + 1O_2}$ is the partial pressure of dry reactants, D is the diameter of the reaction vessel, and $(k\mu/\lambda)''_{\text{corr.}}$ is the velocity constant corrected for the catalytic efficiency of carbon dioxide and for the effect of recoil atoms.[1]

From the inverse square of diameter law[4] the velocity constant in a sphere of this size should be about 31,[1] which may be considered in agreement for experiments of this kind. It then appears that water vapor has little effect on the radiochemical carbon monoxide oxidation. That water vapor has a negligible effect is in accord with its radiochemically inert nature.[5]

The effect of formic acid vapor is given in Table II.

The corrected velocity constants in column I are calculated in the usual manner directly from the pressure of reactants as indicated by the total pressure drop. The low constant for the first interval shows that **formic** acid is being decomposed, the formation of its decomposition products producing a pressure increase which masks the disappearance of carbon monoxide and oxygen.

It is impossible to say for certain what these decomposition products may be. The simplest assumption is either hydrogen and carbon dioxide or water vapor and the monoxide. However, supposing the formic acid to yield twice its volume in decomposition products, the partial pressure of reactants will be considerably less than was calculated simply from the total pressure drop. The result of this recalculation, confining the entire side reaction to the first interval, is shown in column II. These constants are somewhat higher than the expected value of **37.** However, it is apparent that the sole effect of formic acid vapor is to mask the main reaction in its earlier stages, and this only when present in appreciable quantities.

The effect of nitrogen was interesting in that it is an excellent ionic catalyst[6] as contrasted with the inefficient carbon dioxide. Furthermore,

---

[6] **Lind and Bardwell, THIS JOURNAL,** 48, 1575 (1926).

this system involved the simultaneous effect of two radiochemical catalysts, a situation hitherto found only in the case of catalysis of the carbon monoxide oxidation by the relatively inefficient argon. In the following experiment, a mixture containing 33.8% nitrogen was used.

TABLE III

THE EFFECT OF NITROGEN

D = 2.006 cm.; E_1 = 0.0342 curie radon

$e^{-\lambda t}$	P_{2CO+1O_2}, mm.	$(k\mu/\lambda)'_c$	$(k\mu/\lambda)'_{corr.}$		$(k\mu/\lambda)''_{corr.}$	
		I	II	III	IV	V

.8136	365.0	122.0	93.3	52.4	50.3	38.8
.7658	299.0	121.9	88.2	46.7	44.7	34.4
.7321	254.3	140.3	99.0	49.2	46.9	34.6
.6925	207.0	151.8	99.6	46.4	44.1	32.6
.6436	154.7	174.0	103.6	46.4	44.0	31.9

Inspection of velocity constants indicates unmistakably the efficient nature of nitrogen as an ionic catalyst. Column I shows the velocity constant $(k\mu/\lambda)'_c$ calculated from total pressure drop disregarding ionization on the catalysts. Column II corrects for the catalytic effect of carbon dioxide, assuming its efficiency to be 14.5%.[1] Attributing in addition 100% efficiency as a catalyst to the nitrogen, column III is obtained. Making proper correction for the effect of recoil atoms column IV is calculated from column III.

Since the corrected constants $(k\mu/\lambda)''_{corr.}$ should be about **31,** we are evidently faced with a significant velocity increase. The simplest manner of accounting for this increase is to assume an enhanced efficiency of the ionization falling on the carbon dioxide when in the presence of such an efficient catalyst as nitrogen. Assuming an efficiency of 30% for carbon dioxide, column V is obtained, which is a decided approach toward a correct representation of the reaction velocity.

A mechanism for such an unexpected effect cannot be suggested because the bulk of the sensitized radiochemical effects studied have involved only single catalysts. The result in the case here reported seems to indicate transfer of ionization by the efficient catalyst (nitrogen) not only to reactants but as well to the less efficient catalyst (carbon dioxide).

Summary

The effect of water vapor, formic acid vapor and nitrogen on the combination of carbon monoxide and oxygen in the presence of radon was studied. Water vapor had a small retarding effect on the reaction. For-

mic acid vapor did not directly affect the velocity of the main reaction, tending only to mask its course in the early stages by undergoing decomposition. Nitrogen had an extreme accelerating influence on the oxidation, which could be explained by an increase in the catalytic efficiency of carbon dioxide from 14.5 to 30%, in addition to the 100% efficiency of nitrogen.

An Anomalous Decomposition of Ozone in the Presence of Chlorine

BY LAWRENCE J. HEIDT, GEORGE B. KISTIAKOWSKY AND GEORGE S. FORBES

Several investigators[1] of the decomposition of ozone in the presence of chlorine have reported that the quantum yield, ϕ (ozone molecules decomposed per quantum absorbed), is 2.0 ± 0.2 in spectral regions where chlorine only absorbs, that the light reaction is nearly independent of the concentrations, and that the dark reaction[2] is relatively small at room temperature. The dark reaction has since been studied at 35 and 60° by Hamann and Schumacher.[3] The photolysis has been used as an actinometer.[4] The observations by Allmand and Spinks[1a] indicated that the course of the reaction was decidedly irregular. We undertook its further study at lower temperatures using an apparatus—ecently devised for referring ϕ in gas reactions to uranyl oxalate as an actinometer. Attention is called to the stringent precautions there described regarding temperature control and pressure measurement. A second paper of Allmand and Spinks[6] stated, as we had noticed in the meantime, that the dark reaction and wall effects were important, and expressed regret that these had not been further studied. None the less, they still viewed their reaction as essentially photochemical. These workers found that with O_3 greater than 35% and Cl_2 about 1%, values of ϕ up to 59 could be obtained; these values decreased as the light intensity, I, increased, the reaction rate being approximately proportional to I'"; the 10° temperature coefficient of the rate under these conditions was about 1.5, as compared with 1.0 when the chlorine percentage was higher, ϕ smaller, and the rate proportional to I.

When high initial values of ϕ were obtained, they decreased rapidly; a similar sort of decrease is noted, under different conditions, in the present paper.

The quantum yield apparatus (Ref. 5, Fig. 2) was fused to the Pyrex train for introduction of ozone and chlorine at **A** (Fig. **1** of the present paper). Originally, the latter lacked the U tubes, U_1 and U_2, and greased stopcocks were present at F, G, H, I and J. The average quantum yields, ϕ, of thirteen preliminary experiments are noted upon the curves in Fig. 2.

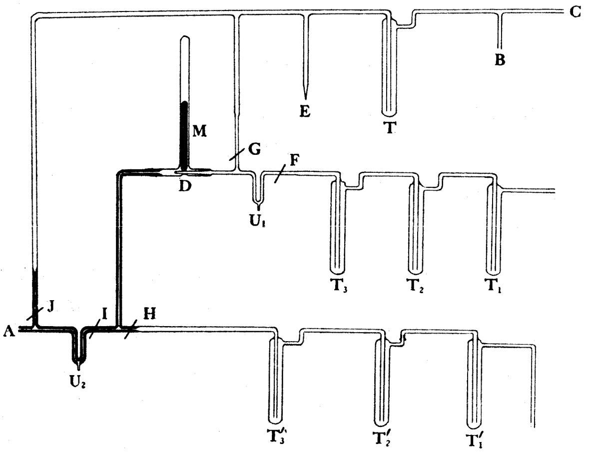

Fig. 1.

In all the figures black circles indicate darkness, open circles light absorption averaging 2.7 X 10^{15} **quanta/sec., λ = 366 mμ,** and half black circles exposure to red and yellow light. Plain circles indicate a temperature constant within **0.1°** at approximately **2°**, one flag **13°**, two flags **25°**. Whenever a new symbol appears, it defines conditions back as far as the last old symbol. Along a dotted line the temperature, θ, is indeterminate. To avoid implications regarding reaction mechanism we report only the rate of increase in total pressure, $dp/dt = m$, referred to **0°** in **mm.** of mercury per minute. Curves representing long experiments, e. **g.**, the fourth, are broken up into sections. When a part of the experiment between sections has been omitted, the total pressure, p, at the beginning of the section is noted. Initial partial pressures are given in the accompanying tables, with $p_f - p_i$, the difference between total final and total initial pressure.

The values of ϕ in Fig. 2 are not concordant, and are in most cases smaller than 2. The irregularities seem to be independent of partial pressures of reactants. The behavior of the mixture when light and dark periods alternated, shown in the group of curves to the left in Fig. 2, differs strikingly from that observed by **Allmand** and **Spinks**[1a] in that no periods of diminishing pressure occur. Our experiments did not become consistent when the rubber grease, R, in the stopcocks was replaced by a mixture of vaseline, V, with naphthalene, N, **refluxed** for many hours in an atmosphere of chlorine, or by concentrated sulfuric acid, S.

Suspecting contamination of the gases or of the cell, we improved the apparatus by adding U_1 and U_2, and by eliminating all stopcocks. All parts were heated in sulfuric plus nitric acid, washed with distilled water several times after washings had become neutral, and scrupulously dried. The quartz reaction cell (Ref. 5, Fig. 2) was pumped out for several hours with a Wagner deka-micro oil pump. Air, dried with resublimed phosphorus pentoxide, was then admitted. While fusing the parts together, we blew through a sodium hydroxide tower and a trap filled with glass wool and immersed in liquid air. At B, connection was made with a McLeod gage (not shown). A two-stage mercury diffusion pump backed up by the Wagner pump was connected to the train at C through the trap, T, immersed in liquid air to intercept mercury vapor. After testing for leaks with a Tesla coil, the train was pumped out with the diffusion pump, while flaming exposed parts. Dried air was admitted through E.

In dim diffused light tank chlorine was fractionally distilled in a vacuum three times, occupying successively traps T_1, T_2, T_3 and the graduated tube below U_1, previously calibrated by measuring the pressure developed in the reaction vessel, C_g, by evaporation of liquid chlorine between various graduations. The chlorine was evaporated each time at $-80°$ and the middle portion only was condensed in liquid air. Seals were made at F and G. Ozone was obtained from an apparatus lent by Professor E. P. Kohler. The electrolytic oxygen passed through sodium carbonate solution, solid potassium hydroxide, sulfuric acid and phosphorus pentoxide, in the order mentioned. The ozone was thrice fractionated much like the chlorine by suitable manipulations of a container of liquid air, the middle fractions occupying successively T'_1, T'_2, T'_3 and the calibrated tube below U_2. A seal was then made at H. Keeping U_1 and U_2 in liquid air, the sealed capillary at D was broken by the magnetic hammer. M, and a predetermined amount of chlorine distilled into the arm of U_2 next to D. Seals were made at I and J and allowed to cool. The total volume of U_2 and connecting capillaries to the left of I and J did not exceed 2 cc. or 5% of C_g. In experiments where much chlorine and little ozone was present in U_2, the liquid air could be removed at once from U_2 so that all the ozone passed into the cell for a pressure reading while the chlorine still remained solid. After the chlorine had evaporated, the pressure was read again. If little chlorine was present in U_2, the liquid air was manipulated so that the gases distilled over together into C_g; the chlorine could then be estimated only from its liquid volume. Exposed tubes connected with C, were wound with black tape.

16	132	97	300	66
17	158	130	651	79

For Experiment 14 the cell was on the diffusion pump for three hours at 25" before filling at 25°. At the start $\phi = 3$ at 2° decreasing toward B, where but a quarter of the ozone had been decomposed. The light was shut off at B. Between A and B the dark reaction was negligible. From B to C, $m = 0$ 006 and no further deceleration was observed. At C, θ was raised to 13° and the ten-degree temperature coefficient, $\delta_{10°}$ m, was 14.6, a highly abnormal value suggesting the emergence of a new type of reaction, possibly a chain reaction starting on the walls. Some deceleration occurs from C to D, presumably due to a decrease in p_{O_3}. At E, e again was lowered to 2° whereupon m from E to F was 0.006 in spite of a loss of three-quarters of the ozone remaining at C. From F to G ultraviolet light was without effect.. From G to H, red light through the exit slit produced acceleration. Beyond the last recorded reading, in this and all other experiments, residual ozone was decomposed by prolonged exposure to the full light of a

Uviarc, 3 cm. from the front window. Given the final reading of total pressure, all partial pressures corresponding to any given reading of total pressure could be calculated.

Before Experiments 15 and **16**, the cell was pumped out at 25° for one day with the oil pump and for a second day with the diffusion pump. Gases were introduced at 2" as in following experiments unless otherwise noted. The initial value of ϕ was 3. In each case a condition was soon attained where alternation of light and darkness had little effect upon the trend of the curves. The "fast" reaction began without elevation of temperature soon after the light was shut off. In 15, and to a considerable extent in **16**, the gases became insensitive to ultraviolet light just before the fast reaction set in. Ozone undecomposed at the end of the experiments amounted to **127** and **108** mm., respectively.

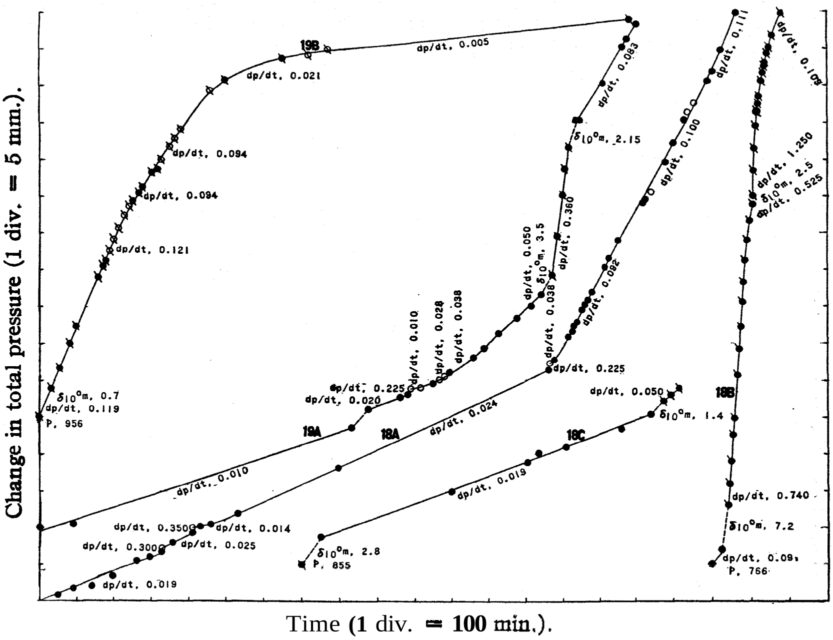

Fig. 4.

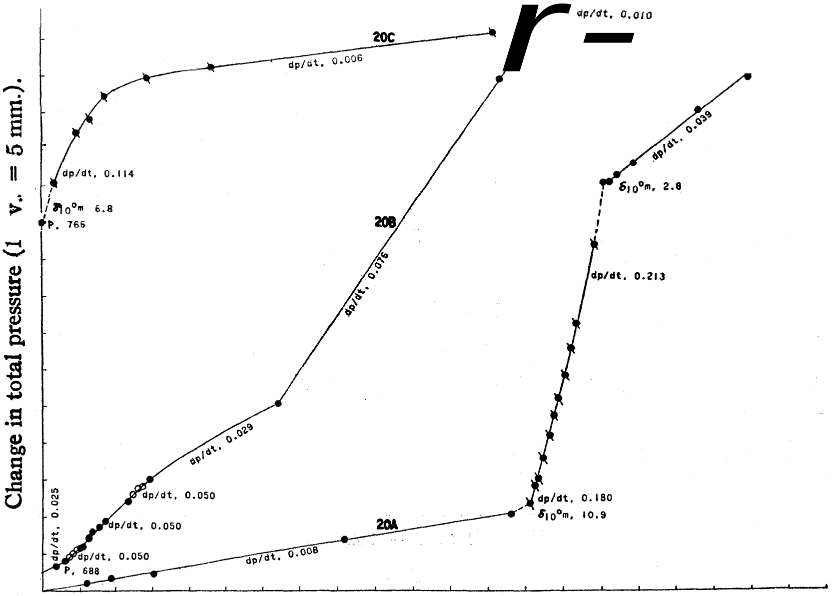
Expt.	p_{O_3}	p_{O_2}	p_{Cl_2}	$p_t - p$
18	570	32	60	285
19	457	249	105	229

Figure **2** should now be reexamined. In Experiment **1** the cell was almost as clean as in 14, and little accumulation of impurities from stopcocks could have occurred; initial $m = 0.006$. The curve up to the intervention of the fast reaction, while somewhat terraced, is not very different from the curve in **14**. Subsequent experiments **2**, 3, 4, 5 and 6, between which the cell was pumped out but not otherwise cleaned, show a pronounced and persistently terraced pattern but no fast reaction occurs except possibly over a short interval in Experiment 6.

Before Experiment **17** the cell was removed from its copper thermostating jacket, cleaned as before **14** and pumped out with the oil pump while heated to dull redness. Dry air was then admitted. Although $\phi = 0.8$ (uncorrected for the dark reaction) was relatively small at the start, the slope attained after admission of light remained nearly unaltered in light and dark alike until θ was raised to 22°; δ_{10° m $= 4.6$ is again large. One is tempted to connect the practical absence of the terraced pattern in the curve after light admission with the fact that the walls were cleaner than in previous experiments. After cooling, the decomposition reverted nearly to the original dark rate, m = 0.006, as against 0.003 and the system had regained its sensitiveness to light. Residual ozone was 24 mm.

Experiments 18, 19 and **20** in Figs. 4 and 5 are characterized by high initial ozone pressures. They show the impossibility of predicting the time intervening or the amount of photochemical or thermal reaction occurring before the beginning of **a** fast reaction. Further, they show that the fast reaction may suddenly start at any one of the temperatures used and is not dependent on a change of temperature or illumination. They also show that the fast reaction may die down and later reappear and that the induction period preceding the inception of the fast reaction decreases as experiments **are** started at successively higher temperatures.



Time (1 div. = 100 **min.**).

Fig. 5.

Expt.	p_{O_3}	p_{O_2}	p_{Cl_2}	$p_f - p_i$
20	406	118	90	203

Since Allmand and Spinks[18] used a sulfuric acid manometer, Experiment **21** was carried out with **1** cc. of pure concentrated acid in the cell (wetting only a corner of C_g). The initial dark reaction at **2°** **was** about the same as in other experiments. Upon **warming** to 21°, $\delta_{10^\circ}\, m$ was 4.6, and upon cooling **to** 2° again, δ_{10° **m** was 11.8. Light now accelerated the reaction moderately and the terraced pattern persisted, the reaction rate promptly decreasing when light was shut off. Again we observed no periods of decreasing pressure, such as those described by **Allmand** and Spinks. In the presence of sulfuric acid only we observed at 2° a white mist, formed in many of their experiments also, and found by them to contain perchloric acid. Our mists slowly disappeared on raising the temperature to 25°.

Experiment **22,** a repetition of **21,** agreed throughout with **21** and need not be discussed in detail.

In Experiment 23 the cell walls were entirely covered with sulfuric acid, the excess being poured out. The photochemical behavior was essentially the same as in **21** and **22,** but δ_{10° **m** is smaller, indicating a further retardation of the fast reaction.

Before Experiment **24** the sulfuric acid was very carefully washed out, and **1 cc.** of water was introduced. After fusing the cell to the train, the cell was pumped and filled while a block of carbon dioxide ice was held in contact with the front window to prevent evaporation of the water. At the start, at 2°, $p_{O_3} = 369$. $p_{O_2} = 125$, $p_{Cl_2} = 300$ and $m = 0.004$. Warmed to 22°, δ_{10° m = **8.25,** after which m suddenly fell off with the cell still at 22°, to a quarter of its previous value. It then suddenly trebled, and was later cut in half. In the final stages of the experiment $\delta_{10^\circ} m$ was **3.5** and **0.9,** respectively, as the reaction progressed

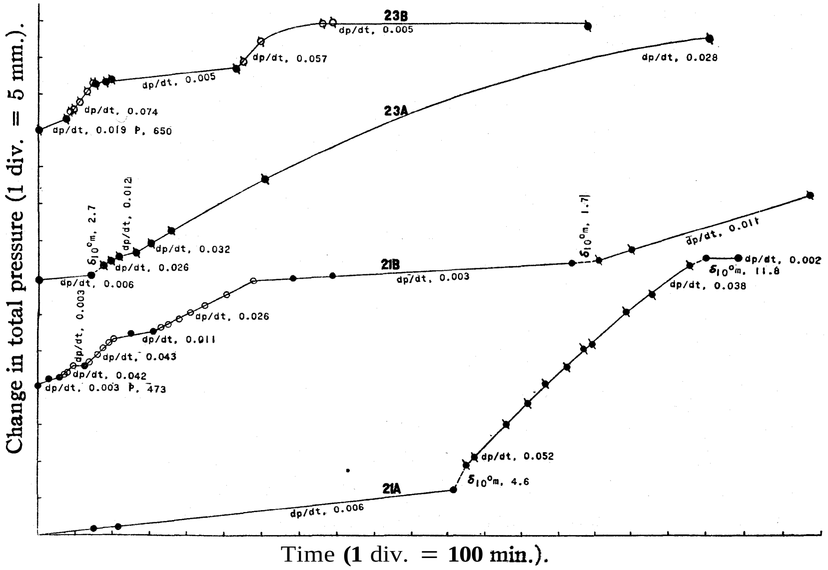


Fig. 6.

Expt.	p_{O_3}	p_{O_2}	p_{Cl_2}	$p_f - p_i$
21	194	54	185	97
23	157	356	80	79

Experiments **21** to **24** prove that variations in m (θ constant) are less striking **in** the presence of sulfuric acid or water, but persist even when the walls are completely covered with one of these liquids, that is, in the absence of an uncontaminated quartz surface. On the other hand, a mixture of ozone and chlorine does not become insensitive to light when the whole surface of the cell is contaminated.

In Experiment **25** ozone without chlorine was carefully investigated over two hundred hours to substantially complete decomposition, one hundred pressure readings being made. The cell had been scrupulously freed from add, flamed and pumped for a whole day. At the start, at **2°**, $p_{O_3} = 490$, $p = 623$ and $m = 1.20$. After two and one-half hours p was only **653,** but m had decreased to **0.026,** following a pseudo-logarithmic curve. Raised to 22°, m was not quite doubled. Exposed behind the slit to red light, m at once increased to **0.165** but fell off gradually without increase at any time to **0.012** for p = **795,** the corresponding dark rate being **0.002.** These results agree substantially with a previous investigation by one of us,[7] except for the initial rapid dark reaction above described. Kassel,[8] indeed, mentions the disagreement among previous workers in this respect. It might be urged that the fast reactions observed in the dark in the earlier stages of our experiments with chlorine present also depend upon the rapid decomposition of ozone per se, but the fast reactions springing up in the later stages of the experiments with chlorine find no counterpart upon the curve of pure ozone.

In Experiment **26** C_8 was replaced by a 50-CCPyrex bulb, very carefully cleaned, and flamed while the diffusion pump was running. The bulb was filled at 23° and the reaction studied only in the dark at 23, 35 and 50° with the usual precautions. From p_{O_3} = **518,** p_{Cl_2} = **70** and p = **652** to p = **705** at 23.2°, m changed from **0.476** to **0.435.** At **35.2"** for p = **740** to **760, m = 0.905** or $\delta_{10°}$ m, **1.74.** At **49.2"** and p = **790,** m = **2.32** decreasing to **1.17** at p = **835** or $\delta_{10°}$ **m = 1.84.** At **25.2"** and p = 843, m = **0.088** decreasing to **0.030** at p = **890** or $\delta_{10°}$ **m** = 5.55, At 35.2° and p = **892,** m = **0.073** decreasing to **0.037** at p = **894** or $\delta_{10°}$ **m** = **2.21.** At **49.5"** and p = **895,** m = **0.070** or $\delta_{10°}$ **m** = **1.35.**

The erratic values of $\delta_{10°}$ m indicate that the reaction is very complex in Pyrex as in quartz over a temperature range including that covered by Bodenstein and co-workers.[2,3] The results of these experiments do not lend themselves readily to a kinetic treatment. However, some general conclusions can be made. It is apparent that the more carefully the gases and the reaction system are purified, the more erratic are the results and the more pronounced is the fast reaction. Hamann and Schumacher[3] found some indications of this fast reaction with gases which perhaps were as pure as those used here. This undoubtedly constitutes an agreement between their work and ours. Experiments with sulfuric acid and water point rather against a pure wall reaction as the cause of phenomena here described. It seems instead more likely that an unstable intermediary product (Hamann and Schumacher suggest ClO) accumulates in the absence of impurities and causes a fast decomposition of ozone in a chain reaction which is sensitive to alterations in experimental conditions so minute that they were beyond our control. This last circumstance makes it unprofitable to discuss here the reaction mechanism in greater detail.

The fast reaction observed in our experiments is very probably analogous to the explosions of bromine–ozone mixtures reported by Lewis and Feitknecht.[9] The difference appears to be in degree only,[and attributable to the stability of chlorine oxides, greater than that of bromine oxides, which prevents the production of a real explosion.

Summary

The decomposition of ozone in the presence of chlorine has been reinvestigated at 2, 13 and 22° in quartz and in Pyrex at 23, 35 and 50° with

---

[9] Lewis and Feitknecht, THIS JOURNAL, **53**, 2910 (1931).

great care in pressure measurement, temperature control and avoidance of contaminations. Each gas was thrice fractionated, stopcocks were eliminated and the cell walls freed from adsorbed impurities. As such precautions became more stringent, the speed of the dark reaction following a brief exposure to light, an increase in temperature or even a period in the dark at 2, 13 or 23° tended to increase surprisingly. After this, an equally striking decrease often occurred.

The time intervening before inception of the fast reaction decreased with an increase in the temperature and was shortened by absorption of light by chlorine. Temperature coefficients became highly abnormal, ranging from 0.7 to 14.6. At the same time the quantum yield, corrected for the dark reaction, fell off from two or more to very small values. Reaction velocities and temperature coefficients sometimes became small again, after which the system tended to regain sensitiveness to light.

Concentrated sulfuric acid or water, within the cell, inhibited but did not eliminate these anomalies. They were at a minimum when greased stopcocks were used in the gas train.

Uncontaminated ozone, without chlorine, gave a fast dark reaction at the start which died down during the first two and one-half hours and could not be restored during the next seven days by light of any available wave length or by temperature changes.

The fact that light is readily capable of starting the "fast" reaction is evidence for the essential similarity, if not identity, of the mechanisms of light and dark reactions.

We have attempted to explain the above observations in terms of a heterogeneous or a homogeneous reaction chain or in terms of a combination of both. No mechanism so far considered by us, including those given in the literature, seems to fit all our experimental data. We, therefore, prefer for the present to reserve their discussion.

The Formation of Sodium Thiosulfate from the Oxidation of Sodium Sulfides by Means of an Aromatic Nitro Compound

BY JESSE LUNT BULLOCK AND GEORGE SHANNON FORBES

The oxidation of sulfide with the subsequent formation of thiosulfate has been recorded as early as 1798 by Berthollet.[1] Since that time many investigators have contributed to knowledge in this field, among whom may be mentioned Gay-Lussac, Vauquelin, Thomas and Rule, Kiister and Heberlein, and most recently Pearson and Robinson.[2]

In the field of organic chemistry, especially in the case of aromatic nitro compounds, the use of sulfide ion as a reducing agent has had wide application. This phase of the subject has been studied by Zinin, Beilstein and Kurbatow, Lobry de Bruyn and Blanksma, Brand, Vesely, J. B. Cohen and Flürscheim.[3]

We have restricted our work to the oxidation of sulfide, hydrosulfide, and polysulfide ions by aromatic nitro compounds. We have obtained information concerning the formation of thiosulfate ion.

Previous workers in this field have used nitro compounds that were not appreciably soluble in aqueous solution and have employed higher temperatures and mixed solvents. By the use of sulfonated aromatic nitro compounds—in particular sodium m-nitrobenzenesulfonate-we were able to work in aqueous solutions of 0.1 M concentration and at room temperature. In this oxidation thiosulfate ion and sodium *m*-amidobenzenesulfonate are the only products formed—sulfite ion was not found in any of our oxidations, see page 236. This enabled us to study the course of the reaction, which is traditionally formulated as follows

$$RNO_2 + Na_2S_2 + H_2O = RNH_2 + Na_2S_2O_3$$

Purification of Materials.—The materials involved could all be obtained in a very pure state or could be purified easily. In the case of sodium hydroxide this was prepared from C. P. sticks made up to a saturated solution with water in a seasoned Pyrex flask. The impurities, chloride, carbonate, and silicate, which may be present settle out on standing quite completely but the small quantities which remained in solution were without effect on the reaction as was proved by a series of blank tests.

Sulfur was purified by recrystallization from carbon disulfide.

Hydrogen sulfide was prepared by heating *p*-toluidine and sulfur together at 200–220°.[4] The resulting gas which is very pure was washed through water to remove any entrained solid.

The nitrobenzenesulfonate was prepared from purified nitrobenzene and the resulting sodium salt recrystallized.

Analytical Methods.—The standard iodine titration was used throughout for the determination of sulfide and thiosulfate ion. In the latter case the sulfide was removed by addition of a freshly prepared suspension of cadmium carbonate. Pure iodine was used as a standard of reference. Weighing burets were employed except in a few instances where time was of more importance than accuracy. Polysulfide sulfur was determined by a method of Küster and Heberlein.[2]

The Synthesis of Sodium Sulfides.—A very complete résumé of the work in this field is found in the paper of Pearson and Robinson already mentioned. We investigated all methods recorded in the literature. For the preparation of monosulfide and polysulfide in aqueous solution the method detailed by Kuster and Heberlein was employed with slight variations. By its use with all precautions it was possible to prepare solutions which contained only traces of thiosulfate. In non-aqueous solvents the tetrasulfide was prepared by bringing sodium and sulfur together under boiling toluene. This method has been variously described[2e] but by use of excess sulfur and boiling for twelve hours we obtained the tetrasulfide in a pure state. Pentasulfide was prepared by the method of Hugot.[5]

Another synthesis of sulfide which we employed in this investigation was to heat sulfur in aqueous sodium hydroxide until complete solution was obtained. The resulting solution was then allowed to stand at room temperature for forty-eight hours to attain equilibrium. This solution while it contained large amounts of thiosulfate gave valuable information when oxidized as will be shown later.

Experimental

The first part of the work was to determine the course of the oxidation. As has already been stated only thiosulfate results from the oxidation of sulfide ion by means of an aromatic nitro compound. Further in the case of mononitro compounds only amine is formed. One of us had established this point. The system that we were to study would contain, then, only sulfide, thiosulfate, and hydroxyl ions together with amine and the nitro compound. These latter had no effect on the analytical methods.

In the preliminary work we employed the solution obtained by the use of sodium hydroxide and sulfur. This solution is in equilibrium when $OH^-/S_x^=$ is 2.4 and polysulfide $S/S_x^=$ is 3.4. The thiosulfate ion does not enter into the equilibrium but is always formed according to reaction (4) page 236.

The reactions were carried out in a liter round-bottomed flask provided with a mechanical agitator. The flask was swept free of air by means of nitrogen and the solution introduced. Temperature was maintained within 0.1° by immersion in a thermostat of the usual type. Samples were withdrawn by means of a pipet, added directly to weighing bottles which contained weighed quantities of standard iodine or cadmium carbonate suspension as the case might be and the weight of the sample determined. A slow stream of nitrogen was passed into the reaction flask throughout the experiment. Blanks in this apparatus showed no air oxidation during six hours.

*** Represents increase over amount initially present. No. 52 solvent molal sodium chloride. No. 54 0.15 molal sodium hydroxide. No. 51 sodium sulfate, ionic concentration equal to unity. No. 53 polysulfide from solution of sulfur in sodium hydroxide.**

It will be noted that in every case the sulfide concentration diminishes rapidly at first while the thiosulfate-ion concentration does not increase at a proportional rate. The color of the reaction mixture is intensified and frequently there is a definite precipitation of sulfur. If a test of an early stage of the oxidation which has been treated with cadmium carbonate to remove sulfide ions is titrated with standard acid it is found that there is a large increase in the hydroxyl-ion concentration which is equal to the loss of anions containing sulfur, $S_x^=$ and $S_2O_3^=$. This would indicate that thiosulfate is not a direct product of the reaction as the stoichiometric equation shows but that the first products of the reaction are hydroxyl ion and sulfur—this is established in a quantitative way on page 236 reaction (2a). The sulfur as it is formed is taken up by the sulfide ion to saturation. However, when the hydroxyl-ion concentration has increased to the value given on page 233 for the $OH'/S_x^=$ ratio then the thiosulfate formation progresses uniformly (Table I, No. 53). Further oxidation is then conditioned by the thiosulfate formation since by equation (4), page 236, two sulfide ions are regenerated for each thiosulfate ion formed.

The data set forth in Table I can be utilized to give evidence of what has been briefly outlined above. In the case of disulfide oxidations at 25° there is no appreciable precipitation of sulfur and so from these few data the complete condition of the system is easily calculated.

The equation

$$S_2^{=} + RNO_2 + H_2O = S_2O_3^{=} + RNH_2 \qquad (1)$$

it is shown is made up of several, the first of which may be written

$$3S^{=} + RNO_2 + 4H_2O = 6OH^- + 3S + RNH_2 \qquad (2)$$

and the second

$$S^- + xS = S^{=}_{x+1} \qquad (3)$$

The cases of monosulfide and hydrosulfide were next investigated and it was found in both cases that there was an induction period of about thirty minutes before any appreciable oxidation began. Since the reaction was autocatalytic in character we investigated the effect of each of the known products of the reaction, RNH_2, OH^-, $S_2O_3^{=}$ and polysulfide S.

Table II shows this effect during the first minute of the oxidation.

TABLE II

Polysulfide sulfur	Fraction oxidized	Polysulfide sulfur	Fraction oxidized
0.00	0.0007	1.00	0.0295
.25	.0098	1.20	.0285
.50	.0225	1.50	.0260
.75	.0262	2.00	.0220
.83	.0263	3.00	.0160
		Satd.	.0146

Oxidations of saturated polysulfide were carried out in neutral salt solution and a good velocity constant obtained, using the bimolecular formula for different concentrations of (a) the oxidizing agent and (b) the total sulfide ion, both in moles per 1000 g. of solution.

TABLE III

Time	Total iodine	$S_2O_3^{=}$	$S_x^{=}$	k^a
0	0.1621	0.0020	0.0801	..
15	.1230	.0195	.0517	0.308
30	.1030	.0266	.0382	.292
60	.0840	.0410	.0215	.308
90	.0750	.0485	.0132	.320
120	.0715	.0535	.0090	.318

$^a\; k = \dfrac{1}{t(a-b)} \ln \dfrac{a(b-x)}{b(a-x)}$

Using concentrations greater than 0.11 molal of either sulfide or nitro compound the reaction ran too fast to measure with the requisite accuracy.

According to reaction (2) there should be a definite P_H which would allow the oxidation to progress without favoring the formation of thiosulfate. This was found to be close to PH 8. By the use of a borax-boric acid buffer oxidations were carried out which contained only a small amount of thiosulfate ion. Substituting boric acid in reaction (2) we obtain

$$3S^{=} + 12H_3BO_3 + RNO_2 = 3B_4O_7^{=} + 3xS + 17H_2O + RNH_2 \qquad (2a)$$

In an oxidation using this buffer the sulfur was filtered, thoroughly washed and dried. It was then dissolved in carbon disulfide, filtered, the solvent evaporated and the sulfur dried and weighed: calcd., 3.65 g.; found, 3.62 g.

The Formation of Thiosulfate.—As has been shown the oxidation of sulfide ion leads to the formation of hydroxyl ion and free sulfur. The formation of thiosulfate ion then takes place by a subsequent reaction which may be written as

$$6OH^- + 12S = S_2O_3^{=} + 2S^{=} + 3H_2O \qquad (4)$$

With regard to the formation of sulfite ions which are sometimes considered as intermediate in the formation of thiosulfate, we have shown that when a buffer is used only hydroxyl ion and sulfur result. All investigators agree that from the reaction between hydroxyl ion and sulfur only thiosulfate and polysulfide ions result. But if it were assumed that without a buffer the oxidation were carried further and sulfite were formed, then our analyses would show it. For it is well known and we have checked the fact in our work that sulfite and sulfide ions do not react rapidly or completely in alkaline solution. The behavior of solutions containing sulfite and hydrosulfide ions has been studied extensively by Foerster and his coworkers.[6] Their work shows that only under conditions of very careful adjustment of hydrogen-ion concentration is sulfite ion ever completely converted into thiosulfate. We employed the same method of analysis to determine sulfite as did Foerster and were not able to obtain a positive test in a single case.

Reaction (4) takes place rather rapidly at elevated temperature even with ordinary rhombic sulfur but at 25° the reaction is slow unless the sulfur is in an "active" state—set free by an oxidation of sulfide or in some similar way. We spent much time trying to prepare "active" sulfur but without success.

If one treats a pentasulfide ion with an excess of hydroxyl ion some of the sulfur in the polysulfide is available for this reaction and the solution on analysis shows an increase in sulfide and thiosulfate. Such a solution which tested 4.15 polysulfide sulfur, 0.675 sulfide and 0.207 thiosulfate after dilution with an equal weight of water was diluted with an equal weight of 0.1 M hydroxide and allowed to stand for two days. It then gave on analysis 0.748 sulfide and 0.243 thiosulfate. The sulfide increase is 0.073, that for thiosulfate 0.036—almost exactly two to one as shown by

---

(6) *Foerster, Z. anorg. allgem. Chem., 177, 61* (1928)

equation (4). This ratio holds for all temperatures. The value of the polysulfide sulfur/$S_x^=$ ratio is a function of the temperature, the hydroxyl-ion concentration and the ionic strength of the solution where neutral salt is employed.

In a series of experiments where neutral salt was employed—sodium sulfate in ionic strength equal to unity—together with hydroxyl ion of varying concentration, we obtained for variation of hydroxyl ion from 2.4–5.7, polysulfide sulfur 3.4–1.0 correspondingly. Kiister and Heberlein, in a paper already cited, obtained in pure monosulfide solution the value 4.24 for polysulfide sulfur.

The Use of Other Aromatic Nitro Compounds.—While the greater part of the work was carried out with m-nitrobenzenesulfonate we prepared a set of other nitro compounds and measured their oxidizing rate against the one just mentioned. These results are set forth in Table IV. The compounds were synthesized with great care and were recrystallized from aqueous solution and dried to constant weight as sodium salts.

TABLE IV

Name	Relative speed of oxidation of disulfide
1-Nitro-4-carboxybenzene	1.263
1-Nitro-3-sulfobenzene	1.000
1-Nitro-3,5-disulfobenzene	0.962
1-Nitro-5-sulfonaphthalene	.95 app.
1-Nitro-4-methyl-3-sulfobenzene	.935
1-Nitro-3-carboxybenzene	.918
1-Nitro-2-oxy-3-carboxy-5-sulfobenzene	.425
1-Nitro-2-methyl-5-sulfobenzene	.417
1-Nitro-8-sulfonaphthalene	.4 app.
1-Nitro-2-carboxybenzene	.089

The chloro derivatives were abnormal, giving very rapid oxidation analogous to dinitro compounds.

From the data in Table IV it is seen that the para substituted compound oxidizes most rapidly. The meta substituted compounds all react at about the same rate while the ortho substituted compounds have very little oxidizing power.

The Effect of Temperature.—While reduced temperature slows down the rate of oxidation—reaction (2)—the effect is much more pronounced in thiosulfate formation—reaction (4). Below 25° the solution of sulfur is so slow that the greater part of it is precipitated in an unreactive form even in excess of hydroxyl ions. Thus the oxidizing power of sulfide ion is diminished, for it will be noted by reference to reaction (4) that two sulfide ions are formed for each thiosulfate ion produced.

If an oxidation of disulfide is carried out slowly no appreciable amount of thiosulfate is formed until the system is saturated with sulfur. On the other hand, in the normal case where equal concentrations of sulfide ion and nitro compound are added together at the start, about 30% of the initial sulfide is oxidized in the first minute—Table II. Under these conditions there is a large amount of sulfur present in the "active" state at any particular time during the first few minutes. This sulfur would normally be dissolved by the sulfide ion still present but the large concentration of hydroxyl ion also present slows down this process and forms thiosulfate and regenerates polysulfide from the "active" sulfur. In the presence of other anions, as when neutral salt is employed, some of the sulfur is precipitated in solid form. This redissolves, in part at least, unless temperatures lower than 25° prevail. At higher temperatures the sulfur held in the polysulfide ion is more reactive and thiosulfate is formed at a much lower value of the ratio $xS/S_x^=$. Tartar and Draves[7] have shown that this ratio may be less than one with excess hydroxyl ion at 100°.

Summary

The oxidation of sulfide ion by means of an aromatic nitro compound progresses only as far as free sulfur. This sulfur is then removed from the system either by the formation of thiosulfate ion with regeneration of polysulfide ion or the sulfur is precipitated in solid form.

Thiosulfate ion is formed from free sulfur in the presence of hydroxyl ion with the simultaneous formation of two polysulfide ions. This reaction progresses slowly at room temperature unless the sulfur is in an active form.

Various ortho, meta and para substituted mononitro compounds were used as oxidizing agents and their rates of oxidation compared.

Electrical Conductivities of Mixtures of Sulfuric Acid, Acetic Acid and Water

BY NORRIS F. HALL AND HERVEY H. VOGE

Introduction

As part of the general program of acidity studies from this Laboratory, a rather careful investigation has been made of the highly acid homogeneous system: sulfuric acid, acetic acid, water. The study has included measurements of conductivities, electromotive forces, vapor pressures and colorimetric measurements. Some freezing points have been determined, and the results of others recalculated. Other investigators who have recently studied certain aspects of this problem include Hall and Conant,[1] Hall and Werner,[2] Hantzsch and Langbein,[3] Hutchison and Chandlee,[4] Hammett and Deyrup,[5] James Kendall,[6] La Mer and Eichelberger[7] as well as Dr. Sprinkle and Mr. Freeman of this Laboratory.

The present paper describes the conductance measurements, and is divisible into three parts: (I) the conductance of dilute solutions of sulfuric acid in acetic acid; (II) concentrated solutions, and (III) conductivities in the ternary system sulfuric acid–acetic acid–water.

I. Dilute Solutions

A. Apparatus and Materials.—The resistances were measured by means of a Jones[8] bridge manufactured by Leeds and Northrup. A simple Hartley oscillator with a 201A tube, operating at 1400 cycles per sec., was used, as well as a two-stage transformer-coupled audio frequency amplifier and head phones. The oscillator and amplifier were separated from the bridge and each other and (with all leads) completely shielded. Absolutely silent minima and precisions of the order of 10^{-6} were readily obtained. Standard Oil Company "Finol" was used in the thermostat, which was heated by a bare wire and controlled by a mercury-in-glass regulator with oscillating contact. The bath was set at 25 ± 01° with a B. S. standard thermometer and held a constant temperature within 0.005'. The cells were made of glass with platinum electrodes and were of the usual design. Their constants were obtained by means of the 0.01D solution of Parker[S] prepared from "equilibrium" water and purified potassium chloride. Solutions were made up and kept with every care to exclude moisture before and during the measurements.

Acetic acid was prepared by fractional distillation in an all-glass still of glacial acid obtained from the Niacet Chemical Company. That used had a melting point of 16.63° and a specific conductance (K) of 3×10^{-8}. In the course of its preparation freezing

points as high as 16.65" were recorded and values of κ as low as 1.05 X 10^{-8}. There is not a simple relationship between maximum freezing point and minimum conductance. This point is being further studied.

Sulfuric acid was obtained by mixing reagent quality fuming acid with 95% acid until a maximum freezing point of 10.46° was reached. This acid had κ = 1.02 X 10^{-2}, which may be compared to the values 0.97 X 10^{-2} obtained by Hantzsch and by Bergius,[10] and 1.04 × 10^{-2} obtained by Lichty.[11]

Acetic anhydride from Merck was fractionally redistilled. The corrected boiling point was 138.2" and κ = 1.94 X 10^{-7}.

B. Results.—The results are shown in Table I. No solvent correction has been made, and it is probable that none should be made. V is the molar dilution in liters, and λ is as usual $1000 V\kappa$. The results are calculated for sulfuric acid as a uni-univalent electrolyte as it certainly is in these solutions.[1,4,7]

In order to detect possible errors and because of the interest attached to such measurements, the effects of water and of acetic anhydride on the conductance were studied. For the former, acetic acid containing a very small amount of water *(0.08%* by the freezing point curve of Richmond and England)[12] was used as solvent. The results are shown in Table II.

Addition of acetic anhydride also caused an increase in the specific conductance. Thus a 0.119 *M* solution of sulfuric acid in acetic acid had κ = 7.21 X 10^{-6}, while when it was made 0.0357 *M* in acetic anhydride, κ rose to 8.01 $\times$ 10^{-6}. A 0.107 *M* solution of acetic anhydride in acetic acid had a κ of only 3.91 X 10^{-8}.

From these facts it is evident that the conductivities recorded in Table I are very near minimum values, and that the solutions contained neither water nor acetic anhydride in appreciable amounts. The data of Tables I and II and also those of Hantzsch and Langbein[3] and of Jones[13] are shown in Fig. 1. A possible reason for the difference between our results and those of the other investigators is suggested by our measurements on "moist" acetic acid solutions. Incomplete drying of the solvent produces just such a fairly uniform increase in conductance as is shown by the other measurements. In Fig. 1 the anomalous decrease of X with dilution (often previously noted for all types of electrolyte in this solvent) is clearly seen. The complete conductivity curve (not shown, *cf.* Fig. 3), also shows a maximum value of X in more concentrated solutions. These peculiarities have been discussed by Walden[14] and by Bjerrum[15] among others.

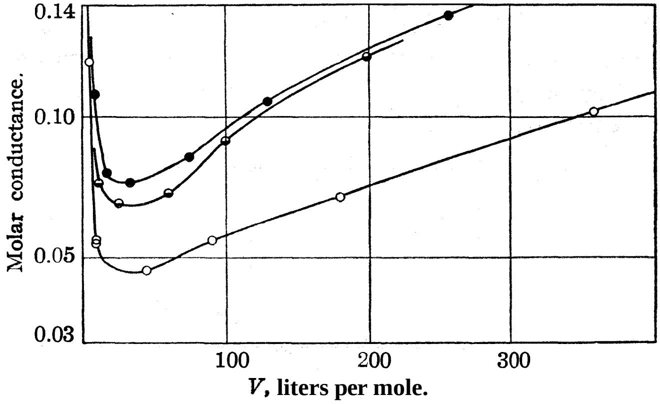

Fig. 1.—Molar conductance of sulfuric acid in acetic acid at 25°: ○, Voge; ⊖, *Voge*, solvent containing 0.08% H_2O; ●, Hantzsch and Langbein.

In the most dilute solutions the variation of λ with V is more nearly what would be expected from an ordinary weak electrolyte. A test of this type of behavior is furnished by a plot of CX against 1/λ.[16] If the Ostwald dilution law is obeyed, such a plot should yield a straight line from which both K and λ_0 might be derived. Figure 2 shows such a plot for the five

most dilute solutions of Table I. It is seen that from the conductimetric viewpoint sulfuric acid is a typical weak electrolyte in the most dilute solutions. It is not possible, however, to determine λ_0 or K with any degree of precision from measurements on such high-resistance solutions as these. Even if the accuracy of the measurements were greatly increased this would not be possible. Walden[14] has given two useful generalizations which should establish the order of magnitude of λ_0. These are $\eta\lambda_0$ = const., and $\lambda_0\partial\lambda/\lambda\partial t$ = const. where η = viscosity and $\partial\lambda/\lambda\partial t$ is the temperature coefficient of the conductivity. By comparison with water as a solvent, these lead to the values $\lambda_0 = 280$ and $\lambda_0 = 70$, respectively, for the conductivity at infinite dilution of $H^+(HSO_4^-)$ in acetic acid. Use of these figures gives values for K ranging in the one case from 3.3 to 3.9 X 10^{-10} and in the other from 5.3 to 6.2 X 10^{-9}. While these figures are very approximate, they probably indicate the correct order of magnitude for the dissociation constant.

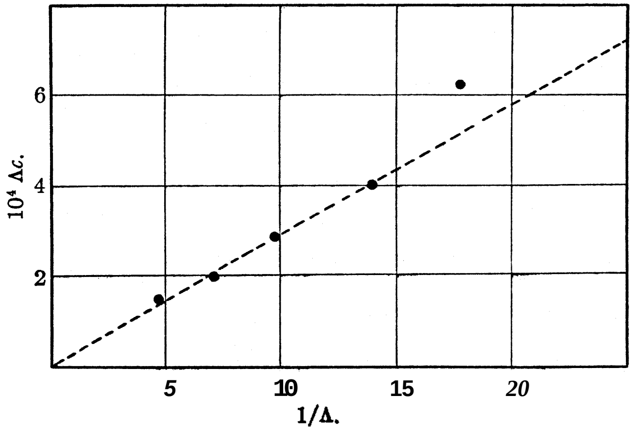

Fig. 2.—Sulfuric acid in acetic and the dilution law.

II. Concentrated Solutions and the Complete Conductivity Curve for the System H_2SO_4–CH_3COOH

This system has been investigated over a small range by Jones[13] and by Hantzsch and Langbein.[3] For these measurements a cell in the shape of an inverted Y was used which had a constant of 18.684 and to which varying amounts of liquid could be added without affecting the cell constant. The procedure adopted was as follows. The cell was cleaned, rinsed, dried at 140° and flushed with dry air. It was then weighed, filled with one component, and weighed again. The other component was added in successive portions from a weight buret, and the two were mixed in the glass-stoppered cell; after cooling at 25° in the thermostat, the conductivity was measured.

In Table III the results are shown Here the mole fractions are calculated from the weights in air against brass because of the low absolute accuracy. The conductivity curve is shown in Fig. 3, together with the viscosity curve of Drucker and Kassel.[17] It adds a little to the favorable evidence for the molecular compound AcOH·H_2SO_4 of which Kendall[6] finds indications in an unpublished freezing point curve, but which Lehrman could not crystallize.[18]

TABLE III

SPECIFIC CONDUCTANCES FOR THE SYSTEM H_2SO_4–AcOH AT 25°

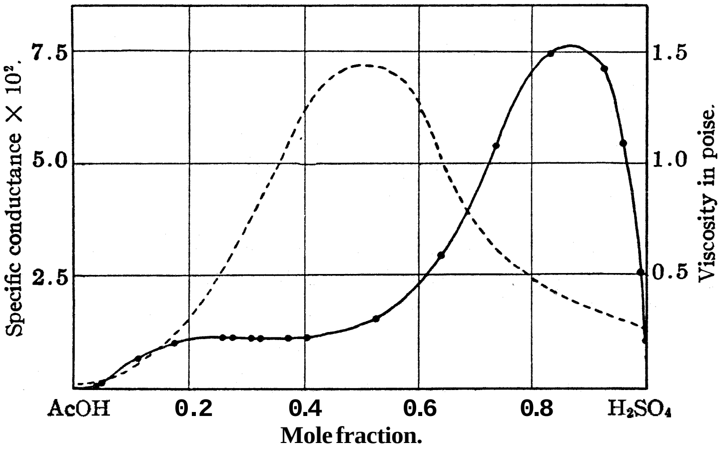

Fig. 3.—Conductance and viscosity of AcOH–H_2SO_4 mixtures: ——— specific conductance curve for the system H_2SO_4–AcOH at 25°; – – – – viscosity curve from Drucker and Kassel at 15°.

Complete explanation of the form of the curve is not possible, but the following factors may be pointed out. Solutions of acetic acid in sulfuric acid conduct better than those of sulfuric acid in acetic acid because of the much higher dielectric constant of sulfuric acid, although this must be

---

(17) Drucker and Kassel, *Z. physik. Chem.*, 76, 367 (1911).

(18) Lehrman, Trans. *Am. Inst. Chem. Engrs.*, 18, 187 (1926).

partially offset by its greater viscosity. Equal rate of change of conductance in opposite directions caused by increasing concentration and decreasing ionization of acetic acid accounts for the pronounced maximum on the sulfuric acid side. The slight maximum on the acetic acid side doubtless has a similar explanation. The slight central minimum, while apparently arising from the increased viscosity at this point, cannot be separated in origin from the associative tendencies which cause the latter. Kendall[19] has given an excellent discussion of such systems and has pointed out our very incomplete knowledge of them.

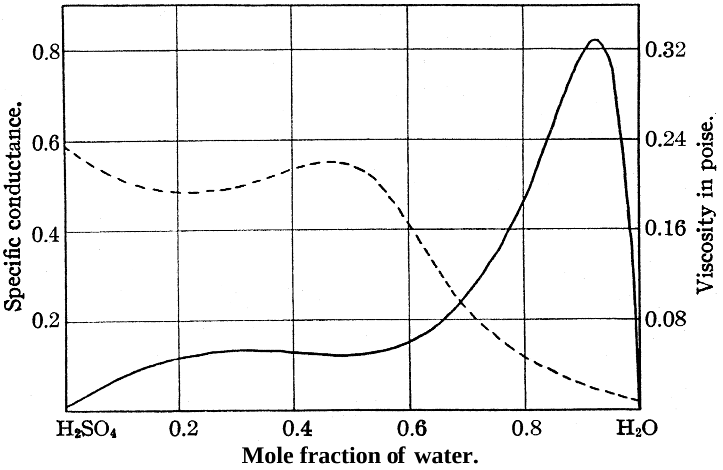

Fig. 4.—Conductance and viscosity of H_2SO_4–H_2O mixtures: ——— specific conductances for the system H_2SO_4–H_2O at 25° (Kohlrausch); — — — — viscosities for the system H_2SO_4–H_2O at 25° ("I. C. T.").

Conductivity curves[20] for the related systems H_2SO_4–H_2O and CH_3CO-OH–H_2O are of almost exactly the same form as that for this system. They are shown, corrected to 25°, and with their viscosity curves, in Figs. 4 and 5.

III. Conductivities for the Three Component System H_2SO_4–H_2O–AcOH

In the hope of more closely relating the highly acid solutions involved, and because of the rather novel interest attached to such measurements, the three component system H_2SO_4–H_2O–AcOH was next investigated conductimetrically. Almost no data exist on such mixtures; a few points of Jones[21] which lie quite close together and which were determined at an unspecified temperature are the only ones to be found in the literature.

In this portion of the research precision was less essential; hence the

---

(20) Landolt-Bornstein, "Tabellen," H W II, pp. 1075–77.

following procedure was adopted. Mixtures of acetic acid and sulfuric acid were made up by weight in cell 7. Water was then added from a microburet, and on mixing and cooling to 25° the conductivity was measured. The composition of all mixtures was calculated from the weight in air.

ing conductivity in such solutions. Here the trough may be related to loose compound formation or other associative phenomena, while the maxima serve to indicate roughly the points of greatest ion concentration. More complete explanation of these conductivities is not possible at present.

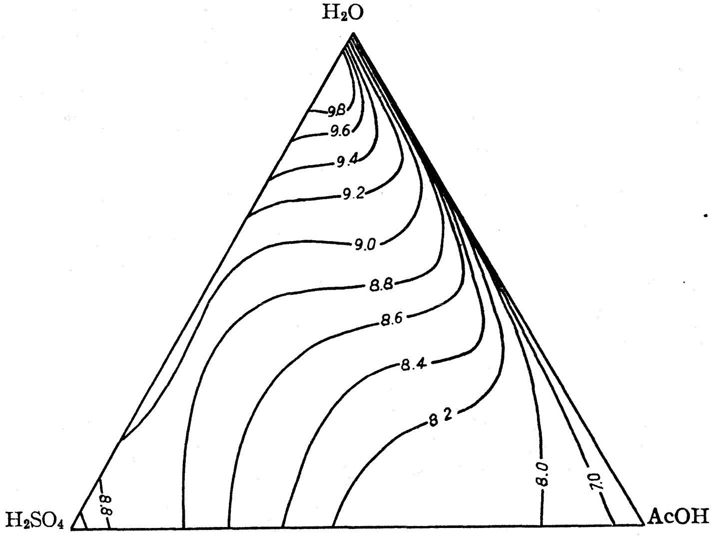

Fig. 6.—Iso-conductive lines showing log specific conductance + 10 for the system H_2SO_4–H_2O–AcOH at 25°; concentrations are in mole fractions.

Attempts to extend the study to the more general system SO_3–H_2O–Ac_2O were not successful. On adding acetic anhydride to 30% fuming sulfuric acid, chemical reaction took place and the solution turned orange in color. It was noted that the resistance was increased on adding the acetic anhydride but no quantitative conclusions could be drawn. These data will be discussed further in later papers dealing with the thermodynamic properties of the system.

Summary

1. The conductance of dilute solutions of sulfuric acid in acetic acid has been carefully redetermined. It is shown that the solute behaves as a typical weak electrolyte and its dissociation constant is tentatively calculated as 10^{-9}.

2. The complete conductance curve is determined for the binary system H_2SO_4–CH_3COOH and discussed in connection with similar curves for the systems H_2SO_4–H_2O and H_2O–CH_3COOH.

3. The complete conductance diagram is given for the system H_2SO_4–CH_3COOH–H_2O.

Galvanic Cells Containing Potassium Triphenylmethyl

BY H. E. BENT AND E. S. GILFILLAN, JR.

One of the most interesting properties of organic free radicals is the reaction with an alkali metal to give a compound having many of the properties of a simple salt. Such a compound will react metathetically with an acid (*i.* e., a methane),[1] will dissolve to give a solution which is an electrolytic conductor[2] and is formed with the liberation of an amount of energy not greatly different from that accompanying the formation of a typical inorganic salt.[3]

In spite of the salt-like character of these compounds we have been able to find no records of experiments in which solutions of them have been used as electrolytes in galvanic cells. Should they behave as normal salts in such experiments they would supply just the required properties for solving the problem of determining the standard electrode potential of cesium. The measurements would consist in determining the potential of a cell composed of electrodes of cesium and a dilute cesium amalgam and then the potential of another cell containing this same amalgam in contact with cesium ion in aqueous solution.[4]

In order to determine the suitability of these compounds for use in galvanic cells we have studied the behavior of cells in which the electrodes were potassium and potassium amalgam and of cells containing two electrodes of dilute amalgams. The electrolyte in these cells was a solution in diethyl ether of the potassium addition compound of triphenylmethyl or a closely related compound containing biphenyl or naphthyl groups.

Our experiments show that cells which have potassium amalgams for both electrodes give potentials which one would expect for a normal salt, *i.* e., the same potential as is found when the electrolyte is potassium iodide dissolved in ethylamine or potassium hydroxide dissolved in water. However, cells containing one potassium amalgam electrode and one potassium electrode give very erratic potentials which are less than correspond to the transfer of one gram atom of potassium for each Faraday of current. A number of cells designed to determine the cause of this behavior show that it is not due to impurities in the electrodes or to surface effects but to some change in the electrolyte which takes place in the presence of potassium.

These observations indicate that these compounds are quite unsuited to the problem of determining the cesium electrode potential. They also

[4] Lewis and Kraus, *ibid.*, 32, 1459 (1910).

suggest that a cell reaction cannot be taken for granted in determining potentials. Finally these results further justify the assumption that these compounds are simple salts except when undergoing a transformation in the presence of alkali metal.

Experimental

Eleven cells have been prepared and their potentials measured. A Wolff potentiometer and a Leeds and Northrup type HS galvanometer, which is sensitive to 10^{-11} ampere, were used. In general the technique consisted in evacuating the cell until the pressure was too small to be measured on a McLeod gage (less than 10^{-4} mm. of mercury), distilling the potassium into the cell, introducing the amalgam by means of a stopcock, and introducing the electrolyte by breaking the tip of a glass capsule with a magnetic hammer.

In order to test the materials and method of assembly, one cell was prepared as nearly as possible like the ones used by Lewis and Keyes in the determination of the standard electrode potential of potassium;[5] *i. e.*, potassium | potassium iodide in ethylamine | 0.2216 weight per cent. potassium amalgam. The e. m. f. obtained by Lewis and Keyes was 1.0481 volts. We obtained a value of 1.0487 ± 0.0002 volts using an amalgam containing 0.2216 weight per cent. potassium. This agreement indicates that the method of handling the materials is satisfactory.

The evidence that potassium addition compounds of free radicals behave in a perfectly normal manner in cells containing amalgam electrodes is furnished by the data from three cells. The first of these cells furnished the best evidence. It was constructed to give a very low resistance in order to give very high accuracy in the e. m. f. measurements. It consisted of a tube twenty centimeters long containing a ridge the length of the tube, formed by pushing in the glass with a copper tool. The amalgams extended the length of the tube but were kept separate by this ridge. The tube was then nearly filled with the ether solution of potassium triphenylmethyl. The e. m. f. could be measured to two one-hundredths of a millivolt and was found to be 0.12835 ± 0.0002. Amalgams from the same storage flask were then used in another cell of the type used by Richards and Conant,[6] using as electrolyte an aqueous solution of potassium hydroxide. The e. m. f. so obtained was 0.12835 ± 0.0001, in perfect agreement with the value previously obtained.

A second cell with amalgam electrodes was constructed to test the behavior of other organic free radicals and different methods of preparing the potassium addition compound. The electrolyte was prepared by treating a mixture of methyl diphenylbiphenylmethyl ether, methyl α-naphthyldiphenylmethyl ether and methyl-α-naphthylphenylbiphenyl methyl ether with metallic potassium. The observed e. m. f. was 0.0291 ± 0.0001. The value found for the same amalgams when using a solution of potassium iodide dissolved in ethylamine as the electrolyte was 0.0291 ± 0.0001. Here again the agreement is within the experimental error.

A third cell which was designed primarily for a different purpose gave still further proof that in such cells the electrolyte is behaving in a perfectly normal manner. The e. m. f. found was 0.0655 ± 0.0005. The value found with potassium iodide dissolved in ethylamine as the electrolyte was 0.0652 ± 0.0001.

Eight cells were constructed which contained one amalgam electrode and one electrode of potassium. With the exception of one cell which was doubtless defective[7]

---

[5] Lewis and Keyes, THIS JOURNAL, 34, 119 (1912).

[6] Richards and Conant, *ibid.*, 44, 601 (1922).

[7] The defective cell gave very erratic potentials and soon exhibited so high a re-

the e. m. f. was always too low and was inconstant. Most of these cells could be measured with an experimental error of not more than 0.01%. However, the e. m. f. was from 0.5–0.95 of the correct value and usually decreased during a period of a week or two by 10–20% of its value.

The construction of these cells will not be discussed in detail. However, in their construction the following factors were considered as possibly related to their behavior: surface films on the potassium; mercury dissolved in the surface layer of potassium coming from the pump, amalgam or electrolyte; a change in the concentration of amalgam due to transfer of potassium; polarization; and the nature of the free radical. In addition cells were constructed which differed greatly in resistance. The concentration of the electrolyte was varied from a highly supersaturated solution to one whose mole fraction was 10^{-7}. This very high dilution was accomplished by decantations in a closed system and subsequent distillations of the ether back into the cell The effect of time was studied by making measurements within a few seconds of the time of contact with the potassium and extending the measurements for a period of months. In order to avoid the possibility of traces of mercury from the solvent contaminating the potassium, the electrolyte was prepared in the absence of mercury. The usual way of making the electrolyte was to shake a solution of triphenylchloromethane with dilute potassium amalgam. In order to avoid the presence of mercury and vary the method of preparing the electrolyte, three ethers were prepared and then treated with metallic potassium. The reaction required five weeks for completion, the solution being shaken mechanically during this period. The resulting solution did not differ in appearance from solutions prepared from the chlorides. These ethers have apparently not been described in the literature. They were prepared by dissolving the chlorides in benzene, adding methyl alcohol and recrystallizing the products from dry ether. The three compounds were methyl diphenylbiphenylmethyl ether, m. p. 94–95", methyl diphenyl-α-naphthylmethyl ether, m. p. 142°, and methyl-phenyl-a-naphthylbiphenyl ether, m. p. 190–191°.

The last cell which we constructed seems to shed the most light on the behavior of these cells. This cell contained three electrodes, two of dilute amalgams and one of potassium. The electrolyte was introduced in such a way as to come in contact with only the amalgams. The observed e. m. f. was 0.0655 ± 0.0005. The correct value is 0.0652 ± 0.0001. The cell was then tipped so that electrolyte came in contact with all three electrodes. As was to be expected, the value obtained using the potassium as one electrode was too small. However, the value obtained using the two amalgams was changed to 0.0605, a difference ten times the experimental error of measurement. Tipping the cell so as to remove the electrolyte from the potassium did not alter this value but after three weeks a value of 0.0599 was obtained. Further standing in contact with potassium resulted in a value of 0.0523. This cell indicates clearly that the electrolyte undergoes some slow irreversible reaction such that the cell reaction is no longer the transfer of one gram atom of potassium for each faraday of current passing through the cell.

Conclusions

1. Potassium triphenylmethyl and some related compounds function as normal electrolytes in galvanic cells containing amalgam electrodes.
2. Potassium triphenylmethyl and some related compounds undergo a slow irreversible reaction when in contact with potassium which precludes their use in galvanic cells containing potassium.

Improved Method of Sealing the Capillary Tubes in the Rast Modification of the Barger Method of Molecular Weight Determination

BY JOSEPH R. SPIES

In the determination of molecular weights by the Rast modification of the Barger method it has been found that by operating in the manner described below the comparatively large air space at one end of the capillary tube and also the necessity of twice drawing out one end of this capillary can be avoided. The method has the further advantage that the liquid is fixed in both ends of the capillary without heating the capillary close to the enclosed solutions. This minimizes the danger of volatilizing some solvent or possibly decomposing some of the solute.

Assume that the standard solution and the test solution have been introduced into the capillary with the prescribed 3 4 mm. air space separating them, and that the tube has been melted shut on the right and drawn out 2 cm. to hairbreadth on the left as Rast describes.[1] Now instead of breaking off the left end at the end of the hair, it is allowed to remain, leaving a funnel-shaped reservoir. The tube then appears as illustrated in Fig. 1. The right end is now broken off and the tube tilted so that the liquid flows back through the hair to a position "a." The tube is then drawn out on the right to hairbreadth for 2 cm., broken at the end of this hair and tilted so that the liquid runs into and fills it, whereupon it is sealed by carefully touching it in a micro flame. Some of the liquid should remain in the funnel on the left so that the hair on the left is still filled. This funnel is then broken off and the end of the hair passed rapidly through a micro flame to expel a small portion of the solution before sealing as on the right.

Fig. 1.

A 5 × 17 cm. glass plate with a line etched through the center parallel to the short side supplants the 1–2 X 17 cm. plate used by Rast. This allows eight to ten tubes to be placed on one plate. The etched line takes the place of the hair covered with Canada balsam. When it stands in water, balsam gradually becomes opaque and must be replaced daily.

The Dielectric Constant of Solid Hydrogen Sulfide

BY J. D. KEMP AND G. H. DENISON

Preliminary measurements have been made on the variation of the dielectric constant of solid hydrogen sulfide with temperature. Heat capacity measurements made in this Laboratory by Professor W. F. Giauque and Dr. R. W. Blue[1] have shown the existence of three crystalline modifications of hydrogen sulfide. It was therefore of interest to learn whether any rotational motion of the electric moments of the molecules in the crystal was taken up at the transitions.

A heterodyne beat method similar to that described by Zahn[2] with the oscillators operating on a wave length of 649 meters was used for the measurement of the dielectric constant. The test condenser (cap. 150 $\mu\mu$f) consisted of three concentric cylinders of gold rigidly separated by four glass rods cutting diametrically through them. The condenser was sealed in a glass cylinder and the temperature controlled by an apparatus similar to that used by Giauque and Wiebe,[3] the gold condenser replacing their calorimeter. A copper–constantan thermocouple was used for the temperature measurement.

The value of the dielectric constant below the lower transition at 103.5° K. is about 2.9 and above the lower transition for the second modification about 9, a discontinuous change taking place at the temperature of the transition. At the upper transition at about 126.3°K., there is apparently no marked change of the dielectric constant taking place. The value of the constant for the liquid at the melting point 187.6°K. is about 9.4. The accuracy of the measurements in the solid state is probably no better than 10% due to the effect of the large cracks encountered in warming the hydrogen sulfide.

From the results given above it appears that there is little or no rotation of the electric moment of the hydrogen sulfide molecule below the lower transition. At this transition a change in crystalline form must take place permitting rotation of the electric moments and from the large change in the dielectric constant it can be concluded that the molecules go from a state of little or no rotation of the electric moment to one of almost complete rotational freedom of the electric moment. This is further verified by the facts that at the upper transition there is no great difference between the dielectric constants of the two crystalline modifications of hydrogen sulfide concerned in the transition and that the value of the dielectric constant for the liquid at the melting point is of the same magnitude as the values for the crystalline modifications above the lower transition.

The Number of Structurally Isomeric Hydrocarbons of the Acetylene Series[1]

BY DONALD D. COFFMAN, AND CHARLES M. BLAIR WITH HENRY R. HENZE

It has previously been possible, by means of a separation into types, arbitrarily chosen upon the basis of their structural formulas, to establish a relationship between the number of structurally isomeric hydrocarbons[2] and the alkyl groups of which the former may be considered to be composed. It can now be shown that an analogous method of separation into structural types may be utilized successfully in calculating the number of structurally isomeric hydrocarbons of the acetylene series.

The homologs of acetylene are divided into two groups: A, consisting of those hydrocarbons which may be formed, theoretically, by replacing one hydrogen atom of acetylene by an alkyl radical, and B, consisting of those which may be formed by replacing both hydrogen atoms of acetylene by alkyl radicals.

The structural formula of each of the homologs of acetylene of N carbon atoms of group A, R—C≡C—H, may be formed by replacing one hydrogen atom of acetylene by an alkyl radical of $N - 2$ carbon atom content. The total number of structural formulas that may be thus formed will equal the total number of alkyl radicals of $N - 2$ carbon atoms or $T_{(N-2)}$.

$$A_N = T_{(N-2)} \qquad \text{(A)}$$

The number of paraffin alkyl radicals of each carbon content through C_{20} has been previously reported.[3]

The structural formulas of the hydrocarbons of group B, R—C—C—R′, of N total carbon atom content may be formed by attaching to the —C≡C— group the alkyl radicals R— and R′— (the carbon content of R— plus R′— always equaling $N - 2$). The number of isomers that may be thus formed will equal the total number of possibilities, without exception or repetition, of combining simultaneously with the —C≡C— group every value of R—, taken one at a time, and every complementary value of R′—, also taken one at a time. These possibilities are theoretically of two types: (a), those in which the two alkyl radicals R— and R′— are of unequal carbon content; and (b), those in which the two alkyl groups are of

---

[1] This joint contribution arose from independent and essentially concurrent efforts by the authors. The initial draft of Dr. Coffman's manuscript was presented to the editorial board of the Experiment Station of E. I. du Pont de Nemours & Co. on April *25, 1932,* and was approved by them for publication as a personal contribution. It was received in the office of the Editor of THIS JOURNAL on June 9; substantially identical results were presented on April *23* by C. *M.* Blair and H. R. Henze before the annual meeting of the Central Texas Section of the American Chemical Society at Waco, Texas, and their paper (Blair and Henze) was received by the Editor on June 18.—THE EDITOR.

(2) Henze and Blair, THIS JOURNAL, **53,** *3077 (1931).* It should be noted that the number of structurally isomeric nondecanes given erroneously as *147,248* in Table II, page *3084,* should be corrected to read *148,248,* as indicated by Perry, ibid., **54,** *2918 (1932).*

(3) Henze and Blair, ibid., 53, *3042 (1931).*

equal carbon content. In type (b) there may be further recognized two sub-types; (b_1), in which the two alkyl groups although of the same carbon content are not structurally identical; and (b_2), in which the two alkyl groups are structurally identical. Type (b) is actually impossible with a hydrocarbon of uneven carbon content, for in that type N − 2 should be divisible by two. The total number of isomeric homologs of acetylene of all types included in group B may be calculated by the following (finite) recursion formulas according to whether the carbon content is odd or even.

Odd:

$$B_N = T_1 \cdot T_{(N-3)} + T_2 \cdot T_{(N-4)} + \ldots\ldots + T_{(N-3)/2} \cdot T_{(N-1)/2} \qquad (B_o)$$

Even:

$$B_N = T_1 \cdot T_{(N-3)} + T_2 \cdot T_{(N-4)} + \ldots + T_{(N-4)/2} \cdot T_{N/2} + \frac{T_{(N-2)/2} \cdot [1 + T_{(N-2)/2}]}{2} \qquad (B_e)$$

Note that the subscripts in each term add up to $N - 2$, and that the number of terms is $(N - 3)/2$ for odd carbon atom content and $(N - 2)/2$ for even.

Table I indicates the number of structurally isomeric hydrocarbons of the acetylene series as calculated by the use of the recursion formulas.

TABLE I

NUMBER OF ISOMERIC HYDROCARBONS OF THE ACETYLENE SERIES

Carbon content	Number of isomers	Carbon content	Number of isomers
2	1	16	38,422
3	1	17	97,925
4	2	18	251,275
5	3	19	648,061
6	7	20	1,679,869
7	14	21	4,372,872
8	32	22	11,428,365
9	72	23	29,972,078
10	171	24	78,859,809
11	405	25	208,094,977
12	989	26	550,603,722
13	2,426	27	1,460,457,242
14	6,045	28	3,882,682,803
15	15,167	29	10,344,102,122
		30	27,612,603,765

Summary

1. Formulas of the (finite) recursion type are advanced which permit the calculation from their carbon content of the number of structurally isomeric hydrocarbons of the acetylene series. In using these recursion formulas to calculate the total number of such hydrocarbons of any given carbon content, the total number of alkyl radicals of N − 2 and all lesser carbon contents must be known.

Technical Refinements for the Micro Colorimetric Method of Iodine in Blood

BY R. G. TURNER AND MINA Z. WEEKS

Several investigators are studying the determination of small amounts of iodine by use of the blue color formed with iodine and starch. Leitch and Henderson[1] and Aitken[2] oxidize the iodide to iodate with bromine, liberate the iodine by addition of an excess of potassium iodide and titrate with thiosulfate using the blue color produced by starch as the indicator. Aitken modified the method in that he devised a titration vessel in the form of a short tapering tube in which solutions can be brought with ease to a volume of 0.2 cc. Titration is made with $N/1000$ thiosulfate. In a later report[3] he recommends the use of a micro buret in which the standard solution floats on a thread of mercury, the position of the latter being adjusted by means of a fine screw projecting into a mercury reserve. Reith[4] and the author[5] have studied the same reaction, omitting the titration, comparing the color produced against known standards. Reith prepares several standards and matches these with the unknown, while in our method one standard is prepared and the unknown compared in a micro colorimeter. The stability of the color and its proportionality to the amount of iodine present have been found by the author[6] to be sufficiently accurate for the estimation of small amounts of iodine ranging from 0.0005 to 0.005 mg.

During the course of our study certain difficulties have arisen. At times we have encountered a complete failure, either slight or no color developing or an intense black color resulting. These two difficulties have been overcome by the use of special purified reagents The purpose of the paper is to give in detail the factors which we have found to cause failures and the necessary procedures to overcome these difficulties.

Experimental

The first difficulty encountered with the method was a partial or complete failure of color development. Reith (personal communication) wrote that iodine is lost if added to alcohol and the alcohol removed by ignition instead of evaporation. To 10 cc. of 94% alcohol he added potassium iodide sufficient in amount to bring the iodine content to 10γ. The alcohol was burned off and the iodine recovered was 0.7γ. Three

other experiments like the above were carried out with the exception that he added 2, 5 and 20 mg. of potassium carbonate. The results found were, respectively, 7.0, 7.4 and 10.1γ iodine. Therefore, he assumes that the alkalinity must be very marked before no loss of iodine occurs from ignition.

In the method described by one of us[5] it was stated that the absolute alcohol must be freed from traces of iodine by redistillation over potassium hydroxide. This practice worked successfully with some grades of alcohol but at times when new supplies of alcohol were used the development of color failed to appear.

The following experiments were undertaken to determine whether the failure encountered was due to ignition of the alcohol.

To two centrifuge tubes containing **50** cc. of water each, **0.001** and **0.002** mg. of iodine in the form of potassium iodide were added. Potassium sulfate and barium chloride were added as described in our method.[5] This was centrifuged and extracted and the solution evaporated to dryness in an oven. The dry residue was extracted with the non-redistilled alcohol and the alcohol btuned in a platinum crucible as described in the publication.

The above was duplicated in the same manner but instead of igniting the alcohol in the crucible, they were placed in an oven at 100° and allowed to evaporate. **The** residue in the platinum crucibles was then extracted with water as in the method given and a color developed. In both cases our results showed only a slight color not comparable with a 0 001-mg. standard.

Since both tests gave negative results it was thought that possibly some interfering substance such as aldehydes in the alcohol might have an inhibiting effect on color production. Alcohol was treated by the Winkler method[7] and by the method of Castille and Henri.[8] **A** modified form of the latter method has been adopted

Procedure for Purification of Alcohol.—One-half gram of iodine crystals is added to **500** cc. of absolute alcohol. The mixture is allowed to stand for twenty-four hours. Distil off the alcohol, discarding the first **25** cc. of distillate, and retain **50** cc. of the residue. Shake the distillate with **100 g.** of granulated zinc until the yellow color disappears. Distil off the alcohol again as above. To this distillate add as before **100** g. of granulated zinc and shake continuously for fifteen minutes. Distil as before. The alcoholic distillate thus obtained is free from iodine and interfering substances.

TABLE I

THE EFFECT OF PURIFICATION OF ALCOHOL ON COLOR PRODUCTION

Tube no.	Alcohol used for extraction	Results
1	Not purified	Negative
2	Purified by Winkler's method	Slight color but less than standard
3	Purified by modified method of Castille and Henri	Color equivalent to twice the standard or **0.002** mg. of iodine

If aldehydes are responsible for the interfering substance, they are not removed completely by the Winkler method. At present no claim is made

---

(7) Winkler, Ber., 28, 612 (1905).

(8) Castille and Henri, *Bull. soc. chim. biol.*, 6, 299 (1924).

as to the identity of the interfering substance. Results have been satisfactory if the alcohol is treated by the iodine–zinc method as described. The experiment conducted to determine the possibility of loss of iodine by ignition of alcohol as described (on page 4) was repeated with alcohol purified by the iodine–zinc method. Complete recovery was obtained in both cases. Therefore, the failure of color production is not due to loss of iodine by ignition of the alcohol but to impurities which may be present in the alcohol and which are removed by the method presented.

The second difficulty in which the final reaction turned black due to oxidation of excess potassium iodide involves two factors. First, different samples of potassium carbonate may vary as to the amount of iodine present. The following method has been adopted for purification of all potassium carbonate used in the determination of small amounts of iodine.

Method for Purification of Potassium Carbonate.—To 100 g. of potassium carbonate in a liter beaker add 500 cc. of 95% alcohol. Stir with an electric stirrer for ten hours, decant the alcohol and dry the residue by pressure between filter paper. Dissolve the dried residue in 200 cc. of boiling water. Filter and evaporate the filtrate to one-third its original volume. Place in an ice-box to crystallize. When equilibrium is maintained filter and place the residue in an oven at 110° to dry. When dry powder and dissolve the contents in 100 cc. of hot water. Cool and pour the solution into a 500-cc. separatory funnel with an equal volume of absolute alcohol and shake continuously for thirty minutes. Transfer the aqueous layer to a 250-cc. beaker and evaporate over a flame to one-third its volume. Place in an ice-box until crystallization is complete, filter, and dry in an oven at 110°. Under these conditions no iodine could be detected in the purified potassium carbonate. 4 N potassium hydroxide may be used satisfactorily in place of the 4 *N* potassium carbonate solution. If chemically pure potassium hydroxide is used no purification is necessary.

Second, the iron content of the concentrated sulfuric acid used in preparation of the 2 N sulfuric acid solution must be taken into account. It is known that oxidized iron will set free iodine from potassium iodide. An investigation was made regarding the iron content of sulfuric acid and its effect on the starch–iodide reaction as used for the estimation of iodine in blood. One of the experiments is given as an example of the mode of investigation.

The following three samples of sulfuric acid diluted to the strength as used in the method (2 N H_2SO_4) were taken for examination.

Sample No. 1. Baker and Adamson containing 0.0002% iron

Sample No. 2. Baker and Adamson containing 0.00008% iron

Sample No. 3. Baker and Adamson reagent three months old. Iron content unknown. Tested negative when first prepared by the following method.

Method for Testing Purity of Sulfuric Acid.—Three drops of purified potassium iodide solution (1%) was added to each of three test-tubes (125 X 15 mm.) graduated to 1 cc. Distilled water (iodine-free) was added to the 1-cc. mark and 5 drops of the starch solution introduced. Two drops of sulfuric acid solution (No. 1 above) was added to tube No. 1. Likewise the same quantity of sulfuric acid solution (No. 2 above) was added to tube No. 2 and the sulfuric acid solution (No. 3 above) to tube No. 3. Another set of three tubes was prepared in a like manner with the exception that the 1% potassium iodide solution added had not been prepared with potassium iodide purified as described in our first publication.[5] These were numbered 1A, 2A and 3A, respectively.

The potassium iodide used in preparing the above solutions was Baker and Adamson (Lot 3A, Code Ba 4220). The results are shown in Table II.

TABLE II

THE EFFECT OF IMPURE REAGENTS ON COLOR PRODUCTION

Reagent no.	Color development Time in minutes 15	30	After addition of excess sulfuric acid reagent thirty minutes after development of the color Excess, 10 drops
1	+	++	+++
1A	++	+++	++++
2	−	sl +	sl +
2A	+	+	+
3	+	+	++
3A	++	++	+++

+ Equivalent to blue color produced with 0.001 mg. of iodine standard prepared as directed in the method. ++ Equivalent to a 0.002 mg. standard. +++ Dense, not matched against standards. ++++ Black, not matched against standards. sl + slight, not sufficient color to match against 0.001 mg. standard diluted to 2 cc.

The results show that if the sulfuric acid solution is fresh and sufficiently iron-free, no color is developed within fifteen minutes after adding the acid to the purified potassium iodide solution containing starch. The slight color produced at the end of thirty minutes with acid No. 2 (low in iron content) is believed to be due to the effect of the atmosphere on the oxidation of potassium iodide solution. This slow oxidation was recognized as stated in our publication[6] but if standard and unknown are prepared at the same time, the change is proportional for at least an hour and the colorimetric reading remains the same. The above experiment shows the effect of foreign oxidizable substance, presumably oxidized iron, on potassium iodide in acid solution. Potassium iodide is in excess when the final reaction for production of the color is carried out, therefore, the purity of the reagents used in this step must be watched. If foreign oxidizable substances are eliminated, iodine is not liberated from potassium iodide in acid solution within thirty minutes.

Conclusions

This investigation includes necessary procedures to avoid certain factors which cause failures in the author's method[6] for the estimation of iodine in blood.

To obtain satisfactory results it is essential to treat the absolute alcohol by the modified iodine–zinc method of Castille and Henri for removal of aldehydes.

Potassium carbonate must be freed from iodine by the method described or chemically pure potassium hydroxide used in its place to produce the desired alkalinity.

The sulfuric acid used for preparing the 2 N solution should not contain over 0.00008% iron, and at all times this reagent should be tested with the 1% potassium iodide solution for the presence of oxidizable foreign substance, assumed to be oxidized iron.

Under these conditions the above mentioned difficulties do not arise and the method of analysis can be carried through with the accuracy mentioned in the former publication.[5]

Carbohydrate-Fatty Acid Linkings in Corn Alpha Amylose[1]

BY T. C. TAYLOR AND RUTH T. SHERMAN

The fatty acids associated with corn starch occur entirely in the *a*-amylose[2] or insoluble portion of the starch, while the soluble β-amylose is pure carbohydrate. Thus the presence of the fatty acids affords one means of differentiating between the two corn amyloses. In the interests of obtaining more data on chemical make-up of each of the corn amyloses, an examination of the linkage between the fatty acid groups and the carbohydrates in corn a-amylose is desirable. This investigation is concerned with that problem.

It has been shown that the fatty acid compounds in corn a-amylose are derived from palmitic, oleic and linolic acids,[3] which are chemically combined with carbohydrate for they are not extracted by solvents, but are liberated only after relatively long aqueous acid hydrolysis of the amylose.

In spite of the fact that these acids are in chemical combination with the carbohydrate, no corn a-amylose has been prepared which contains all that is in the original starch. Some is always lost in the process of separating the a-amylose from the β-amylose. This applies also to the derivatives of starch. Acetylated and methylated products of corn starch containing fatty acids have been prepared,[4] but in neither case do the products contain more than half of the original acids. This suggests that the fatty acids may not all be linked to the carbohydrate molecule in the same manner.

As starch is a polyhydroxylated compound, the fatty acids can be combined to the carbohydrate through an oxygen linking at any one or more of the otherwise free hydroxyl groups of the glucose residues which form the amylose molecule.

The most direct and satisfactory way of determining the position of the fatty acids on the carbohydrate molecule would be to hydrolyze α-amylose to a glucose unit with the fatty acid radicals still attached and investigate the fragment. This cannot be accomplished at present, as the hydrolyzing agent splits off some fatty acids in the very early stages of hydrolysis of the starch.

Another method by which some light might be shed on the structure of corn α-amylose is to study the ease of removal of the fatty acids by hydrolysis. If the fatty acid residues are not all attached at the same relative positions on the glucose residues in the a-amylose, the stability of the starch–fatty acid linkages toward hydrolytic reagents ought not to be the same. Some linkages may be expected to be more easily broken than others, according to the methods of hydrolysis employed, if one uses the behavior under similar conditions of derivatives of glucose with substituents in various positions as a criterion. Here, in general, a substituent at position 1 in the glucose molecule is found to be the easiest to split off.[5]

The immediate purpose of this paper is to report the results of the effect of acid, alkali and enzymic hydrolytic reagents on corn α-amylose.

I. The Effect of Acid on the Liberation of the Fatty Acids from Corn Starch.—First, the preferential removal of these acid residues by a mild hydrolyzing agent, hydrogen chloride in 95% alcohol,[6] was studied. Samples of corn starch were treated with the reagent for different lengths of time, and the fatty acid content of the carbohydrate *residue* was determined.

After a given treatment the residue was freed from extraneous fatty acids and then completely hydrolyzed. Any newly liberated fatty acids were extracted and their iodine number determined. When this iodine value is compared with the iodine number of the fatty acids liberated by complete hydrolysis of the original starch, it is possible to determine the order in which the fatty acid groups are split off in the partial hydrolyses. If the iodine number of the acid in the residue increases, the palmitic acid must have been liberated more rapidly; if it decreases, the unsaturated acid linkings must have been hydrolyzed more readily than that of the palmitic acid.

Experimental

Five hundred cc. of a solution of 0.12 g. of hydrochloric acid in 95% alcohol was added to a suspension of 500 g. of corn starch in 500 cc. of alcohol. Samples of this mixture were heated under a reflux condenser on a water-bath for twenty minutes, forty minutes and one hour, respectively, after which they were filtered while hot on a suction filter and extracted for eight hours with ether. A weighed part of the treated

(6) By the use of alcoholic acid the amount of reducing sugar usually formed when aqueous acid is used is greatly diminished The alcohol also cuts down the tendency of the granules to swell and disrupt

starch in each case and a sample of untreated but ether-extracted starch was completely hydrolyzed with aqueous acid according to the method of Taylor and Nelson[2a] and the liberated fatty acids washed, dried, extracted, weighed and their iodine number found.

The iodine number was determined by the pyridine-dibromide method of Rosenmund and Kuhnhenn[7] except that after adding the pyridine-dibromide solution, the mixture was kept in the dark and shaken frequently, and that the excess of iodine was titrated with 0.05 N sodium thiosulfate solution.

The results are given in Table I. It can be seen that as the amount of the still-combined fatty acid in the treated starch decreases, its iodine number decreases. This shows that on treatment of corn starch with a mineral acid, the unsaturated acid radicals, oleyl and linolyl, are split more readily from the amylose than the saturated palmityl radical. The latter remains with the amylose and is only liberated when the amylose is more completely hydrolyzed.

TABLE I

THE EFFECT OF ALCOHOLIC HYDROGEN CHLORIDE ON THE FATTY ACID CONTENT OF CORN STARCH

[a] Average of two analyses.

II. The Effect of Basic Reagent on the Liberation of the Fatty Acids from Corn Starch.—In alkaline solutions, unmodified starch granules swell and form viscous pastes, but they still give a characteristic blue color with iodine after acidification. However, the fatty acid content of corn starch is greatly decreased by certain alkaline treatments. Rask and Phelps[8] report that heating corn starch for a short time with alcoholic ammonium hydroxide removes the fatty acids quantitatively, although in this Laboratory it has been shown that eight successive treatments with this reagent are needed before the fatty acid content of the starch becomes negligible.[9]

This reagent was used therefore in studying the action of alkaline reagents on the removal of the fatty acids from corn starch. In Table II will be found the results.

III. The Effect of Amylases on the Liberation of Fatty Acids.—The fate of the fatty acids in corn starch after treatment with an amylase has been reported in only one instance. Taylor and Nelson[2a] have found that on allowing corn starch to react with malt amylase, most of the fatty acids were liberated during the early stages of hydrolysis, but the amylase

preparation used by them had not been tested for fat-splitting enzymes. Any lipase present might be expected to hydrolyze the fatty acid compounds, irrespective of the action of the amylase. This will be demonstrated below.

In this work the action of a substantially lipase-free amylase on corn starch was investigated in order to ascertain its hydrolytic effect on the combined fatty acids. Should such an amylase attack the fatty acid bearing portion of the corn starch (the a-amylose), it could either split the carbohydrate, leaving the fatty acids combined with some product of lower molecular weight, or it could attack the carbohydrate–fatty acid linkages or both.

Corn starch was treated with several commercial amylases of different lipase content, in order to determine whether the presence of lipase will affect the quantity of fatty acid liberated during the course of the hydrolysis. The two most likely amylases were "Taka" diastase and "Superase."[10]

The lipase content of the enzyme was estimated by allowing the amylase to react on triolein and titrating the ether-extracted free oleic acid formed after the well-shaken samples had stood for twenty-four hours. The "Taka" diastase mixture was buffered at a P_H of 4.52 and held at 30° while the "Superase" was buffered at a P_H of 7.3 and held at 60°.

One sample of "Superase" liberated no oleic acid and another liberated about 0.5% while the "Taka" diastase liberated 1.5% of the acid. The first "Superase" sample is apparently substantially free from lipase.

Both the "Superase" and the "Taka" diastase were allowed to react with corn starch and the effect on the liberation of fatty acids studied. The results are given in Table III.

Experimental

Twenty-gram samples of starch were mixed with 100 cc. of cold distilled water and poured into 700 cc. of boiling water, taking care that no lumps were formed. To those samples containing the Taka diastase, 100 cc. of acetate buffer of P_H 4.52 was added; to those containing "Superase," 100 cc. of phosphate buffer of P_H 7.2–7.3. The samples were well stirred and kept in an oven for twenty-four hours. For those containing

---

"Taka" diastase the temperature was kept at 30°, and for those with "Superase," at 60°. They were then acidified with acetic acid until acid to methyl red, and a small quantity of mercuric chloride was added to each as a preservative. They were filtered through wet filter papers and washed with distilled water; the filter papers were dried overnight in an oven at 40°, and extracted for three days in a Soxhlet apparatus with ether and the residue in the flask weighed after evaporation of the solvent.

TABLE III

THE AMOUNT OF FATTY ACID HYDROLYZED FROM CORN STARCH BY THE AMYLASES

Amylase per 20 g. starch, g.	Fatty acid split by Taka diastase, g.	% of Total fatty acids split by Taka diastase	Fatty acid split by "Superase," g.	% of Total fatty acids in starch split by "Superase"
0.050	0.0162	12.2	0.0057	4.3
.100	.0244	18.4	.0075	5.6
.200	.0451	33.9	.0103	7.7

Fatty acid content of the starch, 0.73%. Time of treatment, 24 hrs.

From the results recorded in Table IV it is evident that the amylase containing lipase ("Taka" diastase) hydrolyzes the greater quantity of fatty acid from corn starch. The "Superase," which showed a practically negligible amount of lipase in the test on olein, also liberates the smallest amount of fatty acids from the corn starch.

When "Superase" is used directly on the corn a-amylose instead of the starch containing a-amylose there are similar results as shown in Table IV.

TABLE IV

THE REMOVAL OF THE FATTY ACID FROM α-AMYLOSE BY AN AMYLASE

Grams of amylase per 3 g. of a-amylose	Grams of fatty acid split from 3 g. of α-amylose		% Total fatty acid split	
0.050	0.0054	0.0048	4.5	4.0
.100	0.0060	0.0057	5.0	4.8
.200	0.0050	0.0056	4.2	4.7
.400	0.0078	0.0079	6.6	6.6
.600	0.0077	0.0083	6.5	6.9
1.000	0.0125	0.0127	10.7	10.7

The fatty acid content of the a-amylose was 3.8%.

Turning to the production of reducing sugar during this treatment, it was found in two preliminary experiments that when using. 0.05 g. of "Superase" per 20 g. of starch made as a 2% paste, the maximum amount of reducing sugar occurred after twenty-four hours. For example, when several 50-cc. aliquots of the mixture were titrated iodimetrically by the Willstätter–Schudel[11] method the reducing sugar expressed in milligrams of iodine per 500 mg. of starch (50-cc. aliquots contain 500 mg. of dry starch) was 170 and 171 for a twenty-four hour treatment and 169 and 170 for a forty-eight hour treatment.

By increasing the amount of amylase that acts on a given amount of

(11) (a) Willstätter and Schudel, *Ber.*, **51**, 780 (1918); (b) Goebel, *J. Biol. Chem.*, **72**, 801 (1927).

starch, the production of reducing sugar increases to a maximum for that concentration also at about twenty-four hours for optimum conditions.

That the degree of dispersion plays no essential part is shown by the fact that the results from ground corn starch[12] which disperses easily to give a limpid paste in hot water are practically the same as those from the thicker whole starch pastes.

As the ratio of "Superase" to starch is increased, a larger amount of fatty acids is liberated up to a certain point. Increasing the amount of "Superase" relative to the starch beyond that point causes no further splitting of fatty acid residues from the amylose.

The "Superase" produces reducing sugars from both corn alpha and corn beta amylose, so that its action on whole corn starch is not confined to the beta amylose alone. The average amount of reducing sugar from 500 mg. of whole starch is equivalent to 190 mg. of iodine and from the same weight beta amylose is equivalent to 202 mg. of iodine, but beta amylose constitutes only 85% of the whole corn starch.[2b] Therefore some of the reducing material must have come from the alpha amylose. During this breaking away of carbohydrate from the main portion of the alpha amylose under the influence of the "Superase" only a small portion of the combined fatty acids were freed.

Any residue, therefore, which is left unattacked will have a new ratio of carbohydrate to fatty acid which will be unlike the original. Beta amylose is completely hydrolyzed to reducing sugars so if whole corn starch is treated with "Superase" any unattacked residue must come from the α-amylose alone.

Acting on these observations a large amount of a 2% corn starch paste was treated with the requisite amount of "Superase" under optimum conditions for twenty-four hours and a residue obtained by centrifuging the mixture kept mold free with toluene. This residue after washing was dried, ground and extracted for ten hours in a Soxhlet apparatus with ether to remove any free fatty acids. Subsequently a sample of the oven-dry material was hydrolyzed completely with aqueous acid and the fatty acids liberated, extracted, weighed and their iodine number determined. This analysis of the carbohydrate–fatty acid compound showed that it contained a large amount of combined fatty acids, namely, 6.3%, whose iodine number was 60.7. The whole corn starch from which the alpha amylose had come showed 0.66% fatty acids (all in the alpha) whose iodine number was 95.8 while the alpha amylose separated from the same starch before the attack of the "Superase" contained 3.8% combined fatty acids.

Discussion of Results

In this work it has been shown that by the use of three methods, namely, hydrolysis by acid, by base and by amylase, the fatty acid groups com-

---

(12) Taylor and Beckmann, THIS JOURNAL, **51,** 294 (1929).

bined with the α-amylose portion of corn starch are preferentially liberated. In all three cases the unsaturated acid radicals are the more easily removed. This result may be accounted for in two ways. It may be due either to a general lesser stability of compounds of carbohydrates with the unsaturated acids (oleic and linolic) in comparison with those of palmitic acid, or to the fact that these unsaturated acid residues are linked at positions different from that of the saturated one on the carbohydrate molecule. Position isomerism is known in the case of glucose derivatives to be the cause of differences in ease of hydrolysis.

Summary

1. The fatty acids associated with corn starch are hydrolyzed preferentially by acid, by base and by lipase-free amylase.

2. The linking between the unsaturated portion of the fatty acids and the carbohydrate is less stable to hydrolytic agents than that between the saturated portion and the carbohydrate.

The Action of Aqueous Alkali on Starches, Amyloses and Modified Starches

BY T. C. TAYLOR AND G. M. SALZMANN[1]

The most common form of chemical change which starches or amyloses undergo gives rise to reducing sugars and is therefore probably a scission of glucosidic linkings. During the early stages of these transformations rather large changes in the physical aspects of the starches, or more particularly the pastes made from these starches, are obvious without any great accompanying changes in reducing value as measured by any of the common methods. By allowing the hot aqueous alkali to act on the sample, however, and then neutralizing and determining the new reducing matter iodimetrically by a modified Willstatter method,[2] it was found possible to magnify small differences among the starches and amyloses that would not be significant when based on the initial reducing value alone. This was possible because it was found that when any starch or amylose had an appreciable initial reducing value the aqueous alkali produced many times that amount after treatment.

While some inquiry was made into the nature of these reducing sub-

---

(2) (a) Willstatter and Schudel, *Ber.*, **51**, 78 (1918); (b) Goebel, *J. Biol. Chem.*, **72**, 802 (1927); (c) Kline and Acree, *U. S. Bur. Standards J. Research*, **5**, 1063 (1932).

stances, the main purpose of this investigation was to use this alkaline treatment followed by an iodimetric determination of reducing material as a means of discovering whether this behavior toward hot aqueous alkali is a property of the original amyloses or is due really to some altered material admixed with the amyloses either as they occur in the starches or as they are isolated after disrupting the granules. The technique was employed further to find the type of treatment which would have to be given a starch or amylose so that it would give subsequently some material susceptible to aqueous alkali.

It will be shown that when a starch or amylose is modified, apparently only a part of the original polysaccharide is changed, the unattacked portion remaining stable to the alkali. The altered portion is completely broken down by the alkali but the stable portion is substantially nonreducing and similar to glycogen in its resistance to hot aqueous alkali. Original starch or amyloses with no history of hydrolytic attack from aqueous acid, enzymes, etc., are unaffected by repeated treatments with hot aqueous alkali and the amyloid material after such treatments is still like the original qualitatively by any of the criteria such as specific rotation, blue color with acidulated iodine-iodide test solutions and quantitative production of glucose.

It has been well established by Nef[3] and Evans[4] that glucose and maltose are decomposed by aqueous alkali, giving ultimately numerous non-carbohydrate substances such as pyruvic and lactic acids, etc. Many of these substances consume iodine under the slightly alkaline conditions that obtain in the iodimetric technique[2] employed here. The amount of iodine used up, however, is always much less than that used initially to oxidize the aldose. The breakdown with alkali through the enediol form of the glucose or maltose gives, according to Evans, the new products and obliterates the original sugar.

On the other hand, while the attack of alkali also begins apparently at the reducing group in a degraded amylose, the iodine consumption is always much *greater* after the treatment with hot aqueous alkali than it was initially.

Since aqueous alkali might give decomposition products in some enol form which would give fictitiously high reducing values,[5] some of the material after decomposition of the degraded amylose was allowed to remain acidified for one hour before the iodimetric determination was made. There was no change in the amount of alkali consumed.

Combination of the alkaline treatment with the iodimetric titration after neutralization gives a rather unique method of attack on the problem, the

iodimetric method for determining reducing substances avoiding effects of alkali that the Fehling method would introduce and measuring somewhat more of the decomposition products than the copper method.

In establishing the optimum conditions for the estimation of alkali labile material in starches and amyloses it was necessary to find the effect of concentration of alkali and time of treatment on them. Since the iodine consuming material produced by the alkali is in the main unknown, all results are expressed in milligrams of iodine per 100 milligrams of sample, except glucose and maltose. Here, usually, a weight was taken that consumed as much iodine initially as the particular starch or amylose with which it was compared. Due to the production of acidic substances during the decomposition with alkali, the total available alkalinity at low concentrations (0.025 N) in the volume of solution used was insufficient but larger volumes of the same normality gave the expected results. At higher concentrations there was no difficulty even with small volumes of reagent.

Experimental

Fifty milligrams of the dry sample was added to 2 cc of water and to this mixture was added 2 cc. of a potassium hydroxide solution of such a concentration that the final mixture would have the desired normality with respect to the water. In a few cases where the total alkali was insufficient, 4 cc. of the aqueous alkali was taken but the normality of the mixture was fixed at the desired point by using the appropriate concentration of potassium hydroxide. The solution was placed in a large test-tube (8 X 1″) and the tube held in a boiling water-bath by a heavy asbestos board cover through which were bored holes just large enough to accommodate the test-tube. The test-tube was immersed in the water below the level of the cover, to a depth slightly greater than that of the contents of the tube. The purpose of this was to secure the maximum reflux action upon the walls of the tube. In *each case* the test-tube containing the alkaline mixture was heated for a definite selected length of time. At the end of the period the tube was removed from the bath, the contents transferred by washing into a 250-cc. Erlenmeyer flask, one drop of phenolphthalein solution[6] added and the solution neutralized with dilute hydrochloric acid.

For the titration, $N/20$ sodium hydroxide and $N/40$ standard iodine solutions were employed. As recommended by the Bureau of Standards[2] the iodine and sodium hydroxide solutions were added dropwise in four alternate portions using 3 volumes of the alkali to 4 volumes of the iodine solution. An excess of 2 or 3 cc. of iodine and 3 or 4 cc. of sodium hydroxide solution was usually added and the mixture allowed to stand about five minutes so that the total time before the back titration was twelve to fifteen minutes. After acidification with $N/5$ hydrochloric acid the excess iodine was titrated with $N/80$ thiosulfate solution. The presence of sulfuric acid or sulfates always led to recurring end-points and inconsistent results.

When using glucose in similar experiments, the sample was 3.4 g. which by iodimetric titration reduced 4.3 mg. of iodine. This amount was taken because in subsequent experiments its behavior with hot aqueous alkali was compared with that of the particular corn beta amylose which had an

---

[6] Both the alcohol solvent and the phenolphthalein consume iodine so the minimum amount must he used. For very accurate work, say on glucose, it is better to use an aqueous solution of methyl orange which does not use up iodine [Mallen, *Analyst*, **54**, 244 (1932)]

initial reducing value of about the same amount. In this experiment, however, glucose and another corn beta amylose[7] were run.

The results are summarized in the graph, Fig. 1.

It is evident from the curve that there is always *more* iodine consuming material produced from the corn beta amylose than is initially present while with glucose there is always *less.* The maximum production from the amylose is with 0.1 *N* alkali while glucose is steadily decomposed at all normalities.

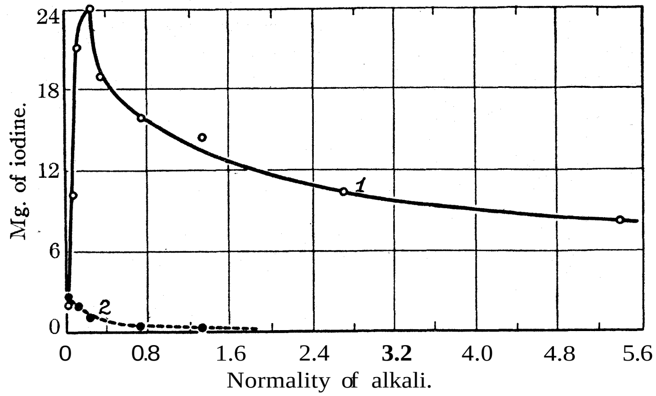

Fig. 1.—Reducing material expressed as mg. of iodine after treatment at normalities indicated: time constant at 15 minutes; Curve 1, corn beta amylose 100 mg.; Curve 2, glucose 3.4 mg.

To show that water alone has no effect, a sample of the beta amylose was treated for fifteen minutes and for two hours under conditions identical with the regular run but alkali was omitted. The reducing value was the same after the treatment as it was initially within the limits of the iodimetric determination.

Using 0.1 N solutions of potassium hydroxide a series of experiments was carried out on some corn beta amylose and on glucose in which the time of treatment was varied. This was done to see how the alkali effect changed when the treatment was prolonged beyond the fifteen-minute period. Each run was made for the specified time, the solution neutralized, cooled and the iodimetric titration made. The results are given in a graph, Fig. 2.

After a half-hour treatment the maximum amount of iodine consuming material is produced from this sample of corn beta amylose. Continued heating produces no more and after the one-hour period there is apparently some slight destruction of the reducing material already produced. On the other hand, glucose is decomposed to substances of less reducing value very early in the treatment.

---

(7) Taylor and Beckmann, THIS JOURNAL, 61,294 (1929).

Although the maximum effect of the aqueous alkali is noticed with the 0.1 N concentration, many of the subsequent experiments were carried out using 5.45 N alkali because it was desired to make comparisons with the results obtained by McBride,[8] who used that concentration on glycogen in a similar set of experiments (this is the concentration of alkali used in the Pflüger method for glycogen isolation from tissue).[9] While the magnitude of the effect is not as great as with 0.1 *N* alkali, it is in the same direction.

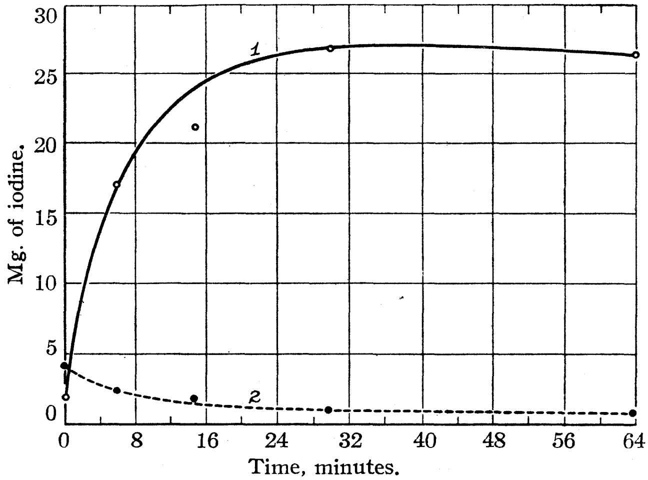

Fig. 2.—Reducing material expressed as mg. of iodine after treatment for periods indicated: normality of alkali constant at 0.1; Curve **1,** corn beta amylose 100 mg; Curve 2, glucose **3.4** mg.

To find out what the tendencies were when other samples were run with the 5.4 *N* alkali the following materials were taken: (a) corn beta amylose separated from ground starch by the electrophoretic method,[7,10] (b) corn beta amylose separated from alcoholic-hydrochloric acid treated corn starch after gelatinization and rupture with ammonium thiocyanate,[10] (c) corn white dextrin made by heating moist acidulated starch. This material has a rather high initial reducing value of 4.1 mg. of iodine. (d) A mixture of 100 mg. of corn beta amylose as in (a) with an initial iodine reducing value of 2.0 with 3.4 mg. of glucose with initial reducing value of 4.3 to make the total **6.3.** This was done to see if the method would discriminate between glucose and other reducing materials already present in the amylose. The complete record is shown in Fig. **3.**

It is interesting to note that there is more alkali labile material in the beta amylose separated from the acid-treated, thiocyanate gelatinized corn

starch[10] than from that separated from the ground starch[7] or even a commercial white dextrin made by the dry heating of acidulated corn starch. As in previous experiments the glucose is quickly destroyed when alone and also when present with the beta amylose. After the first two minutes of the alkaline treatment the glucose is no longer a factor while the beta amylose runs its course as in the experiments without the presence of glucose.

These data point again to the fact that the initial reducing material in the amyloses and in the white corn dextrin is ***not,*** in the main, glucose.

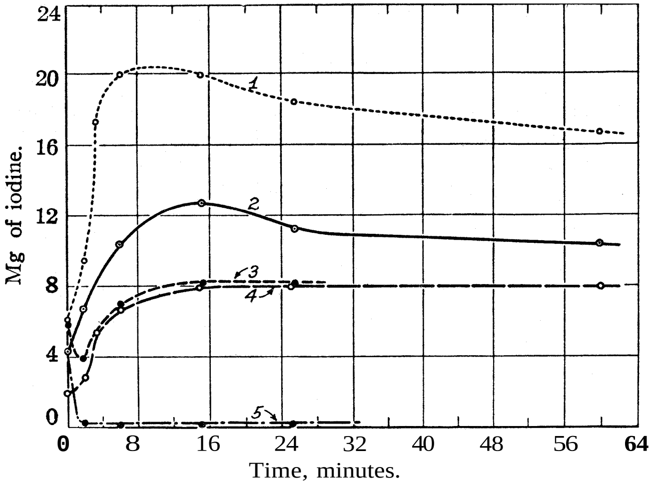

Fig. 3.—Reducing matter expressed in mg. of iodine after treatments of materials for period indicated with 5.4 *N* alkali: Curve 1, corn beta amylose from acid-treated thiocyanate-gelatinized starch; Curve 2, corn white dextrin; Curve 3, mixture of glucose, 3.4 mg., and corn beta amylose, the latter is the same material used in getting values in Curve 4; Curve 4, corn beta amylose from ground starch; Curve 5, glucose, 3.4 mg.; all amylose samples, 100 mg.

The reducing material present initially which is not glucose must be, therefore, closely allied to the amyloses and must have its source in them. It is probable that the reducing groups are the point of departure for the subsequent alkaline attack and the reducing material produced by this decomposition is substantially non-carbohydrate for it has no optical activity or other carbohydrate properties. In the absence of glucose the initial reducing value presages the amount of new reducing material which will be formed after the alkaline treatment.

That not all the starch or amylose is attacked by the alkali is shown by the fact that after neutralization of the alkali in any experiment, considerable quantities of starchy material may be precipitated by alcohol or, better, acetone. This slightly yellow precipitate when redispersed in water gives a clear blue color with acidulated iodine–iodide test solution and has a specific rotation practically the same as that of the original amylose. On complete acid hydrolysis this alkali stable residue yields glucose, quantitatively.

Either the precipitation method or the hydrolysis to glucose and subsequent iodimetric determination of it may be used to estimate the amount of amylose which is not susceptible to the attack of aqueous alkali. When concentrated alkali is used the latter method is somewhat better since a small amount of salt is precipitated with the amylose by the alcohol or acetone.

Experimental

The Precipitation Method.—1.250 grams of starch or amylose was placed in a 250-cc. Erlenmeyer flask to which was added 30–35 cc. of water, this mixture usually being warmed until a paste formed. To this was added 15 cc. of 0.4 N potassium hydroxide, which made the final solution approximately 0.1 N with respect to potassium hydroxide. The flask was then placed in a beaker two-thirds full of water and heated in this water-bath at 100° for one hour. When using whole starches, it was necessary to keep them for one and a half to two hours at 100° with 0.1 N potassium hydroxide instead of one hour, since it usually required one-half hour for the thick paste to become limpid and only after the production of this thin dispersion due to gelatinization and rupturing of the granules, does the alkali destructive action occur as evidenced by the production of the yellow color. After this treatment the flask was cooled and the contents slightly acidified with 2 N hydrochloric acid. Due to slow evaporation, the total volume was usually about 10–15 cc. less than at the start. To precipitate any unattacked amyloses 100 cc. of ethyl alcohol was now added. Vigorous shaking helped in coagulating the colloidal material. When a yellow dextrin was similarly treated, it was found that acetone gave a quantitative precipitation, which alcohol often fails to do. After the material had completely coagulated, which in some cases occurred almost immediately, while in others several hours of standing were required, the clear supernatant liquid was decanted off, the residue transferred to a mortar, ground using two 15-cc. portions of alcohol and twice washed with ether. This dried residue was placed in the oven at 60–70° for ten to fifteen minutes to remove traces of ether and then weighed. This weight represents the recovered amyloses after an alkaline treatment. Precipitations of hot water dispersed starch or amylose without an alkaline treatment were made so that the percentage recovery could be determined by proportion. For this purpose 1.250 g. of starch was placed in an Erlenmeyer flask to which 40–50 cc. of water was added. A dispersion was again made by heating, alcohol was subsequently added and the precipitated amyloses dried and weighed.

The "Hydrolysis Method" for Determining Alkali Stable Residue.—Fifty milligrams of the starch was placed in an 8-inch test-tube and dispersed in 1 cc. of water, to which was added either 1 cc. of 10.4 N potassium hydroxide or 1 cc. of 0.2 N potassium hydroxide, so that the final concentration of alkali would be approximately 5.4 *N* or 0.1 N with respect to water as desired in each instance. The mixture was kept at 100" for one hour in the water-bath, then cooled and neutralized with 2 N hydrochloric acid. To hydrolyze the remaining amylose 5 cc. of *2* N hydrochloric acid was added, and the tube placed in the water-bath at 100". It was found that hydrolysis was complete at the end of thirty-five minutes. The solution was cooled and neutralized with potassium hydroxide, and the reducing value determined in the usual way. This reducing value consists of the sum of the reducing value due to the glucose formed by acid hydrolysis, and the reducing material left after the action of the alkali. It will be shown later that this treatment with acid does not produce any change in the reducing material already present from the alkali treatment. In order to determine the reducing value due to the glucose from the unattached amylose, it is necessary to subtract from the total value the reducing value due to the alkali treatment.

To avoid any error in the percentage of amyioses stable toward the alkaline treatment, it is also necessary to make conversions of the same amounts of starch or amyloses to glucose, but with no alkali pretreatment. Fifty milligram samples of starch or amylose were hydrolyzed with 5 cc. of 5 *N* hydrochloric acid for thirty-five minutes and the reducing value in milligrams of iodine found. Then the percentage of unaltered residue could be calculated on the basis of the ratio of the glucose from the residue to the glucose from the original starch or amylose.

By multiplying the weight of glucose by the factor 0.9 a weight is obtained which is recorded as starch.

The precipitation method and the hydrolytic gave results that differed among themselves on repetition on the same sample by about 0.75%, and with one another from 2 to 4%.

The amount of alkali stable material in the particular samples used in the above experiments seems to vary according to the source of the sample. From whatever source they appear to be similar in character and all show an iodine consumption of one or two milligrams, due probably to adsorbed reducing material from the solution out of which they were precipitated. When subjected again to the hot aqueous alkali no appreciable change takes place even after heating with 0.1 N alkali for three hours. This is evident for no reducing material is formed in the presence of alkali, the amount of residue after the alkali treatment is substantially the same after this second treatment as after the first and the specific rotation and iodine color are the same as for samples of original starch.

To get some clue to the type of treatment that might cause a part of the starch or amylose to be converted to alkali labile material, a number of starches, amyloses and modified starches were investigated. The initial reducing value was determined, they were subjected then to hot aqueous alkali, neutralized and the new iodine consumption noted, after which the amount of stable residue was estimated. The results have been arranged in order of decreasing amounts of alkali stable fractions (see Table I).

There is an inverse relationship between the initial reducing value and amount of amylose remaining after the alkali treatment. Some samples of starch have practically no alkali labile material in them while others have more. This is due very probably to the method of manufacture and possibly to agricultural conditions under which the starch was grown. Of the definitely controllable factors aqueous acid is the most potent in producing alkali labile material although other conditions such as grinding the starch in a ball mill also cause degradation of a part of the amyloses as the results under items G and H in Table I show.

TABLE I

STUDY OF FACTORS INVOLVED AND RESULTS OBTAINED BY ALKALI TREATMENT OF STARCHES AND AMYLOSES

Sample	% Alkali stable residue by alcohol precipitation method	Initial reducing value of orig. substance on 100-mg. samples, mg. of iodine	Reducing value after 5.4 N KOH 1 hr. at 100° on 100-mg. samples, mg. of iodine
Potato starch, Sample A	97		3.3
Corn starch, Sample B	90		5.1
Ground tapioca starch, Sample C	83	1.4	4.6
Ground potato starch, Sample D	75	...	8.2
Lintner's sol. starch, Sample E	74	0.6	7.2
Corn beta amylose, Sample F	73	2.0	8.0
Ground corn starch, Sample G	68	1.9	8.8
Reground corn starch, Sample H	67	2.6	9.9
Corn alpha amylose, Sample I	62	1.6	9.6
Ground corn starch, Sample J	59	3.0	11.6
Corn white dextrin, Sample K	56	4.1	10.5

Corn beta amylose, Sample N	49	6.0	16.8

NOTES

Sample A represents a good grade of commercial potato starch. Sample B represents a good grade of commercial alkali-washed corn starch. Sample C represents a tapioca starch which has been ground for eighteen hours with quartz balls in a ball mill.[7] Sample D represents potato starch which has been similarly ground for 120 hours.[7] Sample E represents Lintner's soluble potato starch made by keeping potato starch in contact with dilute hydrochloric acid for six days at room temperature and washing twenty-two times with water.[11] Sample F represents corn beta amylose, the soluble component of 168-hour ground corn starch after electrophoresis and precipitation.[7] Sample G represents corn starch ground for 168 hours. Sample H represents sample G ground corn starch which had been subjected to an alkali treatment, and reprecipitated out as the stable portion, which in turn was reground for another 140 hours in a small ball mill. Sample I represents corn alpha amylose, the insoluble component of 168-hour ground corn starch after electrophoresis.[10,7] Sample J represents 168-hour ground corn starch, reground another 160 hours in a small ball mill, so that the total time of grinding was 320 hours. Sample K represents corn white dextrin made commercially by spraying whole starch with dilute hydrochloric acid and heating this damp product around 180° for a short period of time.[12] Sample L represents a "thin-boiling" corn starch made by giving whole starch an acid treatment similar to that given Lintner's soluble potato starch.[12] Sample M represents potato starch ground for 500 hours in a ball mill. Sample N represents corn beta amylose made by treatment of corn starch with an alcoholic solution of hydrochloric acid, followed by an ammonium thiocyanate gelatinization.[10]

It is interesting to note that the iodine consuming value after a $N/10$ alkaline treatment is considerably higher than after the treatment with the more concentrated alkali as exemplified by samples as marked in Table II, giving for "C," 11.7 mg.; "F," 26.5 mg.; "G," 25.1 mg.; and "K," 36.5 mg.

(12) Walton, "A Comprehensive Survey of Starch Chemistry," The Chemical Catalog Co., New York, 1928.

Further, by grinding a corn starch and determining the alkali stable residue from time to time, it has been found that the effect increases with increase in time just as is the case in making "soluble" or "thin-boiling" starches by acid treatment in the cold. In the latter instance, of course the granules are not broken (see Fig. 4).

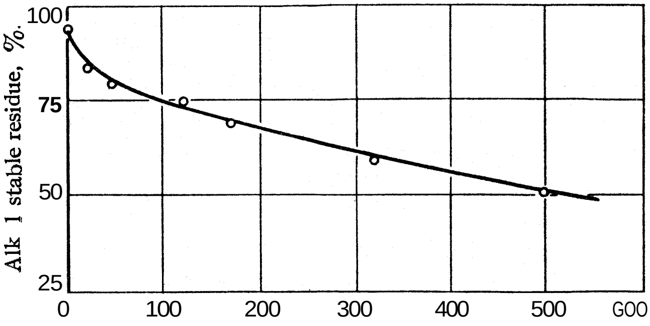

Fig. 4.—Relation between time of grinding of corn starch and amount of alkali stable residue.

The amount of surface exposed to the reagent at first in the case of the ground starch or amyloses is much greater than in the case of the soluble or modified starches where the granules are intact but the reagent soon swells and ruptures the latter, so conditions are about the same soon after the reaction has proceeded for a short time. Even a part of the less easily dispersed corn α-amylose[13,7,10] changes with acid treatment or grinding to give alkali labile material in a manner similar to the corn beta so that in the whole corn starch each of these amyloses is affected by various treatments to give alkali susceptible material. A sample of corn alpha amylose with an initial iodine reduction of 1.6 mg. per 100-mg. sample gave 10.9 mg. of iodine reducing material after a thirty-minute treatment at 100° in 5.4 N alkali.

When drying a sample of neutral ground starch already containing some alkali susceptible material, there was a slight increase in it (or decrease in alkali stable material). For example, when the initial alkali stable residue is 68.0% it changes to 67.0% after four hours, to 62.3% after sixteen hours, and to 61.5% after fifty hours at 105°.

On oven drying moist acidulated starch, which is essentially the process of white dextrin manufacture, there is, however, rather extensive breakdown of the starch, see Table I, item K. Apparently the acid causes this change during the early stages of the treatment when there is still considerable moisture present. Later if the temperature is raised, the white dextrin changes to yellow and a loss of water ensues. Finally no more

---

(13) Taylor and Lifschitz, THIS JOURNAL, 54, 1054 (1932).

alkali labile material is formed, but on the contrary any alkali labile material already present is transformed over to alkali *stable*. This is illustrated rather strikingly by an experiment where a "thin boiling" starch containing but 56% alkali stable material (see Table I, Item L) was acidulated and roasted to make a yellow dextrin. This new dextrin contained 86% alkali stable material even though its initial reducing value was 10.6 mg. of iodine per 100 mg. of sample.

A rather large portion of the labile material must have been converted to some kind of stable material and the initial reducing value which normally would indicate a high alkali susceptible portion in an amylose must be in this case due to glucose or maltose or something similar to it for the high alkali susceptible portion does not materialize as it would in an amylose or starch with this initial reducing value. Some studies are being made now on the glucosan types in order to shed more light on these findings because the new stable material is not like the original amylose and synthetic dextrins from levo-glucosan are stable as is levo-glucosan itself toward hot aqueous alkali.

It must be remembered that every starch, amylose or dextrin whether it contains a large or small amount of alkali stable material will hydrolyze practically quantitatively to glucose on boiling with aqueous acid for a sufficient time. All these substances are therefore built up from glucose units whether they are alkali stable or alkali labile.

It is evident that starches and their amyloses may contain relatively large amounts of hydrolytically degraded but still very similar polysaccharides associated with them. While reducing in character this material is not in the main glucose or maltose and not truly water soluble although it may disperse. Pastes made from starches containing much of this material are less viscous than pastes made from the same weight of that same starch which contains but little of the partially broken down alkali-labile material. Such degraded starches are known as "thin-boiling" or "soluble starches." These changes may come about through enzymic attack before the starch is isolated, during the process of manufacture, or may be deliberately brought about by acid treatment as in making soluble starches, etc. The general appearance of the granule is substantially unchanged while these modifications are taking place in the amylose within.

When such partially degraded starches are used to make derivatives or as a substrate for enzyme action, it is probable that the speed and possibly the course of the reaction will be different with the two closely related but chemically different products. Such degraded products are very often employed for experiments on starch, for one of the first operations is often the "solubilizing" of the starch so that the pastes can be handled more conveniently. This lack of homogeneity throws some doubt on the results when these degraded substrates are used.

Another point of interest that develops from this work is the difference between the very alkali labile hydrolytic-type dextrins from the continued attack of the aqueous acid and the very alkali stable yellow dextrins from long roasting of starch. The two types of "dextrins" are obviously not the same chemically.

Summary

1. When a given starch, amylose or dextrin is heated with dilute or concentrated alkali, only a very definite fraction is destroyed by the alkali with a corresponding increase in the reducing value of the system as measured by the hypoiodite method.

2. Starch or amylose which has not been degraded is substantially unaffected by hot aqueous alkali.

3. Two methods are given for quantitatively estimating the portion of starch which is stable toward alkali.

4. Aqueous acid, certain heat treatment or grinding in the presence of moisture are capable of producing a high alkali unstable fraction from a given starch or amylose.

5. Yellow dextrin made by roasting starch contains a large amount of material stable toward alkali.

The Interaction of Ketene with Aromatic Aldehydes and its Bearing on the Perkin Reaction

BY CHARLES D. HURD AND CHARLES L. THOMAS[1]

Shortly after discovering diphenylketene Staudinger[2] found that it would add to quinone and produce a β-lactone. Ketene itself failed to do this. Hence, this property of addition at carbonyl groups was ascribed to the disubstituted ketenes.

The present work concerns itself with the reaction of ketenes with aromatic aldehydes. From Staudinger's work it would be anticipated that no reaction should occur when ketene was passed into benzaldehyde. None was observed. If, however, a little anhydrous potassium acetate was present, ketene then reacted vigorously with benzaldehyde or furfural or m-nitrobenzaldehyde to produce dark colored, viscid liquids.

If the mechanism of the reaction consisted merely in direct addition, β-lactones should have been the major products. They were formed but the chief reaction products were mixed acid anhydrides, namely, cinnamic

---

(2) Staudinger, *Ber.*, 41, 1355 (1908).

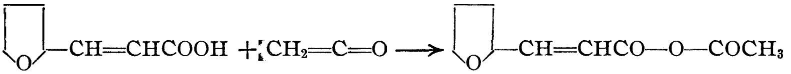
acetic anhydride, furylacrylic acetic anhydride and m-nitrocinnamic acetic anhydride. Such an effect may be summarized in the equation

$$\mathrm{ArCHO} + 2\mathrm{H_2C{=}C{=}O} \xrightarrow{\mathrm{KOAc}} \mathrm{ArCH{=}CH{-}CO{-}O{-}COCH_3}$$

Considering the reagents which are taken, this reaction with aromatic aldehydes, potassium acetate and ketene resembles the Perkin reaction which employs aromatic aldehydes, potassium acetate and acetic anhydride. This is obvious since both ketene and acetic anhydride give rise to acetic acid when treated with water.

Beta **Lactones** in the Reaction Product.—The presence of the β-lactones was established by pyrolysis. Styrene distilled from the benzaldehyde material and furylethylene[3] from the furfural material. The styrene could not have come from cinnamic acetic anhydride or from cinnamic anhydride for they were shown to pyrolyze differently. Furthermore, its forerunner could not have been cinnamic acid since it was not present and since the decomposition temperatore was lower than that required for cinnamic acid. Even milder conditions (steam distillation) were found to suffice in the production of furylethylene. In the case of the *m*-nitrobenzaldehyde reaction product, a small amount of liquid was formed as a product of pyrolysis. This may have contained m-nitrostyrene but it could not be established with certainty. Nor was it possible to isolate the β-lactone which, in this case, is known[4] to be fairly stable.

Synthesis and Reactions of Mixed Acetic Anhydrides.—Prior to the search for the mixed anhydrides in the reaction mixture they were prepared for study. The general method of Hurd and Dull[5] was used. Acetic cinnamic anhydride was prepared by passing ketene into a solution of cinnamic acid in ether. Acetic furylacrylic anhydride was prepared similarly from ketene and furylacrylic acid



Acetic furylacrylic anhydride is new and but little information exists regarding acetic cinnamic anhydride. Gerhart,[6] who prepared it from sodium cinnamate and acetyl chloride, reported it to be a very unstable oil. Using cinnamic acid and acetic anhydride, Autenrieth[7] obtained cinnamic anhydride but not the mixed anhydride.

Three reactions of acetic cinnamic anhydride were studied: (a) disproportionation into the symmetrical anhydrides. This occurred on distillation

$$2\mathrm{C_6H_5CH{=}CHCOOCOCH_3} \longrightarrow (\mathrm{C_6H_5CH{=}CHCO})_2\mathrm{O} + (\mathrm{CH_3CO})_2\mathrm{O}$$

[7] Autenrieth, Ber., 34, 186 (1901).

(b) reaction with phosphorus trichloride. Besson[8] reported the following reaction between acetic anhydride and phosphorus trichloride

$$(CH_3CO)_2O + PCl_3 \longrightarrow 2CH_3COCl + POCl$$

Repetition of this reaction showed that an 85% yield of acetyl chloride was formed. Similarly, the mixed anhydride was found to give an 85% yield of acetyl chloride with phosphorus trichloride

$$C_6H_5CH{=}CHCOOCOCH_3 + PCl_3 \longrightarrow C_6H_5CH{=}CHCOCl + CH_3COCl + POCl$$

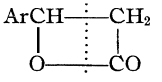
(c) analysis[5] with dry oxalic acid and pyridine. The reaction seems to hold quantitatively for the mixed anhydrides of the acetic type; *e. g.*

$$CH_3COOCOCH{=}CHC_4H_3O + (COOH)_2 \xrightarrow{C_5H_5N} CH_3COOH + \\ C_4H_3OCH{=}CHCOOH + CO + CO_2$$

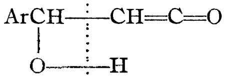
It is not quantitative for all acid anhydrides, however, as cinnamic anhydride gave but nine-tenths of the calculated volume of gas and *m*-nitrocinnamic anhydride did not react at all.

Mixed Anhydrides in the Ketene–Aldehyde Reaction Products.—The reactions just described were applied on the brown, viscous products of the reaction between ketene, aldehydes and potassium acetate. (a) Vacuum distillation of the reaction product from ketene and benzaldehyde produced some crystalline cinnamic anhydride. The corresponding product from *m*-nitrobenzaldehyde gradually deposited crystals of m-nitrocinnamic anhydride on standing. (b) When phosphorus trichloride was mixed with the benzaldehyde–ketene product, the yield of acetyl chloride indicated **50%** of acetic cinnamic anhydride in the material. (c) Using the oxalic acid and pyridine method of analysis there was found 59% of furylacrylic acetic anhydride and 30% of cinnamic acetic anhydride, respectively. The amounts of furylacrylic and cinnamic acids isolated agreed with these values.

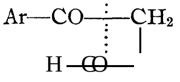
Mechanism of the Reaction.—If one assumes that a molecule each of ketene and aldehyde participate in the first stage of the reaction, there are three modes of addition to be considered:



I



II



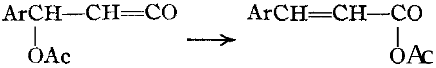
III

Formula (I) represents a *β*-lactone. This is undoubtedly formed but whether it is formed directly or by isomerization of (II) is debatable. Formula (II) represents an hydroxyketene, a new type of compound which might isomerize into (I) and concurrently might form an acetic ester with an excess of ketene. In this ester, the acetate radical is at an end of a "three carbon system," with an aryl group at the same end. Hence, a

---

(8) Besson, *Compt. rend.*, 125, 771 (1897).

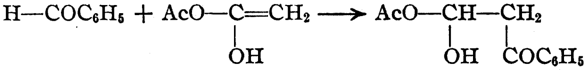
rearrangement[9] typical of such systems would be anticipated. The resultant compound would be the mixed anhydride



$$\underset{\displaystyle\text{OAc}}{\text{ArCH}}\text{—CH=CO} \longrightarrow \text{ArCH=CH—}\underset{\displaystyle\text{OAc}}{\text{CO}}$$

The β-lactone provides a satisfactory explanation for the arylethylenes which were isolated and the hydroxyketene for the mixed anhydrides. It would be conceivable to consider the 8-lactones as forerunners of the mixed anhydrides if they could rearrange into unsaturated acids. These acids add ketene normally and give mixed anhydrides. However, β-lactones do not undergo rearrangement by heat to unsaturated acids. They give unsaturated hydrocarbons and carbon dioxide instead. Furthermore, the β-lactone, , is stated[4] to be stable at the temperatures used. Hence if formed it should not have decomposed into *m*-nitrocinnamic acid, yet m-nitrocinnamic acetic anhydride was formed.

Formula (III) lacks support in the present work since benzoylacetaldehyde was not found and since it cannot be regarded as a probable intermediate in the production of either the arylethylenes or the mixed anhydrides. Mention is made of formula (111), however, because of its bearing on Kalnin's recently proposed mechanism[10] for the Perkin reaction. Kalnin assumed the first step to be enolization of acetic anhydride by potassium acetate. Then he postulated addition of benzaldehyde to it with scission of the aldehyde into hydrogen and benzoyl



$$\text{H—COC}_6\text{H}_5 + \text{AcO—}\underset{\displaystyle\text{OH}}{\text{C}}\text{=CH}_2 \longrightarrow \text{AcO—}\underset{\displaystyle\text{OH}}{\text{CH}}\text{—}\underset{\displaystyle\text{COC}_6\text{H}_5}{\text{CH}_2}$$

Because of the structural similarity of ketene to enolized acetic anhydride  $\left(\text{CH}_2\text{=C=O and CH}_2\text{=C}\begin{matrix}\text{OAc}\\ \text{OH}\end{matrix}\right)$ it is reasonable to think that benzaldehyde should add to ketene analogously and produce benzoylacetaldehyde, were this equation correct. However, as stated above, this was not found. Furthermore, with this mechanism it is not apparent why potassium acetate is necessary in the ketene–benzaldehyde reaction, for C=C exists in ketene (whereas it does not in acetic anhydride).

Other objections to Kalnin's mechanism are these. Phthalic anhydride[11] or benzoyl cyanide,[12] with no labile hydrogen, may replace benzaldehyde in the reaction with acetic anhydride and potassium acetate. Also, the fact

---

[9] Burton and Ingold, *J. Chem. Soc.*, 906 (1928); Burton, *ibid.*, 1650 (1928); 248 (1930): 759 (1931). The wandering of not only the acetate radical but also others such as chloride, bromide, trichloroacetate and *p*-nitrobenzoate is shown and the influence of aryl groups in facilitating the change of ArCHXCH=CH_2 to ArCH=$CHCH_2X$ is demonstrated.

[10] Kalnin, *Helv. Chim. Acta*, 11, 977 (1928).

[11] Michael and Gabriel, *Ber.*, 10, 391 (1877): Gabriel and Michael, *ibid.*, 11, 1007 (1878).

[12] Mueller, Ann., 491, 251 (1931).

that bases induce the condensation of methyl benzoylformate, which contains no labile hydrogen, with methyl cyanacetate[13] is a similar objection.

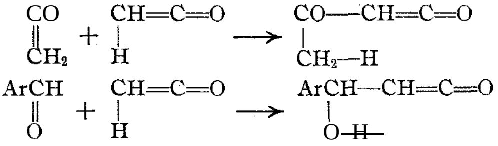
The most satisfactory interpretation of the Perkin reaction is one originally suggested by Michael,[14] which aligns it with well-known condensations of aromatic aldehydes with other aldehydes, ketones and esters, all of which are catalyzed by a base. The general equation becomes

$$\mathrm{ArCHO + RCH_2{-}CO{-}Z \xrightarrow{base} Ar{-}CHOH{-}CHR{-}CO{-}Z}$$

wherein Z represents H, R, OR or OCOR. Whether or not dehydration to $\mathrm{ArCH{=}CR{-}CO{-}Z}$ occurs depends on the conditions of the reaction. In such a process, the base may be considered to loosen the C—H bond in $\mathrm{RCH_2{-}CO{-}Z}$. Two carbonyl groups are present to compete for the hydrogen, namely, the one in benzaldehyde and the one in acetic anhydride. The former gives rise to the Perkin reaction (irreversible) and the latter to enolized acetic anhydride (reversible). With this viewpoint, the double bond of enolized acetic anhydride loses the significance ascribed to it by Kalnin.

A strictly analogous mechanism best pictures the formation of the hydroxyketene (II) in the ketene–aldehyde reaction.

Finally, it is interesting to call attention to the polymerization of ketene. If the dimer of ketene is regarded as acetylketene, $\mathrm{CH_3COCH{=}C{=}O}$, rather than cyclobutanedione, a preference which seems necessary to account for its polymerization[15] into dehydroacetic acid, then the mechanism for the addition of ketene to itself resembles that of its addition to aldehydes



$$\begin{array}{l}\mathrm{CO}\\ \|\\ \mathrm{CH_2}\end{array} + \begin{array}{l}\mathrm{CH{=}C{=}O}\\ |\\ \mathrm{H}\end{array} \longrightarrow \begin{array}{l}\mathrm{CO{-}CH{=}C{=}O}\\ |\\ \mathrm{CH_2{-}H}\end{array}$$

$$\begin{array}{l}\mathrm{ArCH}\\ \|\\ \mathrm{O}\end{array} + \begin{array}{l}\mathrm{CH{=}C{=}O}\\ |\\ \mathrm{H}\end{array} \longrightarrow \begin{array}{l}\mathrm{ArCH{-}CH{=}C{=}O}\\ |\\ \mathrm{O{-}H}\end{array}$$

Experimental Part

Ketene was synthesized from acetone by pyrolysis.[16] In experiments where it was desired to have the ketene completely free from acetone vapor, the latter was removed by passing the gases through a −80° condenser.

Acetyl Chloride from Acetic Anhydride and Phosphorus Trichloride.—Twenty cc. (21.6 g.) of acetic anhydride and 20 cc. (32.3 g.) of phosphorus trichloride were distilled together with a good column. The acetyl chloride which formed distilled between 51–52°. The yield was 29.5 g. or 89% of the calculated amount. The residue was a yellow, paraffin-like solid.[8]

Mixed Anhydrides from Ketene

Furylacrylic Acetic Anhydride.—Fifteen grams of furylacrylic acid was suspended in 50 cc. of dry, ice-cold ether and ketene was passed in until it was no longer absorbed.

(14) Michael, Ber., 34, 918 (1901).

(15) Hurd, Sweet and Thomas, THIS JOURNAL, 55, 335 (1933).

(16) Hurd, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1924, Vol. IV, p. 40.

The ether was then evaporated *in vacuo*. The product was a slightly brown liquid which possessed a sharp odor. On standing it gradually changed into a black jelly, a change which was facilitated by heating. The compound (freshly prepared) was analyzed[5] with dry oxalic acid and pyridine.

Anal. Anhydride calcd. for $C_9H_8O_4$, 100%. Found: anhydride, 99.5%.

Cinnamic Acetic Anhydride.—Just as in the previous case, 15 g. of cinnamic acid was suspended in 50 cc. of cold, dry ether and treated with ketene. The residue on evaporation of the ether was a slightly colored liquid with a sharp odor.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.5; H, 5.26. Found: C, 69.1; H, 5.22.

On standing at room temperature, cinnamic acetic anhydride slowly deposited cinnamic anhydride.[17] This action was rapid on heating.

Ten grams of cinnamic acetic anhydride was distilled with 11 g. of phosphorus trichloride. There was formed 3.5 g. (84.5%) of acetyl chloride, b. p. 52°, which gave acetanilide, m. p. 114°, on reaction with aniline.

Cinnamic Anhydride.—Cinnamic anhydride, prepared by pyrolysis of the acetic cinnamic anhydride and recrystallized from xylene, melted at 134°. It was found to distil practically unchanged at 23 mm. at a bath temperature of 270°. Search was made for styrene as a decomposition product without success.

When pure cinnamic anhydride was analyzed by the oxalic acid and pyridine method the reaction was not quantitative. Thus, in one experiment 0.2778 g. of anhydride gave rise to 40.2 cc. (corr.) of gas which represents a conversion of 89.5%. In three similar runs the values were 87.0, 88.8 and 91.1%. Since the purity of the cinnamic anhydride was not in question, the method evidently is not a quantitative one in this case.

Reaction of Aldehydes with Ketene and Potassium Acetate

Ketene–Furfural Reaction Product.—Fifty cc. (58 g. or 0.6 mole) of furfural and 3.3 g. of freshly fused potassium acetate were placed in a flask and 0.8 mole of ketene passed in. The furfural warmed up to about 60° and turned dark rapidly. It required about three hours to generate this amount of ketene and the furfural was quite warm until the last half hour of the reaction. The total increase in weight was 27 g. and the product was a thick, dark brown liquid having an odor of furfural. It was analyzed for its acetic furylacrylic anhydride content by the oxalic acid and pyridine method. A molecular weight determination was also made on this material.

Anal. Subs. 0.4358: cc. of gas (corr.), 64.3. Anhydride content calcd. as $C_4H_3OCH{=}CHCOOCOCH_3$, 59.3%. *Mol. wt.* Subs. 0.3883. Solvent (benzene), 21.9. Freezing point lowering, 0.505". Mol. wt. calcd. for $C_9H_8O_4$, 180; found, 175.

Conversion into Furylethylene

(a) Direct Heating.—Some of the tarry reaction product was heated in a small distillation flask. The liquid distillate was collected in a test-tube which contained a trace of pyrogallol to prevent polymerization. This distillate possessed the properties of furylethylene.3 It was a liquid insoluble in water. It boiled at 100°. It polymerized and turned dark colored on standing and it decolorized potassium permanganate solution instantly.

(b) Steam Distillation.—Steam was passed into the reaction mixture of a new run starting again with 50 cc. of furfural. The non-aqueous layer of the distillate was the top layer. Its volume was 32 cc. It was separated and dried over calcium chloride. In these and in subsequent manipulations, a trace of pyrogallol was always present. When dry, 16.5 cc. was collected by distillation to 110°. The remaining 10.5 cc, was largely furfural. After washing the 16.5 cc. to remove acetone, about 9.5 cc. of liquid

---

(17) Compare Autenrieth, Ber., *34*, 186 (1901).

remained which was very unsaturated toward permanganate solution and bromine water. After drying and distilling all boiled at 97° or below showing it to be chiefly furylethylene.

The residue from which the furfural and furylethylene had been steam distilled was made alkaline with aqueous sodium hydroxide. Four grams of a black tar remained undissolved. The yield of furylacrylic acid (m. p. 139°) which separated by adding acid to the alkaline solution was 36 g. This 36 g., coming from 58 g. of furfural, is a 43.5% yield. From the furylacrylic acetic anhydride content (59.3%) of the crude reaction product which weighed 85 g., it would have been possible to obtain 38.6 g. of furylacrylic acid. The value of 36 g., therefore, is confirmatory evidence that the mixed anhydride was present in the amount indicated.

Ketene–Benzaldehyde Reaction Product.—Fifty cc. (53 g. or 0.5 mole) of benzaldehyde which had been freshly distilled and 3 g. of fused potassium acetate were treated with ketene until there was no further action as evidenced by a heating effect (tested by feeling with the hand). During most of the time the ketene was being added the reaction mass maintained itself at a temperature of about 60°. The gain in weight of the reaction flask was 26 g. which, if caused entirely by addition of ketene, represents 0.62 mole. The product was a thick, brown liquid having the odor of benzaldehyde as well as a slight ester odor. Actually, its benzaldehyde content was at least 14% since from one gram of the crude substance there was produced 0.25 g. of benzaldehyde phenylhydrazone. The crude material was analyzed for its acetic cinnamic anhydride content with anhydrous oxalic acid and pyridine. Also, its apparent molecular weight was determined.

Anal. Subs., 1.0437, 1.0712; cc. of gas (corr.), 75.4, 76.4. Anhydride content calcd as $C_6H_5CH{=}CHCOOCOCH_3$, 30.6, 30.2 Mol. wt. Subs. 0.7847; g. of solvent (benzene), 30.7; depression of freezing point, 0.745°. Calcd. for $C_{11}H_{10}O_3$, mol. wt., 190; found, 172.

By steam distilling the ketene–benzaldehyde product from one run as above the excess of benzaldehyde was removed. The residue was extracted with alkali and the extract acidified to precipitate the cinnamic acid, m. p. 126°. Sixteen grams of it was isolated, which is a 21.8% yield based on the original benzaldehyde. Since the cinnamic acetic anhydride content of the crude reaction mixture which weighed 79 g. was 30.6%, the weight of cinnamic acid which this should create is 18.8 g. The 16 g. which was isolated is satisfactory agreement.

The product from another identical run was vacuum distilled at 6 mm. Between 40–55°, 25 cc. of benzaldehyde which was admixed with a little styrene distilled. From 55–170°, there was collected 5 cc. of styrene which contained a little benzaldehyde. From 170–174°, a light yellow solid distilled (5 g.) which was colorless when purified. It melted at 129° and was shown to be cinnamic anhydride. The styrene was identified by converting it into the dibromide which melted at 61°.

Five grams of the ketene–benzaldehyde product was distilled with 5 g. of phosphorus trichloride and the liquid boiling up to 85° was collected. On redistillation, 0.5 cc. of liquid was collected up to 65°. Assuming a quantitative reaction, this yield of acetyl chloride would require 2.4 g. of acetic cinnamic anhydride. When treated with aniline, this acetyl chloride gave acetanilide, m. p. 114°.

m-Nitrobenzaldehyde and Ketene.—Fifty grams of m-nitrobenzaldehyde was suspended in 100 cc. of benzene and a little fused potassium acetate added. Ketene was then passed in till there was no longer a heating effect. This aldehyde gradually went into solution and the solution turned dark brown Toward the end of the reaction an almost black oil separated on the bottom of the flask. After standing for several days, this black oil changed into a light yellow solid. This solid was filtered off and washed with benzene; yield, 15.5 g. or 25%. It melted at 206". Its insolubility in 5% potassium hydroxide combined with the fact that a mired melting point value of 180° was obtained with known m-nitrocinnamic acid demonstrated that it was not *m*-nitrocinnamic acid. When some of the solid was boiled with 5% potassium hydroxide solution it slowly dissolved Acidification of this solution gave m-nitrocinnamic acid melting at 196°. The melting point of known m-nitrocinnamic acid was not lowered by mixing with this acid. Thus, the original substance was a hydrolyzable derivative of m-nitrocinnamic acid.

m-Nitrocinnamic Anhydride.—This compound has not been described in the literature. Elemental analyses cannot be used to identify it since the percentages are so nearly identical to the values with the free acid. A molecular weight determination and an equivalent weight titration were used to prove that the 206° compound was m-nitrocinnamic anhydride. The former was determined by Pastak's method[18] using trinitrotoluene as solvent.

Mol. wt. Subs. 0.2443, 0.5269; g. of solvent (TNT), 12.569, 12.790. Depression of freezing point, 0.65°, 1.3". Calcd. for $C_{18}H_{12}O_7N_2$, mol. wt., 368; found, 344, 364. ($K = 11.5°$/mole/1000 g. of solvent.) *Equiv. wt.* Subs. 0.1123 g. dissolved in 5.00 cc. of alc. KOH (5 cc. ≈ 25.88 cc. of 0.2016 *N* HCI); cc. 0.2016 *N* HCl, 22.95. Calcd. for $C_{18}H_{12}O_7N_2$, equiv. wt.. 184; found, 190.

The benzene filtrate from which the 15.5 g. of m-nitrocinnamic anhydride precipitated was evaporated. The residue was a thick brown liquid. It reacted with concd. alcoholic potash so vigorously as to make the alcohol boil. However, the reaction was quite slow when 20 g. of it was treated at 0° with a solution of 10 g. of potassium hydroxide in 250 cc. of alcohol. After standing overnight the solution was evaporated on the steam-bath. No success attended efforts to extract the tar with ether or benzene. On adding water a brown solution formed but most of the tar remained behind. The solution was decolorized with charcoal and acidified. Three grams of m-nitrocinnamic acid separated; m. p. 193° and mixed m. p. 195°. This is a 15% yield.

The original *m-nitrobenzaldehyde–ketene* product does not contain acid since on standing for one week with sodium carbonate solution there was no brown color in the aqueous layer and there was no evidence of gas being evolved at any time.

Twenty grams of the m-nitrobenzaldehyde–ketene product was heated by an open, moving flame in an evacuated apparatus. Before there was any profound decomposition, 3.5 g. of a liquid was collected as a distillate. This liquid was thought to contain m-nitrostyrene for it decolorized potassium permanganate solution readily, it absorbed bromine instantly and its odor was similar to that of styrene. It froze at a temperature below −20°, whereas m-nitrostyrene is stated to freeze at −15° and to melt at −5°. Although the liquid absorbed bromine it was not possible to isolate any *m*-nitrostyrene dibromide from the reaction mixture. Hence, it cannot be stated definitely whether or not m-nitrostyrene was formed, but its presence is strongly indicated.

Synthesis of *m*-Nitrocinnamic Anhydride.—One gram of m-nitrocinnamic acid was refluxed with 3 cc. of acetic anhydride for five minutes. White crystals separated on cooling. These were washed with benzene and then with ether; yield, 0.3 g.; m. p. 206° A mixed melting point with the product obtained by the action of ketene gave 204°. m-Nitrocinnamic anhydride did not react with a mixture of dry oxalic acid and pyridine.

The anhydride was further identified by converting it into the methyl ester. One gram of the anhydride was refluxed for four hours with 10 cc. of methanol, the insoluble part filtered off, and the filtrate diluted with water. Methyl m-nitrocinnamate separated as small, slightly colored crystals. With no further purification, it melted at 118° as compared with the literature value[19] of 124".

---

(19) *Sudborough* and *Lloyd, J. Chem. Soc.*, **73**, 85 (1898).

By warming 7 g. of m-nitrocinnamic anhydride with 5 cc. of aniline, *m*-nitrocinnamanilide was prepared. The solid was washed with dilute alkali and then with dilute acid. After recrystallization from benzene the needle crystals melted at 194–195°.

Summary

In the presence of a little potassium acetate, ketene reacts exothermically with aromatic aldehydes (benzaldehyde, furfural, *m*-nitrobenzaldehyde). The primary product was considered to be a non-isolable hydroxyketene, Ar—CHOH—CH=C=O, but the chief product isolated was a mixed acetic anhydride, $ArCH{=}CH{-}CO{-}O{-}COCH_3$. The presence of a @-lactone was indicated in lesser amounts inasmuch as moderate heating of the reaction product gave rise to arylethylenes, $ArCH{=}CH_2$. The mechanism for the production of these substances is given. The similarity of this reaction to the Perkin reaction is pointed out and the mechanism for the latter reaction discussed. In this connection, some serious objections to Kalnin's mechanism are raised.

Acetic cinnamic anhydride and acetic furylacrylic anhydride were synthesized by the reaction of ketene and cinnamic acid or furylacrylic acid. These mixed anhydrides undergo pyrolysis into the symmetrical anhydrides. Also, they give good yields of acetyl chloride with phosphorus trichloride and they react quantitatively with dry oxalic acid and pyridine, each mole of mixed anhydride giving rise to a mole each of carbon monoxide and carbon dioxide. Cinnamic anhydride reacts with oxalic acid and pyridine, but not quantitatively.

m-Nitrocinnamic anhydride was synthesized and studied.

The Rearrangement of Alkenyl Phenyl and Cresyl Ethers and the Syntheses of Isopropenyl Phenols and their Reduction Products[1]

By JOSEPH B. NIEDERL AND EDWARD A. STORCH

Theoretical Part

In previous publications report was given on the successful rearrangement of saturated alkyl phenyl ethers[2] brought about chiefly by the action of an acetic–sulfuric acid mixture. That the chemical nature of the catalyzer does not play any integral part in these molecular migrations had been shown[3] and has been further verified recently by Sowa, Hinton and Nieuwland,[4] who checked the experimental findings of this Laboratory in the synthesis of thymol and its isomers from the corresponding isopropyl phenyl ethers. The purpose of the research presented in this communication was to extend these studies in molecular rearrangements to short-chain, alkenyl phenyl ethers (isopropenyl phenyl and cresyl ethers) in order to establish the limitations, general applicability, rules of migration, and, in general, to obtain a better theoretical understanding of this phenomenon. The latter object gains in interest, especially in view of the present-day conceptions of the reaction mechanism involved in such molecular transitions. As will be shown later, the accomplished rearrangement of the various isopropenyl phenyl ethers, as set forth herein, makes a rigid application of some of the present-day theories quite difficult. Therefore, in the following, attempts have been made to harmonize and to bridge various gaps between such accepted theories and the new experimental findings by broadening the scope of the former and incorporating certain physico-chemical energy principles.

Any such attempts, however, required first of all the determination of the structure and especially the position taken up by the migrating group in the benzene nucleus.

The isopropenyl phenyl and cresyl ethers mentioned above were prepared by treating isopropenyl bromide with the appropriate potassium phenolate. The rearrangement of the ethers was carried out by refluxing with a 10% solution by volume of sulfuric in glacial acetic acid.

Ortho Rearrangement.—The first point of attack was isopropenyl

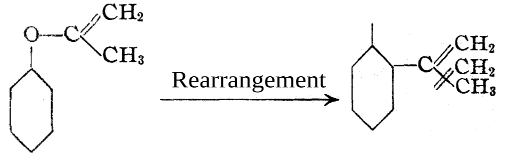
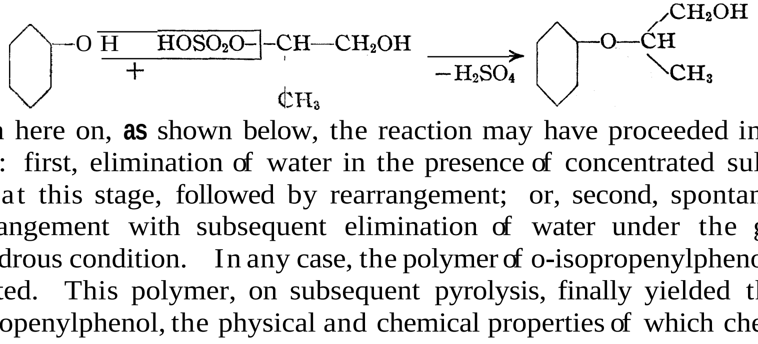
phenyl ether. Its rearrangement gave rise to a product, the main portion of which was identified as *o*-isopropenylphenol.[5] It yielded upon catalytic reduction *o*-isopropylphenol,[6] which was identified as *o*-isopropylphenoxyacetic acid.[7] The original isopropenylphenol yielded a crystalline hexabromo derivative which was different from the corresponding bromine derivative of *p*-isopropenylphenol, reported in the literature.[8] The above evidence suggests that ortho migration was favored and that the final product was o-isopropenylphenol.



This same product: was resynthesized from allyl alcohol and phenol in the presence of concentrated sulfuric acid in the cold. A polymer was obtained which on distillation gave o-isopropenylphenol, and the following mechanism explaining its formation has been shown to be a general one for addition of phenols to an ethylenic linkage, with sulfuric acid as the condensing agent.[9] The first step involved the addition of sulfuric acid to allyl alcohol with the formation of a-ally101 sulfate

$$CH_2{=}CHCH_2OH + H_2SO_4 \longrightarrow CH_3CH(CH_2OH)OSO_2OH$$

In the next step ether formation can be assumed to take place[10] with the formation of β-phenoxypropylene glycol



From here on, as shown below, the reaction may have proceeded in two ways: first, elimination of water in the presence of concentrated sulfuric acid at this stage, followed by rearrangement; or, second, spontaneous rearrangement with subsequent elimination of water under the given anhydrous condition. In any case, the polymer of o-isopropenylphenol was isolated. This polymer, on subsequent pyrolysis, finally yielded the *o*-isopropenylphenol, the physical and chemical properties of which checked with the material obtained upon the rearrangement of the isomeric ether and with the constants given in the literature.

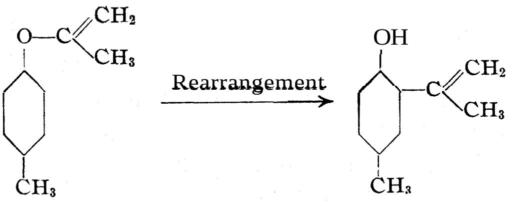
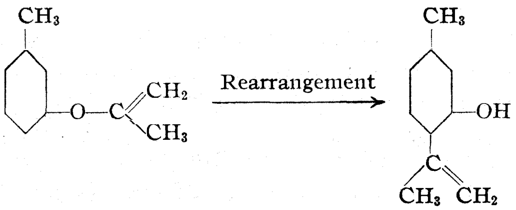
In the rearrangement of isopropenyl *p*-cresyl ether, the isopropenyl group could migrate to the ortho position only, the para position being occupied and meta rearrangement being unusual. The properties of the resulting product, 1-hydroxy-4-methyl-2-isopropenylbenzene, were in agreement with the literature.[11] As before, the same product was prepared from allyl alcohol and *p*-cresol in the presence of sulfuric acid. The compound obtained was identical with the one mentioned above and its formation by rearrangement may be represented as follows



The rearrangement of the isopropenyl m-cresyl ether resulted in a phenol which corresponded with the 3-hydroxy-1-methyl-4-isopropenylbenzene known in the literature.[11] The product obtained by the condensation of allyl alcohol and *m*-cresol was identical with the above. The phenol yielded a bromine derivative corresponding with the pentabromodehydrothymol (2,5,6,4^2,4^2-pentabromo-3-hydroxy-1-methyl-4-isopropenylbenzene) reported in the literature.[12] This evidence would tend to indicate that the isopropenyl group migrated to the ortho position.



This product was reduced catalytically first to thymol and further to a menthol.

---

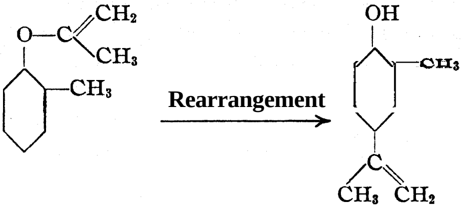
[11] (a) Fries and Fickewirth, Ann., 362, 46 (1908); (b) Guillaumin, Bull. soc. chim., [4] 7, 381 (1910).

[12] Baeyer and Seuffert, Ber., 34, 47 (1901).

It may be mentioned that in the case of the condensation of o-cresol and allyl alcohol an alkali-insoluble higher boiling liquid was obtained in small amounts as a by-product. The formation of such a compound is open to several interpretations, included among which are a dehydration reaction or possibly migration into the side chain ortho to the hydroxyl group[13] followed by ring closure.

Para Rearrangement.—The rearrangement of the isopropenyl *o*-cresyl ether yielded chiefly a product which proved to be the 1-hydroxy-2-methyl-4-isopropenylbenzene. A product obtained on condensing allyl alcohol with o-cresol was identical with it. As mentioned above, along with this main product in each case was isolated a small quantity of higher boiling, alkali-insoluble liquid.

Inasmuch as all the foregoing reactions showed the isopropenyl residue migrating in an ortho position to the hydroxyl group, the above case seems to show a peculiarity in that para rearrangement is favored.



Furthermore, this case is worthy of careful study since Hurd[14] states, "If either one of the ortho atoms of the aromatic nucleus is unsubstituted, the allyl group almost invariably migrates into the ortho position; if both, however, are substituted, para rearrangement occurs."

There have been cases recorded where although one or even both ortho positions were vacant, para rearrangement ensued.[3,4,15]

In attempting to establish the structure, the product obtained by the rearrangement of isopropenyl o-cresyl ether was reduced catalytically and the crude material on distillation at ordinary pressure yielded a colorless liquid the characteristics of which were in close agreement with 1-hydroxy-2-methyl-4-isopropylbenzene.[16]

On bromination of this reduced product and recrystallization of the reaction material from alcohol, there was isolated a crop of very characteristic lustrous, golden-yellow plates which resembled in physical appearance those described in the literature.[17] However, on continued purification

[17] Jesurun, *Ber.*, 19, 1414 (1886).

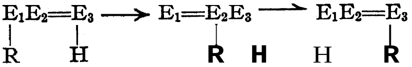
this product not only showed a higher melting point, but also analysis proved it to be a tetrabromo derivative.

The 1-hydroxy-2-methyl-4-isopropenylbenzene was itself further characterized by an acetic acid and a pentabromo derivative.

In conclusion, on the basis of the work done so far with the isopropyl, vinyl, and isopropenyl phenyl and cresyl ethers and the corresponding phenols, it appears that migration of the alkyl or alkenyl side chain ortho to the hydroxyl group is favored, except where one or both of the ortho positions are already occupied or are influenced by steric hindrance, then para rearrangement predominates.

As was previously stated, in view of these advances in the rearrangement of alkyl and alkenyl ethers a satisfactory reaction mechanism that would be in harmony with these experimental findings should be sought. Evidently, Claisen's mechanism[18] for the rearrangement of unsaturated alkyl phenyl ethers, in which the migration is claimed to take place through the gamma carbon atom, cannot be applied to the cases cited here due to the absence of the required atomic grouping. Hurd and Cohen's[19] suggestion of free radical formation would require the production of certain by-products, that so far could not be found, while Kursanov's[20] hypothesis of scission of the ether into an alkali halide and recombination with a nuclear carbon atom in the manner of the Friedel–Crafts reaction[21] is *a priori* out of the question for the cases cited. In consideration of the rearrangement mechanism offered by Van Alphen,[13] involving oxonium compound formation and the one advanced by Lapworth[22] for various other types of molecular rearrangements and already applied in the synthesis of thymol, its derivatives and homologs,[22a] the following reaction mechanism is herewith offered.

As the following arrangement of atomic groupings appears to be fundamental for the migration of the alkyl radical to the nuclear carbon atom ortho to the ether oxygen



$$\underset{R}{E_1}E_2{=}\underset{H}{E_3} \longrightarrow E_1{=}\underset{R}{E_2}E_3 \;\; H \longrightarrow \;\; H \;\; E_1E_2{=}\underset{R}{E_3}$$

it must be applicable to the cases presented herein. Where ortho rearrangement takes place, namely, isopropenyl phenyl, m-cresyl and #-cresyl ethers, the following reaction mechanism could be given. It should be noted that these ethers possess two of the active atomic groupings.

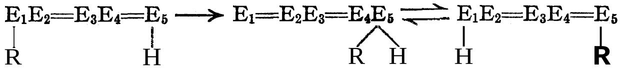
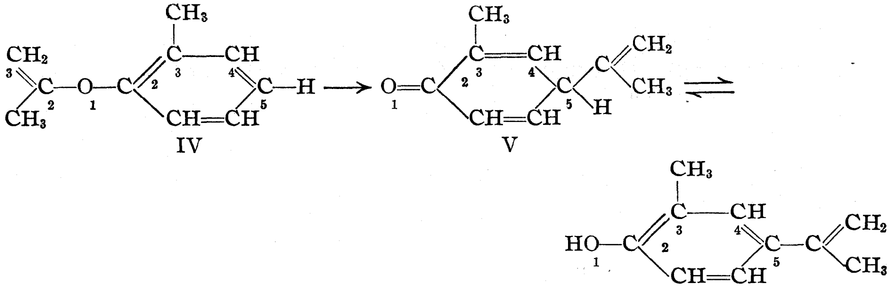
I II III

The original Lapworth theory must be extended to explain the formation of a para isomer.



$$\underset{R}{E_1}E_2{=}E_3\underset{H}{E_4}{=}E_5 \longrightarrow E_1{=}E_2E_3{=}\underset{R\ H}{E_4}E_5 \rightleftharpoons \underset{H}{E_1}E_2{=}E_3E_4{=}\underset{R}{E_5}$$

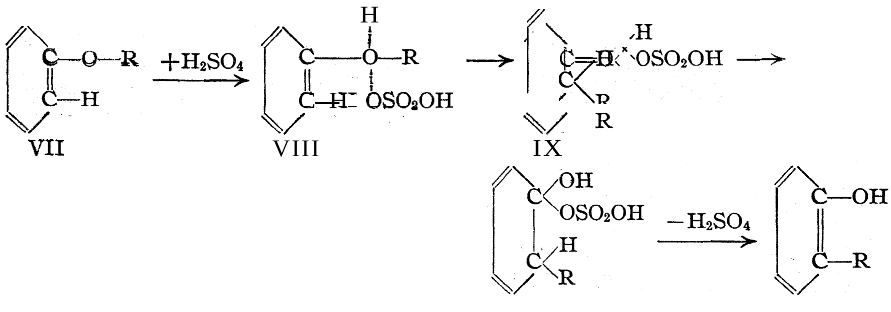
Applied to the case of the observed formation of the para isomer of isopropenyl o-cresol, the intramolecular rearrangement can then be illustrated in the following manner.



IV V VI

Quite obviously, the ether does not pass to the quinoid form (II) without some impulse; nor is it expected that the ether changes directly to the phenol, in spite of the fact that the phenol has a lower energy potential than the ether.. It is assumed therefore that the ether first passes to the intermediate structure II, at a higher energy level, from which it now readily goes to the phenol III, at the lowest energy level.

The impulse for the change from the ether to the intermediate compound is postulated as arising directly from an addition of sulfuric acid to the ether oxygen, forming a transitory phenyl isopropenyl oxonium sulfate (VIII) with a higher energy potential.



VII VIII IX

Related oxonium sulfates of ethers are known in the literature.[23]

The oxonium compound then passes to the more stable quinoid configuration (IX—similar to II). These quinoid addition compounds have been reported by Richter.[24]

The next step in the mechanism involves a change from the quinoid carbonyl addition compound to a still more stable one of a hemi-acetal structure (X). Hydrolysis with the elimination of sulfuric acid is brought about resulting in the final phenolic product (XI).

An effective rationalization of the suggested mechanism may be attained from a consideration of the repulsion energies of the atomic kernels in the bonds involved. The following scheme represents the changes in the bonds during the rearrangement.

$$\underbrace{(\mathrm{O—C}) + (\mathrm{C—H})}_{\text{VII. Ether}} \longrightarrow \underbrace{(\mathrm{O—C}) + (\mathrm{O—H}) + (\mathrm{O—O}) + (\mathrm{C—H})}_{\text{VIII. Ether oxonium compound}} \longrightarrow$$

$$\underbrace{(\mathrm{O—H}) + (\mathrm{O—O}) + (\mathrm{C—H}) + (\mathrm{C—C})}_{\text{IX. Quinoid carbonyl addition compound}} \longrightarrow \underbrace{(\mathrm{O—H}) + (\mathrm{O—C}) + (\mathrm{C—H}) + (\mathrm{C—C})}_{\text{X. Quinoid hemi-acetal}} \longrightarrow$$

$$\longrightarrow \underbrace{(\mathrm{O—H}) + (\mathrm{C—C})}_{\text{XI. Phenol}}$$

According to Latimer[25] the values of the repulsion energies expressed in kilocalories, in the above linkages are

(C—H)	550 kilocal.	(O—C)	2800 kilocal.
(O—H)	940 kilocal.	(O—O)	4550 kilocal.
(C—C)	1700 kilocal.		

Substituting these values in the above equation

$$\underset{\text{VII}}{3350} \xrightarrow[+5490]{} \underset{\text{VIII}}{8840} \xrightarrow[-1150]{} \underset{\text{IX}}{7690} \xrightarrow[-1700]{} \underset{\text{X}}{5590} \xrightarrow[-3350]{} \underset{\text{XI}}{2640}$$

It can now be seen that to pass from the ether (VII) to the oxonium compound (VIII) involves a gain of repulsion energy amounting to 5490 kilocalories, which appears to furnish the necessary impulse for the following changes. All the succeeding intramolecular rearrangements are accompanied by losses of repulsion energy amounting to 1150, 1760 and 3350 kilocalories, respectively, until the more stable phenol with the least intramolecular energy content is obtained.

This mechanism is not specific for a rearranging mixture of sulfuric and glacial acetic acids. Where boron trifluoride[4] or other substances have been used, the reaction mechanism may be postulated as being quite similar except that an addition of boron trifluoride takes place instead of sulfuric acid to form the transitory oxonium compound.

Furthermore, in isolated cases (allyl, cinnamyl and diisobutyl phenyl

[25] Latimer, THIS JOURNAL, 51, 4168 (1929).

ethers) where heat alone has been employed to effect rearrangement, the above mechanism offers a satisfactory explanation. Assuming the formation of oxonium compounds between identical molecules, then the succeeding transitory bimolecular addition compounds of the quinhydrone type may be formed and finally the substituted phenol is obtained.

In regard to the velocity of reaction in the rearrangement of alkyl and alkenyl phenyl ethers, work in this Laboratory with vinyl, isopropyl, isopropenyl, secondary-butyl and -amyl and diisobutyl phenyl ethers tends to indicate that the longer the wandering side chain (greater the molecule), the more rapid is the migration. On the basis of physical principles such a tendency may be explained as being due to the greater possibility of collision with larger molecules proceeding through the changes indicated by the above mechanism ("Zweistoss" system).

In the accomplished rearrangement of isopropenyl phenyl ethers, the postulated mechanism, based upon the changes in the inner energy potentials of the compounds suggested, is further enhanced by the fact that these migrations involve the passing from an isolated system of double bonds to a conjugated system. Examination of the structures I and IV indicates that the unsaturation of the alkenyl group of the ethers is not in conjugation with the double bonds in the cyclic nucleus, forming an isolated system. On the other hand, the phenol structures III and VI have the double bonds arranged in the form of conjugated systems. Henrich[26] states that substances which possess conjugated double linkages "are more highly saturated" than substances which possess two separate pairs of double bonds. This would account for the greater stability of the conjugated system and elucidates once more the tendency of the isopropenyl phenyl ethers to pass to the corresponding phenols under the proper conditions.

Experimental Part

Preparation of Isopropenyl Phenyl and Cresyl Ethers.—The isopropenyl phenyl and cresyl ethers were obtained by the action of isopropenyl bromide upon potassium phenolate (cresolate). 2,2-Dibromopropane was first prepared by the method of Friedel,[27] which consists in treating acetone with phosphorus dibromotrichloride. The dibromopropane was converted to isopropenyl bromide by the method of Réboul[28] whereby hydrogen bromide is eliminated by the use of sodium ethylate. The potassium phenolate was then prepared by adding a mole of potassium hydroxide to a mole of the phenol with mild heating. When a homogeneous system was obtained a mole of the isopropenyl bromide was slowly added and the whole refluxed for two hours. Water was then added to dissolve the potassium bromide, and the ether separated as a colorless liquid. On distillation at ordinary pressure the pure product was obtained.

Rearrangement of Isopropenyl Phenyl and Cresyl Ethers.—The ethers prepared

[28] Réboul, *ibid.*, [5] 14, 475 (1878).

in the above manner were rearranged according to the method found most satisfactory in this Laboratory for phenyl ethers.[29,15b] The ether was refluxed for five hours with a 10% solution of sulfuric acid in glacial acetic acid, where the quantity of sulfuric acid was equimolar to the ether. The reaction mixture was allowed to stand overnight. After transferring to a separatory funnel, a volume of salt solution somewhat greater than that of the reaction mixture was added and the liquid layer which separated was drawn off. This consisted of unrearranged ether and the substituted ether; this latter was extracted with a 10% caustic potash solution and reprecipitated with concentrated hydrochloric acid. An ether extract was made; this was dried with calcium chloride and the substituted phenol was obtained pure by distillation.

Preparation of Isopropenylphenols and Cresols by the Condensation Method.—The method employed in these condensations is a modification of that reported in earlier articles.[30] To a solution of molar quantity of allyl alcohol and of the phenol, a fifth mole of sulfuric acid was added drop by drop. The mixture was cooled in an ice-bath and well shaken throughout the addition of the acid. The reaction flask was then stoppered with a stopper containing a calcium chloride drying tube and slowly allowed to come to room temperature. After standing for one week, the reaction mixture, a hard reddish mass, was pulverized and then washed with cold water to remove unreacted allyl alcohol, sulfonic acids and sulfuric acid. The washed product, an orange-red solid was a polymer of the isopropenylphenol On distillation at ordinary pressure (slight decomposition took place), depolymerization was effected and a monomer was obtained as a colorless liquid which darkened on standing.

Catalytic Reduction of Isopropenylphenols and Cresols to the Corresponding Isopropyl Compounds.—With the use of a catalytic reduction apparatus a calculated quantity of hydrogen was allowed to react with a weighed sample of the unsaturated alkyl phenol in an absolute alcohol solution. A platinic oxide catalyst was employed. After the required amount of hydrogen had reacted the solution was decanted from the catalyzer, and the alcohol allowed to evaporate spontaneously, while the solution was kept free from dust. The resulting product was then fractionally distilled to yield the pure isopropylphenol.[31]

Preparation of Phenoxy and Cresoxy Acetic Acids.—Two grams of the substituted phenol was added to one gram of solid potassium hydroxide dissolved in 15 cc. of water. This mixture was warmed on a water-bath until complete solution took place. Two grams of bromoacetic acid was dissolved in 10 cc. of water and 3 drops of phenolphthalein added; 10% potassium hydroxide was then added until a permanent pink color was obtained. The two solutions were then mixed and gently boiled for ten minutes. When cool, the mixture was placed in an ice-bath and neutralized with concentrated hydrochloric acid. Precipitation in the cold avoids the formation of undesirable oils. If an oil was formed, it solidified on standing. The product was then recrystallized from water.

Preparation of Bromine Derivatives.—These were prepared by treating the pure phenol with an excess of bromine in the cold, without the use of a solvent. The whole was then allowed to stand until all the hydrogen bromide and excess bromine had evaporated. The dark mass was then transferred to a porous tile and washed suc-

[a] The lustrous, golden-yellow plates obtained were shown to be identical with the 2,4,5-tribromo-6-hydroxy-1-methyl-3-isopropylbenzene, melting point 223°, reported previously by Niederl and Natelson. THIS JOURNAL, 53, **1931** (1931). It is postulated that it is also identical with the 2,4,5-tribromo-6-hydroxy-1-methyl-3-isopropylbenzene, melting point 221°, reported by Jesurun, *Ber.*, **19**, 1414 (1886), who offered no analysis for the compound.

---

cessively with small quantities of benzene to remove the tarry material and last traces of bromine. Recrystallizations were then effected from alcohol or benzene.

The quantitative determinations were performed microanalytically according to Pregl.[33]

Summary

1. Short-chain alkenyl phenyl ethers (isopropenyl phenyl and cresyl ethers) were rearranged to the corresponding isomeric substituted phenols by means of a mixture of concentrated sulfuric and glacial acetic acids. Proofs for the structure of the products were advanced and a general rule as to the position of migration of the alkenyl side chain was postulated.

2. The rearranged products were resynthesized by the addition of the corresponding phenols to allyl alcohol. These extensions of this addition reaction show that addition of phenols to allyl alcohol is a general process.

3. A reaction mechanism was advanced for the rearrangement as well as for the addition reaction, involving the postulations of Van Alphen, Lapworth, Latimer and others.

4. The generally acknowledged rearrangement mechanism of Claisen for unsaturated alkyl phenyl ethers was found inapplicable to isopropenyl phenyl ethers. Preliminary work in the field of related compounds such as cinnamyl alcohol, cinnamyl chloride, the various cinnamyl phenyl ethers and esters, further indicate the insufficiency of the Claisen mechanism.

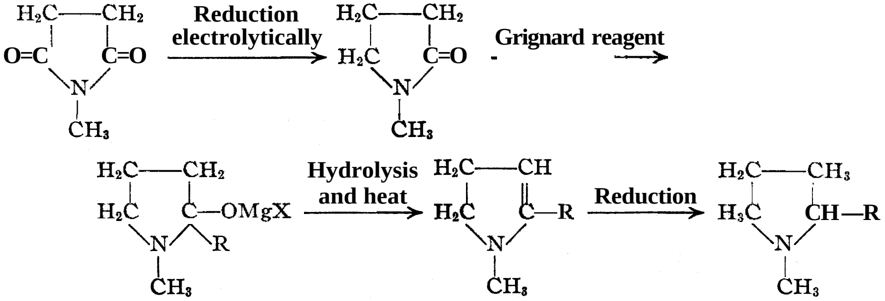
Synthesis of a Series of Alpha-Substituted N-Methylpyrrolines

BY LYMAN C. CRAIG[1]

Introduction

As part of a systematic study of structure and physiological action in the nitrogen heterocyclics it seemed desirable to prepare and study a series of a-substituted N-methylpyrrolidines. Although several members of the series have previously been prepared a suitable general method of synthesis was lacking.

Loffler[2] prepared several of the aliphatic members of the series by ring closure of a-substituted butylmethylamines but LaForge[3] was not able to effect ring closure of 1-methylamino-1-phenylbutane by the same method. Methylation of the corresponding a-substituted pyrrolidine offers another possibility since a general method of synthesis of a-substituted pyrrolidines has been given[4] but methylation of heterocyclic nitrogen is usually a poor and oftentimes impossible procedure from a synthetic standpoint. The following synthesis was proposed in this Laboratory and proved satisfactory for the preparation of the compounds in the quantity desired.



The α-substituted N-methylpyrrolines are intermediates in the above synthesis. As these compounds have been little studied[5] it seemed well to report their synthesis and properties in a separate preliminary paper.

a-Methylpyrroline has been found by Marz[6] to react with hydroxylamine, semicarbazide and phenylhydrazine in aqueous solution. The following equilibrium has been postulated to account for the reaction.

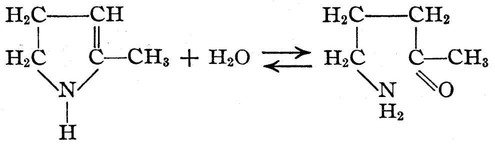
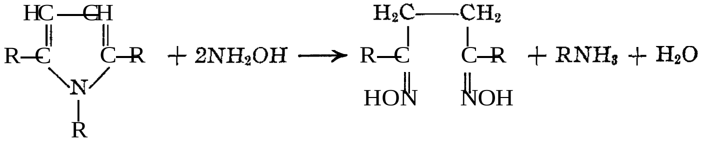
(6) Marz, Diss. Techn. Hochsch.. München, 1913.

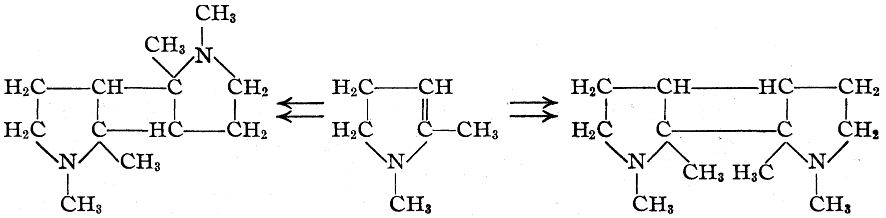


The same equilibrium has been found in the case of the analogous tetrahydropyridine series.[7] However, the compounds prepared in this Laboratory did not appear to exhibit the equilibrium. None of the series gave any indication of a reaction with semicarbazide or phenylhydrazine. When added to a solution containing equivalent quantities of hydroxylamine hydrochloride and potassium carbonate all of the derivatives readily dissolve but this fact cannot be taken as evidence for an equilibrium in the aqueous solution of the compound. A curious reaction of pyrrole derivatives with hydroxylamine according to the equation



has long been known.[8] It is only logical to expect that the half reduced pyrrole will act similarly with regard to the unreduced half of the ring. a-Methyl-N-methylpyrroline is the only member of the series that is soluble to any extent in water. All the other derivatives, when shaken with water and the layers separated, show little if any water to be present in the oily layer.

a-Methyl-N-methylpyrroline is the only member of the series which does not distil normally. Its behavior upon distillation can best be explained by a reversible polymerization to a dimer according to either or both of the following equations



This view is supported by the behavior of the compound upon reduction. The reduction products contain a 45% yield of a-methyl-N-methylpyrrolidine but also a 50% yield of a compound boiling at 132–134° (20 mm.). Analysis shows the compound to have the empirical formula $(C_8H_{12}N)_n$ which corresponds with that of the dipyrrolidine expected from either of

the two postulated dimers if the unstable cyclobutane ring is ruptured. It has been shown by Lipp[9] that the analogous compound N-methyltetrahydropicoline polymerizes to a dimer which dissociates again quite easily.

As a class the a-substituted N-methylpyrrolines are all unstable and quickly develop a deep red color after distillation when exposed to the atmosphere. However, they may be preserved colorless indefinitely if carefully sealed in ampoules with the exclusion of air. They are soluble in all organic solvents but insoluble in water with the exception of a-methyl-N-methylpyrroline, which is soluble in almost all proportions. They have a characteristic unpleasant odor.

Reduction of the series of a-substituted N-methylpyrrolines will be reported in a later paper.

The writer wishes to thank Professor E. Emmet Reid for his encouragement and advice during this work.

Experimental

Synthesis of N-Methyl-a-pyrrolidone.—This compound was first synthesized by Tafel and Wassmuth;[10] later by Spath and Bretschneider.[11] They reduced succinimide electrolytically at a lead cathode using a high current density. The resulting pyrrolidone was converted to the sodium derivative and methylated with methyl iodide or sulfate. A much more convenient synthesis is the electrolytic reduction6 of N-methylsuccinimide[12] by the method of Tafel and Stern.[13] The reduction product is isolated from the 50% sulfuric acid solution by a continuous extractor which is a modification of the Soxhlet extractor designed to extract aqueous solutions by chloroform. This method of isolation almost doubles the yield obtained by the method of Lukes.[5] Fractionation of the chloroform extract gives a yield of 80% of the theoretical amount of N-methyl-a-pyrrolidone boiling at 94–96" (20 mm.) and a small amount of unreduced succinimide.

Synthesis of a-Substituted N-Methylpyrrolines.—The Grignard reagent is prepared in the usual way using 2 moles of RX. One mole of pyrrolidone in an equal volume of ether is added dropwise. The mixture is allowed to stand overnight and hydrolyzed with an equivalent of hydrochloric acid. The aqueous layer is treated with excess sodium hydroxide solution and steam distilled. The base recovered from the distillate is dried over solid potassium hydroxide.

TABLE I

Compounds		Analysis, % Calculated C	H	Found C	H
α-Phenyl-N-methylpyrroline	$C_{11}H_{13}N$	82.4	8.24	82.7	8.5
α-*n*-Butyl-N-methylpyrroline	$C_9H_{17}N$	77.5	12.3	77.3	12.2

TABLE II

Compounds	Yield, %	B. p., °C.	Picrate	Oxalate
a-Phenyl-N-methylpyrroline	70	105–109 (11 mm.)	M. p., 139°	M. p., 138"
a-n-Butyl-N-methylpyrroline	54	86–87 (30 mm.)	M. p., 66°	Oil
a-n-Propyl-N-methylpyrroline	50	176–177	Oil	Oil
a-Ethyl-N-methylpyrroline	53	148–149	M. p., 114°	Oil
α-Methyl-N-methylpyrroline	50	130–131	Decd. upon heating	Oil

The measurement of other physical properties of the series is impracticable due to the speed with which the colorless freshly distilled base decomposes or reacts with the atmosphere. a-Methyl-N-methylpyrroline does not always distil in the same way in separate preparations. While in one run it distils completely at 130°, in another it cannot be distilled at atmospheric pressure. This run, at 30 mm. pressure does not give a well-defined distillation but the entire lot distils over, the temperature reaching as high as 140° (30 mm.) depending on the rate of distillation. The entire distillate comes over at 125–130° at atmospheric pressure when immediately redistilled.

Hielscher[14] first prepared a-methyl-N-methylpyrroline by ring closure of $CH_3COCH_2CH_2CH_2NHCH_3$. He reported that the compound could not be distilled under atmospheric pressure but gave no explanation of its instability. LaForge[3] reported the preparation of α-phenyl-N-methylpyrroline. The properties of a-n-propyl- and a-ethyl-N-methylpyrroline correspond substantially with those reported by Lukes.[5] α-*n*-Butyl-N-methylpyrroline could not be found in the literature.

Summary

N-methylsuccinimide was reduced electrolytically and N-methyl-α-pyrrolidone recovered in a yield of 80% of the theoretical.

A series of a-substituted N-methylpyrrolines have been prepared and their properties discussed. a-Substituted N-methylpyrrolines were not found to react with water in aqueous solution to give amino ketones and an explanation of the reaction with hydroxylamine in aqueous solution has been given.

α-Methyl-N-methylpyrroline has been shown to polymerize to a dimer which dissociates again quite easily.

Structure of Reactants and the Extent of Acetal Formation

BY NELS MINNÉ AND HOMER ADKINS

A study of the relationship between the concentration at equilibrium in the acetal reaction and the structure of the alcohol and aldehyde has been continued, particularly with reference to the effect of the structure of the alcohol upon the extent of its reaction with tetrahydrofurfural.[1,2] The object of the experimentation was to measure the effect of various typical structures upon carbon to oxygen linkages.

Tables I and II contain a summary of all the reliable data, obtained in this Laboratory during the past ten years, upon the effect of the structure of the alcohol and aldehyde upon the conversion at equilibrium in the acetal

[1] Adkins and Wade Adams, THIS JOURNAL. 47, 1368 (1925); Hartung and Adkins. *ibid.*. 49, 2517 (1927); Street and Adkins, *ibid.*. 50, 162 (1928); Adkins and Broderick. *ibid.*, 50, 178 (1928); Adkins, Semb and Bolander, *ibid.*, 53, 1853 (1931).

[2] There has apparently been little done outside of this Laboratory upon the effect of the structure of the reactants upon the concentration at equilibrium in the acetal reaction. Attention should, however, be called to the very extensive studies of Skrabal and co-workers upon the rate of hydrolysis of acetals in rather dilute water solutions [Z. *Electrochem.*, 33, 322 (1928), and *Z. physik. Chem.*, 122, 357 (1926)]. The work of Herold and Wolf [*ibid.*, B5, 124 (1929), B12, 165 (1931)] upon the extent of hemiacetal formation as measured by absorption in the ultraviolet is also of interest. Their observations upon the effect of structure upon the extent of the hemiacetal reaction are, for the fifteen cases which they studied, in general agreement with the observations made in this Laboratory upon the extent of the acetal reaction with the same pairs of reactants. However, their prediction that the alcohols of higher molecular weight would show a decreasing affinity for acetal formation is not borne out by observations herewith reported. Further, their view that the efficacy of calcium chloride as a catalyst for the acetal reaction is due to its removing water from the sphere of reaction is not in accord with the results previously reported [Adams and Adkins, THIS JOURNAL, 47, 1358 (1925)] upon experiments intended to test out that hypothesis. They have apparently overlooked this paper as well as another upon hemiacetal formation [Adkins and Broderick. *ibid.*. 50, 499 (1928)].

value of K_e. The observer of each reaction mixture has been indicated by a letter placed after the percentage conversion for the acetal (**A** for Adams B for Broderick, Bl for Bolander, H for Hartung, M for Minné, S for Street and Sb for Semb).[3]

One of the primary objects of this investigation was to ascertain whether, if an alcohol, for example, gave the same percentage conversion at equilibrium with two aldehydes, a second alcohol would give the same conversion with one aldehyde as with the other. In seeking an answer to this question nineteen alcohols have been tested with acetaldehyde and tetrahydrofurfural. Among these there is fair agreement in fifteen cases between the values of K_e for the reaction of the alcohol with the two aldehydes. With eight of these fifteen alcohols there is almost perfect agreement, that is to say, the percentage conversion at a given ratio of reactants is not more than 1% different for one aldehyde than for the other. However, the four secondary and tertiary alcohols listed below show a very different conversion with acetaldehyde as compared with tetrahydrofurfural: cyclohexanol, 56 and 88%; butanol-2, 46 and 65%; octanol-2, 46 and 90%; *tert.*-butyl, 23 and 38%. These results indicate very definitely that the relative affinity manifested by two compounds for the formation of a given type of linkage is not independent of the second component of the reaction.

The effect of lengthening the chain of the alcohol is not so clear in the case of the data for acetaldehyde as it is for tetrahydrofurfural, since most of the determinations for the former aldehyde were made for such a high ratio of alcohol to aldehyde that the conversions for this type of alcohol are so high that small differences between alcohols are not apparent. The values of K_e for tetrahydrofurfural and the primary alcohols with normal chains and the carbon content indicated in parentheses are: (1) 2.34, (2) 1.26, (3) 1.44, (4) 1.44, (5) 3.55, (7) 9.48, (8) 9.48, (12) 4.03. The values for the same aldehyde with three secondary alcohols are propanol-2, 0.166; butanol-2, 0.47; and octanol-2, 4.03. Somewhat similar values hold for the reaction of four secondary alcohols with acetaldehyde. These values

---

[3] All of the values for K_e reported by Adams, Broderick, Hartung and Street have been recalculated and a majority of them have been checked by experiment if two observers had not previously done so. The values of K_e were recalculated upon the basis of concentrations expressed in mole fractions. The values of K_e reported in the earlier papers were calculated upon concentrations of moles per liter and comparisons between aldehydes made upon the calculated values of the decrease in free energy. These original calculations were ill advised for two reasons. First, compounds which show the same percentage conversion but have a different molecular volume will have therefore different values of K_e, and so appear to have different affinity values when as a matter of fact they are identical in their chemical behavior in the acetal reaction. Second, the use of values for the decrease of free energy so calculated adds nothing significant to the comparison of aldehydes and alcohols in the acetal reaction and is open to misinterpretation.

indicate that affinity in acetal formation first decreases slightly with increase in length of the carbon chain and then materially increases.

Simple branching of the chain has relatively little effect upon the extent of the acetal reaction. Isobutyl alcohol with acetaldehyde and *n*-butyraldehyde shows values which are not essentially different from those for butanol-1. Isobutyraldehyde has a lower value than n-butyraldehyde but very little lower than propionaldehyde, which has the same length of chain. However, branching of the carbon chain as exemplified in the cyclohexyl group is rather effective in lowering affinity for acetal formation. Five moles of cyclohexylcarbinol reacted with one mole of acetaldehyde to the extent of only 56% while hexylcarbinol, having the same carbon content, reacted to the extent of 92%. A similar negative though less marked effect of the cyclohexyl group was observed in the reaction of cyclohexylcarbinol with isobutyraldehyde. It was surprising that cyclohexylcarbinol reacted to a less extent with acetaldehyde than did phenylcarbinol despite the unsaturation and general negative character of the benzenoid nucleus.

The effect of an alkene linkage in a molecule either of an alcohol or an aldehyde, but especially the latter, was very marked in lowering affinity for the acetal reaction. Tetrahydrofurfural with ethanol had a value of K_e of 1.26, while furfural had less than one-half the percentage conversion with a value for K_e of 0.041. Propionaldehyde and butyraldehyde had 1.21 while the corresponding unsaturated aldehydes had 0.176 (acrolein) and 0.011 (crotonaldehyde). Benzaldehyde was almost identical with acrolein, and cinnamic aldehyde with crotonaldehyde. Unsaturation in the alcohol was apparently much less effective, as allyl alcohol was 0.54 with acetaldehyde, and 0.77 with tetrahydrofurfural, values which are not so much lower than for propanol-1, *i.* e., 1.06 and 1.44.[4]

The primary alcohols, if there were no complicating substituent, reacted with acetaldehyde to the extent of about 90% at a ratio of one mole of aldehyde to 5 moles of alcohol, while secondary alcohols gave conversions less than one-half as great. Simple tert. alcohols reacted with acetaldehyde to about one quarter the extent of the primary alcohols, the value of K_e for n-butyl, *sec.*-butyl and *tert.*-butyl being 3.08, 0.136 and 0.019, respectively. However, with alcohols and aldehydes of more complicated structure these relationships are far from being so simple. For example, cyclohexylcarbinol, a primary alcohol, behaved like a *sec.* alcohol in its reaction with acetaldehyde and isobutyraldehyde, having values of K_e of 0.26 and 0.100. Similarly octanol-2 behaved like a simple secondary alcohol with acetaldehyde (K_e 0.130) but with tetrahydrofurfural it had a value of 4.03, which is materially higher than that shown by the simple

---

[4] It must be kept in mind that while unsaturation *decreased* the extent of the acetal reaction it greatly *enhanced* the rate of the reaction. Furfural, for example, reacted several hundred times as rapidly as tetrahydrofurfural under the same conditions but it proceeded less than one-half as far.

primary alcohols. Octanol-2 also gave a higher conversion with benzaldehyde than did any of the primary alcohols. In contrast with the abnormally high value of octanol-2 for benzaldehyde and tetrahydrofurfural was its abnormally low value (0.003) for furfural, with which it reacted to less than half the extent of propanol-2.

The effect of the phenyl group upon the acetal reaction might be ascribed to a combination of unsaturation and branching of the carbon chain but it seems simpler to regard it as a substituent. If the phenyl group in benzyl alcohol is regarded as substituted in methanol, then it had a small influence in decreasing the reaction with acetaldehyde or tetrahydrofurfural to the extent of about 7%. However, when substituted in ethyl or propyl alcohol the phenyl group increased the extent of the acetal reaction just as did the corresponding large alkyl groups. When directly attached to the aldehyde group as in benzaldehyde, the affinity of the aldehyde for acetal formation was low, being only 56% with 11 moles of ethanol to 1 mole of benzaldehyde, and not much greater than that given by furfural. When the phenyl group was further from the aldehyde group, as in cinnamic aldehyde, it was almost without effect since crotonic and cinnamic aldehydes gave approximately the same conversions with ethanol.

Certain substituents in ethanol show the following values of K_e in the reaction with acetaldehyde: iodo the same as the unsubstituted ethanol, 1.21, chloro 1.06, methoxy and ethoxy 0.94, bromo 0.76, nitro 0.52, and carbethoxy 0.155. When some of these groups were substituted in acetaldehyde they showed the following values for K_e in the reaction with ethanol: amino 1.63, cyano 1.30, bromo 1.21 and chloromethyl 0.56. The most striking effect was the negativity of the cyano group in β-cyanoethyl alcohol (ethylene cyanohydrin), which reacted with tetrahydrofurfural to the extent of only 32% ($K_e = 0.045$).

The extents of the reactions of the three methylcyclohexanols with tetrahydrofurfural were also determined. Samples of the three structural isomers (each a mixture of geometrical isomers) were obtained from the Eastman Kodak Company and upon fractionation showed the following boiling points: 2-methylcyclohexanol 162–163.5°, 3-methylcyclohexanol 168.5–170°, 4-methylcyclohexanol 169.5–171.5°. These compounds just after distillation gave the following conversions to acetal when allowed to react (5 moles) with tetrahydrofurfural (1 mole): 2-methylcyclohexanol 85%, 3-methylcyclohexanol 50% and 4-methylcyclohexanol 60%. Samples of the 2-methyl and the 4-methyl compound prepared in this Laboratory by hydrogenation of the corresponding phenols over nickel at 175°, 120–200 atmospheres, and having the same boiling points as the Eastman products, gave conversions in the acetal reaction of 87 and 82%, respectively. The first of these values is in good agreement with that obtained with the Eastman product while the value for the 4-methyl compound is

22% higher than previously observed. Moreover, the sample of the 3-methyl compound gave, when allowed to stand for several months after distillation and before use, a conversion of 68%, or 18% higher than when freshly distilled. All of these variations are understandable since it is well known that different methods of hydrogenation produce different proportions of isomers, and that one geometrical isomer is labile, so that changes in their proportion may occur on standing. The conclusion seems inescapable that different geometrical isomers show different affinity values for acetal formation although this must be confirmed by ascertaining the affinity for acetal formation of the pure cis and *trans* isomers of the three structurally different methylcyclohexanols.[5]

Experimental Part

Tetrahydrofurfural has apparently not hitherto been prepared in any considerable quantities. Scheibler, Sotscheck and Friese[6] prepared as much as 6 g. of "crude product" in a single experiment and unreported amounts of a relatively pure compound. The quantities needed for the investigation described herewith were relatively large so that it was necessary to make a thorough study of its preparation. Bolander[1] worked out the first step, *i.* e., the preparation of furfural acetal. The procedure for the hydrogenation of furfural acetal in good yield to tetrahydrofurfural acetal over a nickel catalyst was developed by Covert and Connor.[7] The third step in the preparation of the desired aldehyde, that is, the hydrolysis of tetrahydrofurfural acetal, proved to be a difficult one because of the readiness with which the aldehyde is resinified and also because of the difficulty of separating it from the alcohol and water in the mixture after hydrolysis. It appears unnecessary to give a detailed account of the various modifications of the procedure which were made in developing a satisfactory process, so it must suffice to describe briefly the preferred procedures.

One mole (174 g.) of diethyl tetrahydrofurfural acetal with 15 moles of water (270 g.) and 0.015 g. of hydrogen chloride were placed in a 2-liter 3-necked flask provided with a reflux condenser, a mechanical stirrer with a mercury seal, and a thermometer. The reaction mixture was heated on a steam-bath at 80° with stirring for five to ten hours, the mixture being homogeneous after about one hour. When hydrolysis was complete, as determined by a titration of an aliquot by the sodium sulfite method, the hot solution was left just acid to litmus by almost neutralizing with solid sodium carbonate (about 0.5 g.). It was found advisable to calculate the amount of sodium carbonate necessary by titrating an aliquot with 0.02 N sodium carbonate solution using methyl orange as an indicator. The reaction mixture was then rapidly cooled and 150 g. of anhydrous sodium sulfate added. After several hours the liquid was filtered off the sodium sulfate and another portion of the drying agent added. The process was repeated until 500 g. of sodium sulfate had been used, the drying process requiring twenty-four hours. The dried product was then fractionated at 6–10 mm. from a 250-ml. flask through a Widmer column having a spiral 24 cm. in length. The fraction 25–35" was about 60% aldehyde, while that from 35–45" was fairly pure. The lower fraction was dried with sodium sulfate together with the aldehyde (5–10 g.) extracted with ether from the 500 g. of sodium sulfate used earlier in the process. All the aldehyde was then carefully refrac-

---

[5] The separation of the isomers has just been reported. Skita and Faust, *Ber.*, 64B, 2878 (1931); Hückel and Hagenguth, *ibid.*, 2892.

[7] Covert, Connor and Adkins, THIS JOURNAL, 54, 1655 (1932).

tionated, from 35 to 50 g. being obtained, b. p. 35–37° (8 mm.). The excess water may also be largely removed by fractionation at 25–32° (13–15 mm.) through a Widmer column having a spiral 35 cm. in length and the residue dried as described above. About 15–20% of the aldehyde was lost in the water distillate but the yield of aldehyde obtained was about the same as by the less tedious process described above.

The yield of diethyl furfural acetal from furfural was from 15 to 20%, the yield of the tetrahydrofurfural acetal was 75 to 80%, while the conversion of the latter to tetrahydrofurfural in eight preparations was 35 to 50%. This is an over-all yield of 4 to 8% of tetrahydrofurfural based upon the furfural.

Tetrahydrofurfural is a colorless, somewhat viscous liquid of acrid though not sharp odor. It has the following constants: b. p 144–145° corr. (740 mm.); d_4^{25} 1.10947, n_D 1.4700 to 1.4708; M_D 24.54, calcd., 24.72. Samples of the aldehyde during the course of several weeks became yellow, solid particles appeared and formic acid was apparently produced. The aldehyde showed no signs of change at 20–25° in a desiccator during the course of a week. Scheibler, Sotscheck and Friese in their first publication on tetrahydrofurfural gave the following constants: b. p. 45–47" (29 mm.), b. p. 142–143' (779 mm.), d_4^{20} 1.0501, *n*, 1.47036, M_D 26.60. In their second paper they report d_4^{20} 1.0727, n_D 1.43658, M_D 24.43. The writers found that products of n_D 1.4330 to 1.4350 showed a lower tetrahydrofurfural content by titration than did the product n_D 1.4700–1.4708.

Di-(β-Ethoxyethyl) Acetal of **Tetrahydrofurfural.**—The di-(β-ethoxyethyl) acetal of furfural was prepared from furfural and β-ethoxyethanol (cellosolve) by the method described for the diethyl acetal. Three moles of furfural, 18 moles of cellosolve and 0.0036 g. of hydrogen chloride were allowed to react for four days until the conversion to the acetal was 40% of the theoretical. The water, cellosolve and furfural were then largely removed by distillation up to 76° at 18 mm. through a Widmer column. The residue was then fractionated at 2 to 4 mm. through a heated Widmer column. A yield of 212 g. of acetal (27.4%), b. p. 131–132° (2 mm.), 259" (740 mm.) was obtained.

The acetal (104 g.) was hydrogenated during the course of four hours at 150°, 130–200 atm., over 4 g. of a nickel catalyst of the ammonium carbonate type.[4] The product was fractionated twice through an electrically heated Widmer column. Twenty-eight grams (69%) of di-(β-ethoxy ethyl) acetal of tetrahydrofurfural, b. p. 131–136" (4–5 mm.), was obtained. There was an additional yield of slightly impure material corresponding to 8%. The compound was analyzed not only for carbon and hydrogen (see Table III) but a weighed sample was also subjected to hydrolysis and the tetrahydrofurfural so produced titrated. The amount of aldehyde formed was 98.8% of the amount calculated from the weight of acetal taken. Cellosolve (4.5%) (0.044 mole) and the β-ethoxyethyl ether of tetrahydrofurfuryl alcohol (6.7%) (0.040 mole) were also produced during the process of hydrogenating the acetal of furfural. The correspondence in molecular equivalents of cellosolve and ether formed indicates that these two compounds may be considered to be formed as in the hydrogenation and splitting of ethyl furfural acetal.[4]

Determination of the Concentration of Aldehydes.—The sodium sulfite method of titration was used for the determination of all the aldehydes except benzaldehyde, for which the hydrogen peroxide method was used. The acid solution for the sulfite method was not only standardized against the appropriate aldehyde but in the presence of the alcohol which would be in the sample later submitted to analysis. The ratio of alcohol to aldehyde in the sample used for standardization should be the same as that in the sample to be analyzed. The importance of this is evidenced by the following. A solution of sulfuric acid which was 0.202 *N* against sodium carbonate was 0.241 N against furfural, 0.2335 N against tetrahydrofurfural and 0.222 N against acetaldehyde, in the presence of ethanol. However, in the presence of an alcohol (in the ratio of alcohol to aldehyde which existed at equilibrium starting with the reactants in a 5 to 1 ratio) the normality figure for tetrahydrofurfural must be multiplied by 1.008 for cellosolve, 1.22 for heptyl, 1.72 for benzyl, 1.85 for phenylethyl and 3.64 for phenylpropyl alcohol. The factor for furfural in the presence of heptyl alcohol was 1.19 and 1.18 for octanol-2.

The procedure used in carrying out the studies on concentration at equilibrium was essentially the same as that previously described except in a few particulars. In the case of acetaldehyde a known weight of the aldehyde was sealed up in a glass tube and cooled to 0° before it was introduced into the alcohol. In the case of acetaldehyde, n-butyraldehyde and isobutyraldehyde, a titration was made to ascertain the exact concentration of the aldehyde in the alcohol solution before the catalyst was added. The concentration of the catalyst, hydrogen chloride, was 5 milligrams per mole of aldehyde except that in order to secure a sufficiently rapid rate of reaction 100 milligrams of hydrogen chloride per mole of tetrahydrofurfural was used

Homogeneity of the Reaction Mixtures.—All of the reaction mixtures contained a considerable excess of alcohol over that required for the formation of an acetal. This was in order to prevent the separation of water formed in the reaction. However, the solubility of water in some of the alcohols of higher molecular weight is sufficiently low that it was feared that the high conversions to acetal observed were due in part to the separation of water. However, observations of the reaction mixture under a microscope at a magnification of 350 diameters, even after long standing, failed to show any lack of homogeneity. The solubility of water was found to be greater than 1 ml. in 25 ml. of heptanol-1, or 37.5 ml. of octanol-2. The amount of water formed by the reaction of either of these alcohols with tetrahydrofurfural never exceeded 1 ml. of water in 45 ml. of alcohol, so there seems no reason to doubt that the reaction mixtures were in all cases homogeneous.

Hydrolysis of Acetals.—There has never been any evidence for false equilibria or side reactions under the conditions of these studies. However, the extent of hydrolysis of the diethyl acetals of furfural and of tetrahydrofurfural and of the di-(β-ethoxyethyl) acetal of tetrahydrofurfural was determined. For example, 0.091 mole of diethyl furfural acetal. 0.091 mole of water, 0.27 mole of ethanol and 0.000465 g. of hydrogen chloride were allowed to react at 25°. Thirty-five per cent. of the acetal was hydrolyzed after twenty-five minutes, 55% after fifty minutes and 66% at the end of one and one-half hours; reaction ceased with a total hydrolysis of 67% of the acetal. This value is in excellent agreement with that for synthesis under similar conditions, although less than thirty minutes was required for the completion of synthesis

Similar experiments were conducted with the acetal of ethanol and of cellosolve with tetrahydrofurfural. The ratio of reactants was 0.01 mole of acetal, 0.03 mole of alcohol, 0.01 of water and 0.001 g. of hydrogen chloride. Hydrolysis had proceeded to equilibrium after about one month. In the case of cellosolve the hydrolysis was 20 to 22%. while for ethanol it was 20 to 21%. These experiments demonstrate again the enormous difference in the rate of reaction of furfural as contrasted with the saturated aldehydes, and also the greater speed of synthesis as compared with hydrolysis.

Isolation of Various Acetals.—Small amounts of a number of acetals of tetrahydrofurfural were isolated, from the reaction mixtures set up for the purpose of determining the extent of the reaction, in essentially the same manner as the ethyl acetal. These products were fractionated as carefully as the small quantity of material involved would permit but in a few cases they were perhaps not entirely free of the alcohol involved. Qualitative tests showed them in every case to be free of tetrahydrofurfural. Their boiling points were in general determined by the capillary tube method described by Kamm[8] except that the determination was made under reduced pressure. The sam-

---

ple was placed in a test-tube 1 cm. in diameter, which was attached to a small reflux condenser the outlet from which led to a vacuum pump. The data on the analysis and certain of the physical constants of these and other compounds not hitherto described are given in Table III.

Time for Attainment of Equilibrium.—The alcohols and aldehydes were allowed to react in a thermostat at 25°. The reaction of furfural and some of the other unsaturated aldehydes was complete after an hour or two, the saturated aldehydes other than tetrahydrofurfural after two days, while the latter required six to eight days. Titrations were usually begun after two days and continued at intervals of two days until variations in analyses were less than 0.5%. In many cases titrations made after several months confirmed the fact that equilibrium was attained in almost all cases after ten days. It was interesting to observe that tetrahydrofurfural, which in the pure state began to deteriorate after a week or so, appeared to remain unchanged for many months in the presence of alcohol.

Purification **of** Reagents.—The alcohols and aldehydes, other than those that have been described in the preceding paragraphs, were purified as previously described in this series of papers or by standard methods.

Reliability of Data in Tables I and II.—An experienced operator can readily duplicate analyses for aldehyde to within 0.5%, and duplicate his observations on the percentage conversion of an aldehyde to its acetal in different reaction mixtures to within less than 1%. In many cases, as indicated in the tables, different operators have observed percentage conversions which agreed to within less than 1%. However, it seems safer to attach no significance to variations in extents of conversion of less than 3%. The value of K_e changes very rapidly with small changes in the percentage conversion, so that if the latter is very high (93–95%), little significance should be attached to *variations* of K_e. The data on representative acetals presented by Semb and Bolander and in this paper show that the value of K_e is independent of the ratio of reactants and thus is a

true equilibrium *constant. The redetermination and recalculation of results previously reported have led to the elimination as unreliable of the values previously given for isoamyl, β-phenylethyl and benzyl acetals of acetaldehyde, and for the n-butyl acetal of butyraldehyde. The percentage conversions reported for the first time in this paper represent on the average six analyses of three different reaction mixtures at equilibrium.

Summary

The extent of reaction of tetrahydrofurfural with a variety of alcohols has been determined and the extent of the reaction of a number of other aldehydes and alcohols has been determined or redetermined and all previous results on the extent of this reaction have been recalculated to a comparable basis. All of these results on the relation of structure to affinity in the acetal reaction have been summarized as briefly as is feasible in Tables I and II and in the ensuing discussion.

The relative reactivity of the secondary and tertiary alcohols with acetaldehyde and tetrahydrofurfural, and the behavior of cyclohexylcarbinol and the three methylcyclohexanols with acetaldehyde all point to an important conclusion, *i. e., the spacial characteristics of a molecule may be an important factor in determining the binding power at a linkage, just as it has long been known that space relationships may modify the rate at which a reaction proceeds. In other words, steric as well as structural factors determine the strength of bonds.*

A process has been developed for preparing tetrahydrofurfural of excellent quality in fair yields. A number of acetals not hitherto described are reported.

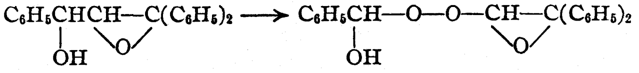
The Autoxidation of Certain Ethylene Oxides

BY E. P. KOHLER AND E. M. NYGAARD

In a recent paper we reported that when α,α-diphenyl-β-(hydroxybenzyl) ethylene oxide is exposed to the air it is oxidized to a peroxide.[1]

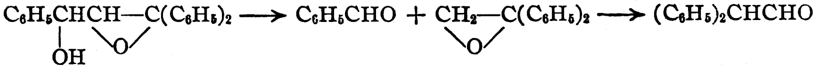


$$\underset{\substack{|\\ \mathrm{OH}}}{\mathrm{C_6H_5CH}}\underset{\diagdown\mathrm{O}\diagup}{\mathrm{CH{-}C}}\mathrm{(C_6H_5)_2} \longrightarrow \underset{\substack{|\\ \mathrm{OH}}}{\mathrm{C_6H_5CH}}\mathrm{{-}O{-}O{-}}\underset{\diagdown\mathrm{O}\diagup}{\mathrm{CH{-}C}}\mathrm{(C_6H_5)_2}$$

This peculiar case of autoxidation first aroused our interest because it was erratic, some specimens apparently being perfectly stable in the air while others, which had been prepared in the same manner, were oxidized with sufficient rapidity to cause a perceptible rise in temperature. Another incentive to further investigation appeared when the structure of the oxidation product was definitely established, showing that the substance is a peroxide of the type that is usually obtained from free radicals.

We have found that the erratic character of the oxidation is not due to differences in the purity of the oxide but to variations in the quality of the air. No oxidation occurs either in air containing a trace of ammonia or in air that has been washed with bases, but when a little hydrogen chloride is added to the washed air, oxidation starts after a time and the principal product is the peroxide. The odor of benzaldehyde is perceptible whenever oxidation occurs, and benzoic acid, benzophenone and formic acid are always formed along with the peroxide.

We have found also that, in all probability, the function of the acid is to cleave the oxide—a rather surprising role in a reaction between a gas and a solid. In solutions containing a trace of base the oxide can be preserved indefinitely but in solutions containing even traces of acid it is rapidly destroyed in accordance with the equation



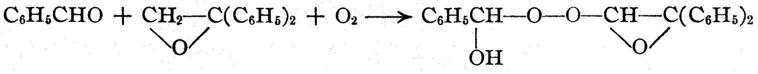
$$\underset{\substack{|\\ \mathrm{OH}}}{\mathrm{C_6H_5CH}}\underset{\diagdown\mathrm{O}\diagup}{\mathrm{CH{-}C}}\mathrm{(C_6H_5)_2} \longrightarrow \mathrm{C_6H_5CHO} + \underset{\diagdown\mathrm{O}\diagup}{\mathrm{CH_2{-}C}}\mathrm{(C_6H_5)_2} \longrightarrow \mathrm{(C_6H_5)_2CHCHO}$$

This transformation is complete and the process cannot be reversed either in the presence or the absence of a solvent. In solutions containing equivalent quantities of benzaldehyde and diphenylethylene oxide and a trace of base, both the aldehyde and the oxide slowly disappeared but no oxido alcohol was formed. When a solution of diphenylethylene oxide in an equivalent quantity of benzaldehyde was left to itself in an atmosphere of nitrogen, no change whatsoever occurred in the course of a month. When the solution was heated on a steam-bath the oxide slowly changed to diphenyl acetaldehyde but there was no condensation of the oxide and the aldehyde; and the addition of a few bubbles of hydrogen chloride merely accelerated the rearrangement of the oxide. But when a similar solution of

---

[1] Kohler, Richtmyer and Hester, THIS JOURNAL, 53,205 (1931).

the oxide in the aldehyde was exposed to the air it soon began to deposit a solid and it ultimately solidified completely. Under favorable conditions the solid contained nearly 50% of the possible amount of the peroxide, mixed with smaller quantities of the mono benzoate of diphenyl glycol, benzoic acid, benzophenone and formic acid. Here the peroxide is manifestly formed from the primary cleavage products of the oxide in accordance with the equation

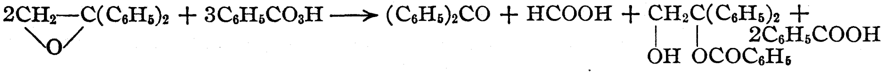


$$C_6H_5CHO + \underset{\diagdown O \diagup}{CH_2—C}(C_6H_5)_2 + O_2 \longrightarrow C_6H_5\underset{\underset{OH}{|}}{CH}—O—O—\underset{\diagdown O \diagup}{CH—C}(C_6H_5)_2$$

In this manner it was established that the oxide is not attacked by oxygen in the absence of acid, that acids cleave the oxide to benzaldehyde and diphenylethylene oxide, that the oxido alcohol cannot be regenerated from these cleavage products, and that in the air these primary cleavage products are oxidized to the peroxide The conclusion seems inevitable that the peroxide is formed in a series of reactions involving, first, cleavage of the oxide by acid, then autoxidation of the primary cleavage products, and finally synthesis of the peroxide from the products of oxidation.

The nature of the oxidation products from which the peroxide is formed is still somewhat mysterious. Diphenylethylene oxide is not attacked by free oxygen either in the presence or in the absence of acids. Benzaldehyde readily undergoes autoxidation being converted, first, into benzoperacid and finally into benzoic acid under all conditions hitherto investigated. Both of these oxidation products react with diphenylethylene oxide at the ordinary temperature but the reactions do not lead to the peroxide.

The reaction between benzoperacid and diphenylethylene oxide has been investigated with care by Meerwein and Bodendorf.[2] It is represented by the equation



$$2\underset{\diagdown O \diagup}{CH_2—C}(C_6H_5)_2 + 3C_6H_5CO_3H \longrightarrow (C_6H_5)_2CO + HCOOH + \underset{\underset{OH}{|}}{CH_2}\underset{\underset{OCOC_6H_5}{|}}{C}(C_6H_5)_2 + 2C_6H_5COOH$$

As will be seen, this reaction accounts for approximately half of the material and nearly all of the products that are formed in the autoxidation of the mixture of benzaldehyde and diphenylethylene oxide, but it does not account for the peroxide.

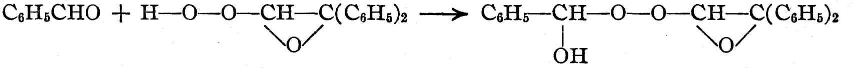
The experimental conditions under which the reaction was studied were quite different from those under which the peroxide is formed but differences in the experimental conditions could hardly account for oxidation to open chained compounds in the one case and the formation of the peroxide, in which the oxide ring is intact, in the other. Evidently benzoperacid—like benzoic acid—readily opens the oxide ring; after that has happened, the formation of the peroxide is impossible. For these reasons it seemed to us highly improbable that benzoperacid was an intermediate in the forma-

---

[2] **Bodendorf,** Dissertation, Königsberg, 1928.

tion of the peroxide, but we nevertheless decided to repeat the work of Bodendorf under conditions as nearly as possible like those which prevailed in the autoxidation of the cleavage products. To this end we prepared nearly pure benzoperacid by the method of Smit[3] and added it very slowly, in an atmosphere of nitrogen, to a solution of the oxide in benzaldehyde. The products were the same as those obtained by Bodendorf; no peroxide could be detected at any stage of the operation.

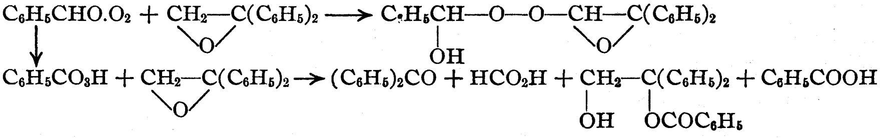
From the foregoing facts it is certain that benzoperacid is not an intermediary in the formation of the peroxide. In form and in behavior this peroxide most nearly resembles the monohydroxy dialkyl peroxides which are obtained by the addition of alkyl hydroperoxides to aldehydes.[4] In the case under consideration this mode of formation would be represented by the equation



$$C_6H_5CHO + H{-}O{-}O{-}\underset{\diagdown O \diagup}{CH{-}C}(C_6H_5)_2 \longrightarrow C_6H_5{-}\underset{\underset{OH}{|}}{CH}{-}O{-}O{-}\underset{\diagdown O \diagup}{CH{-}C}(C_6H_5)_2$$

Here the intermediary is a derivative of hydrogen peroxide which could not be formed under the conditions of the experiment.

There remains only the possibility that benzoperacid does not represent the primary oxidation product of benzaldehyde. This possibility has often been discussed in connection with observations that newly oxidized benzaldehyde is a more powerful oxidizing agent than benzoperacid[6] but no positive evidence of such a product has hitherto been obtained. It seems not improbable, however, that oxidation of a concentrated solution of the oxide in benzaldehyde, or of the intimate mixture of the aldehyde and the oxide that would be formed by cleavage on the surface of the solid oxido alcohol, would present an unusually favorable condition for catching some of the moloxide before its rearrangement to the peracid. Such an energetic, neutral antecedent of the peracid would account both for the peroxide and for the other oxidation products that are always formed at the same time



$$\begin{array}{l} C_6H_5CHO.O_2 + \underset{\diagdown O \diagup}{CH_2{-}C}(C_6H_5)_2 \longrightarrow C_6H_5\underset{\underset{OH}{|}}{CH}{-}O{-}O{-}\underset{\diagdown O \diagup}{CH{-}C}(C_6H_5)_2 \\ \quad\downarrow \\ C_6H_5CO_3H + \underset{\diagdown O \diagup}{CH_2{-}C}(C_6H_5)_2 \longrightarrow (C_6H_5)_2CO + HCO_2H + \underset{\underset{OH}{|}}{CH_2}{-}\underset{\underset{OCOC_6H_5}{|}}{C}(C_6H_5)_2 + C_6H_5COOH \end{array}$$

Experimental

All the oxide used in the investigation was isolated and purified in the same manner. It was prepared in quantity as directed in the earlier paper and left in the alkaline solu-

Phys. Chem.*, 33,1204 (1929).

tion until it was needed. A suitable quantity was then precipitated with ice water. rapidly washed and dried, and recrystallized from ether and petroleum ether.

Oxidation.—For the purpose of determining all the products of oxidation, three lots of 5 *g.* each were exposed to the air in thin layers at the bottom of large Erlenmeyer flasks until the odor of benzaldehyde had disappeared completely. The average gain in weight was 6.2%. The resulting solids were cooled in a freezing mixture and washed, repeatedly, with small quantities of equally cold ether, which removed about 20% of the material. From the ethereai solution sodium bicarbonate extracted formic acid—recognized by its reducing action on mercuric oxide—and benzoic acid which was identified in the usual manner. The ethereal layer, on distillation, left an oil which solidified almost completely when it was inoculated with benzophenone, and which formed a phenylhydrazone melting at 137°. The ethereal extract therefore contained formic acid, benzoic acid and benzophenone.

The solid was recrystallized from acetone and ether; it contained two substances: the peroxide which had been obtained before in the same manner and a small quantity of another compound which crystallized in needles and melted at 156°.

Anal. Calcd. for $C_{21}H_{18}O_3$: C, 79.2; H, 5.7. Found: C, 79.0; H. 5.8.

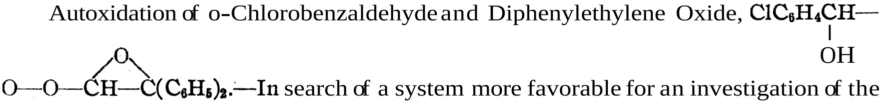
This substance is the monobenzoate of diphenyl glycol which was first obtained by Bodendorf by oxidizing diphenylethylene oxide with benzoperacid. Bodendorf assumed, perhaps correctly, that the peracid first combines with the oxide to form the corresponding perbenzoate, and that this substance is subsequently reduced to the benzoate. But the course of the reaction may be quite different because the benzoate is also formed very readily by simply dissolving benzoic acid in the melted oxide. The ratio between the amounts of peroxide and other oxidation products was not constant, the yields of peroxide varying between 70 and 80%.

Conditions Essential for the Formation of the Peroxide.—In a search for conditions more favorable for investigating the mechanism of the oxidation we passed air for twenty-four hours through neutral solutions of the oxide in alcohol, ether, acetone and benzene, but in no case obtained any oxidation. In faintly acid solutions there was a very slow oxidation but no peroxide was formed; after seventy-two hours, benzoic and diphenylacetic acids were the only oxidation products which could be detected.

In order to ascertain the importance of acid, three portions of the same preparation of the oxide were placed in large vacuum desiccators which were first exhausted, then filled—the one with air that had been passed through very dilute ammonia, the second with air which had been passed through sodium hydroxide—and the third with air that had been passed first through sodium hydroxide and then through moderately dilute hydrochloric acid. After five days only the third sample had been oxidized, the crystals of the first and second still retaining both their shape and their luster.

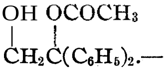
Autoxidation of the Cleavage Products.—A large number of solutions of diphenylethylene oxide in benzaldehyde were oxidized both in air and in oxygen. Peroxide was formed in every experiment but in many cases the amount was small and we failed to find any conditions under which the yield was equal to that which had been obtained from the oxido alcohol. Thus, in a typical experiment a solution of 2.5 g. of diphenylethylene oxide in 1.4 g. of benzaldehyde was exposed to the air in a large Erlenmeyer flask. After five hours solid began to appear and after two days the odor of benzaldehyde had disappeared completely. The resulting solid, manipulated like the product from the oxido alcohol yielded 1.8 g. of peroxide, 0.76 g. of the monobenzoate of diphenyl glycol and smaller quantities of benzoic acid and benzophenone.

Oxidation of the Cleavage Products with Benzoperacid.—A solution of the sodium salt of benzoperacid, prepared by the method of Smit, was acidified in a dropping funnel which was surrounded with ice water. At intervals small quantities of the resulting liquid acid were drawn into a solution of *2.5* g. of diphenylethylenc oxide in **1.4** g. of benzaldehyde which was likewise cooled with ice water and which was kept in an atmosphere of nitrogen. After twenty-four hours the mixture was a solid free from benzaldehyde. By the usual manipulation, this solid yielded the monobenzoate of diphenyl glycol, benzoic acid and benzophenone, but no peroxide could be detected.



Autoxidation of o-Chlorobenzaldehyde and Diphenylethylene Oxide, $\underset{\textstyle OH}{ClC_6H_4CH}—O—O—\overset{O}{CH—C}(C_6H_5)_2$.—In search of a system more favorable for an investigation of the mechanism of autoxidation, we examined the behavior of solutions of diphenylethylene oxide in a few other aldehydes. A solution of *2* g. of the oxide in **1.5** g. of *o*-**chlorobenzaldehyde** remained liquid after exposure to the air for several days, but solidiied in the course of a week. After extraction with ether, there remained 0.9 g. of **a** solid which decomposed briskly at the melting point. This solid was recrystallized from acetone and ether from which it separated in very thin needles melting at **140–141°** with evolution of gas.

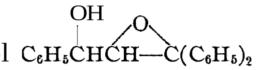
Anal. Calcd. for $C_{21}H_{17}O_4Cl$: C, **68.4;** H, 4.7. Found: C, **68.1;** H, **4.8.**

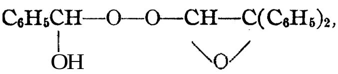


Autoxidation of Acetaldehyde and Diphenylethylene Oxide, $\underset{}{\overset{OH}{CH_2}}\overset{OCOCH_3}{C}(C_6H_5)_2$.—Various solutions of diphenylethylene oxide in acetaldehyde were exposed to the air until they had solidified completely. No peroxide could be detected in any of them; the principal product in every case was the monoacetate of diphenyl glycol, which separates from ether and petroleum ether in large prismatic crystals, and melts at **91°**.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 75.0; H, **6.2.** Found: C, **74.8;** H, **6.6.**

Summary



The autoxidation of the oxido alcohol $C_6H_5\overset{OH}{CH}\overset{O}{CH—C}(C_6H_5)_2$ to the peroxide $C_6H_5\underset{OH}{CH}—O—O—\underset{O}{CH—C}(C_6H_5)_2$, in all probability involves first cleavage


to benzaldehyde and diphenylethylene oxide, then autoxidation of the benzaldehyde, and finally synthesis of the peroxide from the autoxidation product of the aldehyde and diphenylethylene oxide. The intermediate in this synthesis is not benzoperacid; it appears to be an unstable "moloxide" antecedent to the peracid.

Diarsyls. IV. The Interaction of Diphenyldiiododiarsyl with Alkali, with Phenylarsine and with Diphenylarsine[1]

BY F. F. BLICKE AND L. D. POWERS

It seemed that diphenyldihydroxydiarsyl, a substance which has never been described, should be produced from the interaction of diphenyldiiododiarsyl[2] and alkali

$$C_6H_5(I)As—As(I)C_6H_5 + 2NaOH = C_6H_5(OH)As—As(OH)C_6H_5 + 2NaI$$

Diphenyldiiododiarsyl, suspended in ether, was shaken with excess sodium hydroxide solution in a free radical apparatus filled with nitrogen. The halogen was removed rapidly and quantitatively from the diarsyl and a crystalline, alkali-insoluble material remained partly dissolved and partly suspended in the ether layer. Upon separation and acidification of the alkaline solution a considerable amount of phenylarsine oxide was obtained. The alkali-insoluble product, after it had been recrystallized twice from benzene, possessed properties which in some respects resembled those of arsenobenzene; in certain other characteristics, however, the material was decidedly dissimilar to this substance as is shown by the following tabulation.

ALKALI-INSOLUBLE PRODUCT	ARSENOBENZENE
Separates from a benzene solution in the form of large, granular crystals	Separates from a benzene solution in the form of fine needles
M. p. 195–197°.[a] Mixed with arsenobenzene, m. p. 190–195°[b]	M. p. 210–212°
Mol. wt., 603[c]	Mol. wt. 867;[d] calcd. 304
% As, 47.12[e]	% As, 49.31
Absorbs oxygen rapidly[f]	Does not absorb oxygen
Dissolves rapidly in ether upon the addition of HCl or HBr; arsenobenzene precipitates quickly from the solution	Does not dissolve in ether upon the addition of a halogen acid
One hundred cubic centimeters of boiling benzene dissolve 7.9 g. of the material	One hundred cubic centimeters of boiling benzene dissolve 1.4 g. of this compound
Yields diphenyldiiododiarsyl when treated with iodine in ether	Yields diphenyldiiododiarsyl when treated with iodine in ether

[a,b] The melting point was determined in a sealed tube filled with nitrogen. [c] This result represents the average of six determinations on three different samples of material. The determinations were made in boiling benzene in a stream of nitrogen. [d] This value was obtained in boiling benzene in a stream of nitrogen; previously the molecular weight had been found to be 895 and 915, under the same experimental conditions [Blicke and Smith, THIS JOURNAL, 52, 2950 (1930)]. [e] This figure represents the average value of six analyses made with three different samples of material. [f] 1.042 g. of the product absorbed 73 cc. (N. T. P.) of oxygen in five minutes.

---

(1) This paper represents the second part of a dissertation submitted to the Graduate School by L. D. Powers in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

(2) Blicke and Smith, THIS JOURNAL, 52, 2937 (1930).

Diphenyldibromodiarsyl, when hydrolyzed, yielded products identical with those obtained from diphenyldiiododiarsyl. Di-*p*-anisyldiiododiarsyl yielded panisylarsine oxide and an alkali-insoluble compound which, to some extent, resembled di-*p*-methoxyarsenobenzene, yet seemed to be different from this material.

It has been claimed by Steinkopf and Smie[3] that diphenyldiiododiarsyl, suspended in alcohol, reacts with diphenylarsine at 70" to form hexaphenyltetraarsine $(C_6H_5)_2As—As(C_6H_5)—As(C_6H_5)—As(C_6H_5)_2$. The only experimental fact offered in support of this structure was an arsenic analysis, which differed from the calculated amount of arsenic by 2.98%, and the behavior of the material with iodine; in the latter reaction phenyldiiodoarsine and diphenyliodiarsine were formed in approximately equivalent amounts. No melting point was recorded and the above mentioned investigators admitted that their product was impure.

We have found that the compounds under discussion react at ordinary temperature in an entirely different manner, namely, with the formation of tetraphenyldiarsyl and arsenobenzene. Such a mixture would, of course, contain the same amount of arsenic as hexaphenyltetraarsine and, upon treatment with iodine, would yield phenyldiiodoarsine and diphenyliodoarsine in equivalent amounts. It seems very probable that the tetraarsine of Steinkopf and Smie was, in reality, a mixture of tetraphenyldiarsyl and arsenobenzene.

$$C_6H_5(I)As—As(I)C_6H_5 + 2(C_6H_5)_2AsH = (C_6H_5)_2As—As(C_6H_5)_2 + C_6H_5As{=}AsC_6H_5 + 2HI$$

Diphenyldiiododiarsyl and phenylarsine react to form arsenobenzene.

$$2C_6H_5(I)As—As(I)C_6H_5 + 2C_6H_5AsH_2 = 3C_6H_5As{=}AsC_6H_5 + 4HI$$

Steinkopf and Smie[3] stated that these compounds yield cyclic triphenyltriarsine, $C_6H_5As—As(C_6H_5)—AsC_6H_5$, but since no melting point was reported for the triarsine and the calculated analytical data for this compound are the same *as* for arsenobenzene, the alleged formation of the triarsine in this reaction seems to have been based on an insufficient amount of experimental evidence.

Experimental Part

Hydrolysis of **Diphenyldi-iododiarsyl.**—The diiododiarsyl was prepared from 24.4 g. of **phenyldiiodoarsine,**[4] 50 cc. of absolute alcohol and 40 g. of crystalline phosphorous acid, dissolved in 200 cc. of alcohol. The diarsyl was then suspended in 100 cc. of ether, shaken for one hour with 100 cc. of 10% sodium hydroxide solution, the alkaline layer decanted and the ether layer extracted three times with 50-cc. portions of alkali. Upon neutralization of the alkaline extracts with sulfuric acid in a nitrogen atmosphere,

---

(3) Steinkopf and Smie, Ber., 69, 1462 (1926).

(4) This material, after it has been preserved for some time in a glass-stoppered bottle, becomes very dark in color and often contains a considerable amount of a crystalline product. The iodide, however, seems to undergo little, if any, decomposition if it is kept under a layer of concd. hydriodic acid.

3.8 g. of phenylarsine oxide was obtained, mixed m. p. 145–147°,[5] after recrystallization from benzene–ether.

The ether layer, which contained suspended material, was concentrated to a volume of 15 cc. and the liquid decanted. The latter possessed a very strong odor similar to that of phenylarsine. The slightly yellow crystalline material was washed with alcohol, then with ether and dried under diminished pressure. After a second recrystallization from benzene the product, which was halogen free, weighed 3.2 g.

When 2.06 g. of the material, suspended in 50 cc. of ether, was shaken with 25 cc. of hydrobromic acid 1.13 g. of arsenobenzene, m. p. 210–212°, was obtained.

Anal. Calcd. for $C_{12}H_{10}As_2$: As, 49.31. Found: As, 49.26.

From 1.72 *g.* of the product, 50 cc. of ether and 1.4 g. of iodine there was produced 1.45 g. of diphenyldiiododiarsyl; m. p. 177–178°.

Hydrolysis of Di-*p*-anisyldiiododiarsyl.—When the diiododiarsyl,[6] obtained from 13.1 g. of *p*-anisyldiiodoarsine,[7] was hydrolyzed in the manner described above, there was obtained 2.5 *g.* of p-anisylarsine oxide, m. p. 136–138°, and 1.7 g. of a crystalline halogen-free, alkali-insoluble product, m. p. 220-230": % As found, 40.02 and 40.20.

Dissolved in bromobenzene 1.082 g. of the alkali-insoluble product absorbed 61 cc. of oxygen in two minutes.

When the alkali-insoluble material was suspended in ether and treated with hydrochloric or hydrobromic acid di-@-methoxyarsenobenzenewas obtained; mixed m p. 233–235°.[8]

Phenylarsine and Diphenyldi-iododiarsyl.[9]—To 6.79 g. (0.012) mole of diphenyldiiododiarsyl, suspended in 75 cc. of absolute alcohol, there was added 2.4 g. (1.8 cc., 0.015 mole) of phenylarsine. After the mixture had been shaken for twelve hours the deep yellow color of the diiododiarsyl had disappeared and a pale yellow compound remained suspended in the solvent. The alcohol was decanted, the solid material washed with alcohol and ether and then dried for some time in the radical bulb under diminished pressure. This material melted from 140–212° and absorbed oxygen: 0.600 *g.* absorbed 11 cc. in two minutes. The smallest possible amount of boiling xylene necessary to dissolve the product was introduced into the radical bulb; after two days 2.8 g. of pure arsenobenzene had separated from the solution; mixed m. p. 209–210°; calcd. yield 5.5 g.[10]

Anal. Calcd. for $C_{12}H_{10}O_2$: As, 49.31. Found: As, 49.07.

When alcohol was replaced by absolute ether in the above experiment and the mixture shaken for three days, 87% of the diiododiarsyl was recovered unchanged.

Diphenylarsine and Diphenyldiiododiarsyl.—The diphenyldiiododiarsyl, obtained from 8.12 g. (0.02 mole) of phenyldiiodoarsine, 14 g. of crystalline phosphorous acid and 100 cc of absolute alcohol—approximately 0.01 mole[11]—was suspended in 60

---

[5] For further identification the oxide was converted into phenyldichloroarsine and the latter identified as phenylarsplene N-pentamethylenedithiocarbamate [Blicke and Oakdale, THIS JOURNAL, **54, 2995 (1932).** The melting point of this compound should be 183–184° instead of 173–174° as recorded previously.

[6] Blicke and Smith, ibid., 52, **2043 (1930).**

[7] Blicke, Powers and Webster, *ibid.*, **54, 2946 (1932)**

[8] A sample of di-p-methoxyarsenobenzene, obtained by reduction of p-anisylarsine oxide in acetic acid with hypophosphorous acid, melted at 228–230° after recrystallization from bromobenzene.

[9] A description of the apparatus used in this and the following experiment was published previously [Blicke and Powers, ibid., 54, **3356** (1932)].

[10] The yield was, undoubtedly, lowered to a decided extent by recrystallization. In the recrystallization of pure arsenobenzene from xylene the yield of crystalline product which separated from the xylene was about **50%;** only gummy material could be obtained from the mother liquor.

[11] The diiododiarsyl was not removed from the free radical bulb in which it had been prepared. In a number of instances in which the diarsyl, prepared by this method, had been isolated the yield of pure product was never less than 90% of the calcd. amount.

cc. of absolute alcohol and 4.60 g. (3.54 cc., 0.02 mole) of diphenylarsine added.[12] The mixture, initially yellow in color, was shaken vigorously for twelve hours; after thirty minutes it had become colorless. The alcohol was decanted from the solid material into a second radical bulb and the alcohol removed by distillation under reduced pressure. In order to separate the compounds formed, arsenobenzene and tetraphenyldiarsyl, advantage was taken of the fact that the latter substance is soluble in ether while arsenobenzene is practically insoluble in this solvent. One hundred cubic centimeters of ether was poured onto the mixture, whereupon most of the tetraphenyldiarsyl dissolved. The ether solution was then decanted through a Jena filter into the second bulb. The purpose of the filter was to retain finely divided arsenobenzene which remained suspended in the ether. The arsenobenzene was washed with ether until free from the diarsyl. The residue of arsenobenzene weighed 2.97 g.; m. p. 203–207"; calcd. yield 3.04. After recrystallization from bromobenzene it melted at 208–210°.

The ether solution in the second bulb was shaken with alkali to remove traces of unchanged iodides, washed free from alkali and then concentrated to a volume of 25 cc.; a copious precipitate of tetraphenyldiarsyl was obtained. After recrystallization from absolute alcohol, the material weighed 2.6 g., m. p. 128–130°.[13] Upon concentration of the mother liquor an additional 0.4 g. of product was obtained; calcd. yield 4.58 g.

Anal. Calcd. for $C_{24}H_{20}As_2$: As, 32.73. Found: As. 32.72, 32.69.

Summary

Several diaryldihalodiarsyls were treated with alkali whereupon an arylarsine oxide and an alkali-insoluble product were formed.

Phenylarsine and diphenyldiiododiarsyl react to form arsenobenzene; diphenylarsine and the diiododiarsyl yield arsenobenzene and tetraphenyldiarsyl. It has been claimed in the literature, on the basis of meager experimental data, that cyclic triphenyltriarsine is formed in the first instance and hexaphenyltetraarsine in the second.

The Structure of X-Chlororesorcinol

BY BENJAMIN F. CLARK

In a recent investigation, the author obtained a considerable quantity of a material which corresponded in all its characteristics with the compound listed in Beilstein as "x-chlororesorcinol." This material was first prepared by Reinhard,[1] who obtained it by treating resorcinol with sulfuryl chloride. In an attempt to determine the structure of this compound, Reinhard endeavored to replace the chlorine atom with a hydroxyl group by fusion of the compound with sodium hydroxide and also potassium hydroxide, but he obtained no trihydroxybenzene, even when he heated the materials as high as 250°. Heating above 250" caused charring to take place.

The author attempted to convert chlororesorcinol into the corresponding trichlorobenzene by prolonged heating with phosphorus pentachloride. A sample of chlororesorcinol, even when heated for eight hours at 250" with phosphorus pentachloride, gave only a rubber-like residue from which no material resembling any of the trichlorobenzenes could be extracted. When a temperature lower than 250" was used, no reaction took place.

It seemed likely that the chlorine atom was in the ortho position with respect to one hydroxyl group and para with respect to the other; accordingly, a synthetic method for making this compound was devised. The physical constants of the material obtained, as well as those of several of its derivatives, were then found and compared with those obtained by Reinhard with his "x-chlororesorcinol."

Chlorobenzene was chosen as the starting point, and from it 2,4-dinitrochlorobenzene was prepared. The nitro compound was then reduced to the corresponding amine, 2,4-diaminochlorobenzene. The physical constants for these materials compared closely with those recorded in the literature, The amino compound was diazotized and the diazonium groups then replaced by hydroxyl groups.

Experimental

2,4-Dinitrochlorobenzene.—The method of Einhorn and Fry[2] was used in the preparation of this compound, m. p. 49.5° **(corr.)** from alcohol.

2,4-Diaminochlorobenzene.—For the reduction of the nitro compound, the method of Beilstein and Kurbatow was used, m. p. 90–91° **(corr.)** from **alcohol.**[3]

Chlororesorcinol.—20.0 grams (0.140 mole) of 2,4-diaminochlorobenzene was dissolved in 500 cc. of 10% hydrochloric acid, to which had been added 200 **g.** of cracked

ice; 19.5 g. (0.280 mole) of C. P. sodium nitrite, dissolved in 200 cc. of water, was slowly added and the solution stirred constantly. The solution was then allowed to come slowly to room temperature. After standing overnight, the solution was distilled with steam. Nitrogen was evolved and a cream-colored crystalline material appeared in the distillate. When no more crystals came over, the distillate was filtered and the crystals carefully dried on a porous plate; yield 15.2 g. (96%). The crude material melted at 87–87.5°, and after two recrystallizations from alcohol it melted at 88.5–89.0° (corr.). Reinhard obtained a melting point of 89° for "x-chlororesorcinol." A mixed melting point determination, made on a portion of the material mixed with a sample of chlororesorcinol made by Reinhard's method, gave a value of 88.5–89.0°.

The bromine derivative, prepared according to Reinhard's method, melted at 103.5–104.0°, after one recrystallization from alcohol. Reinhard obtained a melting point of 105° for this compound.

The dibenzoyl derivative melted at 97° as compared with the value of 98° reported by Reinhard.

Analysis of the purified chlororesorcinol, as obtained by the above method, gave the following results: calcd., Cl, 24.53; found, Cl, 24.63. The method of Lemp and Broderson[4] was used in this analysis.

Conclusion

As a result of a synthetic method, in which chlororesorcinol was prepared from compounds of known structure, it has been shown that "x-chlororesorcinol" has the structure 1-chloro-2,4-dihydroxybenzene.

Lipases of Wheat. I

BY B. SULLIVAN AND M. ALLISON HOWE

No studies of any of the lipases of wheat or its products have been reported in the literature. Furthermore, no references have been made concerning the importance of lipase in relation to the quality and storage of wheat products. Therefore considerable preliminary work is necessary in establishing the following fundamental facts (a) the most reliable method for the measurement of the lipase activity of wheat; (b) the best methods of extraction to increase the concentration of the enzyme from any given wheat product; (c) the distribution of the enzyme in the different milling separations of wheat; (d) the optimum conditions of time, temperature and PH for wheat lipase activity as well as the specificity of different buffer mixtures, the effect of various activators and inhibitors and the action of the enzyme on various substrates. These preliminary experiments described here are intended to establish some of the variables influencing the activity of the lipases of wheat and its products.

Experimental

An arbitrary method of measuring the lipase activity was first developed based on a number of different methods previously reported in the literature. Ground wheat was used as the source of the enzyme. The method used was as follows: 0.5 g. of finely ground wheat was incubated for twenty-four hours at 37.9° in a 250-cc. Erlenmeyer flask with 10 cc. of water, 2 cc. of toluene, the substrate (1 cc. of liquid or 1 g. of solid fat) and 10 cc. of buffer solution. At the end of the incubation period, 100 cc. of 3:1 acetone–ether mixture was added to the sample and also the blank which had been boiled previous to incubation; 0.1 *N* sodium hydroxide was used for the titration with 1% phenolphthalein as an indicator. The results obtained from various substrates are given in Table I. The action of the enzyme was tried in the alkaline and also in the acid range on all the substrates used. It will be noted that in the case of the liquid triglycerides of the saturated fatty acids, the titration value decreases with an increase in molecular weight. Since a few of these substrates are solids, there would be less surface than in the case of the liquids and this would affect the rate of enzyme action. It is generally assumed that wheat germ which has the highest fat content of all the milling separations also has the highest lipolytic activity. However, in comparing all the milling separations, other fractions showed greater activity in the hydrolysis of certain neutral triglycerides. The PH of the boiled preparation including the sample, substrate, toluene and buffers was determined potentiometrically in all cases. Since phosphates are the natural buffers of wheat, it was desirable to use phosphate buffers wherever possible. Mixtures of primary potassium phosphate and secondary sodium phosphate were employed for one group of determinations, and primary potassium phosphate and borax for the more alkaline range. Graphs I and II show the results obtained. In Table II, the results are given of various methods tried in an effort to increase the activity of the enzyme. None of these methods was found to

give more than a very slight increase in the titration value over that obtained on the untreated and unextracted sample when using triacetin as the substrate. When germinated wheat was used with some of the higher triglycerides, an increased action was observed. As these higher triglycerides are the natural components of wheat, further work is to be done on the higher fats.

cubated products with ninhydrine, eliminating the possibility of any increase in titratable acidity being due to amino acids.

Discussion

Glycerides of the lower fatty acids, particularly triacetin and tripropionin, were acted on to the greatest extent, triacetin giving considerably higher results than any other substrate tried. Ethyl acetate gave a higher titration value than ethyl butyrate, which showed very little action, although neither of these esters was acted on to the extent of triacetin and tripropionin. This fat splitting enzyme of wheat acts on the glycerides of the fatty acids to a greater extent than on the corresponding esters. The higher titration values given by triacetin and ethyl acetate compared to the higher members of their series is, however, undoubtedly purely physical and is probably due to the relatively greater water solubility of these lower members. No triolein or glycerides of other unsaturated fatty acids were tried in these experiments, although olive oil was found to give a titration value comparable to the higher saturated glycerides. With olive oil as a substrate, the enzyme has its optimum P_H in the acid range. Many investigators in this field have measured the extent of lipase activity by the use of triacetin, tributyrin, ethyl butyrate and such compounds of the lower fatty acids as substrates. Since the higher fatty acids, such as stearic, palmitic and oleic, are those commonly present in plant and animal tissues, it would seem to the authors that lipase studies to be of any practical significance should be directed toward the use of such substrates as are present in greatest amounts in natural products.

This study is being continued in an effort to find the optimum conditions of time, temperature and P_H under which the higher triglycerides, lecithin and other lipides naturally present in wheat are hydrolyzed. An effort is being made to obtain a more active enzyme preparation by other methods than those already described and to study the effect of various activators and inhibitors on such preparations.

The authors wish to thank Dr. G. O. Burr and Dr. W. M. Sandstrom for valuable suggestions.

Summary

1. A method has been described for the measurement of the activity of the lipase of wheat products and it has been shown that with the time and temperature employed, and with triacetin as the substrate, the enzyme was most active on the alkaline side at P_H 7.3 to 8.2 and that it has a wide optimum range. All wheat products show a marked action in cleaving triacetin, the highest values being given by low grade flour rather than by germ or bran. When the higher triglycerides of fatty acids naturally present in wheat were used as substrates, the enzyme showed an optimum on the acid side. Germination of wheat increased the activity of its lipase when the higher triglycerides were used as substrates, but made very little difference when triacetin and the glycerides of the lower fatty acids were employed.

Condensations of Isatin with Acetone by the Knoevenagel Method[1]

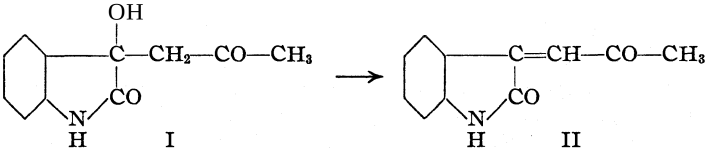
BY F. BRAUDE WITH H. G. LINDWALL

In a recent article it was shown[2] that isatin and acetophenone will condense, in the presence of certain bases, to yield 3-hydroxy-3-phenacyloxindole. This reaction suggested the use of other methyl ketones like acetone. Isatin and acetone condense when present with small amounts of diethylamine to yield 3-acetonyl-3-hydroxyoxindole (I).

The condensation involves the β-carbonyl of the isatin molecule rather than the nitrogen, for N-methylisatin will also react with acetone to yield a product with chemical properties similar to those of (I).

Compound (I) decomposes upon the application of heat, or upon being warmed with aqueous alcoholic potassium hydroxide solution, into isatin and acetone. This decomposition is evidently another example of a reversed aldol reaction. A longer period of heating with the potassium hydroxide solution results in the formation of 2-methylcinchoninic acid, not, apparently, through rearrangement of the 3-acetonyl-3-hydroxyoxindole, but rather through its decomposition into isatin and acetone followed by a Pfitzinger[3] type of condensation of the acetone with the *o*-aminobenzoylformic acid, formed by the hydrolysis of the isatin.

Treatment of I with certain acidic reagents effects the loss of one mole of water with the resulting formation of 3-acetonylideneoxindole (11), a highly colored red-orange compound.



I II

It might be expected that II, upon ring opening through hydrolysis, would form 2-methylcinchoninic acid as a result of subsequent reaction of the ketone carbonyl with the nuclear NH_2 group. However, II could not be rearranged to the corresponding quinoline derivative by treatment with potassium hydroxide. This is in agreement with the failure of 3-phenacylideneoxindole and 3-phenacyloxindole to rearrange to cinchophen and 3,4-dihydro-2-phenylcinchoninic acid, as noted in our previous paper. Therefore 3-acetonylideneoxindole cannot, apparently, be considered an intermediate in the Pfitzinger synthesis of 2-methylcinchoninic acid from isatin

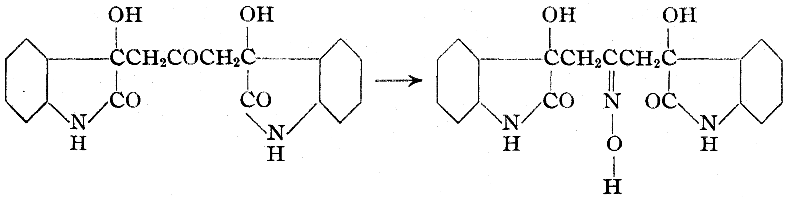
and acetone. It is possible that II is a *trans* isomer and will not form the quinoline derivative for this reason. This point has not yet been completely investigated.

3-Acetonyl-3-hydroxyoxindole will condense with a mole of isatin to yield 1,3-bis-(3-hydroxy-3-oxindyl)-2-propanone (III). This compound also results when 2 moles of isatin condense with one of acetone. N-Methylisatin behaves in an analogous manner with acetone. Compound III yields a monoxime (IV)



III IV

Experimental Part

3-Acetonyl-3-hydroxyoxindole (I).—A mixture of 25 g. of isatin, 139 g. of acetone and 13.9 g. of diethylamine was allowed to stand for twenty-four hours at room temperature. Pale yellow crystals separated which became white upon recrystallization from acetone. The product is soluble in ethyl alcohol, n-butyl alcohol, acetone and ethyl acetate, but is insoluble in water; m. p. 166–167° with decomposition; yield, 75%.

Anal. Calcd. for $C_{11}H_{11}O_3N$: C, 64.62; H, 5.44; N, 6.83. Found: C, 64.48; H, 5.42; N, 6.82.

3-Acetonyl-3-hydroxy-1-methyloxindole.—The same proportions and procedure were used as for I (above), replacing the isatin by N-methylisatin The product was recrystallized from benzene: m. p. 145°; yield, 79%.

Anal. Calcd. for $C_{12}H_{13}O_3N$: N. 6.39. Found: N, 6.28, 6.31.

Isatin by the Decomposition of 3-Acetonyl-3-hydroxyoxindole (I).—A mixture of 2 g. of (I), 22.5 cc. of ethyl alcohol and 10.5 cc. of 33% potassium hydroxide was heated on a steam-bath for one hour. The resulting solution was acidified with dilute hydrochloric acid. A brown precipitate resulted which proved, upon crystallization, to be isatin; m. p. 198°; m. p. mixed with a known sample of isatin, 198°.

2-Methylcinchoninic Acid from **3-Acetonyl-3-hydroxyoxindole.—The** mixture described above was heated for eight hours on a steam-bath. Acidification with hydrochloric acid yielded a light brown precipitate. Crystallization from boiling water gave a white crystalline product which was identified, by melting point and mixed melting point, as 2-methylcinchoninic acid.

3-Acetonylideneoxindole (II).—3-Acetonyl-3-hydroxyoxindole (10 g.) was heated with 45 cc. of ethyl alcohol and 11.5 cc. of concd. hydrochloric acid until a clear solution was obtained. The solution was then poured over 80 g. of ice. A bright yellow-red solid formed. Recrystallization from ethyl alcohol yielded red needles, soluble in ether, acetone, ethyl acetate, ethyl alcohol and hot benzene: m. p. 168–171°; yield, 42%

Anal. Calcd. for $C_{11}H_9O_2N$: N, 7.49 Found: N, 7.43, 7.48.

3-Acetonylidene-1-methyloxindole.—3-Acetonyl-3-hydroxy-1-methyloxindole was treated as outlined above in the preparation of II. The product is red and soluble in alcohol and ether: m. p. 120–122"; yield, 57%.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.90; H, 5.51; N, 6.97. Found: C, 71.45; H, 5.51; N, 6.84, 7.00.

Attempted Rearrangement of 3-Acetonylideneoxindole to 2-Methylcinchoninic Acid.—A mixture containing 1.25 g. of 3-acetonylideneoxindole, 2.9 g. of sodium hydroxide and 22 cc. of water was heated on a steam-bath for eight hours. Acidification with hydrochloric acid caused the precipitation of a brown solid. Attempts to isolate 2-methylcinchoninic acid from this material were not successful.

1,3-Bis-(3-hydroxy-3-oxindyl)-2-propanone (III).—(A) A mixture of 2.9 g. (1 mol), of isatin, 4.1 g. (1 mol) of 3-acetonyl-3-hydroxyoxindole, 2.7 g. of diethylamine, and 27 cc. of absolute ethyl alcohol was allowed to stand for forty-eight hours. The solid material which separated was recrystallized from ethyl alcohol and obtained as colorless prisms: m. p. 212–214°, with apparent decomposition; yield, 78%.

(B) A solution of 4.5 g. of isatin, 1.8 g. of acetone, 2.5 g. of diethylamine, and 25 cc. of absolute alcohol was allowed to stand at room temperature for twenty-four hours. A solid formed which, after crystallization from alcohol, was found to be identical with the product from method "A"; yield, 16%.

Anal. Calcd. for $C_{19}H_{16}O_5N_2$: C, 64.76; H, 4.58; N, 7.95. Found: C, 64.54; H, 4.75; N, 7.80, 7.85.

1,3-Bis-(3-hydroxy-3-oxindyl)-2-propanone Oxime (IV).—Compound III (4.3 g.) was dissolved in 50 cc. of hot ethyl alcohol, and a water solution of 2.6 g. of hydroxylamine hydrochloride and 4.8 g. of sodium acetate was added. The solution was boiled gently for a half hour. After cooling and evaporation of solvent a solid resulted which was crystallized from 50% ethyl alcohol, and thus obtained as colorless needles, decomposing at 158–160°.

Anal. Calcd. for $C_{19}H_{17}O_5N_3$: N, 11.45. Found: N, 11.64.

1,3-Bis-(3-hydroxy-1-methyl-3-oxindyl)-2-propanone.—3-Acetonyl-3-hydroxy-1-methyloxindole and N-methylisatin were allowed to react using the procedure described in method "A" for the preparation of III. The product was recrystallized from toluene and obtained thus as colorless plates: m. p. 178–181°, with apparent decomposition.

Anal. Calcd. for $C_{21}H_{20}O_5N_2$: N, 7.39. Found: N, 7.24.

Summary

Isatin and acetone condense in the presence of certain organic bases to yield 3-acetonyl-3-hydroxyoxindole and 1,3-bis-(3-hydroxy-3-oxindyl)-2-propanone.

3-Acetonylideneoxindole is apparently not an intermediate in the Pfitzinger synthesis of 2-methylcinchoninic acid, since it does not yield that product upon treatment with alkali.

Physico-Chemical Properties and Hypnotic Action of Substituted Barbituric Acids

BY D. L. TABERN AND E. F. SHELBERG

Henderson,[1] in a recent review, has enumerated no less than ten distinct theories that have been proposed to account for the mechanism of hypnotic action. The one which has best stood the test of time, or perhaps we should say, has developed the fewest shortcomings, is that of Meyer and Overton. This states that all chemically indifferent bodies which are soluble in fats or lipoids act as narcotics to living protoplasm; the relative degrees of activity of such narcotics depend on their affinity for fat-like substances on the one hand and for other body constituents on the other; as an approximate measure of this ratio, one may determine the distribution coefficient of the substances between oil and water.

Within the last ten years, barbiturates have come to occupy a prominent place among hypnotics, not only in routine medical practice, but in the more specialized fields of pre-anesthetic sedation and the prevention of local anesthetic reactions. These newer uses have been made possible by the development of new members possessing specifically valuable properties. For instance, certain members containing the (1-methyl butyl) group are not only the most potent yet described,[2] but are quickly broken down in the body. This leads to a period of intense hypnosis followed by rapid recovery without the prolonged depression characteristic of longer acting substances. The advantage of such rapid recovery following operative procedures is self obvious. Tatum[3] has recently shown that *n*-butylethylbarbituric acid is particularly effective in the prevention of local anesthetic intoxication.

There have now been synthesized and accurately evaluated pharmacologically more than one hundred barbiturates of relatively similar structure; over sixty have been tested in our own laboratories by a standard procedure; in addition, we have available a considerable mass of clinical data regarding prominent members. We may not only vary the number of carbon atoms in each of the alkyl groups present, but in the higher members we have many possibilities of isomerism.

It seemed of interest, therefore, to study the applicability of certain of the above-mentioned theories of hypnotic action to the barbiturates.

Of practical importance was the possibility that, if a definite relation could be established between certain physical-chemical properties and the hypnotic activities, a chemical method could be made available for the

preliminary evaluation of newly synthesized compounds. We have selected fifteen members, some because of their commercial importance, others because they contained interesting chemical groupings. The total length of the carbon chains attached to the "5" carbon varied from 2 to 11 atoms, covering not only the rise in hypnotic efficiency, but also its subsequent decrease in higher members. Two isomeric butyl and three isomeric amyl groups were included. Two compounds contained asymmetric carbon atoms.

Distribution coefficients of the barbituric acids were determined between water and a specially purified fatty acid free olive oil at 20°. Equal amounts of the oil and the aqueous solutions were continuously agitated for a number of hours until equilibrium had been established. Analyses of the aqueous phase were made by the Kjeldahl method.

TABLE I

No.	Barbiturate	Mol. wt.	Sol. g. per liter	Dist. coeff.. av.	Efficiency[a] rating
1	Dimethyl	156	2.419	0.066	0
2	Diethyl (Barbital)	184	6.00	.014	+
3	Ethyl i-propyl (Ipral)	198	1.36	.73	+
4	*i*-Propyl allyl	212	4.02	1.12	+++
5	Diallyl (Dial)	208	1.465	0.85	++
6	n-Butyl ethyl (Neonal)	212	1.90	2.58	+++
7	*Sec.*-butyl ethyl	212	1.987	1.36	+++
8	*Sec.*-butyl allyl	224	2.16	2.48	++++
9	*n*-Amyl ethyl	226	0.554	2.92	+++
10	*i*-Amyl ethyl (Amytal)	226	.530	2.895	+++
11	Ethyl (1-methyl butyl) (Nembutal)[b]	226	1.20	4.4	++++
12	*Sec.*-butyl β-bromoallyl (Pernocton)	304	0.684	4.3	++++
13	Phenyl ethyl (Phenobarbital)	234	.970	1.34	++
14	Allyl (methylhexylcarbinyl)	280	3.06	0.306	0
15	Ethyl (methylhexylcarbinyl)	267	0.414	.408	0

[a] Since variations of technique such as the route of administrations, etc., lead to slightly divergent numerical data, it seems most satisfactory to employ only comparative values. [b] Nembutal (pentobarbital sodium) is the sodium salt of this acid.

Table I demonstrates a definite parallelism between the partition coefficients and hypnotic efficiency, both increasing from a low value in dimethyl to a maximum in ethyl (1-methyl butyl), *sec.*-butyl allyl, and *sec.*-butyl (β-bromoallyl)-barbituric acids, and then decreasing rapidly to small figures for ethyl and allyl octyls. The only outstanding exception is diallylbarbituric acid, although in general the unsaturated members are somewhat more effective than the coefficients would lead us to expect.

Within the last year, Barlow and associates[4] have carefully compared a number of barbiturates with particular reference to efficiency in preanesthetic sedation. They place Nembutal (Pentobarbital) at the top,

---

(4) Barlow, Duncan and Gledhill, J. *Pharmacol.*, 41, 366 (1931)

followed by Pernocton and Dial; barbital and phenobarbital were found relatively ineffective. If we employ, instead of the pharmacologic data recently published comparisons of certain members when used intravenously in human beings, the correlation is even closer; for instance, both Fitch, Waters and Tatum[5] and Lundy[6] have reported Nembutal twice as effective as Amytal and "somewhat" more effective than Pernocton, and we find the coefficients of 4.4, 2.8 and 4.3, respectively.

Since the theory of Meyer and Overton is based essentially upon the high lipoid content of nerve tissue, it seemed of interest to determine the distribution of various barbiturates between water and a chemically neutral medium such as ash-free charcoal.[7] Adsorption (by 1 g. of charcoal) from (300 cc. of a 0.12%) aqueous solution was remarkably rapid, equilibrium with resultant removal of 75% or better of the barbiturate being complete in less than fifteen minutes. To our surprise the order of the members studied follows qualitatively at least the order of hypnotic efficiency.

TABLE II

Barbiturate	% Adsorp
Dimethyl	79
Diethyl (Barbital)	88
Diallyl (Dial)	92.5
n-Butyl ethyl (Neonal)	96
i-Amyl ethyl (Amytal)	95 app.
Ethyl (1-methyl butyl) (Nembutal)	96
Octyl ethyl	83.5

Traube has suggested[8] that the surface tension of the hypnotic solution may be the deciding factor in determining its efficiency. We have, therefore, determined the surface tension of the aqueous solutions of the above barbiturates at two concentrations. Measurements were made by the De Nouy tensiometer at 20°, and the results expressed as the percentage of the normal value for water determined at the same time. From Table III, it is seen that while surface activity does increase with increasing hypnotic efficiency, it does not decrease in the octyl homologs as the theory would lead us to expect. Furthermore, Amytal is more surface active than Nembutal (Pentobarbital acid) but much less effective.

Chemical stability and rate of excretion are becoming important factors now that we appreciate the superiority of short-acting barbiturates as preanesthetic sedatives. Barbital is largely (70–80%) excreted unchanged in the urine, while with certain higher homologs the majority is apparently decomposed in the body.[9] Shonle and Keltch[10] have stated that neither Amytal nor Nembutal is eliminated as such in the urine.

A definite amount of the pure sodium salt was dissolved in carbon dioxide free water in a sealed tube and held at 100° for sixteen hours. After cooling, the contents were acidified with sulfuric acid and the liberated carbon dioxide absorbed in "Ascarite." From this, the amount of decomposition was calculated. We find that stability toward hydrolysis of the sodium salts in aqueous solution to the corresponding acetyl ureas does not run inversely parallel to hypnotic efficiency but is dependent upon the groups attached to the "5" carbon atom. The presence there of any "secondary" linkage increases stability threefold. The additional presence of the unsaturated negative β-bromoallyl group still further enhances resistance to hydrolysis of the ester linkage. In other words, we find the unexpected fact that other things being equal the powerful barbiturates containing a secondary group are on the one hand very stable in the test tube, and very unstable in the body.

TABLE IV

Bancroft and Richter[11] have recently revived Bernard's theory of narcosis and presented evidence that hypnosis is in most instances associated with reversible coagulation of cell colloids. While there has been no

---

(11) Bancroft and Richter, J. Phys *Chem.*, **35**, 215 (1931).

opportunity for us to study in this way the action of the barbiturates upon living cells, it does not seem to us that their findings conflict with the evidence here presented. Coagulation may be the mode of action within the cell, but there remains in clinical practice the all-important necessity for transporting the hypnotic from the point of administration to the interior of the cell through a series of transferences. Here, surface tension, absorption and more particularly lipoid solubility appear to be the limiting factors in the chain of events.

Adsorption Experiments with Vitamins $B(B_1)$ and $G(B_2)$

BY H. C. SHERMAN AND NELLIE HALLIDAY

Seidell's adsorption of the antineuritic vitamin upon Lloyd's reagent[1] has led to considerable experimentation with this and other forms of hydrous aluminum silicate looking to partial separation of vitamins $B(B_1)$ and $G(B_2)$.[2]

The experiments here recorded were planned in quantitatively graded series, and were carried out upon protein-free milk as being a material of special scientific interest in this connection because of the extent to which it has been used as a source of the vitamin-B complex in numerous researches, beginning with the work of Osborne and Mendel.[3] As adsorbent, we have used a preparation of Lloyd's reagent kindly furnished us by Professor John Uri Lloyd. This has been used in the proportions of 5, 10, 20 and 40 g. per liter of protein-free milk, prepared as described below and adjusted to p_H 3.0 and also to p_H 4.0.

The original untreated protein-free milk, the activated Lloyd's reagent and the filtrates remaining after adsorption were tested quantitatively for their vitamin $B(B_1)$ and G potencies according to methods previously developed in this Laboratory.* The preparations were fed in graded amounts corresponding to definite quantities of protein-free milk or of the original skimmed milk powder. No attempt was made to study the possible supplementary relation of the two fractions, activated solids and remaining filtrates to each other. In view of the recent evidence suggesting

the multiple nature of both the more heat labile and the more heat stable components of the vitamin-B complex and in view of the further investigations of Halliday and of Stiebeling: it is conceivable that some part of our apparent losses in vitamin potencies might possibly be due to a partial separation of the component factors of what are here treated as entities, i. *e.*, vitamins B and G, respectively.

This would not change the general bearings of our findings, but might influence slightly the details of the numerical data or of graphs plotted therefrom. For this reason and in the interest of brevity, the details are omitted from this paper. They may be consulted, if desired, in the privately printed dissertation of the junior author, copies of which have been distributed by Columbia University to a number of other university libraries.

Experimental Procedure

The protein-free milk was prepared as follows. A weighed quantity of skimmed milk powder was thoroughly mixed with eight times its weight of distilled water. To this mixture was added sufficient 0.3 M hydrochloric acid (usually 175 cc. per 100 g. of the milk powder) to completely precipitate the casein. After filtration through several layers of cheesecloth, the resulting filtrate was heated to boiling for five minutes to precipitate the heat coagulable protein and filtered through filter paper. The filtrate or protein-free milk had a reaction as determined by electrometric measurements using a hydrogen electrode and saturated calomel half-cell, of about P_H 4.2.

The protein-free milk volume was measured and divided into three aliquots; one aliquot after being adjusted to about P_H 5.7 with 0.2 M sodium hydroxide was without further treatment fed as vitamin B(B_1) and as vitamin G supplements; a second aliquot after being adjusted to P_H 3.0 with 0.3 M hydrochloric acid was further divided and each portion treated with a definite amount of Lloyd's reagent; the third aliquot was adjusted to P_H 4.0 previous to treatment with the different amounts of Lloyd's reagent. The Lloyd's reagent was added to portions of the protein-free milk adjusted to P_H 3.0 and (or) P_H 4.0 in ratios of 40, 20, 10 and 5 g., respectively, per liter of the protein-free milk. The adsorbent and solutions, after thorough mixing, were allowed to stand in contact in a refrigerator overnight. The "activated solids" were then separated by use of a Büchner funnel, washed with dilute hydrochloric acid (P_H 3.0 or P_H 4.0), dried at room temperature for twenty-four hours, pulverized and used thus as vitamin B(B_1) and as vitamin G supplements for the experimental animals. Each filtrate remaining after adsorption was evaporated under reduced pressure (30–40°) to approximately one-fourth of its original volume, adjusted to about P_H 5.7 and the respective volumes measured in order that known equivalents in terms of the protein-free milk could be fed for measurements of their vitamin B(B_1) and vitamin G potencies.

These several preparations were kept in an ice-box and freshly prepared each week. As supplements the liquid preparations were fed in six equal amounts weekly, the solid preparations were incorporated in the basal rations each week using such quantities of the basal ration for this as would be somewhat less than the animal would eat during the week as judged by previous weekly food records, basal diet alone being fed for the remainder of the week. The experimental animals were in all cases weighed weekly.

Results

Animals receiving the original skimmed milk powder and animals receiving corresponding amounts of untreated protein-free milk as sources

(5) Halliday, *J. Biol. Chem.*, 96, 479 (1932); Stiebeling, *Proc. Soc. Exptl. Biol. Med.*, 29, 1156 (1932).

of vitamin $B(B_1)$ showed practically the same average responses in growth, indicating little or no loss of potency in the preparation of the protein-free milk. The same was true as regards the vitamin G content of the protein-free milk.

When the amount of Lloyd's reagent employed was 40, 20, 10 or 5 g. per liter of protein-free milk, the filtrates were without appreciable vitamin $B(B_1)$ activity; approximately 50% of the original vitamin $B(B_1)$ potency was usually accounted for in the activated solids. Whether the protein-free milk had been adjusted to P_H 3.0 or to P_H 4.0 previous to the addition of the adsorbent made no significant difference in the vitamin **B** or in the vitamin G potencies of the activated solids or filtrates. In all cases the difference between the average growth rates of animals receiving, respectively, the product prepared from protein-free milk adjusted to P_H 3.0 and that adjusted to P_H 4.0 was less than the probable error of that difference. The addition of the adsorbent caused a decrease in the acidity of the solutions, and this was more marked with the larger amounts of adsorbent. When the adsorption processes were carried out in an atmosphere of nitrogen rather than air, the activated solids instead of showing only 50% of the original vitamin $B(B_1)$ of the protein-free milk showed from 60 to 70% of the potency. The activated solids carried about one-third of the vitamin **G** potency of the protein-free milk and the filtrates regularly contained about one-sixth of this original potency, so that in all 50% of the vitamin G activity of the protein-free milk could be accounted for after the fractionation by adsorption with Lloyd's reagent.

When the adsorption processes were carried out in an atmosphere of nitrogen both activated solids and filtrates showed somewhat higher vitamin G potency than when the adsorption was carried out in air, the recovery under nitrogen being about two-thirds as compared with about one-half in the presence of air. The nature of these apparent losses is being studied further.

Summary

1. Protein-free milk may be prepared from skimmed milk powder without appreciable loss of vitamin $B(B_1)$ or vitamin $G(B_2)$ potency.

2. Vitamin $B(B_1)$ is relatively more efficiently adsorbed from protein-free milk on Lloyd's reagent than is vitamin G.

3. Varying the amount of Lloyd's reagent used from 5 to 40 g. per liter of protein-free milk (initially adjusted to P_H 3.0 or P_H 4.0) did not result in appreciable differences in the amounts of vitamin $B(B_1)$ or vitamin $G(B_2)$ adsorbed.

4. Under the conditions of these experiments approximately one-half of the vitamin $B(B_1)$ potency and one-third of the vitamin **G** potency of the original protein-free milk was adsorbed on the Lloyd's reagent; but no appreciable amount of the original vitamin $B(B_1)$ potency and only about

one-sixth of the vitamin G potency was shown by the filtrates after removal of the activated solids.

5. When the adsorption processes were carried out in an atmosphere of nitrogen rather than air and under otherwise comparable conditions, the activated solids were somewhat more potent in both vitamins B(B_1) and G and the filtrates were more potent in vitamin G. The apparent losses are being studied in other ways and in the light of the newer evidence as to probable multiple nature of vitamins B and G.

Liquid Ketene and Ketene Polymers

BY CHARLES D. HURD, AMOS D. SWEET AND CHARLES L. THOMAS

In a study of liquid ketene which was prepared by liquefaction from the gas stream from the pyrolysis of acetone, a few new items of interest were found. (1). Polymerization, which occurs even at $-80°$, may be retarded by a trace of hydroquinone (2 mg. for 2 cc. of liquid). (2). No reaction was observed in twelve hours between liquid ketene and metallic sodium or sodium–potassium (1:2) alloy or sodamide (suspended in toluene) or isoprene. Thus, the alkali metals did not bring about rearrangement of ketene into hydroxyacetylene ($HC{\equiv}COH$) and the isoprene did not add in the way it adds to maleic anhydride.[1] Possibly the low temperature was a contributing factor in these negative effects. **(3).** An extremely vigorous reaction was observed between liquid ketene and the Grignard reagent. Even at $-78°$ and diluted with ether the reaction with n-butyl- or phenylmagnesium bromide was so vigorous that each added drop of Grignard reagent produced a crackling sound. The voluminous yellow solid which precipitated hydrolyzed to a sticky gum from which nothing was obtained. This is a modification of the experiment of Deakin and Wilsmore.[2] They diluted gaseous ketene with hydrogen and observed a very complex reaction as it was passed into a cold ether solution of methylmagnesium bromide.

(4). Tertiary alcohols react with liquid ketene giving tert-alkyl acetates. In previous unpublished work,[3] it was demonstrated that ketene gas also acetylates these tertiary alcohols but less effectively. This confirms Davis and Murray[4] who stated: "Tertiary butyl acetate, a typical tertiary ester, is suitably prepared by the action of ketene with tertiary butanol." However, Davis and Murray cited no experimental work.

(4) Davis and Murray, *Ind. Eng. Chem.*, **18**, 846 (1926).

Six cc. of *tert.*-butyl alcohol (b. p. 79.5–80°) at 20° was added dropwise during ten minutes to 6 cc. of liquid ketene at −78°. The alcohol solidified but gradually dissolved. After three hours the mixture was distilled. About 3 cc. of the alcohol was recovered and 4.5 cc. of a *tert.*-butyl acetate fraction (92–98") formed which, on redistillation, gave these constants: b. p. 96°; $n_{D}^{18.5}$ 1.386 as compared with the recorded value[6] of 1.3887.

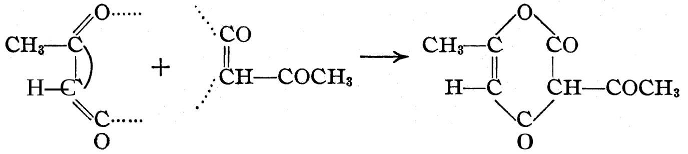
Similarly, 5 cc. each of *tert.*-pentyl alcohol and ketene were admixed and the mixture distilled after three hours. Three cc. was collected below 120° and 2.6 cc. above 130". The *tert.*-pentyl acetate fraction, b. p. 120–130°, was 4.0 cc. On redistillation, it boiled at 123° (747 mm.); n_{D}^{20} 1.392.

Polymers of Ketene.—It was found that both ketene dimer and dehydroacetic acid were by-products in the preparation of ketene from acetone. Accordingly, an apparatus was constructed to facilitate the separation of these polymers. Acetone was boiled into the bottom of a vertical Pyrex reaction tube (2.5 X 90 cm.) the temperature of which was held at 700° by an electric furnace. The escaping gases were directed downward through a water cooled condenser and the condensate returned to the acetone flask to be recycled. The acetone which remained in the gas stream was separated with a coil condenser at −15". When acetone was boiled into the apparatus at such a rate that 2 drops per second of condensed acetone fell from the water condenser, then the flow of ketene in the uncondensed gas was 0.3 mole per hour. Part of this ketene could be liquefied in a trap at −78° but for complete removal a liquid air trap was necessary.

Fractionation of the condensate to 70° at the end of a day's run left a residue weighing 30–50 g. From 15 liters of acetone, 300 g. of this residue was obtained. Two hundred grams of this was crude ketene dimer, b. p. 120–130°, and 100 g. was still higher boiling. Both fractions were contaminated with some acetic anhydride, the presence of which was no doubt due to the fact that the technical acetone used contains some water: $2CH_2CO + H_2O \longrightarrow (CH_3CO)_2O$. The identity of ketene dimer was confirmed not only by its boiling point, 125°, but also by its derivative with aniline, namely, acetoacetanilide, m. p. 84".

The 100 g. of higher boiling residue was about two-fifths dehydroacetic acid. This was separated by two methods: (1) chilling in a refrigerator and recrystallization of the crystals thus produced from either water or benzene; (2) vacuum distillation. The melting point by either method was 108" and it was not depressed by mixing with known dehydroacetic acid. In the vacuum distillation of a 25-g. portion of the 100 g. of residue, 3 cc. of liquid distillate was collected, after which a 10-g fraction appeared which solidified on cooling. This was dehydroacetic acid. The higher boiling residue was a brown tar which appeared to decompose as it was distilled further.

Chick and Wilsmore[6] obtained dehydroacetic acid[7] by treating ketene dimer with a little pyridine. This polymerization is most simply explained on the assumption that ketene dimer is acetylketene rather than cyclobutanedione. Using partial valence formulas it is a straightforward addition



---

(5) Smith and Olsson, Z. *physik. Chem.*, **118**, 99 (1925).

(6) Chick and Wilsmore, *J. Chem Soc* , **93**, 946 (1908): **97**, 1987 (1910).

(7) For its structure, see Rassweiler and Adams, THIS JOURNAL, **46**, 2758 (1924).

The acetylketene formula may be reconciled with Chick and Wilsmore's observation that ketene dimer gives rise to γ-bromoacetoacetyl bromide on bromination by assuming the following rearrangement

$$CH_3COCHBrCOBr \longrightarrow CH_2BrCOCH_2COBr$$

That the —COBr group may facilitate this rearrangement is very reasonable in view of the similar rearrangement[8] which is promoted by the —$COOC_2H_5$ group: $CH_3COCHBrCOOC_2H_5 \longrightarrow CH_2BrCOCH_2COOC_2H_5$.

In a recent paper by Berl and Kullman[9] entitled "Preparation of Ketene by the Catalytic Decomposition of Acetone," acetone vapors were decomposed in an apparatus of the customary type.[10] One gains the impression that a pronounced catalysis was observed, but as a matter of fact any catalytic effects were very small. The yield of ketene depended in large measure on the temperature (about 700°, whereas for useful catalysis one might anticipate about 300 or 400°) and on the ratio of vaporized to decomposed acetone. The best yield (77%) was obtained at 680° with the above ratio as 22:1. The fact that a V_2O_5 filler was present in the reaction tube seems less important than Berl and Kullmann infer, for similar results were obtained[11] with about the same conditions when the reaction tube was quite empty.

Summary

Liquid ketene fails to react with sodium, sodium-potassium, sodamide or isoprene. Its reaction with Grignard reagents is violent and complex. Liquid ketene reacts satisfactorily with tert-butyl and tert-pentyl alcohols to give the tert-alkyl acetates.

Ketene dimer and dehydroacetic acid are by-products of the ketene synthesis. A method of isolating them is described.

The Analysis and Composition of Fatty Material Produced by the Decomposition of Herring in Sea Water[1]

BY ROGER C. WELLS AND E. THEODORE ERICKSON

The widely accepted theory of the origin of petroleum in sedimentary deposits through the decomposition of organic matter derived from plants or animals, or both, adds special interest and importance to our knowledge of observable changes in such materials under natural conditions. The material described in this paper, found to be calcium and magnesium salts of fatty acids, came from a wrecked boat load of herring, and had apparently resulted from the action of sea water on the herring, though for exactly how long a period is not known.

This material was collected at Mole Harbor, Admiralty Island, Alaska, by Mr. A. Hasselborg, and sent to Dr. David White, of the United States Geological Survey, who turned it over to the Chemical Laboratory of the Survey for study and analysis. It was reported that the wreck had long rested in fifteen fathoms of water. As it finally broke up Mr. Hasselborg observed that pieces of this particular material rose to the surface, broke up, and gradually sank again. The material, as received in Washington, sank in sea water of specific gravity 1.03, unlike free fatty acids, which float. This fact indicates that such material might be deposited directly in sediments. The sample consisted of fairly uniform pieces with a greasy feel, somewhat porous and nearly white in appearance, with some finer broken material. The larger pieces seemed to consist of layers.

ANALYSIS (BY E. T. ERICKSON) OF FATTY MATERIAL DERIVED FROM THE DECOMPOSITION OF HERRING

C	**63.63**
H	**10.06**
N	**0.43**
S	**0.93**
Ca	**5.00**
Mg	**0.82**
K	**0.03**
Na	**0.26**
Fe_2O_3	Trace
Al_2O_3	**0.12**
PO_4	**0.19**
SO_4, CO_3	None
NaCl	**2.72**
SiO_2	**0.20**
	84.39
Undetermined, mainly oxygen, by difference	**15.61**
	100.00

This analysis was made with material dried at 105° for one hour, during which the loss was 5.90%. This loss was found to be practically all the water and did not include a significant quantity of organic matter. Nitrogen was determined by the Dumas method, and sulfur by the Carius method. The difference represents mainly organic oxygen. The most striking features shown by the analysis are the high percentages of calcium and magnesium and low percentage of phosphate;

---

[1] Published by permission of the Director of the U. S. Geological Survey.

the calcium cannot be present as calcium phosphate or carbonate but must be mainly in an organic compound.

Further tests to determine the identity of the organic material were made by decomposing it with hydrochloric acid. The resulting insoluble fatty acids were filtered off, dried, extracted with benzene, and the unsaturated and saturated acids separated by the Varrentrap method.[2] The saturated fatty acids probably include palmitic acid, myristic acid, and some acids of lower molecular weight. These conclusions are based on determinations of the melting points of the fractionated material. Three small fractions were separated by adding magnesium acetate to the alcoholic solution of the mixed acids. These fractions, freed from magnesium, had melting and solidifying points of 58 and 56°, 5S.5 and 55°, and 57 and 55.5°, respectively. The melting and solidifying points of the original saturated fatty acid material were 53 and 51°; those of material remaining from the fractionation 48 and 47".

Stearic acid did not seem to be present, although Lexow[3] states that its glyceryl ester occurs in Norwegian herring oil, together with the esters of palmitic and myristic acids. On the other hand, Fryer and Weston[4] state that the "stearine" obtained from Japanese herring and other fishes is chiefly "palmitin." Tsujimoto[5] isolated palmitic and myristic acids from fatty material obtained from the great herring at Hokkaido (Hokushu) but found the glyceryl ester of stearic acid present in relatively small quantities. Thus the range of saturated fatty acids recovered from the Mole Harbor material is about the same as that in glyceryl ester form in herring oil.

The unsaturated fatty acid portion was amber colored, of an oil-like appearance, and gave an iodine adsorption figure of 70 by the Wijs method. This figure is low compared with that of known herring oils. Lexow,[6] in 120 Norwegian herring oils collected from different localities and at different seasons of the year, found a high average of 148 during August and a low average of 115 during March.

A summary of the findings in the quantitative work is given in the following table.

The non-saponifiable matter yielded a small quantity of the characteristic cholesterol precipitate with digitonin. This precipitate was converted to acetate, the melting point of which confirmed the presence of cholesterol. Because of lack of material the state of occurrence of the cholesterol was not determined.

SUMMARY OF CHEMICAL SEPARATIONS ON SAMPLE FROM MOLE HARBOR

		Per cent.
Loss on heating for one hour at 105°		5.90
Organic matter extracted with benzene after treatment of the sample with hydrochloric acid	Unsaturated fatty acids	8.20
	Saturated fatty acids	64.50
	Non-saponifiable matter	0.60
Protein calculated from nitrogen (N X 6.25)		2.80
Inorganic matter, including sulfur and 2.72 NaCl		10.27
Undetermined, including possibly some carbohydrate substance and oxygen required by sulfur compounds, less replaceable hydrogen of fatty acids (0.33)		7.73
		100.00

The material insoluble in benzene was found on ignition to contain some organic matter. At the beginning of the ignition carbonization was noted, followed by the characteristic odor of burning protein. The material extracted with benzene gave no evidence of undecomposed glyceryl ester. Most of the fatty acids in the original sample must have been combined with the inorganic bases, though some free acids may have been present.

Geochemical Features.—The well-known Engler–Hofer theory of the origin of petroleum from fatty materials in sediments[7] seems to assume that the fatty substances are isolated in some way from the saline constituents of the water of the sediments during the stage of microbiochemical decomposition, so that calcium and magnesium compounds of the liberated fatty acids are not formed. According to this theory the fatty substances first change into free fatty acids and glycerin, either by hydrolysis or by microbiochemical-fermentation, or both. Eventually, the fatty acids are assumed to split off carbon dioxide and the hydrocarbons to polymerize into petroleum. It is impossible here to go into the many details of this theory. The present writers wish to emphasize a possibility not heretofore considered—that calcium and magnesium salts may be formed even before or as the material is inclosed in sediments, and that such compounds deposited with the sediments can then yield petroleum under proper environmental conditions, whether by heat, base exchange or otherwise.

The experiments described below were made to find out whether the material from Mole Harbor would show any marked disinclination to form oil upon thermal decomposition in sealed glass tubes. They indicate that such material requires but a slightly higher temperature than free fatty acid material to form oil.

The free fatty acid, palmitic acid, some calcium palmitate and the herring residue from Mole Harbor were each subjected to successive heat treatments in sealed glass tubes during eighteen-hour intervals at 200, 300 and 350° and then finally for seven days at 350°, and any effects that might indicate decomposition noted.

---

[7] "Das Erdöl," Leipzig, 1909, II Band, 114–128. E. Engler, *Petroleum Zeitschrift*, 7, 399403 (1912); "Das Erdol und seine Verwandten," Braunschweig, 1922, p. 329.

At 200° the palmitic acid and the herring residue darkened slightly and each of the materials melted into a mass that solidified on cooling.

At 300° the palmitic acid darkened further in color and still solidified on cooling. The calcium palmitate and the herring residue remained apparently unchanged from the previous heat treatment.

Under the initial heat treatment at 350° for eighteen hours the palmitic acid yielded a still darker brownish product that remained fluid at ordinary room temperatures. The calcium palmitate and herring residue changed but slightly in color and gave but little appearance of having undergone any further decomposition.

In the further heating for seven days at 350° all the materials yielded a greenish fluorescent petroleum-like product. The yield was similar in each experiment and appeared relatively high compared to the quantity of original material taken. When the tube which had held the calcium palmitate was opened considerable pressure was shown. The odor resembled gasolene. The residue consisted of carbonaceous matter, a little tiapthenic-like oil, and calcium carbonate.

Summary

This paper describes the analysis of calcium and magnesium salts of fatty acids derived from herring buried under sea water, and discusses some geochemical possibilities related to the origin of petroleum in sedimentary deposits.

The Preparation and Optical Resolution of Ammonium *dl*-Alpha-Bromocamphor-Pi-Sulfonate

BY A. W. INGERSOLL AND S. H. BABCOCK

The preparation of many asymmetric acids and bases is necessary for a comprehensive study of optically isomeric salts.[1] Obviously those acids and bases whose racemic forms are capable of resolution and whose active forms are useful resolving agents are especially valuable. Also the racemic forms are as necessary for this type of study as the active forms. Bases suitable for resolution work and available in both the racemic and active forms are fairly numerous, but there are relatively few acids of this description. Thus d-tartaric, *l*-malic, d-camphor-10-sulfonic and *d*-α-bromocamphor-n-sulfonic acids are the only ones that have been much used. The optical antipodes and the racemic forms of these, though known in

---

[1] (a) Ingersoll and White, THIS JOURNAL, 54,274 (1932); (b) Ingersoll and **Burns,** *ibid.*, 54, 4712 (1932).

most cases, are comparatively uncommon. Satisfactory methods for preparing the rarer varieties of these and other suitable acids are therefore being studied. The preparation of dl-a-bromocamphor-n-sulfonic acid (as ammonium salt) and a simple method for resolving it into the pure d- and l-forms are described in this paper.

d-a-Bromocamphor-n-sulfonicacid has found extensive use as a resolving agent since its advantages for this purpose were pointed out by Pope and Peachey.[2] It is prepared by the sulfonation of d-a-bromocamphor derived from ordinary *d*-camphor[3,4] and is therefore readily accessible. The corresponding I-acid has been prepared similarly from *l*-camphor.[5] Since the latter is usually not entirely pure and is difficult to obtain, the *l*-acid is somewhat rare. The dl-acid and its simple salts appear not to have been completely described. It is said to be formed in traces when d-a-bromocamphor is sulfonated,[6] but in the few other instances in which this acid[7] or its derivatives[8,9] are mentioned in the literature, these appear to have been made only by mixing the active forms.

The method of preparation described in the present paper is based upon the direct sulfonation of dl-a-bromocamphor derived from commercial dl-camphor. This apparently simple method has not previously been described, doubtless because the necessary dl-a-bromocamphor has not been available in sufficient amounts. A method for obtaining this intermediate in good yields and large amounts was therefore first developed. It was found that dl-camphor reacts with one mole of bromine to form a semi-solid mass. This appears to contain chiefly dl-a-bromocamphor and the isomeric dl-a'-bromocamphor, together with dl-camphor and *dl*-α,α'-dibromocamphor. The separation of crystalline dl-a-bromocamphor was at first troublesome because of its excessive solubility and the presence of the even more soluble by-products. However, it was found that most of the a'-compound was converted to the a-compound by heating the mixture and then crystallizing the a-compound from slightly alkaline alcohol at -10°. This method of isomerizing the a'-compound was suggested by the experience of Marsh[10] and of Lowry[11] in the preparation of d-a-bromocamphor from d-camphor, though in this case the less soluble active compound crystallized readily. Haller[12] has described the bromination product

of *dl*-camphor as a "buttery mass." He was unable to crystallize this under any conditions, but did prepare a specimen of *dl*-α-bromocamphor, m. p. 51°, by mixing the active forms. His description of this compound was confirmed.

dl-α-Bromocamphor was sulfonated with chlorosulfonic acid and ammonium *dl*-α-bromocamphor-π-sulfonate isolated. Although the yield was somewhat low (30–35%) it was not difficult to prepare large amounts of the pure salt. The optical resolution was then carried out. In a recent paper[1b] it was shown that the active forms of α-*p*-tolylethylamine can easily be prepared in good yields by resolving the dl-base with d-camphoric acid. When ammonium *dl*-α-bromocamphor-π-sulfonate is combined with the *l*-form of this base in dilute acetic acid, the *l*B*l*A salt and, in smaller amounts, the *l*B*d*A salt can be gotten pure from the solution. The ammonium salts of the corresponding acids were obtained from these salts in good yields. This method of resolution appears to be more satisfactory than that of Pope and Gibson.[7] These workers resolved the dl-acid, whose source was not mentioned, by means of *d*-1,2-dihydropapaverine (*d*-pavine). This base had been obtained from synthetic dl-pavine by resolution with d-a-bromocamphor-a-sulfonic acid. Although the resolution was apparently not difficult, the base employed is too rare for general use.

Experimental

Preparation **of *dl*-α-Bromocamphor.**—*dl*-Camphor (152 g.) was placed in a three-necked flask on a steam-bath and bromine (163 g.) was slowly added while the mixture was stirred.[13] It gradually liquefied and hydrogen bromide was evolved. Including two hours for adding the bromine, the mixture was heated for ten hours. While still warm it was then poured with stirring into two liters of water containing a few grams of sodium sulfite. The waxy solid, when broken up, filtered, washed with fresh water and air-dried, weighed 220–235 g. and was slightly brown. Many unsuccessful attempts were made to crystallize the substance from the usual organic solvents, in which it is very soluble. Finally it was found that a filtered solution in 95% ethanol (1 cc. per gram), when held at −10° in the freezing chamber of an electric refrigerator and inoculated with crude or previously purified material, slowly deposited about half the material as a colorless, crystalline mass, m. p. 47–49°. Recrystallization under similar conditions gave back about 80% of the first crop, m. p. 49–50°. On concentration the mother liquors gave some crystalline material, but principally a reddish-brown oil. The initial yield of crystalline product was considerably increased when the alcoholic solution of the crude product or the oil was made slightly alkaline with sodium hydroxide and warmed for a few minutes before cooling. Also the oily material from several runs, when distilled at 4 mm., was separated into a small forerun (chiefly dl-camphor), a dark residue, and a main fraction boiling at 108°. This solidified, and then melted at 44–46°. It contained 34.2% of bromine instead of 34.6% calculated for monobromocamphor, and when crystallized from alkaline alcohol gave back about half its weight as crystals, m. p. 49–50'. By thus alternately distilling and crystallizing an average yield of 178 g. (77%) of crystals, melting at 49° or higher. was obtained in five runs.

Pure dl-a-bromocamphor separates from 95% ethanol in large, monoclinic hemimorphic crystals, melting at 50.5–51° (corr.), in agreement with Haller's value.

[13] Armstrong and Mathews, *Chem. News*, **37**, 4 (1878).

Anal. Calcd. for $C_{10}H_{15}OBr$: Br, 34.6. Found: Br, 34.4.

Ammonium-dl-or-Bromocamphor-T-sulfonate—Pure dl-a-bromocamphor was sulfonated in 230-g. lots with chlorosulfonicacid and converted to a solution containing the ammonium sulfonate. The procedure used by **Kipping** and Pope[3] for the preparation of the corresponding dextro compound was followed. When the initially dark brown solution was concentrated in stages the crude ammonium salt separated and was systematically recrystallized. Much of the material remained as a sirupy residue and the yield of pure salt (100–115 g. or 30–35%) is considerably lower than claimed for the dextro salt.

The pure salt crystallizes from water as a dense crystalline mass or in thick transparent prisms and is anhydrous. It melts with decomposition at 250–254'. The solubility is 15.9 g. per 100 g. of water at 25°. This is smaller than that of the corresponding d-salt, which was found to be 20.6 g. at 25°. The crystal form is also different.

Anal. Calcd. for $C_{10}H_{18}O_4NSBr$: N, 4.27; Br, 24.36. Found: N, 4.25; Br. 24.69.

Resolution of Ammonium dl-a-Bromocamphor-T-sulfonate.—The ammonium salt (49.2 g.) was dissolved in 400 cc. of boiling water and 20.3 g. of **l-α-p-tolylethylamine** and 13 g. of glacial acetic acid were added. Upon cooling most of the salt separated as a colorless oil and then solidified. This was redissolved and the solution inoculated with a sample of the solid. The first fraction of crystals then obtained on cooling was levorotatory, but successive fractions were alternately dextro- and levorotatory. After some experimentation it was found that the less soluble *l*B*l*A salt tends to form large prisms on the bottom of the vessel while the *l*B*d*A salt forms needles filling the solution Also the salts differ more in solubility at 50–80° than at lower temperatures. Hence when levorotatory fractions were recrystallized at 80 to 50° from about seven parts of water, after inoculation with the prisms, principally the *l*B*l*A salt separated. The warm mother liquor, when decanted and cooled, then gave strongly dextrorotatory deposits. By judicious combination of fractions similar in appearance and rotation and inoculation with the appropriate crystals, there was soon obtained about 75% of the *l*B*l*A salt and 55% of the *l*B*d*A. The intermediate fractions could be further separated but it was better to combine them with similar fractions from following runs The total yields of the salts in three runs were then 92 g. (89%) and 80 g. (76%), respectively.

l-α-p-Tolylethylamine-l-α-bromocamphor-π-sulfonate forms coarse, hydrated prisms, solubility 2.10 g. per 100 g. of water at 25°. The anhydrous salt melts at 165" (corr.).

Anal. Calcd. for $C_{19}H_{28}O_4NSBr \cdot H_2O$: H_2O, 3.87. Found: H_2O, 3.97.

Rotation. Hydrated salt, 0.8445 g. made up to 50 cc. in water gave α_D^{25} −2.12 in 2 dm.; $[\alpha]_D^{25}$ −62.7'; M_D −291" (10^2).

l-α-p-Tolylethylamine-d-α-bromocamphor-π-sulfonate crystallizes initially in needles or narrow prisms. These change to irregular masses on standing in the solution for several days; both forms are the monohydrate. The needles lose their water on exposure to air for several days, and then melt at 232' (corr.). The solubility (hydrated needles) is 2.96 g. per 100 g. of water at 25°.

Anal. Calcd. for $C_{19}H_{28}O_4NSBr \cdot H_2O$: H_2O, 3.87. Found: H_2O, 3.80.

Rotatzon. Subs., 1.2297 g. (anhydrous) made up to 50 cc. in water gave α_D^{25} +3.09° in 2 dm.; $[\alpha]_D^{25}$ +59.4°; M_D +265° (10^2).

Ammonium **l-α-Bromocamphor-π-sulfonate.**—The *l*B*l*A salt described above was treated with a slight excess of dilute barium hydroxide and the base distilled with steam. The barium was completely removed with ammonium carbonate and the filtered solution evaporated to obtain the 1-ammonium salt. This resembled the familiar d-salt, and its rotation, $[\alpha]_D^{25}$ −86.6°, agrees with the value of Pope and **Harvey**.[5] The yields of recovered base and ammonium salt were nearly quantitative.

Ammonium d–a–Bromocamphor–r–sulfonate was similarly obtained from the *l*B*d*A salt. The specific rotation was +85.8°.

Summary

1. A satisfactory method for preparing dl-a-bromocamphor from *dl*-camphor is described.
2. Ammonium *dl*-*α*-bromocamphor-*π*-sulfonate was prepared from *dl-or*-bromocamphor, and this salt and its optical resolution by means of *I-a*-*p*-tolylethylamine are described.

Higher Alkyl Sulfonates

BY VLADIMIR C. SEKERA AND C. S. MARVEL

Although alkyl esters of the aromatic sulfonic acids have long been known as alkylating agents, the real development of these reagents has been more recent and even now they are used only for the unusual alkylation reactions. The alkyl halides and sulfates are the common reagents for introducing alkyl groups and are unquestionably the most useful reagents for the lower molecular weight radicals. However, the higher alkyl halides (ten carbons or more) are somewhat sluggish in their alkylation reactions and the higher sulfates are not easily obtained. The work which is reported in this paper was undertaken in order to find a satisfactory method of preparing the higher aliphatic esters of the aromatic sulfonic acids, to study these esters as alkylating agents, and to compare the corresponding esters of aliphatic sulfonic acids and aromatic sulfonic acids in simple alkylation reactions.

It has been found that the method of preparing sulfonic acid esters from an alcohol, a sulfonyl chloride and pyridine can be extended to the alkyl esters of both aliphatic and aromatic sulfonic acids. Patterson and Frew[1] were apparently the first to use this general method. Ferns and Lapworth[2] pointed out the difficulty of obtaining ethyl and benzyl esters of sulfonic acids because they readily combined with pyridine to give water-soluble products which were evidently quaternary ammonium salts. However, this side reaction has not been found to be serious with the higher alkyl esters when they were prepared at 0°. The yields of esters which were obtained varied from 60–80% of the theoretical amounts.

Two series of esters, the *p*-toluenesulfonates and the *p*-bromobenzenesulfonates, were prepared from the higher normal alcohols with an even

---

[1] Patterson and Frew, *J. Chem. Soc.*, 89,332 (1906).

[2] Ferns and Lapworth. *ibid.*, 101, 273 (1912).

number of carbon atoms. These esters are solids which all melt below 65° yet are easily purified by recrystallization from petroleum ether and seem to be of promise as derivatives for identification.

A few experiments demonstrated the usefulness of the higher esters as alkylating agents. Lauryl and cetyl *p*-toluenesulfonates alkylated n-butylamine quite readily to give a mixture of the expected secondary and tertiary amines in yields which were almost identical with those obtained from n-butyl *p*-toluenesulfonate in a similar reaction. Cetyl cyanide was obtained in 85% yield from cetyl *p*-toluenesulfonate and potassium cyanide whereas the butyl ester gave only a 46% yield of cyanide. Lauryl p-toluenesulfonate combined with pyridine to give a crystalline quaternary ammonium salt in excellent yields when the two reagents were warmed together.

In order to compare the esters of aliphatic and aromatic sulfonic acids as alkylating agents, the reactions of n-butyl methanesulfonate and n-butyl p-toluenesulfonate with sodium phenolate, sodium acetate and aniline were studied. The yields of ether, ester and secondary amine, respectively, were practically the same with these two reagents. These experiments showed that the esters of the aliphatic sulfonic acids offer no advantage over the more readily available aromatic sulfonic acid esters.

Experimental

_n_-Butyl Methanesulfonate.—A mixture of 14.8 g. of n-butyl alcohol and 22.9 g. of methanesulfonyl chloride was placed in a 500-cc., three-necked flask, equipped with a mechanical stirrer and a separatory funnel and cooled in an ice–salt bath to 0°. The stirrer was started and 31.6 g. of pyridine was added slowly over a period of three to four hours. An excess of dilute hydrochloric acid was added to the cold solution to remove the pyridine and the aqueous solution was extracted with ether. The ether solution was dried over anhydrous potassium carbonate, filtered and evaporated. The ester was distilled under reduced pressure. The yield was 24.2 g. (79.5% of the theoretical amount) of a product boiling at 105–106° (6 mm.); d_4^{20} 1.1074; n_D^{20} 1.4319.

Anal. Caicd. for $C_5H_{12}O_3S$: S, 21.07. Found: S, 20.86.

_n_-Butyl _p_-Toluenesulfonate.—This ester was prepared in the same manner from 14.8 g. of *n*-butyl alcohol, 41.9 g. of *p*-toluenesulfonyl chloride and 31.6 g. of pyridine. The yield was 39.3 g. (86% of the theoretical amount) of a product boiling at 169' (4 mm.); d_4^{20} 1.1319; n_D^{20} 1.5085.

Higher **Alkyl _p_-Toluenesulfonates** and **_p_-Bromobenzenesulfonates.**—The esters of the alcohols with ten or more carbons were solids and their preparation varied slightly from the above procedure.

A solution of one equivalent of the alcohol in four equivalents of pyridine was cooled to below 20' and with stirring 1.1 equivalents of pure arylsulfonyl chloride was added in portions. The reaction mixture was stirred for about three hours after the addition was complete. The temperature of the reaction mixture was always held below 20". The reaction mixture was treated with a fairly large excess of cold dilute hydrochloric acid and the ester which separated was collected on a Biichner funnel. After drying in the air the ester was recrystallized from alcohol or better from petroleum–ether. Usually one recrystallization gave a constant melting product. The esters were prepared in 12–26 g. lots.

The esters prepared and the yields and melting points of the purified products are listed in Tables I and II.

TABLE I

SOME ALKYL ESTERS OF *p*-TOLUENESULFONIC ACID

Stearyl	62	64–65	16.3	16.2

Alkylation Experiments. (a) **Pyridine**

n-Butyl **Pyridinium *p*-Toluenesulfonate.**—A mixture of **22.8** g. of n-butyl *p*-toluenesulfonate and **7.9** g. of pyridine was heated in an oil-bath at **130–140"** for two hours On cooling the mixture solidified and was recrystallized from a mixture of ethyl acetate and acetone. The yield of product was **27** g. (88%of the theoretical amount); m. p. 114°.

Anal. Calcd. for $C_{18}H_{21}O_3NS$: S, **10.44.** Found: S, **10.36.**

Lauryl Pyridinium *p*-Toluenesulfonate.—This quaternary ammonium salt was obtained in the same manner from **8** g. of lauryl *p*-toluenesulfonate and **1.9** g. of pyridine. The yield was **8.5** g (86% of the theoretical amount) of a product melting at 135–136° after recrystallization from acetone.

Anal. Calcd. for $C_{24}H_{37}O_3NS$: S, **7.65.** Found: S, **7.38.**

(b) n-Butylamine

***n*-Butyllaurylamine** and ***n*-Butyldilaurylamine.**—A solution of **7.3** g. of n-butylamine and **34.1** g of lauryl p-toluenesulfonate in **50** cc. of dry toluene was refluxed for about six hours. The mixture was treated with a concentrated solution of aqueous sodium hydroxide and distilled with steam to remove the toluene and any remaining hutylamine. The residue in the distilling flask was extracted with ether, and the ether solution was dried over anhydrous potassium carbonate, filtered and evaporated. The residue was distilled under reduced pressure. There was thus obtained **11.9** g. (49% of the theoretical amount) of n-butyllaurylamine, b. p. 138–140° **(6** mm.); d_4^{20} **0.8174;** n_D^{20} **1.4491;** and **6.9 g. (44%** of the theoretical amount) of *n*-butyldilaurylamine, b. p. **224–226° (6 mm.)**; d_4^{20} 0.8281; n_D^{20} **1.4582.**

Anal.[3] Calcd. for $C_{16}H_{35}N$: N, **5.81.** Found: N, **5.77** Calcd. for $C_{28}H_{59}N$: N, **3.42.** Pound: N, **3.62.**

***n*-Butylcetylamine** and ***n*-Butyldicetylamine.**—In exactly the same manner, **7.3** *g*. of *n*-butylamine and **39.4** g. of cetyl *p*-toluenesulfonate gave **15.1** g. (51% of the theoretical amount) of *n*-butylcetylamine, b. p. **193–197" (6** mm.); m. p. 31–32°; and **8.7** g.

---

[3] These analyses were made by Mr. K. Eder.

(33% of the theoretical amount) of n-butyldicetylamine, b. p. 295–297° (6 mm.); m. p. 44–46°.

Anal.[3] Calcd. for $C_{20}H_{43}N$: N, 4.71. Found: N, 4.58. Calcd. for $C_{38}H_{75}N$: N, 2.69. Found: N, 2.58.

(c) Potassium Cyanide

Cetyl Cyanide.—To a solution of 13 g. of potassium cyanide in 150 cc. of water was added 39.6 g. of cetyl p-toluenesulfonate. The solution was boiled under a reflux condenser for about six hours, and then cooled and extracted with ether. The ether was evaporated and the residue was distilled under reduced pressure. The yield was 21.5 g. (86% of the theoretical amount) of cetyl cyanide which melted at 26–29°. The melting point of pure cetyl cyanide is given as 29.5–30°.[4]

n-Butyl Cyanide.—The reaction between *n*-butyl p-toluenesulfonate and potassium cyanide under similar conditions gave only 46% of the theoretical amount of n-butyl cyanide; b. p. 136–140°.

Comparison of n-Butyl Methanesulfonate with n-Butyl p-Toluenesulfonate as a Butylating Reagent. (a) Phenol.—To a solution of 9.4 g. of phenol in 40 cc. of 10% sodium hydroxide was added 22.8 g. of n-butyl p-toluenesulfonate. The mixture was gently refluxed for about three hours, cooled and extracted with ether. The ether solution was dried over potassium carbonate, filtered and evaporated On distillation of the residue under reduced pressure. a yield of 11 g. (73% of the theoretical amount) of n-butyl phenyl ether was obtained, b. p 72–73" (6 mm.); d_4^{20} 0.9515; n_D^{20} 1.5049.

When 15.2 g. of n-butyl methanesulfonate was substituted for the n-butyl p-toluenesulfonate in a similar experiment, the yield of ether was 12.2 g. (81% of the theoretical amount); b. p. 72–73' (6 mm.); d_4^{20} 0.9516; n_D^{20} 1.5046.

(b) Aniline.—A mixture of 9.3 g. of aniline and 22.8 g. of n-butyl p-toluenesulfonate was heated in an oil-bath at 130–140° for about two hours. On cooling the mixture a white solid was obtained. Addition of excess concentrated aqueous sodium hydroxide solution liberated the mixed amines. The amines were collected in ether, dried over potassium carbonate and distilled under reduced pressure. The yield of n-butylaniline was 9.6 g (64% of the theoretical amount); b. p. 115–120° (15 mm.); d_4^{20} 0.9358; n_D^{20} 1.5381.

Repetition of the experiment with the substitution of 15.2 g. of n-butyl methanesulfonate for the p-toluenesulfonate gave 10.1 g. (68% of the theoretical amount; of n-butylaniline; b p. 112–114° (9 mm.); d_4^{20} 0.9362; n_D^{20} 1.5373.

(c) Sodium Acetate.—A mixture of 13.6 g. of powdered sodium acetate ($CH_3CO_2Na\,2H_2O$) and 22.8 g. of *n*-butvl p-toluenesulfonatr was thoroughly mixed and heated to 130–140° in an oil-bath for about five hours. The mixture was then cooled, treated with 100 cc. of water and extracted with ether. On distillation 7 g. (60% of the theoretical amount) of n-butyl acetate was obtained; b. p. 123–125°; d_4^{20} 0.8797; n_D^{20} 1.3989

In a similar run 15.2 g. of *n*-butyl methanesulfonate gave 7.3 g. (63% of the theoretical amount) of *n*-butyl acetate, b. p. 123–125°; d_4^{20} 0.8799; n_D^{20} 1.3990.

Summary

1. Some higher alkyl (C_{10} and above) esters of p-toluenesulfonic acid and *p*-bromobenzenesulfonic acid have been prepared.

2. These esters have been found to be useful alkylating agents in such typical reactions as alkylation of an amine or the preparation of an alkyl

---

[4] Shriner, Fulton and Burks, THIS JOURNAL, 55 (1933).

cyanide. The yields of product are approximately the same or better than can be obtained from lower alkyl sulfonates in the same reaction.

3. Comparison of n-butyl methanesulfonate with n-butyl *p*-toluenesulfonate has shown that there is no advantage of an ester of an aliphatic sulfonic acid over an ester of an aromatic sulfonic acid for alkylation reactions.

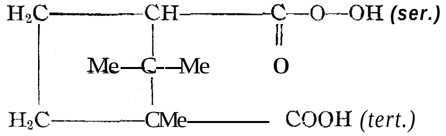
Studies in Organic Peroxides. I. Peroxides in the Camphoric Acid Series

BY NICHOLAS A. MILAS AND AMBROSE MCALEVY

Introduction

In connection with our general studies in auto-oxidation reactions[1] and especially the catalytic effects produced by organic peroxides on these and other related reactions, we had occasion to synthesize and study the properties of several new peroxides. The present communication describes the successful synthesis of some peroxides and peracids which are structurally related to camphoric acid.

A careful search of the literature revealed that up to the present time no definite peroxides of the camphoric acid series have been prepared.[2] We have obtained from camphoric anhydride and sodium peroxide a camphoric acid peracid which has the peracid group attached to the secondary carbon atom.



We have also prepared the methyl ester of this peracid by converting the tertiary monomethyl ester of camphoric acid to the acid chloride, to the ester peroxide and finally to the ester peracid.[3] The possibility of making the isomeric acid peracid through its ester derivative was precluded by the fact that the secondary monomethyl ester yields the tertiary ester secondary acid chloride[4] which gives the same ester peracid obtained from the tertiary monomethyl ester of camphoric acid. This conclusion was

verified experimentally. Experiments are being conducted with the monocholesteryl and monoergosteryl esters of camphoric acid to determine the effect of the size of the alcohol group on the migration from the secondary to the tertiary carboxyl.

Experimental Part

d-Camphoric Acid Peracid.—To 200 cc. of water at 0° is added with vigorous stirring and cooling during fifteen minutes, 4.3 g. of sodium peroxide, and to this mixture is then added during one hour, 400 cc. of ethyl ether containing 10 g. of *d*-camphoric anhydride (freed from acid by shaking with saturated sodium bicarbonate solution). Stirring is continued for one hour longer, then the ether is removed and 200 cc. of fresh cold ether added. If the peracid is to be used for the estimation of unsaturation, chloroform may be substituted for ether at this stage. The mixture is then acidified in the cold with 25 cc. of 6 *N* splfuric acid, transferred to a separatory funnel and violently shaken once or twice; the ether layer is separated, shaken with about 100 cc. of saturated ammonium sulfate solution to remove any free hydrogen peroxide present, and dried overnight at 0° with anhydrous sodium sulfate. When the ether is removed at room temperature and under reduced pressure, a highly viscous liquid is obtained having a purity of 87–92% peracid; yield, 6–8 g. A white solid is obtained from the viscous liquid by treating the latter several times with ice-cold low-boiling petroleum ether (freed from unsaturated hydrocarbons) and scratching the vessel with a glass rod. The peracid is finally dried in a vacuum desiccator over concentrated sulfuric acid; m. p. 49–50° (in a sealed tube).

Anal. Calcd. for $C_{10}H_{16}O_5$: C, 55.53; H, 7.46; active (O), 7.40. Found: C, 55.21; H, 7.45; active (O), 6.93, 7.16, 6.77.

Camphoric acid peracid is soluble in water, and in dilute aqueous solution hydrolyzes to yield camphoric acid and hydrogen peroxide. It is soluble in nearly all organic solvents and slightly soluble in petroleum ether. If kept at 0° and in an atmosphere of dry air, it retains its stability for several weeks. At room temperature camphoric acid peracid decomposes slowly to yield camphoric acid and oxygen, and when heated to 80–100° this reaction proceeds explosively. Its sodium salt reacts in the cold with acid chlorides and anhydrides to give acyl peroxides.

Dicamphoryl Peroxide.—To a mixture of 400 cc. of ethyl ether and 10 g. of *d*-camphoric anhydride is added slowly at 0° with vigorous stirring, a mixture of 50 g of chopped ice and 2.15 g. of sodium peroxide. After stirring for three-quarters of an hour, the ether is replaced with 400 cc. of fresh ether and the aqueous layer carefully acidified with 6 *N* sulfuric acid. The ether layer, which now contains the peroxide, is removed, dried with anhydrous sodium sulfate and the ether removed in vacuum. The solid which separates out consists of dicamphoryl peroxide and camphoric acid and to remove the latter the solid is extracted several times, each time with a few cc. of anhydrous ethyl ether, the mixture centrifuged and the Supernatant ether decanted. Finally the residue is recrystallized several times from an acetone-petroleum ether mixture (4 to 1) and the product dried in a vacuum desiccator over sulfuric acid; m. p. 142° with explosive decomposition; yield of the pure product, 3.4 g.

Anal. Calcd. for $C_{20}H_{30}O_8$: C, 60.28; H, 7.59; active (O), 4.02. Found: C, 60.34, 60.14; H, 7.83, 7.58; active (O), 4.00, 3.92.

The active oxygen was determined in acetone containing sodium iodide and acidiied with glacial acetic acid. This peroxide was also obtained in poor yields by the action of camphoric anhydride on the sodium salt of camphoric acid peracid. It is sparingly soluble in water, soluble in acetone and chloroform, somewhat soluble in ether and only slightly soluble in benzene and petroleum ether. It explodes when heated in a flame, producing substances of terpene-like odor.

Camphoryl Tert-monomethyl Ester **Sec-chloride.**—This chloride was obtained from the *tert.*-**monomethyl ester,**[5] m. p. 85.4°, and from the *sec.*-**monomethyl ester,**[5a] m. p. 77°, by the action of phosphorus trichloride in yields of **90%.**

Anal. Calcd. for $C_{11}H_{17}O_3Cl$: Cl, 15.42. Found: Cl, 15.60.

Several attempts to distil this acid chloride, even at very low pressures, resulted in its complete decomposition with the formation of camphoric anhydride, **dimethyl** ester of camphoric acid and hydrogen chloride. Upon hydrolysis it yields *tert.*-**monomethyl** ester d-camphoric acid.4

Bis-[tert.-methyl Ester **Sec.-camphoryl]** Peroxide.—To **80** g. of finely chopped ice is slowly added with shaking **5** g. of sodium peroxide, and to this mixture is added slowly in one hour with continuous shaking **150** cc of cold ethereal solution containing **10** g. of *tert.*-**methyl** ester camphoryl chloride. The mixture is violently shaken for half an hour longer to cause the complete conversion of the acid chloride to the peroxide, the ether layer separated, dried by shaking several times with fresh anhydrous sodium sulfate and the ether removed by suction in the cold. The white solid residue is then recrystallized several times from warm low-boiling petroleum ether; m. p. **102";** yield of the pure product, **3.17** g.

Anal. Calcd. for $C_{22}H_{34}O_8$: **C, 61.96; H, 7.98;** active **(O), 3.75.** Found: C, **61.52; H, 7.95;** active (O) in acetone, 3.52, 3.18.

The above preparation has been repeated using a sample of acid chloride obtained from *sec.*-**monomethyl** ester d-camphoric acid; the same peroxide has been obtained, m. p. **102°. A** mixed melting point with the peroxide obtained in the first case showed no depression.

Sec.-methyl Perester Tert.-methyl Camphoric Ester.—This **perester** is prepared by adding slowly with vigorous stirring to an ice-cold aqueous solution containing the calculated amount of the barium salt of methyl **hydroperoxide,**[6] **5** g. of *tert.*-**methyl** ester camphoryl chloride in **200** cc. of ethyl ether. The mixture is shaken at 0° for fifteen minutes longer, the ether layer separated, washed with a saturated solution of sodium bicarbonate, dried with anhydrous sodium sulfate and the ether removed in vacuum; a sirupy liquid is obtained which failed to crystallize.

Anal. Calcd. for $C_{12}H_{20}O_5$: C, **58.99;** H, **8.26.** Found: C, **58.79;** H, **8.50.**

Analysis for active oxygen in various solvents yielded rather unsatisfactory results which are in accord with observations of other **investigators.**[6,7] The **perester** on standing at room temperature and in the presence of moisture hydrolyzes to yield methyl hydroperoxide and the original monomethyl ester of camphoric acid.

Tert.-methyl Ester **Sec.-camphoric** Peracid.—To **3** g. of **bis-[*tert.*-methyl** ester *sec.*-**camphoryl]** peroxide in **20** cc. of ethyl ether is slowly added at 0° and with vigorous stirring the calculated amount of sodium methylate, and to this mixture is then added **20** cc. of ice water, the mixture well shaken and the ether layer removed. The aqueous layer, which now contains the sodium salt of the **peracid,** is acidified in the cold with **6** N sulfuric acid and the **peracid** formed extracted with cold ethyl ether, the latter separated, dried over anhydrous sodium sulfate and removed from the **peracid** by suction at very low pressures. The residue, a highly viscous liquid **(1.5** g.), showed distinctly the properties of a **peracid,** but had a purity of only **50%.** Its purity was increased by dissolving the original liquid in pentane, cooling the solution in ice, and subsequently centrifuging

the suspension formed and rapidly removing it from the supernatant liquid. By repeating this process several times, a product is obtained which has an active oxygen content of 5.44%, corresponding to a purity of 78%. Other methods of purification resulted in the decomposition of the peracid.

The authors take this opportunity to express their gratitude to Prof. James F. Norris for his interest and cooperation.

Summary

1. d-Camphoric acid peracid and related peracids and peroxides have been prepared and some of their properties studied.

2. The identity of the acid chlorides obtained from the *sec.*- and *tert.*-monomethyl esters of camphoric acid has been confirmed by conversion into the same ester peroxide.

Studies in Organic Peroxides. II. The Use of Camphoric Acid Peracid for the Estimation of Unsaturation

BY NICHOLAS A. MILAS AND IVAN S. CLIFF

One of the important reactions of the organic peracids is their reactivity with unsaturated groups, but more particularly with substances containing double bonds. This reaction has been studied by various investigators,[1] but cannot be generalized since it depends not only upon the reactivity of the unsaturated group which is usually governed by the adjacent groups attached to the latter,[2] but also upon the activity of the peracid itself. Furoic peracid, for example, is far more reactive than benzoperacid or camphoric acid peracid, while phthalic acid peracid fails completely to add to many unsaturated compounds.[3] Although numerous abnormalities have been reported[4] with benzoperacid and aceto-

peracid, these peracids are the only ones used extensively for the quantitative estimation of the double bond.

The recent synthesis[5] of camphoric acid peracid suggested its use as a reagent for the estimation of unsaturation and for the preparation of oxides and glycols from the corresponding ethylenic compounds. The present communication, therefore, deals with some of the quantitative results obtained with several unsaturated compounds chosen from various branches of organic chemistry. Because of its comparative ease of preparation, camphoric acid peracid may prove a more desirable reagent than benzoperacid.

The stability of camphoric acid peracid and that of benzoperacid has been determined quantitatively in chloroform solution at 0° and at 25° and the results are plotted in Fig. 1. Both peracids were prepared at the same time and their chloroform solutions dried with anhydrous sodium sulfate to exactly the same extent, e. g., shaken twice each time with fresh anhydrous sodium sulfate, then allowed to stand over this reagent for twenty-four hours at 0°. Each solution was then filtered and divided into two portions, one kept at 0° and the other at 25°. To determine the concentration of peracid in each solution, 1-cc. portions were pipetted from time to time and titrated in the usual manner against standard sodium thiosulfate solution. The concentration of each peracid expressed in millimoles per liter of chloroform solution is plotted in Fig. 1 against time. The results seem to indicate clearly that camphoric acid peracid is slightly more stable at 0° but decidedly more stable at 25° than benzoperacid.

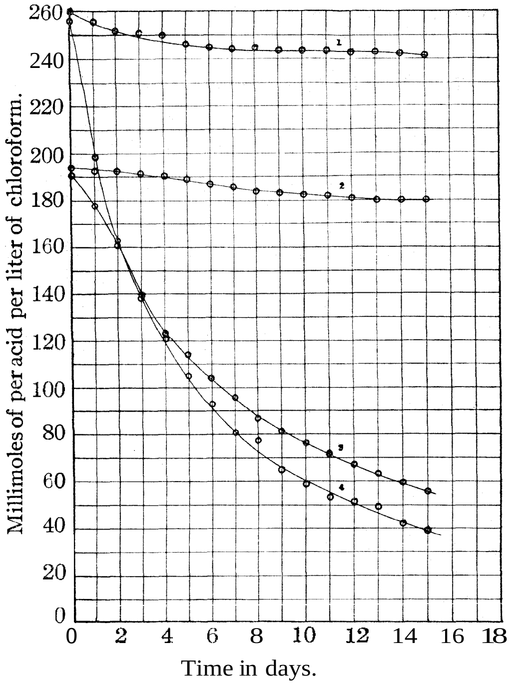

Fig. 1.—The stability of benzoperacid and camphoric acid peracid in chloroform: Curve 1, benzoperacid in chloroform at 0°; Curve 2, camphoric acid peracid in chloroform at 0°; Curve 3, camphoric acid peracid in chloroform at 25°; Curve 4, benzoperacid in chloroform at 25°.

Quantitative Estimation of **Unsaturation.**—All unsaturated substances used in this investigation were of the purest quality obtainable and in cases of doubtful purity

---

[5] Milas and McAlevy, THIS JOURNAL, 55, 349 (1933).

each compound was carefully purified and its constants determined. The procedure adopted for the determination of unsaturation consists in mixing a weighed amount of the unsaturated substance with an excess amount of peracid in chloroform solution and allowing the mixture to stand at room temperature for one-half hour; the excess peracid is then titrated in the usual manner The results are given in Table I in which the theoretical and observed values are expressed in moles of camphoric acid peracid required and moles actually used It may be seen from this table that camphoric acid peracid could be successfully used with several substances for the quantitative estimation of unsaturation Similar exceptions to those recorded in this table have been observed by Boeseken[2] and others with benzoperacid and acetoperacid.

TABLE I

Isolation of Products Formed by the Interaction of Camphoric Acid Peracid with Unsaturated Compounds. d-Pinene Oxide.—Five grams of d-pinene was mixed with a large excess of camphoric acid peracid in chloroform and the mixture was allowed to stand at 0° for three days It was then shaken with a 10% solution of sodium hydroxide to remove the unused peracid and camphoric acid, and finally washed with water and dried over anhydrous sodium sulfate for twenty-four hours. The chloroform solution was then removed by distillation and the remaining liquid subjected to fractional distillation under reduced pressure; the fraction distilling at 102–103° (50 mm) was collected and its physical constants determined.

TABLE II

PHYSICAL CONSTANTS OF THE PRODUCT BOILING AT 102–103° (50 MM.)

	Pinene oxide[1a] (Prileschajew)	Our product
B. p. (50 mm.)	102–103°	102–103°
d_{16}^{16}	0.9689	0.9675
n_D^{16}	1.4708	1.4740

Cholesterol Oxide.—Eight-tenths of a gram of cholesterol (Eastman Kodak c. p. product) was mixed with a large excess of camphoric acid peracid in 200 cc. of chloroform and the mixture allowed to stand at 0° for five days. The mixture was then shaken twice, each time with 200 cc. of 1 *N* sodium hydroxide solution, then with water and dried over calcium chloride. It was filtered and the chloroform removed by distillation. The residue, a white solid (m. p. 125–130°), was recrystallized three times from ethyl acetate, giving a constant melting point of 141–142°. Westphalen[6] gives a melting point of 140–141° for cholesterol oxide.

Hydrolysis of Cholesterol Oxide.—To prove definitely that our product was the oxide, 0.4 g. of the latter was heated with 4 cc. of water in a sealed tube at 115° for twelve hours. The resulting white solid was recrystallized twice from ethyl alcohol, tn. p. 239.3°. The melting point of cholestantriol has been reported by Pickard and Yates[7] and by Westphalen[6] to be 239°.

Summary

1. The stability of camphoric acid peracid and benzoperacid, in chloroform, has been measured at 0° and at 25°.

2. At 25° camphoric acid peracid is more stable, in chloroform solution, than benzoperacid, while at 0° the difference in stability is not significant.

3. Camphoric acid peracid was found to add quantitatively to certain types of unsaturated substances.

4. Pinene and cholesterol oxides have been definitely isolated from the interaction of camphoric acid peracid and *d*-pinene and cholesterol.

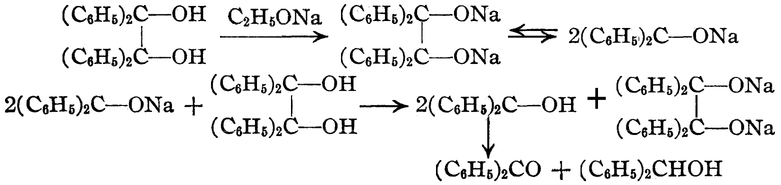
The Action of Sodium Alcoholate and of Sodium Amalgam on Aromatic Pinacols

BY W. E. BACHMANN

Reaction of Pinacols with Sodium Alcoholate.—According to Schlenk and Thal[1] sodium ketyl radicals are formed when a suspension of benzopinacol in alcohol is treated with a concentrated alcoholic solution of sodium alcoholate. We found, in agreement with Schlenk and Thal, that the deep blue color of the ketyl is produced in the reaction, but we observed further that the color disappeared completely after a short time. At first this disappearance of color was attributed to oxidation of the ketyl by oxygen of the air. That this was not the case was definitely proved when the same disappearance of color occurred when air was excluded. Hydrolysis of the colorless solution gave a mixture of equal parts of benzophenone and benzohydrol.

[1] Schlenk and Thal, Ber , 46,2841 (1913).

An insight into the mechanism of the reaction was gained by the observation that a small amount (1% by moles) of sodium alcoholate suffices to produce exactly the same phenomena: formation of the blue color followed by disappearance of the color; moreover, it was found that all of the pinacol was converted to ketone and hydrol by this small amount of sodium alcoholate. The mechanism of the reaction is considered to be the following: sodium pinacolate is formed which partly dissociates into sodium ketyl radicals; the radicals so formed then react with unchanged pinacol or with alcohol



$$\begin{array}{l}(C_6H_5)_2C{-}OH\\ \quad\ |\\ (C_6H_5)_2C{-}OH\end{array} \xrightarrow{C_2H_5ONa} \begin{array}{l}(C_6H_5)_2C{-}ONa\\ \quad\ |\\ (C_6H_5)_2C{-}ONa\end{array} \rightleftarrows 2(C_6H_5)_2C{-}ONa \qquad (1)$$

$$2(C_6H_5)_2C{-}ONa + \begin{array}{l}(C_6H_5)_2C{-}OH\\ \quad\ |\\ (C_6H_5)_2C{-}OH\end{array} \longrightarrow 2(C_6H_5)_2C{-}OH + \begin{array}{l}(C_6H_5)_2C{-}ONa\\ \quad\ |\\ (C_6H_5)_2C{-}ONa\end{array} \qquad (2)$$

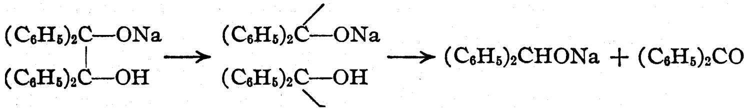
$$\downarrow$$

$$(C_6H_5)_2CO + (C_6H_5)_2CHOH \qquad (3)$$

The products are diphenylhydroxymethyl and sodium pinacolate. The diphenylhydroxymethyl immediately disproportionates into benzophenone and benzohydrol; the sodium pinacolate can dissociate into ketyls which in turn can react with more pinacol. This mechanism satisfactorily accounts for the production and the disappearance of the color as well as for the products of the reaction. Moreover, it is clear that only a small amount of sodium alcoholate is necessary; as soon as a small amount of sodium pinacolate is produced, decomposition of the remaining pinacol is assured.

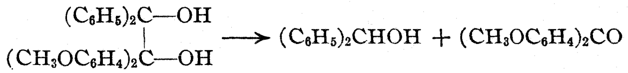
If this mechanism is correct, then according to Equation 2 a small amount of ketyl should be capable of promoting the decomposition of a large amount of pinacol. Such was found to be the case. When a small amount of ketyl was added to a solution of benzopinacol, the blue color remained for a time, then disappeared, and it was found that all of the pinacol had been converted to a mixture of ketone and hydrol. From this it follows that benzopinacol will be decomposed into a mixture of ketone and hydrol by the addition of a small amount of any sodium compound which is capable of replacing the hydrogen of the hydroxyl group by sodium.

It is not unlikely that the following reaction takes place in addition or in some cases exclusively: only one hydrogen is replaced by sodium and the mono-sodium pinacolate which results undergoes cleavage either with or without the intermediate formation of free radicals



$$\begin{array}{l}(C_6H_5)_2C{-}ONa\\ \quad\ |\\ (C_6H_5)_2C{-}OH\end{array} \longrightarrow \begin{array}{l}(C_6H_5)_2C{-}ONa\\ \\ (C_6H_5)_2C{-}OH\end{array} \longrightarrow (C_6H_5)_2CHONa + (C_6H_5)_2CO \qquad (4)$$

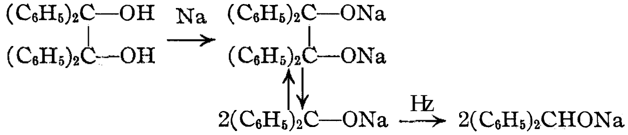
Support for this mechanism is found in the fact that the quantity of color seems less than that which would be expected if all of the pinacol passed through the ketyl stage. This second formulation would account for the results obtained with asymmetrical pinacols. When *as*-diphenyldianisylglycol reacts with sodium alcoholate the products are benzohydrol and dianisyl ketone exclusively



$$\begin{array}{l}(C_6H_5)_2C\text{—}OH \\ \quad\quad\quad\ | \\ (CH_3OC_6H_4)_2C\text{—}OH\end{array} \longrightarrow (C_6H_5)_2CHOH + (CH_3OC_6H_4)_2CO \qquad (5)$$

If the reaction proceeded according to the first formulation, one should expect the products to be benzophenone, benzohydrol, dianisyl ketone and dianisylcarbinol.

Reaction of Pinacols with Sodium Amalgam.—Linnemann,[2] the discoverer of benzopinacol, reported that benzopinacol is converted to benzohydrol when its alcoholic solution is treated with sodium amalgam and he formulated the reaction as $C_{26}H_{22}O_2 + H_2 = 2C_{13}H_{12}O$. Thorner and Zincke[3] did not believe that the pinacol was reduced directly to the hydrol in this manner; they considered that reduction to hydrol occurred only after previous cleavage of the pinacol into a mixture of ketone and hydrol. More recently, Schlenk and Weickel[4] reported that an entirely different reaction takes place. According to these investigators, hydrogen is evolved and the product is sodium ketyl $(C_6H_5)_2C\text{–}ONa$. If this reaction is correct, then hydrolysis would give a mixture of benzophenone and benzohydrol and not benzohydrol alone as Linnemann had reported. We have now found that in the reaction between benzopinacol and sodium amalgam (1.5%) in a mixture of anhydrous ether and benzene, no hydrogen is evolved; the solution becomes dark blue but after a short time nearly colorless; hydrolysis gives benzohydrol in nearly quantitative yield. Several reactions seem to be involved. In the first place, the reaction may be assumed to proceed as follows



$$\begin{array}{lcl}\begin{array}{l}(C_6H_5)_2C\text{—}OH \\ \quad\quad\ \ | \\ (C_6H_5)_2C\text{—}OH\end{array} & \xrightarrow{Na} & \begin{array}{l}(C_6H_5)_2C\text{—}ONa \\ \quad\quad\ \ | \\ (C_6H_5)_2C\text{—}ONa\end{array} \\ & & \quad\quad\ \ \uparrow\downarrow \\ & & 2(C_6H_5)_2C\text{—}ONa \xrightarrow{H_2} 2(C_6H_5)_2CHONa\end{array} \qquad (6)$$

We believe that very little of this reaction takes place. Instead, as soon as a small amount of sodium pinacolate or sodium benzohydrolate is formed, decomposition of the pinacol rapidly takes place; the mixture of benzophenone and benzohydrol so produced then reacts with the amalgam and gives benzohydrol. In support of this view it was found that if the reaction is interrupted before reduction is complete, there is obtained a mixture of pinacol, benzophenone and benzohydrol. Moreover, separate experiments showed that a mixture of equal parts of benzophenone and benzohydrol in

---

[2] Linnemann. *Ann.*, **133,** 28 (1865).

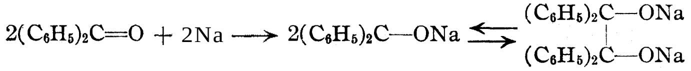
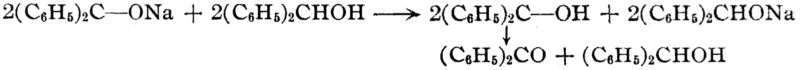
ether and benzene reacts rapidly with sodium amalgam and gives benzohydrol; during the reduction the solution becomes dark blue in color and this color disappears when the reduction is complete. In all respects this reaction is like the reaction of the pinacol with amalgam. The deep blue color indicates that the reduction proceeds through the intermediate formation of sodium ketyl radicals and the reactions that occur are best expressed by the formulation



$$2(C_6H_5)_2C{=}O + 2Na \longrightarrow 2(C_6H_5)_2C{-}ONa \rightleftarrows \begin{array}{l}(C_6H_5)_2C{-}ONa\\ \quad\;\; | \\ (C_6H_5)_2C{-}ONa\end{array} \tag{7}$$



$$2(C_6H_5)_2C{-}ONa + 2(C_6H_5)_2CHOH \longrightarrow \begin{array}{c}2(C_6H_5)_2C{-}OH\\ \downarrow \\ (C_6H_5)_2CO + (C_6H_5)_2CHOH\end{array} + 2(C_6H_5)_2CHONa \tag{8}$$

It is possible that the ketyl is reduced to some extent by the hydrogen liberated by the action of the amalgam on the benzohydrol although experiment showed that the amalgam and hydrol react very slowly with each other. Forty per cent. sodium amalgam reacts with benzopinacol in a similar manner without liberation of hydrogen; the product is nearly pure benzohydrol.

Not only benzopinacol but also substituted benzopinacols react with sodium alcoholate and with sodium amalgam. In each case the solution assumes the color characteristic of the ketyl corresponding to the ketone. In the following table are presented the results obtained by treating a number of pinacols with sodium alcoholate and with sodium amalgam.

TABLE I

ACTION OF SODIUM ALCOHOLATE AND SODIUM AMALGAM ON PINACOLS

	Sodium ethylate			Sodium amalgam	
	Color of solution	Yield, %		Color of solution	Yield, % hydrol
Pinacol		Ketone	Hydrol		
Benzopinacol	Blue	50	50	Blue	98
4,4′-Diphenylbenzopinacol	Green	50	50	Green	95
4,4′,4″,4‴-Tetraphenylbenzopinacol	Green	50	50	Green	98
Fluorenopinacol	Brown-green	50	50	Brown-green	95
4,4′,4″,4‴-Tetramethylbenzopinacol				Blue	95
as-Diphenyldianisylglycol	Blue	50	50		

Experimental

Benzopinacol (1 Mole) + Sodium Ethylate (0.1. Mole).—Although the reaction between benzopinacol and sodium ethylate takes place in alcoholic solution, the rate of reaction is slow because the pinacol is not very soluble in alcohol. As a rule a mixture of equal volumes of anhydrous ether and benzene was used. In all experiments air was excluded; this was usually accomplished by having the mixture completely fill the flask. The rate of reaction depends upon the concentration of sodium ethylate. When 0.01 mole of sodium ethylate was used for each mole of pinacol about two hours was required for decomposition of twenty grams of pinacol This time was shortened to a few minutes when 0.1 mole of alcoholate was used.

To 1 cc. of absolute alcohol contained in a 150-cc. Erlenmeyer flask was added 0.12 g. of sodium. The sodium alcoholate was dissolved in ether and benzene, 20 g. of benzopinacol was added, and the flask was then filled with solvent, stoppered and shaken. Almost immediately the solution became green and then dark blue in color; the large amount of solid pinacol disappeared; after a few minutes the color became lighter and after ten minutes the solution was colorless. Hydrolysis with dilute acid gave an oil which consisted of equivalent quantities of benzophenone and benzohydrol. It is difficult to separate this mixture quantitatively into its two components. The proportion of benzophenone in the mixture was determined by treating a portion of the oil with phenylhydrazine and estimating the amount of benzophenone-phenylhydrazone that was formed. In another portion the amount of benzohydrol was estimated in the form of the urethan formed with phenyl isocyanate.

Experiments with a number of alcoholates were carried out in a similar manner. Sodium methylate, sodium isopropylate, sodium benzohydrolate, potassium ethylate and lithium methylate induced decomposition of the pinacol. Neither magnesium methylate nor calcium methylate reacted with benzopinacol. The magnesium methylate was prepared by allowing 0.03 g. of magnesium ribbon to react with 1 cc. of methyl alcohol; the alcoholate was dissolved in 30 cc. of ether and benzene and 1 g. of benzopinacol was added. No color developed in the course of twenty-four hours and the pinacol was recovered practically unchanged. In like manner no reaction occurred when 1 g. of benzopinacol was shaken for twenty-four hours with a solution of calcium methylate which had been prepared from 0.05 g. of calcium and 1 cc. of methyl alcohol in ether and benzene.

It is now easy to interpret the results that have been reported in the past on the behavior of pinacols in the presence of alkali. Thus, Thorner and Zincke found that benzopinacol is cleaved into a mixture of ketone and hydrol by the action of a boiling alcoholic solution of potassium hydroxide. We found that the reaction between benzopinacol and an alcoholic solution of potassium hydroxide takes place readily at room temperature; in the reaction the blue color of the ketyl radicals is visible. Cohen[5] observed that complete decomposition of pinacol occurred even when small amounts of alcoholic potassium hydroxide were employed. A number of investigators have followed the directions of Thorner and Zincke; of these only Montagne and Koopal[6] report that colors are visible during the reaction. They report that benzopinacol gave a feeble blue color only when it was heated with an alcoholic solution of potassium hydroxide; tetrachlorobenzopinacol gave a blue color even at room temperature and this color disappeared on shaking the solution and then reappeared. Their failure to obtain a color with benzopinacol at room temperature as well as the loss of color on shaking the solution are attributed to oxidation of the ketyl radicals by oxygen of the air.

Benzopinacol + Sodium Ketyl.—A solution of 0.1 g of benzophenone in 20 cc. of ether and benzene was shaken with a small amount of 40% sodium amalgam which was wrapped in a piece of filter paper. As soon as the solution showed the blue color of the sodium ketyl, the amalgam was withdrawn and 1.0 g. of benzopinacol was introduced. The blue color remained as long as pinacol was present. After five minutes the colorless solution was hydrolyzed; it was found that all of the pinacol was converted to a mixture of benzophenone and benzohydrol.

Substituted Pinacols + Sodium Ethylate.—A stock solution of sodium ethylate was prepared by dissolving the alcoholate from 0.23 g. of sodium and 5 cc. of alcohol in a mixture of ether and benzene to make 100 cc. of solution. Enough of this solution was used for 1 g. of pinacol to correspond to 0.1 mole of alcoholate per mole of pinacol.

---

[5] Cohen, Rec. *trav. chim.*, **38**, 72, 113 (1919).

[6] Montagne and Koopal, *ibid.*, 29, 148 (1910).

One grain of pinacol was suspended in 30 cc. of ether and benzene mixture in a test-tube and the sodium ethylate solution (3–5 cc.) was added. The solution became colored as soon as the mixture was shaken; as a rule the color disappeared after a few minutes. In most cases the mixture of ketone and hydrol was resolved into the two components by making use of the differences in solubilities of the two compounds. The yields of pure ketone and of pure hydrol which were isolated always corresponded to more than 90% of that theoretically possible.

The mixture of 4-phenylbenzophenone and 4-phenylbenzohydrol was separated by recrystallization from n-propyl alcohol; the ketone crystallizes out while the more soluble hydrol can be isolated from the liquid. 4,4′-Diphenylbenzohydrol can be easily separated from the corresponding ketone by warming the mixture with enough n-propyl alcohol to dissolve the hydrol (6 cc. per gram); the ketone is practically insoluble in the hot alcohol.

Fluorenone is readily separated from fluorenol by dissolving the mixture of the two in hot benzene; on cooling, fluorenol crystallizes out in the form of the insoluble addition compound with benzene. The mixture of benzohydrol and 4,4′-dimethoxybenzophenone which was obtained from *as*-diphenyldianisylglycol was treated with 10 cc. of 80% alcohol; this solution dissolves all of the hydrol but only a trace of the ketone. In this manner from 1 g. of pinacol there was obtained 0.55 g. (96%) of 4,4′-dimethoxybenzophenone and 0.45 g. (96%) of benzohydrol. Erdmann[7] reported that *as*-diphenyldi-*p*-tolylglycol was decomposed into a mixture of benzohydrol and di-p-tolyl ketone when it was heated with an alcoholic solution of potassium hydroxide.

When xanthopinacol was treated with a solution of sodium ethylate the solution became intensely blue in color. From the mixture xanthone but not xanthydrol was isolated in a pure state.

Benzopinacol + Sodium Amalgam (1.5%).—Three grams of benzopinacol was shaken with 65 g. of 1.5% sodium amalgam in a mixture of 30 cc. of ether and 30 cc. of benzene. In a short time the mixture was dark blue in color. After one-half hour most of the color had disappeared; after two hours the solution was nearly colorless. Hydrolysis gave 2.95 g. (98%) of pure benzohydrol. It was found that the greater part of the reaction is over in a short time. Thus, in one experiment the mixture though still colored was hydrolyzed after fifteen minutes of shaking and there was obtained a 95% yield of benzohydrol.

The substituted pinacols were allowed to react with sodium amalgam in the same manner. As a rule the mixture was hydrolyzed after being shaken for two hours. The results of these experiments are recorded in Table I.

Benzophenone + Benzohydrol + Sodium Amalgam (1.5%).—Sixty-five grams of 1.5% sodium amalgam was added to a solution of 1.50 g. of benzophenone and 1.52 g. of benzohydrol in 60 cc. of ether and benzene. After less than a minute of shaking the solution was blue in color; after one-half hour most of the color had disappeared and after two hours the solution was nearly colorless. Hydrolysis gave 2.90 g. (97%) of benzohydrol. In another experiment the solution was hydrolyzed after fifteen minutes of shaking; the yield of benzohydrol was nearly quantitative.

Benzopinacol + Sodium Amalgam (40%).—One gram of benzopinacol was added to 2.5 *g*. of 40% sodium amalgam in 15 cc. of ether and 15 cc. of benzene in a test-tube. On being shaken the mixture became dark blue in color; no hydrogen was evolved. After five minutes the blue color changed to violet and after ten minutes to violet-red. Hydrolysis gave a 94% yield of benzohydrol. Although the solution had the violet-red color characteristic of benzophenone-disodium $(C_6H_5)_2CNaONa$, only a trace of this compound was present. This was shown by passing carbon dioxide into the solution

---

[7] Erdmann, Thesis, Rostock, 1910.

prior to hydrolysis; only a trace of benzilic acid was formed. Other pinacols were converted to hydrols by 40% sodium amalgam in the same manner.

When a solution of **0.50** g. of benzophenone and **0.51** g. of benzohydrol was shaken with **2.5** g. of 40% sodium amalgam in a mixture of ether and benzene, no hydrogen was evolved; the solution became dark blue and later violet red in color. Hydrolysis after fifteen minutes gave a 95% yield of benzohydrol.

The formation of the violet-red color was an indication that benzophenone is converted to benzophenone-disodium by 40% sodium amalgam. This was surprising in view of the work of Schlenk and Bergmann,[8] who showed that mercury removes one sodium from benzophenone-disodium and gives sodium ketyl. We find that a small amount of mercury removes little or no sodium and consequently 40% sodium amalgam can be used to prepare disodium derivatives of ketones. We have prepared a number of disodium derivatives by this method; in one instance, fluorenone, the disodium derivative is formed when 1% amalgam is used. The amalgam has certain advantages over the free metal and the method promises to be a convenient way of making these derivatives. Details of these experiments will be published in a future communication.

Summary

Benzopinacol and substituted benzopinacols are converted by a small amount of sodium alcoholate into a mixture of equivalent parts of ketone and hydrol. Free ketyl radicals are formed as intermediate products; these radicals are then converted by unreacted pinacol into the ketone and hydrol.

The pinacols are reduced quantitatively to hydrols by sodium amalgam in anhydrous ether–benzene solutions. This reaction, likewise, takes place through the intermediate formation of free ketyl radicals.

Tertiary Aliphatic Alcohols and Chlorides Containing Normal Butyl Groups

BY FRANK C. WHITMORE AND H. MILTON WOODBURN[1]

While most alcohols are capable of rearrangement,[2] those which show this tendency to the greatest degree contain the grouping, $R_3C\overset{|}{\underset{|}{C}}OH$. Tertiary alcohols and their halides are needed for the preparation of these substances. To make such tertiary alcohols available for this work and to gain experience in handling them, this research was undertaken. The alcohols studied contain only normal aliphatic groups, including in each case at least one n-butyl group but no groups higher than butyl. All ten alcohols of this type were made and their boiling points, densities and

refractive indices were determined under comparable conditions. Of the ten alcohols, seven have been mentioned in the literature but no adequate studies have been made with most of them. Of the ten chlorides only one, 2-chloro-2-methylhexane, has been described.[3] It was made from the carbinol by the action of hydrogen chloride or acetyl chloride.

In a few cases olefins were obtained from the carbinols or their chlorides. Preliminary studies were made on the action of bromine with some of the alcohols and on the hydrolysis of the resulting dibromides.[4]

Experimental

Preparation of the Alcohols.—All of the alcohols were made by the action of suitable Grignard reagents and carbonyl compounds.[5] These methods are summarized in Table I. The alcohols were fractionated through effective columns.[6] The higher ones were distilled under reduced pressure.

[a] A large by-product, b. p. 100–125°, was obtained.

[b] By-products of b. p. 105–108" and 119–121°.

[c] The methyl propyl ketone was first made from acetoacetic ester ("Organic Syntheses," 1928, Vol. VIII, p. 36). As only a 20% yield was obtained, the ketone was then made by dehydrogenating (brass catalyst at 375°) methylpropylcarbinol made from methylmagnesium chloride and n-butyraldehyde (from commercial "Butalyde" supplied by the Commercial Solvents Corporation). The boiling points (at 740 mm.) of the carbinol and ketone used were 118–119° and 100.0–101.5°.

[d] Ethyl propyl ketone, b. p. 122–123" (730 mm.), was prepared in 70% yield by dehydrogenating ethylpropylcarbinol, b. p. 132–134° (730 mm.), prepared in 58% yield from ethylmagnesium chloride and butyraldehyde.

[e] During the addition of the ethyl carbonate to the Grignard solution, the latter was kept at about 30°. If cooling was used, the ethyl carbonate accumulated in the solution and later reacted violently.

Properties of the Alcohols.—In determining the physical constants of the alcohols, the same apparatus and method were used throughout. All constants for a given alcohol were determined on the same sample. The boiling points were determined by actually distilling a large amount of each alcohol and taking the boiling range of the main fraction. When reduced pressure was used a barostat was employed to maintain constant pressure. The densities were determined at **20** and 25° with a bottle type pycnometer. Refractive indices were determined with an Abbé refractometer with its prism controlled by water from an automatic thermostat held at 20.0 ± 0.2°. The alcohols were all colorless. In one case, methyldibutylcarbinol, the sample became slightly yellow on standing for several weeks. The odors were pleasant. In viscosity they ranged from limpid liquids (dimethylbutylcarbinol) to thin syrups (tributylcarbinol). Table II gives the physical properties of the alcohols.

With one exception, the refractive indices increase in a fairly regular way with increasing molecular weight. Such is not the case with the densities. The properties of methyldibutylcarbinol seem to be peculiar.

Preparation and Properties of the Chlorides.—The method of Halse[7] was used. The carbinol, cooled to −10°, was saturated with dry hydrogen chloride. The halide layer was dried and freed from hydrogen chloride by standing in a vacuum desiccator over sodium hydroxide. It was also found possible to wash the chlorides with cold 5% sodium carbonate solution. In distilling the chlorides it was necessary to use a much lower pressure than with the carbinols as they are much more sensitive to heat. The decomposition appeared to be catalyzed by traces of hydrogen chloride. In such cases it was necessary to wash the chloride again with cold 5%

---

[7] Halse, *J prakt Chem.*, [2] **89, 451** (1913).

sodium carbonate solution and dry it before redistilling at a lower pressure. In preparing the chlorides, deep colors often developed. These ranged from purple to black and were most noticeable with the chlorides from dimethylbutyl, methylethylbutyl and methylpropylbutylcarbinols.

The pure chlorides were colorless liquids. The odor was fainter and slightly less pleasant than that of the carbinols. There was no odor of hydrogen chloride. The pure chlorides were remarkably stable on standing. Impure samples of the chlorides darkened rapidly and gave considerable amounts of hydrogen chloride. The physical properties of the chlorides were determined as with the alcohols.

The samples were purified by distillation at reduced pressures (McLeod gage for pressures below 5 mm.) through a 30 × 1 cm. indented insulated column with complete condenser and variable take-off.[6] This arrangement was far superior to an ordinary vacuum distillation because it allowed the use of a high reflux ratio. The yields of purified products were 65–75%. The properties of the chlorides are given in Table III. Again the properties of the methyldibutyl derivative were irregular.

[a] This chloride was most difficult to distil unless all traces of hydrogen chloride had been removed by long standing in the vacuum desiccator over alkali.

[b] These are the changes in the chlorides on standing for 26 months in the laboratory in ordinary bottles. 3. Slight yellow color developed. 4. No odor of hydrogen chloride. 5. Change in refractive index of about +0.001. 6. Still colorless. 7. Odor of hydrogen chloride. 8. Change in refractive index of less than +0.0004.

Preparation of Various Olefins.—In one preparation of methylethylbutylcarbinol partial dehydration took place. Five fractionations of the low boiling material gave 20 cc. with b. p. 105–108° and 125 cc. with b. p. 119–121° at 734 mm. Both reacted with bromine water to give dibromides but were not further identified.

Dehydration of 240 g. of crude methyldibutylcarbinol gave on fractionation 107 g. of olefin of b. p. 162–164° (739 mm.). The distillation of tributylcarbinyl chloride at 20 mm. gave 5-butylnonene-4,[8] b. p. 212.5–213° (735 mm.) and 60° (1.2 mm.), d_4^{20} 0.7724, n_D^{20} 1.4392.

Summary

1. Ten aliphatic tertiary alcohols containing n-butyl groups have been prepared and some of their properties have been determined.

2. Ethylpropylbutyl, ethyldibutyl, dipropylbutyl and propyldibutyl carbinols have been prepared for the first time.

3. The ten corresponding tertiary chlorides have been prepared and studied. All except one of these are new.

Alkamine Esters: Novocaine Analogs. III

BY MARLIN T. LEFFLER[1] AND HARVEY C. BRILL

In accord with the statement in a previous communication:[2] "In the absence of any considerable number of trustworthy generalizations that relate chemical structure and physiological activity, the only means of learning of the effects of such relationships are to prepare compounds of slight structural differences and study the effects of such changes," the data herewith accumulated from further studies of anesthetic compounds are presented

The anesthetic properties of the compounds that have been prepared and are herein described were determined by the use of goldfish as detailed by Adams and co-workers[3] with this slight modification, that the water used in the tests was in all cases aerated to avoid any possible effect on the fish from lack of oxygen in the water in which they were submerged.

The compounds synthesized and studied are listed below. The hydrochlorides of the esters formed by esterification of β-4-morpholinoethanol with benzoic acid, phenylacetic acid, β-phenylpropionic acid, cinnamic acid and tetrahydropyran-4-carboxylic acid, respectively; a second series of these same acids with β-N-piperidinoethanol; and a third series of esters from β-menthylethylaminoethanol with benzoic acid and tetrahydropyran-4-carboxylic acid.

Experimental

Preparation of the Alkaminoethanols.—Menthylamine was synthesized by means of the following series of reactions: menthol (U. S. P.) → menthone → menthone oxime → menthylamine. Reduction of the oxime and its recovery were carried out in accordance with the procedure detailed by Wallach and others.[4] The amine, distilled in an

atmosphere of hydrogen, boiled at 97° at a pressure of 56 mm.; yield, 75%. A mixture of equivalent amounts of menthylamine and of ethyl bromide dissolved in dry benzene was heated on a steam-bath for two hours. Precipitation of the hydrobromidc began almost immediately, so that a solid mass of crystals resulted. The free menthylethylamine distilled at 70 5° at a pressure of 4 mm.; yield 74%. β-Menthylethylaminoethanol prepared in a manner similar to the preceding synthesis was obtained in a 62% yield, boiling point 79° at 4 mm. pressure. β-N-Piperidinoethanol is best prepared by warming equivalent amounts of piperidine and ethylene chlorohydrin in the absence of a solvent in order to increase the yield of the nitrogen substituted derivative of piperidine.[5]

A number of methods were tried in the preparation of *β-4-morpholinoethanol*[6] with varying yields of morpholine and the' ethanol derivative. The results obtained are not distinctly different from those reported by Gardner and Haenni[7a] and will not be reported in detail, except to state that none were so satisfactory as the method described by the investigators just cited.

Preparation of Acids.—Tetrahydropyrancarbonic acid is the only acid used in thia study that needs any statement in regard to its preparation. The method announced by Gibson and Johnson[8] gave the best yields of those tried.[9] An attempt was made to prepare this acid by substitution of acctoacetic ester for the malonic ester with unsatisfactory results. β,β'-Dichlorodiethyl ether had not condensed completely with acetoacetic ester after refluxing for thirty-five hours and the cleavage of the condensation product did not go smoothly, consequently the effort was discontinued.

Tctrahydropyrancarbonyl chloride was prepared by heating 20 *g*. of the acid on the water-bath with 30 cc. of thionyl chloride The product distilled at 85–86° at a pressure of 16 mm.

Preparation of Esters.—In all cases the esters were produced by warrning dry benzene solutions of the various alcohols with 5% excess of like solutions of the acid chlorides until the reactions appeared to be completed.

The hydrochlorides of the esters of β-menthylethylaminoethanol apparently lose a molecule of hydrogen chloride so readily that recrystallization from alcohol and solution in water result in the production of the free base. The hydrochlorides of these esters are precipitated by the customary reactions in benzene solution; when recrystallized from alcohol–ether mixture it was found that their solubilities have changed, they are markedly more soluble in ether and hydrocarbon solvents and hardly at all soluble in water than when precipitated from the benzene solutions of the reacting base and acid chlorides. Their melting points have changed and they give no test for chlorine A portion of the ester of tetrahydropyran-4-carbonic acid was recrystallized from dry ether before this sensitiveness to alcohol and water had been observed. The melting point of this is reported in Table II. As this melting point is lower than that for the free base and the

K, L and M could not be tested for reasons already noted.

[a] The PH values were found by means of a Hellige comparator.

percentage of chlorine found is likewise low, it is apparently a mixture of the hydrochloride and the basic ester free of hydrogen chloride. Solutions of these basic esters in dry benzene or ether did not form precipitable hydrochlorides or hydrosulfates when dry hydrogen chloride and sulfuric acid, respectively, were added under the conditions used.

Their study is being continued and they will be reported upon in more detail later.

Surface Tension Relationships.—The surface tensions of three of these esters, namely, the hydrochlorides of β-N-piperidinoethylcinnamate (the most active anesthetic of those studied), β-4-morpholinoethylcinnamate (ot intermediate activity) and β-N-piperidinoethyl-β-phenylpropionate (of low activity) were determined. The results of these tests show so little differences in values that no conclusion can be drawn as to the influence of surface tension on the anesthetic powers of the compounds. The compound with the highest anesthetic effect has the highest surface tension instead of the lowest as would be expected from Traube's theory. Certainly the chemical constitution appears to be one of the more important factors in the establishment of physiological activity as Adams has noted in his study of the relationships between surface tension and bactericidal activity.[10]

TABLE IV

SURFACE TENSIONS AND DENSITIES (0.006 MOLAR CONCENTRATIONS), 25°

Compound, hydrochlorides	Density of solution	Surface tension, dynes/cm.
β-N-Piperidinoethylcinnamate	0.9965	71.96
β-4-Morpholinoethylcinnamate	.9969	69.30
β-N-Piperidinoethyl-β-phenylpropionate	.9969	69.00
Redistilled water	.9970	71.80

Discussion and Conclusions.—The menthyl derivatives were included in this investigation in the hope that they might show marked surface penetration because of their high radical weight and favorable configuration. Rather convincing evidence of this relationship is furnished by the marked surface penetrating power of cocaine and of the greater activity of Butyn[11] over Novocaine in this regard. The former two are more penetrating and of higher molecular weight than the last named anesthetic.

The morpholine esters are not as active anesthetics as the piperidine esters. This structure appears to have no advantage over other basic groups in endowing compounds with anesthetic powers. They are likewise somewhat more acid in properties, and high acidity in local anesthetics appears to be undesirable and unfavorable to the best results. For this same reason the esters of tetrahydropyran-4-carboxylic acid are likely to possess low activity. This configuration apparently has no pronouncedly unfavorable toxic effect on compounds.

[10] Stanley and Adams, THIS JOURNAL, 54, 1548 (1932).

[11] Schmitz and Loevenhart, J. *Pharmacol.*, 24, 167 (1924).

The cinnamates are the most active of all studied, which is evidence of the favorable effect of a double bond in enhancing the anesthetic powers of compounds.

Summary

1. Esters of β-4-morpholinoethanol with benzoic, phenylacetic, β-phenylpropionic, cinnamic and tetraphydropyran-4-carboxylic acids; a second series of β-N-piperidinoethanol with these same acids; and a third series of β-menthylethylaminoethanol with benzoic and tetrahydropyran-4-carboxylic acids are described under the following heads: (a) preparation, (b) physical properties, (c) PH values, (d) anesthetic activities, (e) surface tension.

2. The cinnamates are the most active physiologically of those studied.

3. No apparent relationship between surface tension and surface penetration was indicated.

4. The menthylethylamino derivatives differ from the others studied in the ease with which hydrogen chloride is lost.

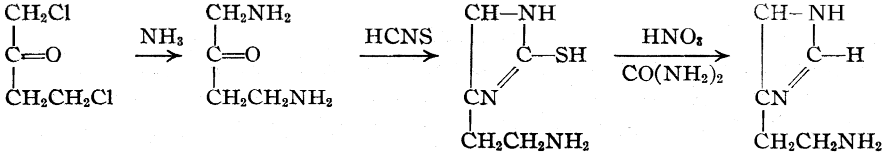
α′,β-Dichloromethylethyl Ketone (1,4-Dichlorobutanone-2)[1]

BY R. H. CARROLL AND G. B. L. SMITH

Introduction

The preparation of α′,β-dichloromethylethyl ketone is not recorded in the literature, and this relatively simple substance is important because of the possibility of using it as an intermediate in the synthesis of compounds of biological and pharmacological interest. For instance it might be employed in the synthesis of histamine, as follows[2]



The present paper describes two methods for the preparation of α′,β-dichloromethylethyl ketone.

The Nierenstein Reaction.—In 1915, Clibbens and Nierenstein[3] reported that acid chlorides react with diazomethane to produce α-chloro

---

[1] This paper is constructed from part of the thesis submitted by Mr. Carroll to the faculty of the Polytechnic Institute of Brooklyn in June, 1932, in partial fulfilment of the requirements for the degree of Master of Science in Chemistry.

[2] Now being investigated in this laboratory.

[3] Clibbens and Nierenstein, J. *Chem. Soc.*, 107, 1491 (1915).

ketones, but Bradley and Robinson[4] in employing this reaction obtained instead the diazo ketone. Bradley and Robinson[5] and Bradley and Schwarzenbach[6] found that when one molecular equivalent of an acid chloride is allowed to react with two molecular equivalents of diazomethane, the diazo ketone is obtained in excellent yields. Bradley and Schwarzenbach[6] were able to obtain the a-chlor ketone from the diazo ketone by treatment of the latter substance with dry hydrogen chloride.

α′,β-Dichloromethyl ethyl ketone was prepared through the Nierenstein reaction from diazomethane and β-chloropropionyl chloride and subsequent treatment of the product with dry hydrogen chloride. The α′,β-dichloromethylethyl ketone was identified by analysis and by the preparation of the hydrochloride of a new thiazole, 4-(β-chloroethyl)-2-aminothiazole. The ketone itself was a strong lachrymator. It distils at 65° at 3 mm. and changes from a colorless to a brown liquid on standing. Its specific gravity 20°/4° is 1.3295 (±0.0005)

Condensation of Ethylene and Chloroacetyl Chloride with Aluminum Chloride.—Lippmann[7] in 1864 prepared β-chloropropionyl chloride from ethylene and phosgene. This reaction suggested that if chloroacetyl chloride were used instead of phosgene, a',@-dichloromethylethylketone might be formed. Various condensation agents such as mercuric sulfate, sulfuric acid, stannic chloride and aluminum chloride were used to bring about this reaction between chloroacetyl chloride dissolved in diethyl ether and ethylene, the ethylene being passed into the ethereal solution. These attempts were not successful.

Petroleum oils have been condensed[8] by the use of the addition compound of ethylene and aluminum chloride. Accordingly this ethylene–aluminum chloride addition compound was prepared in a dry petroleum ether solution and chloroacetyl chloride was added. α′,β-Dichloromethylethyl ketone was obtained in small yield and it was identified through the condensation product with thiourea."

Experimental

Materials.—Diazomethane was prepared by the method of von Pechman[10] using nitrosomethyl urethan.[11] The ether was dried over sodium, distilled, dried over phosphoric anhydride and redistilled. β-Chloropropionic acid was prepared by the method given by Powell in "Organic Syntheses."[12] β-Chloropropionyl chloride[13] was prepared

by heating together a mixture of 15 g. of β-chloropropionic acid and 18 g. of thionyl chloride for ninety minutes. The mixture was fractionated at 5 mm.; 13 g. was collected at 44°, b. p. 144°.

α',β,-Dichloromethylethyl Ketone (1,4-Dichlorobutanone-2) through the Nierenstein Reaction.—4.75 grams of β-chloropropionyl chloride was dissolved in 25 g. of absolute ether and the solution was cooled to −5°; 1.8 g.[14] of diazomethane was dissolved in 75 g. of absolute ether contained in a 500-ml. suction flask, cooled to −5°, and protected from moisture by a calcium chloride tube. This solution was treated with the ethereal solution of β-chloropropionyl chloride, taking about five minutes for the addition The temperature was maintained at −5° and the solution was allowed to stand for one hour, at the end of which period a second portion of 1.8 g. of diazomethane was added to the solution, nitrogen being again evolved. The solution was now placed in an ice box and allowed to stand for thirty-six hours. The yellow colored solution was treated with dry hydrogen chloride until the color was pale yellow and the evolution of nitrogen had ceased. During the treatment with hydrogen chloride the temperature was held below 10". The ether was evaporated by a current of dry air and the residue was fractionated at reduced pressure. The portion distilling at 65° under a pressure of 3 mm. was collected; yield 3.2 g. The liquid had powerful lachrymatory properties and the density was 20°/4°, 1.3295. Refractive index [n_D] 1.480 at 20°; molecular refraction calcd., 30.59; found, 30.10. This sample was two weeks old and a sample two months old gave a value [n_D] 1.473 at 20°.

Anal. Calcd. for $C_4H_6OCl_2$: C, 34.04; H, 4.25. Found: C, 34.29; H, 4.09.

This preparation was repeated using 22 g. of β-chloropropionyl chloride and 14.4 g. of diazomethane; yield 18 g. at 65° and 3 mm. pressure.

Hydrochloride of 4-(β-Chloroethyl)-2-aminothiazole.—2.8 Grams of α', β-dichloromethylethyl ketone was added to a solution of 1.4 g. of thiourea in 25 ml. of water and' heated on the water-bath under reflux for thirty minutes. The mixture was frequently agitated and at the end of this period the insoluble layer of the ketone had entirely disappeared. The solution was evaporated under reduced pressure to 15 ml. and then made alkaline by adding 20 ml. of a solution of 0.1 *N* sodium hydroxide. It was then extracted with diethyl ether and the ethereal solution was dried with anhydrous sodium sulfate. The ether was evaporated and the residue crystallized; yield 1.4 g.; m. p. 60°. This base could not be recrystallized readily and accordingly the hydrochloride salt was prepared.

One-half gram of 4-(β-chloroethyl)-2-aminothiazole base was dissolved in 20 ml. of absolute ether and filtered; 20 ml. of absolute ether was saturated with dry hydrogen chloride and this was added to the solution of the base. The crystals which separated were filtered, washed with absolute ether, and dried *in vacuo* over calcium chloride and paraffin. The substance, m. p. 166°, started to melt at 144" but then solidified. The analyses were made on reprecipitated material.

Anal. Calcd. for $C_5H_8N_2SCl_2$: C, 30.15: H, 4.02; S, 16.08. Found: C, 31.01, 31.11; H, 4.56, 4.54; S, 16.62.

α',β-Dichloromethylethyl Ketone from Ethylene and Chloroacetyl Chloride.—Two hundred and fifty ml. of dry petroleum ether (b. p. 40–60°) was placed in a three-necked flask fitted with a mechanical stirrer and a reflux condenser which was protected against moisture with a tube of calcium chloride, and 13.3 g. of powdered aluminum chloride (Akatos) was added. Ethylene was passed into the solution for two hours while the solution was maintained at the boiling temperature (47°) and most of the aluminum chloride dissolved; 11.3 grams of chloroacetyl chloride was added slowly through a separatory funnel and the mixture was boiled for thirty minutes after the addition of

---

[14] Determined by titration by the *p*-nitrobenzoic acid method

the chloroacetyl chloride. The mixture was poured into 600 ml. of ice water and stirred until the aluminum chloride had decomposed. The layer of petroleum ether was separated and the aqueous solution was extracted three times with a total volume of 300 ml. of diethyl ether. The combined extract was dried with anhydrous sodium sulfate, evaporated by a current of dry air and fractionated under reduced pressure. The fraction distilling at 63–65° under **3** mm pressure was collected; yield 2 8 g.

0.14 Gram of this product and 0.076 g. of thiourea ucre dissolved in 4 ml. of water and heated for thirty minutes. The solution was made alkaline with a solution of sodium hydroxide and extracted with ether. The residue remaining after the evaporation of the ether melted at 60°. A mixed melting point determination of this material with the previously prepared thiazole base gave no depression. The hydrochloride of this substance was prepared as previously described, it melted at 166" and showed a tendency to fuse at 140° after which it solidified. This substance gave no depression in a mixed melting point determination with 4-(β-chloroethyl)-2-aminothiazole hydrochloride prepared from the larger sample of α',β-dichloromethylethyl ketone. These facts are taken as positive proof that aluminum chloride can be used as a condensing agent for the preparation of this ketone.[15]

Summary

1. α',β-Dichloromethylethyl ketone, 1,4-dichlorobutanone-2, has been prepared by the action of diazomethane on β-chloropropionyl chloride and subsequent treatment with dry hydrogen chloride.
2. α',β-Dichloromethylethyl ketone has been prepared by the direct addition of ethylene to chloroscetyl chloride, using aluminum chloride as a condensing agent.
3. 4-(β-Chloroethyl)-2-aminothiazole has been prepared from a',β-dichloromethylethyl ketone and thiourea. The hydrochloride of this base was identified by analysis.
4. Mixed melting point determinations have been used to identify the α',β-dichloromethylethyl ketone prepared from ethylene and chloroacetyl chloride.

Studies on Acid Iodides. I. The Preparation of Halogen Substituted Aliphatic Acid Iodides with a Note on the Atomic Refractivity of Iodine

BY EDWIN L. GUSTUS AND PHILIP G. STEVENS

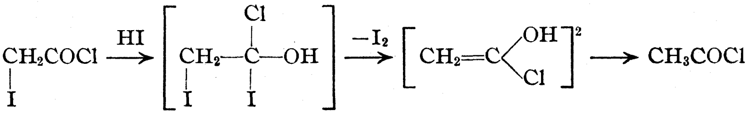
Knowledge of the chemistry of acid iodides is very meager. The difficulties of their preparation, their reactivity and instability doubtless are responsible for the neglect which this group of substances has received. We have been attracted to their study through the hope that their reactivity might make them useful as reagents for achieving unusual chemical transformations.

This paper, the first of a series, deals with the preparation of certain halogen substituted aliphatic acid iodides, and the determination of some of their physical constants.

The most satisfactory method for the preparation of acid iodides is that of Staudinger and Anthes,[1] who prepared acetyl, diphenylacetyl and benzoyl iodides by passing a stream of dry hydrogen iodide into the corresponding acid chloride. This method proved to be very successful for the preparation of chlorinated acid iodides. In this way, monochloro-, dichloro- and trichloroacetyl iodides were easily prepared from the corresponding acid chlorides.

Bromoacetyl chloride was also converted into the corresponding iodide, but attempts to obtain it in a pure form were unsuccessful. It failed to crystallize at --80°, and when warmed to 32° during an attempt at distillation it decomposed with the evolution of heat, forming large amounts of a black crystalline solid, presumably iodine monobromide.

Attempts to prepare iodoacetyl iodide failed completely, as iodine was instantly liberated, even at $-10°$. This was not surprising, however, as the following set of reactions suggests.



$$\underset{\text{I}}{\text{CH}_2}\text{COCl} \xrightarrow{\text{HI}} \left[\underset{\text{I}}{\text{CH}_2}\text{—}\overset{\text{Cl}}{\underset{\text{I}}{\text{C}}}\text{—OH}\right] \xrightarrow{-\text{I}_2} \left[\text{CH}_2\text{=C}\begin{matrix}\text{OH}\\ \text{Cl}\end{matrix}\right]^{2} \longrightarrow \text{CH}_3\text{COCl}$$

The following table is a summary of the physical constants of these acid iodides.

Iodide	B. p , °C.	Mm.	d^{20}_{4}	d^{20}_{20}	n^{20}_{D}	Condition at $-80°$
CH_3COI	104–106	735	2.0674	2.0710	1.5491	Not crystalline
CH_2ClCOI	36.5	4	2.2607	2.2647	1.5903	Crystalline
$CHCl_2COI$	54–54.5	15	2.2508	2.2547	1.5754	Not crystalline
CCl_3COI	74–74.2	30	2.2549	2.2589	1 5711	Crystalline
CH_2BrCOI	32°, dec.					
CH_2ICOI	Below $-10°$, dec.

[1] Staudinger and Anthes, *Ber.*, 46, 1417 (1913)

[2] Compare Aschan, *ibid.*, 45, 1913 (1912).

No determination of the atomic refractivity of iodine in the form of acid iodide has been thus far reported. For this reason the densities and refractive indices of the iodides were determined where possible. The atomic refractivity of iodine as acid iodide has been calculated from the molecular refractivity of acetyl iodide.

Iodide	M_D observed	M_D calculated for CH_3CO	Atomic refractivity I^{-CO-}
CH_3COI	26.08	10.35	15.73

Using this value for iodine, the exaltation of the molecular refractivity, EM_D, has been calculated for the chloroacetyl, dichloroacetyl and trichloroacetyl groups as acid iodides. The exaltation was found to be negative in each case.

Iodide	M_D observed	M_D calculated	EM_D
CH_2ClCOI	30.52	30.94	−0.42
$CHCl_2COI$	35.08	35.81	− .73
CCl_3COI	39.83	40.68	− .85

For purposes of comparison, the atomic refractivities of chlorine, bromine and iodine are shown.

Halogen X	A X^{-CO-}	B X^{-CH_2-}	A − B	A ÷ B
Cl	6.336^3	5.9673	0.369	1.0618
Br	9.595^4	8.748^4	0.847	1.0968
I	15.73	13.900^3	1.83	Calcd. 1.133^5; found, 1.131

We wish to express our thanks to Dean Frank C. Whitmore for the facilities of this Laboratory, and to the Mallinckrodt Chemical Works for so generously donating the large quantities of iodine necessary for this work. Part of the funds required for this research were privately contributed.

Experimental Part

Acetyl Iodide, CH_3COI.—This substance, b. p. 104–106° (735 mm.), was prepared from purified acetyl chloride by the method of Staudinger and Anthes.[1] These workers, however, submitted no analyses or physical constants other than the boiling point. The iodide did not solidify at −80° (solid carbon dioxide and alcohol). When shaken with mercury, it became colorless.

Anal. (PdI_2) Calcd. for C_2H_3OI: I, 74.69. Found: I, 74.44.

Chloroacetyl Iodide, CH_2ClCOI.—198 grams of chloroacetyl chloride, b. p. 105–106" (740 mm.), cooled to −5°, was treated with 672 g. of dry hydrogen iodide. The resulting reddish liquid was fractionated *in vacuo*.

1st fraction b. p. 30–36.5° (4 mm.)	40 g.	
2d fraction b. p. 36.5° (4 mm.)	245 g.	68% yield
3d fraction b. p. 36.5–37.5° (4 mm.)	25 g.	

---

(3) Eisenlohr, *Z. physik. Chem.*, **75**, 605 (1911).

(4) Karvonen, *Ann Acad Sci. Fennicae, AS*, 62 (1914)

(5) Calculated from above two ratios.

The second fraction, b. p. 36.5" (4 mm.) was a heavy, mobile, highly refractive, cherry red liquid of penetrating odor, fuming strongly in moist air. It could be obtained colorless by shaking with mercury, but the red color rapidly returned even if protected from the light at 0°. The iodide sinks in water and, due to its slight solubility, reacts rather slowly to form chloroacetic and hydriodic acids. It dissolves without reaction in the laboratory hydrocarbons, chloroform and carbon tetrachloride. It dissolves in alcohol, reacting instantly with the formation of ethyl chloroacetate. It is soluble in ether and slowly reacts with it, forming ethyl iodide and ethyl chloroacetate. When cooled to −80° the iodide solidified to a mass of colorless leaflets. When shaken with mercury, it became colorless.

Anal. (PdI_2). Calcd. for C_2H_2OClI: I, 62.12. Found: I, 62.39

Dichloroacetyl Iodide, $CHCl_2COI$—Seventy grams of dichloroacetyl chloride, b. p. 106.1–107.1° (739 mm.), was treated with 192 *g.* of dry hydrogen iodide at −5°. The resulting golden-yellow liquid was distilled *in oacuo.* The distillate, b. p. 50–58° (14 mm.), was then fractionated.

1st fraction b. p. (15 mm.)	50–54	27 g.	
2d fraction b. p. (15 mm.)	54–54.5°	66 g.	58.2% yield
3d fraction b. p. (15 mm.)	54.5–58°	15 g.	

The second fraction, b. p. (15 mm.) 54–54.4°, entirely resembles chloroacetyl iodide in appearance, properties and solubilities. It reacts, however, much more slowly with ethers. It failed to crystallize at −80". When shaken with mercury. it became colorless.

Anal. (PdI_2). Calcd. for C_2HOCl_2I: I, 53.13. Found: I, 53.60.

Trichloroacetyl Iodide, CCl_3COI.—The preparation of this substance was previously reported by Gal,[6] who obtained a low yield of doubtless impure material from the reaction of an excess of phosphorus triiodide with trichloroacetic acid. It is easily prepared by the action of hydrogen iodide on trichloroacetyl chloride. 100 g. of trichloroacetyl chloride, b. p. (726 mm.) 116–117°, was treated with 220 g. of dry hydrogen iodide at −5°. The resulting dark red liquid was freed from dissolved iodine by distillation *in vacuo* from mercury, and then fractionated.

1st fraction b. p. (30 mm.)	below 74°	31.2 g.	
2d fraction b. p. (30 mm.)	74--74.2"	107.5 g.	71.5% yield

The second fraction, b. p. (30 mm.) 74–74.2°, resembles in appearance and' solubilities the other chlorinated acid iodides, but it is less sensitive to light, and reacts more slowly with water. The most marked difference, however, is its inability to cleave ethers. It solidifies readily at −80° to colorless leaflets. When shaken with mercury, it became colorless.

Anal. (PdI_2). Calcd. for C_2OCl_3I: I, 46.44. Found: I, 46.41.

From the first fraction, after decomposition with water, was obtained a small quantity of an inert liquid with an odor of carbon tetrachloride, b. p. 77–102° (735 mm.), which was not further investigated.

Bromoacetyl Iodide, CH_2BrCOI.—One hundred grams of bromoacetyl chloride, b. p. (737 mm.) 125.0–125.3°, prepared by the method of Hans Meyer[7] was treated with 244 g. of dry hydrogen iodide at −5°. The liquid rapidly became dark brown. When about one half of the hydrogen iodide had been bubbled in, noticeable amounts of a black crystalline material commenced to precipitate. At the end, the deep reddish

---

(6) Gal, *Bull. soc. chim.*, [2] *20*, 13 (1873).

(7) Hans Meyer, *Monalsh.*, 22, 418 (1901).

liquid was decanted from the black precipitate. This crystalline substance gave strong tests for both iodine and bromine, and was possibly a mixture of iodine monobromide and iodine. After unsuccessfully trying to purify the decanted liquid by freezing out crystals of bromoacetyl iodide, an attempt was made to distil it in *vacuo.* When the bath temperature reached 32°, the liquid suddenly decomposed with the evolution of considerable heat, and the formation of large amounts of the black crystalline material mentioned above.

Iodoacetyl Iodide, CH_2ICOI.—Spindler[8] attempted to prepare this substance by heating chloroacetyl chloride with calcium iodide in a sealed tube. The method of Staudinger and Anthes proved to be equally unsuccessful. Fifty grams of freshly redistilled iodoacetyl chloride, b. p. 31–32° (4 mm.), prepared by the method of Abderhalden and Guggenheim[9] was placed in a gas wash bottle and cooled to –10°. When dry hydrogen iodide was passed into the liquid, there was an instantaneous precipitation of iodine crystals completely stopping the passage of the gas. Evidently iodoacetyl iodide, if formed, is unstable at –10°.

Summary

1. The method of Staudinger and Anthes for the preparation of acid iodides has been extended to include the preparation of several halogenated aliphatic acid iodides.

2. Chloro-, dichloro- and trichloroacetyl iodides have been prepared by this method, and some of their physical constants and chemical properties have been determined.

3. Bromoacetyl iodide has been prepared, but it was too unstable to permit purification by distillation.

4. Iodoacetyl iodide could not be prepared.

5. The atomic refractivity of iodine as acid iodide, and the exaltation of molecular refractivity for chloro-, dichloro- and trichloroacetyl iodides have been determined.

Studies on Acid Iodides. II. The Cleavage of Aliphatic Ethers by Acid Iodides

BY EDWIN L. GUSTUS AND PHILIP G. STEVENS

It has long been known that aliphatic ethers may be cleaved by acid chlorides at elevated temperatures in the presence of catalysts.[1] Recently it has been shown that the reaction proceeds at ordinary temperatures, though very slowly.[2] With acid chlorides it has not been possible to dispense with a catalyst.[3] Acid bromides, however, cleave ethers without the use of catalysts, though high temperatures are required to accomplish this result.[4]

More than twenty years ago Kishner[5] observed that benzoyl iodide was able to cleave ethers readily at 100° without a catalyst, forming alkyl iodides and benzoates. Since this isolated observation has not received the further investigation which its suggestive character would indicate, we have undertaken a comprehensive study of the reaction between acid iodides and ethers with the hope not only of developing a useful method for the investigation of ethers, but also of adding to our knowledge of the mechanism of the reaction between acid halides and ethers.

Due to the sluggishness of the reaction between benzoyl iodide and ethers, requiring a temperature of 100° for several hours, we have directed our attention to aliphatic acid iodides[6] with the hope that they would prove more reactive and that transformations with them might be obtained at ordinary temperatures. Thus the detrimental effect of elevated temperatures on unstable substances would be eliminated. This expectation has been entirely fulfilled.

When an aliphatic ether is treated with acetyl iodide, the reaction mixture becomes warm after a short induction period of often less than **a** minute. This heat, which we believe is due to the formation of an oxonium complex, is soon dissipated. If the mixture is allowed to stand at room temperature for two to five days, it is found that the ether has been cleaved with the formation of an alkyl iodide and an alkyl acetate. This reaction was found to proceed much faster with di-secondary ethers than with di-primary.

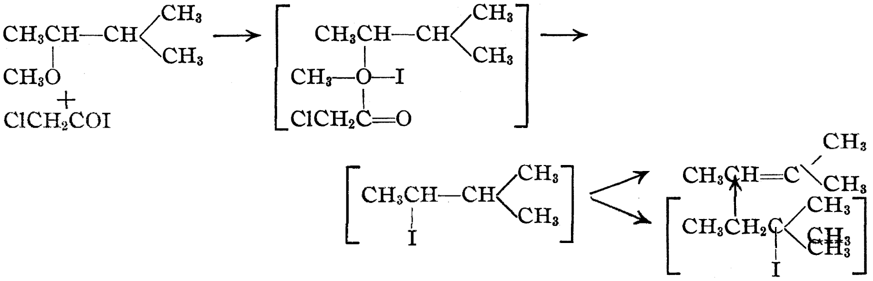
After this work had been completed, a paper by Meerwein and Maier-Hüser[1] appeared in which these workers suggested the oxonium salt mechanism in the case of the acid iodides. Meerwein and Maier-Hiiser, however, were not the first to use such a mechanism. Kishner,[5] the first to study ether cleavages by acid iodides, had already considered oxonium complex formation as a preliminary step to cleavage.

The molecular weight of primary ethers appears to influence slightly the ease with which they are cleaved. Thus the cleavage of di-n-propyl, di-n-butyl and diisoamyl ethers by acetyl iodide proceeds less readily as the molecular weight of the ether increases.

The introduction of chlorine into the ether molecule in the a-position was found to affect greatly its stability toward acid iodides. Thus chloroacetyl iodide, which cleaves ordinary ethers readily, caused no cleavage of sym-dichlorodimethyl ether in twenty-five days at room temperature followed by six days at 100°. There was here no apparent evidence of oxonium complex formation. Possibly no oxonium complex formed, thus prohibiting cleavage.

The cleavage of unsymmetrical aliphatic ethers by acid iodides was also investigated. It was found with di-primary ethers that the greater proportion of iodine attached itself to the smaller alkyl group. This confirms Kishner's[5] observation with benzoyl iodide and is in accord with the work of Norris and Rigby[2] with acid chlorides. With mixed primary–secondary ethers about one-half of the iodine went to the smaller (in this case the primary) radical. In addition rearrangement products appeared. Thus the methyl ether of methylisopropylcarbinol with chloroacetyl iodide formed methyl iodide and trimethylethylene in about equal quantities. The latter substance may have come from methylisopropyliodomethane, or from tertiary-amyl iodide, a rearrangement product[7]



Norris and Rigby[2] have already shown that methyl isobutyl ether and acetyl chloride in the presence of zinc chloride form mainly isobutyl chloride with some tertiary-butyl chloride, a rearrangement product.

Acid iodides are practically always contaminated with dissolved iodine. It was thought that this substance might be acting as a catalyst in ether

---

(7) Compare Wischnegradski, Ann., 190, 342 (1878).

cleavages. For this reason attempts were made to cleave ethers with acetyl chloride using iodine as a catalyst. After long standing at room temperature, no evidence of any reaction could be found.

The structure of the acid iodide in ether cleavage reactions is almost as important as the structure of the ether itself. The introduction of chlorine into the iodide has a marked effect. Thus chloroacetyl iodide was found to cleave ethers less readily than acetyl iodide, and dichloroacetyl iodide was very much less reactive. Definite evidence of a reaction between trichloroacetyl iodide and either primary or secondary ethers at room temperature could not be obtained. The same result was observed when zinc iodide was used as a catalyst. It is probable that an oxonium complex was first formed in each case, for heat was liberated when the iodide and ether were mixed. This was particularly noticeable with diisopropyl ether, but no cleavage took place. A very small amount of cleavage possibly occurred with diethyl ether at 100° after three hours. This failure of trichloroacetyl iodide to cleave ethers cannot be attributed to the lack of a hydrogen atom in the α-position to the carbonyl group since benzoyl iodide, which has no a-hydrogen atom, is able to cleave them.

Acid iodides not only cleave oxygen ethers, but thioethers as well. This was not unexpected for Cahours[8] had already reported the cleavage of thioethers by acid bromides at elevated temperatures, and had mentioned that acid iodides behaved similarly, though more vigorously. He failed, however, to report any experimental evidence. Owing to the criticism of his work by Obermeyer,[9] and the doubtful purity of the acid iodide available to him, this unsupported statement required further investigation.

While thioethers are cleaved by acid iodides, the rate of cleavage is very much slower than that of oxygen ethers. The cleavage products, in the case of diethyl sulfide, were ethyl iodide and ethyl thiolacetate. This slower cleavage may be due to the fact that the —S—C bond is in general stronger than the —O—R bond. Acetyl chloride without catalysts failed completely to cleave diethyl sulfide after seven days at 100°.

One of the most reactive ethers is ethylene oxide. Little work has been done on its reaction with acid halides.[10] Ethylene oxide reacts so vigorously with halogen acids that reactions with acid halides might be easily misinterpreted as true cleavages by the halide rather than as a chain reaction caused by small amounts of halogen acid present. Acetyl iodide reacts very vigorously with ethylene oxide even at $-80°$, and the reaction is so rapid that it seems quite reasonable to suppose true cleavage takes place. The product is β-iodoethyl acetate. The reaction with acetyl chloride was also tried, using acetyl chloride which had been freed from hydrogen chloride by distillation from dimethylaniline. Precautions were

(8) *Cahours, Bull. soc. chrm.,* [2] **25, 563 (1876)**; *Compt.* **rend., 81, 1163 (1876).**

(10) Bodforss, *Ahrens Sammlung, 26,* **221 (1920)**; *Altwegg* and *Landrivon, U. S. Patent* **1,393,191.**

taken to exclude all moisture. There was no apparent reaction at −80° nor at room temperature. After forty-four days, the material was fractionated directly. The yield of β-chloroethyl acetate was about 90%.

A similar experiment was made with acetyl chloride and ethylene oxide in the presence of a small amount of iodine. Here considerable heat was evolved at the outset. After three and a half days at room temperature, the yield of β-chloroethyl acetate was about 30%. If instead of iodine one drop of concentrated hydrochloric acid was used, the yield of β-chloroethyl acetate after two and a half days was about 75%. From these experiments it appears as if acetyl chloride may slowly cleave this very reactive ether without a catalyst at room temperature. A further investigation of this reaction, however, is now in progress.

When equivalent quantities of ethylene oxide, acetyl chloride and iodine were mixed at —SO°, at first no reaction occurred. The sealed tube containing the reaction mixture, now dark brown from dissolved iodine, was removed from the freezing mixture and shaken in the daylight. About fifteen seconds later, the tube exploded with great violence, although still at a low temperature. The formation of an iodo-hypoiodite at −80° reasonably accounts for the detonation.[11]

Although aromatic ethers, such as diphenyl ether and diphenylene oxide are unattacked by hydriodic acid even at 250°,[12] they were found to react vigorously with acetyl iodide at room temperature. This reaction will be made the subject of a future communication.

Though all acetyl iodides form oxonium complexes with ethers, the progressive introduction of chlorine decreases their ability to cleave ethers. The formation of a complex is, therefore, no criterion of subsequent cleavage. Halogen substitution apparently stabilizes the oxonium complex in some way not yet understood.

If the acid halides are compared with the hydrogen halides in regard to their reactivity toward ethers,[13] it will be seen that acid chlorides resemble hydrogen chloride. Since hydrogen halides, acid bromides[14] and iodides do form oxonium complexes with ethers, it is not unreasonable to suppose that acid chlorides may also do so, though to a very much less extent. The metal or non-metal halide used with acid chlorides as a catalyst for ether cleavage may greatly facilitate the formation of the oxonium complex, but it seems to us that the important role of the catalyst is rather the promotion of the decomposition of this complex.

We wish to express our thanks to Dean Frank C. Whitmore of the School of Chemistry and Physics of the Pennsylvania State College for laboratory

facilities, to the Mallinckrodt Chemical Works for so generously donating the large quantities of iodine consumed in this research, and to E. I. du Pont de Nemours, Inc., for kindly contributing the dimethyl ether used in our experiments. Part of the funds required for this research were privately contributed.

Experimental Part

Acetyl Iodide and Di-n-propyl Ether.—12.25 grams (0.12 mole) of di-n-propyl ether, b. p. 89–90.2' (from metallic sodium) was treated with 17 g. (0.10 mole) of acetyl iodide. The usual warming of the mixture was noticed, and the tube was allowed to stand protected from light at 25°. After eighty-nine hours, the reaction mixture was shaken with a saturated sodium carbonate solution, and 50 cc. of diisoamyl ether was added. After drying over anhydrous potassium carbonate, the solution was cooled, treated with 10 g. of anhydrous trimethylamine, and allowed to stand for twelve days at 25°, and then for six days at 65°. At the end of this time the solution was repeatedly washed with water, and the washings evaporated in *vacuo* over sulfuric acid; 10.5 g. of trimethyl-*n*-propylammonium iodide was obtained, which separated as platelets from absolute alcohol. The diisoamyl ether extract, after drying, was fractionated twice, finally yielding 0.45 g. of n-propyl acetate.

The following reactions were carried out in essentially the same way as described for n-propyl ether. Those marked with an asterisk are described in detail.

Iodide	Ether	Ammonium iodide	M. p., °C.	Yield, %	Acetate	B. p., °C. (730 mm. ±)	n_{D}^{20}	Hours
Acetyl	Dimethyl	Trimethylphenyl	210–211	88.2	Methyl	55 – 56.6	1.3636	240
	Di-n-propyl	Trimethyl-n-propyl	185–186	45.8	n-Propyl	100 –102	1.3839	89
	Di-n-butyl	Trimethyl-n-butyl	230–231	45.2	n-Butyl	126 –130	1.3969	89
	Diisoamyl	Trimethylisoamyl	193–194	41.2	Isoamyl	139.2–141.2	1.4054	89
	Diisopropyl	Trimethylisopropyl	285–286	73.1	Isopropyl	87 – 88	1.3954	89
	*Diethyl sulfide	Triethyl sulfonium cadmium iodide double salt	154	13.2	Ethyl thiol	See text		1296
	*Ethylene oxide			73.8	β-Iodoethyl	95 – 96 (43 mm.)	1.5072	20 ±
Chloro-acetyl	*Diethyl	Dimethylethyl-phenyl	135–136	90.9	Ethyl chloro	141.6–141.9	1.4217	120
Dichloro-acetyl	Diethyl	Dimethylethyl-phenyl	135–136	24.6	Ethyl dichloro	150 –152	1.4308	144
Trichloro-acetyl	*Diisopropyl	No reaction						168

Acetyl Iodide and **Diethyl** Sulfide.—37.5 grams of acetyl iodide was treated with 70.5 g. of diethyl sulfide in the usual way. After twenty days, golden-yellow crystals of triethylsulfonium iodide began to separate. After fifty-four days the reaction mixture was shaken well with water, the aqueous layer separated, and the non-aqueous layer shaken for twenty-four hours with water to convert any ethyl iodide into the soluble triethylsulfonium iodide. This aqueous layer was separated, added to the previously obtained washings, and the whole neutralized with dilute sodium hydroxide. There was a large amount of acid, indicating much unreacted acetyl iodide. The neutralized solution was concentrated in *vacuo* to about 150 cc., filtered hot and treated with an excess of hot, filtered, half-saturated cadmium iodide solution. After twelve hours at 0°, the sparingly soluble crystalline double salt, $[(C_2H_5)_3SI]_2CdI_2$, was collected, washed with water and alcohol and air dried. It weighed 25 g., corresponding to 4.54 g. of ethyl iodide. It melted at 119–120° and showed no depression when mixed with a known sample which had been recrystallized from dilute cadmium iodide solution.

When recrystallized from alcohol, it melted at 154°[15] and showed no depression when mixed with a known sample, also from alcohol. It lost no weight in drying at 110° and 20 mm.

Anal. Calcd. for $C_{12}H_{30}S_2I_4Cd$: I, 59.13. Found: I, 58.95.

The non-aqueous portion consisted of excess dicthyl sulfide and ethyl thiolacetate. As it was impossible to separate these two compounds by distillation, the diethyl sulfide was removed by diluting with diethyl ether, shaking up with water and excess methyl iodide until the aqueous extracts gave no precipitate of $[CH_3(C_2H_5)_2SI]_2CdI_2$ with cadmium iodide solution.[16] The ether extract, having the odor of ethyl thiolacetate, was dried and fractionated. The residue, boiling above 92°, was converted into ethyl mercaptochloride for identification according to the method of Sachs.[17] The ethyl mercaptochloride was recrystallized from a large volume of boiling xylene, separating in the form of characteristic hexagonal plates. It was dried at 110° and 20 mm.

Anal. (micro Carius). Calcd. for C_2H_5SHgCl: S, 10.79. Found: S, 10.70.

Acetyl Iodide and Ethylene Oxide.—Sixty-two grams of acetyl iodide, dissolved in an equal volume of carbon tetrachloride, was placed in a strong Pyrex tube, and the solution was frozen and cooled to —80°, carefully excluding moisture. An excess (20 cc.) of ethylene oxide was distilled in, and the tube sealed and shaken in the freezing bath. As soon as the reaction started, the frozen layer began to melt, and in a few moments complete mixing had occurred. The reaction proceeded with the liberation of much heat, as evidenced by the rapid vaporization of the carbon dioxide from the cooling bath. Within five minutes, the violence of the reaction had subsided, and the contents of the tube consisted of a dark, mobile liquid. After standing overnight at 25°, the tube was opened and the excess ethylene oxide allowed to evaporate. The reaction product, examined in the usual way, was fractionated *in vacuo.*

1st fraction	b. p. (43 mm.) 90–95°	2.4 g.	73.8% yield
2d fraction	b. p. (43 mm.) 95–96'	46.7 g.	
Residue		8.5 g.	

The second fraction, β-iodoethyl acetate, had a sharp, fruity odor, and its vapor attacked the eyes. When colorless the refractive index was n^{20}_{D} 1.5072.

Anal. (PdI_2). Calcd. for $C_4H_7O_2I$: I, 59.30. Found: **1,** 58.99.

Acetyl Chloride and Ethylene Oxide.—25.3 grams of acetyl chloride, freshly distilled from dimethylaniline, was treated with 18 g. of dry ethylene oxide. There was no obvious reaction at —80° nor at 25°. After standing for forty-four days at 25°, the excess of ethylene oxide (contaminated with acetaldehyde) and unreacted acetyl chloride were removed at 25° *in oacuo* and the residue fractionated, the second fraction being practically pure β-chloroethyl acetate.

1st fraction	b. p. (733 mm.) up to 142.4°	n^{20}_{D} 1.4215	2.5 g.	95.7% yield
2d fraction	b. p. (733 mm.) 142.4–143.8"	n^{20}_{D} **1.4235**	29.0 **g.**	
Residue		n^{20}_{D} 1.4333	6.3 g.	

Acetyl Chloride, Ethylene Oxide and Hydrochloric Acid.—25.3 grams of the same pure acetyl chloride, 18 g. of dry ethylene oxide, and one drop of concentrated hydrochloric acid were treated exactly as in the preceding experiment but for only two and a half days.

[15] Compare Ray, Adhikari and Banerjee, J. *Indian Chem. Soc.*, 8, 739 (1931); *Chem. Abstracts*, 26, 3199 (1932).

[16] Procedure suggested by Mr. J. M. Herndon of this Laboratory.

[17] Sachs, *Ber.*, **54B**, 1851 (1921).

1st fraction b. p. (732 mm.) 138–143°	n^{20}_{D} 1.4229	6.0 g.	77.9% yield
2d fraction b. p. (732 mm.) 143–144°	n^{20}_{D} 1.4240	18.8 g.	
Residue	n^{20}_{D} 1.4316	6.0 g.	

Acetyl Chloride, Ethylene Oxide and **Iodine.**—"A," 25.3 g. of the same pure acetyl chloride was treated with 18 g. of dry ethylene oxide and 10 mg. of resublimed iodine. At −80° there was no apparent reaction but on warming to room temperature the iodine dissolved, giving the solution a brown color, which, however, soon disappeared. The tube became slightly warm and remained so for several minutes. After three and a half days at 25° the material was treated exactly as before.

1st fraction b. p. (723 mm.) 138–143°	n^{20}_{D} 1.4235	3.5 g.	31.3% yield
2d fraction b. p. (723 mm.) 143–144°	n^{20}_{D} 1.4242	3.5 g.	
Residue	n^{20}_{D} 1.4401	5.4 g.	

"B," 26.5 g. of the same pure acetyl chloride was treated with 17.5 g. of dry ethylene oxide and 38.6 g. of dry, powdered, resublimed iodine. After sealing, the tube was removed from the cooling bath and shaken without protection from light. After fifteen seconds the tube exploded with great violence.

Acetyl Chloride, Diisoamyl Ether and Iodine.—Eighteen cc. of the same pure acetyl chloride was treated with 25 cc. of diisoamyl ether and 15 mg. of resublimed iodine. The iodine color slowly disappeared. After 44 days at 25°, the contents of the tube were examined in the usual way. The diisoamyl ether was recovered unchanged, and no evidence of cleavage of the ether could be found.

Chloroacetyl Iodide and **Diethyl** Ether.—Fifty-six grams of chloroacetyl iodide was treated with an excess (44 g.) of diethyl ether in the usual way. After five days, the products were carefully fractionated:

1st fraction b. p. (736 mm.) 36–71.7°	n^{20}_{D} 1.4524	7.2 g.
2d fraction b. p. (736 mm.) 71.7–72.2°	n^{20}_{D} 1.5077	28.5 g.
3d fraction b. p. (736 mm.) 72.2–74°	n^{20}_{D} 1.5098	4.9 g.
4th fraction b. p. (736 mm.) 74–141.6°	n^{20}_{D} 1.4292	8.0 g.
5th fraction b. p. (736 mm.) 141.6–141.9°	n^{20}_{D} 1.4217	19.5 g.
Residue	n^{20}_{D} 1.4262	4.0 g.

The second and third fractions were practically pure ethyl iodide, further identified by conversion into dimethylethylphenylammonium iodide. The **fifth** fraction, as shown by analysis and physical constants, was pure ethyl chloroacetate.

Anal. (micro). Calcd. for $C_4H_7O_2Cl$: C, 39.18; H, 5.76. Found: C, 39.30; H, 5.85.

The total yield of ethyl iodide was 90.9% and of ethyl chloroacetate 92.2%.

Chloroacetyl Iodide and n-Butyl Methyl Ether.—Forty-five grams of chloroacetyl iodide was treated with 22 g. of n-butyl methyl ether, b. p. (737 mm.) 69.8–70° (from metallic potassium). On mixing, the usual increase in temperature was noticed. After two weeks the contents of the bulb were partially fractionated to obtain the methyl iodide formed.

1st fraction b. p. (729 mm.) 42–43°	22.6 g.
2d fraction b. p. (729 mm.) 43–75°	12.0 g.

The residue was then treated to remove any acetyl iodide, dried and fractionated.

3d fraction b. p. (727 mm.) 72–111°	n^{20}_{D} 1.4325	1.0 g.
4th fraction b. p. (727 mm.) 111–135°		4.4 g.
5th fraction b. p. (727 mm.) 135–178.2°	n^{20}_{D} 1.4522	4.9 g.
6th fraction b. p. (727 mm.) 178.2–179°	n^{20}_{D} 1.4313	17.4 g.
Residue		4.8 g.

The first fraction, consisting of practically pure methyl iodide, and the second fraction were converted into trimethylphenylammonium iodide, giving 42 5 g. of the salt, m. p. 211–12°, 73.2% yield. The fourth fraction was n-butyl iodide, identified as trimethyl-n-butylammonium iodide, m. p. 230°, yield 13.3%. The sixth fraction was pure n-butyl chloroacetate.

Chloroacetyl Iodide and Methylisopropylcarbinol Methyl Ether.—Forty-five grams of chloroacetyl iodide was treated with 25 *g.* of methylisopropylcarbinol methyl ether. The usual increase in temperature was noticed on mixing. After sixteen days the tube was opened and the low boiling products were fractionated off directly: 36.5 g. of material, b. p. (731 mm.) 33–53°, was obtained. Floating on this distillate was about 0.5 g. of water. At present it is not possible to account definitely for the formation of water in this reaction. The distillate was diluted with benzyl alcohol, washed with dilute sodium carbonate, dried and treated with an excess of freshly distilled dimethylaniline. After standing for twenty-four hours the trimethylethylene was fractionated from this mixture; 13.9 g. of material, b. p. (730 mm.) 33–36°, was obtained which had the odor of trimethylethylene, reacted instantly with bromine in carbon tetrachloride without the formation of hydrogen bromide and gave a copious yellow precipitate with Denigès' reagent.[18] The trimethylphenylamrnoninm iodide in the residue was precipitated with benzene, collected and washed with petrolic ether; wt. 20 *g.*, m. p. 208°, 33.5% yield. The original residue from which the methyl iodide and trimethylethylene had been distilled was so decomposed that no homogeneous material could be isolated from it.

Preparation of Methylisopropylcarbinol Methyl Ether,  $CH_3—\overset{OCH_3}{\overset{|}{C}H}—CH(CH_3)_2$.—132 grams of methylisopropylcarbinol, b. p. (734 mm.) 111–112°, dissolved in 800 cc. of pure *p*-cymene, was treated with a large excess (120 g.) of bright potassium shot. The material, after six hours on the steam-bath, was boiled for two hours. After cooling, 340 g. of redistilled dimethyl sulfate was slowly added. When the reaction had subsided, the reaction mixture was boiled for twelve hours and fractionated several times, yielding 86 g. of pure methylisopropylcarbinol methyl ether, b. p. (737 mm.) 81.2–81.5°, d_{20}^{20} 0.7600, d_4^{20} 0.7586, n_D^{20} 1.3850.

Anal. (micro). Calcd. for $C_6H_{16}O$: C, 70.51; H, 13.82. Found: C, 70.45; H, 13.78.

Preparation of Methylisopropylcarbinol Chloroacetate,  $CH_3\overset{OCOCH_2Cl}{\overset{|}{C}}H(CH_3)_2$.—This substance was an expected cleavage product from methylisopropylcarbinol methyl ether, but was not thus obtained. It was prepared from the carbinol with chloroacetyl chloride in benzene solution and potassium carbonate, b. p. (738 mm.) 180–181°, d_{20}^{20} 1.0437, d_4^{20} 1.0418, n_D^{20} 1.4298.

Anal. (micro). Calcd. for $C_7H_{13}O_2Cl$: C, 51.05; H, 7.96. Found: C, 51.15; H. 8.20.

Chloroacetyl Iodide and *Sym*-dichlorodimethyl Ether.—Fifty grams of chloroacetyl iodide was treated with 31.25 g. of sym-dichlorodimethyl ether, b. p. (736 mm.) 101.2–101.5". The usual increase in temperature on mixing was not noticed. After twenty-five days, a small sample was withdrawn. It reacted with water and dissolved completely, indicating that no reaction had occurred. The tube was re-sealed and heated to 100° for six days. On re-examination, large amounts of unchanged acid iodide and sym-dichlorodimethyl ether were found, and no material insoluble in water save a little separated iodine was observed. Since the products expected, chloroiodomethane which is insoluble in water, and chloromethyl chloroacetate which reacts slowly with water and

---

(18) Denigès, *Compt. rend*, 126, 1145, 1277 (1898).

is Sparingly soluble, were obviously absent, it was concluded that no reaction had taken place.

Trichloroacetyl Iodide and **Diethyl** Ether.—32.7 grams of trichloroacetyl iodide was treated with an excess (23.3 g.) of diethyl ether. There was a very slight increase in temperature on mixing. After one hundred and twelve hours, the reaction products were examined in the usual way, but only unchanged diethyl ether was recovered, and no evidence of any cleavage could be found. A similar result was obtained with one gram of zinc iodide dissolved in the reaction mixture.

Trichloroacetyl Iodide and Diisopropyl Ether.—Thirty grams of trichloroacetyl iodide was treated with 12 g. of diisopropyl ether. On mixing there was a very considerable increase in temperature. After seven days at 25°, the contents of the tube were examined in the usual way. Diisopropyl ether was recovered, and no evidence of any cleavage of the ether was observed. Another tube containing, in addition, 1 g. of zinc iodide gave a similar result. In this case, however, practically all of the zinc iodide remained undissolved.

Trichloroacetyl Iodide and Diethyl Ether at 100°.—Twelve grams of trichloroacetyl iodide was treated with 4 g. of diethyl ether and heated to 100° for three hours. On working up the material in the usual way, about 0.2 cc. of a heavy liquid with a fruity odor was obtained which gave qualitative tests for both chlorine and iodine. While too small in amount to permit separation and purification of the components, it probably consisted of ethyl trichloroacetate and ethyl iodide, contaminated with unchanged diethyl ether. It is possible that a slight amount of cleavage of the ether took place.

Summary

1. The reactions between acetyl iodide and dimethyl ether, di-n-propyl ether, diisopropyl ether, di-n-butyl ether, diisoamyl ether, diethyl sulfide and ethylene oxide have been studied.

2. The reactions between chloroacetyl iodide and diethyl ether, n-butyl methyl ether and methylisopropylcarbinol methyl ether have been studied.

3. The introduction of chlorine into acetyl iodide has been found to diminish progressively its ability to cleave ethers, trichloroacetyl iodide being unable to cleave ethers at room temperature.

4. Di-secondary ethers react much more rapidly with acid iodides than di-primary ethers. Increasing the molecular weight of di-primary ethers decreases slightly the rate of cleavage.

5. Sym-dichlorodimethyl ether could not be cleaved by chloroacetyl iodide.

6. No reaction was observed at room temperature between primary ethers and acetyl chloride in the presence of dissolved iodine.

7. No reaction was observed between diethyl sulfide and acetyl chloride after one week at 100°.

8. The reaction between acetyl chloride and ethylene oxide has been studied.

9. The preparation and some physical constants of methylisopropylcarbinol methyl ether and methylisopropylcarbinol chloroacetate have been described.

Levulinic Acid. IV. The Vapor Pressures of its Normal-Alkyl Esters (C_7-C_{10})

BY MILFORD A. COWLEY AND H. A. SCHUETTE

In an earlier study[1] of the temperature–vapor pressure relationships of an homologous series of alkyl esters of levulinic acid, questions arose concerning the preparation and the stability of its higher members in the region of their boiling points. In order to obtain more information about members of this series and to test the validity of a formula, at that time presented, for calculating the specific gravities of the normal alkyl esters, the n-heptyl, n-octyl, n-nonyl and n-decyl esters were prepared and certain of their simpler physical properties determined as before. Because the work has been temporarily halted, it seems desirable to record now the data that have been obtained.

Experimental

Preparation of the Esters.—Levulinic acid (n^{40} 1.4342) was directly esterified with the appropriate alcohol[2] (molecular ratio of acid to alcohol, 1.1 to 1) using as a catalyst hydrogen chloride in the amount of 3% of the weight of the alcohol. Carbon tetrachloride served the dual role of solvent for the reactants and of agent for the removal of water from the reaction mixture by means of a continuous separator. Although the higher alcohols themselves are sufficiently insoluble in water to make possible their use as separating agents, such procedure is undesirable because of the high boiling temperature of the alcohols and the inevitable waste of such valuable reagents.

As was previously found in the cases of the n-amyl and n-hexyl esters, complete separation of the higher esters from the excess levulinic acid was not accomplished by a single fractional distillation under reduced pressure. Satisfactory removal of the acid from the ester fraction of the first distillation was brought about by shaking the mixture with dry, powdered sodium carbonate (6 to 8 g. of Na_2CO_3 to 50 g. of ester). Water was added dropwise with thorough shaking after each addition. The close approach of neutrality was indicated when the sodium carbonate particles agglomerated and settled as a granular mass. Although this mode of procedure for neutralizing the ester fraction proved effective, yet it was observed that the addition of water in excess of the amount needed to bring about this change

---

[1] Schuette and Cowley, THIS JOURNAL, 53, 3485 (1931).

[2] The alcohols, with one exception, were Eastman products. They were distilled before use. n-Decanol was prepared for us in the laboratory of Professor Homer Adkins by B. H. Wojcik, who hydrogenated ethyl n-caprate over a copper-chromium-barium oxide catalyst [Folkers and Adkins, *ibid.*, 54, 1145 (1932)]. Their assistance is gratefully acknowledged.

in appearance of the carbonate is to be avoided, otherwise troublesome emulsions form. The neutral esters, without exception, were again fractionated under reduced pressure. Molecular refractions, computed by the formula of Lorenz and Lorentz, were used as a measure of the purity of the final product.

The properties of the esters so prepared are listed in Table I.

TABLE I

PHYSICAL PROPERTIES OR LEVULINIC ACID ESTERS

Alkyl	n^{20}	Specific gravity (20°/4°)	Molecular refraction (Lorenz–Lorentz) Obs.	Calcd.
n-Heptyl	1.4360	0.94332	59.365	59.391
n-Octyl	1.4380	.93635	63.754	63.994
n-Nonyl	1.4400	.93360	68.386	68.597
n-Decyl	1.4417	.92653	73.141	73.200

Specific Gravities.—Elsewhere[1] the suggestion was made that the specific gravities of the higher (liquid) members of this homologous series might be predicted with fair accuracy by means of the empirical formula $488.18d^2 - 1029.1d + 543.34 = c$, in which d and c represent specific gravity and number of carbon atoms in the alkyl radical, respectively. This was, however, not found to be the case with respect to all of the four new esters herein described for, with the exception of the n-heptyl derivative, each showed a deviation above the predicted value which is too large to be disregarded. Obviously the mathematical expression in question has a very limited use for predicting by extrapolation the specific gravities of the higher esters ($C_7 - C_{10}$). A better summation of the data at hand for the ten normal esters is given by the expression

$$d = 0.868686 + 0.772094/(c + 3.29699),$$

in which d and c have the same significance as in the preceding formula. The deviations will in no case exceed three-tenths of one per cent. when this formula is applied to these ten esters.

Vapor Pressures.—The isoteniscopic method of Smith and Menzies[3] was used for the determination of vapor pressures because it is more economical of material and more sensitive to the decomposition of these esters than is the dynamic method of Ramsay and Young.[4] Pressures were read from a closed manometer which had been checked against a standard barometer. Temperatures were determined by means of a two-junction, iron–constantan thermopile in connection with an accurate potentiometer and a reflecting galvanometer. The thermopile was calibrated against Bureau of Standards thermometers over the temperature range of the experiments. The isoteniscope bulb was suspended in a well-insulated air-bath provided with a carefully controlled electrical heating

---

[3] Smith and Menzies, THIS JOURNAL, 32, 1412 (1910).

[4] Ramsay and Young, J. Chem. *Soc.*, 47, 42 (1885).

unit, a rapid stirrer and a small observation window. Maintaining the temperature constant to ±0.1° for a period of one-half minute was sufficient to allow for lag in the temperature-measuring device. Pressures are accurate to ±0.2 mm.; temperatures to ±0.2°.

Temperature–pressure relationships are expressed by means of the Kirchhoff[5] formula (Table II).

TABLE II

PRESSURE–TEMPERATURE RELATIONSHIPS OF LEVULINIC ACID ESTERS

Alkyl	Log P	B. p. (760 mm.), calcd. °C.
n-Heptyl	$19.3441-3.4634 \log T-3876.49/T$	283.5
n-Octyl	$16.9838-2.5904 \log T-3938.57/T$	291.1
n-Nonyl	$13.0149-1.2273 \log T-3855.21/T$	298.0
n-Decyl	$28.5652-6.0977 \log T-5120.54/T$	306.5

Discussion

That the esters decompose to form more volatile compounds upon heating was demonstrated by several observations. Vapor pressure data obtained for isobutyl levulinate by the static method[3] showed values in excellent agreement in the lower temperature range with those previously found by the dynamic method,[4] but definite deviations above those determined by the dynamic procedure were observed as the temperature was raised and the time of heating prolonged (Fig. 1). That this phenomenon may be indicative of decomposition has been noted in the case of *n*-valerolactone.[6] The beginning of the deviation is so definite that it recommends this method of dual determinations as a means of ascertaining the temperature at which decomposition begins. Data obtained for the new esters by the static method show at elevated temperatures similar high pressure values that cannot be made to conform to the Kirchhoff formula. Besides this, substantiation of this conclusion was found in the fact that a test run using n-octyl levulinate that had been once used for a vapor pressure determination gave high pressure values throughout the entire temperature range. Furthermore, it may not be without significance that all of the esters turned from colorless to yellow during the runs, the color being more intense at the surface exposed to the air.

The inconsistent pressure values (near atmospheric pressure) were disregarded in the formulation of the equations (Table II). The effect of decomposition is, therefore, to produce only a slight modification of the slope of the equation in the region of high pressure, which tends to make the calculated values for the boiling points slightly low and the values for the heats of vaporization and molar entropies slightly high.

Although the purified esters were kept in brown bottles protected from the light, they appeared to decompose partially upon standing. A fraction

[5] Kirchhoff, Ann. *physik. Chem.* (*Poggendorf*), 103,185 (1858).

[6] Schuette and Thomas, THIS JOURNAL, 52,2028 (1930).

more volatile than the freshly prepared ester was obtained upon redistillation, the refractive index was lowered and the esters assumed a faint yellow color after a period of weeks. For this reason, freshly distilled material was used in the vapor pressure measurements.

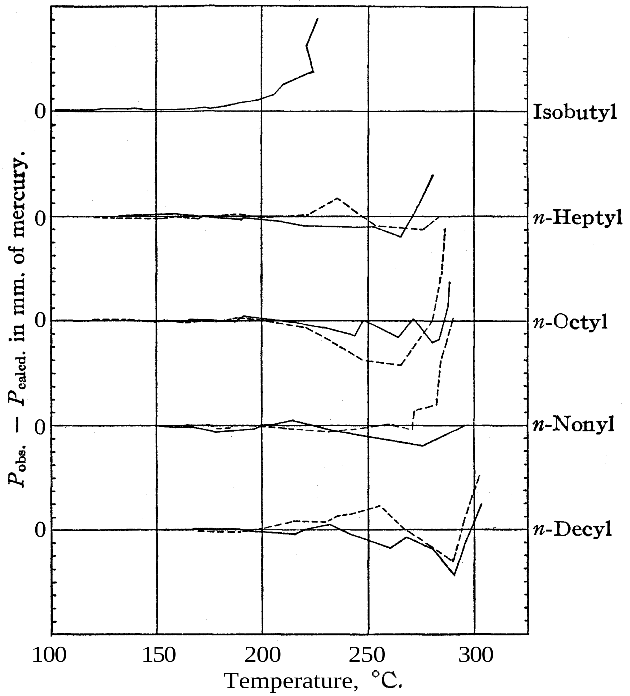

Fig. 1.—Deviation between observed and calculated vapor pressures of alkyl esters of levulinic acid. Ordinate graduations represent 10-mm. intervals; duplicate runs are indicated by unbroken and broken lines, respectively.

The excess of the molar entropies (Table III) over the average value of 27.3 given by Hildebrand[7] for normal liquids, is due in part to the result of decomposition though there is no apparent reason to suspect that the excess is not due partially to association of the liquids since all of the lower esters showed entropy values above the normal figure.

TABLE III

ENTROPIES OF VAPORIZATION OF THE ALKYL LEVULINATES

Alkyl	Temperature, °A.	Molar heat of vaporization (cal. mole)	Entropy of vaporization
n-Heptyl	496.2	14339.0	28.9
n-Octyl	507.2	15559.5	30.7
n-Nonyl	515.9	16341.8	31.7
n-Decyl	524.4	17210.0	32.8

Summary

Four new esters of levulinic acid have been prepared and characterized by some of their physical properties. Evidence has been presented to show that these esters decompose at their boiling points near atmospheric pressure.

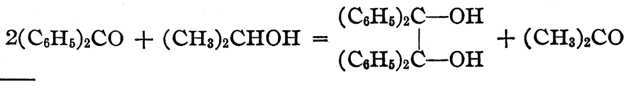
The Photochemical Reduction of Ketones to Hydrols

BY W. E. BACHMANN

It has recently[1] been shown that a small amount of sodium alcoholate can effect the decomposition of a large amount of benzopinacol into a mixture of benzohydrol and benzophenone. It occurred to us that through this reaction it should be possible to obtain hydrols by photochemical reduction of ketones. From the classical work of Ciamician and Silber[2] it is known that if an alcoholic solution of benzophenone is exposed to sunlight, the benzophenone is reduced to benzopinacol at the expense of the alcohol, which is oxidized to aldehyde. Cohen[3] showed that a number of substituted ketones can be reduced to pinacols in the same manner and he found that a variety of primary and secondary alcohols can be used as reducing agents. It appeared that if a small amount of sodium alcoholate was present in the alcoholic solution of the ketone which was exposed to sunlight, a combination of the two reactions would take place: (1) reduction of the ketone to pinacol and (2) decomposition of the pinacol into hydrol and ketone. The ketone that is regenerated in the second reaction would go through the series of reactions until the hydrol was the sole product.

Actually, we found that if a small amount of sodium alcoholate is present in the alcoholic solution, the reduction proceeds exactly as expected; no pinacol is obtained; instead, the hydrol is formed in nearly quantitative yield. For the reaction we employed isopropyl alcohol in preference to ethyl alcohol because the reduction with this alcohol is more rapid and the oxidation product, acetone, is not affected by alkali so readily as is acetaldehyde. The reactions that take place are expressed in the following formulation



$$2(C_6H_5)_2CO + (CH_3)_2CHOH = \begin{array}{c}(C_6H_5)_2C\text{—}OH\\ |\\ (C_6H_5)_2C\text{—}OH\end{array} + (CH_3)_2CO \qquad (1)$$

---

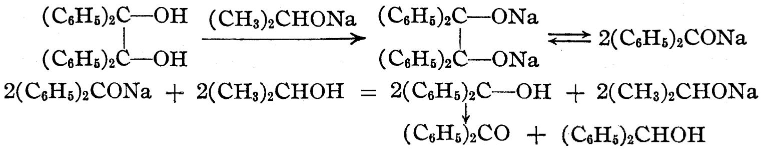
[2] Ciamician and Silber, *Ber.*, 33,2911 (1900).

[3] Cohen, *Rec. trav. chim.*, 39,242 (1920).



$$\begin{array}{c}(C_6H_5)_2C{-}OH\\ |\\ (C_6H_5)_2C{-}OH\end{array} \xrightarrow{(CH_3)_2CHONa} \begin{array}{c}(C_6H_5)_2C{-}ONa\\ |\\ (C_6H_5)_2C{-}ONa\end{array} \rightleftharpoons 2(C_6H_5)_2CONa \qquad (2a)$$

$$2(C_6H_5)_2CONa + 2(CH_3)_2CHOH = 2(C_6H_5)_2C{-}OH + 2(CH_3)_2CHONa \qquad (2b)$$

$$\downarrow$$

$$(C_6H_5)_2CO + (C_6H_5)_2CHOH \qquad (2c)$$

As fast as the pinacol is formed by the photochemical reaction (Equation 1) it reacts with the sodium alcoholate and gives sodium pinacolate[4] (Equation 2a). The sodium ketyl radicals[5] produced by dissociation of the sodium pinacolate react with isopropyl alcohol or with pinacol (Equation 2b); one molecule of the ketyl is converted to hydrol as another goes to ketone (2c). The ketone and sodium alcoholate which are regenerated go through the series of reactions until all of the ketone has been converted to hydrol.

In support of this mechanism may be cited the fact that a solution of benzophenone in isopropyl alcohol containing sodium isopropylate becomes greenish-blue on exposure to sunlight, the greenish-blue color being characteristic of the sodium ketyl radical. If the flask containing the colored solution is protected from sunlight, the greenish-blue color disappears, an indication that the reaction represented in Equation 2b is taking place. Renewed exposure to sunlight restores the color. Finally, if this mechanism is correct, then the greenish-blue color should disappear completely when all of the ketone has been reduced. Such is the case. After several days of exposure, the solution becomes colorless and remains so. Indeed, this proved to be a convenient visual indication that the reaction was at an end

Further support for this mechanism was furnished by a comparison of the rate of reduction of benzophenone to benzohydrol with the rate of reduction to benzopinacol. Since the decomposition of the pinacol by sodium alcoholate is very rapid, the rate of reduction to hydrol should be nearly the same as the rate of pinacol formation. Experiment showed that the rates of reduction are practically equal; under nearly identical conditions of exposure, a 93% yield of benzohydrol was obtained when sodium alcoholate was present in the time that a 97% yield of benzopinacol was formed in absence of sodium alcoholate.

Not only benzophenone but a number of other ketones can be reduced to hydrols. In every case the alcoholic solutions of the ketones become colored on exposure to sunlight and this color disappears after several days of exposure. The yields of hydrols varied from 80–95%. Cohen found that Michler's ketone, phenyl α-naphthyl ketone, fluorenone and 4-phenylbenzophenone were not reduced to pinacols on exposing alcoholic solutions of the ketones. In agreement with our view that the pinacols are the

---

[4] For an alternate mechanism of the decomposition of pinacol see Ref. 1.

[5] Compare Cohen [*Rec. trav. chim.*, 38, 113 (1919)], who considers that pinacols, or more likely diphenylhydroxymethyl radicals, $(C_6H_5)_2COH$, are intermediate products in the reduction of ketones to hydrols by alkaline reducing agents.

initial products in the reduction to hydrol, it was found that Michler's ketone and phenyl α-naphthyl ketone are not reduced to hydrols; in fact, most of the ketone can be recovered unchanged after prolonged exposure. In like manner, fluorenone is not reduced in the manner of benzophenone; however, the ketone does not remain unaffected but undergoes a reaction which is not a photochemical process. To our surprise 4-phenylbenzophenone was reduced nearly quantitatively to 4-phenylbenzohydrol. According to our mechanism the ketone should give pinacol when an alcoholic solution without sodium alcoholate is exposed. Actually we found that in isopropyl solution the ketone is reduced to the pinacol, 4,4'-diphenylbenzopinacol.

Experimental

Photochemical Reduction of Ketones to **Hydrols.**—Three grams of benzophenone was added to a solution of sodium isopropylate which had been prepared from 0.03 g. of sodium and 30 cc. of anhydrous isopropyl alcohol in a 30-cc. test-tube. The tube was corked and exposed to direct sunlight. Almost immediately the solution assumed a greenish-blue color. This color disappeared when the solution was exposed to air or when it was protected from sunlight. After four days the solution was colorless in bright sunlight, indicating that the reaction was at an end. The solution was poured into an evaporating dish and was diluted with an equal volume of acidified water. On evaporation the benzohydrol crystallized out; it was filtered off, dried and recrystallized from petroleum ether; yield, 2.98 g. (98%). Experiments in which ethyl alcohol was used were not successful because of the reactions undergone by the acetaldehyde.

In one experiment 25 g. of benzophenone in a 150-cc. Pyrex flask was dissolved in 125 cc. of isopropyl alcohol with which 0.25 g. of sodium had reacted. After one week of exposure 20 g. of benzohydrol was obtained. When the reaction was carried out in a long tube the reaction was complete in three days.

A comparison of the rate of reduction to hydrol with the rate of reduction to pinacol was made by exposing two tubes of the same size side by side; one tube contained sodium alcoholate, the other did not. After four days the one tube gave a 93% yield of benzohydrol and the other gave a 97% yield of benzopinacol.

In Table I are given the results obtained by reducing a number of ketones; in each case 3.0 g. of ketone was reduced in the same manner as described for benzophenone. The crude hydrol was recrystallized from a mixture of benzene and petroleum ether; the yields given in the table are based on recrystallized product.

The reaction between fluorenone, isopropyl alcohol and sodium isopropylate is not a photochemical process since the same products result when the mixture is kept in a dark place; heat and not light is the chief factor in hastening the reaction. It is well known that ketones are reduced to hydrols when the ketone is heated for a long time with an alcoholic solution of sodium hydroxide but it is not recognized that the reaction occurs at room temperature with a small amount of sodium alcoholate as it does with fluorenone. We have found that the reaction takes place with benzophenone to a considerable extent under the influence of heat. Five grams of benzophenone was added to a solution of sodium alcoholate prepared from 0.06 g. (10%) of sodium and 20 cc. of isopropyl alcohol and the mixture was refluxed for fifteen hours on a steam-bath; hydrolysis gave 3.92 g. (78%) of benzohydrol. The reaction is best explained by the following formulation which shows that a small amount of sodium alcoholate should be sufficient for reduction

$$(C_6H_5)_2CO + (CH_3)_2CHONa \longrightarrow (C_6H_5)_2CHONa + (CH_3)_2CO \qquad (3)$$

$$(C_6H_5)_2CHONa + (CH_3)_2CHOH \rightleftharpoons (C_6H_5)_2CHOH + (CH_3)_2CHONa \qquad (4)$$

TABLE I

PHOTOCHEMICAL REDUCTION OF KETONES TO HYDROLS

Ketone	Color during reduction	Time of exposure, days	Hydrol yield, %
Benzophenone	Greenish-blue	4	98
4-Methylbenzophenone	Greenish-blue	6	95
4,4'-Dimethylbenzophenone	Blue	6	90
4-Methoxybenzophenone	Greenish-blue	6	90
4-Chloro-4'-methylbenzophenone[a]	Blue	7	80
4-Phenylbenzophenone[b]	Green	7	95
4-Chlorobenzophenone	Green	7	80
Michler's ketone[c]	None	33	00
Phenyl α-naphthyl ketone[d]	None	15	00
Fluorenone[e]	......	7	

[a] The yields of halogen-substituted hydrols are lower because some of the halogen is removed in the reaction. This is especially true when the halogen is in the ortho position; the corresponding hydrols cannot be prepared conveniently by this method.

[b] Although Cohen reported that this ketone is not reduced to the pinacol in ethyl alcohol solution, we find that the reduction took place when a suspension of the ketone in isopropyl alcohol was exposed to sunlight. The pinacol was recrystallized from a mixture of acetone and chloroform and was obtained in the form of colorless needles which melted at 198° and which proved to be identical with the pinacol produced by reduction of the ketone by a mixture of magnesium and magnesium iodide [Gomberg and Bachmann, THIS JOURNAL, 49, 236 (1927)].

[c] After thirty-three days of exposure, 80% of the ketone was recovered; some decomposition products were present.

[d] A 70% yield of pure ketone was recovered.

[e] Three tubes containing isopropyl alcohol solutions of fluorenone were exposed simultaneously. One tube contained no sodium alcoholate; another tube had sodium alcoholate in it; the third tube contained sodium alcoholate but the tube was wrapped in a black cloth. The tube that contained no sodium alcoholate remained unchanged; after twenty-two days of exposure the fluorenone was recovered entirely unaffected. Both tubes containing sodium alcoholate became dark-brown and nearly black in color; after six days the solution was light-brown. Hydrolysis gave a 44% yield of fluorenol from the uncovered tube and a 56% yield from the covered tube. Prolonged exposure gave fluorenone and other products. Practically the same results were obtained from a solution which was kept in the dark for the same length of time.

A study is being made of the action of this reducing mixture on other ketones and on other types of compounds. In order to determine whether any benzohydrol is formed by this reaction by the heat received during exposure to sunlight, two tubes were exposed side by side, one of which was wrapped in a black cloth. In the time that the uncovered tube gave a 93% yield of benzohydrol, only 10% of the ketone in the covered tube was affected. The products presented in Table I represent, therefore, the results of photochemical reduction nearly entirely.

Preparation of Benzopinacol by Photochemical Reduction of Benzophenone.—We have confirmed the excellent work of Cohen,[6] who obtained a quantitative yield of benzopinacol by exposing 10 g. of benzophenone in 16 cc. of isopropyl alcohol. From the standpoint of preparation we find it more convenient to use a larger amount of alcohol and have prepared benzopinacol by the procedure which follows. A solution of 50 g. of

---

[6] Cohen, Rec. trav. *chim.*, 39, 245 (1920).

benzophenone in 450 cc. of isopropyl alcohol contained in a 500-cc. round-bottomed Pyrex flask is supported in an inverted position on a tripod and exposed to direct sunlight. After three hours crystals of benzopinacol are present. After one week 45 g. of benzopinacol is filtered off. To the filtrate is added a further 50 g. of ketone and the solution is again exposed to sunlight. This procedure was repeated until 300 g. of pinacol was obtained.

In one experiment a solution of 400 g. of benzophenone in 400 cc. of isopropyl alcohol and 400 cc. of benzene was exposed. After one month a quantitative yield of pinacol was obtained. The disadvantage of using benzene lies in the fact that the pinacol crystallizes with benzene of crystallization in the form of a compact mass which is difficult to remove from the flask.

Summary

Benzophenone and certain substituted benzophenones are reduced nearly quantitatively to hydrols when solutions of the ketones and a small amount of sodium isopropylate in isopropyl alcohol are exposed to sunlight.

The mechanism of the reaction has been elucidated. The ketone is reduced initially to the corresponding pinacol by a photochemical reaction; the pinacol is then converted to a mixture of ketone and hydrol by the action of the sodium alcoholate and alcohol; the ketone that is regenerated in this manner goes through the series of reactions again.

Researches on Nitrogenous Glycosides. II. The Synthesis of Glycosido Ureides[1]

BY KATHERINE M. HARING AND TREAT B. JOHNSON

The present investigation[2] was undertaken in order to develop a general method for the preparation of glycosido ureides of the hydantoic acid and hydantoin types. Glycosidohydantoins and their reduced forms, the unknown glycosidoimidazoles, are of interest because of their structural relationship to the natural purine nucleosides. In addition, it was believed that a study of such nitrogenous glycosides would be of biochemical importance in relation to the problem of the structure of naturally occurring protein-carbohydrate complexes.

The interest in the latter field has recently received an added stimulus in the discovery that carbohydrate units form integral parts of the proteins of blood serum[3] and egg white,[4] which were formerly considered simple

proteins. Furthermore, since bacterial polysaccharides which in the free state show typical hapten reactions, exist in the bacteria in a state which renders them not only type specific but also antigenic, it is believed that they must be joined to another molecule—probably protein. The most striking evidence in favor of this view has been contributed by the researches of Goebel and Avery.[5]

Since carbohydrate fractions appear to be intimate parts of the structure of certain simple proteins and since there is evidence that bacterial polysaccharides may be associated with proteins in the parent cell, it becomes very important to study the kinds of linkages which might exist between them. The carbohydrates of serum proteins and of egg proteins have been found to be very firmly bound in the combined molecules, whereas several bacterial polysaccharides have easily been obtained in the free state. It is probable, therefore, that the types of linkages involved in such cases vary widely.

The method of coupling sugars with amino acids by direct union with the free amino groups gives combinations which are easily susceptible to hydrolysis. A synthetic compound resulting from such a union was obtained by Euler and Zeile,[6] who condensed glycine ester with glucose in the presence of active aluminum. Maurer and his co-workers[7] had previously studied the reaction between bromoacetoglucose and sarcosine amide. They were able to deacetylate the resulting compound to obtain sarcosine amide glycoside. An extension of this method to other amino acids and peptides led to the formation of a number of acetylated derivatives. Euler was able to apply Maurer's method further to the preparation of glycylglycine glycoside. Both Maurer and Euler found that these derivatives which contained glucose directly linked to the amino acids or peptides were unstable in aqueous alkali solution.

The main object of the research presented here has been to develop a general method for coupling amino acids with sugars through an urea bridge. The synthetic methods which are involved in the preparation of glycosidothiohydantoic acid (VII), N-1-glycosido-2-thiohydantoin (VI), glycosidohydantoic acid (VIII), and N-1-glycosidohydantoin (IX) are shown in the accompanying chart.

Tetracetylglucose isothiocyanate, which was described originally by Fischer,[8] condensed smoothly and almost quantitatively with glycine ethyl ester hydrochloride, in the presence of pyridine, to give ethyl tetracetyl glycosidothiohydantoate (I). The practically quantitative removal of the acetyl groups from (I) with the formation of ethyl glycosidothiohydantoate (III) was accomplished by the use of alcoholic hydrogen chloride. It was

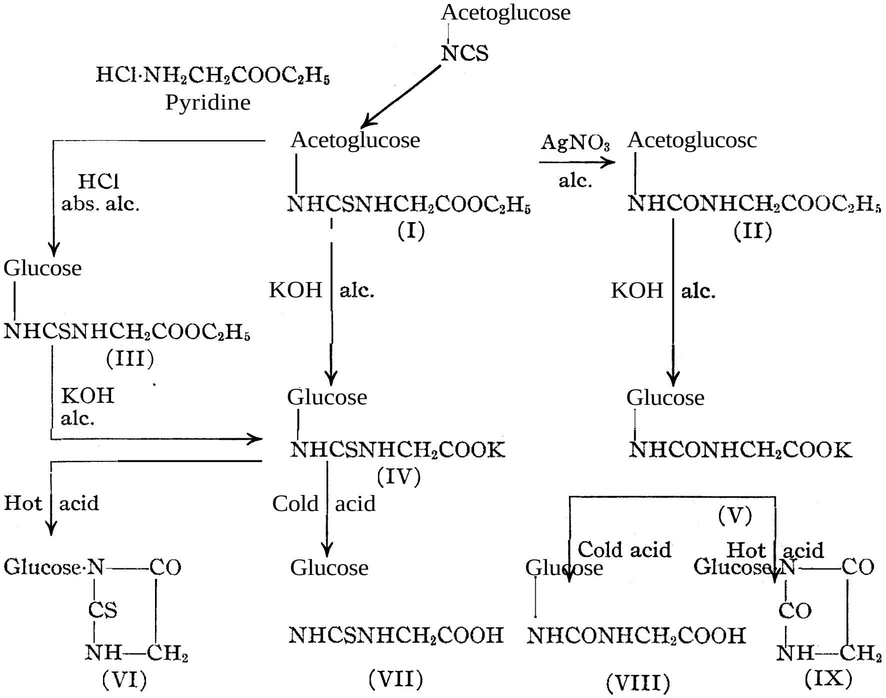
more practical, however, to simultaneously deacetylate and deesterify (I) by saponification with alcoholic potassium hydroxide. The potassium salt (IV) which resulted could be subsequently hydrolyzed with cold acid to give glycosidothiohydantoic acid (VII) or with hot acid to give N-1-glycosido-2-thiohydantoin (VI).

The oxygen analogs of the compounds which have been described were prepared from ethyl tetracetylglycosidohydantoate (II). This substance resulted when ethyl tetracetylglycosidothiohydantoate (I) was treated with alcoholic silver nitrate solution according to the procedure described by Dixon[9] for the desulfurization of thioureas. Deacetylation and deesterification of (II) was accomplished by saponification with alcoholic potassium hydroxide. The resulting potassium salt (V) was then transformed with cold acid into glycosidohydantoicacid (VIII) or with hot acid into N-1-glycosidohydantoin (IX).

SYNTHESIS OF GLYCOSIDO UREIDES



The glycosido ureides prepared in this investigation resemble the glycosido amino acid and peptide combinations of Euler and Zeile and Maurer and Schiedt in their behavior toward hydrolytic agents. On the other hand, they show a marked contrast to the purine and pyrimidine glycosides described in the literature. The purine nucleosides are readily hydrolyz-

---

(9) Dixon, *J. Chem. Soc.*, 556 (1895).

able by acids but remain intact on treatment with alkalies, whereas the pyrimidine nucleosides are much more resistant even to acid hydrolysis.[10] Glycosidohydantoic acid (VIII) and N-1-glycosidohydantoin (IX), however, represent a type of glycoside which is much more susceptible to hydrolysis than the purine nucleosides since they readily reduce Fehling's solution. In the case of glycosidothiohydantoic acid (VII) and N-1-glycosido-2-thiohydantoin (VI) colored side reactions make it impossible to observe any reduction with Fehling's solution although hydrolysis probably does occur. The ease with which these compounds are hydrolyzed by hot acid has been shown to be one of the factors which causes the small yields in the preparation of both N-1-glycosido-2-thiohydantoin and N-1-glycosidohydantoin. Research will be continued in this field in order to extend the method of synthesis, which has been described, to other sugars and to other amino acids and peptides.

Experimental Part

Tetracetyl-*d*-glucose Isothiocyanate.—For the preparation of tetracetylglucose isothiocyanate a modification of Fischer's method[8] was found necessary.

A solution of 25 g. of bromoacetoglucose in 150 cc. of xylene was treated with 16 g. of solid silver thiocyanate. The mixture was refluxed over a small free flame for one to two hours until the supernatant liquid became reddish-brown. The solution was then allowed to cool, filtered from the silver salts, and diluted with about 100 cc. of petroleum ether. The red-brown gum which in most cases was thrown out on the stirring rod and sides of the beaker was discarded. Tetracetylglucose isothiocyanate was precipitated by slowly decanting the supernatant liquid from the red gum into 250 cc. of iced petroleum ether. The total yield varied from 50–87%.

The crude isothiocyanate could be recrystallized from a hot alcohol solution which was cooled quickly in an ice-bath or from a chloroform solution which was poured slowly into a large volume of petroleum ether. The latter method was more satisfactory. The products from the two methods of recrystallization did not show the different characteristics which Fischer described. In either case the purified compound melted at 112–114°.[11]

Ethyl Tetracetyl-d-glycosidothiohydantoate (I).—Eight grams of glycine ethyl ester hydrochloride was suspended in a solution of 20 g. of tetracetylglucose isothiocyanate and 6 cc. of pyridine in 150 cc. of chloroform and the mixture was refluxed on the steam-bath for at least three hours. When heating was discontinued the chloroform solution was evaporated to dryness *in oacuo*. The residual gum was stirred vigorously with 100–150 cc. of water and was alternately warmed on the steam-bath and cooled in ice until it hardened. Incomplete removal of the chloroform occasionally prevented the hardening of the gum. After standing in the ice-bath the caked product could be crushed to a powder. The yield was 96%.

Ethyl tetracetylglucosidothiohydantoate was very soluble in acetone and hot ethyl alcohol, soluble in cold ethyl alcohol (1 g. in 20 cc.), cold methyl alcohol, and cold benzene, and practically insoluble in ether, petroleum ether and water. Twenty-two grams of crude material was recrystallized from about 300 cc. of 50% alcohol. The purified substance separated in rosets of short, creamy-white needles which melted at 151–152.5°. Its specific rotation was $[\alpha]^{22}_{D}$ +6° in chloroform solution. A sample was dried *in vacuo* at 100° for analysis.

---

(11) The melting points given are corrected melting points.

Anal. Calcd. for $C_{19}H_{28}O_{11}N_2S$: C, 46.34; H, 5.72; N, 5.69; S, 6.50. Found: C, 46.43; H, 5.68; N, 5.68; S, 6.50.

If the time of heating the original reaction mixture was less than three hours, small amounts of tetracetylglucose thiourethan, melting at 156–157°, were isolated from the recrystallization filtrate, showing that the reaction had been incomplete. Mixed with tetracetylglycosidothiohydantoic ester, this compound melted at 129–131°.

Ethyl d-Glycosidothiohydantoate (III).—Ethyl tetracetylglycosidothinhydantoate (1) could be deacetylated either in acid or alkaline medium. When alcoholic hydrogen chloride was the reagent used, the product was ethyl glycosidothiohydantoate.

Five cc. of absolute alcohol saturated with dry hydrogen chloride was added to a warm solution of 10 g. of ethyl tetracetylglycosidothiohydantoate in 100 cc. of absolute alcohol. After this solution had stood overnight at room temperature it was concentrated to a thick sirup, diluted with absolute alcohol and concentrated again. It was then diluted once more with 100 cc. of absolute alcohol and again allowed to stand in the ice box. The total yield of ester obtained by carrying out this procedure repeatedly was 95%.

Ethyl glycosidothiohydantoate crystallized in iridescent, white plates which contained alcohol of crystallization. It was very soluble in water, soluble in hot absolute alcohol (1 g. in 50 cc.) and hot ethyl acetate (1 g. in 230 cc.), but much less soluble in cold absolute alcohol (1 g. in 400 cc.) and cold ethyl acetate (1 g. in 1100 cc.). It could be recrystallized from either of the latter solvents. The melting point of the purified product was indistinct. It softened at about 110" and melted with the evolution of gas at 119–121°. If the heating was more rapid it melted only partially with the evolution of gas at 119–121° and liquefied completely at 154–155°. Its optical rotation was $[\alpha]^{22}_{D}$ −31.3" in water solution. A sample, dried to constant weight *in vacuo* at room temperature, gave analyses showing the presence of one mole of alcohol of crystallization.

Anal. Calcd. for $C_{11}H_{20}O_7N_2S \cdot C_2H_5OH$: N, 7.57. Found: N, 7.52, 7.44.

This crystalline form of the product could be freed from alcohol only with great difficulty due to its tendency to decompose on prolonged heating. The best result was obtained when a sample was heated in an Abderhalden drier over calcium chloride at 76° for six weeks and then at 100° for two days. The total loss in weight was 12.97%. This corresponded to the theoretical loss in weight of 12.44% due to one mole of alcohol of crystallization. The alcohol-free product was a tan colored powder which melted at 152–155° and decomposed at about 162°.

Anal. Calcd. for $C_{11}H_{20}O_7N_2S$: N, 8.64. Found: N, 8.69.

When this alcohol-free modification was recrystallized from absolute alcohol it reverted to the original crystalline form.

When a large excess of alcoholic hydrogen chloride was used to catalyze the deacetylation of (I), the monohydrochloride of ethyl glycosidothiohydantoate was formed as a by-product. It was precipitated by pouring dropwise into a large volume of dry ether the sirupy alcoholic filtrate from which ethyl glycosidothiohydantoate itself had been separated. Purification of the hydrochloride could be accomplished by dissolving it in absolute alcohol and reprecipitating it with dry ether. The purified substance was a tan, amorphous powder which was very hygroscopic. When dry it melted with the evolution of gas at 73–75°.

Anal. Calcd. for $C_{11}H_{20}O_7N_2S \cdot HCl$: N, 7.76; HCl, 10.11. Found: N, 7.58, 7.50: HCl, 10.25.

Potassium d-Glycosidothiohydantoate (IV).—When alcoholic potassium hydroxide was the reagent used to deacetylate (I), the ester grouping was saponified simultaneously and potassium glycosidothiohydantoate was formed. Alcoholic potassium hydroxide was used in preference to alcoholic ammonia because the potassium salt which resulted was more satisfactory to handle than the corresponding ammonium salt.

A solution of 1.5 g. of potassium hydroxide in 20 cc. of alcohol was added to a warm solution of 5 g. of ethyl tetracetylglycosidothiohydantoate in 75 cc. of alcohol. A flocculent pink precipitate was formed immediately when the two solutions were mixed. When the supernatant liquid had become clear the pink solid was filtered and washed with alcohol. When dry it was a hygroscopic, pink powder which decomposed at 137–141°. It could be prepared equally well by the saponification of (III) with alcoholic potash. Potassium glycosidothiohydantoate was used in the crude state for the preparation of glycosidothiohydantoic acid (VII) and N-1-glycosido-2-thiohydantoin (VI).

***d*-Glycosidothiohydantoic Acid (VII).**—A water solution of 5 g. of potassium glycosidothiohydantoate was treated with 4 cc. of approximately 6 *N* sulfuric acid and the mixture was allowed to stand for four hours at room temperature. It was then concentrated *in vacuo* and poured into about 200 cc. of absolute alcohol. The filtrate from the precipitated potassium sulfate was concentrated again *in vacuo* until crystals of glycosidothiohydantoic acid separated. The maximum yield was 54%. If a considerable excess of sulfuric acid was used originally to neutralize the potassium salt, the mother liquor yielded finally crystals of ethyl glycosidothiohydantoate which evidently resulted from the esterification of the free acid.

The crude acid was recrystallized from alcohol. One gram dissolved very slowly in about 300 cc. of boiling alcohol. Since the solubility of the acid was not appreciably greater in hot than in cold alcohol, the solution was concentrated to half volume or less before cooling. The recrystallized compound decomposed at 180.5-181" when it was heated slowly. Rapid heating raised the decomposition point several degrees. Its specific rotation was $[\alpha]^{22}_{\rm D}$ −36.1° in water solution. A sample was dried at 100° *in vacuo* for analysis.

Anal. Calcd. for $C_9H_{16}O_7N_2S$: C, 36.49; H, 5.45; N, 9.46. Found: C, 36.45; H, 5.50; N, 9.46, 9.39.

When a water solution of (VII) was boiled with Fehling's solution it became dark gray-green. The precipitate which settled was dark brown. Probably the sulfur caused side reactions which made it impossible to observe the reduction.

N-1-*d*-Glycosido-2-thiohydantoin (VI).—N-1-Glycosido-2-thiohydantoin was prepared by heating a solution of 2 g. of potassium glycosidothiohydantoate in 50 cc. of approximately 6 *N* hydrochloric acid for one-half hour on the steam-bath. The solution was then concentrated *in vacuo* to about 10 cc. and poured into 50 cc. of absolute alcohol. The precipitate of potassium chloride which formed was filtered out and the filtrate was concentrated *in vacuo* to a thin sirup which was diluted with about 50 cc. of amyl alcohol. The cloudy solution which resulted was concentrated *in vacuo* until an amorphous precipitate began to form on the sides of the flask. This product, which shriveled at about 70° and decomposed at 111–121°, was discarded. The filtrate, when concentrated further *in vacuo*, yielded fine, yellow crystals of glycosidothiohydantoin, which decomposed at about 226°. The maximum yield was 33%.

This compound was recrystallized from absolute alcohol. One gram dissolved slowly in about 85 cc. of boiling alcohol and was about one-half as soluble cold. The purified product separated in the form of pale yellow plates which darkened when heated at about 216° and melted with decomposition at 224225". Its specific rotation was $[\alpha]^{22}_{\rm D}$ +22.8° in water solution. A sample was dried at 100° *in vacuo* for analysis.

Anal. Calcd. for $C_9H_{14}O_6N_2S$: C, 38.86; H, 5.08; N, 10.07. Found: C, 39.22; H, 5.17; N, 9.87.

When a water solution of N-1-glycosido-2-thiohydantoin was added to Fehling's solution it turned yellowish-brown in the cold and formed a dark yellow precipitate on heating. Since N-1-glycosidohydantoin reduced Fehling's solution under similar conditions, it is probable that the sulfur in the former case caused the colored side reactions.

In addition to glycosidothiohydantoin, the amyl alcohol mother liquor from the reaction previously described yielded a second type of crystalline compound. When heated, it turned dark brown at about 199° and decomposed at 221–231°. It could be recrystallized from absolute alcohol but was more soluble in amyl alcohol than glycosidothiohydantoin and much less soluble in water. Nitrogen analyses did not serve to identify the substance as thiohydantoic acid or thiohydantoin but indicated clearly that the glucose part of the molecule was no longer present. The latter conclusion was supported further by the fact that this was the only crystalline product which resulted when the original reaction mixture was heated for periods longer than one-half hour. N-1-Glycosido-2-thiohydantoin was apparently not very stable toward acid hydrolysis.

Ethyl Tetracetyl-*d*-glycosidohydantoate (II).—Ethyl tetracetylglycosidohydantoate was prepared by desulfurizing (I).

A hot solution of 10 g. of ethyl tetracetylglycosidothiohydantoate in 150 cc. of alcohol and a solution of 7.5 g. of silver nitrate in 20 cc. of water were mixed and heated on the steam-bath. After five minutes an alcoholic solution of 2.2 g. of potassium hydroxide was added to neutralize the nitric acid set free from the silver nitrate. This promoted the coagulation of the silver sulfide and helped to prevent the nitric acid from hydrolyzing off the acetyl groups of the sugar. The solution was heated until the silver sulfide coagulated. Then it was cooled and filtered through a norit mat. The filtrate was concentrated *in vacuo* to about 50 cc. and diluted with 3-4 volumes of water. When the solution was stirred vigorously to start precipitation the desulfurized ester was obtained in 48% yield.

Ethyl tetracetylglycosidohydantoate was recrystallized from absolute alcohol. One gram was soluble in about 10 cc. of hot and about 30 cc. of cold absolute alcohol. It was practically insoluble in water but was much more soluble in 50% than in absolute alcohol. The recrystallized product separated in the form of long, white needles which melted at 149–149.5°. Its specific rotation was $[\alpha]_D^{22}$ $-3°$ in chloroform solution. A sample was dried at 100° *in vacuo* and analyzed.

Anal. Calcd. for $C_{19}H_{28}O_{12}N_2$: C, 47.89; H, 5.92; N, 5.88. Found: C, 47.57; H, 5.93; N, 5.93.

Potassium d-Glycosidohydantoate (V).—A solution of 1.5 g. of potassium hydroxide was added to a warm solution of 5 g. of ethyl tetracetylglycosidohydantoate in 75 cc. of alcohol. A white precipitate of potassium glycosidohydantoate formed immediately. The crude salt, which decomposed at 134–137°, was used in the preparation of glycosidohydantoic acid (VIII) and N-1-glycosidohydantoin (IX).

d-Glycosidohydantoic Acid (VIII).—Twenty cc. of approximately 1 *N* hydrochloric acid was added to a water solution of 4 g. of potassium glycosidohydantoate and the mixture was allowed to stand at room temperature. After four hours the solution was concentrated *in vacuo* to about *10* cc. and diluted with 100 cc. of absolute alcohol. When the filtrate from the precipitated potassium chloride was allowed to stand in the ice-bath crystals of glycosidohydantoic acid separated. The total yield was 55%.

The crude product was recrystallized from alcohol. One gram dissolved in 80 cc. of boiling and in 500 cc. of cold alcohol. The purified acid readily reduced Fehling's solution. It melted with decomposition at 169.5–170° when it was heated slowly and had a specific rotation of $[\alpha]_D^{27}$ $-25.8°$ in water solution. A sample was dried at 100° *in vacuo* and analyzed.

Anal. Calcd. for $C_9H_{16}O_8N_2$: C, 38.57; H, 5.71; N, 10.00. Found: C, 38.40; H, 5.95; N, 9.82, 9.90.

N-1-*d*-Glycosidohydantoin (IX).– A solution of 2 g. of potassium glycosidohydantoate in 25 cc. of approximately 6 *N* hydrochloric acid was heated on the steam-bath for one-half hour. It was then concentrated *in vacuo* to about 10 cc. and poured into 100 cc. of absolute alcohol. The filtrate from the precipitated potassium chloride was concentrated *in vacuo,* diluted with more absolute alcohol and concentrated again to about 25 cc. This thin sirup was diluted with about 75 cc. of amyl alcohol, cooled in an ice-bath and filtered from the sticky, amorphous precipitate which formed. This product, which shriveled at 60° and decomposed at 110–115°, was discarded. When the mother liquor was cooled further in the ice-bath fine, white crystals of N-1-glycosidohydantoin were deposited on the walls of the beaker. The total yield was 25%.

The crude product was very slightly soluble in hot absolute or 95% alcohol. It could best be recrystallized by dissolving it in cold 50% alcohol, adding 3–4 volumes of absolute alcohol and concentrating the resulting solution until crystals just began to separate. When the concentrated solution was allowed to stand in the ice box, N-1-glycosidohydantoin crystallized in rosets of very short, fine, white needles, which decomposed at 270–271°. Its specific rotation was $[\alpha]^{22}_{D}$ +5° in water solution. When it was boiled with Fehling's solution there was a decided reducing effect. A sample was dried *in vacuo* at 100° and analyzed.

Anal. Calcd. for $C_9H_{14}O_7N_2$: C, 41.22; H, 5.39; N, 10.69. Found: C, 40.98; H, 5.46; N, 10.63.

The amyl alcohol mother liquor yielded, in addition to N-1-glycosidohydantoin, small amounts of a second crystalline compound which melted with decomposition at about 178–194°. Further work will be necessary to identify it. Probably, however, as in the case of the second compound isolated from the preparation of N-1-glycosido-2-thiohydantoin, this compound had also lost the glucose part of the molecule.

Summary

1. A general method has been developed for the synthesis of four new glycosido ureides, d-glycosidothiohydantoic acid (VII), N-1-*d*-glycosido-2-thiohydantoin (VI), d-glycosidohydantoic acid (VIII), and N-1-*d*-glycosidohydantoin (IX). This investigation involved the preparation of a number of intermediate acetylated and deacetylated derivatives of glycosidothiohydantoic acid and glycosidohydantoic acid.

2. A study of the final glycosido ureides has shown that they differ in chemical properties from the synthetic glycosido pyrimidines and purines, but resemble the synthetic glycosido amino acids and peptides which have been described in the literature.

Orientation in the Furan Nucleus. III. 5-Methyl-3-furoic Acid[1]

BY HENRY GILMAN, ROBERT R. BURTNER AND E. W. SMITH

Introduction

It is rather astonishing that despite the long history of furan compounds very little is known definitely concerning orientation in the furan nucleus. There are several reasons for this. First, furan compounds are reputedly highly sensitive to acidic reagents, and it is just such reagents which are most commonly involved in substitution reactions such as halogenation, nitration and sulfonation. Second, there is a pronounced tendency for substituents to occupy the alpha-positions when these are available. This makes the determination of the position of substituents in furan more difficult than in benzene, for absolute methods of orientation (like those used with signal success in the classical studies by Korner with benzene) are of limited application because not all of the theoretically possible isomers are formed in a given substitution reaction starting with furan or a mono-substituted furan or a di-substituted furan. Furthermore, if all possible isomers were formed and could be isolated, the absolute method for orientation would be of restricted applicability as can be readily ascertained by a comparison of isomeric furan and benzene types. Third, it is, at present, difficult to obtain beta-substituted furans, even by indirect methods, and only very recently have the simple beta-substituted furans like 3-furaldehyde, 3-furansulfonic acid, 3-chloromercurifuran, etc., become accessible. Fourth, analogies cannot be made confidently with related heterocycles like thiophene. Not only are there essential differences between thiophene and furan, but (and this is of greater importance) the positions of elements and groups in many nuclear substituted thiophenes have not been determined unequivocally. Furthermore, it appears that the structures now assigned to some nuclear substituted thiophenes are incorrect, and it would not be very surprising to find that analogies, if any are to be drawn, will be with furan and not with thiophene as a type. Fifth, physico-chemical methods have a particularly circumscribed utility, at this time, for such methods in general turn on comparisons with compounds of known constitution as standards, and relatively few such compounds are available.

The particular need is for reference or standard compounds having two nuclear substituents. Theoretically, there are four isomeric di-substituted furans, in which the nuclear substituents are alike. The paucity of reference compounds becomes obvious when we learn that there is no single, complete series of di-substituted furans having two like substituents.

---

(1) For preceding papers in this series see: Gilman and Wright, *Iowa State Coll. J. Sci.*, **5**, 85 (1931); Gilman, Burtner and Smith, *Rec. trav. chim.*, **51**, 407 (1932).

Theoretically, there are six isomeric di-substituted furans, in which the nuclear substituents are unlike. The present synthesis of 5-methyl-3-furoic acid (Formula VI) completes such a series, and makes available for the first time a group of reference compounds for the determination of the position of substituents in poly-substituted furans having both like and unlike substituents.

m. p. 119°
(VI)

The 5-methyl-3-furoic acid (VI) was synthesized by the following sequence of reactions

$$3,5\text{-}C_4H_2O(COOH)_2 \longrightarrow 3,5\text{-}C_4H_2O(COOCH_3)_2 \longrightarrow$$
$$3,5\text{-}C_4H_2O(COOCH_3)(COOH) \longrightarrow 3,5\text{-}C_4H_2O(COOCH_3)(COCl) \longrightarrow$$
$$3,5\text{-}C_4H_2O(COOCH_3)(CHO) \longrightarrow 3,5\text{-}C_4H_2O(COOH)(CHO) \longrightarrow$$
$$3,5\text{-}C_4H_2O(COOH)(CH{=}NNH_2) \longrightarrow 3,5\text{-}C_4H_2O(COOH)(CH_3).$$

The constitution of 5-methyl-3-furoic acid was confirmed by other reactions. First, it is known that one of the carboxyl groups in the initial dibasic acid occupies a 8-position, because preferential pyrolytic decarboxylation gives 3-furoic acid. Second, the methyl group in the ultimate product (a methyl-3-furoic acid) is in an a-position because decarboxylation yields 2-methylfuran (or sylvan). Only two α-methyl-β-furoic acids are possible: namely, IV and VI, and the new methylfuroic acid is certainly quite unlike the well-known 2-methyl-3-furoic acid (IV).

Experimental Part

Dimethyl 2,4-furandicarboxylate was obtained in a 90% yield in accordance with the directions of Feist.[7]

4-Carbomethoxy-2-furoic Acid, $C_4H_2O(COOCH_3)(COOH)$.—One-tenth mole of potassium hydroxide in 50 cc. of absolute methyl alcohol was added to 0.1 mole of the dimethyl ester in 50 cc. of methyl alcohol, and after refluxing until no color test was observed with phenolphthalein, the ester salt was acidified in the cold with hydrochloric acid to yield 14.5 g. of the ester acid melting at 100–105°. Crystallization from water

yielded lustrous white plates melting at 132.5°; neutralization equivalent, calcd., 170; found, 172.8.

Anal. Calcd. for $C_7H_6O_5$: C, 49.41; H, 3.56. Found: C, 49.42; H, 3.85.

4-Carbomethoxy-2-furoyl Chloride, $C_4H_2O(COOCH_3)(COCl)$.—The ester acid chloride was prepared by heating (after the initial vigorous reaction) a benzene solution of the ester-acid with thionyl chloride; and, on recrystallization from carbon tetrachloride. it melted at 83–84"

Anal. Calcd. for $C_7H_5O_4Cl$: Cl, 18.81. Found: Cl, 18.86 and 18.63.

4-Carbomethoxy-2-furaldehyde, $C_4H_2O(COOCH_3)(CHO)$.—Catalytic reduction was effected by the procedure of Rosenmund.[8] A few details will be given because the method has not been described for furan compounds and we have had consistent success in converting a miscellany of furoyl chlorides to the corresponding furaldehydes. Four and one-half grams (0.023 mole) of the ester acid chloride, 1.8 g. of the palladium–barium sulfate catalyst and 25 cc. of dry xylene were placed in a 200-cc. three-necked flask provided with a stirrer, condenser and delivery tube for admitting hydrogen. A small U-tube containing sulfuric acid was attached to the end of the condenser to prevent the entry of moisture and to serve as an indicator for the pressure of hydrogen. The mixture was gently refluxed (bath temp., 125°) with vigorous stirring, and a stream of dry hydrogen was bubbled through at a rate to maintain a slight positive pressure. Hydrogen chloride was evolved immediately, and reduction was continued until no further hydrogen chloride was evolved. The cooled mixture was filtered, and after removing the solvent there remained 3.5 g. of a pale yellow solid melting at 91–92°. After crystallization from methyl alcohol the ester aldehyde melted at 93.5°. The yield was 99%, and the compound gave positive Schiff and aniline acetate tests. The phenylhydrazone of 4-carbomethoxy-2-furaldehyde is a tan crystalline compound melting at 114–115°.

Anal. Calcd. for $C_7H_6O_4$: C, 54.54; H, 3.89. Found: C, 54.68; H, 3.62.

4-Carboxy-2-furaldehyde, $C_4H_2O(COOH)(CHO)$.—Hydrolysis of the ester aldehyde, by refluxing 3.5 g. with 50 cc. of 6 N hydrochloric acid for fifteen minutes, gave a 94% yield of the acid aldehyde which, after crystallization from hot water, melted at 158–159°. This compound also gave the above-mentioned aldehyde tests; neutralization equivalent, calcd., 140; found, 143.1.

4-Carboxy-2-furaldehyde Hydrazone, $C_4H_2O(COOH)(CH{=}NNH_2)$.—A 90% yield of the hydrazone, melting at 145–146°, was obtained from 2.9 g. of the acid aldehyde and 2.1 g. of hydrazine hydrate in 10 cc. of absolute ethyl alcohol. The mixture, kept initially at about −15° for one and one-half hours, was warmed for a few minutes at about 75° and then worked up in a customary manner.

5-Methyl-3-furoic Acid, $C_4H_2O(COOH)(CH_3)$.—The hydrazone was converted by the usual Wolff–Kischner method to the methylfuroic acid by means of potassium hydroxide (pellets) and absolute ethyl alcohol. A slight evolution of gas was noticed during a two-hour period of heating at about 70°, and after standing overnight at room temperature, heating was continued for four hours, at the end of which time gas evolution had practically ceased. The yield of 5-methyl-3-furoic acid was 31%, and the compound melts at 119° after crystallization from hot water; neutralization equivalent, calcd., 126; found, 130.

Anal. Calcd. for $C_6H_6O_3$: C, 57.14; H, 4.76. Found: C, 56.91; H, 5.32.

Decarboxylation to 2-Methylfuran, $C_4H_3OCH_3$.—Decarboxylation of 0.9 g. of 5-methyl-3-furoic acid by the method of Johnson using quinoline and copper–bronze was effected at 215'. The evolution of carbon dioxide commenced at about 200°, and the

(8) Rosenmund and Zetzsche, *Ber.*, 51, 578 (1918).

reaction product when worked up in a customary manner gave about 0.5 cc. of a clear. pleasant smelling liquid. This was definitely identified as 2-methylfuran by converting it to 5-methyl-2-chloromercurifuran by means of mercuric chloride and sodium acetate. A mixed melting point determination with an authentic specimen melting at 132° showed no depression.

Summary

The first complete series of di-substituted furans, particularly useful as reference or standard compounds in studies on orientation of nuclear substituents of furan, has been made available by the synthesis of 5-methyl-3-furoic acid.

Aliphatic Tertiary Alcohols and Chlorides Containing the Normal Amyl Group and the Related Olefins and their Ozonolysis

BY FRANK C. WHITMORE AND F. E. WILLIAMS[1]

The primary purpose of this research was to supply intermediates for the preparation of certain complex pinacolyl alcohols for use in rearrangement studies.[2] The series of tertiary alcohols chosen contained combinations of the five normal alkyls up to amyl with each alcohol containing at least one amyl group. The n-amyl group was chosen because of the present availability of that alcohol in large quantity.[3] Twelve of the fifteen possible alcohols of this type have been prepared in this study. Of these only four have been prepared elsewhere. These are dimethylamylcarbinol,[5] methylethylamylcarbinol,[3] diethylamylcarbinol[3,4] and triamylcarbinol.[6] The triamylcarbinol was kindly supplied by Dr. Marvel. The twelve carbinols were prepared by means of the Grignard reagent in yields of 40–75%. The chief difficulty was in the distillation of the carbinols. All traces of acid had to be removed before distillation and a suitably low pressure was necessary.

---

[1] Presented in partial fulfilment of the requirements for the Ph.D. degree at the Pennsylvania State College. This study was finished in August 1930.

The alcohols were all colorless sirupy liquids. The higher ones were entirely odorless. Dimethylamyl and methylethylamyl carbinols had pronounced camphor odors and methylpropylamylcarbinol had a slight odor of similar nature. As the number of simple aliphatic tertiary alcohols is increased[2b] regularities in physical properties are appearing. These will be discussed in a later paper.

The chlorides were prepared by hydrogen chloride in the usual way.[2b] The higher members could not be distilled without decomposition even at pressures below 1 mm. These were successfully purified by shaking with cold concentrated sulfuric acid,

The only one of the alcohols which had been previously converted to an olefin is dimethylamylcarbinol,[7] whose chloride was distilled with solid potassium hydroxide to give 2-methylhexene-2. Of the eleven other carbinols, ten were successfully dehydrated by Hibbert's iodine method. The triamylcarbinol carbonized so badly that its study was abandoned. The alcohols fell in two groups according to their ease of dehydration, (1) those easily dehydrated, methylethylamyl, methylbutylamyl, diethylamyl, ethyldiamyl, and butyldiamyl carbinols, and (2) those which required longer heating, methylpropylamyl, methyldiamyl, propyldiamyl and dipropylamyl carbinols. The fact that the second group contains only alkyls with odd numbers of carbon atoms may or may not be fortuitous. Ozonolysis of the olefins gave ketones which could be isolated and identified but great difficulty was experienced with the aldehyde products? The carbinols, $R(CH_3)(C_5H_{11})COH$, formed olefins which gave as their chief ozonolysis product methyl amyl ketone, indicating that the dehydration involved mainly the ethyl, propyl or butyl group rather than the methyl or amyl group. The olefin from diethylamylcarbinol gave ethyl amyl ketone. Similarly propyl amyl ketone was obtained from dipropylamylcarbinol. Ethyldiamylcarbinol gave ethyl amyl ketone. No products were identified from dibutylamyl, propyldiamyl or butyldiamyl carbinol. Thus the chief dehydration products identified are as follows: methylethylamylcarbinol, 3-methyloctene-2; methylpropylamylcarbinol, 4-methylnonene-3; methylbutylamylcarbinol, 5-methyldecene-4; methyldiamylcarbinol, 6-methylundecene-5; dipropylamylcarbinol, 4-propylnonene-3; ethyldiamylcarbinol, 6-ethylundecene-5.

Experimental

The bromides used in the syntheses of the tertiary alcohols were prepared by the methods of Kamm and Marvel[9] with the following properties and yields: n-propyl bromide, b. p. 70–70.3° (740), 70%; n-butyl bromide (stirring and refluxing for eight

[8] This problem has been studied intensively and successfully by J. M. Church in this Laboratory since 1930 and will be reported on shortly

[9] **Kamm** and Marvel, "Organic Syntheses," Vol. I, 1921, p. 5.

hours), b. p. 99–101° (730), 75%; *n*-amyl bromide (from Sharples *n*-amyl alcohol, b. p. 135–136.5° (748)), b. p. 127–128° (736 mm.), 50%. Ethyl caproate was prepared in 53% yield from the acid and alcohol and dry hydrogen chloride, b. p. 163–164° (733). Methyl *n*-amyl ketone (b. p. 148–151° (738), yield 67%) was prepared from ethyl *n*-butylacetoacetate[10] supplied by the Mallinckrodt Chemical Works.

The Grignard reagents were prepared in the usual way.'' The reactions with the carbonyl compounds involved no unusual features except that the reaction product was decomposed by pouring on ice and only a slight excess of dilute sulfuric acid. The last traces of acid were removed from the ether extracts by standing with solid anhydrous sodium carbonate. The alcohols were distilled at 15 mm. or below using a barostat to control the pressure. Heat for the distillations was supplied by an oil-bath. The study of the carbinols is summarized in Table I.

[a] Barostat set at 15 mm. [b] Pressures of 2.0 mm. and lower were measured with a McLeod gage; *cf.* Gross and White, Ind. Eng. *Chem.*, 13, 702 (1921). [c] This low value is unexplained. [d] For methods used see Reference 2b.

The tertiary chlorides were prepared from the carbinols and hydrogen chloride gas.[2b] All the alcohols darkened in the process but this was especially noticeable with diethylamyl- and methylpropylamylcarbinol. This phenomenon has not been explained. Most of the chlorides were distilled at pressures of about 1 mm. (McLeod gage). In several cases this was impossible because of decomposition even at these pressures. Such chlorides were treated as follows. The dissolved hydrogen chloride was removed at room temperature and low pressure. The crude chloride was then washed with one-half volume of concentrated C. P. sulfuric acid. After separating the acid, the cloudy chloride layer was centrifuged until clear. The chloride layer was removed and allowed to stand at 0° for twelve hours with anhydrous sodium sulfate

and carbonate. Filtration gave a clear colorless odorless liquid. The analyses of chlorides purified in this way indicated a higher purity than that obtained in the other chlorides which were distilled. The crude chlorides are stable at 0° but at room temperature slowly decompose with the evolution of hydrogen chloride and with darkening. The purified chlorides underwent little or no change in two years. The chlorides are summarized in Table II.

[a] Bouveault and Locquin, Bull. *soc. chim.*, [3] **31**, 1158 (1904), give 117–117.5° as the m. p. of the semicarbazone of ethyl n-amyl ketone.

[b] They give 73–74' for the corresponding derivative of n-propyl n-amyl ketone.

[c] The semicarbazone obtained did not correspond to any known substance.

[d] Each fraction gave mixtures of semicarbazones which could not be separated by repeated crystallizations.

[e] The first two fractions gave impure semicarbazones.

The ozonization of the olefins was performed in 29–35° ligroin at –15° with ozonized oxygen.[13] The ozonides, freed from solvent, were surprisingly stable even to boiling water. They were finally decomposed by boiling water and zinc dust.[14] All attempts to identify aldehyde or acid products failed. The ketones could be identified, however, as their semicarbazones. These were confirmed by mixed melting point determinations with known materials. The ozonolysis results are summarized in Table IV.

Summary

1. A series of twelve aliphatic tertiary alcohols of the general types, $R(CH_3)(n\text{-}C_5H_{11})COH$, $R_2(n\text{-}C_5H_{11})COH$ and $R(n\text{-}C_5H_{11})_2COH$, in which R is methyl, ethyl, n-propyl, n-butyl and n-amyl, has been synthesized and studied.
2. The tertiary chlorides have been made from the alcohols.
3. The alcohols have been dehydrated.

[14] Cf. Noller and Adams, *ibid.*, 48, 1077 (1926).

4. Six of the resulting olefins have been identified by their ozonolysis products. These are 3-methyloctene-2, 5-methyldecene-4, 6-methyl undecene-5, 3-ethyloctene-2, 4-propylnonene-3 and 6-ethylundecene-5. In addition a mixture of 4-methylnonene-3 and -4 was identified.

5. Alcohols of the type, $R(CH_3)(n\text{-}C_5H_{11})COH$, were dehydrated chiefly through the R group.

Solubility Relationships among Optically Isomeric Salts. III. The Mandelates and Alpha-Bromocarnphor-Pi-Sulfonates of Alpha-Phenylethylamine and Alpha-Para-Tolylethylamine

BY A. W. INGERSOLL, S. H. BABCOCK AND FRANK B. BURNS

The following five types of optically isomeric salts represent all the possible combinations of active and inactive acid and base ions.

(*d*B*d*A or *l*B*l*A); (*d*B*l*A or *l*B*d*A); *dl*B*dl*A; (*d*B*dl*A or *l*B*dl*A); (*dl*B*d*A or *dl*B*l*A)

The stabilities and relative solubilities of these types of salts determine which of them can exist in solution, and the order in which the stable salts can be separated from a mixture by fractional crystallization. It has been shown in previous papers[1] that these factors are of primary importance for a method of complete optical resolution in which mixtures containing several varieties of isomeric salts may be encountered. It was shown that not more than three of the nine varieties of salts represented above can result from the evaporation of a solution, no matter what proportions of active and inactive acid and base ions may have been introduced originally. Nevertheless, it was pointed out that there are some twenty[2] different orders in which these coexistent salts may separate during fractional crystallization. At present it seems impossible to predict the stabilities and relative solubilities of the salts of a particular acid and base. Hence numerous groups of isomeric salts are being studied for the purpose of gaining a comprehensive knowledge of these factors. Five such groups of salts have already been described and classified. This paper describes a similar study of the four additional groups of salts named in the title.

The salts previously described illustrated two instances each of Cases 4[1a] and 7[1b,1d] and one of Case 8.[1c] The salts described in this paper were found to illustrate the previously unobserved cases (1) and (6), another instance of Case 8, and an instance of either Case 4 or 7, depending on the

(2) Only eight orders (Cases 1–8) are possible in the mixtures resulting from the usual procedure for complete resolution. All of the cases were described and numbered in Part I.[1c]

procedure. Thus the mandelates of a-phenylethylamine were found to include four stable types of salts in the solubility order

(*d*B*l*A or *l*B*d*A) < (*dl*B*d*A or *dl*B*l*A) < *dl*B*dl*A < (*d*B*d*A or *ZBZA)*

When the partially active base (*dl*B + *l*B) was combined with the dl-acid the system *l*B*d*A<*dl*B*dl*A<*l*B*l*A (Case 4) resulted; when partially active acid (*dl*A + *d*A) was combined with the dl-base the system *dl*B*d*A<*dl*B*dl*A (Case 7) resulted. Both procedures permitted the purification of active acid and active base. Cases 4 and 7 have been observed previously, but the order of solubility for the four salts is new. It may be noted that the modified procedure for complete resolution would place the resulting salts in the favorable cases (10) or (15) depending on the proportions of active and inactive acid and base.

The mandelates of the closely related base, a-p-tolylethylamine, were then studied and the order of solubility was found to be

*dl*B*dl*A < (*d*B*l*A or *l*B*d*A) < (*d*B*d*A or *l*B*l*A)

Thus, while the acid and base were reciprocally resolvable, only the inactive forms could be obtained pure from partially active specimens by either the usual or the modified procedure. This is the first example of an authentic Case 6. Perkin and Robinson[3] found a similar order of solubility in ethyl acetate for the corresponding a-bromocamphor-a-sulfonates of narcotine, but did not examine the (*d*B*dl*A or *l*B*dl*A) type of salt. Hence their salts cannot be definitely classified as Case 6.

The a-bromocamphor-a-sulfonates of a-phenylethylamine were found to exhibit the solubility order

*dl*B*dl*A < (*d*B*dl*A or *l*B*dl*A) < (*d*B*l*A or *l*B*d*A) < (*d*B*d*A or *l*B*l*A)

Thus the dl-base can be resolved by the active forms of the acid,[4] but the dl-acid was found to form stable partially racemic salts with the active forms of the base. The order of solubility corresponded to Case 8 in the usual procedure and would have given cases (19) or (20) in the modified procedure. All of these cases are unfavorable for the purification of salts containing active ions. A similar solubility order for four salts has not previously been encountered.

It was shown in a recent paper[5] that dl-a-bromocamphor-a-sulfonic acid was resolved by the active forms of a-p-tolylethylamine. It has now been found that the dl-base can also be resolved, though not so readily, by the active forms of the acid. The stable salts were in the solubility order

(*d*B*d*A or *l*B*l*A) < (*d*B*l*A *or* *l*B*d*A) < *dl*B*dl*A

This is the first observed instance of Case 1.

The above results show that even two bases as closely related as α-phenylethylamine and α-*p*-tolylethylamine form entirely different systems

(5) Ingersoll and Babcock, THIS JOURNAL, 55, 341 (1933).

of salts with mandelic acid, and that these systems are again quite different from those formed from the same bases and α-bromocamphor-π-sulfonic acid. Hence it would not be safe to predict that the isomeric salts of structurally similar bases or acids should be similar in their stabilities and relative solubilities. It may be noted also that the order of solubility among all of the stable salts in each group has been found to be different in eight of the nine groups thus far described. In six of these the solubilities were favorable for the application of the method for complete resolution in its usual form. More groups of salts must be studied before the relative frequency of occurrence of the various cases can be estimated, though thus far Cases 4 and 7 have appeared rather often.

Experimental

α-Phenylethylamine Mandelates.—The resolution of dl-mandelic acid with d- and l-a-phenylethylamine has been briefly described by L. Smith.[6] The intermediate salts were not described. Since this method appears to be more satisfactory than any other given in the literature, it is briefly described here. dl-Mandelic acid (38 g.) was combined with 30 g. of d-a-phenylethylamine in 350 cc. of hot water and the solution cooled. The first fraction, when recrystallized three times from about four parts of water, was practically pure *d*B*l*A salt. By systematically working the mother liquors 29.5 g. (86%) of this salt was obtained. For analysis the salt was recrystallized from 95% ethanol.

d-α-**Phenylethylamine**-*l*-**mandelate** formed elongated hexagonal plates or flattened prisms, m. p. 177° (corr.), and was anhydrous. The solubility was 4.91 g. per 100 g. of water at 30°.

Rotation. Subs. 1.7486 g. made up to 50 cc. in water gave α^{25}_{D} $-4.23°$ in 2 dm.; $[\alpha]^{25}_{\mathrm{D}}$ $-60.4°$, $[\mathrm{M}]_{\mathrm{D}}$ $-165°$ $(10)^2$.

A sample of the salt was decomposed with a small excess of concentrated hydrochloric acid and the mandelic acid extracted with ether. After one crystallization from water with decolorizing carbon it melted at 133° and had $[\alpha]^{25}_{\mathrm{D}}$ -154.8 (5% in water) in close agreement with published values. The active base was recovered by making the hydrochloric acid solution alkaline and distilling with steam. The distillate thus obtained was used directly in the next run.

d-α-**Phenylethylamine**-*d*-**mandelate.**—The mother liquors from the separation of the *d*B*l*A salt became sirupy and discolored on concentration and slowly set to a mass from which the *d*B*d*A salt could not be obtained pure. This salt was therefore prepared from its pure components, but remained somewhat sticky and discolored slightly on drying. The solubility was about 18 g. per 100 g. of water at 30° and the molecular rotation was about $+180°$ $(10)^2$. These values are slightly inaccurate but the salt is certainly the most soluble one of the group.

dl-α-**Phenylethylamine**-*d*-**mandelate.**—The partially resolved mandelic acid (*dl*A + *d*A) was recovered from the mother liquors of the resolution and crystallized once from the least possible amount of water. The crystalline fraction (principally *d*-mandelic acid) was reserved and the mother liquor, which then contained about 17 g. of mandelic acid, [a], +48.5, was neutralized with *dl*-α-phenylethylamine. The resulting salts formed the system *dl*B*d*A < *dl*B*dl*A and the partially racemic salt (5.2 g.) was obtained by systematic crystallization from water. After crystallization from 95% ethanol and again from water it formed large, transparent plates, m. p. 176° (corr.), and was anhydrous. The solubility was 5.81 g. per 100 g. of water at 30°.

---

[6] Smith, *J. prakt. Chem.*, [2] **84**, 743 (1911).

Rotation. Subs., 1.3904 g. made up 50 cc. in water gave α^{25}_{D} +3.53 in 2 dm.; $[\alpha]^{25}_{D}$ +63.5°, $[M]_D$ +174° (10)^2.

The mandelic acid was recovered from this salt with ether as described for the *d*B*l*A salt, washed with a little water and dried. It then melted at 131° and had $[\alpha]^{25}_{D}$ +152.5° (3% in water). The recovered base was inactive.

dl-a-Phenylethylamine-dl-mandelate.—The mother liquors from the separation of the *dl*B*d*A salt deposited a mass of small crystals consisting largely of the *dl*B*dl*A salt. A sample melted at 133" and was faintly dextrorotatory. The pure salt was therefore made from its components. It formed small plates, m. p. 138° (corr.), and was anhydrous. The solubility was 12.29 g. per 100 g. of water at 30°.

2-a-Phenylethylamine-d-mandelate.—In a separate experiment 30 g. of the partially active amine (*dl*B 80% + *l*B 20%) was combined with 38 g. of dl-mandelic acid and the salts fractionated. The system *l*B*d*A < *dl*B*dl*A < *l*B*l*A resulted. After prolonged fractionation 3.2 g. of pure *l*B*d*A salt (calcd. 6.8 g.) was obtained. This had $[\alpha]^{25}_{D}$ +58.9° and otherwise closely resembled the *d*B*l*A salt described above. The intermediate fractions were faintly dextrorotatory and the final mother liquors strongly levorotatory.

α-*p*-Tolylethylamine Mandelates.—The base used in the following experiments was prepared and resolved by a recently described modification[1d] of the method of Stenberg.[7]

dl-a-p-Tolylethylamine-dl-mandelate.—A quantity (13.5 g.) of partially active base (*dl*B + dB, [a], +19°) was combined with dl-mandelic acid (15.2 g.) in 100 cc. of hot water and the salts fractionally crystallized. After six recrystallizations the head fraction, which at first was levorotatory, became inactive. The salt (8.2 g.) formed transparent prisms or rhomboidal plates, m. p. 136° (corr.), and was anhydrous. It was identical with the salt prepared from equivalent amounts of the dl-base and dl-acid. The solubility was 4.89 g. per 100 g. of water at 25°.

d-α-*p*-Tolylethylamine-*l*-mandelate.—The intermediate fractions from the crystallization described above contained a salt only slightly more soluble than the *dl*B*dl*A salt. From the maximum rotation observed (−41°) this appeared to be the impure *d*B*l*A salt. In a separate experiment this salt was prepared from the pure components. It formed slender prisms, m. p. 146° (corr.) and was anhydrous. The solubility was 5.18 g. per 100 g. of water at 25°.

Rotation. Subs., 1.3963 g. made up to 25 cc. in water gave $[\alpha]^{25}_{D}$ −6.42° in 2 dm.; $[\alpha]^{25}_{D}$ −57.5°, $[M]_D$ −165° (10)^2.

d-α-*p*-Tolylethylamine-*d*-mandelate.—The foot fractions from the crystallization described above yielded crops of dextrorotatory needles (maximum rotation +24°) but the *d*B*d*A salt could not be obtained pure from the mixture. It was therefore prepared from its components. It formed small needles, m. p. 140" (corr.), and was anhydrous. The solubility was 7.12 g. per 100 g. of water at 25°.

Rotation. Subs., 1.2345 g. made up to 25 cc. in water gave $[\alpha]^{25}_{D}$ +6.45° in 2 dm.; $[\alpha]^{25}_{D}$ +65.3°, $[M]_D$ +188°(10)^2.

l-x-*p*-Tolylethylamine-*l*-mandelate.—This salt was made from the pure components. It melted at 140" (corr.), had $[\alpha]^{25}_{D}$ −65.0°, and was otherwise closely similar to the *d*B*d*A salt.

Instability of *dl*B*d*A or *dl*B*l*A Type.—A small-scale experiment was made to determine whether the dl-base could be resolved with I-acid. The salt formed from these was fractionated and finally gave three successive fractions having rotations —61.3, —62.3 and −64.8°, respectively. The base liberated from the head fraction was dextrorotatory, that from the foot fraction levorotatory. The resolution therefore occurred, but appeared too tedious for practical use and was not further studied.

---

(7) Stenberg, *Z. physik. Chem.*, **70**, 534 (1910).

α-Phenylethylamine-α-bromocamphor-π-sulfonates.—The pure *l*B*d*A salt and the impure *d*B*d*A salt of this series have been prepared by Hunter and Ripping[4] by the partial resolution of the dl-base with the d-acid. This work was repeated. The dl-a-bromocamphor-r-sulfonic acid required for the study of the other types of salts has been described in a recent paper.[5]

l-α-Phenylethylamine-d-α-bromocamphor-π-sulfonate.—This salt formed large, transparent prisms, m. p. 205° (corr.), and is anhydrous. These properties and the rotation, $[\alpha]^{25}_{D}$ +62.6°, $[M]_D$ +270°(10)^2, agreed with the data of Hunter and Kipping. The solubility was found to be 5.40 g. per 100 g. of water at 25°.

d-α-Phenylethylamine-d-α-bromocamphor-π-sulfonate.—This salt was not obtained completely pure during the resolution referred to above. Also an attempt to prepare it from its components gave a dense mass of needles that could not be entirely freed from the sirupy mother liquor. The salt after drying at 100" melted at 183–186° and had $[\alpha]^{25}_{D}$ +63.3°. It was by far the most soluble type of salt in the group.

dl-α-Phenylethylamine-dl-α-bromocamphor-π-sulfonate.—This salt was prepared from the ammonium salt of the dl-acid and an acetic acid solution of the dl-base. It separated from water as coarse needles which melted at 155° (corr.) after drying at 110°. It was probably the monohydrate, but a sample kept for several weeks became anhydrous. The solubility of the hydrated salt was 2.05 g. per 100 g. of water at *25".*

Anal. Calcd. for $C_{18}H_{26}O_4NSBr\cdot H_2O$: H_2O, 4.00. Found: H_2O, 3.47 (air-dry salt).

d-α-Phenylethylamine-dl-α-bromocamphor-π-sulfonate.—This salt was formed in an attempt to resolve the dl-acid with d-base. The resulting salt was crystallized from water, 95% ethanol, moist ethyl acetate, and chloroform under various conditions but was not thereby resolved. It formed massive prisms from water or ethanol and was probably the monohydrate. The solubility of this was 3.11 g. per 100 g. of water at 25". The anhydrous salt melted at 170° (corr.).

Anal. Calcd. for monohydrate: H_2O, 4.00. Found: H_2O, 3.64.

Rotation. Subs., 1.4505 g. (anhydrous) made up to 50 cc. in water gave $[\alpha]^{25}_{D}$ +0.07° in *2* dm.; $[\alpha]^{25}_{D}$ +1.20, $[M]_D$ +5.2°(10)^2.

a-p-Tolylethylamine-a-bromocmphor-r-soate — The resolution of the *dl*-acid with the I-base and the pure *l*B*l*A and lBdA salts were described in a recent paper.[5] For convenience in comparison these salts are briefly described here.

*l*B*l*A·H_2O formed coarse prisms, $[\alpha]^{25}_{D}$ −62.7°, $[M]_D$ −291°(10)^2. Solubility 2.10 g. Anhydrous salt m. p. 165° (corr.).

*l*B*d*A·H_2O formed needles; after drying these had $[\alpha]^{25}_{D}$ +59.4°, $[M]_D$ +265°(10)^2. Solubility (hydrated salt) 2.96 g. Anhydrous salt m. p. 232° (corr.).

Resolution of dl-Base **with** d-Acid.—The base (67.5 g.) in dilute acetic acid was combined with ammonium *d*-α-bromocamphor-π-sulfonate (130 g.) in 1 liter of hot water and the salts fractionated. Although the salts (*d*B*d*A and *l*B*d*A) are the same *types* as those described above, they could not be separated with equal ease. Apparently the partially racemic salt, which in this case would be ***dl*B*d*A**, was considerably more stable than the *l*B*dl*A type from which the salts *l*B*l*A and lBdA were formed. Fractionation was conducted, as previously described, by allowing the first fraction to separate from about seven parts of water at 80 to 50° and the remaining material from 50° to room temperature. Similar fractions were then combined and recrystallized similarly. In this way an apparently homogeneous head fraction (80 g.) and a fraction consisting of the pure lBdA salt (52 g.) were obtained. The lBdA salt was practically identical in properties with the salt described above, but the head fraction melted at 162°, had $[\alpha]^{25}_{D}$ \$63.4" and solubility 2.67 g. at 25°. The base obtained from it had $[\alpha]^{25}_{D}$ +28.2° instead of the value +34 6° previously obtained. When the salt was recrystallized repeatedly at 80 to 55° there was finally obtained 54 g. of pure *d*B*d*A salt. The intermediate crops were not further fractionated since this base can be much more easily resolved by means of d-camphoric acid.[1d]

d-α-*p*-**Tolylethylamine**-*d*-α-**bromocamphor**-π-**sulfonate.**—This salt crystallized as monohydrate in transparent prisms; solubility 2.12 g. per 100 g. of water at 25°; m. p. (anhydrous) 165° (corr.).

Anal. Calcd. for $C_{19}H_{28}O_4NSBr \cdot H_2O$; H_2O, 3.87. Found: H_2O, 3.89.

Rotation. Subs., 0.9280 g. (hydrated) made up to 50 cc. in water gave $[\alpha]^{25}_D$ +2.32° in 2 dm.; $[\alpha]^{25}_D$ +62.5°, $[M]_D$ +290°(10)².

dl-α-*p*-**Tolylethylamine**-*dl*-α-**bromocamphor**-π-**sulfonate.**—This salt was prepared from the inactive components. It first separated as an oil, which solidified. It crystallized from water in anhydrous needles, m. p. 161° (corr.). The solubility was 3.38 g. per 100 g. of water at 25°.

Summary

1. The resolution of dl-mandelic acid by an improvement of the method of Smith[R] has been described.

2. All of the stable isomeric mandelates and α-bromocamphor-π-sulfonates of a-phenylethylamine and a-p-tolylethylamine have been described and classified according to their stabilities and relative solubilities.

3. The significance of these factors for the separation of mixtures of optically isomeric salts has been discussed.

The Acetoacetic Ester Condensation. IV. The Reaction Product of Certain Aliphatic Esters and Sodium Ethoxide

BY JOHN M. SNELL AND S. M. MCELVAIN

During the course of a study of the reaction of metallic sodium on various aliphatic esters[1] a product, which from its boiling point and method of isolation was thought at first to be ketene acetal,[2] was obtained in a small yield from the reaction of sodium and ethyl acetate in absolute ether. Further investigation of this product, however, showed it to be merely a mixture of alcohol and xylene. The latter compound had been used to powder the sodium for the reaction and, presumably, had not been completely removed from the metal by ether washing, for in subsequent experiments when the powdered sodium, after decantation of the xylene, was washed more thoroughly with ether no product was obtained at the point

(2) (a) Scheibler and Zeigner, *Ber* , 55, 801 (1922): (b) Scheibler and Marhenkel, Ann., 468, 15 (1927).

where ketene acetal should appear. It was decided then to attempt the preparation of a ketene acetal by the improved method described by Scheibler, Marhenkel and Nikolic.[3] Several attempts, in which the directions of these authors were followed in every detail, to duplicate this preparation were unsuccessful.

In the view of these failures to obtain ketene acetal it seemed advisable to examine Scheibler's so-called "primary reaction product," *i. e.*, the residue left after evaporation of the ester and ether from the sodium ethoxide. This was done using ethyl acetate and ethyl isobutyrate as representative esters.

Experimental Part

Materials Used.—The sodium ethoxide was prepared as recommended by Scheibler, Marhenkel and Nikolic[3] by treating powdered sodium under ether with the theoretical amount of absolute alcohol. The product obtained was white and granular and contained 33.75% Na; calcd. for C_2H_5ONa, 33.80. The ether and esters were purified by washing with water, drying over calcium chloride (in the case of ether) or potassium carbonate (in the cases of the esters). Each of these materials was then allowed to stand over phosphorus pentoxide for twenty-four hours and then distilled directly from this reagent.

An Attempted Preparation of Ketene Acetal.—The following procedure describes in detail a representative attempt to prepare ketene acetal from ethyl acetate and sodium ethoxide according to the procedure described in the literature.[3] Twenty-three grams (1 atom) of sodium was finely powdered in a 1-liter round-bottomed flask by shaking under heated xylene. After cooling and decantation of the xylene the powdered metal was washed thoroughly with four or five portions of absolute ether, and then covered with 500 cc. of fresh ether. A reflux condenser was fitted to the flask and 50 g. (1.1 mole) of absolute alcohol was slowly run in from a dropping funnel at the top of the condenser. The reactants were protected by calcium chloride tubes from atmospheric moisture. After all the alcohol had been added the mixture was allowed to stand for fifteen hours or longer. Then 200 g. (2.2 moles) of ethyl acetate was added. At this point cooling the flask, as recommended by the original investigators,[3] was unnecessary as no perceptible heat was generated. The mixture was allowed to stand with occasional shaking for twenty-four hours, and then was poured into a shallow dish and placed in an empty vacuum desiccator. The volatile substances were removed by evacuation with a water pump, a calcium chloride tower being interposed to prevent backward diffusion of water vapor. The dry residue (which generally weighed 90–100 g. as compared to 125 g., the weight of reaction product obtained by the original investigators[3]) was scraped from the walls of the dish and the desiccator, pulverized in a porcelain mortar, and triturated with 125 g. of ice water. The resulting solution was extracted with ether in a continuous extraction apparatus[4] for twelve hours, the solvent vapors passing through a 25-cm. spiral Widmer column on the return path to the extraction vessel The ether solution was shaken intermittently for three or four hours with three successive portions of powdered calcium chloride and then washed with a small volume of a saturated solution of calcium chloride. After standing overnight with anhydrous sodium sulfate the ethereal extract was distilled through the Widmer fractionating column mentioned above. It all passed over at 34–35°. Ketene acetal was reported[3] as boiling at 77–78".

Preparation of the "Primary Reaction Product" from Ethyl Acetate.—Seventeen

---

(3) Scheibler, Marhenkel and Nikolic, *Ann.*, **458**, 28 (1927).

(4) "Organic Syntheses," 1923, Vol. III, p. 88.

grams (0.25 mole) of sodium ethoxide (33.75% Na), under 200–225 cc. of dry ether was treated with 55 g. (0.625 mole) of ethyl acetate and the mixture allowed to stand in a stoppered flask under nitrogen for a period of two to three days with occasional shaking. The ether and ester were then evaporated off under reduced pressure and the residue allowed to stand in a vacuum desiccator over sulfuric acid until it attained a constant weight.

Method of Examination.—The sodium content of the reaction product was determined in the following manner. A sample of approximately 0.25 g. was accurately weighed into a tared porcelain crucible and treated with 0.2 cc. of concentrated sulfuric acid added from a graduated 1-cc. pipet. The crucible was heated gently until most of the volatile matter was expelled and then ignited for thirty minutes in the full flame of a Bunsen burner. The residue was weighed as Na_2SO_4.[5]

In the case of ethyl acetate the only other constituent of the reaction product determined was the sodium derivative of acetoacetic ester. This was estimated by adding about 1 g. of the reaction product to 10 g. of ice, acidifying the resulting solution with acetic acid and extracting with ether. The ether extract was washed until neutral with sodium bicarbonate solution and then made up to 100 cc. with 95% alcohol. A 10-cc. aliquot was treated with 4 drops of a 10% ferric chloride solution and the color compared in a Duboscq colorimeter with that produced by a standard solution of acetoacetic ester in 95% alcohol. This method is accurate to 2–3% if the following precautions are observed, (a) the solutions being compared should be of about the same concentration, (b) the same amount of ferric chloride should be added to equal volumes of the two solutions, (c) the comparisons should be made as soon as possible after the addition of the ferric chloride. A rather imperfect check on this method of estimation was the determination of the amount of 1-*p*-nitrophenyl-3-methyl-5-pyrazolone[6] obtained from an aliquot of the acetoacetic ester solution by the action of *p*-nitrophenylhydrazine. This value was about 70% of that obtained by the colorimetric estimation.

Preparation of the Primary Reaction Product from Ethyl Isobutyrate.—To 6.8 g. (0.1 mole) of sodium ethoxide under 90 cc. of ether was added 29 g. (0.25 mole) of ethyl isobutyrate, and the procedure described above for ethyl acetate followed. In the case of ethyl isobutyrate, however, it was necessary to heat the residue from the evaporation of the ether and ester to a temperature of 100° on a steam-bath for one hour under diminished pressure in order that the excess ester might be completely removed and the residue attain constant weight.

A reaction product was also prepared from ethyl isobutyrate by heating 6.8 g. of sodium ethoxide with 29 g. of the ester alone on a steam-bath for twenty-four to forty-eight hours. The ester was removed by distillation and the residue heated for three hours at 100–150° under diminished pressure. During the distillation of the ester and the heating of the residue the side arm of the receiving flask was connected to a coil condenser cooled in a mixture of ether and solid carbon dioxide. About 1 g. of a mixture of alcohol and ethyl isobutyrate was condensed in this trap.

In addition to the determination of the sodium content of the reaction product, the amount of sodium isobutyrate present was estimated by treating a 5–7 g. sample of the dry reaction product with 50 cc. of water, acidifying with phosphoric acid and distilling the isobutyric acid. This distillate was then titrated with standard alkali. The identity of the isobutyric acid was established by converting it into the *p*-phenylphenacyl ester by the method of Drake and Bronitsky.[7] This ester, which has not been described previously, melts at 88.5°. Calcd. for $C_{18}H_{18}O_3$: C, 76.60; H, 6.38. Found: C, 76.61; H, 6.38.

(7) Drake and Bronitsky, THIS JOURNAL, 52, 3716 (1930).

The results which were obtained from the examination of the various reaction products, prepared as described above, are summarized in the table. The values of sodio-acetoacetic ester in column 5 are calculated from the colorimetric estimation of acetoacetic ester and the percentages of sodium isobutyrate in column 6 are calculated from the amount of isobutyric acid found by titration. The corresponding values for sodium acetate were not determined. Column 7 represents the calculated percentage of sodium which would be present in the reaction product if it consisted only of the product determined (sodio-acetoacetic ester or sodium isobutyrate) and sodium ethoxide.

ANALYSES OF THE REACTION PRODUCTS FROM ETHYL ACETATE AND ISOBUTYRATE WITH SODIUM ETHOXIDE

7[a]	Isobutyrate	None[c]	32.80	...	6.6	32.84

[a] Allowed to react twenty-four hours at 100°. [b] Allowed to react forty-eight hours at 100°. [c] Excess of ester used in these runs.

Discussion of Results

The failure to obtain ketene acetal from the reaction of sodium ethoxide and ethyl acetate in this work must be due to one of the following causes: (a) the present authors do not possess the manipulative skill necessary for the isolation of such a compound, (b) the directions of the original investigators are not sufficiently precise, or (c) the compound in question is not formed in the reaction. Further work along this line by other investigators should show which of these alternatives is responsible for the present disagreement of results. In this connection it should be noted that Arbusow[8] has recently reported his failure to duplicate Scheibler's preparation of carbon monoxide acetal.

It is seen from the data in the above table that in the case of ethyl acetate the values for the sodium content of the reaction product calculated on the assumption that it contains only sodio-acetoacetic ester and sodium ethoxide are only slightly higher than those actually found. This difference is due, in all probability, to small amounts of sodium acetate which were not determined because of the complication introduced by the presence of the acetoacetic ester. With ethyl isobutyrate, however, the absence of the β-keto ester makes possible the accurate determination of

---

(8) Arbusow, *Ber.*, **64**, 698 (1931)

the isobutyric acid in the reaction product. The very close agreement between the calculated values of column 7 and the found values in column 4 definitely shows that these reaction products are simply sodium ethoxide mixed with a small amount of sodium isobutyrate.[9]

These data also confirm the contention made by Adickes[10] in a recent publication that such esters as ethyl acetate and isobutyrate form no stable, isolable compounds with sodium ethoxide. That there is no ester, either combined or adsorbed, in the reaction product from ethyl isobutyrate is shown not only by the above analyses but also by the fact that careful fractionation of the ester which was removed from the reaction product during its preparation gave small amounts of lower boiling fractions consisting of a mixture of ester and alcohol and which contained quantities of alcohol (estimated from the saponification value) approximately equivalent to the sodium isobutyrate present in the reaction product. No product other than alcohol and the ester could be found in these lower boiling fractions.

On the basis of these results it seems safe to conclude that the "primary reaction product" (which contains 11.6% Na when derived from ethyl acetate) postulated by Scheibler and co-workers[11] as an intermediate for both the acetoacetic condensation and ketene acetal formation, does not exist. Earlier evidence has been submitted[12] that the precursor, an ester enolate ($RCH{=}C(ONa)OC_2H_5$), of this intermediate is not formed by the action of sodium ethoxide on such esters. The data for ethyl acetate do not absolutely preclude the presence of a small amount of such an intermediate in the reaction product, but in the case of ethyl isobutyrate the data definitely do indicate the absence of such a compound. Consequently, the claim that ethyl isobutyrate undergoes a reaction with sodium ethoxide to form such a reaction product and that this product is converted by hydrolysis into the corresponding ketene acetal[13] cannot be reconciled with the data presented in the present paper.

Summary

All attempts to prepare a ketene acetal by the directions given by Scheibler and co-workers have been uniformly unsuccessful.

---

[9] The manner in which the sodium salt of the acid was formed is unknown. It may have resulted from traces of moisture present in the ester or entering the reaction mixture during the course of the reaction, although this hardly seems likely in view of the precautions which were taken to exclude moisture. Scheibler [*Ber.*, **65**, 998 (1932)] has reported the formation of sodium benzoate from the reaction of ethyl benzoate and sodium ethoxide, thus $C_6H_5COOC_2H_5 + C_2H_5ONa \longrightarrow C_6H_5COONa + C_2H_5OH + C_2H_4$. It is possible that a similar reaction is responsible for the sodium isobutyrate obtained in the present work. However, for the purpose of the present discussion the origin of this product is immaterial.

[10] Adickes, *Ber.*, **65**, 522 (1932)

[11] Scheibler and Marhenkel, *Ann.*, **458**, 5 (1927).

[12] McElvain, THIS JOURNAL, **61**, 3124 (1929).

[13] Scheibler and Friese, *Ann.*, **445**, 149 (1925); Scheibler and Marhenkel, *Ann.*, **468**, 14 (1927). However, these authors do not describe the properties of this particular ketene acetal.

An examination of the dry, solid residues remaining after the reaction of ethyl acetate and ethyl isobutyrate with sodium ethoxide has been made and from the results obtained the conclusion is drawn that the so-called "primary reaction product" postulated by Scheibler as the intermediate in the acetoacetic ester condensation and ketene acetal formation does not exist.

Aryl *p*-Bromobenzenesulfonates as Derivatives for the Identification of Phenols

BY VLADIMIR C. SEKERA

In connection with the work on the higher alkyl sulfonates[1] one or two aryl esters were prepared. These beautifully crystalline compounds were so readily prepared and so easily purified that further examples were characterized in order to show their value as derivatives for identification of phenols.

The general method of preparation consisted of mixing equimolecular quantities of the phenol and *p*-bromobenzenesulfonyl chloride with about four equivalents of pyridine and stirring the mixture for about three hours at 15° or lower. With small quantities, less time was needed for the reaction. The reaction mixture was decomposed with ice water containing enough dilute hydrochloric acid to combine with the pyridine. The aryl sulfonate was collected on a Buchner funnel and air dried. One recrystal-

Note on the Occurrence of Dehydrodeguelin and Dehydrotoxicarol in Some Samples of Derris Root

BY E. P. CLARK AND GEORGE L. KEENAN

On several occasions during the past two years, specimens of derris root were encountered which yielded no rotenone, but gave instead mixtures of yellow crystals whose melting points ranged from 200 to 225°. After purification by recrystallization from various solvents, these materials gave mixtures of dehydrodeguelin and dehydrotoxicarol. The identity of the substances was proved by the optical immersion method. In two instances, dehydrotoxicarol predominated so that it was possible by fractional crystallization to isolate this substance in an analytically pure condition and identify it by comparison with an authentic sample as to melting point, mixed melting point and optical properties. The materials remaining in the mother liquors were recovered and after recrystallization were shown to consist of mixtures which were impossible to resolve but which when examined by the optical method referred to above were conclusively shown to be essentially dehydrodeguelin and dehydrotoxicarol.

Recently there was obtained from a manufacturer of rotenone an interesting sample of yellow crystals derived from derris root which yielded no rotenone. Upon recrystallization this material yielded a beautiful yellow preparation which melted sharply at 217°. Repeated recrystallizations from various solvents failed to alter the melting point, and it was thought that possibly it was a dehydro derivative of an isomer of deguelin or rotenone. Upon subjecting the material to hydrolysis with alcoholic alkali, an acid corresponding to derrisic acid was readily obtained but it melted at 178° (derrisic acid melts at 158° while deguelic acid melts at 186°). The melting point of this acid did not change after several recrystallizations, which was in harmony with the assumption stated above, especially since analysis of the acid showed its molecular formula to be the same as that of derrisic acid. In the meantime, oxidation of the dehydro derivative (m. p. 217°) with permanganate in acetone and in alkaline aqueous solutions, and also with alkaline hydrogen peroxide, yielded 2-hydroxy-4,5-dimethoxybenzoic, nicouic, risic and derric acids.[1] These facts, especially the isolation of nicouic acid in essentially the same yield as is obtained from dehydrodeguelin, proved that at least the greater part of the original

---

(1) Clark, THIS JOURNAL, 54, 3000 (1932)

preparation was dehydrodeguelin. Repeated recrystallization from toluene of the acid which melted at 178° was then undertaken, and its melting point was finally raised to 186°. It was then shown by its melting point, mixed melting point and optical properties to be deguelic acid.

A careful examination of the original dehydro compound by the optical immersion method then revealed that it consisted of dehydrodeguelin and dehydrotoxicarol. This observation is of interest in that the mixture of the two substances was such that it could not be resolved by repeated recrystallization, and it possessed a sharp melting point. It may be possible that such conditions as here presented were responsible for the recording by the earlier workers upon derris root of various yellow compounds which melted in the range between 200 and 230°.[2,3,4] It is of further interest that dehydrotoxicarol has not hitherto been reported as a natural plant constituent, and it was only recently that Merz[5] reported for the first time the natural occurrence of dehydrodeguelin in the seeds of *Tephrosia vogelii*.

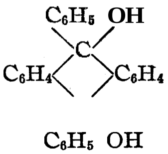
Furan Reactions. V. Derivatives of Furfuryl Alcohol

BY CHARLES D. HURD AND CHARLES L. THOMAS[1]

Furfuryl triphenylmethyl ether, $C_4H_3O\text{-}CH_2\text{-}O\text{-}C(C_6H_5)_3$, was prepared and found to be a convenient derivative for the identification of furfuryl alcohol. Similarly, the furfuryl ether of 9,10-diphenyl-9,10-dihydroanthracenediol was studied.

Nine grams of triphenylchloromethane was added to a cold (0°) mixture of 3.3 g. of furfuryl alcohol and 40 cc. of pyridine. It was left for one and a half days at room temperature. Then it was diluted with 10 cc. of water and the resulting precipitate crystallized from alcohol. The white plates which formed melted at 137–139°; yield, 4 g.

Anal. Subs., 0.1892: CO_2, 0.5837; H_2O, 0.1041. Calcd. for $C_{24}H_{20}O_2$: C, 84.7; H, 5.92. Found: C, 84.2; H, 6.12.



Diphenyldihydroanthroanthracenediol was prepared by the method of Haller and Guyot[2] from phenylmagnesium bromide and anthraquinone. Then 4.4 g. of it was refluxed for one hour with 2.2 g. of furfuryl alcohol and 20 cc. of acetic anhydride.

---

[1] Quaker Oats Fellow, 1929–1930.

[2] Haller and Guyot, *Compt. rend.*, 138, 327 (1904).

On cooling, needle crystals separated which, after recrystallization from alcohol, gave 0.5 g. of light cream-colored needles which melted at 223°. The analytical data were satisfactory for the monofurfuryl ether of the diol.

Anal. Subs, 0.1886: CO_2, 0.5763; H_2O, 0.0928. Calcd. for $C_{31}H_{24}O_3$: C, 83.8; H, 5.41. Found: C, 83.4; H, 5.47.

Note on the Preparation of Trialkyl Phosphates and their Use as Alkylating Agents

BY C. R. NOLLER AND G. R. DUTTON

Alkyl halides, sulfates, sulfites and sulfonates appear to be the best general alkylating agents known but because none of these classes of compounds is entirely satisfactory, it was considered desirable to investigate the use of other esters for this purpose. Preliminary experiments indicated that the alkyl borates, carbonates, nitrites and phosphites would be of no value, but the trialkyl phosphates showed some promise and were further investigated.

None of the various methods for preparing alkyl phosphates reported in the literature[1] proved as convenient as the reaction of phosphorus oxychloride with the alcohol in the presence of pyridine. This method is an adaptation of that used by Milobendski and Sachnovski[2] for the preparation of alkyl phosphites, in which benzene has been used as a solvent instead of ether and in which the pyridine hydrochloride is removed by adding water and removing the water layer instead of filtering off the solid pyridine hydrochloride.

In order to compare the various esters as alkylating agents a standard procedure was developed using one equivalent of alkylating agent per mole of phenol. This method was not devised for producing the maximum yield

of ether but for ease of controlling conditions so that the results would be comparable. This accounts for the fact that the yield of phenetole using ethyl sulfate is not as high as that reported by Cade.[3] The yields of phosphates and phenol ethers are given in Table I.

It should be noted that while the yields of phenol ethers from phosphates are low compared with that from the sulfate, they are based on the amount of alkyl radical available. Many of the higher yields from other esters reported in the literature are based on the substance being alkylated, using a large excess of alkylating agent.

COMMUNICATIONS TO THE EDITOR

PREPARATION OF KETENE DIETHYL ACETAL

Sir:

According to the communication of Snell and McElvain [THIS JOURNAL, 55, **416** (1933)] these authors were unable to duplicate the preparation of ketene diethyl acetal described by me [Scheibler, Marhenkel and Nikolic, Ann., **458, 28** (1927)]. This preparation, however, has often been accomplished in my laboratory by several young chemists. The above failure may have been due to two causes. (1) The residue obtained from sodium ethoxide and ethyl acetate after removal of the volatile substances, containing the so-called "primary reaction product of the acetoacetic ester synthesis," may have lost alcohol during the treatment and been transformed into the sodium derivative of acetoacetic ester which, treated with water, of course did not give ketene acetal [Scheibler and Marhenkel, Ann., **458,** 6, 18 (1927)].

The evaporation of ether and the excess ester must be performed quickly at low temperature under diminished pressure. It is not surprising that Snell and McElvain, who dried the residue in a vacuum desiccator over sulfuric acid until it attained a constant weight, only obtained sodioacetoacetic ester. The weight of the dry residue obtained by them from **23** g. of sodium was only **90–100** g. instead of **125** g. A small amount of ethyl acetate may remain in the residue and be quickly saponified when it is treated with water, in contrast with ketene acetal, which does not undergo any decomposition in aqueous alkaline solution.

(2) The authors may have used too much calcium chloride in shaking the ether solution for three or four hours with three successive portions of powdered calcium chloride. I only employed a quantity just sufficient to fix the alcohol which was mixed with ketene acetal. When being shaken in this way ketene acetal is held by the great surplus of solid calcium chloride, which is not the case when a concentrated aqueous solution of calcium chloride is used. The separation of alcohol is better performed in such a manner. The directions given by me should be changed as follows.

After drying with anhydrous sodium sulfate, the ethereal solution from the extraction of the "primary reaction product" triturated with water, is distilled through a fractionating column. The residue containing ether only in a little amount is shaken intermittently during six hours with four parts of saturated aqueous solution of calcium chloride. Then it is extracted with ether in a continuous extraction apparatus and the resulting solution is dried with anhydrous sodium sulfate. Observing the precautionary measures mentioned before, ether and finally ketene acetal are distilled; yield, 13 g. or 11.2% of the calculated amount based on **23** g. of sodium used.

The preparation of dimethyl ketene diethyl acetal from ethyl isobutyrate was not successful with sodium ethoxide. It was performed in another manner which will be described later.

KINETICS OF THE MERCURY SENSITIZED REACTION BETWEEN HYDROGEN AND OXYGEN

Sir:

Investigations of the mercury sensitized photo-reaction between hydrogen and oxygen have given rise to a large number of conflicting and unconnected data. These have been used to set up mutually conflicting theories of the mechanism of the reaction of hydrogen atoms with oxygen. It can, however, be demonstrated that almost all the known facts can be correlated and be completely in accord if we assume as the true mechanism:

$$\begin{array}{rll}
\mathrm{Hg} + h\nu & \longrightarrow \mathrm{Hg'} & I\ \mathrm{abs} \\
\mathrm{Hg'} + \mathrm{H_2} & \longrightarrow 2\mathrm{H} + \mathrm{Hg} & k_{\mathrm{H_2}} \\
\mathrm{Hg'} + \mathrm{O_2} & \longrightarrow \mathrm{O_2'} + \mathrm{Hg} & k_{\mathrm{O_2}} \\
\mathrm{H} + \mathrm{O_2} & \longrightarrow \mathrm{HO_2} & k_1 \\
\mathrm{HO_2} + \mathrm{H_2} & \longrightarrow \mathrm{H_2O_2} + \mathrm{H} & k_2 \\
\mathrm{HO_2} + \mathrm{HO_2} & \longrightarrow \mathrm{H_2O_2} + \mathrm{O_2} & k_3
\end{array}$$

These give the kinetic expression

$$\frac{d\,[\mathrm{H_2O_2}]}{dt} = \frac{k_2\,[\mathrm{H_2}]}{\sqrt{k_3}}\sqrt{\frac{[\mathrm{H_2}]\,k_{\mathrm{H_2}}\,I\ \mathrm{abs}}{[\mathrm{H_2}]\,k_{\mathrm{H_2}} + [\mathrm{O_2}]\,k_{\mathrm{O_2}}}} + \frac{[\mathrm{H_2}]\,k\mathrm{H_2}\ I\ \mathrm{abs}}{[\mathrm{H_2}]\,k_{\mathrm{H_2}} + [\mathrm{O_2}]\,k_{\mathrm{O_2}}}$$

Assuming $k_2/\sqrt{k_3} = 10^{-3}$, this equation fits exactly the data of Marshall [THIS JOURNAL, 49, 2763 (1927)] on the influence of $[H_2]$ and $[O_2]$ on the rate, if we put for k_{H_2} 1.1 X 10^7, k_{O_2} 0.68 X 10^7 as determined by Zemansky [*Phys. Rev.*, **36,** 919 (1930)]. The constant (Iabs) so obtained is constant to within less than 3% for all the experiments of Marshall not indicated as uncertain. Furthermore, the value of the quantum yield as calculated, using $k_2/\sqrt{k_3} = 10^{-3}$ lies between 1 and 2 in those experiments, in close agreement with those experimentally determined (1–2.5). In addition, the discrepancy between the quantum yield measurements of Frankenburger and Klinkhardt [*Z. physik.* Chem., **15B,** 421 (1931)] and by Marshall [*J. Phys. Chem.*, **30,** *1078* (1926); THIS JOURNAL, **54,** 4460 (1932)] is explained, in that the former used a light intensity a hundredfold greater than the latter. The mechanism postulated calls for a higher quantum yield with lower intensities, which is again in agreement with the experiments. This subject will be given a complete exposition in a paper shortly to be submitted to the JOURNAL.

FURTHER REMARKS ON THE PREPARATION OF KETENE ACETAL

Sir:

Scheibler [THIS JOURNAL, **55,** 425 (1933)] ascribes our failure to obtain ketene acetal [*ibid.*, **55,** 416 (1933)], first, to too long standing of the "primary reaction product" over sulfuric acid, and second, to the use of excessive amounts of calcium chloride in the purification of the product. The first reason is not valid because we did not use a "primary reaction product" which had attained constant weight over sulfuric acid, but rather the residue left after the evaporation of the reaction mixture at room temperature under diminished pressure in a vacuum desiccator as described by the original investigators [Scheibler and co-workers, Ann., **458,** 28 (1927)]. On account of the second reason Scheibler now revises his original extraction procedure.

In consideration of this revised procedure we have made two further attempts to prepare ketene acetal. The same quantities of materials that were used in our earlier work were employed. The preparation of the "primary reaction product" was carried out in a tared 3-liter round-bottomed Pyrex flask. In this way it was possible to evaporate the ether and ethyl acetate from the reaction mixture and obtain a dry residue in about six hours, whereas evaporation in a vacuum desiccator according to the original procedure required about ten hours. It is not apparent to us how the time for this evaporation can be further decreased without the application of heat. The weight of the dry residue obtained in our latest experiments was in one case 77 g. and in the other 78 g. instead of 125 g. reported by the original investigators. In fact, intermittent weighing of the tared evaporation flask during the latter period of the evaporation showed that when its contents weighed 125 g. they were still liquid.

On working up these residues according to the revised procedure of Scheibler we obtained in one case 7 g. (A) and in the other 9 g. (B) of product at the point where ketene acetal should appear. In each of these products the amount of ethyl acetate was determined by saponification of an aliquot with 0.1 N potassium hydroxide and the amounts of ethyl alcohol and water were estimated by treatment of an aliquot with phenyl isocyanate followed by the isolation of the phenyl urethan and diphenyl urea. The following summary shows the percentages of these substances which were found to be present in the products which we obtained.

Product	Ethyl acetate, %	Alcohol, %[a]	Water. %	Total % found
A	13.0	72.5	2.2	87.7
B	0	87.5	1.5	89.0

[a] Analyses of a known mixture of alcohol and ethyl acetate, containing 85% of the former and 15% of the latter showed that only 85–90% of the alcohol could be recovered as the phenyl urethan, m. p. 52°.

These results show that the products which we obtained were mainly alcohol containing small amounts of water and ethyl acetate. It is our opinion that the failure of the found values to total 100% is due to the limitations of the procedure used for the determination of alcohol.

On the basis of our experiences, we believe that our failure to prepare ketene acetal is traceable to the discrepancy between the results reported by Scheibler and those obtained by us in connection with the formation of the so-called "primary reaction product" from ethyl acetate and sodium ethoxide. The results which we report now confirm our earlier conclusion that there is not only no evidence for, but definite evidence against, the existence of such a reaction product.

BROMINE SENSITIZED PHOTO-DECOMPOSITION OF CHLORINE DIOXIDE

Sir:

Chlorine dioxide is decomposed by light with production of Cl_2O_6, light in the blue and ultraviolet being equally effective [Finkelnburg and Schumacher, *Z. physik.* Chem., Bodenstein Band, 704 (1931); Spinks, THIS JOURNAL, 54, 1689 (1932)]. Since the region of predissociation in

ClO_2 does not extend above **3750** Å., it was thought that further investigation would prove interesting. It is found that the quantum efficiency at **4360** Å. is only slightly less than that at **3650** Å. ClO_2 does not absorb at **5460** Å. and no photoreaction is obtained on isolating ClO_2 with light of this wave length using a mercury arc and glass filter. On adding a small percentage of bromine a sensitized photoreaction takes place using **5460** Å., the quantum efficiency being practically equal to that at **3650.** The equal efficiency of **3650** and 4360 Å. is explicable by the scheme suggested by Schumacher in which predissociation or the activation of ClO_2 molecules leads eventually to the production of 1ClO + $1ClO_3$ by one quantum of light. Apart from differences in energies of these groups one would expect any chains resulting to be of the same length. The equal quantum efficiency of **5460** Å. could be explained by

$$Br_2 + h\nu \longrightarrow Br_2'$$
$$Br_2' + ClO_2 \longrightarrow ClO_2' + Br_2$$

and then as before. It would be necessary that practically all the activated bromine molecules should be deactivated only by ClO_2 molecules under our conditions.

ROTATORY DISPERSION IN THE VISIBLE AND THE ULTRAVIOLET RANGE OF CONFIGURATIONALLY CORRELATED CARBINOLS, HALIDES AND ACIDS

Sir:

High precision dispersion measurements in the visible and in the ultraviolet to about **2300** Å. have been made on the following substances, the configurations of which have been correlated by Levene and Marker.

Compounds	Sign of observed rotation in the visible	Sign of contribution of the functional group	Sign of contribution of the rest of the molecule
2-Methylbutanol	+	+	−
1-Bromide-2-methylbutane	−	+	−
1-Iodo-2-methylnonane	−	+	−
β-Methyl-*n*-valeric acid	−	+	−

It may be seen from this table that individual substances of this group vary in the direction of their rotation in the visible. An explanation of the differences in the direction of rotations of the correlated substances has been found by the analysis of their rotatory dispersion curves.

The dispersion curves of all these substances may be expressed by the two-term Drude formula

$$[M] = \frac{a}{\lambda^2 - \lambda_0^2} - \frac{a'}{\lambda^2 - \lambda_0'^2}$$

for rotatory dispersion. In our case the higher λ_0 value has a definite physical significance corresponding to a known absorption band (2050 Å. for COOH, 2560 Å. for I in 2-methyl-n-nonyl iodide). The contribution of the functional group (first term of above formula) is of opposite sign to the contribution of the rest of the molecule (second term). The direction of the first term is to the right and that of the second is to the left. It follows from this that in the levorotatory substances the sign of the contribution of the first band is opposite to the sign of the rotation of the substance observed in the visible. Thus, the sign of the rotation in the visible of the two halides is opposite to the sign of the contributions of Br and of I, which is contrary to the view expressed by W. Kuhn *[Ber.*, **63**, 191 (1930)], whereas in the secondary halides as well as in 1-bromo-3-methylpentane and in 1-iodo-4-methylhexane the direction of the contribution furnished by the halides determines the direction of the rotation in the visible.

The most striking example of the first band exerting a minor influence on the rotation in the visible is given by β-methyl-*n*-valeric acid. With decreasing wave lengths, the rotation increases slowly, reaches a maximum at 2850 Å., decreases sharply to a zero value at 2450 Å. and increases in the opposite direction for still smaller wave lengths. The molecular rotation in heptane is accurately represented (* 1%) by the equation

$$[M]^{25} = + \frac{8.088}{\lambda^2 - 0.042} - \frac{11.68}{\lambda^2 - 0.034}$$

The details of this study as well as the results dealing with the influence of the distance of the functional group on the sign of its contribution will be discussed in full in the near future.

AN ABSOLUTE METHOD FOR ESTABLISHING ORIENTATION IN THE FURAN SERIES

Sir:

Identification of the simpler substitution products of furan, such as the methylated and halogenated furans, is not readily accomplished on account of the difficulty of obtaining solid derivatives from them. The observation that addition of maleic anhydride to furan and certain substituted furans[1] gives rise to crystalline solids, has led us to investigate this reaction as a general method for the identification of furan derivatives.[2] We have found that addition of maleic anhydride occurs with a variety of substituted

---

(I) Diels and Alder, *Ber.*, 62, 554 (1929); Rinkes, Rec. *trav. chim.*, **50**, 1127 (1931).

(2) We are indebted to Professor Diels for his courtesy in permitting us to investigate this application of the maleic anhydride reaction.

furans but is hindered by the presence of certain substituents. Crystalline solids were obtained from 2-bromofuran (m. p. 116°), 3-bromofuran (m. p. 131.5–132°), furfuryl methyl ether (m. p. 97°), furfural diacetate (m. p. 126.5–127°), furfurylacetone (m. p. 86–87°) and several others. We have not succeeded in obtaining addition products from compounds containing a carbethoxyl, cyano, nitro or ethylenic group attached directly to the ring.

A study of the effect of hydrolytic agents upon the addition products (substituted 3,6-endoxo-A^4-tetrahydrophthalic anhydrides) has shown that they can be converted directly into the corresponding phthalic acids (or anhydrides).[3] Since the orientation of the substituents in the resulting phthalic acids (or anhydrides) is known, this transformation constitutes an absolute method for establishing the position of substituents in the furan ring. Thus, the substituted 3,6-endoxo-A^4-tetrahydrophthalic anhydrides from 2-methylfuran, 2- and 3-bromofuran on heating with hydrogen bromide in glacial acetic acid gave, respectively, 3-methylphthalic anhydride (m. p. 111–113°), 3-bromophthalic anhydride (m. p. 134–135°), and 4-bromophthalic anhydride (m. p. 108–110°). We are now engaged in extending the observations reported here.

---

(3) Diels and Alder [Ann., 490, 243 (1931)] have shown that the addition product from furan and maleic acid can be converted into phthalic acid by a series of five reactions, involving four intermediate products.

VAPOR PRESSURE AND HEAT OF VAPORIZATION OF GRAPHITE

Sir:

A large amount of experimental work has been carried out in the past decade to determine the vapor pressure and heat of vaporization of graphite and very discordant values are given in the literature. We have recently investigated this problem, determining vapor pressure from the rate of loss in weight of carbon rings heated by high frequency induction in a vacuum [reported to April, 1932, Meeting, American Philosophical Society]. The interpretation of the results is complicated by the fact that carbon vapor exists in both monatomic and diatomic forms, the relative amounts being determined by the total pressure and the temperature. Vaughan and Kistiakowsky [*Phys. Rev.*, 40, 457 (1932)] have independently made calculations, using the equations of quantum statistical mechanics, which support this conclusion.

It is possible to reconcile our results in the temperature range 2350–2800°K. with those of Kohn and Gückel [*Z. Physik*, 27, 305 (1924)] on the vapor pressure of carbon in the arc.

They have taken the value of 4200°K. as the temperature of the positive crater at 1 atmosphere pressure. This value is due to Benedict [*Ann. Physik,* 49, 144 (1916)]. The method used by her has been adversely criticized by others and a careful search of the literature shows that this temperature may be 200° too high.

The following values are the heats of reaction for the two processes involved:

$$C_{\text{solid}} \longrightarrow C_{\text{monatomic vapor}} \qquad \Delta H = 177\ k.\ \text{cals.} \qquad (1)$$
$$C_2 \longrightarrow 2C \qquad AH = 150\ k.\ cals. \qquad (2)$$

The rate of loss in weight in g./sq. cm./sec. as a function of temperature is given by the formula

$$\log m = -\frac{177{,}000}{4.58T} + 2 \log T + \left(\frac{F^\circ - E_0^\circ}{4.58T}\right)_{\text{graphite}} + 3.174 \qquad (3)$$

This equation applies only to the carbon evaporating to form monatomic vapor. In the temperature range 2300–2800°K. this is 92–96% of the total carbon evaporating. The vapor pressure can be calculated from the rate of loss in weight by the equation

$$\log p = \log m + 1/2 \log T - 2.187 \qquad (4)$$

where p is expressed in atmospheres. The equation for the variation of the equilibrium constant of reaction (2) as a function of temperature is

$$\log \frac{(P_c)^2}{(PC\%)} = -\frac{150{,}000}{4.58T} + 3/2 \log T + \log (1 - e^{-2340/T}) + 1.462 \qquad (5)$$

When this equation is applied to the results of Kohn and Gückel the following values are calculated for the partial pressures of monatomic carbon vapor

T, °K.	Total pressure	P_c (atm.)	P_c (extrap.)
4200	1	0.21	0.17
4705	5	1.23	1.50

The fourth column gives the values extrapolated by equations (3) and (4) from the results in the temperature range 2350–2800°K. In making the extrapolation it was assumed that the latent heat of fusion of graphite was 8000 cal.

A SIMPLE TEST FOR STREAMING IN THE POROUS DIAPHRAGM DIFFUSION CELL

Sir:

The diffusion cell of Northrop and Anson [J. Gen. *Physiol.,* **12,** 543 1929)] as further standardized by McBain and Liu [THIS JOURNAL, 53, 59 (1931); see also M. E. Laing McBain, THIS JOURNAL, in press (1933)] is now widely used in this country and abroad as a highly convenient and accurate method. These authors eliminated bulk streaming of liquid through the sintered glass or other porous membrane by careful leveling of the membrane which separates the denser liquid above from the lighter liquid beneath. Several workers have obtained erratic results when using membranes that were too coarse.

We find that it is simplest to test all cells for streaming by using them once tilted at an angle such as 30°. If the pores are too coarse, the values for diffusion may be increased as much as four-fold as compared with either the same cell used horizontally or with a cell of fine pores. Such cells should be discarded because those with finer pores such as glass sintered membranes "G3" (2–5 × 10^4 Å) are scarcely affected by tilting.

THE RADIOACTIVITY OF LANTHANUM, NEODYMIUM AND SAMARIUM

Sir:

In view of the note in *Nature* 1130, 846 (1932)] by Hevesy and Pahl regarding the radioactivity of samarium, we wish to report an independent investigation on this subject. In October of this year we discovered radioactivity in a sample of samarium and since that date we have examined samples of lanthanum and neodymium which are also radioactive.

The method employs the Geiger–Miiller counter set-up as described by Libby [Phys. *Rev.,* 42, 440 (1932)]. The salts investigated have been deposited as a thin film on the inside of a glass tube. This is placed around the counter which is in the form of a long wire enclosed in a metal screen cylinder. In a typical run 20 g. of potassium chloride deposited on the tube increased the zero count of 15 per minute to 160.

The activities of the samples of lanthanum and neodymium are not appreciably screened by 0.07 mm. of aluminum, whereas that of samarium is very largely, if not completely, screened, indicating that the activities of the former are mainly of the beta type and that of the latter alpha. We have used two different samples of neodymium, one sulfate and the other oxalate. Both show an activity which is approximately 2.5 times that of potassium per mole. The lanthanum activity per mole is about 8 times that of potassium and the samarium approximately **3** times. A careful examination of a very pure sample of gadolinium sulfate prepared by Professor B. S. Hopkins gave results which are negative to at least 2% per mole of the activity of potassium.

We believe that the radioactivity of these elements is due to the presence of unstable isotopes, but have not completely eliminated the possibility of actinium as an impurity in the lanthanum and neodymium samples. This point is under investigation.

NEW BOOKS

A History of Chemistry. By F. J. MOORE, **Ph.D.,** Late Professor of Chemistry in the Massachusetts Institute of Technology. Second edition. Revision prepared by William T. Hall. McGraw-Hill Book Company, Inc., **370** Seventh Ave., New York, **1931.** **xxiii + 324** pp. Illustrated. **14.5 × 21** cm. Price, **$3.00.**

The revision of this serviceable book has not involved a departure from the general plan of the first edition. The essential change, apart from restatements necessitated by recent discoveries, is the inclusion of biographical sketches of two groups of chemists, *viz.*, (1) brilliant chemists who died during the last twelve years and (2) deceased American chemists who contributed material to the development of chemistry in this country. It is to be regretted that the bibliography at the end of the chapters has not been enlarged, particularly since so many admirable articles on the history of chemistry have appeared during the last ten years in the ***Journal of Chemical Education.*** The chapter devoted to chemistry in the United States would be more in harmony with the rest of the book, and certainly more useful to American students, if the growth was described as a connected narrative rather than in the form of disconnected biographies. However, the book as revised is an excellent example of books in its field and a faithful expression of the scholarship of the author, whose life as a scientist and as a teacher is briefly recounted in the introductory portion.

LYMAN C. NEWELL

Elementary Qualitative Analysis for College Students. By J. H. **REEDY,** Associate Professor of Chemistry in the University of Illinois. Second edition. The McGraw-Hill Book Co., Inc., **330** West 42d St., New York, **1932.** **x + 163** pp. **13** figs. **14** X **21** cm. Price, **$1.50.**

"The changes consist mainly in the inclusion of new procedures based upon reagents recently developed, and the extension of older methods to more difficult combinations.... Practically the whole book has been rewritten.... If the book has a distinctive feature, it is the emphasis placed upon interpretative work on the part of the student."

Preliminary experiments, notes, and exercises following each group will convince the student that the reagents and conditions as specified are well planned to separate the ions sharply and to detect them with certainty.

The theoretical treatment is clear and helpful. Greater stress might have been laid upon the fact that the whole of qualitative analysis can be formulated in terms of a very limited number of equilibria, and displacements of the same.

Here and there are statements which could be revised to advantage, and without appearance of pedantry. Thus ionic precipitates (p. 2) appear to be produced from insoluble molecules preexisting in solution. Stannic chloride and even stannic ion (p. **25)** are pictured as stable in water. "NH_4OH is a very weak base" (p. **81).** The electromotive series (p. **151)** is merely a column of metals, rather than a comprehensive system of oxidizing and reducing agents arranged in pairs, the order of which depends upon concentrations.

This book is highly teachable. Grounds for criticism are few indeed, and unimportant when contrasted with its many admirable qualities.

G. S. FORBES

Lehrbuch der **Metallkunde. Chemie und** Physik der Metalle und ihrer Legierungen. (Textbook of **Metals.** Chemistry and Physics of Metals and their Alloys.) By GUSTAV **TAMMANN,** Gottingen. Fourth, enlarged edition. **Verlag** von **Leopold** Voss, **Salomonstrasse 18** B, **Leipzig C** 1, Germany, **1932.** xv + *536* pp. **385** figs. **15.5** X **23.5** cm. Price, **RM. 48;** bound, RM **49.50.**

This is the fourth edition of Tammann's well-known work, the first three of which, in **1914, 1921** and **1923** were issued under the title Lehrbuch der Metallographie. The former title connotes a study of the microscopic structure of metals, and since this book covers much more, the title is very properly changed to be more descriptive of the contents. As compared with the last edition, there has been a 50% increase in the number of diagrams, and a somewhat smaller increase in the number of pages and new text. The new text covers both new methods which have come into prominence during the last ten years, such as a description of the work of the German metallurgists on the plastic deformation of single crystals and a more adequate description of x-ray methods of analysis, and also the vast amount of new experimental knowledge of the phase diagrams of alloys. The old text has also in many cases been revised, but not in all. Thus, the very first sentence of the introduction is the same as the introduction of the original **1914** edition: "By the word alloy was understood, **30** or 40 years ago. . . ."

As is perhaps natural for an author who has himself covered so many of the fields of activity of the metallurgist, the emphasis is perhaps too much on Tammann's personal activities to give a well-balanced presentation of the whole subject. Thus it is unfortunate that matters in which Tammann does not agree with other investigators are presented without a reference to the other side or even an intimation that there is difference of opinion, such as the course of the melting curve at high pressures, and the significance of the behavior of eutectic and other mixtures under acid attack. There is also too little tendency to mention work in other countries than Germany. For instance, the important work of Hume-Rothery on intermetallic compounds is not mentioned by name, and in the tables the old formula Ag_2Zn_3 is retained instead of the new Ag_5Zn_8, which is the basis of part of Hume-Rothery's theory, although there is in the text a brief reference to Ag_5Zn_8 in terms which cannot possibly bear on the Ag_2Zn_3 of the table.

When due allowance is made for all defects, however, the book remains a monumental one, and a record of an almost incredible amount of achievement for which Tammann has been personally responsible. No one can read it without being stimulated by the extraordinary range and vivacity of Tammann's imagination. What other author could present us from his personal experience with an array of topics, all of them made to have suggestive implications, such as: "The dependence of nuclear number on subcooling," "The spreading of mercury drops on metallic surfaces," "The precipitation of polonium from its solutions," "Change of color on cold-working," "The change with temperature of the angle at which two polished plates slide on each other," to mention only a few?

P. W. BRIDGMAN

Die experimentellen und theoretischen Grundlagen der Elektronenbeugung. (The Experimental and Theoretical Principles of Electron Diffraction.) By H. MARK and R. WIERL. Verlagsbuchhandlung Gebrüder Borntraeger, Schöneberger Ufer 12a, Berlin W 35, Germany, 1931. iii + 126 pp. 60 figs. 16.5 × 25 cm. Price, to subscribers, unbound, RM. 12; bound, RM. 13.60. Separately, unbound, RM. 16; bound, RM. 18.

What impresses one most about this monograph of Mark and Wierl is its completeness—no paper on the diffraction of electrons by atoms, molecules or crystals, either theoretical or experimental, has eluded the authors' attention, and none has failed to supply illumination to their text. In 126 pages the content of some 150 articles which constitute the literature of their subject up to April, 1931, is organized and reviewed in a discriminating and pleasing manner. This is particularly true of the sections devoted to the experimental work, which together make up about three-fourths of the whole.

The contributions which the authors have themselves made in this field are well known—particularly their important and beautiful work on the diffraction of electrons by molecular vapors. It is not surprising perhaps that with their interests more deeply engaged on the experimental side, their treatment of this part of the subject strikes one as rather more sure-footed than their treatment of the purely theoretical part. The latter is marred unfortunately by numerous typographical errors not all of which are corrected by a table of errata. With this not very important reservation, the monograph may be recommended as a comprehensive survey of its subject and a reliable guide to the literature.

The death of the junior author, announced recently in German periodicals, has come as a shock to physicists the world over. It would be difficult indeed to think of a young experimental physicist who had shown greater promise than Dr. Wierl.

C. J. DAVISSON

Manuale di Analisi Chiiica. Clinica, Fisio-patologica ed Igienica ad Uso dei Medici e Studenti. (Manual of Chemical Analysis: Clinical, Physio-Pathological and Hygienic. For the Use of Physicians and Students.) By CESARE SERONO and ALFONSO CRUTO. Second edition. Unione Tipografico-Editrice Torinese, Torino, Italy, 1932. xv + 483 pp. 85 figs. 15 × 22.3 cm.

This is an elementary textbook of the kind used by medical students thirty years ago, except that many of the biochemical methods described are fairly modern. It deals more exclusively with ordinary qualitative and quantitative analysis than with the analysis of biological material and does not correspond very closely to biochemistry as it is taught in this country.

OTTO FOLIN

Wissenschaftliche Photographie. Eine Einführung in Theorie und Praxis. (Scientific Photography. An Introduction to Theory and Practice.) By Dr. E. v. ANGERER, Professor at the Technical High School of Munich. Akademische Verlagsgesellschaft m. b. H., Leipzig C 1, Germany, 1931. viii + 185 pp. 99 figs. 16 × 24 cm. Price, M. 11, unbound; M. 12.80, bound.

This book fills in the gap between the elementary practical handbooks of photography on the one hand, and the very comprehensive treatises on the other. It provides a good general survey of the most important aspects of practical and theoretical photography, in terms familiar to the physicist and chemist, and in a manner calculated to assist them in an intelligent understanding of the principles of the science which they employ in a considerable part of their work. It is regrettable that the average scientific worker is unable to make the best of use of the photographic process, owing to an incomplete understanding of the properties, and limitations, of photographic materials, and of the elementary principles underlying the photographic process. A study of this book should be of considerable help to him wherever he applies photography to his scientific or technical work.

WALTER CLARK

Les Problêmes de la Biochimie Moderne. (Problems of Modern Biochemistry.) By G. FLORENCE, Professor in the Faculty of Medicine of the University of Lyon, and J. ENSELME, Docteur ès Sciences, Faculty of Medicine, Lyon. Preface by L. Hugounenq. G. Doin et Cie, Éditeurs, 8, Place de l'Odéon, Paris 6^e, France, **1932. 312** pp. Illustrated. **15** X **24.5** cm. Price, fr. **45.**

Reading the table of contents of this book impresses one with its excellent plan. The first half is devoted to a description of biochemical molecules--static biochemistry. The second half includes a section on kinetic biochemistry and another on physiological chemistry. There is an appendix on nomenclature and another on thermodynamics.

The execution of the plan, however, is less satisfactory. Most useful publications relating to biochemistry are textbooks, monographs or accounts of investigations. In writing this book the authors have fallen between two stools; the result is less complete than a textbook and less precise and up-to-date than a monograph. Chapters **5–7** on the amino acids, peptides and proteins illustrate the point. These chapters contain less than one finds in many textbooks. Since the **52** literature references include only **3** which are later than **1927** the treatment is hardly more up-to-date than Cohn's "Physical Chemistry of the Proteins" published in ***Physiological Reviews*** seven years ago.

The numerous typographical errors are irritating and sometimes bewildering. The **24** items listed in the "Errata" are but a small proportion of the errors which occur. Thus on p. **192** one finds $[\bar{O}]$ for [OH], **(H^2)** for $[\overset{+}{H}]^2$ and on p. 197, 6 **1** for **6.1.** One receives the impression that the chances are against correct spelling of English words. There are **4** English titles in the bibliography of Chapter II and a word is misspelled in each, *viz.*, *colloïdal, proteines, leathe, dynamies*. An amusing aspect of the carelessness in proof reading is the originality in abbreviation. At least ten different abbreviations for *Zeitschrift* may be found.

D. B. DILL

Quantitative Clinical Chemistry. Volume II. Methods. By JOHN P. PETERS, M.D.. M.A., Professor of Internal Medicine, Yale University School of Medicine, and DONALD D. VAN SLYKE, Ph.D., Sc.D., Member of the Rockefeller Institute for Medical Research. The Williams and Wilkins Company, Mt Royal and Guilford Aves., Baltimore, Md., **1932.** xix + **957** pp. Illustrated. **15.5** X **23.5** cm. Price. **$10.00.**

This long expected volume has now appeared and it is doubtless being examined by many who knew beforehand that they must own it. Like the first volume, it is primarily a book for clinicians rather than for chemists. Its **32** chapters cover about every kind of quantitative measurement and determination called for in completely equipped clinical laboratories. But the book is not a compendium or handbook giving a description of all of the better known methods. The 200-page section devoted to the description of gasometric methods is by far the most comprehensive and complete and naturally so because of Van Slyke's extensive work in this field of analysis. Many of the other chapters are unexpectedly brief. In these chapters, the authors, as is explained in the preface, have endeavored to confine themselves to the description of one method representing each of the major fundamental principles of analytical chemistry, such as weighing, titration and colorimetry.

This scheme, excellent as it may be in the field of inorganic analysis, does not correspond very well to the development of biochemical analysis during the past twenty years, and the authors have not been able to adhere to it with any high degree of uniformity. The plan has also compelled the authors to assume the responsibility of selecting one out of several methods of sometimes equal and in other cases of unequal merit. In the case of uric acid in urine, for example, nearly all present-day determinations are made colorimetrically, and several reliable procedures based on this principle are known. Only one colorimetric method is given for this determination, however, and it happens to be a short-cut method which is unreliable in practice and theoretically indefensible. The extensive experience of the authors has of course saved them from making many such unfortunate selections. Most of the methods selected for description are undoubtedly capable of yielding valid results even though, in some cases, they are not the best known or most widely employed. Among the methods of doubtful validity should perhaps be cited those given in Chapter 19 on the determination of phenols in blood and in urine. This statement is in no sense a reflection on the authors, but it is probably a fact that the methods as yet available for the determination of phenols, including the methods for which the reviewer is responsible, should still be regarded only as tentative or provisional procedures.

Chapter 15 is rather interesting in that here the authors describe the method for the determination of creatinine in blood and admit that they still use the method while at the same time they endorse the view that blood contains no creatinine. That view rests on rather slender evidence, but the interpretation is important since it carries with it the corollary, also accepted by the authors, that the creatinine in the urine is formed in the kidneys.

Most of the chapters in the book open with a general discussion more or less historical in character, and all of the different chapters contain a generous supply of references to original literature. Some of the described methods are based only on personal communications.

The appearance of this book has one especial significance. As its title indicates, it deals only with quantitative determinations. The innumerable often meaningless and sometimes misleading qualitative tests, which still represent nearly all that many clinicians know about the applications of biochemistry, are omitted. Teachers of biochemistry in medical schools might well note the important hint implied in the appearance of such a book by two such eminent authors.

OTTO FOLIN

Chemistry of the Opium Alkaloids. By LYNDON F. SMALL. Consultant in Alkaloid Chemistry, United States Public Health Service, and ROBERT E. LUTZ, Associate Professor of Chemistry, University of Virginia. Prepared by direction of the Surgeon-General as Supplement No. 103 to the Public Health Reports. Superintendent of Documents, Government Printing Office, Washington, D. C. ix + 375 pp. 15.5 X 23.5 cm.

Seldom, in all probability, has such a wealth of detailed information in reasoned form been presented in so small a compass as in this volume, which is a result of co-operative work between the Committee on Drug Addiction of the Division of Medical Sciences of the National Research Council and the Division of Mental Hygiene of the U. S. Public Health Service. Those who have followed the painstaking investigations in the domain of alkaloid chemistry published from the laboratory of the authors must have recognized the erudition which had necessarily to be acquired before research in this intricate and well-explored field could be undertaken, That the fruit of so much laborious reading has now been laid before the public, in palatable and relatively assimilable form, is truly a matter for congratulation.

The subject matter is divided into two parts, dealing with the alkaloids derived, respectively, from benzylisoquinoline and from phenanthrene; each part is subdivided into about eighteen sections devoted to individual alkaloids and their immediate derivatives. Every section is constructed on the general plan: (1) history, (2) empirical description, (3) development of constitution, (4) synthesis, (5) description of salts and derivatives, (6) bibliography. Not a word is wasted, nor is, apparently, a pertinent fact omitted. By means of an appendix, covering the literature of about two years, the information has been brought up to date of January 1,1932.

Professor Wieland, in an appreciative Foreword, subscribes to the belief of the authors that "every reaction and every compound described in the literature is mentioned," and points out that this book far transcends a mere systematic collection of facts by virtue of its historical and critical treatment of the questions of constitution. Organic chemists should be grateful to the authors and to the government for publishing so impressive and valuable a work.

VOLUME 55 FEBRUARY, 1933 NUMBER 2

Third Report of the Committee on Atomic Weights of the International Union of Chemistry

BY G. P. BAXTER (Chairman), MME. M. CURIE, O. HÖNIGSCHMID, P. LE BEAU AND R. J. MEYER

The following report of the Committee covers the twelve month period, September 30, 1931 to September 30, 1932.[1]

Only two changes in the table of atomic weights are recommended, from 126.932 to 126.92 in the case of iodine and from 138.90 to 138.92 in the case of lanthanum.

Physico-chemical Methods

Carbon.—Moles and Salazar[2] have determined the normal density of carbon monoxide prepared by four methods: (1) reaction of sodium formate with phosphorus pentoxide, (2) dehydration of formic acid with phosphoric acid, (3) dehydration of formic acid with concentrated sulfuric acid, (4) reaction of potassium ferrocyanide with concentrated sulfuric acid. In each case the gas was subjected to chemical purification and then was fractionally distilled.

THE DENSITY OF CARBON MONOXIDE

Preliminary Series

Average	1.24967	1.25081	1.25023
Average of all	1,24990	1.25030	1.25010

This result is in exact agreement with that previously found by Pire and Moles. With the values 22.414 and 1.00050 for R and 1 + λ, respectively, the atomic weight of carbon is calculated to be 12.006. Because of the small coefficient of deviations from Boyle's law, carbon monoxide is as well suited for precise molecular weight determination as the permanent gases, so that this result may be accepted as a valuable addition to the evidence which has been accumulating recently that the atomic weight of carbon is somewhat higher than 12.00.

Nitrogen.—Batuecas[3] has continued the investigation on nitrous oxide, previously reported, by determination of the density at pressures below one atmosphere. The gas was prepared (1) by the reaction of hydroxylamine hydrochloride and sodium nitrite, (2) by the decomposition of ammonium nitrate. Chemical purification was followed by condensation and fractional distillation. The values given in the following table are

THE DENSITY OF NITROUS OXIDE

P = 506.67 mm.

Method	Globe G 1007.56 ml.	Globe N-3 772.58 ml.	Average

referred to one atmosphere without correction for the deviation from Boyle's law.

The limiting density is calculated on the assumption that a linear relation holds between pressure and density referred to one atmosphere.

Pressure, atmospheres	Density	Limiting density	$1 + \lambda$
1	1.9804		
$^2/_3$	1.9746	1.9630	1.00886
$^1/_2$	1.9722	1.9640	1.00835
$^1/_4$	1.9694	1.9639	1.00840
	Average	1.9636	1.00854

The calculation of $1 + \lambda$ by linear extrapolation of values for PV found from the expression $L_1/L_P \frac{P_1}{P}$ gave the following result

Pressure. atmospheres	PV	$1 + \lambda$
I	1,00000	
$^2/_3$	1.00294	1.00882
$^1/_2$	1.00416	1.00832
$^1/_3$	1.00559	1.00839
	Average	1.00851

With the values 1.9804, 22.414 and 1.0085 for the density at one atmosphere, R and $1 + \lambda$, respectively, the molecular weight of nitrous oxide is found to be 44.014 and the atomic weight of nitrogen 14.007.

In an article devoted chiefly to criticism of the report of this Committee for 1931, Moles(4) applies corrections to the above results (1) for diminution in volume of the globes when filled at low pressures and (2) for adsorption as found by Crespi in work as yet unpublished. The corrected figures are as follows

Pressure atmospheres	Density	Limiting density	$1 + \lambda$	N_2O
1	1.98034			
$^2/_3$	1.97459	1.96309	1.00880	44.001
$^1/_2$	1.97223	1.96412	1.00829	44.023
$^1/_3$	1.96946	1.96402	1.00833	44.022
Average		1.96364	1.00845	44.016

Whence N = 14.008

Fluorine.—Moles(5) discusses critically earlier determinations of the atomic weight of fluorine with the final conclusion that the atomic weight of this element is very close to integral, 19.000, and suggests that the higher value recently found by Patterson, Whytlaw-Gray and Cawood, through the density of methyl fluoride, is due to the effect of impurity of methane in the methyl fluoride employed by the latter. Patterson, Whytlaw-Gray and Cawood(6) have prepared methyl fluoride by their own (Collie's) method (pyrolysis of tetramethylammonium fluoride) and that of Moles and Batuecas (action of potassium methyl sulfate on potassium fluoride) and found that the two samples had identical critical constants within the error of the experiments. A direct determination of the compressibility of methyl fluoride yielded the values 1.0114 at 0° and 1.0087 at 21°. The latter is essentially identical with the value calculated from their experiments with the micro-displacement-balance but the former is much lower than that found by Moles and Batuecas from gas density measurements, 1.018. Batuecas(7) discusses the calculation of Patterson, Whytlaw-Gray and Cawood's density determinations with the micro-balance and points out that since the methyl fluoride employed by Moles and Batuecas possessed a vapor pressure obeying the law $\log p = -(A/T) + B$ it must have been essentially free from impurity. The Committee feel that the preponderance of evidence is in favor of the lower value for fluorine and see no reason at present to alter the value in current use.

Potassium.—Heller and Wagner(8) were unable to detect by analysis of potassium chloride from plant sources any concentration of the higher isotope of potassium. This confirms their previous finding.(9)

Selenium.—Hönigschmid(10) has synthesized silver selenide from pure silver and pure selenium. The product was brought to constant weight in

vacuum. Eleven experiments yielded the ratio 2Ag : Ag_2Se = 0.732081 and the atomic weight of selenium 78.962. This value agrees with Aston's value and is considerably lower than the current one. Until further details are available no change is recommended in the table.

Iodine.—Hönigschmid and Striebel[11] have continued their experiments on the conversion of silver iodide to silver chloride, with precipitated silver iodide, instead of material synthesized from the elements used previously.

Iodine was three times distilled from iodide solutions prepared from similar iodine and was sublimed in an oxygen current over red hot platinum. From this iodine hydriodic acid was prepared by direct synthesis with hydrogen and after solution in water this acid was distilled.

Sample A of silver iodide was precipitated by adding an excess of 0.15 N hydriodic acid solution to an acid solution of the purest silver (0.15 N). Sample B was precipitated in ammoniacal solution and then an excess of nitric acid was added. Sample C was prepared by adding 0.2 *N* ammoniacal silver nitrate to an excess of 0.2 N ammoniacal ammonium iodide. Sample D resulted from adding an excess of 0.16 *N* silver nitrate to 0.16 N hydriodic acid.

After washing and drying the silver iodide was fused in an air current containing free iodine and then in pure air in a weighed quartz tube, and weighed. Then the silver iodide was converted to silver chloride by heating in a chlorine current at gradually increasing temperatures up to fusion. Proof was secured that the iodide did not retain iodine and that the conversion was complete. Vacuum weights are given.

THE ATOMIC WEIGHT OF IODINE

		Average	1.638076	126.917

---

(11) Hönigschmid and Striebel, *Z. anorg. allgem. Chem.*, **208**, 53 (1932).

In view of the concordance of this result and the earlier one of Hönigschmid and Striebel (see report for 1931) the atomic weight of iodine is changed in the table from 126.932 to 126.92.

Tellurium.—Hönigschmid[12] has prepared and analyzed tellurium tetrabromide. From the two ratios $TeBr_4 : 4Ag$ and $TeBr_4 : 4AgBr$ the atomic weight of tellurium is found to be 127.587.

Krypton and Xenon.—Allen and Moore[13] have separated krypton and xenon from liquid air residues by means of fractional distillation. The average density of the purest krypton fractions, found with a globe of 22 ml. capacity, was 3.733 and that of the purest xenon 5.887. Using values calculated by Watson in 1910 for the compressibilities of these gases the atomic weights of krypton and xenon are found to be 83.6 and 131.4 with an uncertainty of 0.1 unit in each case. These results, which agree with the recent results of Aston, Watson, and Whytlaw-Gray, Patterson and Cawood (see report for 1931) escaped notice by the Committee in preparing the report for 1931.

Lanthanum — Baxter and Behrens[14] have determined the atomic weight of lanthanum by analysis of lanthanum bromide. Lanthanum ammonium nitrate which had already been brought to a high state of purity in an earlier investigation was subjected to thirty series of fractional crystallizations. After conversion to bromide this salt was carefully dehydrated in a current of dry nitrogen and hydrogen bromide in such a way that melting of the hydrate was avoided, and the salt was finally fused in an atmosphere of pure hydrogen bromide. After being weighed the salt was dissolved and compared with silver in the conventional way and finally the silver bromide was collected and weighed. The following table gives weights corrected to vacuum. The fractions of lanthanum are numbered in the order of increasing solubility of the double nitrate, No. 371 representing the head fraction of the last series of crystallizations.

THE ATOMIC WEIGHT OF LANTHANUM

Fraction	Wt. of $LaBr_3$	Wt of Ag	Ratio $LaBr_3:3Ag$	At. wt. of La	Wt. of AgBr	Ratio $LaBr_3:3AgBr$	At wt. of La
376	4.01090	3.42801	1.170037	138.923	5.96743	0.672132	138.923
379	5.19186	4.43727	1.170057	138.929	7.72475	.672107	138.909
372	6.57727	5.62133	1.170056	138.929	9.78548	.672146	138.931
371	6.38414	5.45612	1.170088	138.939	9.49843	.672126	138.920
372	6.91830	5.91287	1.170061	138.931	10.29285	.672146	138.931
371	6.19359	5.29339	1.170041	138.924			
		Average	1.170057	138.929		.672131	138.923

The average value of the two methods, 138.926, is slightly higher than the value previously found by Baxter, Tani and Chapin, corrected for a new determination of the density of lanthanum chloride, 138.916. The

(14) Baxter and Behrens, *ibid.*, 54, 591 (1932).

average, 138.92, is probably nearer the truth than that recently given in the International table and the atomic weight of lanthanum is therefore changed in the table from 138.90 to 138.92,

Thallium.—Briscoe, Kikuchi and Peel[15] have redetermined the atomic weight of thallium by comparison of the chloride with silver. The processes of purification consisted in repeated crystallization of thallous sulfate and chloride, prepared from (A) English thallium of unknown origin and (B) German thallium obtained from Westphalian pyrites. The novel feature of the investigation lies in the method of titrating the chloride with silver. A few milligrams (2–3) excess of silver was added in every case to the thallous chloride solution and after standing and settling the supernatant solution (6–7 liters) was decanted, evaporated to small bulk and the silver content estimated by titration with *n*/1000 thiocyanate. Vacuum weights are given in the following table.

Exception may be taken to the analytical method, which was adopted because of alleged uncertainty in the conventional nephelometric method of comparison. The large bulk of supernatant liquid and washings must

---

(15) Briscoe, Kikuchi and Peel, *Proc.* ROY. *Soc.*, (London) **A133**, 440 (1931).

have contained many milligrams of dissolved silver chloride, since the excess of silver used was very small. The ultimate fate of this silver chloride is difficult to guess but it is hard to believe that the titration of the excess of silver was not seriously affected by it especially in view of the well-known disturbance of the thiocyanate titration of silver in the presence of silver chloride. In fact it is hard to understand why the excess of silver in the individual experiments was so small as actually found. The effect of this difficulty would be, however, to raise rather than lower the atomic weight of thallium so that it is surprising that the atomic weight found is lower rather than higher than that recently found by Honigschmid, 204.39.

One experiment in which the nephelometric method was used showed erratic behavior, the final result for the atomic weight of thallium being 204.43.

The ratio of thallium to thallous nitrate also was determined. Buttons of fused electrolytic thallium were polished with chamois, fused in hydrogen and bottled in nitrogen for weighing. Solution in nitric acid followed by repeated evaporation with oxalic acid and fusion of the residue failed to give a product of constant weight, so that the authors consider the method (Crookes) unreliable. The results of two experiments are given in which the final weight of thallous nitrate is employed.

Tl	$TlNO_3$	At. wt., Tl
12.08412	15.74910	204.42
12.33736	16.07846	204.46

The results of both methods seem of doubtful value.

Johnson[16] claims that the equal opalescence method of titrating halogen compounds with silver is insensitive and gives erroneous results, and that the silver halide is probably contaminated with adsorption products. A new method of finding the end-point is proposed, by comparing the test solution with standard solutions of the reactants containing known amounts of silver and halide.

Wild[17] has compared the values for $1 + \lambda$ as found (1) by extrapolation of high pressure measurements of PV, (2) from low pressure measurements of PV, and (3) from gas density determinations. In computing the high pressure values the expression $PV = A + Bp + Cp^2 + Dp^4$ was employed. In case of the low pressure and density determinations the relation of PV to P is assumed to be linear.

Atomic Weights from Isotopes

A comprehensive report of the German Chemical Society by Hahn[18] covers the year 1931.

The question of the conversion factor from the physical to the chemical scale still seems to be unsettled. Birge and Menzel[19] prefer the Mecke and Childs value, 1.00022, to that of Babcock and Naudé, 1.00012. Aston[20] has been successful in photographing the lines of $O^{16}O^{17}$ and $O^{16}O^{18}$ of sufficient intensity for comparison with O_2^{16}. From the relative intensities 1 : 4 : 1072 the relative abundance of O_{17}, O_{18} and O_{16} is 0.24 : 1 : 536, a result which seems to support the ratio of O^{18} to O^{16} found by Mecke and Childs, 1 : 630. Since the accuracy of the mass spectrograph is admittedly no greater than $^1/_{10,000}$ and the uncertainty of the conversion factor obviously is as large, while the measurement of isotopic ratios has inherent uncertainties, the degree of precision of the determination of atomic weights from mass spectrographic data still seems to be inferior to that of the best chemical methods, although the striking concordance of the two methods in most cases is reassuring.

Recent results obtained by Aston[21] with the mass spectroscope are given in the following table. The factor used for conversion from the physical to the chemical basis is 1.000125.

Hydrogen.—Urey, Brickwedde and Murphy,[22] by spectroscopic examination of the least volatile fractions remaining from the evaporation of large quantities of liquid H_2, have detected the lines corresponding to the principal series of H^2. Examination of the spectrum of ordinary hydrogen indicated the proportion to be approximately 1 in 4000. Bainbridge[23] finds the mass of H^2 to be 2.01353 assuming He = 4.00216 and H^1 = 1.00778. The atomic weight of hydrogen is therefore slightly higher than the value for H^1 found by Aston.

Mercury	Hg	80	200.61				

Lithium.—Van Wijk and van Koeveringe[24] and Nakamura[25] from a study of band spectra find a low value for the isotopic ratio of Li^7 to Li^6, and the corresponding atomic weight 6.89.

Boron.—Elliott[26] by a study of the band spectrum of boron monoxide finds the isotopic relationship 3.63 and the atomic weight 10.794.

Lithium, Sodium, Potassium, Cesium.—Bainbridge,[27] using a Dempster mass spectrograph, finds the ratio of the abundance of the lithium isotopes to be independent of the temperature of the source of the ions. The abundance ratio was determined in three experiments to be 10.75, 11.28 and 11.51, average 11.18, while Aston finds the ratio 11.

Sodium was found to contain less than $^{1}/_{3000}$ of Na^{21} or Na^{25} and less than $^{1}/_{800}$ of Na^{22}, if any, while potassium was found to be free from more than $^{1}/_{1500}$ of K^{43}, $^{1}/_{600}$ of K^{42} and $^{1}/_{300}$ of K^{40} referred to K^{39}.

Bainbridge[28] supports Aston's conclusion that the cesium mass spectrum is simple. The discrepancy between the atomic weights determined by chemical and physical methods is far larger than the apparent error of either.

Zinc.—The mass spectrum of zinc[29] obtained with a new form of discharge tube which avoids the presence of zinc hydrides gave no evidence of the isotopes Zn^{65} and Zn^{69} reported by Aston. The atomic weight recalculated from Aston's ratios, assuming the relation of the metallic line to the corresponding hydride to be that of the lines 64 and 65 in Aston's spectra, is found to be 65.33, with the conversion factor 1.00022.

Tellurium.—Additional isotopes of tellurium[30] of mass numbers 122, 123, 124 (and 127?) were discovered, the mass numbers and percentages of the complete spectrum being as follows

122	123	124	125	126	127	128	130
2.9	1.6	4.5	6	19.0	?	32.8	33.1

With Aston's packing fraction -5×10^{-4} and the conversion factor 1.00022 the atomic weight of tellurium is calculated to be 127.58, a value in much closer agreement with the chemical value than Aston's, 128.03.

Polarity in Certain Hydrocarbon Vapors

BY K. B. MCALPINE AND C. P. SMYTH

The measurements in the present paper were carried out in order to examine closely certain important molecules possessing little or no polarity. The dipole moments have been calculated from the dielectric constants determined for the substances in the vapor state, the familiar Debye equation being used. In this equation[1]

$$P = a + b/T \tag{1}$$

the polarization $P = \frac{\epsilon - 1}{\epsilon + 2} V$, where ϵ is the dielectric constant and V the molar volume. For an ideal gas, $V = RT/p'$, so that the polarization may be written

$$P = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{RT}{p'} \tag{2}$$

The actual pressure p of a gas under observation may be corrected to the pressure p', which it would exert if it were in the ideal condition and occupying the volume V, by means of the equation

$$p' = p\left[1 + \frac{p}{RT}\left(\frac{a}{RT} - b\right)\right] \tag{3}$$

This equation is derived simply from the van der Waals equation, a and b being the constants of this latter equation, different from the a and b of the Debye equation. Putting in numerical values

$$P = 62{,}371 \left(\frac{\epsilon - 1}{\epsilon + 2}\right) \frac{T}{p'} \tag{4}$$

where p' is expressed in millimeters.

Experimental Method

As the apparatus employed in measuring the dielectric constants was similar in many respects to that used by Zahn,[2] no detailed explanation of the symbolic diagram of it in Fig. 1 is given. Two circuits, I and II, were maintained in a condition of sustained oscillation by electron tubes, the wave length used being about 500 meters, corresponding to a frequency of 6 X 10^5. The individual frequencies were adjusted so that a beat note of 1000 cycles was produced, which could be picked up by a detector–amplifier system and compared with the 1000 cycle note emitted by a Leeds and Northrup hummer. The reference beat note, relative to which all adjustments in the measuring condenser system were made, was the frequency of the hummer, the identity of the beat note between the oscillators and the note emitted by the hummer being indicated by the absence of throbbing in the ear phones. The two oscillatory circuits were shielded by enclosure in large, wooden boxes covered with galvanized iron. Precise adjustment of the frequency of circuit II was made by turning a grounded brass disk D in such a way as to vary its distance from the circuit, changes of a small fraction of a cycle per second being thus securable. All adjustments of the condensers and switches were made from the outside by means of glass rods passing through the boxes.

The gas condenser C in Fig. **1** consisted of two concentric cylinders, of pure copper tubing, 0.3 cm. thick and **13.4** cm. long, the outer grounded cylinder having an external diameter of 6.1 cm. and a separation from the inner of 0.07 cm. The cylinders were, at first, gold-plated, but, as the plate developed imperfections at the higher temperatures used, it was ground off and the pure copper surface employed. When not in use, the apparatus was kept filled with nitrogen to prevent gradual oxidation of the copper. The ends of the inner cylinders were fastened with silver solder and a copper rod holding it in place was insulated from the outer cylinder by quartz rings. The outer cylinder was wrapped with a thin sheet of mica, around which was wound a platinum resistance thermometer. The leads from the thermometer coil and those from the condenser were silver-soldered to tungsten wires, which were sealed through four tubes at the top of the thick-walled 65 mm Pyrex tube T enclosing the condenser (Fig. **2**). Two of these tubes and the **2** mm. capillary D leading to the vacuum system are shown in Fig. 2. The tube T was mounted in a cylindrical electrostatic shield S, closed at the bottom to prevent oil from coming up around the lead tubes. To prevent convection currents within the shield at high temperatures, it was found necessary to provide the top of the shield with a coil H, heated by direct current, which was completely shielded from the ungrounded lead U of the condenser by means of grounded brass plates P. S was bolted securely to a cover consisting of two sheets of *6*.4 mm. asbestos **A,** reinforced by a grounded sheet of **3.2** mm.

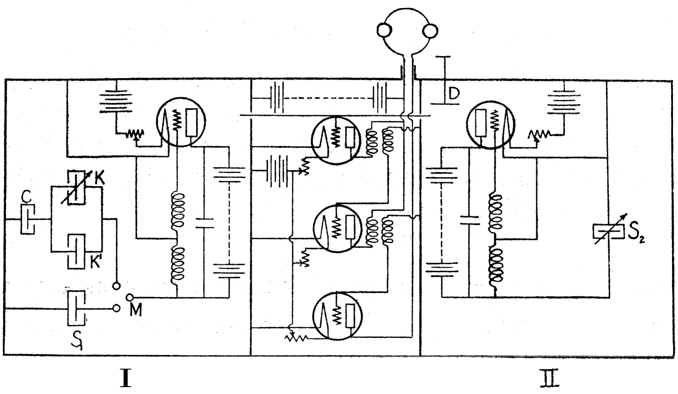

Fig. 1.—Diagram of circuits.

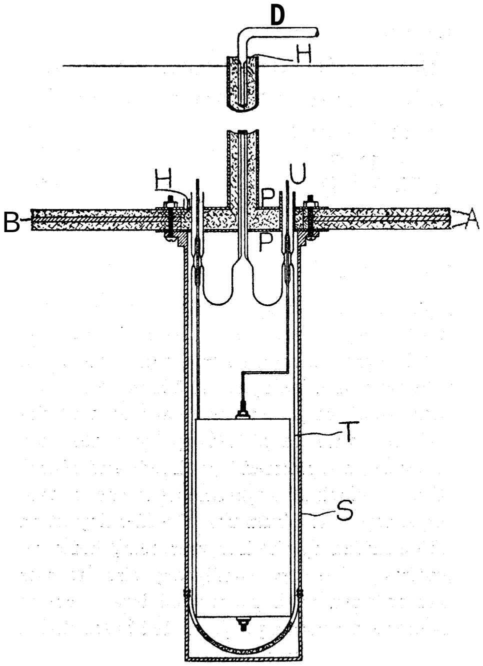

Fig. 2.—Gas condenser and shield.

brass B. The whole was then mounted in a large shielded box into which a large oil heating bath or toluene cooling bath could be inserted without introducing capacity effects. To prevent radiation from the oil-bath from reaching the rest of the oscillatory circuit, the condenser box was situated outside the main generator box, the lead from the condenser being brought through **an** opening in the latter box and supported by a notched sheet of mica fastened over the opening.

Because of small changes in the distributed capacity and inductance of the oscillatory circuits resulting from changes in the room temperature, the filament heating current, and the plate voltage, the beat oote between the oscillators showed a slow and often irregular drift in frequency. In order, therefore, to provide a reference capacity which could be considered as constant during the period of a run, a **1000** $\mu\mu$**f.** variable air condenser S_1 (Fig. **1)** was set in an electrostatic shield immersed in an oil-bath and so connected that the turn of a mercury switch M substituted it in circuit **I** in the place of the gas condenser system. The beat note could then be brought back to **1000** cycles by adjustment of D in circuit **II**.

For the manipulation of the gases, a system of reservoirs, traps, and purification tubes was used in connection with a mercury vapor pump. The gas pressure was read on a large mercury manometer provided with a steel scale. Liquids were vaporized in the apparatus from a U-tube which served as a pressure gage in the manner described hy Zahn.[3]

The gas cell C was connected in series with the two parallel capacities *K* and *K'*, *K* being a General Radio Company Type **222** variable precision condenser of **1500** $\mu\mu$f. capacity. The capacity *C* of the gas condenser when evacuated is made up of a geometrical capacity C_0, which becomes ϵC_0 when gas is admitted, and a fixed capacity L dependent upon the leads and insulators. When gas is admitted to *C*, the increase in its capacity *AC* must be balanced by a change *AK* in *K* in order to hold the frequency constant. The dielectric constant ϵ of the gas is then given by the expression

$$\epsilon - 1 = \frac{C^2}{C_0} \frac{(-\Delta K)}{(K + K' + C)\Delta K + (K + K')^2} \qquad (5)$$

in which the value of AK is **negative.**[2]

The precision condenser *K* was very carefully calibrated in position in the apparatus by a method similar to that previously described by one of the **writers.**[4] The condenser scale divisions, of which there were **2500,** were used as convenient units of capacity. The probable error in *AK* was **0.3** scale division. At first, *K'* consisted of three mica condensers of **1200, 2400** and **4800** $\mu\mu$**f.** capacity in parallel, but as these condensers showed a slight, irregular variation in capacity with the passage of time they were replaced by two variable air condensers, which showed no change with time. The capacity of these two condensers, which were used at their maximum value, was determined by a careful step-by-step calibration as K' = **7097 ± 2** scale divisions on the precision condenser.

The fixed capacity through the quartz insulators in the gas condenser was calculated from the dimensions and the known dielectric constant of quartz as **7.3 ± 0.7** scale divisions. The capacities of the various leads were very carefully determined by the usual methods of short-circuiting or disconnecting the condensers and of setting up imitation leads. The values expressed in scale divisions for the different capacities involved were *C* = **448.6 + 0.7, L = 23 3 + 1.4,** C_0 = **425.3 * 2.1.** An attempt made to determine C_0 and L in the manner commonly used in measurements on liquids by measuring the cell empty and again filled with pure benzene gave less accurate results and was abandoned. The value of *K* needed in the equation for $\epsilon - 1$ was determined

for a number of settings on the high part of the scale by tuning the oscillators to zero beats, short-circuiting C, and changing K by an amount ΔK until the original frequency was restored. K was then calculated from the equation for series capacities. When all the errors in the calibration and capacity determination are taken into account, it appears that the probable error in the absolute value of $\epsilon - 1$ arising from these causes is 0.9%. The relative error from these causes should be less than 0.2%.

During the course of a run the temperature of the gas cell was maintained constant to 0.02° by means of the bath surrounding it. This control was necessitated by the excellent thermal insulation which, unfortunately, existed between the two cylinders of the condenser. A rapid temperature rise of as much as 0.2° caused an unequal expansion of the two cylinders with a resulting change in capacity, and the temperature change resulting from change in gas pressure made it necessary to delay a capacity reading for half an hour after the pressure change had been effected in order that the temperature might become uniform.

The difficulty of temperature equalization made it impossible to obtain an accurate value for the capacity of the evacuated condenser directly. In the most satisfactory method of obtaining it a reading was taken on the precision condenser with the gas or vapor in the condenser at 20–30 mm. pressure and another at 100–150 mm. When these two precision condenser readings were plotted against p' and a straight line drawn through the points, the intercept of the line at $p' = 0$ gave the vacuum reading. The values of $(\epsilon - 1)/(\epsilon + 2)$ were then calculated directly. When working with vapors at low temperatures, measurements were made at several pressures in order to detect possible condensation. The values of $(\epsilon - 1)/(\epsilon + 2)$ were then plotted against the corrected pressures p'. Any condensation was evidenced by a departure of the points for high pressure from the straight line through the lower points. The effect of any drift in the circuits outside the gas condenser was eliminated by repeating every run in the reverse direction.

In order to determine by actual experiment the accuracy of the measurements, a large number of determinations were made upon air carefully dried and purified by passage through a soda lime tower, and upon carbon dioxide, taken from a cylinder and repeatedly fractionated by condensation with liquid air. The values of $\epsilon - 1$ were reduced to 0° and 760 mm., the perfect gas law being employed for air and the van der Waals equation for carbon dioxide. For air, the average deviation from the mean of twenty-three measurements was 0.41%, and, for carbon dioxide, the average deviation in twenty-one measurements was 0.33%. The values have been compared with the results of fifteen other investigations, of which the two most extended and reliable gave the values shown in Table I for comparison with those of the present investigation. At the bottom of the table are the values of $n_\infty^2 - 1$, n_∞ being the index of refraction extrapolated to infinite wave length. Since, for carbon dioxide, correction has been made for infra-red absorption[6] and since, for air, this absorption can be neg-

lected, $n^2_\infty - 1$ should, in the absence of a dipole moment, be identical with $\epsilon - 1$. The ratio of the value for carbon dioxide to that for air is given in the last column.

The results of the present investigation are approximately 1.5% higher than those of Zahn but differ by less than the small average deviation from the mean from the more recent results of Stuart. The close agreement of the ratio with Zahn's ratio shows the difference in the absolute values to be a matter of the respective calibrations, as this difference is within the limits permitted by the errors assigned to the two calibrations. The recent determination of $(\epsilon - 1) \times 10^6$ for nitrogen, 589, by Andrews[9] is higher than Zahn's value 580 by just the same amount as the difference between the value for air in the present work and that of Zahn. It appears probable, therefore, that the values of $(\epsilon - 1) \times 10^6$ for air and carbon dioxide are slightly higher than those given for $(n^2_\infty - 1) \times 10^6$.

Purification of Materials

Benzene.—Merck's C. P. crystallizable benzene was shaken repeatedly with concentrated sulfuric acid, water, dilute sodium hydroxide, and more water, dried over calcium chloride, and crystallized three times (m. p. 5.50°). It was then refluxed over phosphorus pentoxide, distilled, refluxed over sodium wire, and distilled again; b. p. 80.2°; n^{25}_D 1.49823.

Toluene.—Merck's C. P. toluene was washed with concentrated sulfuric acid, water, dilute sodium hydroxide solution, and again with water, shaken with pure mercury, filtered, and dried first with calcium chloride, then with phosphorus pentoxide, and, finally, by refluxing over molten sodium and subsequent distillation; b. p. 110.5°; n^{20}_D 1.4955. A second portion treated in the same way, except for the omission of the refluxing over sodium, had the same constants. A third portion was treated like the first except that between the drying with calcium chloride and that with phosphorus pentoxide, it was crystallized in an ether-bath maintained at –105–110°; b. p. 110.5–6°; n^{20}_D 1.49564. This was distilled directly from the sodium into the gas system of the apparatus for the dielectric constant measurements.

Propane and **Propylene.**—Gases of high purity from the Linde Air Products Company were passed through phosphorus pentoxide into the gas system of the apparatus, where they were repeatedly fractionally distilled.

Experimental Results

When $(\epsilon - 1)/(\epsilon + 2)$ is plotted against p', which is obtained by use of equation (3), the values of the van der Waals constants being taken from Landolt–Bornstein, the slope of the resulting straight line is used to calculate the polarization, since, from equation (4), it follows that

$$P = 62{,}371\ T\Delta\frac{\epsilon - 1}{\epsilon + 2}/\Delta p' \qquad (6)$$

A line was obtained at a given temperature by determining points from pressures of 10–30 mm. up to 800–1100 mm., then down to low pressure again to make sure that no change had occurred during the course of the run. Several such runs were made at each temperature and a value of P obtained from the line for each run, The average value at each tempera-

calculate the values of the constants in equation (1), which are given in Table III. The value of the refraction for infinite wave length, P_E, was obtained by extrapolation from the dispersion data for liquids in Landolt-Börnstein and the values given for the atomic polarization calculated as $P_A = a - P_E$. The electric moment μ was calculated from b as $\mu = 0.0127 \times 10^{-18} \sqrt{b}$, the probable error in the two virtually zero values being 0.05×10^{-18}, and in the other values 0.02×10^{-18}.

TABLE III

VALUES OF FUNDAMENTAL CONSTANTS

Substance	a	P_E	P_A	b	$\mu \times 10^{18}$
C_6H_6	27.0	25.1	1.9	−18	0
C_7H_8	32.5	29.8	2.7	841	0.37
C_3H_8	16.0	15.7	0.3	18	0
C_3H_6	15.7	15.1	.6	745	0.35

After the submission of these results for publication, a new method for the elimination of error due to deviation from the ideal gas laws was adopted in later work to be described elsewhere. Polarizations calculated by means of the ideal gas law are plotted against the pressure and the curve thus obtained is extrapolated to zero pressure to obtain a polarization value unaffected by deviations from the ideal gas law. In propane and propylene, the deviations are so small that the different method of calculation leaves the results in Table II unaltered. For benzene, the polarization values are lowered about 0.5% by the new method of calculation and, for toluene, about 1.2%. The changes in the constants calculated from these polarizations are shown below to be negligible or almost so.

BENZENE			TOLUENE		
T, °K.	P		T, °K.	P	
325.9	26.77	$a = 27.0$	357.3	34.46	$a = 32.3$
375.1	26.94	$b = -55$	378.9	34.18	$b = 740$
428.8	26.96	$\mu = 0$	431.8	34.02	$\mu = 0.35 \times 10^{-18}$
480.1	26.84	$P_A = 1.9$	481.7	33.84	$P_A = 2.5$

Discussion of Results

The mean value, 27.01, of the polarization of benzene vapor, which is independent of temperature, is slightly higher than the values for the liquid, 26.62 at 10° and 26.78 at 60°,[10] which increase slightly with rising temperature, and lower than the value for the solid, 28.5 at 0°, found by Morgan and Lowry. The absence of variation with temperature in the polarizations of benzene and of propane is in contrast to the small but definite increase observed in liquid benzene and in marked contrast to the uniform increase observed in all the liquid paraffins which have been studied over a wide range of temperature.[11] This difference in behavior between the liquid and the vapor is important since it shows that the increase in polarization with rising temperature in the liquid cannot be due to any direct intramolecular effect of temperature, for such an effect would be

apparent in the gas also. As the values of P_E for benzene and toluene are calculated directly from measurements on the liquids and those for propane and propylene as the sum of the atomic refractions obtained from measurements on liquids, it is evident that the values of P_A must be regarded as approximate. The most accurate measurements on the refraction of benzene vapor,[12] when extrapolated to infinite wave length, give a value 26.22 for P_E, which gives $P_A = 0.8$, possibly more accurate than the value in Table III and lower than the values 1.5–1.9 obtained as the difference between the solid and the liquid. Similar use of the refractive index determined for propylene by Trautz and Winkler[13] gives $P_A = 1.0$, higher than the value in Table III. The discrepancies among the results of different investigators of the refraction of vapors make it doubtful whether the P_A values obtained by using the values of the vapor refractions are more accurate than those in Table III, which are certainly comparable with one another.

Krchma and Williams[14] and Williams and Ogg[15] measured benzene in three different solvents, obtaining for the polarization in carbon tetrachloride, 26.7, in carbon disulfide, 28.5, and in hexane, 27.8, and, from these values, using $P_E = 25.8$ and neglecting P_A, values of 0.06×10^{-18}, 0.09×10^{-18}, and 0.08×10^{-18} for the moment of the benzene molecule. An error occurred in these calculations for recalculation from the same data gives 0.21×10^{-18}, 0.39×10^{-18}, and 0.31×10^{-18}, values slightly higher than the figure 0.2×10^{-18}, calculated previously by one of the writers as a value indistinguishable from zero by the method employed.[16] Although it has been generally assumed that the moment of the benzene molecule is zero,[17] it is reassuring to obtain definite experimental evidence that it is within 0.05×10^{-18} of zero. The negative value, -18, of b in Table III has no significance nor has the positive value 18 for propane, both showing merely that the value of the moment is within 0.05×10^{-18} of zero.

The propane molecule may be pictured as a tetrahedral carbon atom with hydrogens on two apices and methyl groups on two. Two planes of symmetry perpendicular to one another may be drawn through the central carbon atom, but, when a third plane perpendicular to these two is drawn, it is apparent that the two hydrogens are on one side of it and the two methyl groups on the other. Because of the tetrahedral angle, any moment in a C–H bond of one of the methyl groups has a component in the direction of the C–C line equal to one-third of its value. The three C–H bonds of the group have, therefore, a resultant moment equal to that of a single C–H bond. The moments in the C–H bonds of the methyl groups

would, consequently, cancel moments of equal size in the two C–H bonds on the central carbon and any moment in the molecule as a whole would have to arise from polarity in the C–C bonds, from inequality in the moments of the C–H bonds of the primary and secondary carbons, or from distortion of the tetrahedral structure by repulsion in such a way as to prevent compensation of the moments of the two central C–H bonds by those of the methyl C–H bonds. If propane had the maximum moment, 0.05×10^{-18}, permitted to it by the accuracy of the measurements, it would be equivalent to the effect of the displacement of a pair of electrons 0.005 Å. from a position of symmetry. Although it is likely that the propane molecule may have a very small moment, it is evidently so small that any polarity in the C–C bonds, electrical dissymmetry caused by repulsion between the different parts of the molecule or difference in electronegativity between the hydrogens on the secondary and those on the primary carbons may be regarded as undetectable by means of the electric moment. This result is in harmony with the absence of any detectable moment in the isomers of heptane and with the consequent absence of variation in the electronegativities of the alkyl radicals detectable by this means.[11a]

The value obtained for the moment of toluene is in excellent agreement with the very approximate value 0.4×10^{-18} found for the liquid.[14,16,18]

The closeness of the accurately determined value[19] for a-butylene, 0.37×10^{-18}, to that for toluene in the present paper and to the 0.35×10^{-18} found for propylene are very striking. It is evident that, although the replacement of a hydrogen by a methyl group in a saturated aliphatic hydrocarbon gives rise to no moment, a similar replacement of a hydrogen attached to an unsaturated carbon gives rise to a definite electrical dissymmetry. Calculation shows that if the C–H bond has a moment of about 0.4×10^{-18} associated with it as commonly supposed,[20] inductive effects should give rise to moments of the magnitude found for these unsymmetrical molecules.

The writers wish to express their gratitude to Dr. C. T. Zahn for his advice on the construction of the apparatus.

Summary

An apparatus for the accurate measurement of the dielectric constants of gases and vapors has been constructed and tested by repeated measurements upon air and carbon dioxide. Values have been determined for benzene, toluene, propane and propylene and used to calculate their polarizations and electric moments.

The absence of any change in the polarizations of benzene and propane with rising temperature indicates that the increase previously observed

with rising temperature in a number of liquid paraffins is due to decrease in intermolecular action.

The zero moment found for the benzene molecule agrees with the less accurate results of the measurements upon the liquid and with the symmetrical structure of the molecule. The zero moment found for propane is consistent with the absence of moment in the higher members of the series and shows that any polarity in the C–C bonds, electrical dissymmetry caused by repulsion in the molecule or difference in electronegativity between the hydrogens on the secondary and those on the primary carbons is too small for detection by means of the electric moment.

The small moments found for toluene and propylene are of the same magnitude as those which might arise from inductive effects in the molecules.

The Possibility of Dipole Rotation in Certain Crystalline Solids

BY S. E. KAMERLING AND C. P. SMYTH

This paper presents the results of an investigation undertaken with the object of studying a possible contribution to the dielectric constants of certain substances through the rotation of a polar group in a molecule fixed in a crystal lattice or through the rotation of the entire molecule in the lattice, the latter possibility having been suggested by the results of Errera.[1,2] When the molecules of a substance are so fixed in the solid state that any dipoles contained by them are unable to orient at all in an externally applied electric field, the dielectric polarization of the substance consists only of the so-called optical part, $P_E + P_A$, which should be virtually independent of temperature and of frequency within the range ordinarily used in dielectric constant measurements. Any considerable variation of polarization with temperature or frequency should, therefore, be evidence of dipole orientation, that is, of rotation of polar groups or molecules in the solid. In the present measurements, a certain number of molecules are placed between the plates of a condenser by filling the condenser with liquid, which is then frozen. Consequently, as the temperature is lowered, the number of molecules between the plates is not appreciably altered by the changing density of the solid and the apparent value observed for the dielectric constant should not alter with the density. Although this apparent value of the dielectric constant evidently differs by a small but increasing amount from the true value as the temperature falls below the freezing point, it makes an excellent substitute for the polarization, which

is hard to obtain because of the difficulty of measuring the densities of the low melting solids as well as the true dielectric constants.

Apparatus

The apparatus used in measuring the dielectric constants was the capacity bridge employed in a previously described investigation,[3] which was actually carried out after the measurements of the present paper Current of a pure sine wave form and of frequencies from 200 to 50,000 cycles was supplied to the bridge from an 8A Western Electric oscillator. At the higher frequencies, a six-tube amplifier with a detector and a multimeter as null instrument was used with the bridge, while, at lower frequencies, a two stage transformer-coupled audio frequency amplifier was employed. A resistance in series with the condenser in each of the two capacity arms of the bridge served to balance any conductance in the other capacity arm. As the only appreciable conductance occurred in the measuring condenser, the series resistance in the opposite arm provided a means of calculating the phase angle of this condenser.4 In the present work, however, only qualitative use has been made of this resistance. When it was large, *a* considerable error was introduced into the results by the capacities of the coils of the non-inductively wound decade box used as the series resistance.

The other apparatus and methods were similar to those described in previous papers from this Laboratory except in the modification of the measuring condenser and its use. A platinum resistance thermometer cased in glass was inserted inside the innermost of the three concentric gold-plated cylinders of the condenser. Before solidification of the liquid in the condenser, dissolved gas was commonly pumped off as far as possible with a water pump. In spite of this, the occurrence of gas pockets and cracks in the solid tended to lower the value observed for the dielectric constant. The solid was melted and slowly frozen again from the bottom up after the cell had been tapped to drive off gas bubbles. This process was repeated several times until an approximately constant value was reached for the dielectric constant, which was then measured at different temperatures below the melting point and at different frequencies. A 10 or 12% increase in the observed value might be brought about by these successive freezings The dielectric constant observed was evidently a minimum value, but the values observed for a given solid were fairly accurate relative to one another, except at the lowest frequencies where it was difficult to balance the bridge.

Preparation of Materials

n-**Heptyl** bromide was obtained as in earlier work.[5]

Anisole.—Kahlbaum anisole was dried with calcium chloride and fractionally distilled. The middle fraction boiling at 153.9–154.1° (769 mm.) was used; n_D^{20} 1.51732; d_4^{20} 0.9951.

Phenol.—Merck "Reagent" phenol was melted and fractionated The fraction boiling at 181.6° (756 mm.) was used.

Benzoyl Chloride.—Eastman Kodak Company benzoyl chloride was fractionally distilled. The middle portion was again distilled, the fraction boiling constantly at 197.9° being used; n_D^{20} 1.55354; m. p. −0 6°.

Experimental Results

The apparent values determined for the dielectric constants ϵ at the temperatures t and at various frequencies from 50 to 0.2 kilocycles are given

in Table I. In Table II the rounded values of ϵ at 50 k. c. and the densities obtained from various sources are used to calculate approximate values of the molar polarization, $P = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{M}{d}$. The values of the atomic polarization P_A are obtained by subtracting from P the values of the electronic polarization P_E obtained by the extrapolation to infinite wave length of data on refraction taken directly from or calculated from material in Landolt–Bornstein (5th edition).[6]

Discussion of Results

A rough attempt has been made to calculate P_A for heptyl bromide because of the surprisingly high value, 15.5, found for it by Smyth and Rogers by means of the variation of the polarization with temperature in solution.[5] The value in Table II is in excellent agreement with that given by the solution measurements, but, if the density of the solid were 10% higher, as is not impossible, the value of P_A given by the solid would drop to 8. The values of P_A for the other substances are of the magnitude usually found for polar molecules of fair size.[7]

The values in Table I show positively that heptyl bromide, hydroquinone dimethyl ether, and anisole give no dipole orientation in the alternating electric field in the ranges of temperature and frequency used. This means not only that the large polar molecules do not turn as a whole in the field but also that the polar CH_3—O group, which might be mobile about its bond to the ring, is not turned by the field. The results on phenol and benzoyl chloride are inconclusive. The dielectric constants increase somewhat with rising temperature and decreasing frequency of the field in the manner that might be expected if an occasional molecule or polar group attached to the ring were able to turn in the field. However, the same effects could arise from the displacement in the field of small amounts of ions, which would be more important as the melting point was approached and the frequency lowered. As phenol and benzoyl chloride are difficult substances to obtain in a very pure state, it appears probable that the small variation of dielectric constant observed is due to the presence of impurities rather than to any motion of the large molecules as a whole or of their polar groups.

Summary

A low frequency capacity bridge is used to measure the dielectric constants of certain crystalline solids over a range of temperature from the melting point down and at frequencies from 200 to 50,000 cycles. Heptyl bromide, hydroquinone dimethyl ether and anisole show no turning of the molecules or of their polar groups in the externally applied field, while, in phenol and benzoyl chloride, effects which might indicate such turning are attributed to the presence of small quantities of impurities. The atomic polarizations of three of these substances are calculated.

Application of the Gibbs Adsorption Theorem to Solid–Liquid Interfaces

BY F. E. BARTELL, F. L. MILLER AND E. G. ALMY

The Gibbs adsorption theorem expressed in the well-known approximate form[1]

$$u = -\frac{c}{RT} \times \frac{\mathrm{d}\,S_x}{\mathrm{d}\,c}$$

has been used by many different investigators in the study of adsorption at liquid–air and liquid–liquid interfaces. Although it has been assumed that the formulation should apply to liquid-solid interfacial systems, it has heretofore not been used because no method has been available for the measurement of the interfacial tension between a solid adsorbent and solution. The recent work of Bartell and Osterhof on adhesion tension[2] has made possible the application of a modified form of the equation to solid–liquid interfaces.[3]

Numerically, adhesion tension is the difference between two quantities which are themselves quite large but not directly measurable, namely, the surface tension of a solid, S_1, and its interfacial tension against a given liquid, S_{12}; *i. e.*

$$A_{12} = S_1 - S_{12}$$

The Gibbs theorem as applied to a solid–liquid interface would be expressed as follows

$$u = -\frac{c}{RT}\frac{\mathrm{d}\,S_{12}}{\mathrm{d}\,c}$$

The measurements made by the Bartell-Osterhof method give the values for A_{12}, but not those for S_{12}. However

$$S_{12} = S_1 - A_{12}$$

Therefore

$$u = -\frac{c}{RT}\frac{\mathrm{d}(S_1 - A_{12})}{\mathrm{d}\,c}$$

and since the surface tension of the solid is independent of the concentration of the solution, we have

$$\frac{\mathrm{d}\,S_1}{\mathrm{d}\,c} = 0, \text{ and}$$

$$u = +\frac{c}{RT}\frac{\mathrm{d}\,A_{12}}{\mathrm{d}\,c}$$

Accordingly, if the addition of solute tends to increase the adhesion tension of the solid–liquid system, it is to be expected that the solute will be pref-

---

(1) In this equation u represents the excess concentration of the solute per sq. cm. of interface. and S_x refers to the interfacial tension at either a liquid–gas, liquid–liquid or liquid-solid interface. In this paper the different phases involved will be designated by the subscripts 1, 2 and 3, indicating solid and the different liquid phases, respectively. Thus S_0 = Surface tension liquid–gas (or air); S_{23} = Surface tension liquid–liquid; S_{12} = Surface tension solid–liquid.

(2) Rartell and Osterhof, Z. *physik. Chem.*, **130**, 715 (1927); *Ind. Eng. Chem.*, **19**, 1277 (1927).

erentially adsorbed at the interface, *i. e.*, positive adsorption demands that the term dA_{12}/dc be positive.

By measuring the adhesion tensions of a series of binary solutions against silica and applying the equation developed above, the adsorption at any concentration may be calculated. Such measurements and calculations have been carried out. In the systems studied the adsorbent in each case was silica and the liquid adsorbed was ethyl carbonate. Adsorption from each of three solvents, namely, benzene, α-bromonaphthalene and dimethylaniline, was investigated. All of the liquids were first purified, then twice distilled and that fraction coming over at constant temperature was used.

It has been frequently pointed out that the behavior of organic liquids at a silica surface is very similar to that at a water surface. The data presented herein will serve to test this statement. By applying Gibbs' equation to values of the interfacial tension between the binary organic mixtures and water, it is possible to calculate the adsorption at the water interface and to compare the values obtained with those for adsorption from the same systems at the silica interface. Such calculations and comparisons have been made and are included in the tables.

Experimental

Adhesion Tension.—The adhesion tension values for the different: solutions were determined by the Bartell–Osterhof[2] method, which consists in measuring the pressure of displacement of the solution by water from the minute pores formed in a tightly packed membrane of finely divided solid. From the equilibrium displacement pressure measured in the above manner, it is possible to calculate the adhesion tension of the solution against the solid by means of the equation

$$A_{12} = A_{13} - S_{23} \cos \theta_{23}$$

A_{13}, the adhesion tension for water against a given solid is specific for that solid; values had previously been determined for water against silica. These values for water were again checked. Cos θ_{23} was determined by the displacement pressure method mentioned above. With these data A_{12}, the adhesion tension of the second liquid system against the solid, was determined.

The solid used in this investigation was silica. It was Tripoli airfloat silica which had been treated several times with boiling 1–1 hydrochloric acid and repeatedly washed with boiling water after each treatment until no trace of acid was found in the filtrate. This treatment removed the impurities of iron and aluminum salts which were present in the original material. The final product contained less than 0.4% of impurities. All of the silica which would pass through a 350 mesh sieve was saved for this work. Before use the silica was heated in an electric muffle at about 950° for not less than two hours.

Interfacial Tension Determinations.—Measurements of the interfacial tensions of each of the solutions of the different binary systems were made by means of the double cylinder type of interfacial tension apparatus developed in this Laboratory.[4] These measurements were carried out in a small water thermostat, the temperature of which was maintained at 25 ± 0.05°.

The solutions of the different binary systems were made up accurately by weight. Concentrations are expressed in terms of mole fractions. The results obtained are given in Tables I, II and III (column 3).

The interfacial tension–concentration curves (plotted from the data) for each of the three systems were found to be smooth and regular. There was no evidence of a minimum point in any of the curves. The curves were concave upward, indicating preferential adsorption of ethyl carbonate at the water interface from each of the liquids which were used as solvents.

The adhesion tension–concentration curves were found to be similar to those expressing the interfacial tension data except that they were concave downward instead of upward. In the former case the slope d S_{23}/d c was negative, whereas d A_{12}/d c is positive. This is in agreement with the theoretical considerations discussed above. Just as in the interfacial tension–concentration curves there was no indication of any irregularity nor of a maximum point in any of the curves.

Calculation of Adsorption at Silica Interface.—If one plots the values of the adhesion tensions of ethyl carbonate solution–silica against the

logarithm of the concentration of ethyl carbonate (in moles per cc.), a curve is obtained, for each solvent, which straightens out and approaches a constant slope as the concentration of ethyl carbonate increases. Since the adsorption of solute at any concentration is, according to the theorem, directly proportional to the slope of the curve at that point, it appears that "saturation" of the surface by adsorption must have been reached when this slope no longer changes. That is, from this point on the concentration of solute in the interfacial layer is in excess of the bulk concentration by a constant amount.

The calculated values for adsorption of ethyl carbonate by silica from each of the three solvents are given in the tables (column **6**). It is seen that at a silica surface ethyl carbonate is adsorbed from benzene to a somewhat greater extent than from alpha bromonaphthalene, while from dimethylaniline the adsorption is much less.

The values for adsorption of ethyl carbonate at a water interface from the same three solvents are also given in the tables (column 7). The adsorption values shown in this table were calculated by applying Gibbs' equation to interfacial tension concentration data. As in the case when silica was the adsorbent, adsorption is greatest from benzene and least from dimethylaniline—an observation which is in agreement with the widely accepted view that silica and water surfaces behave very similarly toward organic liquids.

Calculation of Area of Adsorbed Molecules.—It is of interest also to compare the calculated area of molecules adsorbed at a silica surface with the calculated area of the same molecules adsorbed at a water surface. Such results are summarized in the tables (columns 8 and 9). The method of calculation is one used by Bartell and Mack[5] which has been designated the "modified mixture law" method. It is assumed that if there were no adsorption the adhesion tension–concentration curve would be a straight line. To determine the concentration of solute in the interface corresponding to any given concentration in the bulk of the solution one needs simply to draw a horizontal line from the adhesion tension-concentration curve to the straight line joining the two ends of the curve. The concentration corresponding to the intersection of the two lines is the concentration of solute in the interfacial layer. This gives the value called "total" moles per cc. in the surface. The adsorption as shown in the previous tables is the excess moles per sq. cm. in the surface. The total moles per sq. cm. is obtained by adding to this quantity the value of $c^{2/3}/N^{1/3}$ in which c is the concentration (moles per cc.) in the solution and N is Avogadro's number. The term $(c^{2/3}/N^{1/3})$ is moles per sq. cm. in the bulk of the solution and when added to the excess moles per sq. cm. in the surface (adsorption) gives the total moles per sq. cm. in the surface. The thickness of the surface layer, then, is given by the quotient

$$t = \frac{\text{total moles/sq. cm.}}{\text{total moles/cc.}}$$

and the area of an adsorbed molecule by

$$a = \frac{M}{Ndt}$$

where d is the density and M the molecular weight.

Bartell and Mack showed empirically that for applying the mixture law method to calculations of this sort, it was more suitable to use volume fraction than mole fraction values in expressing solution concentrations

---

(5) Bartell and Mack, *J. Phys. Chem.*, **36**, 65 (1932).

Consequently in obtaining the area values given in the tables mole fractions were converted to volume fractions and graphs were drawn from which the interfacial concentrations were determined.

The area of the ethyl carbonate molecule adsorbed on silica was found to be practically the same from the three different solvents, which indicates that the adsorption calculated by means of Gibbs' equation and adhesion tension data must be approximately correct. By an exactly analogous method the area of the ethyl carbonate molecule adsorbed at the water interface was calculated. (Column 9 in tables.) It had been previously demonstrated[5] that this method gives reliable values for the area of molecules adsorbed at liquid–liquid interfaces. The close agreement between the calculated area at the water interface and the calculated area at the silica interface is further evidence that the calculation of adsorption at solid surfaces from adhesion tension data is justified.

Summary

1. A method was developed for calculating adsorption at solid–liquid interfaces by means of the Gibbs adsorption theorem using adhesion tension data instead of surface tension or interfacial tension data.

2 Adhesion tension values against silica and interfacial tension values against water were determined for three binary liquid systems throughout the entire concentration range.

3. The order of "maximum" adsorption of a given solute from a series of three organic liquids was found to be the same whether silica or water was used as adsorbent. This is in agreement with previous observations concerning the similarity between a water surface and silica surface in their relation to organic liquids.

4. From the adsorption data and by means of the "modified" mixture law method the area of adsorbed ethyl carbonate molecules was calculated. Six values were obtained using three solvents and two adsorbents. The agreement of the values is remarkably good, justifying in large measure the use of adhesion tension data for calculating adsorption at the solid–liquid interface

The Vapor Pressure of Crystalline Benzene and Cyclohexene[1]

BY V. R. DEITZ

In the course of an investigation concerning symmetry calculations for molecules it was necessary to know accurately the vapor pressure of benzene and cyclohexene in the crystalline state at various temperatures. In order to fill this need the Knudsen method of measuring vapor pressure was modified to fit the requirements of low temperature, and measurements were obtained of the vapor pressure of benzene and cyclohexene in the temperature range 165–200°K.

I. Apparatus

A. Temperature Control.—For temperature control a thermostat was used which was an adaptation from that of Andrews and Southard.[2] A block of aluminum was machined to fit into a standard liter Pyrex Dewar flask, evacuated to about 5-mm. pressure. It was non-magnetically wound with about 80 ohms of constantan resistance wire and contained in the center a 3-cm. hole to take the tube in which the diffusion cell was hung. It also was equipped with thermocouples placed on the inside and outside.

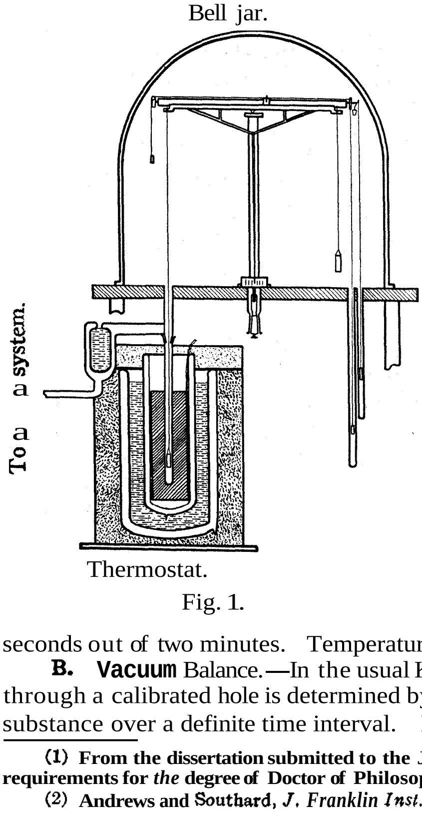

Fig. 1.

The Dewar containing the block was immersed in liquid air contained in a larger one-half gallon Dewar, see Fig. 1. After adjusting the necessary cork insulators, the assembly was raised into position by aid of an auto jack not shown in the figure.

The thermocouples functioned as follows: when the inside thermocouple showed that the temperature desired was being approached, the outside thermocouple current was opposed by the proper e. m. f. from a potentiometer circuit. Hence, when the temperature changed, the galvanometer placed in this circuit reflected a beam of light across a photoelectric cell. This regulation, properly amplified, tripped a relay which caused current to heat the aluminum block. Thus a balance between the cooling effect of the liquid air and the heating of the resistance coil produced a constant temperature. A period of about an hour was necessary before the temperature was constant. Under normal operating conditions, the heating current was on for about three seconds out of two minutes. Temperature control of ±0.05° was readily obtained.

B. Vacuum Balance.—In the usual Knudsen method the amount of vapor escaping through a calibrated hole is determined by noting the loss in weight of the evaporating substance over a definite time interval. Because of the difficulties incident to the low

---

(2) Andrews and Southard, *J. Franklin Inst.*, **207**, 323 (1929).

temperature, it appeared advisable to follow the loss of weight continuously, without removing the diffusion cell from the thermostat.

A Becker analytical balance was mounted on a steel plate and equipped with devices so that it could be operated by controls outside of the vacuum chamber, see Fig. 1. The beam was lifted off and on the knife edges by replacing the usual eccentric mechanism by a screw device. The male screw was fastened to the vertical shaft of the balance release mechanism. The female screw had a flange midway up the side, so placed as to fit into a depression in the surrounding glass tube. The bottom of the female screw fitted snugly into the stopper part of a glass ground joint. This arrangement permitted the turning of the ground-glass stopper to rotate the screw which forced the central shaft up or down.

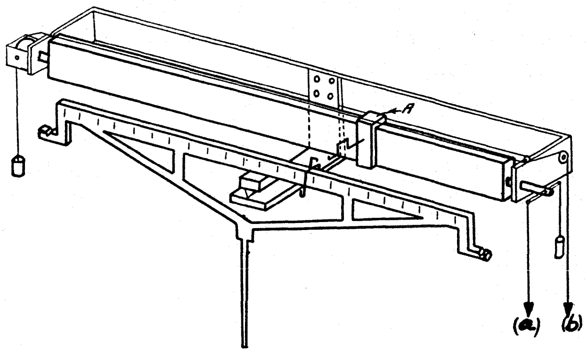

Fig. 2.—Rider adjustment.

A sufficiently heavy rider was used to measure a difference of 0.4 g. The rider was moved along by the mechanism shown in Fig. 2. The carriage A was pulled left or right by means of a solenoid arrangement. Once the carriage was pulled into place under the rider, the carriage was tilted by a second solenoid arrangement so as to pick up the rider. It was then moved into the desired position and lowered on the beam. The weighings were made by the method of swings. The usual index plate of twenty divisions was replaced by one of forty divisions, furnished by Christian Becker, Inc.. New York. The moving pointer was viewed through a telescope, so that the magnification allowed one to estimate tenths of division. Under the conditions and load of the experiment the sensitivity as determined several times averaged 2.05 ± 0.10 divisions per milligram

C. Diffusion Cell.—The substance was placed in a small brass cylinder, see Fig. 3. The platinum disk containing the calibrated hole was held between two thin lead gaskets, compressed by screwing down the top very firmly. The cylinder was threaded with 72 threads per inch. With these precautions, the amount of vapor escaping around the lead washers or down the threaded side was negligibly small.

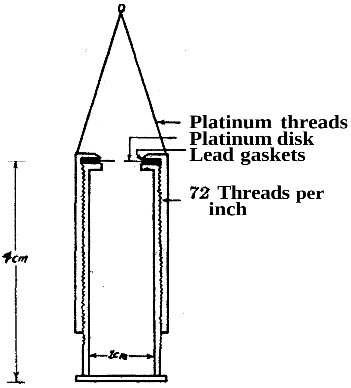

Fig. 3.—Brass diffusion

The freezing point curve of the benzene used in these experiments, after purification, showed the presence of not more than 0.1% impurity, the melting point being

+5.48°. The cyclohexene was purified by Dr. J. H. Bruun of the Bureau of Standards, to whom the author is very grateful. The cooling curve showed the presence of not more than 0.5% impurity; the melting point being −104.1°.

II. Procedure

The diffusion cell containing the substance was suspended from the balance arm and the glass tube put in place surrounding it, see Fig. 1. The system was slowly evacuated with the cell at a temperature of about −20°. This permitted the water vapor to be pumped off without undue loss of benzene. The temperature was then lowered to −78° and the steel mercury diffusion pump was started. After ten hours of pumping, liquid air was placed in the trap nearest the balance. Sublimation occurred then to this trap, instead of through the apparatus to the trap near the mercury pump. The thermostat was cooled in the meantime and quickly slipped into position. While the temperature slowly attained a constant value, the zero of the balance was kept on the scale by adjusting the rider. When the temperature appeared to be constant, readings were begun.

Since preliminary experiments indicated a temperature lag between the cell and the walls of the thermostat, the outside walls of the cell (not the top) were coated with a fine soot. A thermocouple was soldered to a thin copper cylinder which was also covered with soot and placed inside touching the walls and surrounding the cell. Under these conditions the temperature distribution was uniform. A conservative estimate places the temperature control above −100° at ±0.1° and for lower temperatures at 0.3°.

III. Results

It is, of course, necessary to know the total resistance to flow of the vapor from the diffusion cell to the liquid air surface. This was obtained by making several runs with benzophenone and comparing the results with the data of Volmer and Kirchhoff.[3] The value for the total resistance to the flow of the vapor was found to be 726 ± 20 units. There is an advantage in having the resistance at this high figure. In the work of Volmer

TABLE I

t, sec.	Change in scale divisions	Mass (mg.)	m = 1000 sec
900	1.2	0.60	0.65
780	1.1	.55	.70
660	0.95	.45	.70
630	.85	.40	.70
800	1.15	.55	.70
1300	1.9	.90	.70
850	1.15	.55	.65
			0.68 mg.

Hence $p = 7.12$ dynes

[3] Volmer and Kirchhoff, Z. *physik.* Chem., 115, 233 (1926).

and Kirchhoff it was shown that for rapid diffusion of the vapor the surface is cooled quite appreciably. His results show that the values obtained for $w = 17.17$ were 18% lower than for values at $w = 205$. Table I illustrates the type of data obtained for benzene at $T = 195.0°K$.

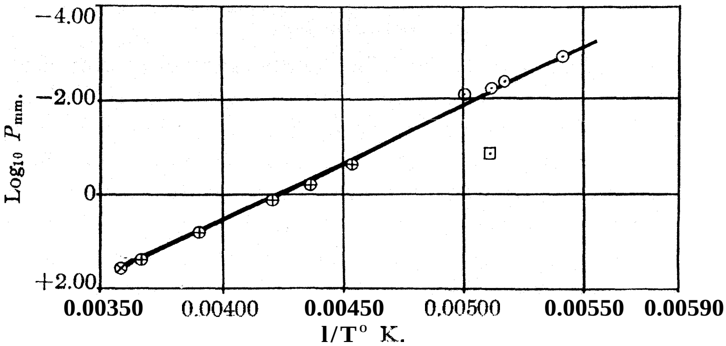

Fig. 4.—⊙, Deitz; ⊕, Mundel;[4] ⊗, Young and Fortey;[5] ⊡, Barker.[6]

Table II summarizes the direct results for benzene and for cyclohexene. The results for benzene are shown in Fig. 4, together with those of previous investigators.[4]

TABLE II

	Temp., °K.	Pressure, dynes
Benzene (s)	200.2	10.40
Benzene (s)	195.0	7.12
Benzene (s)	193.2	5.95
Benzene (s)	184.3	1.93
Cyclohexene (1)	176.2	3.75
Cyclohexene (s)	165.0	1.20

The author wishes to take this opportunity to express his sincere appreciation to Professor D. H. Andrews at whose suggestion this work was undertaken.

Summary

The vapor pressures of crystalline benzene and cyclohexene have been measured by means of a modified Knudsen procedure. An analysis of the experimental errors entailed leads to a probable error in the vapor pressure measurements of about 4%.

Properties of Electrolytic Solutions. II. The Evaluations of Λ_0 and of K for Incompletely Dissociated Electrolytes

BY RAYMOND M. FUOSS AND CHARLES A. KRAUS

I. Introduction

Assuming complete dissociation, the conductance of strong electrolytes in water (at low concentrations) as a function of concentration is well accounted for by the interionic attraction theory. Evidence is accumulating, however, which indicates that for all electrolytes in solvents of lower dielectric constant, as for weaker electrolytes in water, dissociation is incomplete at accessible concentrations. It has been proposed that a mass action effect be combined with the interionic effect[1] in order to account for the observed conductance values. This suggestion was first made by Davies[2] for various weak electrolytes in water and shortly afterward by Sherrill and Noyes[3] and by MacInnes.[4]

Later Onsager[5] derived an approximate conductance equation which took into account the mass action effect as well as interionic forces, and calculated several examples. An extrapolation method based on this equation has been applied by Davies[6] to non-aqueous solutions. Using a combination of the two effects, Martin[7] has computed conductance values for various salts in benzonitrile. The results obtained by the various writers indicate that a mass action effect must be taken into account, but the methods employed in evaluating the limiting conductance and the dissociation constant have been only approximate and it is difficult to determine how closely the experimental results may be accounted for by the assumptions made.

Perhaps the chief source of inconsistency lies in the value assumed for Λ_0, the limiting conductance of the electrolyte. In aqueous solutions, the value of Λ_0 for weak electrolytes may usually be evaluated from data relating to strong salts of the corresponding acid or base. In the case of solutions in solvents of lower dielectric constant, however, it is necessary to evaluate the limiting conductance for a given electrolyte from conductance data relating to that electrolyte alone. At present, only empirical extrapolation formulas have been employed for determining Λ_0 from conductance data which do not show the theoretical slope on a square root plot. For an exact comparison of theory and experiment, however, any

---

(1) We are using the expression "interionic effect" in the sense of the theory of Debye and Huckel, although, of course, mass action likewise depends on an interaction of ions due to their changes, and depends upon the electrical properties of the medium

empirical extrapolation function may be expected to lead to an error in the value of Λ_0. This, in turn, may induce a relatively large error in the value found for the dissociation constant K, since the error in $(1-\gamma)$ will be large if y, the fraction dissociated, is large, and the limiting form of the calculated curve may deviate greatly from the true curve. The difficulty may be overcome by solving the equations connecting conductance and concentration, which involve Λ_0 and the dissociation constant K. While these equations are not readily solved explicitly, they may **be** solved by successive approximation or by graphical means. Below is described a convenient method of solution and this method is applied to **a** variety of binary electrolytes in solvents of dielectric constant varying from 10.4 to 79. The calculated values are in agreement with the experimental values up to ion concentrations of approximately 2 X 10^{-3} *N*.

II. **The** Conductance Function

We consider a solution of a binary electrolyte AB and assume the usual equilibrium

$$A^+ + B \; ' \; A \; B \tag{1}$$

between ions and "undissociated molecules" of solute. It will not **be** necessary to consider the physical picture underlying (1); we shall accept the equation as implying that on the average a certain fraction of the total solute does not contribute to the transport of electricity through the solution during the conduction process. If the stoichiometric concentration is c, and the average fraction of solute free to carry the current is y, then the various concentrations are

$$[A^+] = [B'] = c\gamma$$
$$[AB] = c\,(1-\gamma)$$

where

$$\frac{1}{2}([A^+] + [B']) + [AB] = c$$

We assume as a first approximation that the thermodynamic properties and migration velocities of the ions depend on the total concentration of free ions 2 $c\gamma$ in the manner described by the equations of the interionic attraction theory. The changes in the properties of the solvent and in the distribution of ions in the "ionic atmospheres" which are caused by the presence of undissociated (non-conducting) ion pairs will be neglected. We shall also neglect higher terms[8] in the calculation of interionic effects. Finally, we assume that the undissociated molecules are present as a dilute solution in the classical sense. These assumptions appear to be justified at lower concentrations, even in solvents of quite low dielectric constant.[9]

---

[8] Incidentally, we might mention that, since we limit our discussion to binary one-one salts the odd terms in the power series expansion used in computing interionic effects vanish, and that the valence factor $(z_1z_2)^n$ in the terms of this series always is unity.

[9] By "lower concentrations," we mean up to 0.003–0.004 N in liquid ammonia. for example. The only way to test the validity of the assumptions is to apply them to a practical case and see whether calculated results based on the assumptions agree with the observed experimentalfacts

The equilibrium function describing reaction (1) is then given by

$$\frac{[A^+]\, f_{A^+}\ [B]\, f_{B^-}}{[AB]\, f_{AB}} = K$$

where the activity coefficients are represented by f. Our assumption that the neutral molecules are present in dilute solution is equivalent to setting $f_{AB} = 1$. We shall employ Debye's first approximation to calculate these coefficients for the ions, using, in accordance with our assumptions, $2\,c\gamma$ for the total ion concentration. Then

$$-\log_{10} f = \beta \sqrt{c\gamma}/(1 + \delta \sqrt{c\gamma}) \qquad (2)$$

where

$$\beta = 0.4343 \frac{e^2}{2DkT} \left(\frac{8\pi N e^2}{1000\, DkT}\right)T' \qquad (2a)$$

and

$$\delta = \left(\frac{8\pi N e^2}{1000\, DkT}\right)^{1/2} a \qquad (2b)$$

Here,[10] e = the electronic charge = 4.770×10^{-10} e. s. u., N = Avogadro's number = 6.06×10^{23}, k = Boltzmann's constant = 1.371×10^{-16} erg/1°, D is the dielectric constant of the solvent, T is the absolute temperature, and a is the ionic radius.[11]

If we substitute our symbols for the concentrations, and assume $f_{A^+} = f_{B^-}$ the equilibrium equation becomes

$$c\gamma^2 f^2/(1 - \gamma) = K \qquad (3)$$

For convenience in later manipulation, we shall introduce a variable x defined by

$$x = (1 - \gamma)/\gamma^2 = cf^2/K \qquad (4)$$

For a solution containing $c\gamma/1000$ equivalents per cc. of anions and cations with mobilities v_{B^-} and v_{A^+}, respectively, the specific conductance κ is given by

$$1000\kappa = Fc\gamma(v_{A^+} + v_{B^-}) \qquad (5)$$

where F = 96,494 international coulombs per equivalent.[12] The equivalent conductance is defined as

$$\Lambda = 1000\ \kappa/c \qquad (6)$$

According to the interionic attraction theory, the mobilities vary linearly with the square root of the ion concentration; if we use Debye's equation to represent this change, we have, in view of (5) and (6)

$$A = \gamma(\Lambda_0 - \alpha \sqrt{c\gamma}) \qquad (7)$$

where Λ_0 is the limiting value of the equivalent conductance, and α has the value computed by Onsager

$$\alpha = \frac{8.18 \times 10^5}{(DT)^{3/2}}\Lambda_0 + \frac{82}{\eta(DT)^{1/2}} \qquad (8)$$

---

(10) Birge, *Phys. Rev. Supplement*, **1**, *1* (1929).

(11) The value of a may be estimated from the limiting conductance by means of Stokes' law with sufficient accuracy to be used in a *correction* term,

(12) Ref. 10, p. 36.

Here η is the viscosity of the solvent and the other symbols have their usual meanings.

We now have a system of equations (2), (3) and (7) which implicitly describe the conductance curve

$$A = \Lambda(c)$$

Explicit solution in this form is difficult, due to the mixed form (transcendental, quadratic and cubic) of the system, but by means of the variable x, it is possible to transform the equations in such a way that calculation will be convenient. The explicit solution may be carried out in principle as follows: we regard c and A as known quantities from experiment, and may solve (7) in the form $\Lambda_0 = \Lambda_0(\gamma)$. From (3) and (3), we eliminate f and obtain $\gamma = \gamma(K, a)$, which, in view of the approximate relation between Λ_0 and a contained in Stokes' law, and the relative unimportance of the δ-correction term, may be written $\gamma = \gamma(K)$. From these two equations, we eliminate γ and obtain a relation between Λ_0 and K, $F(K, \Lambda_0) = 0$. We have as many equations (7) as we have experimental points $A = \Lambda(c)$. Corresponding to any two pairs of values of c and A, the equations $F_1(K, \Lambda_0) = 0$ and $F_2(K, \Lambda_0) = 0$ may be solved for K and Λ_0.

Before considering the general case, however, it is of interest to mention two limiting cases. If K is large, γ approaches very near to unity and (7) reduces first to Onsager's equation

$$\Lambda = \Lambda_0 - or\sqrt{c} - \Lambda_0 c/K \tag{9}$$

and, for K still larger, to the limiting law for complete dissociation

$$A = \Lambda_0 - \alpha\sqrt{c} \tag{10}$$

It should also be noted that, in any case, the limiting slope on a Λ–$\sqrt{c}$ plot is α. If, on the other hand, K is very small, (1– y) may be replaced by unity in (3), and a $\sqrt{c\gamma}$ becomes negligible compared to Λ_0, so that

$$\gamma \approx \Lambda/\Lambda_0 \tag{11}$$

and the equilibrium equation becomes

$$c\Lambda^2 = K\Lambda_0^2 \tag{12}$$

We should expect, therefore, that log A plotted against log c would be a straight line with slope

$$\frac{d \log A}{d \log c} \quad \frac{1}{2} = - - \tag{13}$$

when K is small. Also, if the limiting conductance is known, approximate values of K may be computed by (12).

In the general case, both the change of ion concentration and of ion mobility with concentration must be considered. If we rewrite equations (7) and (2) in terms of x, we obtain

$$\frac{A}{\Lambda_0} = \gamma - \frac{or\sqrt{K}}{A,}\,\frac{x^{1/2}\,\gamma^{3/2}}{f} \tag{14}$$

and

$$-\mathbf{flog}\, f = \beta\sqrt{K}\sqrt{x\gamma}/(1 + \delta\sqrt{c\gamma}) \tag{15}$$

By solving (4), we obtain

$$\sqrt{x} = \sqrt{1 - \gamma}/\gamma \qquad (16)$$

$$\gamma = (\sqrt{1 + 4x} - 1)/2x \qquad (17)$$

For small values of x, the power series

$$\gamma(x) = 1 - x + 2x^2 - 5x^3 + 14x^4 - 42x^5 + \dots \qquad (18)$$

may be used to calculate y from x.

The values of the limiting conductance Λ_0 and of the dissociation constant K are determined from conductance data as follows. An approximate[13] value γ' of γ is obtained simply by replacing y in the interionic attraction term of (7) by Λ/Λ_0

$$\gamma' = \frac{\Lambda/\Lambda_0}{1 - \alpha\Lambda_0^{-3/2}\sqrt{c\Lambda}} \qquad (19)$$

The value of Λ_0 used here is obtained by any convenient method, such as a free-hand extrapolation of the experimental Λ–$\sqrt{c}$ curve; the final result is independent of the value of Λ_0 initially assumed. The approximation is repeated according to the scheme

$$\gamma'' = \frac{\Lambda/\Lambda_0}{1 - \alpha\Lambda_0^{-1}\sqrt{c\gamma'}}, \text{ etc.}$$

which converges to a constant value. Having determined γ, $\sqrt{x}$ is computed from (16) and f from (2). The $\sqrt{x}$ is plotted against $f\sqrt{c}$. (The square root plot generally gives the more convenient scale.) According to (4), this plot should be a straight line with slope $\sqrt{K}$, ***passing through the origin.*** If the value of Λ_0 used in (19) is greater than the actual value of Λ_0, the $f\sqrt{c}$–$\sqrt{x}$ curve will have a positive intercept on the $\sqrt{x}$ axis. If this is the case, the computation is repeated for several smaller values of Λ_0, until a small negative intercept is obtained; the Λ_0 values used are then plotted against the corresponding $\sqrt{x}$ intercepts and a value is ***interpolated*** which gives a zero intercept. The value of $\sqrt{K}$ is determined by plotting the slopes of the $f\sqrt{c}$–$\sqrt{x}$ lines against the intercepts and interpolating as above. Since the $f\sqrt{c}$–$\sqrt{x}$ curve is very nearly linear (except in the extremely dilute region) even when the value of Λ_0 chosen is not the true value, it is sufficient to carry out the above calculation at only two concentrations which are taken in the range of concentration where the experimental error is small. This will give a value of Λ_0 which is as accurate as the two data; the computation may then be repeated with this value of Λ_0, using all of the experimental data, and weighting the points according to their accuracy if desired. If the $\sqrt{x}$ intercept thus determined is not quite zero, the values of Λ_0 and K may be corrected by means of the average slope of the interpolation plots. In our calculations we used at least five conductance determinations and, in this case, the interpolated

---

(13) Equation (7) is cubic in $\gamma^{1/2}$ and may be solved by the usual algebraic methods or by the use of tables. In general, however, the convergent approximation method as here outlined is more rapidly handled.

values of Λ_0 and K needed no correction to bring them into agreement with the remaining data.

Figure 1 illustrates the application of the method to Kraus and Parker's[14] data for iodic acid in water. Curve I (scales above and left) covers the entire concentration range (0.0003–0.2 N) and corresponds to Λ_0 = 391.19; the three lower Curves II, III and IV (scales below and right), show the dilute region (0.0003–0.002 N) on a ten-fold magnified scale and correspond to Λ_0 = 390.8, 391.19 and 391.60, respectively. The points in the most dilute region are extremely sensitive to experimental error, because γ is greater than 0.99; nevertheless, it is obvious that Λ_0 = 391.60 is too great and Λ_0 = 390.8 is too small, because the average straight lines corresponding to these values definitely do not go through the origin, while the line for Λ_0 = 391.19 does satisfy this condition. Similar results have been obtained for about twenty-five electrolytes in various solvents.

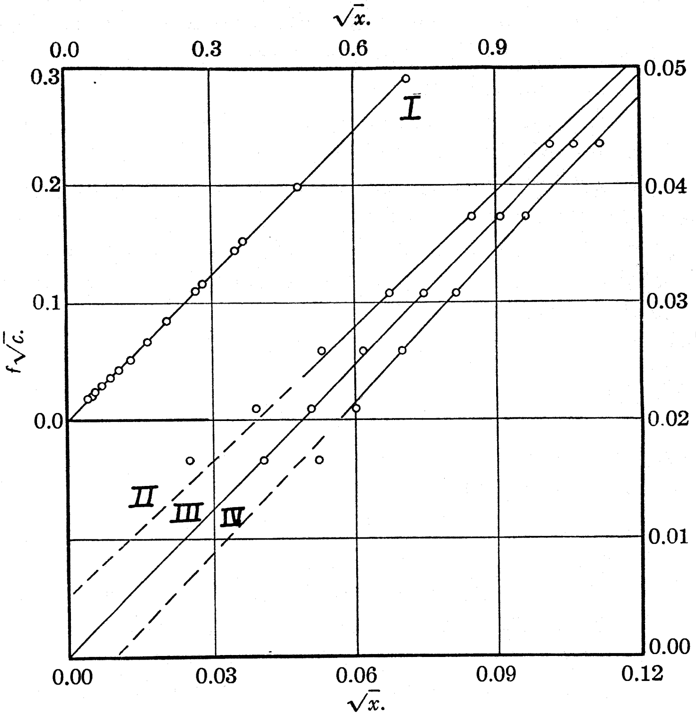

Fig. 1.—$f\sqrt{c}-\sqrt{x}$ plots for iodic acid in water.

The approximate linearity of the $f\sqrt{c}$–$\sqrt{x}$ plots, when the value of Λ_0 used above is near to the true value, is readily accounted for. The mass action equation (3) may be written

---

[14] Kraus and Parker, THIS JOURNAL, 44, 2429 (1922).

$$f^2c\cdot\frac{\Lambda^2(1-\alpha\Lambda_0^{-1}\sqrt{c\gamma})^2}{1-\Lambda(1-\alpha\Lambda_0^{-1}\sqrt{c\gamma})/\Lambda_0}=K\Lambda_0^2$$

Now $f\sqrt{c}$ depends on the chosen value of Λ_0 through y in the expression for log f and hence is not very sensitive to changes in Λ_0. On the other hand, γ, and hence $\sqrt{x}$, depends directly on Λ/Λ_0, so that the main effect of changing Λ_0 is to change the values of $\sqrt{x}$. But, if Λ_0 is near to the true value, the left-hand side of the above function does not change much with c, so that $K\Lambda_0^2$ remains constant except for differences of higher order. For KA_0^2 constant, $f\sqrt{c}$ is linear against the square root of the reciprocal of the second factor on the left, which is the $\sqrt{x}$ value computed for the chosen value of Λ_0. The "true" value of Λ_0, however, is the value approached by A (observed) as c approaches zero, and this value obviously corresponds to the condition that $X = 0$ when c = 0.

If Λ_0 and K are known, the conductance curve may be computed as follows. A sufficiently dense set of values of $\sqrt{x}$ ranging from zero to $\sqrt{c_m/K}$ are listed, where c_m is the maximum concentration to **be** considered, and the corresponding values of y, $x^{1/2}$ y"'/' and $\sqrt{x\gamma}$ are read[15] from the graph (Fig. 2, Curves I, II and III). From a plot of —flog f against f (Curve IV, Fig. 2), approximate values f' off are determined according to the equation

$$-f'\log f' = \beta\sqrt{K}\sqrt{x\gamma}$$

With these values for f, approximate concentrations are computed from

$$\sqrt{c'} = \sqrt{K}\sqrt{x}/f'$$

and are used to determine the correction term in (15); then a second approximation f'' for f is obtained from

$$-f''\log f'' = \beta\sqrt{K}\sqrt{x\gamma}/(1+6\sqrt{c'\gamma})$$

This approximation scheme converges rapidly; when f becomes constant, $\sqrt{c}$ is given by (4). Then A is calculated according to (14) and a smooth curve is finally drawn through the computed (A, $\sqrt{c}$) points.

If it is desired to compute values of A for particular values of c, rather than to draw the conductance curve, a somewhat different procedure is followed. As a zeroth approximation, γ is set equal to unity in (2), and the corresponding value $(f^0)^2$ of f^2 is determined by

$$-\log(f^0)^2 = 2\beta\sqrt{c}/(1+\delta\sqrt{c})$$

The corresponding value x^0 of x is computed from the given concentration by means of (4), and then a first approximation y' for γ is obtained by substituting x^0 in (17) (or in (18) if x^0 is small). Then $(f')^2$ is computed from

$$-\log(f')^2 = 2\beta\sqrt{c\gamma'}/(1+\delta\sqrt{c\gamma'})$$

and the process repeated until y converges to a constant value. Then, with γ and f determined, A is computed according to (7).

---

(15) For calculations requiring a higher accuracy than is permitted by a graph, a table of the values of $\sqrt{x}$, γ, $\sqrt{x\gamma}$ and $x^{1/2}$ $\gamma^{3/2}$ for round values of x is very convenient.

The general nature of the conductance function is evident from (14), where the conductance ratio Λ/Λ_0 is given as the difference between two terms, γ and $(\alpha\sqrt{K}/\Lambda_0)\ (x^{1/2}\gamma^{3/2}/f)$. The first represents the effect of mass action and the second the effect of interionic forces, corrected for incomplete dissociation. When the dissociation constant K is large, γ remains near unity and varies approximately as the *first power* of x, while the interionic attraction term has a large numerical coefficient and varies as the *square root* of x. Consequently, the variation of Λ/Λ_0 with c is governed primarily by the latter term, On the other hand, when K is small, even small concentrations soon correspond to large values of x where γ is decreasing rapidly (Curve I, Fig. 2). The interionic attraction term now has a small numerical coefficient and becomes merely a correction term to γ in determining Λ/Λ_0, since $x^{1/2}\gamma^{3/2}$ reaches a maximum at $x = 2$ (Curve II, Fig. 1). The decrease of f with increasing concentration increases the term in question, but the increase is retarded by the proportionality of f log f with $\sqrt{x\gamma}$. The various relations are illustrated by Fig. 2; if, for simplicity, we neglect the change of f with c, the conductance curve is simply the resultant of Curves I and II, where Curve I has the ordinate scale given in the figure and the scale for the Curve II is multiplied by $(\alpha\sqrt{K}/\Lambda_0)$. As might be expected, the conductance curves for weak electrolytes (*cf.* Fig. 3) markedly resemble the γ-curve of Fig. 2.

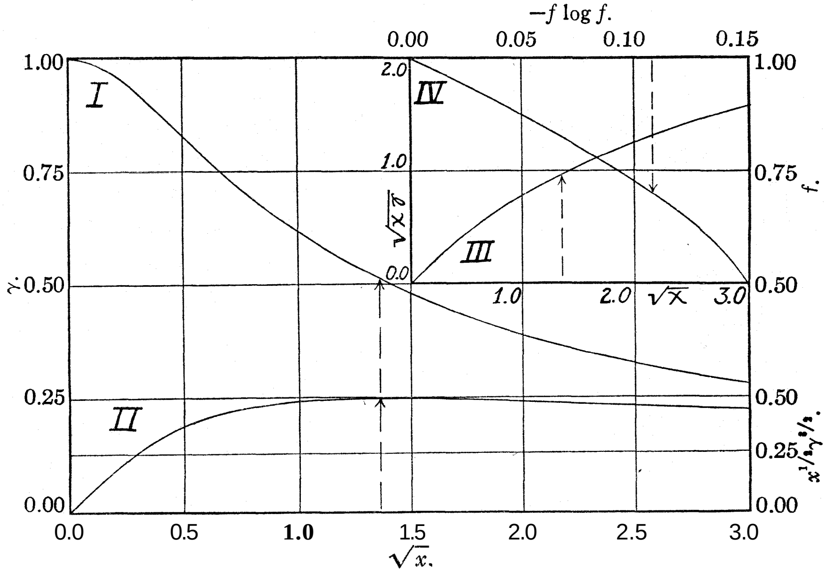

Fig. 2.—Functions involved in calculation of conductance.

The inflection point in the γ–$\sqrt{x}$ curve (I, Fig. 2) lies at

$$\sqrt{x} = \sqrt{\sqrt{3}/8} = 0.4653$$

and the corresponding concentration

$$c_{inf} = 0.2165\,K/f_{inf}^2 \qquad (20)$$

is proportional to the dissociation constant. A rough estimate of the concentration at which the inflection point appears may be obtained by setting f equal to unity. For example, if K is 5 X 10^{-4}, the inflection point in the $\gamma-\sqrt{x}$ curve appears in the neighborhood of 10^{-4} N, and one should not expect a $\Lambda-\sqrt{c}$ plot to have a slope equal to the limiting value at concentrations greater than 10^{-4} *N*. It is only at much lower concentrations that the interionic term becomes the controlling term, rather than a correction term to Λ/Λ_0. Incidentally, the presence of the inflection point accounts for the fact that many conductance curves are apparently linear in $\sqrt{c}$ over a certain range of concentration, but with a slope considerably greater than a.

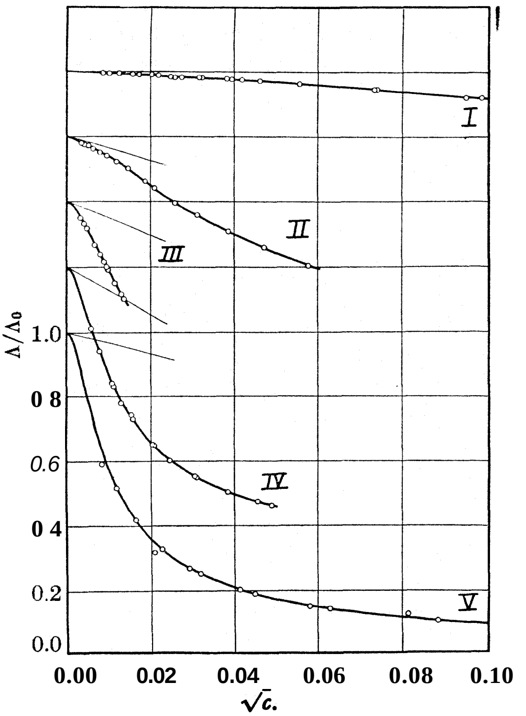

Fig. 3.—Comparison of calculated and observed conductance values: I. iodic acid in water; II, sodium bromate in ammonia; III, sodium iodide in amyl alcohol; IV, tetraisoamylammonium nitrate in ethylene dichloride; V, potassium amide in ammonia.

III. Comparison with Experiments

The method of computation presented above has been applied to a number of sets of conductance data, chosen to cover a fairly wide range of the specific constants involved. The results for several examples are shown in Fig. 3, where the conductance ratio Λ/Λ_0 is plotted against the square root of total concentration. (Each curve begins on the left at ($\sqrt{c} = 0$, $\Lambda/\Lambda_0 = 1$); in order to avoid confusion due to crossing curves, the different curves are displaced vertically. The ordinate unit is 0.2.) The circles indicate the various observed points. The curves are drawn according to equations (2), (3) and (7), where the constants have the values given in Table I, and the limiting tangents are drawn in accordance with (8).

A comparison of calculated and observed values for iodic acid in water is given in Table II. The specific conductance of the water used in Series

beyond this concentration, the small differences increase with concentration. The maximum difference is 0.28%. The last column gives the values of K, calculated for each point.

Kraus and Parker, using the Ostwald dilution law for extrapolation, obtained $\Lambda_0 = 389.55$ and $K = 0.0717$; the present values are $\Lambda_0 = 391.19$ and $K = 0.1686$. Onsager[5] obtained $\Lambda_0 = 391.3$ and $K = 0.17$, which are in substantial agreement with our values. On the scale used, the curve for iodic acid (I, Fig. 2) shows little structure beyond the fact that it is slightly concave toward the concentration axis. Considering the high ionization of the acid, the value of K as calculated for the different points is remarkably constant; this is particularly true of Series 3 and 4. For $c = 4 \times 10^{-4}$ N, $\gamma = 0.998$, and here an error of 0.1% in Λ makes an error of 50% in $(1 - \gamma)$; K was therefore not calculated for the points in the most dilute region. The dissociation is too nearly complete to permit of accurate measurement of the undissociated fraction.

Sodium bromate in liquid ammonia (Curve II)[16] is a relatively much weaker electrolyte than iodic acid in water and, as might be expected from our discussion in the preceding section, gives a steeper conductance curve, which has an inflection point near 0.0003 N. Due to the lower dielectric constant and viscosity of ammonia compared to water, the slope of the limiting tangent for ammonia (Curves II and V) is greater than for water (Curve I), but on a $\Lambda-\sqrt{c}$ plot, the observed points and the calculated curve lie below the limiting tangent even at 10^{-5} N, the lowest concentration measured. Our present values for the constants of sodium bromate are $\Lambda_0 = 286.2$ and $K = 0.002532$. Kraus and Bray[17] obtained $\Lambda_0 = 278$ and $K = 0.0023$, based on the classical mass action equation. Davies[6] gives $\Lambda_0 = 281$ and $K = 0.0073$, using Onsager's approximate equation (9) for extrapolation. With dissociation constants as small as 10^{-3}, this simple parabolic equation may no longer be used (cf. (18)).

The curve for potassium amide[18] in liquid ammonia (V, Fig. 3) repre-

(17) Kraus and Bray, THIS JOURNAL, 35, 1337 (1913). These authors use the data of Franklin and Kraus, Am. *Chem.* J., 23, 277 (1900). The older data are in substantial agreement with the more recent values.

(18) Franklin, Z. *physik.* Chem , 69, 290 (1909).

sents a still weaker electrolyte. The shape of the curve recalls the curve for γ in Fig. 2 and, indeed, mass action controls the gross change of equivalent conductance for this salt. The interionic correction term, nevertheless, remains appreciable at all concentrations in the experimental range. If this correction is omitted and the simple mass action law is used for extrapolation, the resulting values are $\Lambda_0 = 301$ and $K = 1.20 \times 10^{-4}$, given by Kraus and Bray. These diverge widely from our present values: $\Lambda_0 = 351.3$ and $K = 0.700 \times 10^{-4}$. On the other hand, for a salt of this type, extrapolation by means of the simple square root law is impossible, since the approach to the limiting slope α does not appear at accessible concentrations.

Curve IV represents the conductance of tetraisoamylammonium nitrate[19] in ethylene dichloride, a solvent with dielectric constant 10.4. The corrections due to interionic effects are greater in this solvent than in ammonia because of its smaller dielectric constant.

The conductance of sodium iodide[20] in amyl alcohol is shown by Curve III. This solvent has a very high viscosity and a fairly low dielectric constant. The curve was not computed above the range of concentration covered by the data.

The examples described above cover a wide range of the various constants involved: dielectric constant 10.4–78.6; viscosity 0.038–0.00256; equivalent conductance 11.2–391; dissociation constant 0.00007–0.17. The agreement between calculated and observed values is in all cases satisfactory; we may therefore conclude that our assumptions are justified in the range of concentration considered, namely, up to ion concentrations of about 0.002 N.

Attention is called to a group of electrolytes whose behavior is incompatible with the equations here used to describe the conductance of weak electrolytes. A large group of strong electrolytes in water (for example, hydrochloric acid, potassium hydroxide, potassium chloride, etc.) give conductance curves which approach the limiting tangent from above, while a mass action effect causes the curves to fall below the limiting tangent. Apparently, some effect is here coming into play, which either is not taken into account in our equations or has been excluded by our assumptions. This behavior, *i. e.*, observed conductance greater than that calculated from our equations, is not limited to aqueous solutions, for most of the electrolytes which we have examined show positive deviations at higher concentrations (greater than about 0.01 N). In solvents of lower dielectric constant, the conductance curve generally exhibits a minimum. This increase of conductance with concentration at higher concentrations may be analogous to the effect observed in water, which has a very high dielectric constant.

Summary

1. An exact method of solving the conductance equations for incompletely dissociated binary electrolytes is presented.

2. A method is described for determining the limiting equivalent conductance and the dissociation constant.

3. Five examples of application of the method are given, in which the constants of solvent and of electrolyte vary as widely as possible. Calculated and observed conductance values agree within the limit of experimental error up to ion concentrations of several thousandths normal.

The Reaction between Osmium Tetroxide and Hydrobromic Acid. I. Equilibrium Study

BY H. DARWIN KIRSCHMAN AND WILLIAM R. CROWELL

Introduction

A study of the catalytic influence of ruthenium compounds on the decomposition of perchloric acid by hydrobromic acid recently made[1] has led to a similar investigation of the catalytic effect of osmium compounds on this reaction. This work is now under way. Since under certain conditions there is an appreciable action between the hydrobromic acid and octavalent osmium, it became necessary to study the latter effect separately.

The products of the reaction were found to be bromine (largely in the form of tribromide ion) and some form of osmium in a lower valence state. Data obtained in an examination of the reaction rate indicated that a state of equilibrium was reached. In the present paper are presented the results of a study of this equilibrium, together with possible interpretations of the results and an attempt to derive an equilibrium constant at 100°.

Apparatus and Materials

The apparatus used was that employed in the potentiometric determination of bromine, octavalent and quadrivalent osmium.[2] The materials and their preparation have been described in the articles mentioned. In the present work, however, the bromine solution was 1.00 N in hydrobromic acid since it was found that the stability of the solution was much greater than in one-tenth normal acid as previously used, the concentration of the bromine solution in the stronger acid remaining unchanged for a period of

several weeks. The quadrivalent osmium solution was made **2.40** *N* in hydrobromic acid since this concentration was most convenient in the preparation of the reaction tubes.

Experimental Procedure

In obtaining the experimental data the equilibrium was approached from both directions using different concentrations of the reacting constituents. From the direct side the initial reactants were octavalent osmium and hydrobromic acid in solutions of the two alone and in solutions of the two containing initially added amounts of bromine. From the reverse side the initial reactants were quadrivalent osmium and bromine in solutions of hydrobromic acid alone and in the acid solutions containing initially added amounts of potassium bromide.

The method of filling the reaction tubes and analyzing their contents was essentially the same as that described in our previous article.[2c] The various constituents were pipetted into Pyrex test-tubes, using such volumes as to secure the desired initial concentrations and a total volume of 10.0 cc. The tubes were sealed and heated in a water-bath at 100° for three or four days. At the end of that time the tubes were chilled in an ice-bath, broken in about 200 cc. of ice water and titrated with hydrazine sulfate solution. During the process of dilution and titration, the bromine was reduced to bromide and any Os_7 or Os_6 present was reduced to Os_4. Since it was impracticable to distinguish between the bromine and the reduced osmium in the hydrazine titration, it has been termed "total bromine titration." From the initial concentrations of osmium and bromine (in the cases where initial amounts were present) and from the results of the "total bromine titration" the concentrations of Os_8 and of reduced osmium can be calculated. In order to calculate the equilibrium concentration of bromine, it is necessary to know the valence state of the reduced osmium. The method of determining this is explained in the next section.

In Table I are recorded the data on the equilibrium experiments and the results of determinations of the "total bromine" in the reaction tubes. In columns 2, 3, 4 and 5 are shown the original concentrations of acid, bromine, octavalent and quadrivalent osmium in mols per liter at 25°. In column 6 appears the concentration of "total bromine" in mols per liter at 25° as determined by potentiometric titration with hydrazine sulfate. For each run these results represent the average value obtained in the titration of three or four tubes. The data in columns 3, 4, 5 and 6 enable us to calculate the equilibrium concentrations of bromine, octavalent and reduced osmium which are shown in columns 7, 8 and 9. The method of calculating these values will be explained in the next section in connection with the presentation of the proposed reactions.

TABLE I

RESULTS OF TITRATION OF BROMINE IN THE REACTION TUBES

[a] From hydrazine sulfate titration of contents of reaction tube.

Derivation of the Equilibrium Constant

In runs 20 to 27 inclusive, in which the acid concentration was constant at 2.40 *N* and in which the total concentration of tribromide was high enough to be of the same order of magnitude as its equilibrium value, the functional relation of the tribromide concentration in the equilibrium expression was calculated on the assumption that the two forms of osmium appeared as the first power of their concentrations

$$\frac{\mathrm{Os}_{\mathrm{reduced}}}{\mathrm{Os}_8} \times (\mathrm{Br}_3^-)^m = K_{\mathrm{I}}$$

The data indicated clearly that m was approximately 0.50. Similar treatment of runs 32 to 34 inclusive, in which the acid concentration was 3.20 N, gave a like value for m.

In order to determine the effect of the activity of the hydrobromic acid upon the equilibrium an attempt was made to estimate the values of the activities of the hydrobromic acid at the different concentrations used and to determine the approximate value of n in the expression

$$\frac{\mathrm{Os}_{\mathrm{reduced}}}{\mathrm{Os}_8} \times \frac{(\mathrm{Br}_3^-)^{1/2}}{(\mathrm{HBr})^n} = K$$

The values of the mean ion activity coefficients of hydrobromic acid at 25° were estimated from the data of Bates and Kirschman[3] and of Livingston.[4] There was a considerable gap between the minimum values calculated from the vapor pressure measurements of the former and those obtained from the electromotive force measurements of the latter. In order to determine the coefficients in the working range of our experiments it was necessary to plot the two sets of data and extend the curves until a single one was obtained. To convert the vapor pressure results into activity coefficients the free energy data of Lewis and Randall[5] were used. The activity coefficients at 100° (the temperature of the reaction tubes) were then calculated by the use of the heat data given in the "International Critical Tables."[6]

The solution of simultaneous equations containing different values for the activities of hydrobromic acid and different concentrations of octavalent osmium, reduced osmium and of bromine showed n, the power of the hydrobromic acid activity, to be about four.

A reaction scheme which would require a value of one-half for m and approximately four for n seemed to be one of the following.

(1) A single reaction of the type

$$\mathrm{OsO_4 + H^+ + 5/2\ Br^- = Os(OH)O_3Br^- + {}^1/_2Br_3^-}$$

(2) A pair of reactions, the first of which is very rapid, producing a complex with a coördination number of eight and the second of which is the slower and equilibrium-determining step

$$\mathrm{OsO_4 + 7HBr = Os(OH)Br_7 + 3H_2O}$$
$$\mathrm{Os(OH)Br_7 + H^+ + 5/2\ Br^- = OsBr_8^- + {}^1/_2Br_3^- + H_2O}$$

In accordance with these proposed reactions it is assumed that septivalent osmium and tribromide ion are the products of the reduction of the octavalent osmium. The presence of septivalent osmium seems to be the most reasonable assumption to make in order that the tribromide-ion concentration appear in the equilibrium expression to the one-half power.

(6) "International Critical Tables," Vol. V, p. 177.

In preliminary calculations of equilibrium constants using different exponents for the hydrogen and bromide ion activities, the best agreement was obtained when the combined exponent was 3.5 and that of the hydrogen ion was unity. Both in the cases where it was assumed that hydrogen ion had no part in the reaction and in those in which it was assumed that it appeared as the second power, non-concordant constants were obtained. In order to satisfy these requirements the presence of $Os(OH)Br_7$ and of $OsBr_8^-$ are not necessarily the only forms that might be postulated in scheme (2). Such octavalent forms as those ranging in composition from $OsO_3(OH)Br$ to $Os(OH)Br_7$ and such septivalent forms as those ranging in composition from $OsO_3(OH)Br^-$ to $OsBr_8^-$ might also be possible.

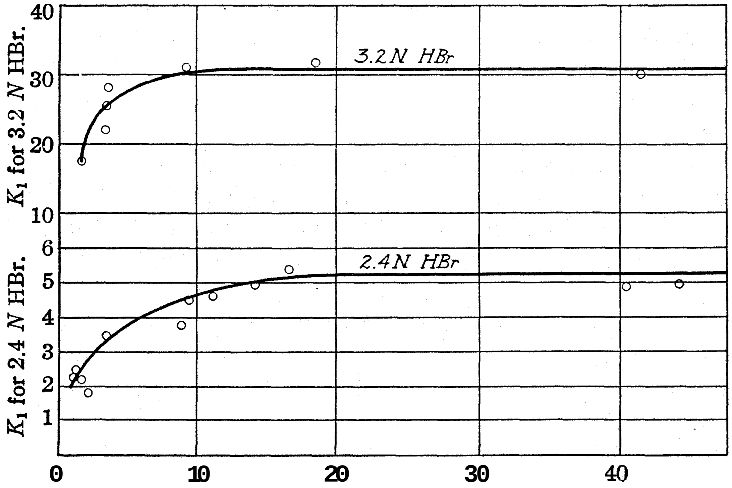

Fig. 1.

The results shown in columns 7, 8 and 9 of Table I were calculated under the assumption that the osmium in the equilibrium mixtures is reduced to a septivalent form and that during the titration with hydrazine sulfate it is further reduced to a quadrivalent form with the liberation of three equivalents of bromine per mol of osmium reduced. Consequently a correction amounting to one and one-half times the molar concentration of the reduced osmium was deducted from the titrated value of the bromine (in column 6) in order to obtain the equilibrium concentration of the tribromide ion. In column 10 are the calculated values of K_I using the equilibrium concentrations of Os_7, Os_8 and of Br_3^- expressed in millimoles per liter at 25°. It was noted that in the runs at 2.4 and 3.2 N in which the bromine and osmium concentrations were varied over a wide range, the constants seemed to depend upon the concentration of bromine present. Accordingly, the values of K_I were plotted against bromine concentrations at equilibrium and the curves shown in Fig. 1 were obtained. It will be seen that at the lower bromine concentrations the constants are also lower, but with increasing concentration of bromine they increase and reach a constant value. The values corresponding to the horizontal portion of the curves were used in the final calculation of the equilibrium constants. In the runs at other acid concentrations the average values for the constant K_I were used.

If the activity coefficient of the osmium tetxoxide is assumed to be unity and that of the septivalent osmium and the tribromide ion assumed to be equal to the mean ion activity coefficient of the hydrobromic acid, we may write for the equilibrium constant in either of the above cases

$$\frac{(\mathrm{Os}_7^-)(\mathrm{Br}_3^-)^{1/2}\,\gamma_\pm^{3/2}}{(\mathrm{Os}_8)(\mathrm{H}^+)(\mathrm{Br}^-)^{5/2}\,\gamma_\pm^{7/2}} = K = \frac{K_I \times g^{-0.5}}{(\mathrm{H}^+)(\mathrm{Br}^-)^{5/2}\,\gamma_\pm^{2}}$$

where Os_7^-, Br_3^-, Os_8, H^+ and Br^- represent the concentrations of these substances in mols per thousand grams of water, g the number of grams of water per liter of solution at 25°, $\gamma_\pm$ the mean ion activity coefficient of the hydrobromic acid at 100°, and K the equilibrium constant at 100° when the concentrations of all the constituents are expressed in mols per thousand grams of water.

In Table II are given the average values of the equilibrium constants as calculated according to the above expression. The results for experiments in which potassium bromide and hydrobromic acid were used are shown in runs 37–41, inclusive. As the literature does not contain data on the activity coefficients of hydrobromic acid in solutions of potassium bromide at the concentrations used in our work, these values at 25° were estimated by use of the results of Harned[7] on the activity coefficients of hydrochloric

acid in solutions of potassium chloride. The coefficients at 100° were calculated by use of the conversion factors employed in the salt-free hydrobromic acid runs. The density–percentage composition data required to convert mols per liter into moles per 1000 g. of water were obtained from the "International Critical Tables."[8]

Since in the absence of direct data on the activity coefficients of the constituents involved it has been necessary to make certain assumptions concerning these coefficients in the calculation of the equilibrium constants; no doubt the latter will be modified to some extent when these data are obtained. The agreement of our results among themselves in most cases is surprising. In a qualitative way, at least, they indicate that at low concentrations of acid and of osmium and at high tribromide concentrations the tendency is for the osmium to be reduced to the septivalent form. At higher acidities and lower tribromide concentrations it is possible that other lower valence forms of osmium, such as sexivalent and quadrivalent compounds, are also present. Due to the instability of the osmium compounds present in the equilibrium mixture, we have not yet been able to isolate them in the original state. It might be recalled in this connection that in the potentiometric titration of octavalent osmium with titanous chloride in hydrobromic acid solutions a double inflection in the curve was obtained when the determination was made at 25° (Ref. 2a, p. 1697). This behavior was not explained at the time but it might be due to the presence of septivalent osmium whose reduction potential might be very near that of octavalent osmium but whose rate of reduction might be somewhat slower.

The color changes of the solutions do not afford much help in the interpretation of results, although at the lower acid concentrations the shade is more toward a brownish-red, while in the more concentrated acid solutions the color is a deeper red. Quadrivalent osmium formed in concentrated hydrobromic acid solutions produces crimson colored solutions and it may be that the deep red color of the equilibrium mixture at the higher acidities is due to the presence of small amounts of the quadrivalent form.

The results of the experiments in which hydrogen bromide and potassium bromide were used show clearly that the hydrogen and bromide ions each have their separate effects upon the equilibrium. Because the method of estimating the activity coefficients in these runs involved greater approximations than in the runs in which potassium bromide was absent, the individual equilibrium constants were not considered in obtaining the final average value. The agreement with the other values, however, is probably as good as could be expected.

In the experiments with 2.00 N hydrobromic acid the constants are much lower than in the runs at lower acidities but are of the same order of magni-

---

(8) "International Critical Tables," Vol. III, pp. 55 and 87.

tude as those for 1.60, 2.40 and **3.20** N acid at low tribromide concentrations. This is probably due to the low concentrations of tribromide in all the runs at 2.00 N acid and to the tendency to form lower valence compounds of osmium at this acid concentration. For these reasons, this constant was also omitted in the calculation of an average value. Using 4.5×10^{-6} for the constant, calculations of the ratios of concentrations of octavalent to septivalent osmium in solutions 0.10 and 8.0 *N* in hydrobromic acid containing equivalent amounts of tribromide ion are in agreement with previous statements[2c] that the conversion of octavalent into reduced osmium in 8.0 normal acid is practically complete and that the reverse reaction is likewise practically complete in 0.1 normal acid.

In conclusion, we take this opportunity to thank Dr. Don M. Yost for the very many helpful suggestions made during the course of this work.

Summary

A study of the equilibrium involved when octavalent osmium reacts with hydrobromic acid in a closed tube at 100° with the formation of bromine and lower oxidation states of osmium has been made. The results indicate that at low concentrations of osmium and of acid and high bromine concentrations the osmium was reduced to the septivalent form.

The mass action expression was found to have the form

$$\frac{(\mathrm{Os}_7^-)(\mathrm{Br}_3^-)^{1/2}}{(\mathrm{Os}_8)(\mathrm{H}^+)(\mathrm{Br}^-)^{5/2}\,\gamma_\pm^2} = K$$

where $\gamma_\pm$ represents the mean ion activity coefficient of the hydrobromic acid; and on the basis of this expression two possible types of reactions were suggested.

The average value for the equilibrium constant K when the concentrations are expressed in moles per 1000 grams of water is 4.5×10^{-6}.

The Effect of Crystal Symmetry and Chemical Composition on the Energy Levels of Solids

BY F. H. SPEDDING[1] AND G. C. NUTTING

In the past few years energy level diagrams have been constructed for most of the gaseous atoms and the more simple gaseous molecules and many relations have been established between the physical and chemical properties of the substances investigated and their energy levels.

As a large part of chemistry deals with solids and solutions it would be very desirable to extend these relations so as to apply to them. Unfortunately, however, very little at present is known about energy levels in solids.

So far the two most promising methods of attack on this problem have been by means of the double crystal x-ray spectrograph and the Raman effect. Both these methods have serious disadvantages. The former deals with spectra in the x-ray region where the energies involved are very large and differences due to chemical causes are hard to measure with any great accuracy as they are only a small percentage of the total energies concerned. In the part of the spectrum ordinarily investigated 15,000 calories correspond to a shift of only 0.1 to 0.01 x-units or about 0.0001 to 0.00001 of the total energies involved. On the other hand, while the Raman effect is free from this objection, it gives only a few lines at most and an energy level diagram without additional help is out of the question.

Another method of investigation[2] which gives great promise but which so far has not produced many quantitative results is the study of the absorption spectra of solids and solutions or glasses particularly at low temperatures. This method is free from the objections raised but unfortunately most of the lines arising from the energy levels are blurred into broad diffuse bands in most of the solids and solutions investigated due to the temperature agitation. The energy levels are non-degenerate due to the electric fields of the neighboring atoms or ions and the amount these levels are split apart depends on the strength of the fields, which at room temperatures are fluctuating very rapidly as the nearby atoms approach and recede from the atoms in question. Since the photographic plate indicates the differences between sets of levels over an interval of time the net effect is the blurred bands observed.

It is probably true also that many of the higher excited states in the free atom tend to become unstable upon the close approach of another atom

---

(1) National Research Fellow in Chemistry.

(2) This subject has received a great deal of attention but usually with the emphasis on other phases than the energy levels. A few investigators who have done considerable work in the field are J. Becquerel, *Leiden* Communications; R. Brunetti, *Il Nuovo Cimento;* P.F Ephrain, *Berichte;* Jones and Strong, *Carnegie* Pub.; Freed and Spedding, *Physical* Review

and an electron which ordinarily would jump to a well-defined level giving rise to a sharp line will move into the unstable region and a continuum will result. This is not true for all states so by cooling the solids or glasses to very low temperatures it is possible to resolve into sharp lines the bands from a large number of compounds.

The absorption spectra of the rare earths offer the most encouraging points of attack upon the problem of the energy levels of solids. The reason for this becomes evident upon examination of their electronic structures.

	1s	2s	2p	3s	3p	3d	4s	4p	4d	4f	5s	5p
La^{+++}	2	2	6	2	6	10	2	6	10	..	2	6
Ce^{+++}	2	2	6	2	6	10	2	6	10	1	2	6
Pr^{+++}	2	2	6	2	6	10	2	6	10	2	2	6
Gd^{+++}	2	2	6	2	6	10	2	6	10	7	2	6
Lu^{+++}	2	2	6	2	6	10	2	6	10	14	2	6

It is seen that the "active[H3] electrons are in the 4f shell and that they are partially shielded from the effects of the neighboring atoms by the completed 5s and 5p shells. These electrons, then, are not nearly so much disturbed as are the active electrons in iron or chromium, where they are not so shielded.

One might expect that the energy levels in a solid would be intermediate in type between those of a gaseous atom and those of a gaseous molecule. To a first approximation, in a gaseous atom the electric field is spherically symmetrical about the nucleus. In a diatomic molecule it is cylindrically symmetrical around the line joining the nuclei. In a polyatomic molecule the symmetry varies widely, but it is apt to be very low.[4,5]

Because of the regularity of the crystal lattice the electric symmetry in a solid is probably higher and in the case of the cubic lattice the levels are much more likely to be similar to atomic than molecular levels. It is to be expected that the fields are of various strengths, some of which make the atomic levels non-degenerate as would weak Stark fields, while others destroy the coupling between the electrons and correspond to strong Stark fields.[6]

The basic levels of the rare earths are atomic, for Hund[7] has shown that the measured magnetic susceptibilities of the rare earth ions in the solid state are those to be anticipated if the lowest levels in the solid and the gas

---

(3) An "active" electron is one which is excited by the light absorbed. The electrons in the completed shells are firmly coupled to give a ^1S term in which the resultant orbital and spin moments are zero. A considerable amount of energy is required to break this coupling

(4) The effect of the electric fields is to make the atomic levels non-degenerate, just as an externally applied electric field produces Stark splitting. When the field is weak it couples with the j of an atomic term, thus splitting the level into a number of components. When it becomes strong it breaks down the coupling between spin and orbital moments themselves. In fields of the higher degrees of symmetry there is partial balancing of forces which tends to diminish the splitting.

(5) Robert S. Mulliken gives an excellent account of this effect in his "Interpretation of Band Spectra," *Rev.* Modern *Phys.*, 4, 1 (1932).

(6) This effect has been discussed by H Bethe, Ann. *Physik,* 3, 133 (1929), from the standpoint of wave mechanics and group theory.

(7) Hnnd, *Z Physik,* **33**, *855* (1926)

are the same. The rare earths offer the further advantage that they give an unusually large number of lines in the photographic region of the spectrum. This is probably due to the fact that while the orbits just outside the completed shells are greatly influenced by the neighboring atoms, they are less influenced than those orbits further out, and electronic states arising from them will have more of their levels potentially stable. Thus in the rare earths electronic transitions occur to levels which in other atoms would correspond to the basic levels.[8]

It is possible also that in strong electric fields of the crystal quadripole radiation may be permitted and jumps take place by a recoupling of the 4f electrons.

This is the first of a series of papers on a systematic investigation of the energy levels of solids and gives in detail the results reported briefly in a letter to the *Physical Review* of December 15, 1931.

Experimental

Gadolinium salts are the most desirable for this sort of work. Gd^{+++} ion gives sharp lines at room temperature; it shows the simplest absorption spectra of all the rare earth ions, its lines and multiplets being well separated from one another, and its basic level $^8S_{7/2}$ is known to be single. Its chief disadvantage is that most of its lines occur in the ultraviolet. The gadolinium material used was from two sources. One, of almost atomic weight purity, was furnished us by Professor B. S. Hopkins of the University of Illinois The other was from the Welsbach Company and contained about 1% Tb and 0.5% Sm.

Crystallographic measurements were made for us by Professor Adolph Pabst of the Mineralogy Department of the University of California and we wish to express our thanks for this assistance.

$GdCl_3 \cdot 6H_2O$.—The spectrum of gadolinium chloride has been reported elsewhere.[9] The crystals belong to the normal class of the monoclinic system,[10] although Benedicks[11] has classified them as tetragonal. The constants are $a:b:c = 1.4725:1:1.2185$; $\beta = 86° 20'$. The frequencies of the lines of seven of the most intense multiplets are given in Table I. Spectra from crystals prepared from both sources of gadolinium were photographed and the positions of the lines were found to be identical.

$GdBr_3 \cdot 6H_2O$.—The spectrum of this compound has also been described elsewhere.[12] The crystals are of the normal class of the monoclinic system. They have a notably

---

(8) Freed [*Phys. Rev.*, 38, 2122 (1931)] photographed the spectra of Ce^{+++} compounds and found only broad, diffuse bands in the ultraviolet. He reasoned that as Ce^{+++} ion has only one 4f electron it must jump to the outside orbits in giving rise to these bands, and as they are diffuse all such jumps must be of this type. He attributed them to a 4f-5d jump. This, however, does not seem reasonable, for as Gibbs and White [*Phys. Rev.*, 33, 157 (1929)] have shown, if one plots the known gaseous energy levels of the isoelectric sequence Cs I, Ba II, La III and Ce IV, the curves are lines of small curvature which cross, and while the 6s orbit is lowest in Cs I, the 5d is probably so in Ce IV. From magnetic researches in solids it is known that for La III the 5d level is lowest, while for Ce IV (Ce^{+++}) it is the 4f. Between these two elements the curves must cross and unless they do so at a steep angle, which is not known to occur in any other case, the 4f-5d jump should be found in the far infra-red. The diffuse bands in the ultraviolet are probably due to electronic jumps to higher orbits which are slightly unstable.

different habit from the chloride crystals, but the axial ratios for the two are almost identical.[10] Because of its extreme deliquescence, only rough measurements were made.

$Gd_2(SO_4)_3 \cdot 8H_2O$.—On account of its small solubility, no large crystals were grown. Instead we have used conglomerates of small crystals fixed to quartz plates by means of a lacquer of pyroxylin dissolved in amyl acetate. The crystals are monoclinic, and although we have made no accurate measurements to confirm them, the data given in Groth, "Chemische Krystallographie" certainly cannot be far from correct. By a reorientation of $Gd_2(SO_4)_3\ 8H_2O$ crystals so that 101 becomes 001, 111 becomes 011 and 100 becomes 101, the new axial elements $83°26^1/_2'$ $a:b:c$ 1.4250:1:1.2224, may be obtained.

$$a:b:c = 3.0086:1:2.0068 \quad \beta = 118°2'$$

$Gd(C_2H_5SO_4)_3 \cdot 9H_2O$.—The salt was prepared by double decomposition between equivalent quantities of barium ethyl sulfate and gadolinium sulfate and was twice crystallized from solution in conductivity water. The crystals are hexagonal, showing the forms $(10\bar{1}0)$ (1120) $(10\bar{1}1)$ and (1121). They probably belong to the normal class. The ratio $c:a$ was found to be 0.5075, although Benedicks has stated that it is 0.5014.

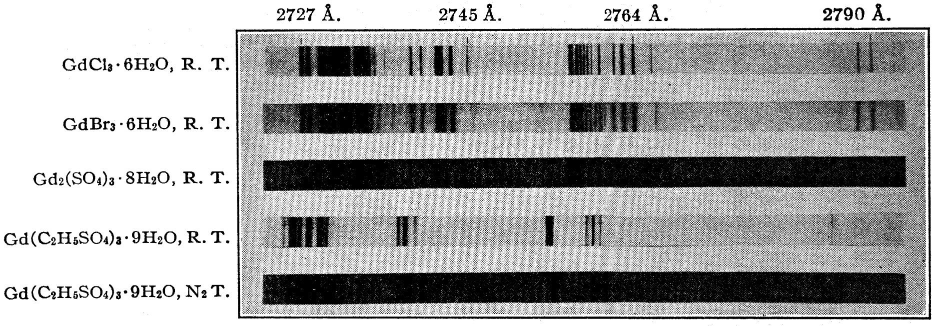

Fig. 1.

$Gd(BrO_3)_3 \cdot 9H_2O$.—A very dilute solution of $Gd_2(SO_4)_3 \cdot 8H_2O$ was added with vigorous stirring to an aqueous suspension of $Ba(BrO_3)_2 \cdot H_2O$. The mixture was kept on a steam-bath for several hours and then filtered. $Gd(BrO_3)_3 \cdot 9H_2O$ crystallized from the filtrate was obtained as large crystals on slow evaporation of a solution in conductivity water. The crystals belong to the hexagonal system, and probably to the normal class, although the possibility of pseudo-symmetry exists. Since the bromate ion begins to absorb near 3000 Å., only two multiplets were observed.

$Gd(NO_3)_3 \cdot 6H_2O$.—Gd_2O_3 prepared from the oxalate was dissolved in 3 N nitric acid and the excess acid removed by boiling. The salt was crystallized from a conductivity water solution. The crystals are triclinic with $a:b:c = 0.5571:1:0.7615$; $\alpha = 90°6'$, $\beta = 109°55'$; $\gamma = 109°48'$.

A Hilger E 185 spectrograph was used in all the work. The dispersion in the photographs of the bromate, bromide and chloride was about 3.0 Å. per mm. at 3000 Å. and 2.0 Å. per mm. at 2700 Å. The spectra of the sulfate and ethyl sulfate were photographed with an additional prism in the train and the dispersion was increased to 1.95 Å. per mm. at 3000 Å. and 1.35 Å. per mm. at 2700 Å.

Discussion of Results

In a previous letter[13] experimental evidence was presented which showed

The multiplets at 2755 Å. and 2730 Å. are not included in this table since they are not completely resolved.

---

[14] There may be two causes for the faintness of these lines. In the first place a conglomerate of many small crystals was photographed, and since these particular lines show strong selective reflection [Spedding and Bear, *Phys. Rev.*, **39**, 948 1932)], there is a tendency toward masking of the absorption. In the second place, at higher temperatures where the field fluctuations become large enough to cause a Paschen–Back effect, the excited levels become partially unstable and the lines blur and fade. At −190° all but one of the lines appear as do also the faint multiplets at 2990, 3180, 3250, 3500, 3920 and 3980 Å.

that all the lines arise from a single basic level, $^8S_{7/2}$, which is almost undisturbed by the crystal fields.[15] For this reason the positions of the lines and multiplets constitute effectivelyan energy level diagram of the excited levels. From Table I it is seen that the negative radicals have very little effect on the number and position of the multiplets which must therefore arise from electronic transitions of the Gd^{+++} ion. On the other hand, the number of lines and their positions within the multiplets are very much dependent on the nature of the chemical compound and evidently have their origin in the forces brought into play by the atoms surrounding the Gd^{+++}. The important factor in determining the splitting of the multiplet or excited level seems to be the crystal symmetry and not the negative radical, except in so far as the negative radical influences the crystal structure. The spectrum of the monoclinic $Gd_2(SO_4)_3 \cdot 8H_2O$ is almost identical with that of the monoclinic $GdCl_3 \cdot 6H_2O$, but very different from the hexagonal $Gd(C_2H_5SO_4)_3 \cdot 9H_2O$.

The symmetry and separation of the ions in the lattice determine the magnitudes and directions of the fields on the electrons of the Gd^{+++} ion and thus the amount and type of splitting of the levels. The lines are so slightly affected by the mass of the negative ions that it is unreasonable to assign their origin to vibrational effects.

While we do not wish to generalize widely from so few examples we shall nevertheless call attention to some of the regularities we have observed in the data. The spectra of the monoclinic crystals are similar, with the lines appearing at nearly the same frequencies in the several cases. The shift in position of the lines between room temperature and that of liquid nitrogen is almost as great as the shift in position of lines from compound to compound.

(15) The basic ^8S level is only very slightly affected by the electric fields since its orbital moment is zero. As Kramers has pointed out, there should be small splitting due to second-order terms, and that this exists is clearly shown by the Zeeman patterns. In the accompanying pictures made at room temperature it can he observed only as a slight widening of the lines.

On the other hand, the spectra of the hexagonal crystals are distinctly different from those of the monoclinic, the multiplets being much narrower and shifted toward higher frequencies (Table III). The spacings are also different and in some cases fewer lines are observed.[16] Since only one band from a triclinic crystal has been measured, no conclusions can be drawn, but preliminary observations on gadolinium acetate, which is triclinic, indicate that its spectrum is different from that of both the hexagonal and monoclinic types.

These results are in qualitative agreement with predictions made by Bethe[6] on theoretical grounds. Quantitative results, however, are not to be expected as he made many simplifying assumptions which do not apply here.

Summary

Absorption spectra of gadolinium inn in crystals consist of lines which arise from electronic transitions from a single basic level $4f^7$, $^8S_{7/2}$, to excited levels which are non-degenerate through the influence of the electric fields of the neighboring ions. The amount and nature of the splitting depend upon the symmetry and separation of the ions in the lattice with higher symmetry corresponding to smaller separations of the levels.

We are continuing this work, extending the number of compounds in each crystal system and including anhydrous as well as hydrated compounds.

(16) While hexagonal crystallographic symmetry does not necessarily mean that there is hexagonal symmetry about the gadolinium ion, it is likely that the symmetry in the hexagonal crystals is much higher than that in the monoclinic.

The Recording of Pressure and Time in Gas Explosions[1]

BY BERNARD LEWIS[2] AND GUENTHER VON ELBE[3]

Numerous investigations have been made of the increase in pressure during gas explosions in closed vessels. Generally, the instrument for indicating the pressure has been a thin metal diaphragm whose deflection is measured by a suitable optical arrangement. These diaphragms are, on the whole, very satisfactory for following rapid pressure changes. As they have been used, however, they possess at least two serious disadvantages. First, the tension of the diaphragm is dependent on the strength with which it is clamped into position. This clamping strength may be

---

(3) Research Associate, University of Virginia.

altered during explosions and so vitiate the calibration of the diaphragm. Second, these diaphragms usually possess apparent hysteresis, which, we believe, is to be attributed not so much to the diaphragm itself as to the inelastic clamping gaskets commonly used.

We have developed a diaphragm indicator which effectively overcomes these difficulties and which has been used successfully for the recording of ozone explosions from which the specific heat of oxygen has been obtained.[4] This diaphragm and a method of dynamic calibration, together with several other features, will be described in this paper.

A sketch of the diaphragm clamped into the opening of the bomb is given in Fig, 1 and Fig. 1a.

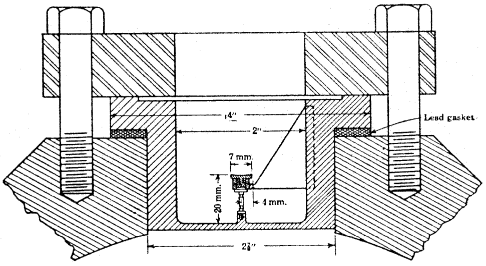

Fig. 1.

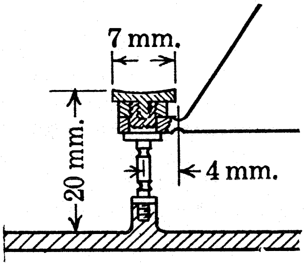

Fig. 1a.

A large cylinder of high-grade nickel steel is worked on the lathe to the shape given in the figure. The diaphragm itself forms the bottom of the piece and has a seat left in its center into which the piece carrying the mirror can be screwed rigidly by means of a conical thread. This piece consists of a thin rod of spring steel in which two necks have been cut to allow flexibility. Over the end of the central piece is fitted a thin ring which is kept rigid by means of a small nut. The ring is a part of a heavy piece of the same spring steel which is firmly dovetailed into the heavy wall of the diaphragm piece Immediately adjacent to the ring and part of the same piece, another flexible neck is cut The mirror, which is screwed into the top of the central piece by means of a conical thread, is concave and made of high-grade stainless steel. It was ground very accurately to a focal length of 1.5 meters by the astronomical instrument makers, John A. Brashear Co., Pittsburgh. Assembled, the whole mechanism was rigid as though made of one piece. When pressure is exerted on the back face of the diaphragm the center piece tends to move out and is forced to deflect to the right by reason of the necks. The mirror therefore moves about a circle with a radius of 4 mm., the distance between the center of the central rod and the center of the adjacent neck. The magnification of this system for a distance of 1 5 meters between the mirror and the film is about 1000. Thus only very small deflections of the diaphragm itself need take place for reasonable movements of the light point on the film This has an obvious and important advantage, since the diaphragm can be made relatively thick and so possess a high natural frequency which is desirable in explosion experiments.

The whole piece was clamped rigidly into the opening of the bomb by bolts and a flange as shown in the figure. The strain was applied to the rim of the piece, leaving the diaphragm proper perfectly free. It was impossible for it to change its position as a result of explosions.

---

(4) Lewis and von Elbe, THIS JOURNAL, 55, 511 (1933).

Calibration of Diaphragm.—Calibrations were made in two ways, dynamically and statically. In the dynamic method the pressure was applied to the diaphragm in a time interval of about 0.01 second, which was about the same order as the time during which the pressures were released in explosions under investigation. The results showed that with this type of diaphragm there was no difference between the two methods of calibration. This strongly indicates that hysteresis effects are negligible for the deflections employed.

For the dynamic calibration, the device shown in Fig. 2 was used. It was fitted into the bomb through a hole directly opposite the hole carrying the diaphragm. The distance between the end face of the calibration cylinder and the face of the diaphragm was about $^1/_{16}$ inch. It is essential for correct results that no part of the diaphragm piece be touched by the calibration cylinder. The space between was sealed from the rest of the bomb space by means of a rubber gasket. The cylinder was filled with hydrogen gas at a known pressure, which was suddenly released onto the diaphragm by quickly turning a quadruple screw which opened a needle valve. A large accurately calibrated gage of the Bourdon type was in the system all the time. The time during which the total pressure was released on the diaphragm depended on the gas used and not on the above manipulations. This was made clear by calibrations with carbon dioxide gas, which showed conclusively that the time required to reach the final pressure in the calibration was a function of the viscosity of the gas used. The line on the film representing the pressure increase coincided with the final pressure line on the film for both carbon dioxide and hydrogen in a time of the order of 0.01 second from the commencement of pressure increase

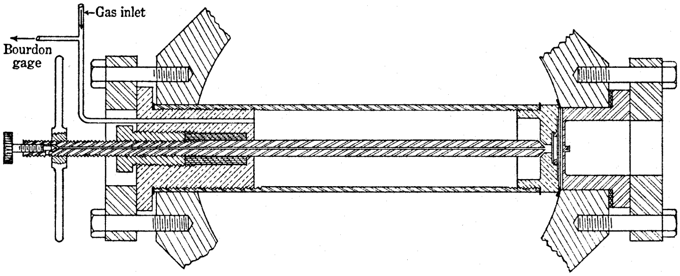

Fig. 2.

The calibration cylinder is easily removed and replaced whenever it is desired to make a new calibration. It may be stated, however, that the diaphragm described above showed the same calibration after it was removed from the bomb and replaced again on several occasions.

Recording on the Film of Instant of Passage of Explosion Spark.—Since it was desired to make time–pressure analyses of the explosions taking place in the bomb,[5] a device was used which essentially is not new but which deserves description. An auxiliary spark was placed at the focus of a parabolic mirror which was built into the housing covering the rotating film. This spark was in series with the main spark at the center of the bomb. By means of a slit the auxiliary spark made a sharp narrow line on the film at right angles to its movement. Both sparks passed when contact was broken by a switch operating with the moving shaft. The procedure was to hold the film stationary and to record the fine light point from a carbon arc and the line from the auxiliary spark on the film. (The bomb spark was disconnected during this operation.) The film was now allowed to rotate at a constant speed and both sparks allowed to pass. The original distance between the auxiliary spark line and the light point made when

---

(5) Lewis and von Elbe, in preparation.

the film was stationary, measured back from the new auxiliary spark line made with film in motion, located the point on the film at which the light point was when the spark passed in the bomb.

Summary

A diaphragm indicator for measuring the pressures developed in explosions is described. Its essential advantages are sensitivity, freedom from hysteresis for the deflections employed, and constancy. A method of calibrating dynamically, without removing the diaphragm from the explosion chamber, is described in which pressures are released against the diaphragm in a time interval of the same order as in explosians. It is shown that for this type of diaphragm the observed deflections for a given range of pressures investigated are the same for dynamic as for static calibration.

Thermal Equilibrium between Oxygen Molecules and Atoms[1]

BY GUENTHER VON ELBE[2] AND BERNARD LEWIS[3]

During the course of experiments carried out at the Pittsburgh Experiment Station of the U. S. Bureau of Mines on the direct determination of the specific heat of oxygen at high temperatures by exploding mixtures of ozone and oxygen,[4] it was necessary to know the degree of dissociation in order to obtain accurate values of the specific heats. Since this information is not available in the literature, we have set up an equation for the equilibrium constant of the reaction 2O O_2 expressed as

$$K_p = \frac{[p_{\text{at.}}]^2}{p_{\text{mol.}}} \tag{1}$$

One commences with the well-known fundamental thermodynamic equation

$$AF = AH - TAS \tag{2}$$

For the condition of equilibrium between atoms and molecules of oxygen $AF = 0$, and therefore

$$0 = (\Delta H/T) - AS \tag{3}$$

The entropy per mole of each participant in the reaction is given by

$$S = C_{p_0} \ln T + \int_0^T \frac{C_{\text{vib}}}{T} \mathrm{d}T - R \ln p + Ri + C_{p_0} \tag{4}$$

where C_{p_0} is the constant part of the specific heat at the temperature T,

(4) Lewis and von Elbe, THIS JOURNAL, 55, 511 (1933).

i. e., due to translation and rotation; $C_{\text{vib.}}$ is the specific heat due to vibrations of the molecule, p is the partial pressure of each constituent at equilibrium, i is the chemical constant of each constituent.

Equation 4 includes the Sackur equation for translational entropy and also the rotational entropy for the case that rotation is fully excited. This may be shown by comparison with the statistical formulas

$$S_{\text{trans.}} = {}^5/_2 R \ln T - R \ln p + {}^3/_2 R \ln m + R \ln \left[(2\pi)^{3/2} k^{5/2}/h^3\right] + R \ln g + {}^5/_2 R \qquad (3a)$$

$$S_{\text{rot.}} = {}^2/_2 R \ln T - R \ln (\text{symmetry number}) - R \ln \frac{h^2}{8\pi^3 Ik} + {}^2/_2 R \qquad (3b)$$

Adding 3a and 3b results in equation 3, less the vibrational part, *viz.*

$$S_{\text{trans.}+\text{rot.}} = {}^7/_2 R \ln T - R \ln p + Ri + {}^7/_2 R \qquad (3c)$$

Giauque and Johnston[5] have calculated the entropy of molecular oxygen from 0°K. to 298°K. which includes ($S_{\text{trans.}} + {}_{\text{rot.}} + {}_{\text{vib.}} + i_{\text{mol.}}$) where $i_{\text{mol.}}$ is the chemical constant of the oxygen molecule. Their value for this at one atmosphere pressure is 49.03 entropy units which we shall employ. Equation 3 transforms to

$$0 = \frac{\Delta H}{T} - \left[2S_{\text{at.}} - \left(S_{\text{mol.}}\Big|_{298}^{T} + 49.03\right)\right] \qquad (5)$$

where $S_{\text{at.}}$ represents the entropy of the oxygen atom and $S_{\text{mol.}}\Big|_{298}^{T}$ is the part of the entropy of the oxygen molecule between 298°K. and T°K. This expands to

$$0 = \frac{\Delta H_0}{T} + \frac{\int_0^T 2C_{p_{\text{at.}}}}{T}\,\mathrm{d}T - \frac{\int_0^T C_{p_{\text{mol.}}}}{T}\,\mathrm{d}T - 2S_{\text{at.}} + S_{\text{mol}}\Big|_{298}^{T} + 49.03 \qquad (6)$$

Substituting for the entropy, equation 4, one obtains

$$0 = \frac{\Delta H_0}{T} + \frac{\int_0^T 2C_{p_{\text{at.}}}}{T}\,\mathrm{d}T - \frac{\int_0^T C_{p_{\text{mol.}}}}{T}\,\mathrm{d}T - 2R\left[{}^5/_2 \ln T - \ln p_{\text{at.}} + i_{\text{at.}} + {}^5/_2\right] +$$
$$R\left[{}^7/_2 \ln T + \frac{1}{R}\int_0^T \frac{C_{\text{vib.}}}{T}\,\mathrm{d}T - \ln p_{\text{mol.}} + {}^7/_2 + i_{\text{mol.}} - \left({}^7/_2 \ln 298 + \right.\right.$$
$$\left.\left.\frac{1}{R}\int_0^{298} \frac{C_{\text{vib.}}}{T}\,\mathrm{d}T - \ln 1 + {}^7/_2 + i_{\text{mol.}}\right)\right] + 49.03 \qquad (7)$$

The expression $\int_0^{298} (C_{\text{vib.}}/T)\,\mathrm{d}T$ is negligibly small. Transposing, dividing by R and changing to logs to the base 10

$$\log \frac{[p_{\text{at.}}]^2}{p_{\text{mol.}}} = -\frac{\Delta H_0}{2.3\,RT} + \frac{3.5}{2.3} + 5 \log \mathrm{T} + \frac{2i_{\text{at.}}}{2.3} - 3.5 \log T + 3.5 \log 298 -$$
$$\frac{49.03}{2.3\,R} - \frac{1}{2.3\,R}\int_0^T \frac{C_{\text{vib.}}}{T}\,\mathrm{d}T \qquad (8)$$

ΔH_0 is the heat of dissociation at absolute zero which is equal to 117,300 calories per mole.[6] This value is for dissociation from the $^3\Sigma$ state of the

(6) Paschen, *Naturwissenschaften*, **84**, 752 (1930); Sommer, *ibid.*, **34**, 752 (1930); Frerichs, *Phys. Rev.*. **36**, 398 (1930).

oxygen molecule to the ${}^3P_2$ state of the atom (see below). The expression $\int_0^T (C_{\text{vib.}}/T)\,dT$ can be evaluated by Einstein functions $(F - F_0)/T$.[7] There is practically no difference between the values so derived and the values derived from the spectroscopic vibrational–rotational levels of the molecule. This is known by a comparison of such calculations.[4] This also makes it unnecessary to account for the change of the moment of inertia $\mathbf{I}$ in $i_{\text{mol.}}$ for higher rotational levels (compare equation 3b). Using the value of **1556.4** cm.$^{-1}$ for the separation of the first vibrational level of the oxygen molecule[8] we obtain

$$\frac{\beta\nu}{T} = \frac{2229}{T}$$

from which $(F - F_0)/T$ can be evaluated. $i_{\text{at.}}/2.3$ is expressed by the well-known equation[9]

$$\frac{i_{\text{at.}}}{2.3} = -1.587 + 1.5 \log M + \log g \qquad (9)$$

where M is the atomic weight of the oxygen atom and g is the statistical weight of the atomic state.

The value of g is derived in the following way. The ground level of the oxygen atom is a triplet state in which the three terms ${}^3P_2$, ${}^3P_1$ and ${}^3P_0$ are separated by small energy differences: ${}^3P_2 - {}^3P_1 = 447$ calories, ${}^3P_2 - {}^3P_0 = 635$ calories. The multiplicity of the separate terms can be obtained from measurements of magnetic susceptibility made by Kurt and Phipps.[10] They find a multiplicity of 5 for the ${}^3P_2$ term, 3 for ${}^3P_1$ and 1 for ${}^3P_0$.

The statistical weight g of the atomic state is given by the sum of the products of the multiplicity of the terms ${}^3P_2$, ${}^3P_1$ and ${}^3P_0$ and the probability of the atoms being in each of these states, referred to the lowest state ${}^3P_2$. Then

$$g = 5 + 3e^{-447/RT} + e^{-635/RT} \qquad (10)$$

The complete equation for $\log K_p$ is

$$\log K_p = -\frac{117300}{4.571\,T} + 1.5 \log T - \frac{(^1/_3 F/T;\ \beta\nu/T = 2229/T)}{4.571} - 0.104 + 2 \log (5 + 3e^{-447/RT} + e^{-635/RT}) \qquad (11)$$

However, equation 11 must be revised by the addition of another term relating to the oxygen molecule, for the following reasons.

In our experimental determination of the specific heat of oxygen up to 2500°K., the results show that the experimental values of the specific heats are always higher than those calculated from the vibrational–rotational levels of the normal state of the molecule[4] in the temperature range investi-

(10) Kurt and Phipps. Phys. Reu., 84, 1357 (1929).

gated. The difference becomes more pronounced with increasing temperature. It has been pointed out[11] that this difference can be accounted for by the predicted metastable 'A level of the neutral oxygen molecule. It turns out that the separation of this level from the ground state $^3\Sigma$ is 0.75 ± 0.05 volt or 17,200 ± 1000 calories.

The ratio of the multiplicities of the $^1\Delta$ and $^3\Sigma$ states is $^1\Delta/^3\Sigma = {}^2/_3$.[11] We therefore obtain for the statistical weights an expression for the molecule similar to that found for the atom: namely

$$\log g_{\text{mol.}} = \log (3 + 2e^{-17{,}200/RT}) \tag{12}$$

This term, except that part representing the multiplicity of the $^3\Sigma$ state, namely, log 3, which is already included in Giauque and Johnston's value of the entropy of the oxygen molecule, must be subtracted from equation 11.

The revised equation for log K_p is then

$$\log K_p = -\frac{117{,}300}{4.571\,T} + 1.5 \log T - \frac{\left(\frac{1}{3}\frac{F}{T}, \frac{\beta\nu}{T} = \frac{2229}{T}\right)}{4.571} - 0.104 + 2 \log (5 + 3e^{-447/RT} + e^{-635/RT}) - \log \left(1 + \frac{2}{3} e^{-17{,}200/RT}\right) \tag{13}$$

We believe that this equation is valid up to 4000°K. and may apply up to 5000°K. without serious error. The following table contains the calculated values of log K_p, and the per cent. dissociation x for one atmosphere pressure up to 5000°K. The value of x is derived from the expression

$$K_p = \frac{4x^2}{1 - x^2} P \tag{14}$$

TABLE I

VALUES OF LOG K_p AND DEGREE OF DISSOCIATION OF OXYGEN AT ONE ATMOSPHERE PRESSURE

T, °K.	Log K_p	x, %	T, °K.	Log K_p	x, %
1400	−11.968	5×10^{-5}	2800	−2.495	2.83
1600	− 9.610	8×10^{-4}	3000	−1.858	5.88
1800	− 7.772	6.5×10^{-3}	3500	−0.577	24.9
2000	− 6.298	0.0353	4000	+0.379	61.3
2200	− 5.091	0.142	4500	+1.120	87.6
2400	− 4.078	0.452	5000	+2.715	96.4
2600	− 3.228	1.22			

Experimental proof for the correctness of the degree of dissociation is given by experiments on the specific heat of oxygen.[4] At high temperatures, say 2400°K., the experimental points are far above the values of specific heats calculated from the vibrational–rotational levels of the molecule. This is accounted for by dissociation and the $^1\Delta$ level contribution to the specific heat. While at lower temperatures the dissociation rapidly disappears, the $^1\Delta$ level contribution decreases slowly. Therefore, at lower temperatures the difference between experimental values and those

---

(11) Lewis and von Elbe, *Phys. Rev.*, 41,078 (1932).

from the vibrational–rotational levels is due only to the $^1\Delta$ level contribution. One can determine the separation of the $^1\Delta$ level from the $^3\Sigma$ level, from the experimental points at lower temperatures, *i. e.*, about 2000°K., and plot the new specific heat values given by the $^1\Delta$ level curve up to 2400°K. From the difference between this curve and the weighted mean of a large number of experimental points at this temperature, one obtains the degree of dissociation given by the above formula.

Summary

A rigorous equation is derived for the equilibrium constant of the reaction $2O \rightleftharpoons O_2$ with the aid of optical data and new determinations of the specific heat of oxygen at high temperatures. A table is given for log K_p and the degree of dissociation up to 5000°K. Experimental proof for the correctness of the degree of dissociation is given.

The Specific Heat of Oxygen at High Temperatures from Ozone Explosions and the Energy of the $^1\Delta$ Level of the Neutral Oxygen Molecule[1]

BY BERNARD LEWIS[2] AND GUENTHER VON ELBE[3]

The theory of specific heats of gases demands that at high temperatures they be represented by the classical translational and rotational values of the specific heats plus the vibrational contribution. As far as molecular vibrations can be considered to be harmonic they are represented simply by the Planck–Einstein equation for an harmonic oscillator. This equation expressing the mean vibrational specific heat of one mole of gas for one vibrational degree of freedom between 300°K. and T is given by

$$\bar{C}_{\text{vib}300}^{\,T} = \frac{1}{T - 300}\left(\frac{\epsilon_0}{e^{\epsilon_0/RT} - 1}\right) \qquad (1)$$

where ϵ_0 is the energy in calories per mole of the first vibrational level of the degree of freedom of the molecule considered. Tables for this function are available for example in Landolt–Börnstein.[4]

For a more rigid calculation involving the anharmonic oscillations of the actual molecule, one would use the actual separations of the higher vibrational levels wherever these are available from spectroscopic data, using the same statistical principles underlying the Planck–Einstein formula.

(2) Physical chemist, U. S. Bureau of Mines, Pittsburgh Experiment Station, Pittsburgh, Pa.

(3) Research associate, University of Virginia.

(4) Landolt-Börnstein, Supplementary Volume 1, p. 702.

The equation would then read

$$\bar{C}^{\,T}_{\mathrm{vib}_{300}} = \frac{1}{T-300}\,\frac{\epsilon_1 e^{-\epsilon_1/RT} + \epsilon_2 e^{-\epsilon_2/RT} + \epsilon_3 e^{-\epsilon_3/RT} + \ldots\ \epsilon_n e^{-\epsilon_n/RT}}{1 + e^{-\epsilon_1/RT} + e^{-\epsilon_2/RT} + e^{-\epsilon_3/RT} + \ldots\ e^{-\epsilon_n/RT}} \qquad (2)$$

where ϵ_1 is the separation of the first vibrational level above the ground state of the molecule, ϵ_2 is the separation of the second vibrational level above the ground state of the molecule, etc., expressed in calories per mole.

To obtain the total mean specific heat there must be added to the vibrational contribution given by equation 2, $^5/_2R$ (translational and rotational contributions) and a small amount due to the fact that the rotational levels are not equally spaced but become more closely packed with each successively higher vibrational level (see below). This closer packing of the rotational levels favors the excitation of the molecule above that which would exist were the packing of the rotational levels identical. In addition, if there is an electronic level lying close enough to the ground state of the molecule so that an appreciable number of molecules reach this level at a temperature T, a further contribution to the specific heat will be made from this source.

The results of the present investigation of the specific heat of oxygen indicate that the predicted but hitherto unknown $^1\Delta$ electronic level of the oxygen molecule[5] must be considered. It is possible from our data to locate this level at 0.75 ± 0.05 volt or 17,200 ± 1000 calories above the normal $^3\Sigma$ state of the molecule.[6]

It is extremely fortunate in an experimental determination of the specific heat of oxygen to be able to explode a single gas such as ozone which results only in one product, namely, the gas being studied. The decomposition of ozone seems to be the only such reaction provided by nature. In addition, it should perhaps be the simplest and most direct case to lend itself to a fundamental study of the propagation of explosions in space. The latter study is in progress in this Laboratory at the Pittsburgh Experiment Station, the details of which will appear in a later publication.

Apparatus, Materials **and** Experimental Procedure.—The bomb in which the explosions were carried out was a chrome-plated iron sphere of 300 mm. diameter. The pressure recording diaphragm used and the method of calibration are described in the preceding publication[7] A 10-inch Duragauge of the Bourdon type reading accurately to 0.1% used in this work, was calibrated by the Bureau of Standards. After the completion of the experiments it was recalibrated by us with a dead weight tester calibrated by the Bureau of Standards and found to check the original calibration. Ignition of the mixture was accomplished by a small spark between two platinum points placed accurately in the center of the sphere. The wires were fused into a glass capillary tube $^3/_{32}$ inch outer diameter which entered the sphere through a hole in the end plug. No organic material was used in construction. With the bomb chrome-plated, the interior became perfectly passive to the presence of ozone after it had been exposed to the gas

for some time. This was desirable, since it allowed one to fill the bomb with any desired mixture of ozone and oxygen.

The ozone was prepared in the liquid state with a purity of nearly 100% (any impurity being oxygen) by the method of Riesenfeld and Schwab,[8] the usual precautions[9] being taken to exclude organic matter. It was allowed to evaporate very slowly[10] into the bomb by surrounding the tube containing the liquid ozone with an empty unsilvered Dewar flask which just previously had been flushed with liquid air.

Pressure readings were taken with a mercury manometer protected by a buffer of oxygen gas. An accurate manometer was constructed with a vernier attachment and readings were made on accurate steel scales. The valves through which the gases entered the bomb were stainless-steel needle valves The temperature of the gases in the bomb was taken with a mercury thermometer inserted deeply into the wall of the bomb and maintained in mercury for good thermal contact. The temperature was read when thermal equilibrium had been established.

After the ozone had entered the bomb its pressure was measured and a suitable amount of pure oxygen was added (electrolytic oxygen with the hydrogen burned out and dried) and allowed to stand to ensure mixing. Measurements of the pressure were taken between time intervals just previous to explosion to measure decomposition, if any. After the bomb had been in use a little while, no decomposition was observed. The explosion was carried out and a time–pressure record was obtained[11] on a rotating photographic film. After the explosion, the temperature in the bomb was allowed to come to equilibrium, and the temperature and pressure readings were taken. The pressure before and after the explosion, corrected to a suitable common temperature. allowed one to determine accurately the amount of ozone originally present.[12]

Method of Calculation.—A series of explosions was made with mixtures having ratios of oxygen to ozone of 0.85 to 3.5, resulting in explosion temperatures ranging between 1400 and 2500°K. Initial pressures were varied between 300 and 760 mm., while the final explosion pressures ranged from about 3000 to 5000 mm.

The method of evaluating the mean specific heat is as follows. The experimental data consist of P_i, initial pressure before explosion; T_i, initial temperature of gases before explosion; P_{ie}, the pressure after the explosion measured at T_i; ΔP, increase in pressure from P_i to maximum explosion pressure as measured on film. All pressure readings were reduced to a mercury column at 0°, accounting for the temperature coefficient of the metal scale. All gas pressures P_{ie} were reduced to the common temperature, T_i.

The reaction considered is $2O_3 = 3O_2 +$ heat of decomposition. For the case of no dissociation

$$T_e = \frac{P_e \times T_i}{P_{ie}} \tag{3}$$

where P_e is the total explosion pressure consisting of $\Delta P + P_i$, and T_e is

---

(8) Riesenfeld and Schwab, *Ber.*, 66, 2088 (1922).

(9) See, for example, Lewis and Feitknecht. THIS JOURNAL, 63,2910 (1931).

(10) The amount of liquid ozone required for one experiment varied from 4 to 10 cc. Care should be exercised in handling these quantities of liquid ozone. If allowed to evaporate too fast or violently, powerful explosions result.

(11) For details of this time–pressure re-ording device see Ref. 7

(12) Ozone decomposition was always complete.

the final explosion temperature. The number of moles of oxygen per mole of ozone present before the explosion is given by

$$\frac{P_i - 2(P_{ie} - P_i)}{2(P_{ie} - P_i]} = \frac{n_{O_2}}{\text{nor}} \tag{4}$$

The heat of decomposition at constant volume of 1 mole of ozone is 34,220 ± 280 calories.[13] Then

$$\bar{C}_{v_{T_i}}^{Te} = \frac{34220}{\Delta T[1.5 + (n_{O_2}/n_{O_3})]} \tag{5}$$

where $\bar{C}_{v_{T_i}}^{Te}$ is the mean specific heat at constant volume between T_i and T_e. T_i was always about 300°K.

For the case of dissociation equation **3** changes to

$$T_e = \frac{P_e}{(1+x)}\frac{T_i}{P_{ie}} \tag{3a}$$

The value calculated from equation (5) is too high by an amount C_D, the specific heat contribution calculated from the degree of dissociation into atoms. This is given by

$$\bar{C}_D = \frac{H_{v_T}\, x}{\Delta T} \tag{6}$$

where H_{v_T} is the heat of dissociation of the oxygen molecule at constant volume and temperature T. It is calculated from the expression

$$H_{v_T} = H_0 + \int_0^T (2C_{v_{at.}} - C_{v_{mol.}})\mathrm{d}T \tag{7}$$

where H_0 is the heat of dissociation at O°K. and is equal to 117,300 calories.[14] $C_{v_{at}}$ is the specific heat of the oxygen atom which is equal to $3/2R$, and $C_{v_{mol.}}$ is the specific heat of the oxygen molecule, which is equal to $^5/_2R$ plus the vibrational specific heat contribution up to T°K. x is the degree of dissociation given by the formula

$$K_p = \frac{[p_{at.}]^2}{p_{mol.}} = \frac{4x^2}{1 - x^2} P_e \tag{8}$$

The equation for log K_p is[15]

$$\log K_p = \frac{-117{,}300}{4.571T} + 1.5 \log T - \frac{(1/3F/T;\ \beta_\nu = 2229)}{4.571} - 0.104 + 2 \log (5 + 3e^{-447/RT} + e^{-635/RT}) - \log (1 + {}^2/_3e^{-17200/RT}) \tag{9}$$

Below 1800°K., dissociation is negligible.

Results

The results of the experiments are given in Fig. 1. The points represent the mean specific heats between 300 and T°K. at constant volume corrected for dissociation.

These will now be compared with the theoretical values of the specific heats. The dotted line represents the specific heats according to the Planck–Einstein equation. A value of 1556.4 cm.$^{-1}$ for the separation of the first vibrational level of the oxygen molecule[16] or 4425.6 calories was used for ϵ_0, giving a value of $\beta\nu = 2229$.

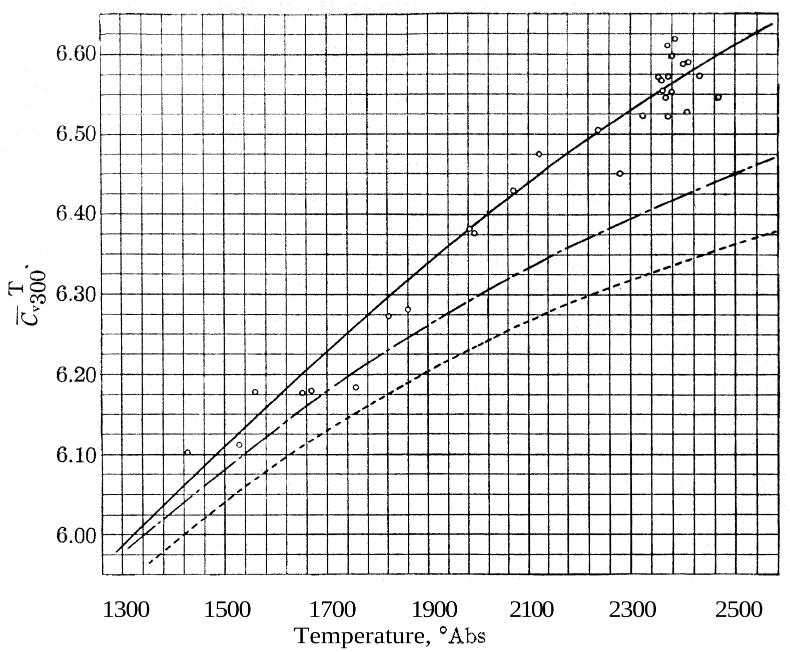

Fig. 1.—Specific heat of oxygen from ozone explosions: - - - - - theoretical specific heat of oxygen from Planck–Einstein equation; — - — theoretical specific heat from values of vibrational–rotational levels of oxygen molecule; ———— new specific heat curve which includes $^1\Delta$, level contribution; ○ experimental values corrected for dissociation.

The more exact theoretical curve is given by the dot-dashed line as calculated from the known separations of the higher vibrational levels of the oxygen molecule, using equation *2*. Professor R. T. Birge kindly provided us with new extrapolated values of the separations of the lower nine levels, which were used. The extrapolated separation of the first level is 1553.8 cm.$^{-1}$, whereas the observed value is 1556.4 cm.$^{-1}$. We solved this difficulty by using the differences between the extrapolated separations and applying them to an initial separation equal to the observed, 1556.4 cm.$^{-1}$. The separations used are as follows

Vibrational level, v =	1/2	3/2	5/2	7/2	9/2	11/2	13/2	15/2	17/2
ΔG, cm.$^{-1}$	1556.4	1533.9	1511.4	1488.9	1466.3	1443.7	1421.1	1398.5	1375.9

Our values of the mean vibrational specific heats so calculated, check with the values calculated by Dr. H. L. Johnston[17] except for the small amount which is due to the fact that the rotational levels crowd together more closely with increasing vibrational states. We call this latter contribution "rotational stretching" of the molecule. For the value of this rotational stretching we are indebted to Dr. Johnston.

Discussion of Results

The experimental values are always higher than the theoretical curve in the temperature range investigated, the difference becoming more pronounced with increasing temperature.

Analysis of the slope of the cooling curves in these explosions led us to believe that heat losses before maximum pressure is established are negligible. Heat losses if any could only be confined to radiation losses because the burned gas is isolated from the wall until the end of the combustion by unburned gas, the increase in temperature of which due to adiabatic compression is small.[18] But even the radiation losses at thermal equilibrium are entirely negligible as is shown by the small slope of the cooling curves on the film. The cooling, as represented by these curves, is by far due to cooling by conduction. Any appreciable activated radiation, that is, radiation due to transitions from higher electron levels, is out of the question, because the first radiating electron levels above the normal state are too high for appreciable numbers of molecules and atoms to be raised to them at the temperature of these explosions. Transition from the predicted $^1\Delta$ metastable level is not possible.

It is inconceivable that so-called "afterburning" should exist in the present case, since the ozone molecule is so sensitive to decomposition and the collision frequency in the flame front is already so high. Moreover, afterburning would round off the maximum in the pressure diagram of which there is no indication especially in the fastest explosions.

The difference between the experimental and theoretical curves must therefore be due to the presence of the predicted $^1\Delta$ metastable level.

It may be remarked that there is a certain amount of scattering in the experimental results, the maximum deviation from the mean being about 0.8%.

By running a considerable number of explosions around 2400°K. we were able to locate an experimental point at 2385°K. which had a weighted mean of $\bar{C}_v = 6.56 \pm 0.02$. The difference of $\bar{C}_v$ at 2385°K. between the theoretical and experimental points is 0.146 ± 0.02.

If n_{1_Δ} is the fraction of one mole of oxygen raised to the $^1\Delta$ level whose energy is E_{1_Δ} calories per mole, then

---

(17) Private communication.

(18) A detailed analysis of the movement of the flame front in these explosions in the spherical bomb will be given in a forthcoming article.

$$0.146 = \frac{n_{1_\Delta}}{T - 300} E_{1_\Delta} \tag{10}$$

The fraction n_{1_Δ} is given by the statistical relation[6]

$$n_{1_\Delta} = \frac{N_{1_\Delta}}{N_{3_\Sigma} + N_{1_\Delta}} \sim {}^2/_3 e^{-E_{1_\Delta}/RT} \tag{11}$$

E_{1_Δ} is equal to 17,200 ± 1000 calories or 0.75 ± 0.05 volt.

The solid lines is the new mean specific heat curve which now includes the ${}^1\Delta$ Level contribution, It is seen that it fits the experimental points very well along the whole range.

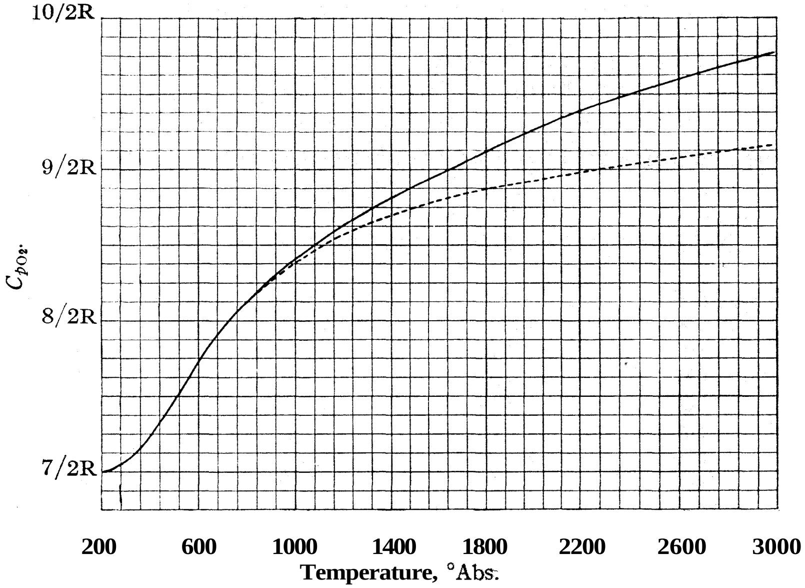

Fig. 2.—C_p of oxygen molecule against absolute temperature: - - - - - includes translation + rotation + vibration + stretching + R + ${}^1\Sigma$ level contribution; ———— same + ^{1}A level contribution.

The results also give a fair experimental proof of the equation for the dissociation of oxygen molecules into atoms proposed by us, for if the degree of dissociation were substantially different from the values calculated at about 2400°K., one would not be able to separate the part of the specific heat due to the ${}^1\Delta$ level and have the curve of the latter fit the experimental points at lower temperatures.[14]

The total specific heat of oxygen up to temperatures of 3000°K. is composed of the translational, rotational, vibrational, rotational stretching and electronic contributions. To calculate the true specific heats from the mean specific heats is a laborious operation. To enable one readily to evaluate the true specific heat of oxygen per mole at any temperature between 200 and 3000°K., we have carried out these operations and have developed two empirical formulas for two ranges of temperature.

The curve for C_p is plotted in Fig. 2. The dotted curve includes translation, rotation, vibration, stretching and the contribution from the $^1\Sigma$ level, which is 37,300 calories above the ground state. The latter contribution to the specific heat becomes appreciable at about 2700°K. The addition of the $^1\Delta$ level contribution to the dotted curve gives the true specific heat and is given by the solid curve.

The formulas representing this curve are

1. Valid between 200 and 800°K.

$$C_{p_{O_2}} = 6.951 + 0.068 \times 10^{-4} (T - 200)^2 - 0.0048 \times 10^{-6} (T - 200)^3 - 0.000225 \times 10^{-8} (T - 200)^4$$

2. Valid between 900 and 3000°K.

$$C_{p_{O_2}} = 6.951 + 2.400 \times 10^{-3} (T - 300) - 0.700 \times 10^{-6} (T - 300)^2 + 0.0270 \times 10^{-12} (T - 300)^4$$

Table I contains values of C_p from 200 to 3000°K.

TABLE I

VALUES OF TRUE SPECIFIC HEAT OF OXYGEN FROM 200 TO 3000°K.

T, °K.	True C_p	C_p from empirical formulas	Deviation of formula, %
200	6.951	6.951	0
300	7.016	7.023	+0.10
450	7.301	7.292	− .13

2750	9.616	9.601	− .16
3000	9.725	9.761	+ .37

As the proof of this paper was being corrected there appeared a paper by **Wohl** and **Magat** [Z. *physik. Chem.*, **19B**, 117 (1932)] on the specific heats and dissociation of gases at high temperatures. Concerning that part of their paper dealing with the specific heat of oxygen, it is noticed that their experimental values are lower than ours. As a matter of fact their values are lower than those calculated from the ordinary Planck–Einstein formula. They attribute this to the incomplete excitation of the oxygen vibrational levels during the time of explosion. On the other hand, our values are higher and they have been well accounted for as outlined in this paper. It may be argued that heat losses would account for our results. This question has been discussed with the exception of possible heat losses through the glass rod ignition system. The surface of the ignition rod is not isolated from the hot gas during the explosion as is the case with the wall of the bomb. It can be shown that in our case the heat loss through the rod is less than 0.02%. This value is arrived at from the slope of the cooling curve immediately following the sharp maximum. From the cooling curve the heat loss after the maximum in a time corresponding to the duration of the explosion is somewhat less than 2%. The surface of the ignition rod is about $^1/_{100}$ the surface of the bomb walls. Not considering the smaller heat conductivity of glass as compared with that of the chromium-plated walls and also the fact that the entire glass rod is not in contact with the hot gases throughout the duration of the explosion, the heat loss through the glass rod is certainly less than 0.02%. This negligible heat loss is in agreement with the findings of Wohl and Magat, who show that only in the case of explosions of hydrogen and oxygen with excess hydrogen but not with excess oxygen is there any appreciable heat loss through the ignition rod. These remarks refer always to explosions in which there is a sharp maximum.

The crucial test is a comparison of explosions at different pressures. Since the heat conductivity of the hot gas is the same at different pressures, the absolute heat loss should be independent of the pressure but the percentage heat loss should be larger in the case of lower pressures and therefore the calculated values of the specific heats should be higher at lower pressures. We find however no influence of pressure on the specific heats.

We are at *a* loss to understand the low values of specific heats obtained by Wohl and Magat unless our explosion times are slightly larger than theirs. However, we hope to repeat that part of Wohl and Magat's work dealing with this subject, in our own apparatus.

Summary

The mean specific heat of oxygen between 300°K. and 1400 to 2500°K. has been determined by exploding ozone–oxygen mixtures in a constant volume bomb. The experimental values after correcting for dissociation are higher than the theoretical values calculated from the known vibrational–rotational levels of the oxygen molecule by an amount which allows one to calculate the energy of the hitherto unknown but predicted $^1\Delta$ metastable level of the neutral oxygen molecule. The $^1\Delta$ level is found to be 0.75 ± 0.05 volt or 17,200 ± 1000 calories above the ground state of the molecule. The new mean specific heat curve of oxygen, which includes the contribution from the $^1\Delta$ level, fits the experimental determinations very well along the whole range of temperatures investigated. It is pointed out that the results also provide a fair proof for the dissociation equation previously proposed by the authors.

A table of true specific heats, C_p, is given from 200°K. to 3000°K. Two empirical formulas have been developed to represent this curve in two different ranges of temperature.

Ternary Systems. XVII. Sodium Iodide, Potassium Iodide and Water. XVIII. Sodium Iodide, Sodium Iodate and Water[1]

BY ARTHUR E. HILL, HERBERT S. WILLSON AND JOHN A. BISHOP

The relationships of the iodides and iodates of sodium and potassium have interest with respect to the preparation and separation of the salts from the Chilean caliche. The two ternary systems have been studied at three temperatures, with a view to obtaining solubility data and information as to double salt formation.

XVII. SODIUM IODIDE, POTASSIUM IODIDE AND WATER

The salts were of C. P. grade and were in some cases purified by recrystallization until experience showed that no measurable change was obtained. They were dried in an electric oven at 100° to constant weight, in order that complexes of exactly known composition might be made up. The salts were weighed into stoppered Pyres tubes with weighed amounts of water and stirred by mechanical inversion in a water thermostat for periods of a few hours, a time which was shown by analysis to be sufficient for attainment of equilibrium. Small samples of the saturated solution were drawn by suction into a pipet with filtration; one such was dried to constant weight in the oven, while a second was analyzed gravimetrically for total iodide content. With these data the composition with respect to the three components was calculated with of course considerable multiplication of errors because of the indirect determination of sodium and potassium. The composition of the solid phases was determined by algebraic extrapolation of the tie lines through the two points representing the saturated solutions and the original complexes taken.[2] The results are given in Table I.

The solubility of the two pure salts at the three temperatures, obtained by the evaporation of the solutions, cannot with advantage be compared with the figures of the average curves given in the "International Critical Tables,"[3] where the inaccuracy given is ±2%, but a comparison with the recent carefully determined figures of Scott and Frazier[4] and Scott and Durham[5] shows agreement with their direct measurements at 25° within one part in 2000 for the potassium iodide and 1 part in 1600 for the sodium iodide; the agreement with their interpolated curves at 8 and 40° appears

to be equally good. The solid phases at the three temperatures, as shown in Fig. 1, are limited to the compounds potassium iodide and $NaI\cdot 2H_2O$; no double salt is found, and solid solution was not found to occur, within the degree of accuracy of the work. This degree of accuracy, as tested by the method of algebraic extrapolation of tie lines, is doubtless lessened considerably by the use of an indirect method of analysis and the large multiplication of errors which therefore follows. Extrapolations of the tie lines at three temperatures to the composition of the simple salts assumed gave an average variation of 0.88% from the potassium iodide and of 1.46% from the $NaI\cdot 2H_2O$, with no steady drift to the variation; this leaves no doubt as to the identity of the salts, whether or not it is definitive as to the possible occurrence of solid solution within very narrow limits. It will be noted that at the three temperatures used the isothermally invariant point is well over toward the side of the sodium iodide. leaving only a comparatively short solubility curve for that compound.

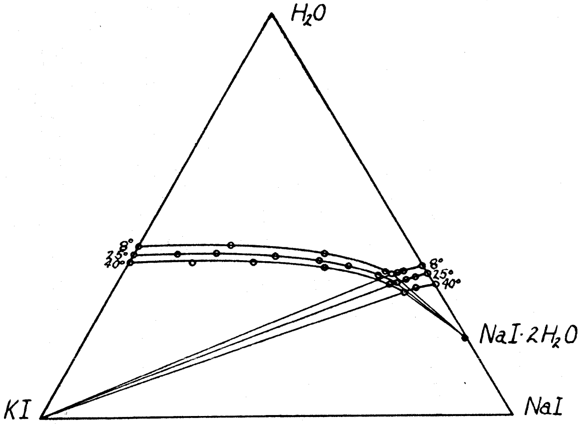

Fig. 1.—The system KI–NaI–H_2O.

XVIII. SODIUM IODIDE, SODIUM IODATE AND WATER

The sodium iodate used in this work was recrystallized from water and dehydrated in an electric oven at 100°. The solubility experiments were conducted as described in the previous section, with the exception that the time given for attainment of equilibrium was from four to seven days. For the analysis, the iodate was determined in a sample by the usual method of iodimetry, thiosulfate being used in the titration. The water was determined in a second sample by evaporation at 100°, the time required for reaching constant weight being about one week. The error brought in during evaporation by oxidation of iodide by iodate was found to be much less than was feared from the color changes which the material showed; it amounted in cases where analysis was made to a loss of only 0.3% of the iodate present, which would affect the figures only in the fourth significant place, and was therefore neglected. During the solubility experiments some slight decomposition, probably photochemical, always took place, as evidenced by the yellow color of the solutions; again, however, analysis showed that the iodine set free amounted to only a few thousandths of one per cent., a wholly negligible amount. The results of the experiments are given in Table II.

Algebraic extrapolation of tie lines through the points showed fairly good concordance; in only four cases is the variation from the true composition more than 1%.

The above figures, when plotted as shown in Figs. 2, 3 and 4, indicate two points of some interest with respect to the system. The first is that the solubility of the iodate is very greatly decreased by the presence of iodide, falling at the saturation point to as low as 0.02% at 8°, and rising

only to **0.3%** at 40°. This indicates that sodium iodide can be freed from iodate by recrystallization only with difficulty and only when the initial iodate concentration is lower than the above figures, which may well be the explanation of the very frequent appearance of iodate as impurity in commercial iodide, if the source of the material is such as would contain iodate. It will be shown in a later publication that this condition does not occur in the system containing the two corresponding potassium salts, which may be the reason that the potassium iodide quite regularly has a higher degree of purity than the sodium salt.

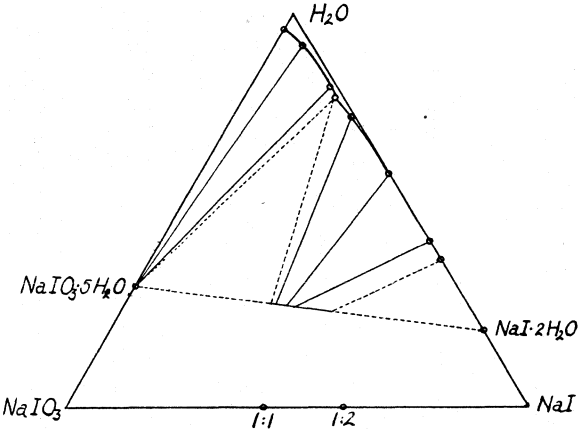

Fig. 2.—8° Isotherm: $NaIO_3$–NaI–H_2O.

The second point of interest is the occurrence of a new complex iodide–iodate, which was found at all three temperatures and which is the saturating phase over a considerable part of the entire range of concentrations. This was found to be not a double salt, but a solid solution of the two hydrated salts $NaIO_3{\cdot}5H_2O$ and $NaI{\cdot}2H_2O$. The evidence lies not merely in the failure of the tie lines to intersect with any reasonable constancy at a single point, but also in the isolation and analysis of the solid phase. For this test the ordinary method of filtration and analysis offered difficulty,

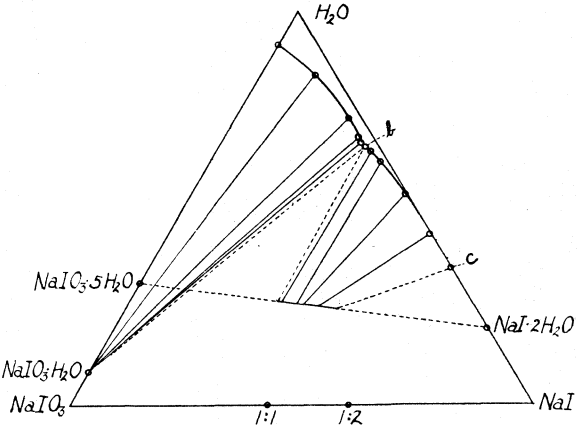

Fig. 3.—25° Isotherm: $NaIO_3$–NaI–H_2O.

for the solid obtained from the solubility experiments was very finely divided and carried a large percentage of highly concentrated solution upon its surface, making a very large correction necessary. To avoid this condition, crystals were slowly grown from a solution made up in the area of undersaturation above the line *b-c* (Fig. **3**) by evaporation over sulfuric acid at room temperatures. The crystals thus obtained were well formed and several millimeters in diameter, and could be quickly centrifuged to a condition of superficial dryness so that they ran easily on the glass of a test-tube with no evidence of stickiness; it is quite certain that they could not have contained more than very small amounts of solution. The results of their analysis are given in the first two columns of Table III.

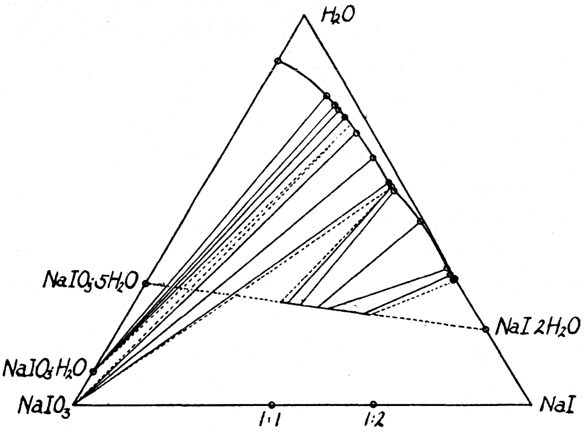

Fig. 4.—40° Isotherm: $NaIO_3$–NaI–H_2O.

TABLE III

ANALYSIS OF SOLID SOLUTIONS

	I	II	III
Wt. % $NaIO_3$	33.24	30.31	35.6
Wt. % NaI	38.09	44.41	40.2

These first two points will be found to represent quite different compositions, and to fall fairly close to the line drawn as representing the series of solid solutions. The third analysis represents a sample taken directly from a solubility experiment and filtered rapidly; it was put to dry in a desiccator containing a partially dehydrated mixture of $NaIO_3{\cdot}H_2O$ and $NaI{\cdot}2H_2O$. In two months time it lost 14.64% of water and reached a constant weight which remained unchanged for seven months. The analysis of the solution from which it was formed being known, the necessary correction[6] was made in the analysis of the solid; the corrected analysis, shown in the third column, also falls close to the expected line.

---

(6) Hill, THIS JOURNAL, 52, 3828 (1930).

The wide variation in the composition of the three samples is convincing evidence of solid solution. The position of the three points is sufficiently close to the line joining the composition of $NaI \cdot 2H_2O$ and $NaIO_3 \cdot 5H_2O$ to indicate that these are the solids entering into the solid solution. That this should be the case at the lower temperature is in no wise striking; but that it should also be so at 40°, some 20° above the transition temperature of $NaIO_3 \cdot 5H_2O$[7] involves the conclusion that the vapor tension of $NaIO_3 \cdot 5H_2O$ in the solid solution is considerably reduced by the presence of the $NaI \cdot 2H_2O$ in the same molecule.

It will be noted that the area of solid solutions begins quite close to the ratio of 1:1 for the two salts, corresponding to the formula of a comparatively simple double salt, $NaIO_3 \cdot NaI \cdot 7H_2O$, and extends with increase in the amount of iodide to a point near to or at the 1:2 ratio, $NaIO_3 \cdot 2NaI \cdot 9H_2O$. This approximation of solid solution to the composition of stoichiometrical ratios, well known in the case of glaserite, has been noted in a number of interesting cases.[8] In commenting upon these, Timmermans[9] remarks that they may possibly be regarded as examples of Berthollidean compounds of variable composition as opposed to Daltonian compounds of fixed composition. Without committing one's self to any fundamental theory in the matter, one is obliged to note the frequency with which such solid solutions approximate the stoichiometrical ratios, and to suspect that doubtless certain substances have been reported as compounds on this basis whereas they are truly solid solutions.

Summary

1. The system $NaI-KI-H_2O$ has been studied at 8, 25 and 40°; no compound formation occurs.

2. The system $NaIO_3-NaI-H_2O$ has been studied at the same three temperatures; at all of these there exists, over a wide range of liquid concentration, a series of solid solutions of the composition $(NaIO_3 \cdot 5H_2O)_n \cdot (NaI \cdot 2H_2O)_m$, beginning at the 1:1 ratio and extending to approximately the 1:2 ratio.

X-Ray Studies of the System Nickel–Oxygen–Water. I. Nickelous Oxide and Hydroxide[1]

BY R. W. CAIRNS AND EMIL OTT

Introduction

Numerous investigators[2] have made x-ray studies of natural and artificial nickelous oxide. The crystal structure has been definitely established as face centered cubic, with a lattice spacing approximately 4.17 Å. The most accurate determinations are probably those of Brentano[3] (4.1705 Å.) and Ksanda[4] (4.171 ± 0.003 Å.). Since both determinations were made with the use of sodium chloride diffraction as a primary standard, there is little doubt as to their accuracy.

There appear in the literature several reports of ostensibly new modifications of NiO. Lachand and Lepierre[5] reported that the oxides prepared by ignition of what they believed to be two crystalline modifications of anhydrous nickel sulfate retained the external crystal form of the sulfates. The densities of the two oxides which they prepared were 6.67 g. per cc. and 6.70 g. per cc., as compared with a density of 6.80 g. per cc. calculated from x-ray data.

Hedvall[6] found that NiO which had been repeatedly heated to 1000° for several hours in molten potassium chloride possessed a density of 7.45 g. per cc. Since this value is considerably higher than the density calculated from x-ray data of the normal form, it would appear that a new modification was present, and it has been treated as such in at least one instance.[7]

Prasad and Tendulkar[8] have investigated the variation in physical properties, as influenced by temperature of preparation, of samples of NiO prepared by heating nickel nitrate, hydroxide and basic carbonate at temperatures of 400 to 1000°. The oxide obtained at 400° was black and the one at 1000° green. They found that the density and electrical resistance increased, and the rate of solution in sulfuric acid decreased as the temperature of preparation was raised. They concluded that there were two forms of NiO, the black form prepared at 400° and the greenish-gray form, at 1000°. The changes in properties were attributed to changes

(1) in particle size, (2) from amorphous to crystalline state, (3) in crystalline form and (4) of an intramolecular nature.

Leblanc and Sachse[9] have shown that the oxide prepared by the same method at 400 to 500° possessed the normal cubic structure of the high-temperature preparation as evidenced by the x-ray diffraction pattern. They have also proved that the black color was due to traces of active oxygen.

Further, a new modification of nickel oxide was reported by Bennett, Cairns and Ott[10] but further work has shown that the reported results were erroneous. The substance then reported as NiO by Dr. Bennett[11] was subsequently found by us to contain active oxygen and water in bound form. That the diffraction pattern appeared in the first approximation to fit a cubic structure, was purely accidental. A search of the literature revealed no other reports of different modifications of nickelous oxide.

Inasmuch as there has been no x-ray evidence to disprove or substantiate the existence of the different modifications as reported, the present investigation was undertaken. Incidental to this work more accurate data were obtained on the crystal structure of nickelous hydroxide. The crystal structure of nickelous hydroxide has previously been determined by Natta.[12] The lattice type was found to be hexagonal with one molecule per unit cell. The lattice constants as determined by the x-ray diffraction were $a_0 = 3.07$ Å. and $c_0 = 4.61$ Å.

Nickelous hydroxide as generally prepared by precipitation from nickel salt solutions contains, after drying, more water than is necessary for a composition of $Ni(OH)_2$. In some cases this has been taken as evidence of the formation of definite hydrates.[13]

Experimental Part

Preparation of Samples

Nickel Oxides from Sulfates.—Twenty grams of ammonium bisulfate and ten grams of nickel sulfate hexahydrate were fused together in a porcelain crucible. The bisulfate was volatilized by heating the mass to red heat for four hours. The residue of crystalline anhydrous nickel sulfate was found by microscopic examination to be in the form of yellow-green transparent octahedra. In a second preparation, the same procedure was followed except that 3 g. of concd. sulfuric acid was added to the mixed sulfates before fusion. The sulfate product in this case crystallized in lens-shaped crystals. x-Ray powder pictures of the two sulfates were identical, and their complexity indicated low symmetry for the crystal structure. Thus the two forms of nickelous sulfate do not represent two different modifications, but are merely different habits.

Each of the two preparations of nickel sulfate was heated at white heat in a platinum crucible for an hour. The oxide products were moss-green in color and retained the external form of the original sulfates.

Pure Nickelous Oxide from the Nitrate.—C. P. nickel nitrate was twice recrystal-

ized from water. The nitrate initially gave a very faint test for cobalt by Vogel's method, but this was negative after one recrystallization. The purified nitrate was heated to white heat in a platinum crucible. A surface layer of dark colored oxide was formed due to contact with air, but beneath this the pure NiO was yellow-green and gave no test for active oxygen by the Bunsen method.

The purified nitrate was also treated in solution with ammonia gas, and the precipitated hexammoniate was further recrystallized twice from strong ammonia solution. The product was ignited in nitrogen in an electric furnace at 1000°. The oxide thus formed was also green and contained no active oxygen.

Nickelous Oxide by Hedvali's Method.—Pure NiO was heated in molten potassium chioride at white heat over a period of five hours. The heating was momentarily interrupted every half hour and the mass allowed to cool for five minutes. At the conclusion of the heating the potassium chloride was leached out with water and the light green oxide filtered off and washed.

Nickelous Oxide by Decomposition of Nickelic Oxide Hydrate.—A sample of nickelic oxide-hydrate, the approximate composition of which was $Ni_2O_3 \, 2H_2O$ (see following paper), was heated for three days at 120°. The black color remained although only a trace of active oxygen was present. The same oxide-hydrate was heated in nitrogen at 1000" for two hours. The green product thus formed contained no active oxygen.

Nickelous Hydroxide.—A solution of 25 g. of potassium hydroxide in 250 cc. of water was added dropwise to a solution of 60 g. of $Ni(NO_3)_2 \, 6H_2O$ in 500 cc. of water at room temperature The precipitation was carried out with rapid stirring in a closed three-necked flask of three liters capacity. Carbon dioxide-free air was kept over the solution. After precipitation the product was washed by decantation three times, in a cylinder of ten liters capacity. The cylinder was kept covered with a ground-glass plate except during decantation. A minimum time of exposure to air was allowed, and carbon dioxide-free water was used in the decantation. After the supernatant liquid had been removed in the last decantation, the precipitate was filtered with suction on a covered Buchner filter. After washing, the product was dried in a desiccator for two weeks over concd. sulfuric acid.

The preparation was repeated with the nitrate solution kept at 100" during precipitation. The final composition of this product, after drying in *vacuo* over calcium chloride for a day, was $NiO \, 1.21H_2O$, as shown by nickel and water analyses. The product contained 0 6% of carbon dioxide. Another preparation was carried out at 0°, and the product was kept in the wet state for x-ray investigation.

Method of x-Ray Analyses.—The source of x-rays was a hot filament metal tube with a copper anticathode (model Dr. Seeman, Freiburg). The tube was operated at *ca.* 20 kilovolts and 30–40 milliamperes. Nickel foil was used for practically complete absorption of Kg-radiation. The radiation was occasionally checked spectroscopically and found to be CuK_α essentially. The camera was of the Debye–Scherrer type (Dr. Leiss, Berlin-Steglitz) with an effective diameter of 114 6 mm The powdered samples were contained in thin collodion tubes of 0.5 mm. diameter. In the accurate determinations the samples were powdered in an agate mortar with equal parts of Kahlbaum "sodium chloride for analysis." The diffraction of sodium chloride thus appeared on the films and was used as a standard in measurement of the diffraction of the nickel compounds. The values of sin Θ for the glancing angles for sodium chloride were first determined from microcomparator measurements of the line spacings on the films and the known diameter of the camera. These values were then compared with the values calculated assuming $a_0 = 5.628$ **Å.** for chemically pure sodium chloride. A plot of these corrections against the values of sin Θ, uncorrected, was used to determine the corrections to the observed sines of the glancing angles for NiO and $Ni(OH)_2$.

Some of the diagrams obtained may be found in a following paper.

Results of x-Ray Analysis

Nickelous Oxide.—The two samples of nickel oxide prepared by ignition of the sulfates gave x-ray diffractions corresponding to the usual face-centered type of crystal. There was no distortion of the lattice within the limits of experimental error. It was evident that the oxides were merely pseudomorphic with the original sulfates.

TABLE I

NiO FROM $Ni(NO_3)_2\ 6H_2O$

NaCl	222	.47486	.47393	....
NiO	220	.52324	.52269	4.1666
NaCl	400	.54756	.54726	....
NiO	311	.61257	.61249	4.1695
NiO	222	.63978	.63983	4.1688
NaCl	422	.67043	.67025	....
NiO	400	.73846	.73896	4.1680
NaCl	440	.77329	.77393	....
NiO	331	.80412	.80490	4.1699
NaCl	442	.82015	.82089	....
NiO	420	.82536	.82616	4.1681
NaCl	620	.86427	.86530	....

Average value for a_0 for NiO = 4.1683

Average deviation from the mean for a_0 = 0.0008

Data on the x-ray diffractions of the two samples prepared from nickel nitrate hexahydrate and hexammoniate are given in Table I and Table II.

The average of these two determinations was then 4.1684 Å. In consideration of the accuracy possible through use of sodium chloride as a primary standard and, because of the purity of the samples, this value is probably accurate to 0.001 Å.

By an identical determination the nickelous oxide prepared by Hedvall's method was found to have the lattice constant, $a_0 = 4.1665$ Å. The average deviation from the mean value for a_0 was in this case 0.0007 Å. Thus this value is identical with the above ones within the experimental error (± 0.001). Hence it appears that Hedvall's density determination was subject to error, as an experimental density of 7.45 g. per cc. would require a lattice spacing of 4.04 Å. or less.

The two samples of nickelous oxide prepared by decomposition of nickelic oxide hydrate at 120 and 1000° possessed identical crystal diffraction, with the exception that the diffraction lines of the low temperature preparation were exceedingly diffuse, while those of the sample ignited at 1000° were very sharp. The differences in properties observed by Prasad and Tendulkar[5] could all be explained on the basis of a difference in particle size. The black color was caused by traces of active oxygen.

Nickelous Hydroxide.—The room temperature preparation gave a very diffuse x-ray diffraction pattern with the innermost line (corresponding to the (001) spacing)[14] a very broad band. The preparation made at 100° gave much sharper diffraction lines and all of the inner lines were clear enough for accurate measurement with a millimeter rule. The diffraction pattern corresponded to that of a crystal of hexagonal lattice type. Data are given in Table III.

The average deviation between the values of $\sin^2 \Theta$ observed and $\sin^2 \Theta$ calculated from the quadratic formula for the hexagonal system was 0.18%, with the values of the lattice constants $a_0 = 3.114$ Å. and $c_0 = 4.617$ Å. A second determination gave agreement to 0.28%. Our more accurate value for a_0 differs by *ca.* 1% from Natta's.[12]

The calculated density was 3.94 g. per cc. for one molecule per unit cell, in fair agreement with a determined density of 3.56 g. per cc., the discrepancy being due probably to adhering air and water.

Expressed on rhombohedral axes the unit cell contained three molecules per unit cell, showing that the hexagonal type was the simplest structure.

In a previous determination[12] the structure was assumed to be of the cadmium iodide type, with the atoms of $Ni(OH)_2$ at the following positions of D^3_{3d}: Ni at 0, 0, 0; OH at $^1/_3$, $^2/_3$, u; $^2/_3$, $^1/_2$, $\bar{u}$. The optimum value of u was found to be 0.25.

In this work the atomic positions were assumed to be the above, and the relative intensities of the planar reflections were computed from the formula

$$I \propto \frac{1+\cos^2 2\Theta}{\sin^2\Theta\cos\Theta}\cdot j\cdot\left(F_{\mathrm{Ni}} + F_{\mathrm{O}}\cos 2\pi\left(\frac{h+2k}{3}+ul\right)\right)^2$$

where j is the heaping factor[15] for the plane (h k l) and F_{Ni} and F_{O} are the atomic reflecting powers for Ni and O atoms.[16]

TABLE IV

$Ni(OH)_2$

$h\,k\,l$	Observed intensity	Calculated intensity $u = 0.23$	0.25	0.27
001	Very strong	93	79	65
100	Medium strong	25	25	25
101	Very strong	50	49	47
102	Medium strong	18	23	28
110	Medium strong	22	23	25
111	Medium weak	8	7	6
200	Very weak	5	5	5
103	Very weak	5.5	5	5
201	Medium weak	7	7	7
202	Medium weak	6	5.5	4.5

---

(14) It is of interest to note that this important spacing was not directly observed in the previous work of Natta.

(15) Schleede and Schneider, "Röntgenspektroskopie und Kristallstrukturanalyse," Rand II, p 250, Table 33, Berlin, 1929.

(16) Wyckoff, Phyr. *Rev.*, **35**, 583 (1930).

The intensities, in arbitrary units, for different values of the parameter u are given in Table IV. The best agreement with observed intensities was found for $u = 0.25$, confirming Natta's results.

The x-ray diffraction of a wet, freshly precipitated sample of $Ni(OH)_2$ prepared at 0° showed a very diffuse diffraction in which all the lines corresponded to the strongest reflections of the dry material. No evidence could be found of any definite hydrates of $Ni(OH)_2$.

A sample of NiO, obtained by decomposition of $Ni(OH)_2$ in nitrogen at 500°, showed no change in its x-ray diffraction after the material had been heated in a bomb tube in water at 150° for five days. Hiittig and Peter[17] have found that nickelous hydroxide cannot be formed by action of water at room temperature on NiO. Thus it appears that the decomposition of nickelous hydroxide to the oxide is not reversible under ordinary pressures.

Summary

1. It has been found that several new modifications of nickelous oxide reported in the literature conform to the usual face-centered type of lattice. The lattice constant for preparations made according to the methods described did not vary from the accepted value for the normal form of the oxide, within the limits of experimental error.

2. The lattice constant of pure NiO has been redetermined more accurately using pure sodium chloride as a reference substance. The value as determined for two different preparations of nickelous oxide was

$$a_0 = 4.1684 \pm 0.001 \text{ Å}.$$

3. It has been possible to redetermine the lattice constants of hexagonal $Ni(OH)_2$ with greater accuracy than heretofore. The lattice constants were found to be $a_0 = 3.114 \pm 0.005$ Å. and $c_0 = 4.167 \pm 0.005$ Å. Intensity calculations indicated that the crystal had the symmetry of the space group D^3_{3d}, with the following atomic coördinates: Ni at (0, 0, 0); OH at ($^1/_3$, $^2/_3$, 0.25), ($^2/_3$, $^1/_3$, -0.25), in accordance with a previously reported structure determination.

4. The reported existence of hydrates of $Ni(OH)_2$ has been disproved.

5. Two crystal forms of nickel sulfate, previously thought to be different modifications, were found to be identical, differing only in crystalline habit. The nickel oxides prepared from the sulfates were merely pseudomorphic with them, and do not represent new modifications.

X-Ray Studies of the System Nickel–Oxygen–Water. II. Compounds Containing Trivalent Nickel[1]

BY R. W. CAIRNS AND EMIL OTT

Introduction

The chemistry of the oxides of nickel and their hydrates has been a controversial subject for a great many years. A number of higher oxides of nickel have been reported, but there has followed positive proof that such oxides do not exist. Wohler and Balz,[2] Baubigny,[3] Rose,[4] Glaser,[5] Moissan,[6] Vaubel,[7] Lunde,[8] and Clark, Asbury and Wick[9] have reported preparations of oxides such as Ni_3O_4, Ni_2O_3 and NiO_2. For the most part the compounds were analyzed for their nickel content alone and the oxygen content determined on this basis. The general methods of preparation in use involved the dry heating of nickel compounds such as the hydroxide, oxide, nitrate, chloride or basic carbonate in air or oxygen, at temperatures of 200 to 500°. Subsequent work by Leblanc and Sachse[10] has shown the above work to be erroneous. The latter made preparations of the black oxide of nickel according to the above methods, and analyzed the products completely, for nickel, active oxygen and water. In all cases, the active oxygen content was very low, corresponding to less than 10% of Ni_2O_3. The errors in the previous results were due to the fact that the water contents were not taken into account. Leblanc and Sachse therefore assumed that the black oxide of nickel, as prepared in the above ways, was not a homogeneous higher oxide of nickel, but was a system of nickelous oxide, active oxygen and water, containing less than ten per cent. of higher oxides. x-Ray diagrams of their products showed only the diffraction lines for NiO. Their work was substantiated by Hendricks, Jefferson and Schultz[11] who were unable to obtain anything but nickelous oxide with traces of active oxygen, by any of the above methods.

It appears quite clear that anhydrous higher oxides of nickel do not exist. However, there remains for consideration another class of nickel compounds containing active oxygen, prepared by quite different methods. These compounds have been previously referred to as higher oxides or oxide-hydrates. The general method of preparation has been oxidation

of nickel salt solutions by basic solutions of oxidizing agents such as bromine, chlorine and persulfates. Belluci and Clavari[12] made a series of preparations, using different oxidizing agents and various temperatures of preparation. The products were analyzed for active oxygen and nickel. They computed the Ni:O ratios from the data and found the values to range from 1:1.3 to 1:1.9, the oxidation taking place to the greatest extent at a temperature of precipitation of 0°. They obtained no definite evidence of the existence of an intermediate oxidation product such as Ni_2O_3, and therefore assumed the products to be mixtures of NiO and NiO_2. No attempt was made to determine the water content of the products, or to find whether this was bound or simply adsorbed. Clark and co-workers[9] reported the preparation of $NiO_2 \cdot xH_2O$ by the same method, and found the product to be amorphous, giving no x-ray diffraction pattern. Howell[13] studied the decomposition of the precipitates formed when basic solutions of chlorine were added to nickel sulfate solutions. The products were instable in suspension at 100°, losing active oxygen fairly rapidly. Howell determined the Ni:O ratios in the manner described above. Initial values for this ratio reached 1:1.65, and approached 1:1 for precipitates decomposed at 100°. There was a rapid initial loss of about 25% of the active oxygen, followed by a more gradual loss of the remainder. He interpreted the results to indicate that two higher oxides were present, NiO_2, which was very instable and accounted for the rapid initial loss of active oxygen, and Ni_2O_3, which lost active oxygen much less rapidly. He made no mention of the possibility that the products might contain bound water.

Hüttig and Peter[14] studied the system nickelic oxide–water. Products prepared by the method of Belluci and by oxidation of suspended nickelous hydroxide had compositions expressible as $Ni_2O_3 \cdot 3\text{–}4H_2O$. The Ni:O ratios were exactly 1:1.5, but the water contents varied with conditions of drying. By the isobaric decomposition of the products at temperatures of 100 to 140° and a total pressure of about 10 mm. they believed to have found evidence for the existence of a monohydrate of Ni_2O_3. They also found that the composition of the product obtained by heating the above preparations in water at 200° was approximately $Ni_2O_3 \cdot H_2O$. x-Ray diagrams of the first two products and of the product of the water heating were obtained. No correspondence between any of the patterns was noticeable. They assumed the latter pattern to be characteristic of the monohydrate of Ni_2O_3, but did not succeed in placing any interpretation on the x-ray results on the original products, other than to suggest that a trihydrate might exist. No evidence of such a compound was indicated in the isobaric decomposition experiments. They found the water con-

tents of the products to be completely reversible at temperatures below 138°, at which temperature the composition of the residue-became $Ni_2O_3\cdot H_2O$. At temperatures above this irreversible decomposition took place according to the equation

$$2(Ni_2O_3\cdot H_2O) \longrightarrow 4NiO + 2H_2O + O_2$$

Leblanc and R. Müller[15] published a thesis which we received after completion of our work in which they study the system of higher nickel oxides and water. Their attempted x-ray study was unsuccessful, due to experimental reasons. They were able to obtain preparations giving a Ni:O ratio as high as 1.75. The isothermic decomposition gave no evidence of any definite oxides or hydrates in strong contrast to the findings of Hüttig and Peter.[15] It is also our conviction that the results of the latter authors were accidental.

Experimental Part

Chemical Analyses.—Nickel was determined electrolytically. Samples were dissolved in very dilute sulfuric acid to avoid loss in spray caused by rapid evolution of oxygen. After electrolysis solutions were tested with hydrogen sulfide to assure that all nickel was recovered.

Active oxygen was determined by a modified Bunsen method, using an apparatus described by Gooch.[16] Samples were dissolved in dilute hydrochloric acid. The chlorine evolved was swept into potassium iodide solution with carbon dioxide, while the acid solution was gently boiled. The free iodine was titrated with thiosulfate.

Water and carbon dioxide were determined by heating the samples in a quartz tube in an electric furnace at about 1000". The vapors were swept into absorption tubes by a stream of purified nitrogen. The carbon dioxide contents were approximately 0.5% for all materials analyzed in this work.

x-Ray Analyses.— The method was identical with the one in our previous article.[17]

The powder pictures thus obtained were measured with a millimeter rule. Since diffraction lines in all cases were rather broad it was not feasible to use a micro-comparator. The x-ray data recorded in the report include the linear distances between corresponding lines on each side of the film, and the estimated relative intensities of the diffraction lines.

Preparation of Samples.—A. A solution of 55 g. of potassium hydroxide and 12 cc. of bromine in 500 cc. of water was added dropwise to a solution of 100 g. of $Ni(NO_3)_2\cdot 6H_2O$ in 1500 cc. of water, with rapid stirring. Precipitation was carried out in absence of carbon dioxide as described in the preceding article.'' The temperature of precipitation was 25°. The precipitate was washed five times by decantation, then filtered and washed thoroughly on the filter, as described in the preparation of nickelous hydroxide. The product was dried over concentrated sulfuric acid for a few days and then over 1:1 sulfuric acid for two weeks. The final analysis corresponded to the composition $Ni_2O_3\cdot 3.19H_2O$ (Ni_2O_3 73.5%, H_2O 25.7%, CO_2 0.5%). This preparation was designated as product A.

The product A was dried more thoroughly at various temperatures: (1) in a vacuum desiccator over calcium chloride, at about 1 mm. pressure, (2) in an electric oven in air,

and **(3)** in **a** metal tube under 10 atmospheres of oxygen, with phosphorus pentoxide present to absorb water. Analyses of products are given in the following table.

Method of drying	Temp., °C.	Time of drying	% Ni_2O_3	% H_2O	% NiO by diff.	$NiO_2O_3:H_2O$ mol. ratio
(1)	25	3 days	80.8	17.3	1.9	1:1.97
(2)	130	24 hours	41.3	9.7	49.0	1:2.16
(3)	320	20 hours	30.7	8.8	60.5	1:2.65

The x-ray diagrams of product A and of the product dried by method **(1)** were identical. Data are given in Table I, 1, and Fig. 1A. The products dried by methods (2) and (3) gave only lines for NiO (see Table 1, 4, and Fig 1B) the decomposition probably destroying the crystallinity of the undecomposed portion. No other foreign diffractionlines were observed

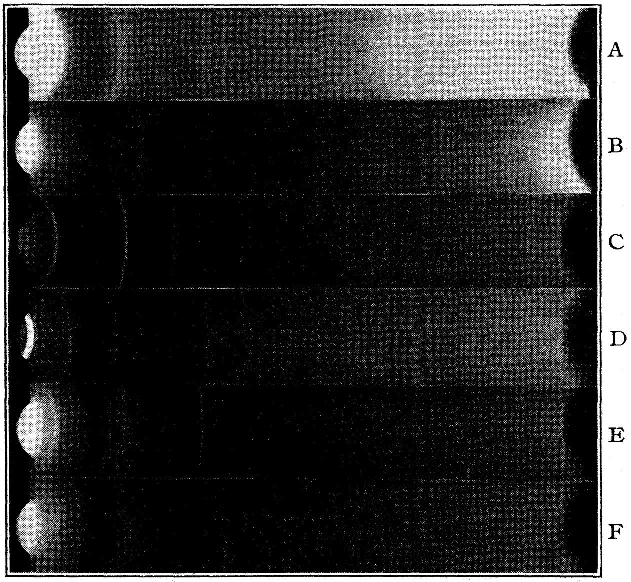

Fig. 1.—A, $Ni_2O_3{\cdot}2H_2O$ (A); B, NiO by decomp. of $Ni_2O_3{\cdot}2H_2O$ in air at 120°; C, $Ni(OH)_2$, obtained by decomposition of $Ni_2O_3{\cdot}2H_2O$ in water at 150°; D, preparation E_1 ($Ni_3O_4{\cdot}xH_2O$); E, preparation E_2 ($Ni_6O_7{\cdot}xH_2O$); F, preparation F ($Ni_2O_3{\cdot}H_2O$).

It was quite evident that removal of water alone above **a** content of two mols per Ni_2O_3 would not affect the x-ray diffraction, and that beyond this point the decomposition took place with loss in active oxygen. This strongly indicated that the original product was $Ni_2O_3{\cdot}2H_2O$, with some adsorbed water.

B. **A** solution of 20 g. of potassium hydroxide in 250 cc. of water was added dropwise to 50 g. of $Ni(NO_3)_2{\cdot}6H_2O$ in 250 cc. of water at 25°. **A** solution of 6 g. of potassium hydroxide and 6 cc. of bromine in 500 cc. water was then added to the suspended nickelous hydroxide. The reaction mixture was allowed to stand for five hours with intermittent stirring, before decantation was started. Purification was carried out as in **A.** The product was dried in an oil-pump vacuum over calcium chloride for three days. The x-ray diagram of the product was identical with that of product A (see Table I, 2). The Ni/O ratio in this case was 1/1.38, compared with the theoretical value of 1/1.5 for a hydrate of Ni_2O_3.

l = linear distance between corresponding lines on each side of film. The following abbreviations are used to indicate relative intensities: s, strong; m, medium; w, weak; v, very; br, broad. The substances to which the various reflections were assigned appear in the columns headed "compd."

It was evident that oxidation of the suspended $Ni(OH)_2$ took place quite slowly, as another preparation with only a half-hour oxidation period resulted in a product of incomplete oxidation and showed only the diffraction of $Ni(OH)_2$. Precipitation and oxidation of $Ni(OH)_2$ at 100° produced a partially oxidized mixture showing the strongest diffraction lines of product A and $Ni(OH)_2$. Longer oxidation periods would doubtless have resulted in complete oxidation. The ultimate oxidation product was the same as by the method **A,** which was quite clearly revealed by the x-ray diffraction data.

C and D. These preparations were identical with **A,** except that the nitrate solutions were kept at 50 and 75°, respectively, during precipitation The products were dried in *vacuo* for three days. The x-ray diffraction patterns in both cases were identical with **A.** The only effect of higher temperatures of precipitation was to cause incomplete oxidation. If the unoxidized portion of product C was assumed to be $Ni(OH)_2$ the composition of the product was expressible as $0.25Ni(OH)_2 \cdot Ni_2O_3 \cdot 1.91H_2O$. With such a relatively small amount of $Ni(OH)_2$ present (ca. 10%) no diffraction effects of this compound were observed.

The product C was heated in air (water vapor pressure ca. 10 mm.) at 110° for periods of two, five and twenty hours. x-Ray diffraction patterns of the products (see Table I, 5) showed lines corresponding to the diffraction of NiO, increasing in intensity as the time of heating was increased The original pattern became much weaker. Analysis of the residue after twenty hours showed the material to contain 45.5% NiO, 40.5% Ni_2O_3, 13% H_2O and 0.5% CO_2. The $Ni_2O_3 : H_2O$ ratio was 1 : 2.9, somewhat higher than would be expected if the initial product was assumed to be $Ni_2O_3 \cdot 2H_2O$. However, about 10% of $Ni(OH)_2$ was evidently present in the initial product C, and as this would not lose water at the temperature of heating,[18] some of the water in the heated product must have been bound to divalent nickel (calculated as NiO).

The products **A,** B and C decomposed to $Ni(OH)_2$ when heated in Pyrex bomb tubes with water at temperatures of 130 to 150° for sufficiently long periods of time (several days). The end-products after three days heating at 150° showed very well defined diffraction patterns of $Ni(OH)_2$. (See Table I, 3, and Fig. 1C.) A few of the strongest diffraction lines of NiO appeared with very weak intensity. This might be expected since the material in the center of the particles would be in poor contact with water and tend to decompose as in the dry way. A portion of product **A** was partially decomposed in water at 128°, over a period of twelve hours. The analysis of the product was 34.0% NiO, 48% Ni_2O_3, 17.1% H_2O and 0.8% CO_2 showing the $Ni_2O_3 : H_2O$ ratio to be 1 : 1.7 on the assumption that all the divalent nickel was present as $Ni(OH)_2$. Since a small percentage of NiO always formed in such decompositions, this assumption was not strictly correct. Hence the $Ni_2O_3 : H_2O$ ratio would fall closer to 1 : 2, if all the water bound to trivalent nickel was taken into account. Such a value would be in agreement with decomposition according to the equation

$$Ni_2O_3 \cdot 2H_2O \longrightarrow 2Ni(OH)_2 + O$$

E_1. This preparation was identical with **A,** except that the nitrate solution was kept at 100° during precipitation. The product was purified in the usual manner, and dried *in vacuo* over calcium chloride for three days. The product was quite incompletely oxidized, the composition being 62.3% Ni_2O_3, 17.8% NiO, 19.9% H_2O, 0.5% CO_2 or $Ni_3O_{4.14} \cdot 3.34\ H_2O$. The x-ray diagram of the product was completely different from that of product **A** (see Table I, 6, and Fig. 1D). No lines of $Ni(OH)_2$ were visible. The product E_1 decomposed almost completely to $Ni(OH)_2$ when heated in water for three days at 150°. The end-product showed a very clear diffraction pattern of $Ni(OH)_2$, and very weak NiO lines (see Table II, 1).

E_2. Product E_1 was heated for four hours at 110° in air. The x-ray diagram of

---

[18] Hüttig and Peter, *Z. anorg. allgem. Chem.*, 189, 183 (1930).

the product was completely different from that of A or E_1 (see Table I, 7, and Fig. 1E). No lines of NiO or $Ni(OH)_2$ were visible. The composition of the product was 31.4% Ni_2O_3, 51.7% NiO, 16.3% H_2O, 0.4% CO_2 or $Ni_6O_{7.06}\cdot 5.01H_2O$. Further heating at 110° for twenty hours caused no further change in the diffraction pattern. The product was heated for one day at 140° in air. The end-product gave a diffraction pattern showing the principal lines of NiO and a weakened pattern of the original product E_2. Product E_2 also decomposed to $Ni(OH)_2$ when heated in water at 150° for three days (see Table II, 2). The pattern of the end-product was identical with that of the end-product of the water-decomposition of E_1.

F. Since it appeared that E_1 was a compound containing both di- and trivalent nickel, and not a mixture of compounds, it was important to know the effects of further oxidation. E_1 was prepared as described above. After precipitation the suspended product was divided into two equal portions. One was purified and dried in air. The x-ray diffraction of this product was identical with that of E_1, and the composition of the product was 54.1% Ni_2O_3, 19.8% NiO, 23.8% H_2O, 1 9% CO_2 or $Ni_3O_{4.07}$ $4.31H_2O$. The other half of the precipitate was further oxidized at 25° by addition of a solution containing 20 g. of potassium hydroxide and 5 cc. of bromine in 250 cc. of water. The product was allowed to stand for an hour and then decanted ten times, filtered, washed and dried in *vacuo*. It was quite noticeable that this precipitate settled more rapidly than the previous preparations. In most cases peptization occurred on the third decantation, and a large percentage of the product was lost during decantation. In this preparation peptization did not occur to any great extent until the eighth decantation, indicating that the excess base was more strongly adsorbed by the product than in the previous cases. The x-ray diffraction pattern of this product, F, was entirely different from any of the foregoing (see Table II, 3, and Fig. 1F). The product had the composition $Ni_2O_{3\ 10}\cdot 1.57H_2O$. The product was heated for ten hours at 110°. The partially decomposed product contained 77.6% Ni_2O_3, 12.3% NiO, 8.5% H_2O and the $Ni_2O_3 : H_2O$ ratio of the undecomposed material was 1 : 1.01. Faint indications of NiO lines appeared on the diffraction diagram of the heated product, along with the weakened lines of the original pattern. Further heating at 120° for five hours produced a mixture the diffraction pattern of which clearly showed the principal lines of NiO (see Table II, 4). These results indicated that the product F was essentially the monohydrate of Ni_2O_3, and decomposed according to the equation

$$2(Ni_2O_3 \cdot H_2O) \longrightarrow 4NiO + 2H_2O + O_2$$

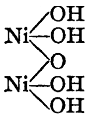
The product F was heated at 150° for three days in a Pyrex bomb tube. The x-ray diagram of the product showed NiO lines and also some new lines which must have been caused by the presence of a nickel silicate, since analysis showed that the end-product contained about 20% of silica The decomposition in water was repeated in a steel bomb, and the product gave strong diffractionlines of NiO along with very weak $Ni(OH)_2$ lines. Comparison with the diffraction pattern of a known mixture of 20% $Ni(OH)_2$ and 80% NiO formed by decomposition of $Ni_2O_3 \cdot 2H_2O$ at 160° in air showed that the amount of $Ni(OH)_2$ present in the end-product was less than 20%. Thus it appeared that the primary decomposition product of $Ni_2O_3 \cdot H_2O$ in both air and water was NiO. The small amount of $Ni(OH)_2$ that formed during the decomposition in water was apparently due to impurities in the original product F.

Discussion

Due to their fine state of subdivision the compounds prepared in this work contained quite variable amounts of water. However, the analyses of the partially decomposed products, obtained by heating in air, coupled with the results of the x-ray diffraction experiments, were successful in establishing for the first time the existence of compounds having the compositions $Ni_2O_3 \cdot 2H_2O$ and $Ni_2O_3 \cdot H_2O$. Although such compounds have been previously termed "hydrates," there is considerable evidence to indicate that they do not possess the properties of true hydrates. Since the compound $Ni_2O_3 \cdot H_2O$ was prepared in water at a temperature at which $Ni_2O_3 \cdot 2H_2O$ was stable, and since there was no indication of formation of the latter compound after the monohydrate had stood in water for two weeks during the purification process, it was evident that the transition $Ni_2O_3 \cdot H_2O + H20 \longrightarrow Ni_2O_3 \cdot 2H_2O$ did not take place. Furthermore, the reverse change did not take place when the dihydrate was decomposed by heat, but instead a complete decomposition took place

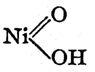
$$2(Ni_2O_3 \cdot 2H_2O) \longrightarrow 4NiO + 4H_2O + O_2$$

The fact that the dihydrate could be prepared by oxidation of $Ni(OH)_2$, and decomposed to that compound on heating in water, was not consistent with the assumption that the compound was a true hydrate. It has been impossible to prepare Ni_2O_3 by dehydration of such compounds, since the loss in water is always accompanied by a loss in active oxygen. There is no reason to believe that the removal of water of crystallization would affect the oxygen linkage. On the other hand, the assumption that the compounds $Ni_2O_3 \cdot 2H_2O$ and $Ni_2O_3 \cdot H_2O$ have the following structures was in complete accord with the experimental observation



I

or $Ni_2O_3 \cdot 2H_2O$



II

or $^1/_2$ $Ni_2O_3 \cdot H_2O$

The decomposition of product F into NiO in water and air alike was strongly indicative of a structure of type II. It was previously shown[17] that the transition $NiO + H_2O \longrightarrow Ni(OH)_2$ would not take place under the conditions of the above experiments, and that $Ni(OH)_2$ was stable in water at the temperatures employed.[18] Hence any NiO or $Ni(OH)_2$ formed in the above decompositions must have been primary decomposition products. It would be expected that $Ni(OH)_2$ could be formed directly from a compound of type I, but not from one of type II, and this expectation was borne out by the results of the decomposition of the mono- and dihydrates in water. Hence the above structures were satisfactory from this standpoint.

Hofmann and Hiendlmaier[19] reported a compound which had the composition $KNiO_2$, by fusion of nickel powder with potassium peroxide. This was possibly a salt of the compound II. Hydrolysis took place in water, and the hydrolyzed product gave the analysis $Ni_2O_3 \cdot 2H_2O$, but part of this water might well have been adsorbed. The acidic nature of the product F was indicated by its relatively slow rate of peptization, indicating a strong retention of base, as would be the case if a weak salt were formed.

It was apparent that the method of isobaric decomposition employed by Hüttig and Peter[1]* in establishing the existence of the monohydrate was not

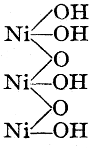
(19) Hofmann and Hiendlmaier, *Ber.*, 39, 3184 (1906).

conclusive, for the decomposition of the dihydrate has been shown to be irreversible. Their initial preparation consisted of the dihydrate, and in view of the present work it is improbable that they obtained the monohydrate by decomposition of this product. Furthermore, they found no evidence for the existence of the dihydrate, which they should have obtained had the method been reliable. Also the later work of LeBlanc and Müller[15] supports this conclusion very strongly.

The present results are not in accord with those of Hiittig and Peter in two other important respects. They found that no active oxygen was lost when a compound corresponding to the dihydrate was heated for several hours in water at temperatures of 120 and 200°. The product formed in the latter case was assumed to be the monohydrate of Ni_2O_3. In the present work it was found that the decomposition in water at 130 to 150° took place directly to nickelous hydroxide. The heating times were much longer than in the case of the previous work, but there was no evidence of intermediate compounds formed in the decomposition. Also the x-ray diagram of the "monohydrate" obtained by them in this way did not correspond to the pattern of that compound obtained in this work.

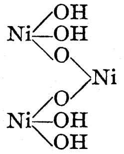
The identity of the diffraction patterns of products A and B left no doubt as to the fact that the oxidized product was the same in each case, *i. e.*, whether by simultaneous oxidation and precipitation, or by oxidation of previously precipitated nickelous hydroxide. Hiittig and Peter obtained differing diffraction patterns for preparations similar to the above, and this might have been due to incomplete oxidation of the nickelous hydroxide, since the oxidation of the suspended material was found to take place quite slowly.

Little could be said as to the exact nature of the preparations E_1 and E_2 other than that it was evident that they were compounds containing both di- and trivalent nickel and not mixtures of a trivalent oxide-hydrate and NiO or $Ni(OH)_2$. If E_1 had been such a mixture, further oxidation would only have oxidized the divalent compounds present and left the trivalent compound unchanged. Thus the properties of the product would have changed very little due to such an oxidation. However, the results were quite different from this. The oxidized product F not only gave a different diffraction pattern, but also behaved completely differently on decomposition in water and air. Hence the original product E_1 must have been completely changed by the oxidation, and this would only be the case if it were a compound of di- and trivalent nickel. The chemical analyses indicated that the compositions of E_1 and E_2 could be expressed as hydrates of the hypothetical oxides Ni_3O_4 and Ni_6O_7, but their properties indicated that the water was bound in the compounds as hydroxyl groups. The following were the simplest structures which could be devised



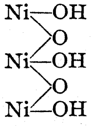
IIIa

or $Ni_3O_4 \cdot 2H_2O$
Mono nickelous (basic)
salt of I



IIIb

Mono nickelous salt of
ortho nickelic acid



IV

or $^1/_2Ni_6O_7 \cdot 3H_2O$
Di-nickelous (basic) salt of
ortho nickelic acid

It is obvious that such compounds might hydrolyze to nickelous hydroxide, as was observed when E_1 and E_2 were heated in water. The water contents of compounds of types III and IV are somewhat below the observed contents of E_1 and E_2, but this does not exclude the possibility that these are the correct structures, for considerable amounts of water are frequently adsorbed by such precipitates, as shown in the previous discussion. We favor formula IIIa over IIIb since IV may be obtained from it without rearrangement. (This transition takes place upon heating of compound III.)

Summary

1. The existence of compounds having the compositions $Ni_2O_3 \cdot H_2O$ and $Ni_2O_3 \cdot 2H_2O$ has been shown. Characteristic x-ray diffraction patterns of these compounds have been obtained.

2. The modes of decomposition of these "hydrates" in water and air at temperatures of 100 to 150° have been established with the aid of x-ray analysis. The results indicated that the compounds were not true hydrates, but contained the water bound as hydroxyl groups. Structural formulas have been assigned.

3. Two compounds of nickel, oxygen and water, at lower stages of oxidation than the above, have been isolated, and their diffraction patterns obtained. Chemical analyses indicated that they were hydrates of the hypothetical oxides Ni_3O_4 and Ni_6O_7, but their behavior on decomposition showed them to be of a type analogous to the above compounds. Reasonable structural formulas have been proposed.

The Diffusion of Colloidal Electrolytes; Sodium Oleate

BY M. E. LAING MCBAIN

Soaps afford one whole family of uni-univalent electrolytes to which the hypothesis of complete dissociation is not reasonably applicable.[1] In very dilute solution they are only moderately strong electrolytes and in more concentrated solutions they are colloidal electrolytes. In such cases the high diffusion constant observed[2] is a composite made up from the various ionic molecular and colloidal species present. The accepted formulas of Nernst[3] and Haskell[4] refer, however, only to infinite dilution and that of Einstein[5] to uncharged spherical molecules or particles. McBain and Liu,[6] from a consideration of the principles of interionic attraction as analyzed in the Debye–Hückel–Onsager theory and from experimental data for potassium chloride, sucrose, and potassium laurate, derived four conclusions for dealing with ordinary finite concentrations: (1) that the resistance of ions to motion, all in the same direction, is nearly independent of their concentration; (2) that the change in diffusion coefficient of an electrolyte such as potassium chloride is dependent primarily upon a direct proportion to the observed osmotic pressure rather than to the numerical value of the activity;[7] (3) for non-electrolytes the diffusion coefficient is not greatly affected by the changes in viscosity with concentration and, therefore, usually diminishes but slowly with increase in concentration; (4) that the total diffusion observed may be arrived at in good first approximation by combining additively (a) the diffusion of known concentrations of molecules and of uncharged colloidal particles, using the Einstein equation, (b) the Nernst equation (for infinite dilution) for the ions of a uni-univalent electrolyte but corrected for decrease in osmotic pressure, and (c) the Haskell formula (for infinite dilution) corrected for change in osmotic pressure for polyvalent electrolytes or charged colloidal particles together with their compensating ions.

(7) Compare G. N. Lewis and M. Randall, "Thermodynamics and the Free Energy of Chemical Substances," 1623, p. 362. The approximate proportionality to the observed osmotic pressure was experimentally demonstrated by Öholm [Z. *physik.* Chem., 60, 343 (1904)] over the whole range of concentrations of solutions of electrolytes up to several times molar. He showed the advisability of correcting for viscosity, but found a direct proportion an over correction; MacInnes much later proposed $\eta^{0.7}$. Hartley [*Phil* Mag., 12, 485 (1931)] used this and compared the replacement of van't Hoff's i by d In $a_{\pm}$/d In C for electrolytes in fairly dilute solution (0.1 N) with an average discrepancy of over 4%. For higher concentrations he writes "... an exact comparison would not, in the present state of the latter, be instructive, even if the method and assumptions of the theory could he considered applicable in the more concentrated solutions."

For the simple case of a highly dissociated uni-univalent electrolyte such as potassium chloride the diffusion coefficient D in sq. cm./day is

$$D = iRT\Big/\left(\frac{1}{U} + \frac{1}{V}\right)$$

where U and V are the mobilities in reciprocal ohms of cation and anion; that is, the denominator is the sum of the resistances to movement and the numerator is the driving force, i being the van't Hoff osmotic coefficient.

Their general equation for such an electrolyte, partially dissociated[8] (or ions, partially "associated), α referring to concentrations, is

$$D = \frac{i}{1 + (n - 1)\alpha} RT \left[\alpha \left(\frac{1}{n_+} + \frac{1}{n_-}\right) \left(\frac{1}{\frac{1}{U} + \frac{1}{V}}\right) + \frac{1 - \alpha}{1/U_m}\right]$$

where n is the number of ions produced by the dissociation of one molecule or particle, n_+ and n– are the valencies of cation and anion, $1/U$ and $1/N$ are the resistance to movement of one electrochemical equivalent (charge of IF) in each case, whereas $1/U_m$ is the resistance to movement of *1* whole gram molecule (or 60.6 X 10^{22} "uncharged particles") as defined in the Einstein equation.

$$D = \frac{RT}{N6\pi\eta r} = \frac{RT}{1/U_m}$$

RT has the value[9] of 0.02246 at 18° and 0.02300 at 25° if $1/U_m$ is expressed in ohms. The formula is for diffusion into pure solvent. For diffusion into another solution, slightly less concentrated, the gradient of osmotic pressure with concentration would be used.

It follows directly from these equations that if a large particle or a molecule of low mobility such as a protein passes from the isoelectric point to become a polyvalent electrolyte, its diffusion is accelerated almost in proportion to the total number of ions of the polyvalent electrolyte. This was first derived implicitly in 1925 by Svedberg,[2c] who suggested that diffusion might thus be used for measuring how many charges are carried by a single particle.

It is interesting that the diffusion constant of mercuric chloride, 0.92, which admittedly consists almost entirely of molecules, is very nearly that

---

(8) Owing to the circumstance that in the special case of potassium chloride $1/U_m = 1/U + 1/V$, McBain and Liu wrote this in the equivalent form, not generally applicable

$$D = \frac{iRT}{\alpha\frac{1}{U} + \alpha\frac{1}{V} + (1 - \alpha)\frac{1}{U_{\text{KCl}}}}$$

They committed the algebraic error of recording D as $iRT/$(sum of resistances), instead of, as in their actual numerical examples, keeping the added fractions separate, the numerators adding to iRT. G. S. Hartley's suggested emendation is obviously erroneous as may be seen if it is considered in connection with a weak electrolyte such as mercuric chloride or succinic acid. He multiplies the diffusion of the neutral molecule by the valencies of the ions into which it would have dissociated had it been dissociated [*Phil.* Mag., 12, 487 (1931)]. He states at the top of p. 487 that McBain and Liu ignored interionic forces, having overlooked their discussion.

(9) Values calculated from data of "International Critical Tables."

calculated for complete dissociation into independent ions, 0.91. The resistance to movement of the molecule is, therefore, one-third the sum of the three ions. For cadmium iodide, a stronger electrolyte, the diffusion coefficient for completely undissociated molecules is 0.67 as compared with 1.18 for complete dissociation, the resistance for the molecule being 58% of the sum of that of the three ions. From these and other data one might tentatively infer that the more polar the molecule the less differences does dissociation cause in resistance to movement and hence, conversely, the greater the importance of the mere number of molecules and ions present.

The present paper supplements the above analysis of the diffusion of potassium laurate[2a] with more extended data for sodium oleate. Here it is possible to test the effect of the linking of the primary particles of oleate by showing that diffusion from sodium oleate jelly into water is just as rapid as the diffusion of the oleate sol.

Experimental

The method employed was that previously described,[2a] in which a Northrop diffusion cell is filled with the soap solution which diffuses through a sintered Jena glass membrane into 0.0015 N sodium hydroxide to prevent hydrolysis. As in previous experiments the same values are obtained with each of the four cells used, lower values being found only with a very tight, slow diffusing membrane when studying the higher concentrations of soap. However, the values for dilute solutions, using the same slow cell, lie on the general curve, and it is supposed then that these finer pores became clogged in higher concentrations, either with soap or with fatty acid formed by hydrolysis. Additional tests with cells at 20 and 25° have been carried out and have checked the previous assumptions that different cells yield the same diffusion constants.

The properties of the cells used are given in Table I. The sintered glass membrane was in every case 5 cm. in diameter and 2 mm. thick.

TABLE I

CHARACTERISTICS OF THE DIFFUSION CELLS

Designation		Volume of cell, cc.	Approx. pore radius, Å.	Cell constant
Trade	Here			
G-4	a	37.08	2.5×10^4	348.2
G-4	b	37.96	2.5×10^4	170.2
G-3	G-3	98.00	$(15–20) \times 10^4$	348.3
G-4	W	106.9	2.5×10^4	253.0
G-4	M	105.3	2.5×10^4	221.8

The diffusion method is accurate to a fifth of one per cent. for electrolytes, but for soaps the error may be increased to several per cent. owing to the extreme difficulty of releasing the air from the soap solutions. Early attempts to find the boiling point of soap solutions[10] failed completely

because of the air obstinately retained. In many of the diffusion experiments recorded here, however, only a few bubbles were developed if the solutions had previously been thoroughly subjected to suction. The experimental results are calculated by the formula developed by Liu, and displayed in Fig. **1,** where data for sucrose and potassium laurate are added for comparison. New values added for **0.05** N_w potassium laurate are D = **0.510** and **0.510.**

Discussion of Results

We may compare the observed results (a) with the predictions of the Nernst and Haskell equations and (b) with values for other substances (see Fig. 1). Taking the mobilities of potassium and sodium from the data of "International Critical Tables" and that of a simple fatty ion as **23.2** and assuming the equivalent conductivity of the ionic micelle to be equal to that of the potassium ions, we calculate from the Nernst equation for complete dissociation into simple ions D = **0.813** for potassium laurate and D = **0.731** for sodium oleate. Again the Haskell formula for hypothetical complete dissociation into a decavalent ionic micelle and **10** alkali ions yields D = **0.936** for the ionic micelle (plus potassium ions) of potassium laurate and D = **0.759** for that of sodium oleate. It is noteworthy that these numbers show a distinctly higher rate of diffusion for the colloid form as compared with the simple ions, assuming infinite dilution in both cases.

However, for colloidal soap this is offset by the much lower diffusion velocity of the undissociated colloid or neutral micelle which is present in even larger quantity than this ionic micelle and for which the driving force per colloid particle is only one-eleventh that on the ionic micelle with its ten compensating ions. Thus in Fig. **1** the observed diffusion values are much lower than those calculated above because of the incomplete dissociation both of the simple molecules in dilute solution and of the colloidal electrolyte in more concentrated solution. Once the colloidal electrolyte is fully formed, as in **0.3** N solution upward, its diffusion, like its apparent degree of dissociation, changes very little with concentration.[11] As a matter of fact, the observed diffusion rate is an approximately linear function of the proportion of total colloid.

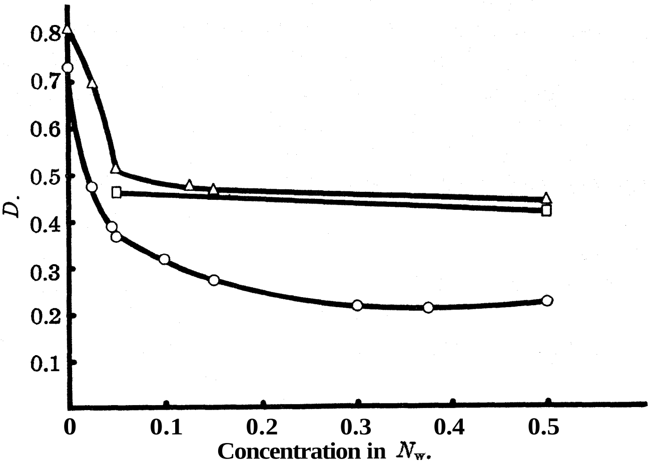

Fig. 1.—The diffusion coefficients D in sq. cm./day of potassium laurate, sucrose, and sodium oleate, at 25°; A, potassium laurate; □, sucrose; O, sodium oleate.

A 0.025 N_w sodium oleate solution contains only 1.5% of colloid, accounting for **0.011** of the observed diffusion, **0.462,** leaving 0.451 for simple ions and molecules. The composition diagram of these solutions was published by McBain, Laing and Titley,[12] but the Arrhenius conductivity ratio was not then corrected for interionic attraction, so that the *25%* Arrhenius dissociation (left after allowing for products of hydrolysis) really means about 26.3% true dissociation. This correction, however, is partly offset by the lowering of osmotic pressure. 26% of **0.731** is 0.190 which

---

[11] This is a further confirmation of the point made by McBain that for the ionic micellrs of soap the charges are so widely spaced that the ionic strength of the solution is only that of a uni-univalent salt [THIS JOURNAL, 50, 1636 (1928)].

[12] McBain, Laing and Titley, *Trans. Chem. Soc.*, 115, 1279 (1919).

when subtracted from 0.451 leaves 0.268 due to the diffusion of simple molecules which comprised 61% of the total soap. Their diffusion constant $D_m = 0.261/0.61 = 0.428$, and their mobility from the Einstein formula 18.6. This is somewhat less than the mobility of the oleate ion (23.2), and the resistance to movement of this more strongly polar molecule is 85% of the sum of its two ions in accordance with the tentative rule on a previous page.

In 0.5 N solution of sodium oleate the only constituents present are ionic micelle and its sodium ions and the neutral colloid. The Arrhenius conductivity ratio was 20%, which as a first approximation may be corrected by comparing it with the Arrhenius ratios for decinormal solutions,[13] thus indicating a true degree of dissociation of about 23.5%. This again from the standpoint of diffusion is partly offset by the lowering of osmotic pressure due to interionic attraction.[14] Approximately, then, the diffusion due to the ionic micelle and its ions may be taken as 22% of 0.759 (see above) = 0.167. This subtracted from the observed value of 0.226 leaves 0.059 for the 76.5% of neutral micelle, whose diffusion coefficient is, therefore, 0.077 and mobility U_m is 3.35. From this, Einstein's equation for a spherical uncharged particle would give a diameter of only 55 Å.

The size of the primary particle of neutral colloid is, therefore, only a little greater for sodium oleate than for potassium laurate[2a] (48 Å.). In both cases the ionic micelle, from the mobility assumed, has an effective diameter of 25 Å. The small size of the primary particles of soap solutions is confirmed by measurements on light scattering to be reported elsewhere. It thus appears that the great difference experimentally observed between potassium laurate and sodium oleate is not essentially due to difference in size of the primary particles but to the fact that in the sodium oleate there is a great tendency for the formation of loose secondary aggregates. The light scattering does not change when sodium oleate sol sets to a clear jelly.[15] Potassium laurate, on the contrary, does not show the slightest tendency to gelatinize even in the presence of salts; and it passes through fine ultrafilters.

Diffusion of Sodium Oleate Jelly.—Having found that the relatively high viscosity and ready ultrafilterability must be ascribed to loose aggregation of the neutral colloidal particles, it becomes of great interest to note that this has interfered to only a very minor extent with the diffusion coefficient of the sol. This may be pictured as a comparison between the diffusibility of a number of particles loosely strung together, as in a flexible necklace, with their diffusibility when completely separated. McBain and Liu[2a] pointed out the remarkable fact that with sucrose a manifold increase of viscosity caused by diffusing molecules themselves only slightly

---

(13) Compare Kraus, "Properties of Electrically Conducting Systems," 1922, p. 35, Table 4

(14) Ref. 13, pp. 233, 234.

(15) McBain and McBain, *Nature*, 126, 125 (1930).

affects the rate of their diffusion. Upon the same principle, the necklace would be expected to diffuse almost *as* fast as the component beads.[16]

The following experiments were carried out to ascertain how fast sodium oleate diffuses from the completely jellied form into water (with **0.0015** N sodium hydroxide). Comparative experiments were likewise made with other portions of the same specimen of solution which had been allowed to crystallize out far enough to form a hard white curd and with two intermediate samples in which only a small amount of curd fibers had separated.

TABLE III

DIFFUSION FROM DIFFERENT SAMPLES OF THE SAME 0.5 N_w SODIUM OLEATE SOLUTION IN DIFFERENT PHYSICAL STATES

State of soap	Temp., °C.	D in sq. cm./day	
Clear sol	25	0.221	0.221
Clear jelly	25	.232	.228
Cloudy gel	25	.186	.194
Translucent cloudy gel	23–25	.187	.189
Hard white curd	22–23	.135	.149

It is really quite remarkable to find that soap can diffuse as fast when its colloidal particles are fixed as when they are fluid and free to move and that the diffusing power is only lessened when the amount of material present decreases by crystallizing out as it does in curding, which removes soap from solution. This finding would exclude loose aggregation as a noticeable cause of lessened diffusibility of colloids.

Summary

1. General equations for diffusion are given to comply with the experimental fact that diffusion is proportional to osmotic pressure and not to activity.

2. It is suggested that the resistance to movement of an undissociated molecule is dependent upon its degree of polarity.

3. Colloidal electrolytes such as soaps exhibit high diffusion coefficients, which are analyzed. Primary particles of sodium oleate are not much larger than those of potassium laurate. The viscosity and gelatinizing power of sodium oleate is due to loose linking of primary particles and this does not appreciably affect the rate of diffusion.

The Free Energy of Formation of Iodine Monobromide in Carbon Tetrachloride Solution

BY DON M. YOST, THOMAS F. ANDERSON AND FOLKE SKOOG

Introduction

Inasmuch as the extent of dissociation of gaseous iodine monobromide into gaseous iodine and bromine is known,[1] it was considered of interest to determine the corresponding dissociation when all substances are present in a nearly ideal solvent, such as carbon tetrachloride. From such data the corresponding dissociation in aqueous solution can also be obtained when distribution experiments are made.

In this paper are presented the results of measurements on the vapor pressures of iodine monobromide above its carbon tetrachloride solutions, together with the thermodynamic quantities calculated by combining the results with other known data.

Experimental Method and Preparation of the Materials

The vapor pressure of iodine monobromide above its solutions in carbon tetrachloride was measured by passing dry nitrogen at constant pressure at the rate of about one liter per hour through a series of bulbs containing the monobromide solution at 25.0". All-glass connections were used throughout. The total amount of halogens removed by the nitrogen was small compared with the amounts present in the solutions, and hence the concentrations were not appreciably changed.

It was necessary in all experiments to analyze for both the total halogen and the iodine in order to establish the composition of the vapor. This was accomplished by the analyses of two separate samples. In one sample the halogens were absorbed in potassium iodide solution and the liberated iodine titrated with standard thiosulfate. this procedure serving for the determination of the total halogen. In a second sample the halogens were absorbed by an excess of sodium sulfite solution, 0.5 N hydrochloric acid was added, and the iodide present was titrated with standard permanganate, the end-point being determined electrometrically.[2] In this latter determination a sudden increase in the e. m. f. takes place when all of the sulfite has been oxidized, and a second increase is observed when all of the iodide has been converted to iodine. For the oxidation of all but a trace of the sulfite a more concentrated permanganate solution was used. It was found that this procedure could be used for quantities of iodine as small as 0.1 milliequivalent with an accuracy of 1.0%, the accuracy increasing with an increase in the amount determined.

The iodine used was a product of high quality, the purity of 99.97% indicated by the manufacturer having been confirmed in this Laboratory. Bromine marked c. p. was twice distilled from very pure potassium bromide and then from phosphorus pentoxide, and the middle fraction from the last distillation was used in the experiments. The resulting material was sealed in glass tubes of known weight and the tubes with their contents weighed. The solutions of iodine monobromide were prepared by dissolving

exactly equivalent amounts of iodine and bromine in measured volumes of carbon tetrachloride.

To obtain pure carbon tetrachloride the C. P. material was saturated with chlorine and the chlorine removed by boiling. The residue was then redistilled and the middle fraction collected and used in the experiments.

Results of Experiments

In Table I are presented the results of the experiments made to determine the partial pressures of iodine monobromide over solutions of it in carbon tetrachloride. Each pressure is the average for several determinations in which the average deviation from the mean was 2%.

TABLE I

PARTIAL PRESSURES OF IODINE MONOBROMIDE ABOVE ITS CARBON TETRACHLORIDE SOLUTIONS

.0224	2.36	2.68	.0207	2.32	112
				Mean	114

[a] This value was not included in estimating the mean.

That Henry's law, p/N = constant, is obeyed over a considerable range of concentration, is evident from the values of the constant given in the last column of the table.

In all experiments the vapor contained an excess of bromine, this excess being due to the presence in the solutions of free bromine, which results from the dissociation of the iodine monobromide. Under the assumption that the free bromine in the vapor is, to a first approximation, equal to the excess found, and by using for the Henry's law constant p_{Br}/N_{Br} for bromine in carbon tetrachloride solution the value[3] 409, expressed in millimeters, an approximate value for the mole fraction of free bromine in solution was calculated. Since iodine and bromine were present in equivalent amounts in solution the mole fraction of free iodine was equal to that of the bromine. The partial pressure of iodine, calculated by employing the value[4] 26.9 for the constant of Henry's law, was used to correct the partial pressure of free bromine. A second approximation was found unnecessary.

It is also possible to estimate the composition of the vapor by applying the known value for the dissociation constant of iodine monobromide to the results of the analyses. The two methods of calculation lead to the same result within the limits of experimental errors. The method used

---

(3) Lewis and Storch, THIS JOURNAL, 39, 2544 (1917).

(4) This value was calculated from known values for the solubility of iodine in carbon tetrachloride and the vapor pressure of the solid at 25.0°. Jakowkin, *Z. physik. Chem.*, 18, 588 (1885); Baxter Hickey and Holmes, THIS JOURNAL, 29, 127 (1907).

above makes possible an independent evaluation of the extent of dissociation of the monobromide both in solution and in the gaseous state, and it was for this reason that it was chosen. It must be noted, however, that small differences between large quantities are involved and consequently the dissociations so calculated are subject to much greater errors than those given below.

The free energy changes accompanying the following changes in state were obtained directly from the literatures or by an application of the relation

$$\Delta F^\circ_{298} = -RT\ln K$$

to the known values K, of vapor pressures, solubilities and constants of Henry's law. The Henry's law constant p/N for the iodine monobromide is 114/760, the numerator being the mean value given in Table I.

$$\begin{aligned}

&\tfrac{1}{2}Br_2\,(\text{in } CCl_4) = \tfrac{1}{2}Br_2\,(l) && AF = -195\text{ cal.}^{5} && (3)\\
&IBr\,(g) = IBr\,(\text{in } CCl_4) && \Delta F^\circ_{298} = -1124\text{ cal.} && (4)\\
&\text{Hence, } \tfrac{1}{2}I_2\,(\text{in } CCl_4) + \tfrac{1}{2}Br_2\,(\text{in } CCl_4) && && \\
&\qquad = IBr(\text{in } CCl_4) && \Delta F^\circ_{298} = -1746\text{ cal.} && (5)
\end{aligned}$$

The final value, −1746 cal., for the free energy change accompanying reaction (5) is nearly equal to the value, −1790 cal., for the corresponding reaction where all substances are in the gaseous state. Both values are subject to an error of ±50 cal. The approximate equality of the free energies of the monobromide under these radically different conditions is of considerable interest because it indicates that the effect of the solvent on the three substances involved is much the same.

It is to be noted that the concentration units used above are mole fractions but since the equilibrium constant for reaction (5) is independent of the units used, the same constant may be employed in calculations in which the concentrations are expressed in moles per liter or moles per thousand grams of solvent. The value for the equilibrium constant for reaction (5) at 25° is 19.0 and the degree of dissociation of the iodine monobromide is 9.5%.

From the data given in Table I it is possible to determine independently, but not with great accuracy, the degree of dissociation of the iodine monobromide both in solution and in the gaseous state. The degrees of dissociation so calculated are 8 and 7% for the solution and gas, respectively, and agree satisfactorily with the corresponding more accurate] values of 9.50 and 8.9%, respectively.

In Table II are presented the thermodynamic constants of iodine monobromide. The standard reference states are indicated in each case.

TABLE II

THERMODYNAMIC CONSTANTS OF IODINE MONOBROMIDE AT 25°

Substance	Reference substances	Free energy, cal.
IBr (g)	I_2 (s), Br_2 (l)	903
IBr (g)	I_2 (g), Br_2 (g)	−1790
IBr (in CCl_4)	I_2 (in CCl_4), Br_2 (in CCl_4)	−1746
IBr (in CCl_4)	I_2 (s), Br_2 (l)	− 221
I_2 (in CCl_4)	I_2 (g)	−1970
IBr (in CCl_4)	IBr (g)	−1124
Br_2 (in CCl_4)	Br_2 (g)	− 366

The Stability of the Iodine Dibromide Ion, IBr_2^-

A large number of distribution experiments were made in which the solvents were carbon tetrachloride and aqueous solutions of hydrobromic and perchloric acids in order to determine the stability of the iodine dibromide ion, IBr_2^-. That there is a fairly strong tendency for the formation of this complex ion was shown by the fact that the monobromide dissolved much more freely in the hydrobromic acid than in the perchloric acid solutions. The results of experiments in which perchloric acid solutions were used showed that the reaction

$$I_2 + 5Br_2 + 6H_2O = 12H^+ + 2IO_3^- + 10Br^-$$

took place, and the bromide ion formed led to the formation of IBr_2^-. This complication rendered the values obtained for the distribution ratio of free iodine monobromide between the acid and carbon tetrachloride of doubtful significance. It is therefore impossible, at this time, to make more than a qualitative statement regarding the stability of the iodine dibromide complex. Its stability is shown roughly by the rather consistent value $300 = (IBr_2^-)/(IBr)(Br-)$, for the equilibrium constant.

Summary

The partial pressures of iodine monobromide above its carbon tetrachloride solutions have been measured at 25.0' and the constant of Henry's law, $k = p_{IBr}/N_{IBr}$, found to have the value 114 where the pressures are in millimeters.

From this result combined with known thermodynamic data it was found that the standard free energy change for the reaction $\frac{1}{2}I_2$ (in CCl_4) + $\frac{1}{2}Br_2$ (in CCl_4) = IBr (in CCl_4) is −1746 cal. at 25°. This value is nearly the same as that for the reaction $\frac{1}{2}I_2(g) + \frac{1}{2}Br_2(g) = IBr(g)$, namely, −1790 cal. The degree of dissociation of iodine monobromide in carbon tetrachloride solution is 9.5%. The standard free energy change for the reaction $\frac{1}{2}I_2(s) + \frac{1}{2}Br_2(l) = IBr$ (in CCl_4) at 25° is −221 cal.

Invertase Action as a Heterogeneous Reaction

BY T. A. WHITE

Introduction

Catalysts of various sorts have been known and investigated for many years. In their efforts to determine the mechanisms by which these various agents can change the rate of a given reaction, investigators have been led to two points of view. With respect to enzymes, these points of view have resolved themselves into the question of whether the reaction is homogeneous or heterogeneous in nature. Since catalysts affect the rate of a reaction, many attempts have been made to determine the mechanism by means of reaction kinetics studies.

Most investigators in the field of enzyme action have applied the mass law to what is assumed to be a homogeneous system. This method of approach has led to an explanation of many observations that have been made by a multitude of investigators from time to time, and, consequently, has led a large group of workers to believe that enzyme reactions are homogeneous in nature. On the other hand, this method of approach has not led to a complete explanation of all the observed facts. For example, Nelson and Griffin[1] showed that not only was invertase active in solution, but it was also active while adsorbed on charcoal, demonstrating that the action may be of a heterogeneous nature. This, as well as the fact that the enzyme itself is of a colloidal nature, led Nelson and Vosburgh[2] to consider the action of invertase in hydrolyzing sucrose as a reaction of a heterogeneous rather than of a homogeneous nature. It should be mentioned, too, that Bayliss[3] also considered enzyme action as heterogeneous, and suggested that adsorption played a part in the reaction; but his views proved to be unsatisfactory. These various suggestions and methods of approach have not led to a picture which on the whole is as acceptable as that offered by Michaelis and Menten[4] from the homogeneous viewpoint.

This is due, to some extent at least, to the fact that equations which have been derived in the past from the heterogeneous viewpoint have not successfully explained the kinetics of enzyme reactions. In recent years, much progress has been made in understanding those gas reactions which take place at the surfaces of certain inorganic catalysts by recognizing that the seat of such reactions lies in the layer of adsorbed molecules on the surface of the catalyst. With invertase as an example and assuming the invertase–sucrose–water system to be heterogeneous in nature, it is the

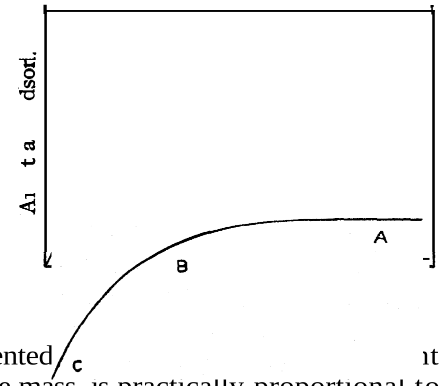
purpose of this paper to utilize these new ideas in showing that the experimental facts can be explained just as well from the heterogeneous as from the homogeneous point of view. Since the homogeneous view is so well known, and can be found discussed in full elsewhere,[5] the remainder of this paper will deal entirely with the presentation of the heterogeneous view.

Theoretical Introduction

While there is no need to give here a complete discussion of the ideas[6] that have developed around heterogeneous reactions, it may be useful to give at this time a brief survey of those principles which will later be employed in discussing the facts of invertase action. The active mass in a heterogeneous reaction is not the total amount of a given substance present, as it is in a homogeneous reaction, but is, according to the chemical adsorption theory, that part of the total mass which is actively adsorbed on the surface of the catalyst. Since only those molecules which are adsorbed by the catalyst react, the problem resolves itself into that of determining how much is adsorbed. If it be assumed that this can be more or less accurately determined by means of what is called the Langmuir[7] adsorption isotherm, which may be expressed in terms of concentration c, a constant b, and the fraction of the surface covered Θ, as

$$\Theta = \frac{bc}{1 + bc} \tag{1}$$

a number of kinetic equations may be derived. Such an adsorption isotherm may, in the general case, be represented by a curve as is shown in Fig. 1. This shows that over the section A the catalyst is completely covered, according to the theory, with a unimolecular layer of adsorbed molecules, but less and less covered at B and C. Moreover, as long as the concentration of the reactant in the solution is at a sufficiently high level to cover the surface of the catalyst with adsorbed reactant, the rate of reaction should be constant. On the other hand, over the portion represented it adsorbed, and consequently the active mass, is practically proportional to the total concentration of reactant. Under such conditions, the reaction



---

[5] See Chap. V, "The Course of Enzymatic Reactions," of "Enzymes" by Haldane (1930) for a discussion of the methods employed in deriving from the homogeneous viewpoint equations which are similar to those that will be derived and used here.

[6] For a fuller discussion of these principles, see, for example: (a) Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems"; (h) Taylor, "Treatise on Physical Chemistry," Chap. XV, 2d ed.

[7] Langmuir, THIS JOURNAL, 88, 2221 (1916).

should be unimolecular in nature. A reaction progressing along the section indicated by B should show an order which gradually changes from zero to unimolecular. Finally, if a reaction started in the region A, and was followed to completion, the reaction should give a constant rate, or zero order, at first, but decreasing constants thereafter, increasing unimolecular constants over the first and middle portions, and regular unimolecular constants during the last part of the reaction. In a general case, where a is the original amount of the reactant, x the amount of product at time t, k and b constants, the rate of such a reaction may be expressed as

$$\frac{dx}{dt} = \frac{k(a - x)}{1 + b(a - x)}, \text{ or } k = 1/t \ln \frac{a}{a - x} + \frac{bx}{t} \tag{2}$$

But the above equation does not take into account the inhibiting action of the products of a reaction, and since the products do inhibit the hydrolysis of sucrose, equations should be derived to fit those conditions. The simplest case of this sort is the one that has an amount of adsorbed reactant which is proportional to the total concentration, namely, over section C of Fig. 1. Under such conditions, the amount of active mass of the reactant is equal to the product of that amount which would ordinarily be adsorbed (in this case, proportional to the total concentration of the reactant) and that fraction of the total surface which is not covered by the product. That fraction of the surface which is covered by the product is given by equation 1. The fraction of the surface which is available for the reactant is equal to

$$1 - \Theta = 1 - \frac{bx}{1 + bx} = \frac{1}{1 + bx} \tag{3}$$

Therefore, the rate under such conditions is equal to

$$\frac{dx}{dt} = \frac{k_1(a - x)}{1 + bx} \text{ or } k_2 = 1/t \ln \frac{a}{a - x} - \frac{k_3 x}{t} \tag{4}$$

Since the products inhibit the hydrolysis of sucrose with invertase, it should be expected that this equation would hold over the last part of the reaction, and it will be shown that it does.

At the beginning of the reaction, where the reactant is in sufficient concentration to cover all the surface left for it by the adsorbed product, the rate should be proportional to the product of the amount of surface available for the reactant and the amount (in this case, constant) of the reactant which would be adsorbed in the absence of any product. Thus, the rate is equal to

$$\frac{dx}{dt} = \frac{k_4}{1 + bx} \text{ or } k_4 = \frac{x}{t} + \frac{bx^2}{2t} \tag{5}$$

It will be shown that this equation holds for a considerable fraction of the invertase reaction.

The final problem, however, is to obtain a single equation that will represent the rate of hydrolysis from the beginning to the end of the reaction. In their studies of the adsorption of gas mixtures by silica, Markham and Benton[8] found that in general the fraction of the surface covered by one gas of a binary mixture followed an equation which is slightly different from equation 1. Considering the reactant and product as such a mixture, and using the same terms as before, the following equation expresses the fraction of the enzyme surface which is covered by the reactant.

$$\Theta = \frac{b(a - x)}{1 + b(a - x) + cx} \tag{6}$$

Under such conditions, therefore, the rate is equal to

$$\frac{dx}{dt} = \frac{k_5(a - x)}{1 + b(a - x) + cx} \text{ or } k_5 = \frac{1 + ac}{t} \ln \frac{a}{a - x} + \frac{(b - c)x}{t} \tag{7}$$

It will be noticed that equation 7 may be reduced to the same form as equation 2. Perhaps it is for this reason that various workers have found that the course of the reaction agreed well with equation 2, which was obtained by others from the homogeneous viewpoint as well as here without considering the products. Further, it should be pointed out that equation 7 reduces to equation 4 toward the end of the reaction, where the value of $b(n - x)$ becomes small in comparison with the other terms.

Experimental Methods

Before the actual results are presented, the methods and types of apparatus employed will be recorded. While no new or unusual methods were used, all recognized methods for obtaining accurate results were carefully observed as far as was possible. The details of such methods are as follows.

The sucrose used in these experiments was prepared by recrystallizing ordinary cane sugar at room temperature by adding enough absolute ethyl alcohol to a saturated water solution of cane sugar to make the concentration of alcohol about 75% by volume. The precipitated sucrose was filtered off, washed several times with absolute alcohol, and dried at room temperature. Fresh solutions were prepared from this preparation just before a hydrolysis was begun by adding to the necessary amount of sugar 25 cc. of buffer and enough distilled water to make the volume 500 cc.; 400 cc. (half quantities were sometimes used) of this solution was placed in a glass-stoppered bottle and allowed a half hour to come to temperature equilibrium in a water thermostat. accurate to ±0.02°, before the reaction was started by pipetting a given quantity of enzyme into the reaction solution. Twenty cc. samples were pipetted from the reaction mixture and run into 5 cc. of 0.2 *M* sodium carbonate at room temperature in order to stop the reaction and to hasten mutarotation. Two drops of 40% sodium hydroxide were used instead of the sodium carbonate in the case of 3% sugar solutions. The delivery time of the pipet was ten seconds, and the mean of this value was taken as the time of taking the sample.

Two buffer solutions were used: P_H 4.7 was obtained with a 0.1 N sodium acetate–acetic acid solution, and P_H 6.4 and 7.4 were obtained with Clark and Lubs'[9] acid potassium phosphate–sodium hydroxide buffer solutions. The invertase was prepared from yeast according to the method suggested by Morrow,[10] and a 2.6% solution was used.

(9) See Clark, "The Determination of Hydrogen Ions," 1928, 3d ed., p. 192.

10) Morrow, "Biochemical Laboratory Methods," 1927, p. 281.

All readings were taken at room temperature in a 2-dm. tube. **A** high grade, triple-field Schmidt and Haensch polarimeter, calibrated to **0.01°**, was employed. While the room temperature varied from day to day by as much as four degrees, such changes were followed, and it is believed that they did not produce trends in the readings, for all readings were generally made within a narrow temperature range. A *Lab Arc*, with a Corning Glass filter to give the **5461 Å.** line, was used as a light source. Rotations due to strains in the cover glasses were avoided by rotating the tube between readings. Readings were always taken until mutarotation was complete, as indicated by the constancy, within **0.01'**, of polarimetric readings over a period of ten minutes. The initial rotation was synthetically determined by taking **20** cc. of a mixture of the original sugar solution with a proportionate amount of water to correspond to the amount of invertase which was added to the reaction solution. The invertase had no measurable optical activity. After allowing the reaction to run for one or two days, the rotation at the end of that time was considered as the final value. These values agreed within the experimental error with the theoretical amounts. The initial concentration of the sucrose, in terms of degrees of rotation, was taken as the initial rotation minus the final rotation; and the concentration of the sucrose at any time t was taken as the rotation at that time minus the final rotation.

Experimental Results

The Beginning of the Reaction.—It was found, as so many investigators have found, that the initial part of the hydrolysis proceeded with a constant rate, and continued to do so up to about ten per cent. hydrolysis. If the products did not inhibit the reaction, one would expect the rate to remain constant so long as the amount of sucrose adsorbed by the invertase is constant; but with the products inhibiting the reaction, the rate, under normal conditions, should gradually fall off. Equation 5 was derived to fit these conditions, and the following values in Table I show that the equation holds over a considerable portion of the reaction. Other values will be found in column 6 of Table IV.

TABLE I

RESULTS FOR 25° AND P_H 4.7

∞	9.79	..	...	m	16.19	..	...

Different Amounts of Enzyme.—Figure **2** gives a series of curves which shows how the unimolecular constant, as calculated from $k_m = l/t \log a/(a - x)$, varies as the reaction progresses. It will be noticed that the constants increase until about 93.5% of the sucrose has been hydrolyzed, and then decrease over the remainder of the reaction. Since the temperature, PH, sucrose concentration, and water concentration were the same, and only the amount of enzyme was varied in these experiments, it must be concluded that the maxima, which come at approximately 93.5% hydrolysis in all the cases, are independent of the amount of enzyme present.

The well-recognized fact that the rate of hydrolysis for a given concentration of sucrose is proportional to the concentration of enzyme present is also illustrated in the curves. This would be expected, for the enzyme will adsorb twice as much of the reactant as half that amount of enzyme will adsorb under the same conditions, and, since the rate is proportional to the amount of reactant adsorbed by the catalyst, the rate of hydrolysis should be twice as great in the former as in the latter case.

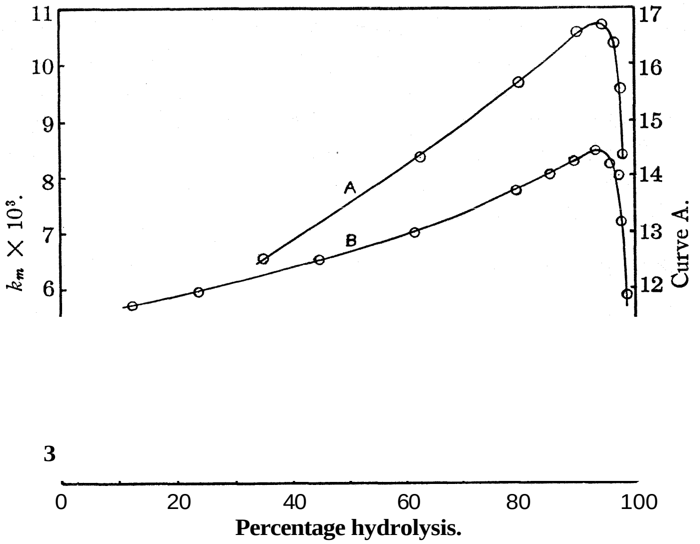

Fig. 2.—400 cc. of 6% sucrose, PH 4.7, 25°, with varying amounts of enzyme: Curve A, run 10, 2.0 cc. of invertase; Curve B, run 13, 1.0 cc. of invertase; Curve C, run 12, 0.5 cc. of invertase.

Different Amounts of Sucrose.—It will be noticed that the curves of Fig. 3 show the same general properties as those of Fig. 2. On the other hand, the additional fact is brought out that while the unimolecular constant goes through a maximum at a definite per cent. hydrolysis for a given initial sucrose concentration, irrespective of the amount of enzyme present, each sugar solution gives a maximum which depends on the initial concentration of the sugar. The maximum comes at 96% hydrolysis for 10% sucrose, at 93.5% hydrolysis for 6% sucrose, and at about 90% hydrolysis for 3% sucrose. These values indicate that the unimolecular constant goes through the transition period when the amounts of sucrose present in the solution are 0.40, 0.39, and 0.30%, respectively.

Different *Ph* Values.—Besides the very interesting fact that the rate of hydrolysis markedly decreases with an increase in the Ph of the solution from 4.7 to 7.4, the curves of Fig. 4 also show that the unimolecular constant goes through a maximum at different percentages of hydrolysis for different values of Ph. For 6% sucrose solutions, the maximum occurs at 93.5% hydrolysis for Ph 4.7, at **91.5%** hydrolysis for *Ph* **6.5,** and at **86.5%** hydrolysis for Ph 7.4. From these values, therefore, it must be concluded that besides decreasing the amount of sucrose adsorbed by the invertase, as indicated by a decrease in rate, an increase in Ph from 4.7 to 7.4 also modifies the general shape of the adsorption isotherm so that the isotherm reaches its saturation value at higher sucrose concentrations with higher values of Ph. It is not known how the surface of the enzyme particles varies with Ph, but it seems reasonable to suppose that the active surface varies considerably with *Ph*; and hence contributes to the above mentioned variations.

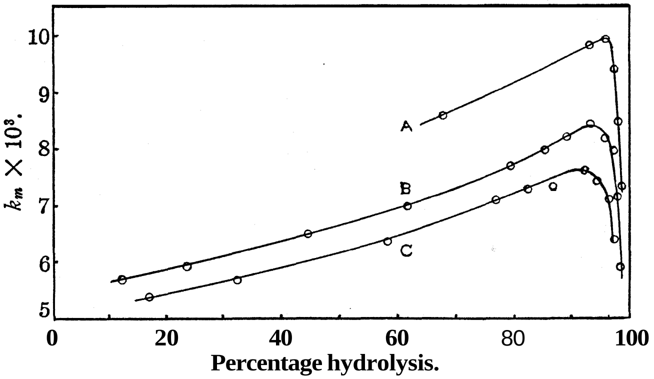

Fig. 3.--400 cc. of sucrose, Ph 4.7. 25°, with varying sucrose concentrations: Curve A, run 17, 10% sucrose, 2.0 cc. of invertase; Curve B, run 13, 6% sucrose, 1.0 cc. of invertase; Curve C, run 15, 3% sucrose. 0.5 cc. of invertase.

Effect of Temperature.—It is a well-recognized fact that the higher the temperature the higher the concentration at which an adsorption isotherm reaches its saturation value. In view of this fact one would expect that. for a given initial sucrose concentration and at the same Ph, the maximum of the unimolecular versus percentage hydrolysis curve would come at a lower percentage of hydrolysis the higher the temperature. The curves of Fig. 5 show that this is actually the case; for, if the curves of Fig. 5 are compared with those of Fig. 4, it will be noticed that with an initial sucrose concentration of 6% the maximum is shifted from 93.5% hydrolysis to 89.0% hydrolysis at Ph 4.7, and from 86.5% hydrolysis to 75.0% hydrolysis at Ph 7.4, for a ten degree rise in temperature. It should be pointed out that, since the dispersion of colloids is affected by temperature, some of this change is probably due to a change in the enzyme surface.

The End of the Reaction.—Throughout the results that have been given, it has been assumed that the variations of the unimolecular constant with percentage hydrolysis are real and that they are the result of the reaction itself. Previous investigators[11] have obtained one or a few unimolecular constants which showed a decreasing tendency toward the end of the reaction, but they have neglected them as due to a destruction of the enzyme by means of heat or as due to experimental error. The fact that

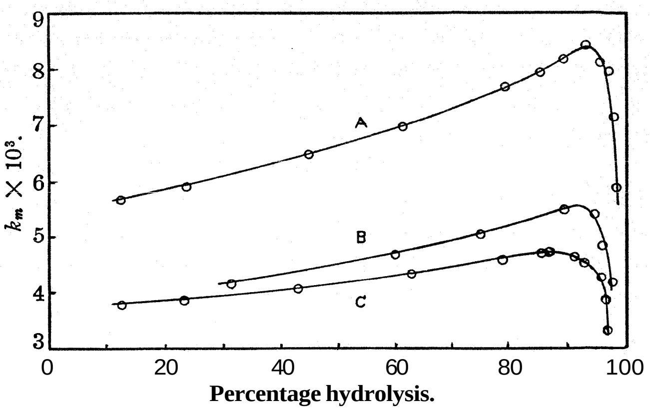

Fig. 4.—400 cc. 6% sucrose, 25°, at various P_H values: Curve A, run 13. P_H 4.7, 1.0 cc. of invertase; Curve B, run 19, P_H 6.5 1.0 cc. of invertase; Curve C, run 21, P_H 7.4, 4.0 cc. of invertase.

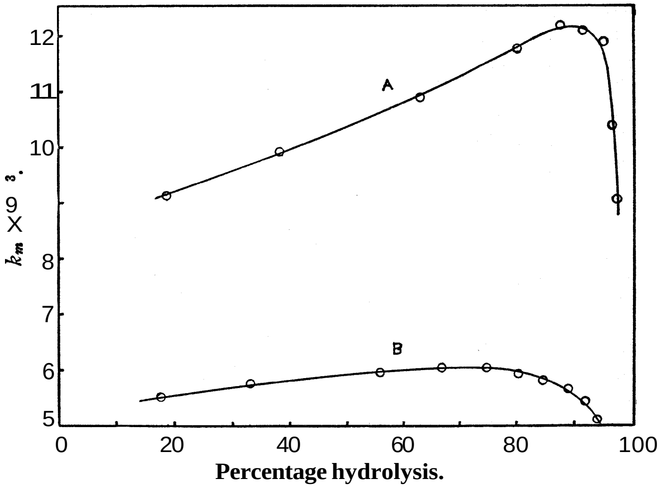

Fig. 5.—400 cc. 6% sucrose, 35°: Curve A, run 25. P_H 4.7, 1.0 cc. of invertase; Curve B, run 24, P_H 7.4, 4.0 cc. of invertase.

---

(11) Auden and Dawson, *Biochem. J.*, 25, 1909 (1931).

the maximum in the unimolecular constants for a given initial sucrose concentration comes at the same percentage hydrolysis, irrespective of the velocity of conversion, indicates that the enzyme is not destroyed at the temperatures used in this investigation. On the other hand, while it must be said that the experimental error toward the end of the reaction is larger than at the beginning, it is felt that a much larger error than was actually present would have to be assumed in order to change the general trend of the curves. The most striking part of the curves, however, is the definiteness with which the unimolecular constant decreases toward the end of the reaction. It is for this last part of the reaction that equation 4 was derived to fit Due to the fact that only a few points could ordinarily be obtained within this range of hydrolysis, only a few constants could be calculated.

240	.60	.00504	.00378				

However, the values in Tables II, III and IV show that equation 4 holds remarkably well.

Summary of Results.—In the preceding sections, it has been pointed out that the velocity of hydrolysis is constant for about the first 10% hydrolysis, but later decreases; that the unimolecular constant increases to a maximum and then decreases as the reaction progresses; that this maximum value changes in a regular manner with P_H, temperature, and initial concentration of sucrose, but not with the amount of enzyme present; and, finally, the various equations which were derived in the theoretical introduction have been applied to the data. As a final summary of the results, however, Table IV shows how those equations hold for a single hydrolysis. It will be noticed that equation 7 holds fairly well over most of the reaction, that equation 4 holds over the last part of the reaction, and that equation 5 holds well over the first half of the reaction. In other words, each equation holds over that part of the reaction which it is theoretically supposed to fit.

General Discussion

The Role of Water.—The foregoing results are in agreement with the recognized fact that the initial velocity of hydrolysis increases to a maximum as the initial sucrose concentration is increased to about 6%, and declines as the sucrose concentration is increased above that amount. Nelson and Schubert[12] showed that the velocity of hydrolysis for strong sucrose solutions decreased as the water concentration decreased, and stated "that the concentration of water is a factor in determining the magnitude of hydrolysis of sucrose by invertase," but they did not show how the water is a determining factor. While Henri[13] regarded the enzyme as containing

---

(13) Henri, *Z. physik. Chem.*, **51**, 27 (1905).

some of the water, it seems that water, as a controlling factor in determining the velocity of hydrolysis, has been rather generally neglected. Moreover, following the views of Michaelis and Menten,[4] it has become customary to explain the increase in initial velocity up to about 6% sucrose concentration as due to increasing amounts of sucrose combined with the enzyme. On the other hand, investigators seem to have forgotten the fact that the initial velocity during this range of sucrose concentration is zero order, and that the velocities can only be of that order when the enzyme is saturated with respect to sucrose, which, according to the views of Michaelis and Menten, is the case only at considerably higher sucrose concentrations.

From the chemical adsorption view, which requires that both the water and the sucrose must be adsorbed before the enzyme can influence the velocity of the combination, water occupies a special position. Except in solutions with high sucrose concentrations, water is always present in large excess. Consequently, the amount of water used up in a given reaction is negligible, and, hence, the amount of water adsorbed by the enzyme remains essentially constant. Therefore, for a given hydrolysis, water plays no important part in the manner in which the velocity changes as the hydrolysis proceeds. On the other hand, since the amount of water present does vary from one initial sucrose concentration to another, water does play an important part in determining the velocity with which the hydrolysis will go at different initial sucrose concentrations.

If it be assumed that water is adsorbed in preference to sucrose, the facts can be explained in this manner. Water molecules will then be adsorbed and will cover the surface of the invertase according to their concentration; and sucrose molecules will saturate, even at quite low sucrose concentrations, that part of the surface which is not covered by water. At low (less than 6%) initial sucrose concentrations, where the water concentration is high, more water is adsorbed than sucrose; but at high (greater than 6%) initial sucrose concentrations, where the water concentration is lower, more sucrose and less water are adsorbed. The maximum velocity would occur at an optimum ratio of adsorbed sucrose to adsorbed water, and the velocity should fall off from this value for both higher and lower initial sucrose concentrations. Furthermore, on the basis of such a mechanism, it is possible for the amount of adsorbed sucrose to reach a saturation value for practically any initial sucrose concentration, and, hence, give a constant rate at the beginning of each hydrolysis.

Inhibition.—The manner in which invert sugar inhibits the hydrolysis deserves special mention. It has been pointed out that the reaction proceeds as a zero order reaction for about the first 10% of hydrolysis. This indicates that the products of the reaction are not adsorbed by the invertase and do not inhibit during that time, for they could only inhibit the reaction by occupying some of the enzyme surface which would ordinarily be active. At least three factors contribute to this delay in the inhibition of the reaction: first, the mutarotated or β-forms of the invert sugar inhibit to a greater degree than the α-forms;[14] second, the slow rate of transformation of the a-form to the β-form produces at a given time a smaller quantity of the inhibiting substances than the equilibrium amount;[15] third, the inhibiting substances may not only be slowly adsorbed, but there may be an induction period before adsorption occurs.[16] All of these factors would be more noticeable at the beginning of the reaction, because there the velocity of the hydrolysis reaction is at its maximum, mutarotational velocities are slowest, and the products (in the presence of large quantities of sucrose) would have more difficulty in being adsorbed by the invertase.

On the other hand, it must not be forgotten that these factors should also be considered during the entire reaction in determining the correct concentration of products which are responsible for the inhibiting action at a given time. In view of the many factors controlling the amounts of products which are adsorbed by the enzyme, it is somewhat surprising that equations 4 and 5 hold as well as they do. However, over a short portion of the hydrolysis, and especially toward the end of the reaction where the rate factors are favorable, the amounts of inhibiting substances which are active are probably more or less proportional to the total quantity of products present. While equation 7 does not fit over the entire reaction, it does express the course of the reaction remarkably well. It is quite possible that the Langmuir isotherm does not fit over the entire range, and, hence, is the root of the difficulty; but it is more probable that most of the trouble is due to an unaccountable variation in the inhibiting action of the various products. Moreover, it is absolutely necessary to know what the concentrations are of those products which inhibit at any given time during the hydrolysis in order to develop for the reaction a theoretical equation that will fit from the beginning to the end of the reaction.

Summary

1. Assuming that sucrose and water are adsorbed by invertase and that the seat of the reaction is in this adsorbed phase, a theoretical treatment of the kinetics of the reaction has been given from that point of view.

2. It has been shown that the unimolecular constants increase at first as the reaction progresses, and then decrease toward the end of the reaction. The influence of the amount of enzyme, PH, initial sucrose concentration, and temperature on this maximum is shown.

3. An explanation of the role water plays in influencing the initial velocity of hydrolysis has been advanced.

The Debye-Hückel Ion Size Parameter in Terms of Individual Ionic Radii. The Activity Coefficient of Lead Chloride in Solutions of Cadmium Nitrate[1]

BY H. D. CROCKFORD AND HENRY C. THOMAS

In the past the ion size parameter of the Debye-Hiickel theory of solutions of strong electrolytes has been determined as a mean value for the ions of a given solution. If the parameter "*a*" could be calculated from the individual ionic radii and the result of this calculation verified experimentally, the physical meaning of the quantity "*a*" would take on added significance. It is the purpose of this paper to present this calculation and to give a preliminary test of its result.

Theoretical Calculation.—Consider a solution containing ions of kinds

$$1 \ldots i \ldots s$$

Let a_{ij} be the mean distance of closest approach for the ions of the i^{th} and j^{th} kinds, *i*. e., the mean collision distance between the centers of the ions considered as spheres. Now if f_{ij} is the time average, or frequency, of collisions between the ions of the i^{th} and j^{th} kinds, then

$$\text{"}a\text{"} = \Sigma f_{ij}a_{ij}/\Sigma f_{ij} \qquad (1)$$

is the mean distance of closest approach for all ions in the solution, the summations being taken over all combinations of values of i and j. On the average for a large number of random collisions between any two ions the distances from the points of contact to their centers may be considered as the radii of spheres surrounding the ions; so that

$$a_{ij} = a_i + a_j$$

The quantities a_i and a_j depend presumably only upon the nature of the individual ions.

The following calculation of the frequency of collisions between the ions is based on the fundamental assumption of the Debye-Hückel theory: the effects between the ions may be attributed wholly to the electrical charges on them. Consider an ion of the i^{th} kind in a solution of

$$n_1 \ldots n_i \ldots n_s$$

moles of ions with valences

$$z_1 \ldots z_i \ldots z_s$$

---

[1] The material for this paper was taken from a thesis submitted by Henry C. Thomas to the Faculty of the University of North Carolina in partial fulfilment of the requirements for the degree of Master of Science.

dissolved in a volume V of solution. The charge on an ion of the i^{th} kind is then $z_i\epsilon$, where ϵ is the charge on the electron. If dV is an elementary volume of solution at a distance r from an ion of the i^{th} kind, the time average of the number of ions of the j^{th} kind in dV is given by the Boltzmann relation

$$\frac{Nn_j}{V}\, e^{-z_j\epsilon\psi/kT}\, dV$$

N is Avogadro's number per mole, Nn_j/V being the number of ions of the j^{th} kind per cubic centimeter of solution; ψ, the electrical potential in dV; k, Boltzmann's constant; T, the absolute temperature; and e, the base of the natural logarithms. On changing to space polar coordinates and performing the indicated integration, there is obtained the number of ions of the j^{th} kind in a spherical shell of thickness dr surrounding and at a distance r from the i^{th} ion in question

$$\frac{Nn_j}{V}\, e^{-z_j\epsilon\psi/kT}\, r^2 dr \int_0^{\pi}\int_0^{2\pi} \sin\theta\, d\theta\, d\phi = 4\pi \frac{Nn_j}{V}\, e^{-z_j\epsilon\psi/kT}\, r^2 dr$$

In order to calculate the time average of collisions between the ion of the i^{th} kind and all the ions of the j^{th} kind, the above expression is integrated through a shell in contact with the i^{th} ion and of such thickness, $2a_j$, that all the ions of the j^{th} kind within the shell must be in contact with the i^{th} ion. Multiplying the resulting expression by the number of ions of the i^{th} kind per cubic centimeter, there is obtained the time average of all collisions per cubic centimeter between ions of the i^{th} and j^{th} kinds

$$f_{ij} = \frac{4\pi N^2}{V^2}\, n_i n_j \int_{a_i}^{a_i+2a_j} e^{-z_j\epsilon\psi/kT}\, r^2\, dr$$

When this expression is summed over all pairs of kinds of ions in solution, the result is the time average, or frequency, of all collisions per cubic centimeter

$$\sum f_{ij} = \frac{4\pi N^2}{V^2} \sum_{i=1}^{s} \sum_{j=1}^{s} n_i n_j \int_{a_i}^{a_i+2a_j} e^{-z_j\epsilon\psi/kT}\, r^2\, dr \qquad (2)$$

In order to obtain this expression in terms of the concentration of the dissolved compound we note that $n_i = \nu_i n$, where n is the number of moles of the compound in volume V of solution and ν_i the number of ions of the i^{th} kind to which one molecule of salt gives rise on ionization. The potential ψ at large distances from an ion is to be determined from the general solution of the Poisson–Boltzmann equation

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2 \frac{d\psi_i}{dr}\right) = -\frac{4\pi\epsilon}{D} \sum_{j=1}^{s} \frac{Nn_j z_j}{V}\, e^{-z_j\epsilon\psi_i/kT}$$

However, in calculating the frequency of collisions only the potential near the surface of the ion is considered. The potential in this neighborhood will be largely due to the charge on the ion itself. Therefore no large error will be introduced if the potential is considered as arising wholly from the charge on the ion

$$\psi = \frac{z_i\epsilon}{D}\frac{1}{r} \tag{3}$$

where D is here the dielectric constant of the solvent. On making these substitutions the expression for the frequency becomes

$$\sum f_{ij} = 4\pi N^2 \left(\frac{n}{V}\right)^2 \sum_{i=1}^{s} \sum_{j=1}^{s} \nu_i\nu_j \int_{a_i}^{a_i+2a_j} e^{-z_iz_j\epsilon^2/DkTr}\, r^2\mathrm{d}r \tag{4}$$

Substituting (3) for the potential receives justification when it is observed that if the integral in (2) should contain concentration terms other than as a factor, the "*a*" value, see (1), would depend on the concentration of the solution. This is contrary to experimental knowledge. Were the potential determined by a solution of the Poisson–Boltzmann equation, concentration terms would enter otherwise than as a factor.

The frequency of collisions between the ions of a single salt in solution is then, in the region of dilute solutions, directly proportional to the square of the concentration.

For a solution of two salts the mean distance of closest approach will be given by an expression of the form

$$\text{“}\bar{a}\text{”} = \frac{A_1 + A_2}{f_1 + f_2} \tag{5}$$

Here A_1/f_1 = "a_1" and A_2/f_2 = "a_2"; the subscripts refer to the values for the individual salts. Expression (5) is the mean of "a_1" and "a_2" in which the separate values are weighted according to the corresponding collision frequencies. This expression may be considered as a close approximation to the value of "$\bar{a}$" given by (1), where the summations are carried over all combinations of *i* and *j*. We have now

$$f_1 = k_1\left(\frac{n_1}{V}\right)^2 = k_1c_1^2 \text{ and } f_2 = k_2\left(\frac{n_2}{V}\right)^2 = k_2c_2^2$$

where k is the coefficient of the concentration term in (4) and c is the molarity of the dissolved salt. Expression (5) shows that the "$\bar{a}$" value of a solution of two salts should remain constant if the ratio of the concentrations of the salts is held constant no matter what the total concentration may be. This fact is at once apparent when (5) is written in the form

$$\text{“}\bar{a}\text{”} = \frac{K_1c_1^2 + K_2c_2^2}{k_1c_1^2 + k_2c_2^2} = \frac{K_1b + K_2}{k_1b + k_2}$$

where b = $(c_1/c_2)^2$ = const. These considerations hold true, of course, only for dilute solutions of completely dissociated electrolytes.

Now the proportionality constants k_1 and k_2 will not in general be the same for different salts. If, however, the salts are of the same valence type, the difference between these constants will be determined solely by the integral in (4). In the following discussion, due to lack of any definite knowledge of the ionic radii, we will assume $k_1 = k_2$; so that

$$f_1/f_2 = (c_1/c_2)^2 \tag{6}$$

A rough graphical integration of the function

$$r^2e^{-z_1z_2\epsilon^2/DkTr}$$

for a **1–2** salt in water at 25° shows that for values of r between 4 **Å.** and 10 **Å.** the difference between the integrals for similar types of salts should not be large. With expressions **(5)** and **(6)** it is a simple matter to calculate any one of "a_1," "a_2" or "a," given two of them.

As an experimental test of the above ideas the results of measurements on the cell

$$\text{Pb–Hg (2 phase)} \mid PbCl_2(m_1),\ Cd(NO_3)_2(m_2) \mid AgCl\text{–}Ag;\ m_1/m_2 = \text{const.}$$

have been applied. The "a" value of lead chloride has been calculated by La Mer, Gronwall and Greiff[2] from measurements by Carmody[3] on a similar cell containing only lead chloride. They find "a_1" = **1.75 Å.** The "a" value for cadmium nitrate has been calculated by the present authors from freezing point measurements of Jones,[4] these being apparently the only available measurements on cadmium nitrate in sufficiently dilute solution. Too much reliance cannot be placed on the results of these calculations, based as they are on data of doubtful precision. Table I gives the results of these calculations.

TABLE I

Molarity	Δt_f obs.	Δt_f "a" = 8.0 Å.	Δt_f "a" = 11.5 Å.	Δt_f "a" = 14.0 Å.
0.001000	0.0054	0.0054	0.0054	0.0054
.002980	.0159	.0157	.0158	.0159
.004920	.0261	.0257	.0260	.0261
.006900	.0362	.0358	.0362	.0364
.00876	.0457	.0453	.0458	.0461
.02000	.1035	(.1000)	(.1038)	(.1046)

As may be seen the value "a_2" = **11.5 Å.** gives the best agreement with the experimental data. The Debye first approximation for the osmotic deviation

$$\Theta = 0.764\sqrt{3c}\ \sigma(K\text{“}a\text{”})$$

was used in the calculation, the "a" value being sufficiently high to warrant the use of the simple equation.

Experimental Part

Purification of Materials.—Kahlbaum lead chloride was recrystallized three times from 0.006 N hydrochloric acid as recommended by Baxter and Grover.[5] **The product**

---

(5) Baxter and Grover, THIS JOURNAL, **37**, 1061 (1915).

was carefully dried and ground. Kahlbaum cadmium nitrate was recrystallized three times from water. Carefully purified mercury was twice distilled as recommended by Hulett.[6] Commercial tank nitrogen was purified by passing it through a solution of acidified potassium permanganate and further treated according to Cowperthwaite and La Mer.[7]

Analytical.—The stock solution of lead chloride was analyzed by the potentiometric titration of the chloride using a silver-silver chloride indicator electrode and a 0.1 *N* calomel half cell with an ammonium nitrate–agar gel bridge. The cadmium nitrate solution was analyzed by electrolytic precipitation from an alkaline cyanide bath.

Preparation of Electrodes.—The silver–silver chloride electrodes were prepared according to the method described by Carmody.[8] The lead amalgam was prepared by dissolving Kahlbaum stick lead, "for analysis" grade, sufficient to make a 6% amalgam, in the purified mercury. After solution had been effected in an atmosphere of nitrogen, the amalgam was drawn into a Pyrex storage bulb similar to that described by La Mer and Parks.[9]

Preparation of Solutions.—The solutions for measurement were made up by diluting the analyzed stock solutions of lead chloride and cadmium nitrate using flasks calibrated to deliver by the Bureau of Standards.

Electrical Apparatus and Cell Vessel.—The potentiometer, which had been calibrated by the Bureau of Standards, was the Type K instrument of Leeds and Northrup. A Leeds and Northrup No. 2500, Type R, galvanometer was used. The standard cell. also calibrated by the Bureau of Standards, was of the Weston unsaturated type. The electrical measuring apparatus was protected against electrical leakage by equipotential shielding. The cell vessel, constructed of Pyrex glass, contained two sets of electrodes. The e. m. f. of each of the four combinations was measured. A reservoir for the solution was attached so that check measurements could be obtained without disturbing the electrodes or opening the cell to the air. The nitrogen served to stir the solution and preserve an inert atmosphere within the cell. No trouble was experienced in obtaining e. m. f. readings constant to 0.02 mv. The cell was placed in a water thermostat at 25 ± 0.02°. The Beckmann thermometer was compared with a thermometer calibrated by the Bureau of Standards.

Results and Calculations

Table II gives a summary of the experimental data together with the activity coefficient of the lead chloride, γ_s, calculated from the equation

$$E_{(\text{mv.})} + 88.725\,(0.2007 + \log m) = E_{0(\text{mv.})} - 88.725 \log \gamma_s$$

this being the equation for a chemical cell without transference after the constants for a 1–2 salt at 25° have been introduced. The value E_0 =

TABLE II

	m $PbCl_2$	m $Cd(NO_3)_2$	E. m. f., volts	γ_s

(9) La Mer and Parks. *ibid.*, 53, 2040 (1931).

0.3432 volt calculated by La Mer, Gronwall and Greiff[2] from Carmody's[3] results was used in the calculations, The values given for the e. m. f. cannot be considered reliable to much better than 0.3 mv.

The values of γ_s here given are uniformly lower than those given by Carmody for lead chloride in solution alone.

The "$\bar{a}$" values for the four most dilute solutions have been calculated from the Debye first approximation for the activity coefficient

$$-\log \gamma_s = \frac{1.53636\,(-z_1z_2)K}{1 + \text{“}\bar{a}\text{”}K}$$

For solutions of a 1–2 salt in water at 25° $K = 0.5686\sqrt{m}$; m is here the total molality. For solutions of this dilution it is unnecessary to distinguish between molality and molarity. Since cadmium nitrate and lead chloride are of the same valence type, the only effect which the presence of cadmium nitrate has on the calculations is to increase the value of K. In this connection see La Mer, Gronwall and Greiff,[2] p. 2282

The results of these calculations are given in Table III.

TABLE III

No.	3	4	5	6

"$\bar{a}$," Å.	3.16	3.76	4.70	6.44

Discussion of Results

As is shown in Table III the "$\bar{a}$" values for mixed solutions of lead chloride and cadmium nitrate at constant ratio of concentration are not constant but increase with decreasing concentration. On the basis of our theoretical discussion this phenomenon would not be expected in such solutions of two strong electrolytes. In the case, however, of solutions containing cadmium and chloride ions this drift in the "$\bar{a}$" values may be accounted for very simply. It has long been recognized that cadmium chloride possesses many of the properties of a weak electrolyte. This salt may not be regarded as completely dissociated even at concentrations as low as 0.0005 m. The cadmium ion is presumably the component of cadmium nitrate which gives rise to its large, 11.5 Å., "a" value. If the cadmium ion is removed from the solution as undissociated cadmium chloride, it becomes in effect a part of the solvent and no longer exerts any influence on the mean distance of closest approach of the ions in the solution. As the dilution increases the cadmium chloride becomes more and more dissociated, and, due to the presence of more cadmium ion in solution, the "a" value increases. A consequence of this idea is that the solution should have a "normal" "$\bar{a}$" value at infinite dilution. When the "a" values given in Table III are plotted against the concentration, the values for the three most dilute solutions fall on a straight line. On extrapolating this line to zero concentration the limiting "$\bar{a}$" value is found to be 6.8 Å. Assuming the value of 6.8 Å. for the mean distance of closest approach of the mixed solutions, the value of 1.75 Å. for lead chloride and using expressions (5) and (6) the "a_2" for cadmium nitrate is calculated to be 11.3 Å. This calculated value is in excellent agreement with the value determined from the experimental work of Jones. It must be remembered that it depends upon the compensation effect ($k_1 = k_2$) in the calculation of the ratio of the frequencies of collision of the two salts and also upon a result obtained from an arbitrarily extrapolated curve. The first of these assumptions cannot be further tested with the data available. Similar and more extended experiments upon solutions of two completely dissociated electrolytes may settle this point.

According to the above result it may be stated that the physical meaning of the ion size parameter in the Debye–Hückel theory of solutions takes on added significance. The fact that this quantity may be used in a logical calculation of mean values is definite although indirect proof of its significance as a distance.

In conclusion we wish to acknowledge our indebtedness to the Rockefeller Foundation for financial aid which made possible the purchase of much of the equipment used in the experimental work.

Summary

A mathematical solution of the problem of the calculation of the mean distance of closest approach of the ions in dilute solutions of strong electrolytes is given. This quantity is obtained as a function of quantities depending upon the valence types of the dissolved compounds and the size of the individual ions.

The activity coefficients of lead chloride in solutions of cadmium nitrate have been determined at six concentrations. The ratio of the concentration of the lead chloride to that of the cadmium nitrate was held constant. The data obtained are used as a preliminary test of the above-mentioned theoretical calculation.

A Comparison of Organic Inhibitors in Chain Reactions

BY KIA-KHWE JEU AND HUBERT N. ALYEA

In the oxidation of sodium sulfite inhibited by alcohols, and of benzaldehyde inhibited by anthracene, Bäckström and co-workers[1] established that the inhibitory process is accompanied by an induced oxidation of the inhibitor. This paper extends the investigation to types of reactions where such an inhibition mechanism seems improbable; for example, a polymerization carried out in a hydrogen atmosphere to the exclusion of oxygen. In place of a detailed study of products formed by one inhibitor in one reaction we have investigated the relative inhibitory effects of numerous classes of substances on several types of reactions: (1) the photo-polymerization of vinyl acetate, (2) the autoxidation of sodium sulfite, (3) the photolysis of hydrogen peroxide.

Our choice of inhibitors was limited by the necessity that they should represent as many different types of compounds as possible, were soluble in our reaction media, water or ethyl acetate, and did not absorb light in the spectral region used, 3000-4000 Å. The latter precautions eliminated any inhibition due to screening effect.[2]

Theoretical

All three reactions are chain reactions and have unimolecular velocity constants. The effect of various organic substances could, therefore, be expressed as relative inhibitory powers, k, in a velocity expression

$$\frac{dx}{dt} = k_1 (1 - x)\left[1 + \frac{k_3}{k_2 + kC}\right] \tag{1}$$

where dx is the fraction reacting in the interval dt and k_1 is the usual unimolecular constant. [1] is the primary step and $k_3/(k_2 + kC)$ is the probable number of links in a chain following the primary step. This probability is governed by k_3, the probability of continuing the chain; and $(k_2 + kC)$, the probability of breaking the chain by some constant factor, k_2, such as walls or impurities, or by the added inhibitor of concentration C.

With chains of any appreciable length the primary step in the reaction becomes negligible, and equation (1) reduces to

$$\frac{dx}{dt} = \frac{(1 - x)K}{k_2 + kC} \tag{2}$$

Integrating this we obtain

$$1/t \ln \frac{1}{1 - x} = \frac{K}{k_2 + kC} \tag{3}$$

---

This equation will apply to photochemical as well as thermal reactions, provided that the reactant absorbs only a small fraction of the incident light, so that the number of chains started is proportional to $(1 - x)$. This condition is fulfilled in both the polymerization of vinyl acetate and the decomposition of hydrogen peroxide, so that equation (3) can be applied to both. The 5% vinyl acetate solutions we employed absorbed only 2% of the 3130 Å. light.[3] The 0.6 M hydrogen peroxide solutions absorbed as much as 50% of the 3132 Å. line[4] and a much smaller percentage of the 3340 and 3663 Å. lines, so that only an approximate agreement with equation (2) may be anticipated.

Experimental

Photopolymerization.—The reaction vessels and mercury lamp were immersed in a de Khotinsky thermostat at 75 ± 0.1°. A Cooper–Hewitt vertical mercury lamp was held in place inside a 2.5 X 25 cm. quartz tubing by an asbestos belt and calked with red lead-linseed oil. A small portion of the mercury reservoir projected from the bottom of the tubing, and was in direct contact with the water in the bath; the amount projecting was so adjusted that the lamp burned at 180 watts. The quartz tube was cemented in a brass collar in the center of a brass rack and tripod. On the periphery of the rack, and equidistant from the mercury lamp, eight holes were bored to accommodate eight Pyrex reaction vessels. Each vessel consisted of two parts: an outer tube 19 cm. long, the lower part 9 X 2 cm., the upper part 10 X 1.5 cm.; and an inner tube of 6 mm. o. d. tubing 37 cm. long with a stopcock 10 cm. from the upper end, below which was an enlargement ground to fit into the outer tube. The lower end was tapered and reached within 0.5 cm. of the bottom of the outer tube, whose contents were thereby well mixed and the gas space thoroughly flushed with hydrogen. The 16-cc. samples used in a run were completely exposed to the rays from the mercury lamp.

Pure vinyl acetate was supplied by the Union Carbide and Carbon Company and c. P. ethyl acetate by Merck and Company. They were simultaneously distilled in a hydrogen atmosphere in separate flasks on a water-bath at 80°. From the moment the distillation was begun to the time when all solutions were mixed and the polymerization measurements commenced, all operations were carried out in an atmosphere of tank hydrogen, to the complete exclusion of air.

8.45 cc. of the middle portion of the vinyl acetate distillate was diluted with 150 cc. of ethyl acetate; 15 cc. of this was mixed in a reaction vessel, with 1 cc. of inhibitor solution. Eight reaction tubes were filled in the same way and placed in the bath at the same time. Two always served as blanks aad contained 1 cc. of ethyl acetate instead of 1 cc. of inhibitor solution. The ground joints were lubricated with completely polymerized vinyl acetate dissolved in ethyl acetate

Merck c. P. or other products of equal quality were used without further purification in preparing the inhibitor solutions in 25.00-cc. lots by dissolving 0.02148 mole of inhibitor in ethyl acetate. This gave a concentration in the reaction vessel of one inhibitor to ten of vinyl acetate molecules. More dilute inhibitor concentrations were prepared by dilution of the 25-cc. lot. The initial vinyl acetate concentration was always 5% (0.536 molar).

At convenient time intervals during a polymerization run two 2-cc. samples were removed and their iodine values determined: 10 cc. of carbon tetrachloride, 2 cc. of un-

(4) Kornfeld, Z. Phot., 21, 66 (1922).

known, and 25 cc. of Wijs solution were allowed to stand in a glass-stoppered 500-cc. bottle for thirty minutes in the dark. Then 10 cc. of 10% potassium iodide solution and 200 cc. of water were added, and the iodide liberated by the remaining Wijs solution titrated at once with $N/10$ thiosulfate solution, starch emulsion being added toward the end.[5]

Wijs solution was prepared by bubbling chlorine gas through 13 g. of Merck resublimed iodine dissolved in one liter of glacial acetic acid until the halogen content was doubled.[6] The acetic acid should not contain reducing substances nor over 0.5% of water, since both affect the keeping quality of Wijs solution.

Autoxibation.—The apparatus and procedure for the thermal oxidation of sodium sulfite was identical with that used by Alyea and Bäckström,[1] except that ordinary distilled water and Merck C. P. anhydrous sodium sulfite were used without further purification. Decrease in sulfite concentration was followed by titration with 0.5 N sulfuric acid to PH 4.3, using brom cresol green as indicator. Since the titration consists in changing SO_3^{--} to HSO_3^-, 5 cc. of 0.6 M sulfite requires 6 cc. of 0.5 N sulfuric acid. Standard aqueous inhibitor solutions were prepared containing 0.012 mole of inhibitor in 50 cc. of solution; 5 cc. of this added to 15 cc. of 0.8 M sulfite buffered with sulfuric acid gave a concentration of one inhibitor to ten sodium sulfite molecules. The initial sulfite concentration was always 0.6 molar.

Photolysis.—The apparatus was the same as in the photopolymerization except that the inner tube was replaced by a loosely fitting stopper. A stock solution of 50 cc. of Merck Superoxol diluted with 450 cc. of distilled water was used to prepare 0.8 molar hydrogen peroxide. For each run 15 cc. of the latter was mixed with 5 cc. of the aqueous inhibitor solutions described above. Two 1-cc. samples were removed from time to time during the run, and the peroxide content determined by titration with $N/10$ potassium permanganate in the usual way. The experiments were made at 75°, the initial peroxide concentration being 0.6 molar.

Results

Wijs Method for Following Polymerizations.—Not more than half of the Wijs solution should be consumed by the vinyl acetate, so that not more than 2 cc. of a 5% solution of vinyl acetate should be used in the directions above. Thus, with 5% solutions we obtained upon titrating 2-cc. samples an experimental iodine number of 294.2; with 4-cc. samples, 266.9. The theoretical iodine number is 294.9, showing that there was incomplete addition with the 4-cc. samples. Ethyl acetate does not react with Wijs solution; nor does the polymerized product, since sections cut from some solid photopolymerized vinyl acetate gave iodine values as low as 9.5 and 6.3, corresponding to 96 and 98% polymerized. In a few cases a blank titration and correction had to be applied for a small amount of Wijs solution reacting with the inhibitor. Wijs solution is rapid in action and keeps for months. It surpasses other methods which have been used in following the polymerization, especially since it is applicable to very dilute solutions. This, aside from obviating experimental difficulties of working with very viscous solutions, evades the danger of association in solutions

which according to Staudinger and Heuer[7] occurs in these solutions whenever the concentration exceeds a few per cent.

Confirmation of the Velocity Equation.—In all three reactions x is the fraction which has reacted after t hours. C is the ratio of the number of inhibitor to number of reactant molecules. Equation (3) may be written

$$\frac{k_2}{t}\ln\frac{1}{1-x} + \frac{kC}{t}\ln\frac{1}{1-x} = K \tag{4}$$

For the photo-polymerization the wattage of the mercury lamp although constant throughout a single run varied between 170 and 200 watts from day to day. This necessitated a correction w the value of which was determined empirically by dividing the value of $x/2-x$ at the wattage used during the experiment by the value of $x/2-x$ at 180 watts, the latter wattage being taken as standard. This introduced into equation (4), in which the expanded form $2x/2-x$ is used in place of $\ln 1/1-x$, gives

$$\frac{Kwt}{(kwt/2)+k_2+kC} \tag{5}$$

That this equation is satisfied over a large range of concentrations is shown for pyrogallol, hydroquinone and benzylamine in Tables I, II and III and in Fig. 1.

For the oxidation of sodium sulfite, if the reaction is followed over small changes in x, the value of $1 - x$ in equation (2) remains essentially constant, and the equation reduces to that already shown by Backstrom[8] to be approximated in inhibited sulfite oxidation.

For inhibited photolysis, a thermal run was made in each case and deducted from the observed light rate to give the true photochemical rate. The uninhibited thermal rate was only 7% of the photochemical one. At a concentration of 1/500 all of the substances inhibited the normal thermal reaction with the exception of ethylamine. The latter accelerated[2] roughly in proportion to its concentration: 14-fold at 1/100, 4-fold at 1/500 and 1.2-fold at 1/2500. However, at no time did the thermal rate exceed the photochemical one, and with most inhibitors it was around 10% of the photochemical rate. At a concentration of one-tenth the thermolysis was accelerated 5-fold by pyrogallol, 4-fold by resorcinol, and 2.5-fold by hydroquinone, possibly due to reaction with the peroxide; so that this concentration was not used in evaluating their inhibitor powers. That a unimolecular equation is obeyed in the

Evaluating the Relative Inhibitor Power k.—It is only possible to give k, k_2 and K in equation (4) numerical values by assigning one of them a definite value for some standard inhibitor. Experimentally, the results with powerful inhibitors were found to be most reproducible; of which pyrogallol was chosen as the standard, and assigned a k-value of 3200 for all three reactions. This number was chosen because ethyl alcohol, one of the weakest inhibitors known, was found thereby to assume a value of approximately unity. All substances, therefore, excepting those whose inhibitory powers were immeasurably small, have a value of k greater than unity.

For the *polymerization* of vinyl acetate, when $kC/t \ln 1/1 - x$ is plotted against $1/t \ln 1/1 - x$ for pyrogallol, all of the values fall along the same line, as shown in curve 1, Fig. 2. This conforms with equation (4) which indicates that when C approaches infinity $C/t \ln 1/1 - x = K$, and that when C is zero $k_2 = K/(1/t \ln 1/1 - x)$. Reading these values from the intercepts at the axes we obtain

$$K = 0.22 \text{ and } k_2 = 0.22/0.170 = 1.30$$

This method is extended to the other inhibitors by graphing $C/t \ln 1/1 - x$ against $1/t \ln 1/1 - x$ and then multiplying the ordinate values by some constant, k, which brings the intercept at the ordinate up to 0.22. Examples are shown in Curve 1, Fig. 2, for hydroquinone and benzylamine.

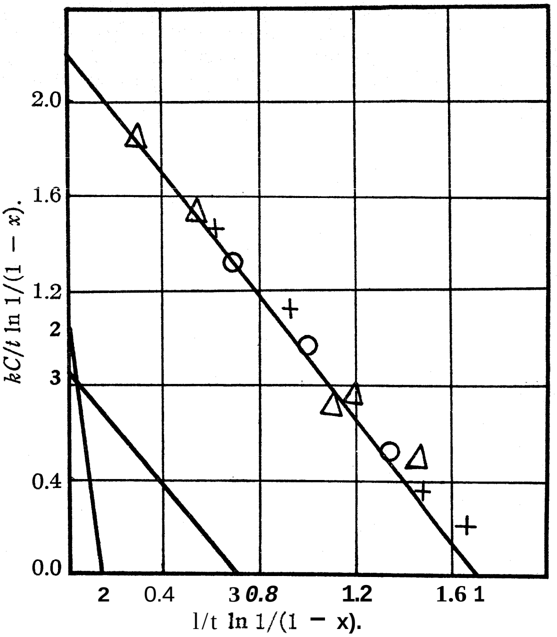

Fig. 2.—General curves for all inhibitors: Curve 1, photo-polymerization of vinyl acetate, 5% solution, in which the scale is increased ten-fold, the observed intercepts being 0.17 and 0.22; △ pyrogallol, ○ hydroquinone, + benzylamine; Curve 2, thermal autoxidation of sodium sulfite, 0.6 molar; Curve 3, photolysis of hydrogen peroxide, 0.6 molar.

The relative inhibitor powers so determined are given in Table VI and have been obtained from at least ten runs on each inhibitor. The intercept at the abscissa, which corresponds to the uninhibited rate, was strictly reproducible.

For the oxidation of sodium sulfite corrections must be applied. Unless there is extreme purification of the sulfite long induction periods are obtained. This difficulty is obviated by referring each run to exactly the same amount oxidized, a drop in sulfite concentration from 0.60 to 0.46 molar being taken as the standard. When this is done all experimental points for any given inhibitor lie along the same line when $C/t \ln 1/1 - x$ is plotted against $1/t \ln 1/1 - x$. The intercepts at the axes for these graphs are given in Table VII. It will be noticed that the intercept at the abscissa is not strictly reproducible, due to varying impurities in the sulfite. This was corrected for by assigning a standard value, 0.15, at the abscissa

TABLE VI

RELATIVE POWERS OF INHIBITORS IN VINYL ACETATE PHOTOPOLYMERIZATION

Inhibitor	Inhibitor constant k	Inhibitor	Inhibitor constant k
Benzene	2.3	Methyl oxalate	1.2
Ethyl alcohol	1.2	Ethylamine	45

Ethylamine	500–2500	.830	.000488	.000410	20000

[a] The corrected intercept at the abscissa is 0.705 for all inhibitors. [b] This number taken as standard.

Some runs were also made on sodium sulfite solutions accelerated by 5×10^{-6} molar copper sulfate. The inhibitory powers for these solutions as given in Table VIII agree with the values in unaccelerated solutions.

For the *photolysis* of hydrogen peroxide there was no induction period, but a blank rate with a value of $l/t \ln 1/(1 - x) = 0.705$ was assigned (see Table IX, Curve 3, Fig. 2).

Photosensitization of Polymerization.—Taylor and Vernon[3] found that the quantum yield for vinyl acetate polymerization is unity at 2300 Å. and 2536 Å. but 1000 between 30004000 Å. The low value might be due to depolymerization occurring simultaneously and thereby masking the true polymerization rate; or to the light being absorbed by a photochemically inactive portion of the molecule, an "intra-molecular screening effect," analogous to the effective decrease in quantum yield with wave length in the decomposition of acetaldehyde.[9] A search was therefore made for photosensitizers to higher wave lengths at which these retarding effects might be nil. No attempt was made to weigh accurately the added sensitizer, our only intent being to discover one which gave a many-fold increase in rate. Semi-quantitative measurements in which the ratio of proposed sensitizer to reactant molecules ranged from 1:1 to 1:10 for liquids, and 1:20 to 1:10,000 for solids, the latter because of extremely low solubilities of some solids, showed the following. The reaction was accelerated from five to twenty per cent. by acetone, sodium benzoate, benzoyl peroxide, chloral hydrate, phosphoric acid, fuchsine, quinine sulfate, malachite green, propionic acid, anisole, chrysaniline, phthalic acid, and alizarin-indigo blue. Without effect, were eosin, phosphine 3R and thymol. The following were weak inhibitors, which reduced the normal rate to about half: bromindigo 2B, barbituric acid, phosphine, methyl oxalate, aniline violet, ethyl alcohol, guaiacol, erythrosine B, thiophene, benzene, acetamide, benzamide *p*-rosaniline, m-cresol, benzoic acid, benzophenone, indole, alizarin red S, caffeine, pyridine, indigo bengal, phenol, cyanin, benzyl alcohol, resorcinol, rosaniline, ethylamine, neo-indol, allyl alcohol, benzil, benzylamine, acetoxime and dinitronaphthol. The following were powerful inhibitors which reduced the rate to three per cent. or less of the normal rate: picric acid, quinoline, o-nitrotoluene, dimethylaniline, aniline, furfural, diethylamine, azobenzene, rhodamine B, o-nitrophenol, salicylic acid, a-nitronaphthalene, rhodinol, nitrobenzene, allyl isothiocyanate, pyrogallol, hydroquinone and pyrocatechol.

Discussion of Results

A summary of these results and other data in Table X at once emphasizes that the relative inhibitor powers are strikingly parallel in the oxidation and polymerization reactions, and that inhibitor power in the photoly-

---

[9] Kirkbride and Norrish, *Trans. Faraday Soc.*, *27*, *404* (1931).

sis, on the other hand, has nothing in common with them. Of all the inhibitors, hydroquinone alone absorbed above 3000 Å. and might well, therefore, sensitize as well as inhibit the photopolymerization; whereas such sensitization is precluded in the thermal sulfite oxidation. Therefore, k is larger in the latter. No explanation is offered for the exceptions pyridine and acetoxime, and the experimental discrepancies between Anderson and Taylor's and our values for benzoic acid and ethyl alcohol. Their value of about 20,000 was a limit of inhibitory power imposed by their experimental accuracy, and agrees well with our values when it is recalled that the concentration of their hydrogen peroxide, and, hence, the value k varied two-fold.

Let us return to the parallelism of inhibitory powers for the oxidation and polymerization. Assuming the function of the inhibitor is to receive and dissipate chain energy,[1] the relative inhibitor powers may be identical with the relative efficiencies of these twenty-odd substances in receiving excess enerpy from a "hot chain molecule." But collisions of the second kind are highly specific processes, and even though the excess energy of a hot polymerized and a hot oxidized molecule be identical, we should hardly anticipate identical collision efficiency, identical inhibitory powers. Another mechanism is possible: if the polymerization involves an initial peroxide step it may be inhibited in the same way as the peroxide stages in

TABLE X

RELATIVE POWERS OF INHIBITORS—SUMMARY

The values in columns 2, 3, 4, 7 are from this paper. Columns 5 and 6 were calculated from data in Raymond, *J. chim. phys.*, 28, 316 (1931), and Anderson and Taylor, ref. 2.

			Oxidation		Photolysis	
Inhibitor	Polymerization, vinyl acetate	Na_2SO_3, no copper	Na_2SO_3 copper accelerated	Benzaldehyde photo	H_2O_2 Anderson and Taylor	H_2O_2 Jeu and Alyea

[a] This number taken as standard.

the sulfite oxidation. Such a mechanism might involve a competition for AO_2 by activated reactant A' molecules

$$A' + AO_2 \longrightarrow O_2 + A_2$$

subsequent rapid polymerization giving rise to A_n, or by inhibitor molecules, B

$$B + AO_2 \longrightarrow BO_2 + A$$

whereby the formation of the polymer is prevented. This of course might give identical inhibitory powers corresponding with and proportional to the oxidizability of the inhibitors by peroxides. However, the only evidence to support this view is that benzoyl peroxide accelerates the polymerization.[10] For such a mechanism an extremely small amount of oxygen may be necessary and the large excess of oxygen used by Taylor and Vernon[3] might well lead to the inhibition which they report.

k_2, a Measure of Chain Length.—Pyrogallol, our most powerful inhibitor, was assigned a standard inhibitory power of 3200. Assume that a collision of a chain molecule with pyrogallol is as efficient in breaking the chain as a collision with a reactant molecule is in continuing the chain, and accordingly assign it an absolute inhibitory power of $k_a = 1 = k/3200$. Now when pyrogallol has reduced the uninhibited rate to half, kC will equal k_2. When k_a is used in place of k, $1/C$ will be half the chain length: thus to cut a one-thousand link chain at the five hundredth link requires a concentration of 1/500 of pyrogallol to reactant molecules. That is

$$\text{chain length} = 2/(k_aC) = 6400/kC = 6400/k_2$$

If an inhibitor more efficient than pyrogallol is found, it would increase the chain length by the factor (k for new inhibitor/3200), so that the assumption that pyrogallol is 100% efficient in breaking chains gives the value of a *minimum chain length.* This calculation has been carried out in Table XI for several measurements where the value k_2 is known.

TABLE XI

CALCULATION OF CHAIN LENGTH FROM k_2

Reaction	k_2	Chain lengths calculated (= 6400/k_2)	Chain lengths probable
Polymerization of vinyl acetate 5% soln.	1.30	5000	2500
Autoxidation of sodium sulfate			
0.6 *M* Jeu and Alyea	7.04	900	1000–10000
Alyea and Bäckström	0.068	100000	100000
Backstrom	0.0059	1000000	100000
Photolysis of hydrogen peroxide 0.6 M	11.8	540 (2000)	1000

The values 1.30, 7.04, 11.8 are from this paper. Alyea and Backstrom's value[1] of $k_2 = 0.0012$, where k for benzyl alcohol was 1 and the concentration was expressed in moles of inhibitor per liter of 0.6 molar sulfite solu-

---

(10) See Conant and Peterson, THIS JOURNAL, 54, 628 (1932), where a peroxide step is postulated for the polymerization of isoprene and for *n*-butyraldehyde at high pressures,

tion, gives in our units 0.0012 X 34 X 1.0/0.6 = 0.068. Bäckström's[8] value of $k_2 = 0.00906$, where k for benzyl alcohol was 60 and concentration was expressed in moles per liter of 0.6 molar sulfite solution, gives in our units 0.00622 X 34/60 X 1/0.6 = 0.0059. The value 2500 in the last column is a semi-quantitative quantum yield which we obtained by comparing the polymerization rate and light absorption of a 100% vinyl acetate solution for which Taylor and Vernon[5] obtained a quantum yield 1000, with the values for a 5% solution. The sulfite we used was not purified and exhibited long induction periods, and undoubtedly the chains were ten to a hundred-fold shorter than in Alyea and Backstrom's sulfite, for which they found chain lengths of 100,000, by induced oxidation of alcohols. Chains of 500 for hydrogen peroxide have been experimentally measured by Allmand and Style[11] and they postulated that they are considerably longer than this. A value 540 is obtained with 3200 for pyrogallol, but using a k of 12,000, which the more powerful amines and phenols possess, gives a minimum chain length of 2000 at 75°. The agreement is all that could be desired except in the case of Backstrom's sulfite measurements, in which different samples of sulfite used in the inhibited reaction and in the photochemical reaction, or even different reaction vessels, are sufficient to cause a several-fold change in reaction rate.

Summary

1. Photopolymerization of vinyl acetate may be followed by determining iodine numbers with Wijs solution.

2. A general equation $\frac{1}{t}\ln\frac{1}{1-x} = \frac{K}{k_2 + kC}$ represents the behavior for chain reactions of the first order in the presence of inhibitors. x is the fraction reacting during time t, K is composite of the number of chains initiated at t = 0 and the probability of continuing the chains; while $k_2 + kC$ is the probability of breaking the chains by a constant factor k_2 or by an inhibitor of concentration C and inhibitor power k.

3. The equation represents the photopolymerization of vinyl acetate, the thermal autoxidation of sodium sulfite and the photolysis of hydrogen peroxide.

4. Among sixteen representative inhibitors which include alcohols, esters, acids, amines, oximes, phenols, aldehydes, and alkaloids, the relative inhibitor power for a given substance is approximately identical in the polymerization of vinyl acetate and oxidation of sodium sulfite. In the photolysis of hydrogen peroxide, however, the values of k have no obvious relation to those in the other two reactions.

5. A maximum of twenty per cent. photosensitization to visible light was found for the polymerization among seventy organic substances tried.

The Photochemical Reaction between Quinine and Dichromic Acid. II. Kinetics of the Reaction

BY GEORGE S. FORBES, LAWRENCE J. HEIDT AND F. PARKHURST BRACKETT, JR.

This paper suggests a kinetic picture consistent with new data and with data already published.[1] The experimental methods have been described[1] except those followed (by the last-named author) at 208, and 254 mμ.

The only primary act (except possibly at 208 mμ) contributing to reduction of dichromic acid disclosed by our results is an activation of the quinine molecule or ion, Q to form Q*. In the secondary act a part of these activated molecules reduces dichromic acid. This picture could be amplified as follows. At the instant of excitation Q may be adjacent to molecules (or ions) of the other reactants, all within possibly effective ranges of distances and of orientations. That is, $n_1[Q] + n_2[H_2Cr_2O_7] + n_3[H^+] \rightleftharpoons$ potentially effective kinetic "clusters," to borrow Weigert's general designation.[2] Such clusters are conditioned by kinetic and electrostatic effects, and are in no sense stable complexes like uranyl oxalate. Photochemical reactivity, while varying with configuration, is practically independent of all activation energies except that of Q*. In a steady state and in a thin layer,

$$K_1\phi_q = [Q^*]_{\text{cluster}}/[Q^*]_{\text{total}} = K_2[Q^*]^{n_1}[H_2Cr_2O_7]^{n_2}[H^+]^{n_3}/[Q^*]$$

or

$$\log \phi_q + \log K_1/K_2 = (n_1 - 1)\log [Q^*] + n_2 \log [H_2Cr_2O_7] + n_3 \log [H^+]$$

where ϕ_q is net quantum yield referred to light absorbed by quinine and $[Q^*] = K'[Q]$ where K' depends, among other factors, upon the reaction cell used. K_1 is itself complex, involving factors such as $K_3e^{-\theta d/\theta_0 d_0}$ where θ_0 and d_0 indicate orientation and distance optimal for the secondary act.

If $[H_2Cr_2O_7]$ and $[H^+]$ are large compared with [Q], or are held constant, $\log \phi_q = (n_1 - 1) \log [Q] + \text{const.}$ For correct evaluation of n_1, deviations from the reciprocity law had to be avoided by stopping down the front lens of the monochromator in each experiment to such an extent that the quinine in the first centimeter of the reaction mixture absorbed just as many quanta per minute, E_q, as in any other experiment in the series. As a consequence, $[Q^*]_{av.}$ was always the same in the layer thus

defined, also in other layers uniformly defined. Table I gives the data for one typical series of experiments. E_0 equals quanta per minute incident upon the cell.

TABLE I

λ, 366 mμ. **Temperature,** 5°

$[K_2Cr_2O_7]$	$[H_2SO_4]$	[Q]	E_0	E_q	ϕ_q
0 00016	0.8	0.000250	$6\ 4 \times 10^{16}$	4.9×10^{16}	0.057
00016	.8	.000025	19.2×10^{16}	4.5×10^{16}	.059
.00016	.8	.000010	47.0×10^{16}	4.8×10^{16}	.057

Table I proves that ϕ_q when properly determined is independent of [Q]. Therefore $(n_1-1) = 0$ and $n_1 = 1$; that is, only one molecule of Q is involved in the secondary act. Similar data plotted at 405 and **313** mμ previously given,' and in Fig. 1 obtained at 366, 280, 254 and 208 mμ, lead to identical conclusions.

the crystal quartz monochromator working at f2 and its operation will be somewhat amplified elsewhere. Quantum yields and absorption coefficients were measured in a rectangular quartz cell (all seams fused) 85 mm. high, 35 mm. wide and 5.7 mm. thick, placed between the exit slit and the thermopile by which the highly divergent beam was integrated. The method, precautions and corrections followed closely previous investigations in this Laboratory.[4] At these wave lengths all experimental difficulties were increased, also the radiometric corrections, made as previously described. ϕ_q is given after correction for direct photolysis of dichromic acid absorbing E_c quanta per minute. The need for such a correction appears in Table II.

TABLE II

Temperature, 25". E_c, 5 X 10^{16}

λ	$[K_2Cr_2O_7]$	$[H_2SO_4]$	ϕ
208 mμ	0.00016	0.8	0.012
208	,00032	.8	.013
254	.00016	.8	.004
254	.00036	.8	.005
280	.003	.8	.000

In Fig. 1 at 254 mμ the curve appears nearly horizontal, as was the case at 280,313,366 and 405 mμ. At 208 mμ, however, the points B', A' and B", as [Q] approaches zero, suggest that the curve may be turning upward as dichromic acid absorbs a greater share of the light. Points A and A', which average a preliminary set of experiments, should be given less weight than the others. Points B and B', on the other hand, each average three very concordant final experiments. It, therefore, appears possible that at 208 mμ we have two activated reactants, each one reacting to a measurable extent with the other in its normal state. Conclusive evidence upon this admittedly important point would require a further refinement of experimentation, hard indeed to attain. Clusters in which both reactants are simultaneously activated[6] might well be exceedingly reactive, but an event of such a type ought to be so infrequent as to contribute negligibly to the total reaction.

The data graphed in curve 1, Fig. 1, at 366 mμ were collected to test Morton's prediction[6] that the efficiency of dichromic acid as an oxidant of quinine should increase, with increase of $[H_2SO_4]$ from zero to 0.37, to a maximum incapable of still further increase through light absorption. In the series, E_q was held constant as described above and no sulfuric acid was added, the quinine bisulfate and dichromic acid being so dilute no precipitate appeared. As in the other curves in the figure, ϕ_q is unchanged even at minimal values of [Q] where the greater part of the

light available is absorbed by dichromic acid. As ϕ_q does not even now increase when [Q] becomes very small, it is evident that at minimal acidity light has not measurably increased the reactivity of dichromic acid toward non-illuminated quinine.

Table III presents typical data for evaluation of n_2.

TABLE III

λ, 280 mμ. *Temperature, 25°*

[Q]	$[H_2SO_4]$	$[K_2Cr_2O_7]$	E_0	E_q	ϕ_q
0.001	0.8	0.00016	2.17×10^{16}	1.26×10^{16}	0.094
.001	.8	.00008	1.71×10^{16}	1.30×10^{16}	.069
.001	.8	.00004	1.50×10^{16}	1.30×10^{16}	.048

Similar series completed at 405, 366 and 280 mμ are shown in Fig. 2, where log ϕ_q is plotted against log $[K_2Cr_2O_7]$ at various wave lengths and temperatures. The black dots are based upon Table VIII of Luther and

Forbes,[7] log of the relative reaction rates in polychromatic light, 405 and 366 mμ, being plotted as ordinates in place of log ϕ_q. It is noteworthy that straight lines result in all cases, log $\phi_q = n_2 \log[H_2Cr_2O_7] + \text{const.}$; n_2 is uniformly **0.43 ± 0.05** irrespective of wave length or temperature, which assigns only half the molecule $H_2Cr_2O_7$ to an effective cluster. Possibly chromic acid reacts more readily with Q* than dichromic acid. Since $[H_2CrO_4] = k[H_2Cr_2O_7]^{1/2}$, a plot of log ϕ_q against log $[H_2Cr_2O_7]^{1/2}$ would have a slope equal to unity within the experimental error and would represent the behavior of clusters containing one molecule of chromic acid. The residue of the chromate molecule, bereft of one oxygen atom, is unstable and would be expected to react again, doubling the immediate quantum yield.

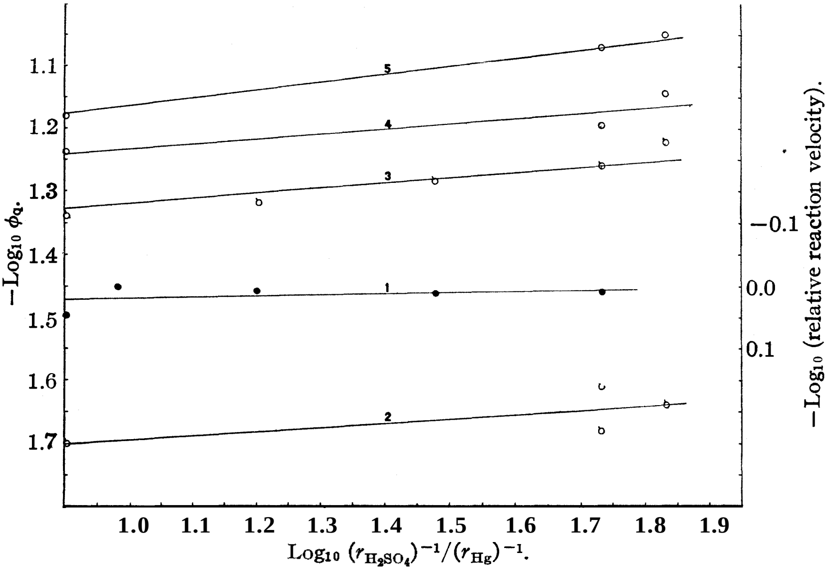

Fig. 3.—○, Temp. 23°; -○, Temp. 5°; ●, Data of F. W. & D.. Ref. 5; $[K_2Cr_2O_7]$, 0.00016; E_q, 5 × 10^{16}.

The evaluation of n_3, for hydrogen ion, was hampered by lack of data on activity coefficients in rather concentrated sulfuric acid. Specific conductivity, r^{-1}, is perhaps the next best measure of the activity of hydrogen ion in clusters. In Fig. 3 log ϕ_q is plotted against $\log[(r_{H_2SO_4})^{-1}/$-

---

[7] Luther and Forbes, This Journal, 31, 770 (1909).

$(r_{Hg})^{-1}$], taken from Kohlrausch's tables.[8] The data of Forbes, Woodhouse and Dean[5] appear as black dots, log of the relative reaction rates in polychromatic light being plotted as ordinates in place of ϕ_q. Straight lines again result, but the average slopes assign to n_3 the value 0.07 and to sulfuric acid a subordinate role in the reaction. Possibly the hydrogen ion already present in $H_2Cr_2O_7$ or H_2CrO_4 usually suffices for the secondary act involving Q*, the additional hydrogen ion in the cluster increasing only slightly the probability of the same.

The data on the reciprocity law, before plotting,[9] were subjected to a correction not discussed at that time, the need for which appears in Table IV.

TABLE IV

λ, 366 mμ. Temperature, 22°

	[Q]	[$K_2Cr_2O_7$]	[H_2SO_4]	$E_q \times 10^{-16}$	Minutes irradiated	Total min. before titration	ϕ_q, uncorrected
1	0.00025	0.00016	0.8	8	60	75	0.062
2	.00025	.00016	.8	8	60	1260	.077
3	.00025	.00016	8	8	120	135	.065

As solution (2) was exposed for the same time as (1), the difference in ϕ_q is attributable to a *dark* reaction between the photochemical oxidation products and dichromic acid during twenty-one hours as the values of ϕ_q in Table IV were corrected for the dark reaction not involving photochemical oxidation products of quinine. Experiments involving exposure to weak light over long periods are misleading until corrected for this dark reaction. Solution (3) was exposed twice as long as (1) and then titrated promptly. It is clear that the oxidation products formed during the first hour contributed little if anything to the photolysis during the second hour; that is, their quantum yield cannot greatly exceed ϕ_q. A fourth solution was photolyzed (λ, 366 mμ) until about half the quinine was oxidized. Absorption of 3×10^{20} quanta (λ, 436 mμ) by the dichromic acid in the solution followed without any effect, proving that the photochemical oxidation products, like quinine, are not photochemically oxidized in blue light.

The corrected decrease in ϕ_q with increase in light intensity,[9] as well as the small size of ϕ_q itself, suggests the hypothesis that photochemically efficient clusters are formed at a relatively slow rate. An increased light intensity might be expected to eliminate such clusters more rapidly, and cut down their concentration which existed in the previous steady state. Thereafter, a smaller fraction of the total quanta absorbed would activate quinine already present in efficient clusters, causing ϕ_q to decrease. This effect was found most striking in solutions most concentrated in dichromic acid, as shown in Table V.

(9) Ref. 1, Figs. 4, 5.

TABLE V

λ, 366 mμ. Temperature. 22°

[Q]	$[K_2Cr_2O_7]$	$[H_2SO_4]$	$E_q \times 10^{-16}$	ϕ_q
0.00025	0.00016	0.8	18.0	0.058
			1.8	.070
.00025	.00008	.8	18.0	.048
			1.8	.052
.00025	.00004	.8	18.0	.039
			1.8	.040

In a previous paper[1] the relation between wave length and quantum yield was discussed. To make the data there more complete, we have since determined ϕ_q, 0.070 at 334 mμ, compared with a value of 0.060 at 366 and at 313 mμ, under conditions otherwise identical.

Using a Judd-Lewis sector spectrophotometer in a more detailed study of the variation of the extinction coefficient of quinine, K_q, with variation of $[H_2SO_4]$ and wave length we found that from 405 to 208 mμ, log K_q is a linear function of either the log $[H_2SO_4]$ or the log [Q], the other being held constant. A shift of 200 cm.$^{-1}$ of the absorption curve of [Q], 0.0001 mole per liter, toward smaller wave numbers was observed in passing from 0.004 to 4.0 *m* H_2SO_4. In the steeper parts of the absorption curve, accurate data regarding $[H_2SO_4]$ are therefore indispensable.

Ten-degree temperature coefficients, $\delta_{10°}\phi_q = (\phi_q)_{t+10}/(\phi_q)_t$, between 5 and 24° (one determination only at 29°) at various wave lengths appear in Table VI. Each entry gives the average of two or more complete experiments. Increments of $[K_2Cr_2O_7]$ seem to lower $\delta_{10°}\phi_q$ slightly, but doubling $[H_2SO_4]$ does not seem to affect it measurably. The increase in $\delta_{10°}\phi_q$ at shorter wave lengths is too small to warrant theoretical argument. Further, the average of $\delta_{10°}\phi_q$, 1.12, approximately equals $(273 + 20)^3/(273 + 10)^3$ which suggests an interesting possibility.

TABLE VI

λ in mμ	$[K_2Cr_2O_7]$	[Q]	$[H_2SO_4]$	ϕ_q at 5 ± 1°	ϕ_q	Ten-degree temperature coefficient

In a gaseous system the number of bimolecular collisions, Z, experienced by a particle having a mean free path l for a mean linear displacement $\overline{X}$ is

$$Z = 3\pi\overline{X}^2/4l^2 \qquad (1)$$

For a particle in a liquid system Einstein[10] and von Smoluchowski[11] showed that in one second

$$\overline{X}^2 = \frac{kT}{3\pi\eta r} \qquad (2)$$

where k is the gas constant per molecule, η the viscosity of the solvent, r the radius of the particle and T the absolute temperature. Granting that (1) can be made applicable to collision numbers involving ions in a liquid system by multiplying Z by a constant factor, we can substitute (2) in (1) and note that η for water between 0 and 30° is proportional to $1/T^2$, whereupon $Z = f(T^3)$. Over the temperature range 5 to 24°, $[(297)^3/(278)^3] \times 10/19 = 1.115$.

The above calculation would be also in accord with our tentative view that activated quinine reacts with dichromic (or chromic) acid in a bimolecular process requiring no additional energy of activation. It should be noted that this is not in harmony with the views held by Moelwyn-Hughes[12] and others, namely, that Z is directly proportional to the viscosity and hence has a negative temperature coefficient. If Moelwyn-Hughes' contentions are correct, a positive heat of activation, smaller than that of the average thermal reaction, would be indicated for the secondary act, and no obvious evidence of a bimolecular reaction would appear.

The investigation of quinine derivatives is being continued.

Summary

The photochemical reaction between quinine and dichromic acid apparently occurs in photochemically efficient clusters (not complexes) containing the above. Individual concentrations were varied; other variables, including concentration of activated quinine, were fixed. Seven wave lengths over the range 405 to 208 mμ were used. By graphical methods, reaction order was found to be zero for quinine and 0.43 for $H_2Cr_2O_7$ or 0.86 for H_2CrO_4. These values correspond to 0.50 and 1.00, respectively, within experimental error. A reaction order of 0.07 for H_2SO_4 assigns a subordinate role to this reactant. It is barely possible that at 208 mμ only, both the quinine and the dichromic acid are photosensitive.

It is shown that when the total absorbed light is divided between two (or more) constituents of the solution, the total intensity must be regulated so as to maintain the same concentration of the effectively activated constituent in all the experiments used to establish the effect of changing the concentration of some other reactant.

Quinine concentration being held constant, an increase in sulfuric acid concentration from 0.004 to 4 moles per liter shifts the whole absorption curve 200 cm.$^{-1}$ toward the red.

The ten-degree temperature coefficient, 1.12, agrees with one mode of calculating the temperature coefficient of the collision number in solution of a bimolecular reaction between activated quinine and H_2CrO_4 without additional energy of activation. Another calculation predicts a small energy of activation.

Ammines of the Lower Chlorides of Titanium

BY WALTER C. SCHUMB AND RICHARD F. SUNDSTRÖM

Although anhydrous titanium dichloride and trichloride have been the subject of numerous investigations, conflicting statements relative to some of their properties, and the absence of data concerning others, make the further study of these compounds desirable. In particular, the recorded observations which concern the preparation of the two chlorides appear in some respects to be in need of revision, and comparatively little is known concerning the reactions of these two substances with ammonia. The aim of the present paper is to contribute further information on each of these subjects.

Ruff and Neumann[1] prepared the anhydrous trichloride by reducing the tetrachloride with various metals. They obtained it as violet crystals, which when heated in a vacuum slowly began to sublime at 425°, and to decompose at 450° into the di- and tetrachlorides. At 475° this decomposition proceeded rapidly, and the dichloride thus obtained was very stable to heat and not volatile in a vacuum even at 600°. It is interesting to note that they were unable to obtain samples of high purity; they accounted for their high titanium content and low chlorine content by assuming that their samples had become oxidized during the course of the preparation. Earlier investigators similarly had failed to obtain pure specimens.

Meyer and co-workers[2] prepared the trichloride by the reduction of the tetrachloride with hydrogen at high temperatures, employing the hot-cold tube previously used by Georges and Stähler.[3] At 800–1000° they obtained a mixture of the di- and trichlorides, which was converted completely into the trichloride by heating to 300° in a stream of hydrogen and

[3] Georges and Stahler, *ibid.*, **42**, 3200 (1909).

tetrachloride vapor. Their final product, which had the appearance of violet scales, represented a yield of approximately **30%.** To account for the large proportion of dichloride in the primary product, they assumed that the reduction to trichloride was not a simple one, but rather one involving two steps

$$TiCl_4 + H_2 = TiCl_2 + 2HCl \qquad (1)$$

$$TiCl_2 + TiCl_4 = 2TiCl_3 \qquad (2)$$

The first reaction supposedly took place in the hotter parts of the reaction tube and the latter in the colder. This assumption evidently presupposes that the dichloride is volatile at high temperatures, as indeed the earlier investigators claimed. Thus Friedel and Guérin[4] reported that the dichloride volatilizes at red heat and Stähler and Bachran[5] stated that the substance sublimes at 300° in *vacuo*. In view of the fact that, according to Ruff and Neumann, the trichloride sublimes at 425°, and then but slowly, the above statements appear doubtful, since in a series of chlorides volatility, in general, decreases with decreasing chlorine content.

Experimental

Preparation of Titanium Trichloride and Titanium Dichloride.—The titanium trichloride used in this work was prepared by reduction of the tetrachloride with hydrogen at 650°. The tetrachloride previously had been distilled several times in an atmosphere of dry carbon dioxide, the colorless fraction, b. p. 136–137°, being collected in sealed tubes each containing approximately 30 g. In the reduction a modified form of the hot-cold tube described by Young and Schumb was employed.[6] In order to minimize the danger of hydrolysis during the transfer of the tetrachloride from its sealed container to the apparatus, the substance was frozen and admitted against a brisk countercurrent of dry carbon dioxide into a flask which formed part of the apparatus; thence it was slowly distilled into a second flask and the former sealed off from the latter. A stream of dry, oxygen-free hydrogen, bubbling through the liquid, carried the tetrachloride vapor into the reaction chamber (35 cm long and 30 mm. wide), which was heated in a hinged type electric furnace. The titanium trichloride formed was collected upon an 8-mm. tube, cooled internally by a rapid stream of water. The unchanged tetrachloride was recovered practically quantitatively from the effluent gas by passage through two traps, chilled to −20 and −78°, respectively.

Due to the reversibility of the reaction, $2TiCl_4 + H_2 \rightleftharpoons 2TiCl_3 + 2HCl$, in order to obtain satisfactory yields of the trichloride it is essential to remove the hydrogen chloride rapidly. Meyer and co-workers,[2] employing a gas mixture containing 16.6 mole per cent. of tetrachloride, and a reaction rate such that 20 to 30 g. of trichloride was formed in from three to four hours, accomplished this with the aid of metallic titanium present in the reaction tube. However, if a slower reaction rate was used together with a rapid hydrogen current, the concentration of hydrogen chloride could be kept low throughout the process. To this end a comparatively low reaction temperature should be used; this has the added advantage of permitting but slight decomposition of the trichloride formed. The gas mixture in the reaction chamber, moreover, should contain relatively little tetrachloride vapor; hence the liquid through which the hydrogen bubbles should be kept at a moderately low temperature. For this purpose the

[6] Young with Schumb, THIS JOURNAL, **52**, 4233 (1930).

vapor pressure of the tetrachloride at 25° was determined and found to be approximately 21 mm. From this it may be estimated that the mixture resulting from the passage of hydrogen through the liquid at 25° contained about 2.75 mole per cent of tetrachloride vapor. The rate of flow 250 cc. of hydrogen per minute was adopted as the most suitable; under these conditions 30 g. of tetrachloride was volatilized in about nine hours. To ensure adequate drying of the gas at this rate of flow, four 60-cm drying tubes, the first two containing "Dehydrite" the latter two phosphorus pentoxide, were used. Since the gas mixture rapidly passed through the reaction tube, a long hot space was desirable, and the cold tube accordingly was allowed to extend only 6 or 7 cm into the heated zone, the resulting area of cooling surface being quite sufficient to collect the product.

The temperature of the reaction tube was raised gradually and at 600° a black deposit appeared on the tip of the cold tube. As the temperature approached 650° this deposit assumed a distinctly crystalline appearance, the crystals consisting of large thin plates as well as short needles, both *black* in color. When two or three grams of trichloride had collected on the cold tube the temperature was lowered to 300°, the stream of cold water shut off and the hydrogen current reduced to two bubbles per second. The flask containing the tetrachloride was warmed so as to allow these vapors to pass through in large quantities, in order that any dichloride present might thus be converted into the trichloride. When all the tetrachloride had vaporized, the slow hydrogen current was continued in order to remove any tetrachloride adhering to the trichloride or to the walls of the apparatus. The reaction chamber was then allowed to cool to room temperature and the hydrogen was displaced by dry, oxygen-free carbon dioxide. The traps containing the unchanged tetrachloride were then sealed off and by suitably rotating the reaction tube the black product was shaken down into a side tube, wherein it could be divided into two samples (each weighing about a gram) and sealed off.

The violet color hitherto ascribed to titanium trichloride is probably due to traces of moisture; when a sealed tube containing the black crystals is opened the color instantly changes to violet, although moist air has no apparent further effect for some time. The needles gave indications of being, in general, somewhat more reactive than the plates.

The action of heat on the trichloride was studied in a vacuum of approximately 0.001 mm. The temperature was raised slowly, and at 425–440° the crystals were observed to volatilize very gradually, thin transparent violet plates 3 or 4 mm. in diameter depositing just beyond the heated portion of the tube. The violet color in transmitted light is here due doubtless to the excessive thinness of the plates. At a slightly higher temperature, approximately 450°, the trichloride was observed to decompose, yielding the di- and tetrachlorides, the latter collecting as a white solid in the far end of the tube, which was chilled to −78°. While at 450° the decomposition was very slow, it proceeded at 475° at such a rate that a 1-g. sample required twelve hours for complete decomposition.

Attempts to prepare a dichloride of high purity failed, despite all precautions to exclude air and moisture. The purest sample obtained gave the following analysis: Ti, 41.5%; Cl, 56.4%; as compared with the calculated values. 40.4 and 59.6%, respectively. When the samples were treated with water, a small fraction, which proved to be elementary titanium, invariably remained unaffected. In order to determine whether this titanium was derived from decomposed dichloride, a specimen of the latter was introduced into one end of an evacuated tube and heated to 475°, the other end being chilled strongly. The appearance within a few hours of a white solid in the chilled end of the tube indicated that the reaction $2TiCl_2 = TiCl_4 + Ti$ had commenced. The volatility of the dichloride was next tested by heating in a vacuum over the range 300–600°, but at no time was any evidence of sublimation observed. The same experiment was repeated in an atmosphere of hydrogen, but the appearance of tetrachloride constituted the only noticeable change. The possibility that the dichloride is appreciably volatile *in vacuo* or in an atmosphere of hydrogen may therefore be excluded, and the hypothesis advanced by Meyer as to the mechanism of the reduction of the tetrachloride cannot be substantiated, The large amount of dichloride obtained was probably due to the decomposition of the trichloride at the high temperature employed.

Since the dichloride is slowly decomposed at 475°, it is hardly possible to prepare it in a state of purity by the method above described. Calculated on the basis of chlorine discrepancy, the decomposition of the dichloride we obtained amounts to approximately 5% of the original sampie. From the results of Ruff and Neumann the figures 8.4 and 9.2% are obtained, while the titanium content of Stähler and Bachran's dichloride ranged from 7.0 to 9.4%.

Reactions of Titanium Trichloride and Titanium Dichloride with Ammonia.—Georges and Stähler[8] reported that when titanium trichloride is shaken with liquid ammonia a yellow emulsion is formed, and part of the substance appears to dissolve, and Friedel and Guérin[7] studied the reaction between the dichloride and ammonia at red heat. In view of the fact that these substances are extremely reactive toward water, it is reasonable to suppose that they should react with ammonia at low temperatures.

In some preliminary experiments ammonia was conducted over the two chlorides at room temperature; both swelled up considerably and heat was evolved. The product formed was white in the case of the trichloride, but the dichloride yielded a pearl-gray substance. The experiments were repeated at −78° and the same results were noted. Two alternative modes of reaction are possible. The two chlorides may form molecular addition compounds, as is generally the case with halides of the metallic elements; or, as frequently happens with halides of non-metallic elements, mixtures of ammonium chloride and an amide or imide of the non-metal (depending on the temperature) may be formed. Stähler and Wirthwein[8] have reported the formation of titanic tetramide by the interaction of the tetrachloride with liquid ammonia. With titanium in its lower valences it is of interest to determine whether, accompanying the increase in basigenic character of the element, the formation of true ammines becomes possible. The following experimental work, undertaken from this point of view, proves such to be the case.

Reaction of Titanium Trichloride with Ammonia.—The apparatus used was a modification of that which Thomas and Pugh[9] recently have employed in similar work on germanium tetrachloride. This apparatus allowed ammonia to act on the chlorides at any temperature between −78° and room temperature, and also permitted the product formed to be thoroughly stirred and washed several times in liquid ammonia, so that any ammonium chloride might be removed. In order to be sufficiently dried, the entire apparatus was alternately thoroughly evacuated and filled with dry carbon dioxide. This gas was taken from a ten-liter reservoir, which was equipped with a manometer and filled from a cylinder after passage of the gas through a purifying train to remove oxygen and moisture. The trichloride was introduced from one of its sealed containers by opening one end and rapidly attaching it to a piece of heavy-walled rubber tubing, the other end of which was connected to the open tube (a), shown in the accompanying figure The system was evacuated and refilled with carbon dioxide. The trichloride was shaken down into the 26-mm. reaction tube (b) and the tube (a) sealed off as indicated. The major portion of the crystals was caught in the shallow, heavily gold-plated copper dish *(c)*. This dish, about two mm. less in diameter than the reaction tube, was held in place

by indentations in the glass above and below, but was free to move vertically about two mm. The reaction tube was surrounded by a cylindrical vacuum jacket closed at the lower end with a rubber stopper. Connection between the receiver (d) and the reaction tube was at first made through a wide-bore stopcock, but this proved unsatisfactory, as when liquid ammonia filled the tube fissures formed in the lubricant, causing leakage of air. The connection was subsequently made with a thick-walled rubber tube, closed with the screw-clamp (g). The ammonia was conveyed from a cylinder into an evacuated bulb (e), where it was condensed and dried with sodium. Approximately one quarter of the liquid was then evaporated, the vapor, sweeping out any air and hydrogen, escaping through the mercury trap (f), which was arranged to serve as a manometer as well.

The cylindrical vacuum jacket surrounding the reaction tube was cooled to −78°, the system evacuated with the screw-clamp (g) closed, and ammonia slowly admitted from (e). The trichloride swelled up to form a spongy mass, six or seven times its original volume, with but slight change in color. Ammonia was allowed to condense until the liquid entirely surrounded the spongy mass, which gradually collapsed to form a grayish powder. The supernatant liquid had a yellow color, as Georges and Stähler reported, but it was less pronounced after the second treatment and finally disappeared altogether. As the liquid was allowed to warm violent bumping commenced, and the vibrations of the dish caused the powder to be thrown about in it. This provided a means of thorough stirring; as the temperature was lowered the bumping ceased, and as the powder settled all but a small portion was caught in the dish. After this stirring process had been repeated a few times and the pressure of the ammonia had become atmospheric, the screw-clamp (g) was opened and the liquid passed down into (d), where it was allowed to evaporate. The clamp was closed, the reaction chamber again filled with liquid ammonia, and the above operations were repeated four or five times. The total time of exposure to ammonia was in no case less than twelve hours. If a mixture of imide and ammonium chloride had been formed, there was thus ample time and opportunity for the latter to be leached out by the liquid. After the last treatment the reaction tube was allowed to warm up to room temperature, the ammonia escaping through the mercury trap. In the first few experiments the ammonia was replaced by carbon dioxide; both gases were sufficiently dry to prevent any observable reaction between them. When the apparatus was completely filled with the latter gas, it was turned to a horizontal position and the product divided into two samples, which, one at a time, were shaken down into (a) and sealed off.

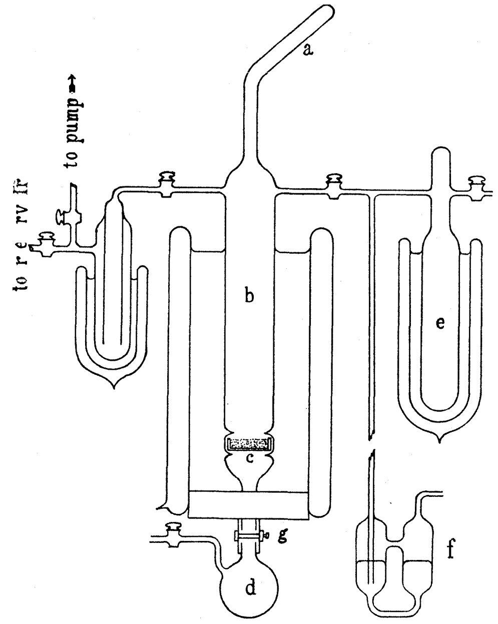

Fig. 1.

The product thus obtained is white, though grayish when moistened with liquid ammonia, and reacts violently with water—more so, in fact, than is the case with the trichloride itself. When kept in a sealed tube in an atmosphere of carbon dioxide it darkens perceptibly within a day or two; hence it was preserved in an atmosphere of ammonia, even though this introduced complications in the subsequent analysis.

Analysis.—The sample was dissolved in dilute nitric acid and then boiled with an excess of alkali, the ammonia being collected in a known amount of acid. The apparatus consisted of a three-necked Woulfe bottle, through one neck of which the sample was introduced, while through a second neck alkali was admitted from a separatory funnel. The liberated ammonia was conveyed through a splash bulb and a condenser into an Erlenmeyer flask containing the acid, the excess of which was then determined by titration, using methyl red as indicator. This method was shown to yield sufficiently accurate results by separate experiments with known weights of pure ammonium chloride.

The sealed glass tube containing the sample to be analyzed, together with some free ammonia, was weighed and opened, correction being made for the buoyancy of the gas.[10] The open end was rapidly inserted into one neck of the thoroughly dried Woulfe bottle, while a counter current of dry air through the apparatus swept out the same neck. The free ammonia, lighter than air, was thus rapidly swept out in a few minutes by the air current. The neck was then closed by a rubber stopper and 2 *N* nitric acid slowly admitted from the funnel until a clear solution was obtained. Sodium hydroxide solution was added in considerable excess and water to make the volume 200 cc. The liquid was carefully boiled until its volume had been reduced to 50 cc., this operation requiring about two hours. The excess acid was then titrated with carbonate-free sodium hydroxide.

The liquid remaining in the Woulfe bottle was diluted and acidified with nitric acid. A precipitate containing titanium hydroxide and silicic acid (derived from the glass) appeared. This was filtered off, silver nitrate was added, and the chlorine determined in the usual manner. Titanium was not determined in the above-mentioned precipitate, but separate samples were dissolved in dilute nitric acid, the titanium precipitated with ammonia, washed, dried, ignited and weighed as TiO_2. The chlorine was also determined in these samples (I and II, below). The results agree reasonably well with the values calculated for titanium trichloride hexammine.

	I	II	III	IV	Calcd. for $TiCl_3·6NH_3$
Ti	18.82	18.59	...	...	18.69
Cl	40.94	41.17	41.11	41.66	41.50
NH_3	...	...	39.74	39.58	39.81

Properties.—Titanium trichloride hexammine is a white powder which reacts violently with water, yielding the familiar solution of trivalent titanium. It dissolves in dilute nitric acid to form a clear solution. When exposed to air it smells strongly of ammonia and darkens rapidly. In a sealed tube filled with dry carbon dioxide it darkens less rapidly, but nevertheless appreciably.[11] It decomposes even when preserved in contact with dry ammonia at atmospheric pressure. Thus after a week a 0.8332-g. sample so preserved contained only 36.6% of ammonia. When gently heated in a vacuum it readily gives up four moles of ammonia and turns black, but the remaining two moles appear to be held tenaciously. The

---

(10) As the tubes were never more than 12 cc. in volume, they contained less than 0.01 g. of free ammonia.

(11) After five days a 0.5037-g. sample kept in a 12-cc. tube showed but 32.4% NH_3.

resulting black substance is so reactive that it catches fire on exposure to moist air.

The thermal decomposition of the hexammine was studied quantitatively. The ammonia set free by heating the substance in a Wood's metal bath at 300° was condensed in a bulb immersed in liquid air. When the decomposition appeared to be complete, as indicated by the color of the residue and by the fact that no further ammonia condensed, the bulb was sealed off and the weights of the black residue and ammonia were determined. The percentages of ammonia released from the original samples correspond to 4.08 and 4.15 moles, respectively.

	Wt. residue	Wt. NH_3	% NH_3 evolved from orig. sample
I	0.4743	0.1760	27.07
II	1.2390	.4722	27.53

The black residue was then analyzed for titanium and chlorine in the usual manner, but the content of ammonia, though its presence was shown qualitatively, was determined by difference. This difference was calculated on the assumption that the original material before heating contained 39.81% of ammonia From this amount the weight of ammonia condensed by the liquid air was deducted, after the necessary corrections for the presence of free ammonia in the sample tube had been made.

	I	II	Calcd. for $TiCl_3 \cdot 2NH_3$
Ti	26.1	26.4	25.5
Cl	55.7	56.0	56.4
NH_3	17.5	16.9	18.1

Although the evidence offered by the preceding analyses is not considered sufficient to afford conclusive proof of the existence of a diammine of titanium trichloride, it indicates that on gentle heating the hexammine gives off four moles of ammonia, and the resulting substance is probably a diammine and not a chloronitride, such as Ruff and Eisner reported in the case of the decomposition of the tetrachloride hexammine.[12] As the temperature is raised, no more ammonia is set free, and finally a second decomposition occurs, involving the disintegration of the trichloride. Ammonium chloride was identified as one of the products.

Reaction of Titanium Dichloride with Ammonia.—The apparatus and procedure employed was the same as that used with the trichloride. The dichloride was in contact with liquid ammonia for a period of twelve hours, during which time the material was thoroughly stirred and washed five or six times. Because the dichloride is a fine dry powder, as compared with the comparatively large crystals of the trichloride, a larger amount was lost during the stirring operations, and therefore the samples were rather small.

(12) Ruff and Eisner, Bn., 41,2280 (1908).

In other respects the dichloride behaved as did the trichloride; the product, however, was pearl gray rather than white.

Analysis.—The method of analysis for ammonia and chlorine was that used with the corresponding compound of the trichloride. A Pyrex Woulfe bottle, which was found to be resistant to the action of a boiling alkali solution, was employed, and the amount of silica dissolved was sufficiently small to allow the determination of titanium in the same sample Before the final weighing of titanium dioxide, any silica that might possibly be present was volatilized by heating with hydrofluoric and sulfuric acids.

Due to the difficulty of obtaining specimens of titanium dichloride free from both the trichloride and elementary titanium, the samples of reaction product were never wholly pure. Inasmuch as elementary titanium does not react with ammonia under the conditions used, it was thought less objectionable to work with samples containing 5% of free titanium, rather than with samples containing small amounts of trichloride. When samples of the reaction product were treated with water a small fraction remained unaffected, as with the dichloride itself, but as the solution above was always turbid from hydrolysis, it was not feasible to separate the free titanium by filtration. The content of elementary titanium in the samples was determined by independent analysis of the original dichloride, and also by noting the amount of titanium in the reaction product in excess of the atomic ratio 1:2. Both methods gave approximately the same results, the composition of the product corresponding reasonably well with the formula $TiCl_2 \cdot 4NH_3$.

	I	II	III	Calcd. for $TiCl_2 \cdot 4NH_3$
Ti	25.26	25.10	25.73	25.63
Cl	37.26	37.14	37.34	37.92
NH_3	35.83	36.61	36.13	36.45

Properties.—Titanium dichloride tetrammine as thus obtained is a pearl-gray powder which smells strongly of ammonia when exposed to air. It dissolves in water with the evolution of hydrogen, yielding a dark brown, turbid solution, but the reaction is slower than that of the dichloride itself. Dilute nitric acid dissolves it with a hissing sound, forming a yellow solution which is not quite clear, and as in the case of the water solution minute particles of elementary titanium remain undissolved. When heated at 300° in a vacuum it gives off ammonia, ammonium chloride appearing simultaneously. This was driven to the cooler parts of the tube, and when the decomposition appeared to be complete the black residue was sealed off and analyzed. It was found to contain approximately 60% of titanium, and is presumably a nitride; a sample free from chlorine was never obtained, five or six per cent. of the latter invariably remaining despite continued heating. The presence of nitrogen was shown qualitatively, but specimens sufficiently pure to justify a quantitative analysis could not be obtained.

The authors are indebted to Dr. E. Lee Gamble for kind assistance in some of the analytical work.

Summary

Anhydrous titanium trichloride, prepared by the reduction of the tetrachloride with hydrogen at 650°, exists in two crystal forms, plates and needles, both *black* in color in reflected light. Exceedingly thin plates show a violet color in transmitted light. The data of Ruff and Neumann relating to the behavior of the trichloride when heated in a vacuum are confirmed.

Anhydrous titanium dichloride, prepared by the thermal decomposition of the trichloride, is slowly decomposed when heated in a vacuum to 475°. Therefore specimens of the dichloride so prepared are inevitably contaminated with free titanium. No evidence of volatility is obtained when the dichloride is heated over the range 300–600°, either in a vacuum or in an atmosphere of hydrogen. The hypothesis concerning the mechanism of reduction of the tetrachloride by hydrogen, advanced by Meyer, Bauer and Schmidt, therefore cannot be substantiated.

The trichloride combines with ammonia at low temperatures to form a white hexammine. Liquid ammonia does not dissolve out any ammonium chloride, despite prolonged stirring and washing. The possibility that the compound is not a true ammine, but rather a mixture of an imide and ammonium chloride, is therefore excluded. On heating to 300° the hexammine readily gives off four moles of ammonia, a reactive, black substance, probably a diammine, remaining behind.

The dichloride likewise reacts with ammonia at low temperatures, yielding a pearl-gray tetrammine, the properties of which are in general similar to those of the hexammine of the trichloride.

The Dissociation Pressures of Magnesium Ammonium Phosphate Hexahydrate and Some Related Substances. VII

BY SAMUEL J. KIEHL AND HENRY B. HARDT

In 1847 Heintz[1] published a method for the determination of magnesium or phosphorus based upon the precipitation of these elements as magnesium ammonium phosphate hexahydrate and the ignition of it to magnesium pyrophosphate. This method, as improved by Gibbs[2] in 1873, has come into very general use. It was and is, however, subject to a large number of possible errors, and there have appeared, therefore, in the last sixty years ninety or more research reports upon its various phases. The facts brought out by these studies fall mainly into two groups: those dealing with the conditions necessary to the quantitative precipitation of the magnesium or phosphorus in the form of pure $MgNH_4PO_4 \cdot 6H_2O$; and those dealing with the ignition of this precipitate to $Mg_2P_2O_7$. The subject has been attacked from almost every conceivable angle.

Nevertheless there remains still a need for some information which may be deemed important for the ignition of the hexahydrate. It seems noteworthy that, although the salt precipitated is a hydrate which loses its water of hydration during the ignition process, there should be a lack of information upon its dissociation pressure. Furthermore, it is not only a hydrated ammonium salt which loses both its water of hydration and its ammonia, but also an orthophosphate which is converted to a pyrophosphate by the loss of water of constitution. Consequently we believe that a knowledge of the pressure developed in the reactions involved during heating will help to ensure an intelligent manipulation of an operation which is so vital a part of a quantitative procedure.

It seems probable, therefore, that a study of the dissociation of magnesium ammonium phosphate from the viewpoint of the phase rule may yield valuable information. According to the phase rule, a salt hydrate that dissociates into a lower hydrate or an anhydrous salt and a gaseous phase is a two-component system, and with three phases present it is univariant. A large number of such systems have been studied and reported in the literature by a number of very able investigators. Among those who have done much in this field to improve the method for measuring dissociation pressures of such systems are: Johnston,[3] whose excellent apparatus and method present a real improvement, Baxter and Lansing, Frowein, Menzies and Wilson.[4] The last two mentioned give good criticisms of the

many preceding researches and list the errors often made in manipulation and measurement.

The studies referred to above deal with univariant systems. Magnesium ammonium phosphate hexahydrate also forms such a system when it dissociates into a lower hydrate and water. However, in its case there is a further dissociation which yields a magnesium acid phosphate and ammonia and forms a third solid phase and a third component. This system, consisting of three components present in four phases, is also univariant and has, therefore, a definite dissociation pressure at any fixed temperature. Therefore both the two-component and three-component systems are represented in this investigation. Systems 1, 4 and 5 listed below consist of two components, while systems 2 and 3 contain three components. The following systems were studied

System 1. $MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, H_2O
System 2. $MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, $MgHPO_4 \cdot 3H_2O$, H_2O, NH_3
System 3. $MgNH_4PO_4 \cdot H_2O$, $MgNH_4PO_4$, $Mg_2P_2O_7$, NH_3, H_2O
System 4. $MgHPO_4 \cdot 7H_2O$, $MgHPO_4 \cdot 3H_2O$, H_2O
System 5. $MgHPO_4 \cdot 3H_2O$, $MgHPO_4 \cdot H_2O$, H_2O

Preparation and Analysis of Materials

$MgNH_4PO_4 \cdot 6H_2O$.—Equivalents of $Na_2HPO_4 \cdot 12H_2O$, carefully purified, and magnesia mixture (usually about one liter of each, of one-tenth molar concentration), were mixed and the precipitate dissolved in hydrochloric acid. Very dilute ammonium hydroxide was then added slowly with constant stirring until the salt was almost all precipitated. Then more concentrated ammonium hydroxide was added until its concentration was approximately one molar. After standing for four hours or more, it was washed with water until a sample of it dissolved in one-tenth molar nitric acid gave no test for chloride with siliver nitrate. After it was filtered on a hardened filter paper in a Buchner funnel and washed with four 50-cc. portions of absolute ethyl alcohol, then with four 50-cc. portions of anhydrous ether, it was transferred to a bottle where suction was applied by means of an oil pump for an hour. The salt adhering to the filter paper was rejected to reduce the danger of organic impurities. By this method a number of lots were prepared, all of which were shown by the microscope to be distinctly and uniformly crystalline, gave the theoretical loss in weight on ignition closer than one part per thousand, gave the theoretical percentage of ammonia within one part per thousand and gave snow-white residues on ignition.

$MgNH_4PO_4 \cdot H_2O$.—This salt was prepared by the same method as the hexahydrate, except that it was precipitated from boiling solution, kept in an oven in the mother liquid at 100–102° for twenty-four hours, washed with boiling water, and dried in an oven at 106° for eight hours. It was very uniformly crystalline, consisting of square, flat crystals, gave the theoretical loss in weight upon ignition, the theoretical ammonia content, and snow-white residues upon ignition.

$MgHPO_4 \cdot 7H_2O$.—Equivalents of $MgSO_4 \cdot 7H_2O$ and $Na_2HPO_4 \cdot 12H_2O$ in solutions were mixed; the precipitate was dissolved by adding a small amount of sulfuric acid, and reprecipitated by adding slowly a dilute sodium hydroxide solution. The salt was washed with water, alcohol and ether, dried on a glass plate until free from ether, and bottled. It consisted of large needle-shaped crystals which gave the theoretical loss of weight upon ignition. This hydrate is very unstable. Further comment will be made later.

$MgHPO_4\,3H_2O$.—When the $MgHPO_4{\cdot}7H_2O$ still in its mother liquid was warmed to 35°, the long needle-like crystals changed to the rhombic form. Upon ignition these gave the theoretical loss in weight for the reaction $2MgHPO_4\,3H_2O \rightleftarrows Mg_2P_2O_7 + 7H_2O$ and a snow-white residue.

Apparatus

The apparatus used for the measurement of pressures is an adaptation of that of Kiehl and Wallace,[5] which was a modification of that of Johnston.[3] Some of the systems, in fact, may well be measured with practically the same arrangement. The first salt studied, $MgNH_4PO_4\,6H_2O$, however. has such an exceptionally high dissociation pressure that with this form of apparatus it was impossible to prevent the condensation of the water. The water vapor pressure produced was so near that of water itself that even a slight difference of temperature between the furnace and the steam-jacket caused condensation in the cooler portion of the system within the steam-jacket.

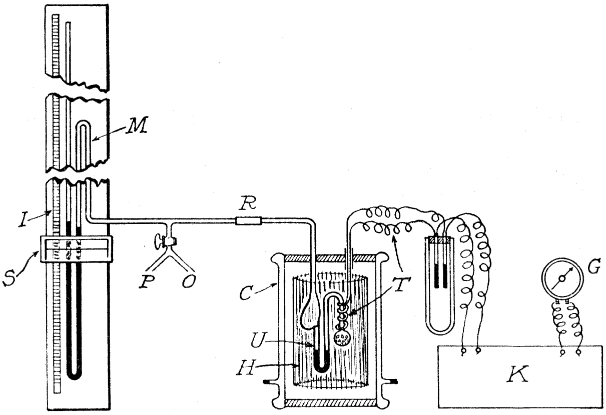

Fig. 1A.—Apparatus for the measurement of dissociation pressures.

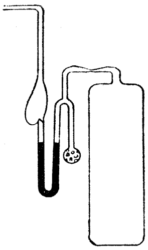

Fig. 1B.—Modified manometer used in determining the ratio of water to ammonia in the vapor phase.

A modification was made, therefore, whereby this condensation was prevented, the arrangement was simplified, and manipulation made much easier. The essentials of the apparatus are shown in Fig. 1A. The furnace and steam-jacket formerly used were combined into a unit consisting almost entirely of Pyrex glass and a resistance wire. A double-walled cylinder, C, of heavy Pyrex glass, with a vacuum between the walls, 27 centimeters long and 6.5 centimeters inside diameter was used as a chamber for the heater. The ends were closed with corks covered with heavy asbestos paper. The heating unit. H, consisted of a smaller Pyrex cylinder upon which was wound 27 feet of 28-gage nichrome wire. When this heater was connected with the 110-volt circuit, any temperature from room temperature up to 425° could be secured by use of appropriate resistance.

The manometer, M, described heretofore,[5] was connected to an oil pump, by which a vacuum of 0.2 mm. pressure could be secured. When pressures less than one atmosphere were to be measured, an air valve at O was used to admit air to counterbalance the pressures developed by the system; and for pressures greater than an atmosphere and for

---

(5) Kiehl and Wallace, THIS JOURNAL, 49,375 (1927).

Wood's metal as a confining liquid, O was connected to a high-pressure hydrogen cylinder by means of heavy-walled rubber tubing which was wrapped tightly with tire-tape. The connection, R, was also wrapped pressure tubing, which permitted tilting the furnace after evacuation. Before it was wrapped the rubber tubing was thoroughly massaged several times, inside and out, with warm castor oil, to make it less permeable to gases. This oiled and wrapped pressure tubing retained pressures of five and one-half atmospheres satisfactorily.

As a confining liquid for the gases formed by the dissociation, mercury is usually the best because it is the least likely to absorb or react with the gases present. In this investigation it was found very satisfactory for low temperatures. Since the nature of the systems measured and the method and apparatus used required the confining liquid to be kept at the same temperature as the system itself, and since mercury boils at 357°, a large correction due to the vapor pressure of mercury thereupon would be required as the temperature approached this point. Besides, as the temperature rose, the mercury would distil from the capillary and condense in the cooler portion of the tube.

In looking for a confining liquid that did not have this limitation at higher temperatures, Wood's metal proved to be excellently suited. It has practically no vapor pressure at the temperatures where its use was required. When a sample of the purest material obtainable was placed alone in the dissociation pressure apparatus no appreciable pressure developed at even the highest temperature used for measuring dissociation pressures. When, however, the temperature was increased to 300°, a pressure of 5 millimeters was developed. Two limitations should be mentioned in connection with its use. At higher temperatures especially, a troublesome scum will form upon the surface of the metal if air is allowed to come in contact with it. Hydrogen was therefore used to counterbalance the pressure developed in the system. The metal should not be allowed to solidify in the capillary as the strain produced by the contraction of the cooling glass and by the solidification of the metal may break the small manometer. After the completion of the experiment the metal in the liquid state may be transferred to the properly constructed reservoir.

A chromium-plated strip of brass 1.9 cm. wide by 7.6 cm. long with a millimeter scale engraved upon it was attached to the legs of the differential manometer within the heater to aid in leveling the confining liquid.

For reading temperatures up to 350° a copper–constantan thermocouple was employed. Above that temperature a platinum–platinum-rhodium thermocouple was used. The thermocouples were standardized against the melting points of samples of tin, lead, zinc and aluminum from the United States Bureau of Standards, the boiling points of water, alcohol and ether and the freezing point of water. A water and ice cold junction was used. The instruments and method of measurement were described heretofore.[5]

For beating the salts in *vacuo*, a thick-walled Pyrex tube 40 cm. in length and 5 cm. in diameter, with a ground-glass cap which was fitted with a stopcock, was used. The lower third was placed in an electric furnace and the upper part protected from the heat of the furnace by two tightly fitting asbestos stoppers, so that when evacuated the lower part could be heated to above 450° while the upper end remained at room temperature. A platinum crucible containing the salt was lowered into the tube by means of a glass rod bent at the bottom into the form of a ring.

For the ignition, when they were required, porcelain Gooch crucibles were used in an electrically heated muffle-furnace.

Method

Dissociation Pressures.—The well-known static method for measuring dissociation pressures of salt hydrates was employed. The bulb, filled with a sufficiently large sample of the salt (0.1 to 0.25 *g.)* was sealed to the small manometer. When mercury was used as a confining liquid it was poured into the reservoir, and the manometer connected at R. The system was then evacuated and left overnight. The next morning the system was again evacuated and the mercury tilted into the capillary. Then the heat was turned on and the desired temperature maintained until the pressure became constant. All reactions attained equilibrium in a reasonable time; the longest time required was about sixty hours, in the case of System 1 at low temperatures, which was unusual. When Wood's metal was used the procedure was exactly the same except that the system **was** heated to 75–100° before the liquid was introduced. When constant pressure had been reached and maintained without change for an hour or more it was recorded; the temperature was then increased and the new equilibrium pressure found. When the highest pressure to be measured had been determined, the process was reversed; that is, the temperature was reduced stepwise, and the pressure found for each temperature. The temperature–pressure curve was considered a true equilibrium curve only when the curve for increasing temperatures coincided with that for decreasing temperatures. The same equilibrium pressure therefore was obtained when approached from either lower or higher temperatures.

The entire experiment was then repeated with a mixture of the substance being studied and the solid phase or phases believed to have formed during dissociation. When no irregular behavior from the beginning throughout the temperature range occurred and when the curve thus obtained was the same as that for the original salt alone, evidence for the identity of the solid phase was established and the equilibrium curve confirmed.

Evidence for Phases Present

Since no distinctive tests are known by which the hydrates of $MgNH_4PO_4$ and of $MgHPO_4$ may be identified when in the presence of each other, it is necessary to establish the presence of all phases by reasoning from the results obtained. The evidence showing which substances are formed by the dissociation in each system is given below.

System 1. $MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, H_2O

1. The monohydrate is formed from the hexahydrate and it may be isolated in fairly pure form if the gas evolved at 50° or less is removed as it is liberated.

2. Red litmus in the reaction chamber does not change to blue below 50°, nor does it change when moistened and exposed to the gas which has been removed from the reaction chamber. Ammonia is not given off below 50°.

3. The hexahydrate forms monohydrate because the two when mixed give the same curve as the hexahydrate alone.

System *2.* $MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, $MgHPO_4 \cdot 3H_2O$, H_2O, NH_3

1. The monohydrate is formed from the hexahydrate and it may be isolated in fairly pure form if the gas evolved at 50° or less is removed as fast as it is formed.

2. $MgNH_4PO_4 \cdot H_2O$, when heated in a closed system under the high vapor pressure of water furnished by the hexahydrate, first loses ammonia, forming $MgHPO_4 \cdot H_2O$ (see System 3), but under the conditions prevailing here, the monohydrate is converted to the trihydrate, because the trihydrate is the salt in whose range of existence the pressure–temperature curve for System 2 lies.

3. The water and ammonia, on cooling, form a solution which quickly turns red litmus blue, and smells strongly of ammonia.

4. A mixture of the first and second, or first, second and third, solid phases gives the same curve as the first alone.

System 3. $MgNH_4PO_4 \cdot H_2O$, $MgNH_4PO_4$, $Mg_2P_2O_7$, NH_3, H_2O

1. Either zinc acetate reagent or silver nitrate gives tests for pyrophosphate[6] whenever both ammonia and water are found in the gaseous phase.

2. When $MgNH_4PO_4 \cdot H_2O$ is heated in an open vessel so as to drive off a part of the volatile matter, it always retains a larger percentage of its NH_3 than of its H_2O as shown below:

Temp. to which heated, °C.	340	335	350	380
NH_3 retained, %	24.5	29.5	17.0	6.0
H_2O retained, %	17.3	24.0	12.0	2.0

This shows that the water of hydration may be expelled while some of the ammonia still remains in the form of anhydrous ammonium salt.

3. When $MgNH_4PO_4 \cdot H_2O$ is heated in the temperature–pressure apparatus, and the gaseous phase at equilibrium is analyzed, the ratio of water to ammonia is found to be about 3:1. Data are tabulated under "Experimental Results." These analyses show that some of the substance which has lost water has not lost ammonia. Each molecule of $MgNH_4PO_4 \cdot H_2O$ contains but one molecule of water of hydration for every molecule of ammonia.

4. The system at equilibrium always gives positive tests for pyrophosphate whenever ammonia is present.

5. Mixtures of the first and second, or first, second and third, phases give the same pressure–temperature curve as the first alone.

System 4. $MgHPO_4 \cdot 7H_2O$, $MgHPO_4 \cdot 3H_2O$, H_2O

1. If the vapors formed are pumped off, it is found that there is a great decrease in pressure at equilibrium when the composition of the resulting solid is approximately $MgHPO_4 \cdot 3H_2O$.

2. Crystals appear which have the same form as those of pure $MgHPO_4 \cdot 3H_2O$.

---

(6) Kiehl and Coats, THIS JOURNAL, 49, 2180 (1927)

3. Either the heptahydrate or a mixture of the two hydrates gives the same curve.

System 5. $MgHPO_4 \cdot 3H_2O$, $MgHPO_4 \cdot H_2O$, H_2O

1. Zinc acetate reagent does not give a test for pyrophosphate even when a great pressure has been developed. (This reagent, consisting of a thirty-two hundredths molar zinc acetate solution in the presence of one-eighth its volume of glacial acetic acid, has been shown by Kiehl and Coats[7] to be sufficiently sensitive to detect 0.0006 molar pyrophosphate in the presence of 0.1 molar orthophosphate.

2. If the vapors formed are pumped off, it is found that there is a great decrease in equilibrium pressure when the composition of the resulting solid is approximately $MgHPO_4 \cdot H_2O$.

Determining the Ratio of Water to Ammonia.—To determine the ratio of water to ammonia in System 3 where both of these substances are liberated as gases, the following method was used. A receptacle resembling a large test-tube was sealed to the bulb containing the salt as shown in Fig. 1B. There was a constriction in the tube which connected the bulb to the remainder of the apparatus to facilitate sealing off the bulb when equilibrium was established. In addition to the regular stopper in the top of the furnace, an extra asbestos stopper with a small hole just over the constriction in the tube was used.

The apparatus was arranged in the usual way except that the salt bulb contained about a gram of salt instead of the usual 0.2 to 0.3 g. charge. When equilibrium was established the temperature was noted, the extra stopper of the furnace removed, and the large bulb quickly sealed off with a small, hot flame. This could be done with practically no change in temperature, and with the leveling liquid showing no change in position. The bulb was then inserted into a measured volume of 0.02 N sulfuric acid and the tip broken off. The excess acid was back-titrated with 0.02 *N* sodium hydroxide and the standard volume of the ammonia as a gas was calculated. The standard volume of all the gas present was also calculated and the water determined by difference. The method worked very satisfactorily up to a total pressure of one atmosphere.

Experimental Results

The temperature–pressure data for four runs on each system studied are given in the following tables. All pressures are recorded in millimeters of mercury at 0°.

In order to select from the temperature–pressure data recorded above those values which would as nearly as possible represent the value most probable for each temperature in each system, the following method was used. From the data for each of the four runs a curve was drawn; from these four curves, one pressure corresponding to the average of the four

Determining the Ratio of Water to Ammonia.—The ratio of water to ammonia in the vapor phase at equilibrium for System **3** was determined at those temperatures at which the dissociation pressures were approximately one atmosphere and one-half an atmosphere. The analysis of the mixtures at these pressures gave the following results.

Discussion of Errors

1. By means of the silver scale and the hair-lined glass which is mounted in a steel frame and slides on a steel rod the manometer may be read to 0.2

TABLE V

THE RATIO OF WATER TO AMMONIA IN THE VAPOR PHASE OF SYSTEM 3 AT EQUILIBRIUM

				At 0° and 760 mm.		Percentage by volume	
	Vol. of gas collected, cc.	Temp., °C.	Total pressure,	Vol. of gas collected, mm.	Vol. of NH_3 by titration, cc.	ammonia, cc.	water vapor
1	52	246	726	28.24	7.82	27.71	72.29
2	52	245	695.8	26.11	6.77	25.95	74.05
3	52	245.3	703.6	25.62	6.65	25.97	74.03
						Av. 26.54	73.46
4	52	229	347.1	12.91	3.45	26.71	73.29
5	52	229	340.9	12.26	3.31	26.59	73.41
6	50	230	340.0	12.17	3.27	26.85	73.15
						Av. 26.72	73.28

The calculated values in the above table were obtained by use of the gas laws uncorrected.

mm. or less. Since most of the pressures read were high, the percentage errors due to this were low. For the lowest readings recorded this is not more than two per cent., while for all readings above 20 mm. it is less than one per cent.

2. The error due to leveling the confining liquid was not more than 0.1 mm., for the two arms of the manometer, very close together, are immediately in front of a bright, metallic millimeter scale.

3. It is impossible to remove all the absorbed air from the system. This is always an error in measuring dissociation pressures by the static method; but, while it cannot be eliminated, it is greatly reduced in this investigation by a more compact apparatus. The surface of the reaction chamber has been decreased to a minimum. The evacuation of the system at least twice at an interval of twelve hours or more before a run was begun aided the removal of adsorbed gases. In System 3, when the tip was broken from the bulb containing the gas which had been generated, all but about one-fourth of one per cent. immediately dissolved in the standard acid.

4. The error due to the vapor pressure of the mercury where it was used as a confining liquid was eliminated by subtracting the vapor pressure of mercury from the total pressures read for the various temperatures.

5. The errors in the measurement of temperature are very small. The electromotive force measurements may be made with a high degree of precision. By means of a curve constructed for this particular thermocouple from the melting points of Bureau of Standards samples of metals, the electromotive force measurements may be very accurately converted to temperatures. The greatest errors in temperature measurements will not exceed 0.1".

6. The error due to the small changes in the temperature of the furnace is more important, The furnace temperature can be maintained within

0.5°, which corresponds to a maximum error of about 7% in the case of $MgNH_4PO_4{\cdot}6H_2O$ at the lower temperatures where 1° is the equivalent of

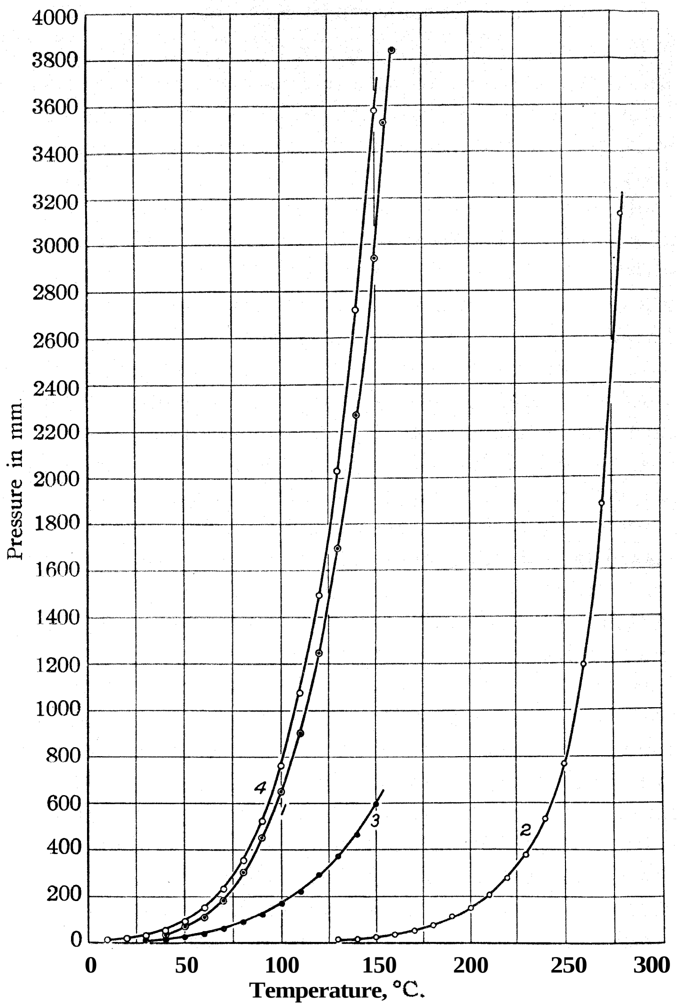

Fig. 2.—The dissociation pressure curves from data in Table IV.

about 7 mm. and the total pressure is about 50 mm. For the exceptionally high dissociation pressures, as of $MgNH_4PO_4{\cdot}6H_2O$ at 150°, a 0.5' error will cause a pressure error of 50 mm., which, however, in a total pressure of 3400 mm., is only one and one-half per cent.

Discussion of Results

The dissociation pressures obtained in this report show that magnesium ammonium phosphate hexahydrate will lose five molecules of water at a very low temperature when heated. Below sixty degrees no ammonia is noticeable in the gaseous phase. The system is univariant and may be expressed by two components. Above sixty degrees, moreover, the ammonium salt has reached an appreciable dissociation which produces another phase while the system still has one degree of freedom. There are consequently two effects, the dissociation of the hexahydrate and the dissociation of the ammonium salt, one superimposed gradually upon the other. Three components are necessary, therefore, to express the system. Data in Table I and Curve 1 in Fig. 2 are the combined results of the systems studied as 1 and 2, both of which are feasibly reversible over the temperature interval investigated. The dissociation pressure of the substance is but slightly below the aqueous tension of water within this temperature range, and it is equal to one atmosphere at 105°. This explains the formation of the monohydrate when magnesium ammonium phosphate is precipitated from boiling solution. The hexahydrate is stable at lower temperatures only. The fact that the dissociation pressure of the hexahydrate reaches a value of 3834 millimeters or over five atmospheres at 159.1° indicates its unstable character.

The dissociation pressures also show that the monohydrate will lose both its water of hydration and its ammonia in an open vessel when it is heated even considerably below 250°, where it reaches the total pressure of one atmosphere. The vapor phase at this temperature consists of approximately three-fourths water vapor and one-fourth ammonia by volume, and equilibrium is quickly established under the prevailing conditions.

In the study of System 3 it was found that in the heating of $MgNH_4PO_4 \cdot H_2O$, magnesium pyrophosphate was formed whenever both water and ammonia were liberated as gases. This indicates that the water vapor pressure due to the loss of water of constitution by magnesium acid phosphate exceeds that due to the loss of water of hydration by magnesium ammonium phosphate monohydrate when both water and ammonia appear in the gaseous phase. Therefore, if $MgHPO_4$ ever should be formed it would dissociate into water and $Mg_2P_2O_7$. Thus another dissociation is gradually superimposed upon both the dissociation of the hydrate and the dissociation of the ammonium salt.

An epitome of the foregoing facts may be given by the following well-known equation, $2MgNH_4PO_4 \cdot 6H_2O \longrightarrow Mg_2P_2O_7 + 13H_2O + 2NH_3$, which summarizes what takes place when the substance is heated to a temperature which need not exceed 250°, in an open vessel where the gases formed escape as liberated. The equilibrium was found to be attained rapidly near 250°. The speed of the reaction therefore when required to proceed in one direction would be sufficiently great to ensure complete expulsion of the volatile substances in a reasonable time.

In System 2 the reaction is quickly and completely reversible up to about 157°, consisting simply of the two hydrates in equilibrium with water vapor. Above 157° the pressure increases in a very rapid and irregular way and the reaction is not feasibly reversible. Pure $MgHPO_4 \cdot 3H_2O$ which has been heated in the reaction vessel to 158° or more gives a positive test for pyrophosphate with zinc acetate reagent,[5] while that kept below this temperature shows no trace of it.

In System **3** the reaction is completely reversible, although extremely slow. Pyrophosphate appears at a very low temperature, at 200° or less. Here, however, the pyrophosphate seems to convert back to orthophosphate much more readily than in a similar situation in System **5**, whose reversibility was found non-feasible when temperatures were reached where pyrophosphate was formed.

The dissociation of System 4, $MgHPO_4 \cdot 7H_2O$, is especially interesting. When freshly prepared, the crystals were exceptionally large and perfectly formed. However, in a day or two, droplets of water appeared on the walls of the glass-stoppered bottle in which the salt was stored. As the long crystals disappeared, the trihydrate, the stable phase, was formed.

It was found, moreover, that the pure heptahydrate, when once inoculated with the trihydrate and evacuated in the pressure–temperature apparatus, formed liquid water in five minutes or less at any temperature from room temperature to at least 100°. The crystals, still in the water from which they were precipitated, left standing on the shelf, also changed completely into the trihydrate at the same temperature at which precipitation took place (about 22°) in about one week. This change, furthermore, was greatly promoted by light. When the pure heptahydrate decomposed, moisture condensed on that side only of the bottle which was turned toward the light. A sample of it, on the other hand, in a glass-stoppered bottle wrapped in a black cloth required a much longer time to change completely into the lower hydrate than an identical unprotected sample standing beside it. It may be concluded, therefore, that magnesium acid phosphate heptahydrate, at room temperature, has a dissociation pressure as great as or greater than the aqueous tension of liquid water.

Summary

1. A modified apparatus is described for measuring the dissociation pressures of substances that give both water and another condensable gaseous substance.

2. A method is given for measuring and for resolving into partial pressures the dissociation pressures of salt hydrates, where both water and

another gaseous substance are produced, and where the total measured pressure may be high.

3. The dissociation pressures for the systems

$MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, H_2O (below 60°)
$MgNH_4PO_4 \cdot 6H_2O$, $MgNH_4PO_4 \cdot H_2O$, $MgHPO_4 \cdot 3H_2O$, H_2O, NH_3 (above 60°)
$MgNH_4PO_4 H_2O$, $MgNH_4PO_4$, $Mg_2P_2O_7$, NH_3, H_2O
$MgHPO_4 \cdot 3H_2O$, $MgHPO_4 \cdot H_2O$, Hz0

have been determined.

4. The use of Wood's metal as a confining liquid is described.

Lead–Mercurous Acetate Voltaic Cell with Acetic Acid as the Solvent[1]

BY GRADY TARBUTTON AND WARREN C. VOSBURGH

The reproducibility that has been attained in the preparation of voltaic cells with non-aqueous electrolytes is in general less than that of cells with aqueous electrolytes. Among those who have attained a reproducibility of within a few tenths of a millivolt are Brodsky,[2] Afanasiew,[3] Isaacs and Partington,[4] and Harned and Fleysher,[5] all with alcoholic electrolytes, and Yoshida,[6] who set up cadmium–mercurous iodide cells with water, methanol, ethanol, propanol and acetone as solvents. The electromotive forces in most other investigations with non-aqueous electrolytes have been reported only to the nearest millivolt.

It seemed worth while to test the reproducibility of cells with acetic acid as the electrolyte solvent. Hutchison and Chandlee[7] have prepared a series of hydrogen–mercurous sulfate cells with acetic acid as the solvent, but the difficulty of either excluding water entirely or keeping its concentration very constant was involved. The cell chosen for this work was a lead–mercurous acetate cell, which when pure acetic acid is the solvent can be represented as follows

$$Pb(Hg) \mid Pb(C_2H_3O_2)_2 \cdot 0.5HC_2H_3O_2 \mid Pb(C_2H_3O_2)_2 \cdot 0.5HC_2H_3O_2, Hg_2(C_2H_3O_2)_2 \mid Hg$$

Materials and Apparatus.—The purification of the acetic acid and of the lead acetate are described in an earlier paper.[8] Mercurous acetate was

prepared by precipitation and lead amalgam electrolytically, both **from** purified materials.

An oil-bath was used for temperature control. At 25° fluctuations in temperature were not more **than** ±0.01°, but at other temperatures about ±0.02'. Temperatures were measured to within ±0.02".

Electromotive force measurements were made as described by Vosburgh and Elmore.[9]

The cell vessels used were of the "H" form of the sizes given below. For the earlier cells vessel 1 was used. Later, on account of low conductance, vessel 2 was used.

No.	Length, cm.	Width, cm.	Cross arm to base, cm.	Diameter of tube, cm.
1	17	4.7	9	1.1
2	14.8	5.5	4	1.8

Preparation of **the** Cells.—A lead acetate solution was prepared by adding an excess of lead acetate to acetic acid or a mixture of acetic acid and water. The solution was saturated either by mechanical shaking or by heating until the solid was dissolved and then seeding with the proper crystal form.[10] The latter procedure is preferable. By the former the wrong crystal form was introduced into some of the cells, which made considerable delay in the attainment of equilibrium. The solution so prepared is designated below as solution 1. A sample of solution 1 saturated at a definite temperature, usually 30°, was analyzed by the methods previously described. Previous to introducing into the cells, dissolved air was removed from solution 1.

A portion of solution 1 was saturated with mercurous acetate, giving solution 2.

The empty cell vessel, which had been properly cleaned, was placed in a beaker of water at about 75°. Lead amalgam, heated to dissolve the solid phase, was placed in one leg of the vessel, covered with a little of solution 1 and allowed to cool slowly to room temperature along with the water in the beaker. It was shown that rapid cooling gave an amalgam of higher lead activity than slow cooling, and that the difference might amount to over 0.1 mv. By slow cooling, amalgam reproducible to less than 0.01 mv. could be obtained.

The amalgam when cool was washed three times with solution 1. Then a portion of the excess solid lead acetate in equilibrium with solution 1 was placed above the amalgam to form a thick layer. This was covered with solution 1.

Mercury was then placed in the other leg of the vessel and washed three times with solution 2.

---

(9) Vosburgh and Elmore, THIS JOURNAL, 63, 2822 (1931).

(10) See Ref. 8, p. 4539.

Some mercurous acetate was filtered by suction from the solution under which it was kept and washed with solution 2. It was transferred to an agate mortar and mixed well with about a fourth of its volume of lead acetate crystals (some of the excess solid from solution 1) and some solution 2. The paste was then washed three times by decantation with solution 2. A layer of this paste about one centimeter thick was placed above the mercury in the cell vessel.

A thick layer of lead acetate crystals (some of the excess solid from solution 1) was placed above the mercurous acetate paste and enough solution 1 added to fill the vessel to a point above the cross-arm. The upper part of the vessel was flushed out with nitrogen and stoppered with paraffined corks. On top of the corks was poured molten sealing wax or ceresin wax. All cells were made in duplicate.

Electromotive Force Measurements.—It has been shown that three different solid phases can exist in equilibrium with saturated solutions of lead acetate in acetic acid–water mixtures. The cells can be divided into three groups, each group containing a particular solid phase. The electromotive forces over a period of several months are given in Tables I, II and III.

TABLE I

CELLS WITH $Pb(C_2H_3O_2)\cdot 3H_2O$ AS THE SOLID PHASE

Cells	$HC_2H_3O_2/H_2O$[a] ratio by wt.	Electromotive force at 25° 7 Days v.	1 Month v.	6 v.	12–14 v.	15–18 v.
12, 13, 16	0.1969	0.74715	....	0.74729	0.74708	0.74709
17, 18	0.4757	....	0.74480	.74463	.74462	,74462
19, 20	1.144	.73938	.73945	,73921	.73924	....
21, 22	1.552	.73491	.73497	.73444	....	....

[a] The samples analyzed were saturated with lead acetate at 30°. At 25° the ratio would be somewhat larger.

Many of the cells decreased 0.2 to 0.5 mv. between the first and sixth months, but were nearly constant after the sixth month. That the decrease is not continuous is an indication that it is the result of faults of technique. A continuous change might be the result of reaction of the acetic acid with the lead of the amalgam or diffusion of the appreciably soluble mercurous acetate to the amalgam and its reaction with the lead. No evolution of hydrogen at the amalgam was observed. The conductance was sufficient for measuring the electromotive forces to 0.01 mv. The average difference between duplicate cells was 0.07 mv.

Cells 23–26 of Table II decreased appreciably in electromotive force over a period of a year. They may have contained some of the wrong solid phase at the beginning. Cells 38–39 increased. The others changed only a little. Improvements in technique, especially the method of preparing the solutions, were probably responsible for the better results in cells 44–47. The average difference between duplicates omitting cells 25–26 was 0.04 mv.

TABLE II

CELLS WITH $Pb(C_2H_3O_2)_2 \cdot 0.5H_2O$ AS THE SOLID PHASE

Cells	$HC_2H_3O_2/H_2O$ ratio by wt.	Electromotive force at 25° 7 Days v.	1 Month v.	4–6 v.	10–12 v.
38, 39	3.886[a]	0.72846[c]	0.72851"	0.72877	0.72883
23, 24	4.715"	.72807	.72802	.72792	.72767
25, 26	4.932"	.72940	.72897	.72852	.72832
34	5.617[a]	.72772[c]	.72744[c]	,72760	.72763
46, 47	6.746'	.72632	.72632	.72623	....
44, 45	7,730[b]	.72609	.7261	.72614	....

[a] The samples analyzed were saturated at 30°. [b] The samples analyzed were saturated at 25°. [c] Calculated from measurements at 30°.

The solubility of lead acetate was large in the range of the cells of Table II. The solutions were quite viscous, and the conductance was such in some cases that it was difficult to read the electromotive force to better than 0.1 mv. The use of the larger cell vessels helped in this respect.

It can be seen that the electromotive force changes quite appreciably with change in the ratio of acetic acid to water in the electrolyte. This shows that the solid phase is a solvated compound, in agreement with the analytical data presented in the earlier paper.

TABLE III

CELLS WITH $Pb(C_2H_3O_2)_2 \cdot 0.5HC_2H_3O_2$ AS THE SOLID PHASE

Cells	$HC_2H_3O_2/H_2O$ ratio by wt., 25°	Electromotive force at 25° 7 Days v.	1 Month v.	3 v.	6 v.
42	10	0.7268	0.7270	0.7272	0.7272
43	10	.7271	.7270	.7272	.7272
40	26	.7216[a]	.7279	.7279	.7279
41	26	.7216[a]	.7279	.7279	.7279
48	90[b]	.72902	.72903	.72900	...
49	90[b]	.72908	.72903	.72902	...
54	..[c]	.72895[d]	.72864[d]	.72908	...
55	..[c]	.72895[d]	.72866[d]	.72908	...

[a] These cells had fine needle-like crystals when prepared. After a week the cells were opened and seeded with the stable solvated crystals. The solid phase began to change over immediately, and the electromotive force became constant within a few hours. [b] The solution was nearly anhydrous; the ratio is subject to considerable error of method. [c] The solution was made to duplicate that of cells 48–49, but was not analyzed. [d] Calculated from measurements at 30°.

With regard to constancy and reproducibility the cells of Table III were the most satisfactory yet considered. Cells 42–43 were not as good as the others at first, but became constant later. Cells 40–43 had so much solid phase in them that the resistance was high and the electromotive force could not be measured to better than ±0.05 mv. Cells 48–49 and 54–55 had not as much solid phase and could be measured more precisely.

The change in electromotive force with composition again shows that the solid phase is solvated. As the water content decreases, the solubility of lead acetate decreases rapidly, and the mole fraction of acetic acid increases. The increase in electromotive force with increase in mole fraction of acetic acid would be expected if the solid phase is an acetic acid solvate, because in this case acetic acid is one of the reactants in the cell reaction. The cell data again confirm the solubility results previously reported.

The electromotive force of cells **4041** after seven days is of interest. These cells contained a solid phase obtained by spontaneous crystallization from a supersaturated solution. It consisted of fine needle-like crystals. The electromotive force after seven days is nearly in agreement with that of an earlier pair of cells, which was **0.72166** and **0.72173** v., respectively. These latter cells were made with an electrolyte containing quite a bit of water and with dehydrated lead acetate as the solid phase. The constant electromotive force with the different composition in the two pairs indicates that both had the unsolvated salt as the solid phase.

The unsolvated lead acetate of cells 40–41 changed over to the solvated form on being seeded, and the electromotive force increased. The electromotive force of the earlier cells increased slowly without seeding.

While the electromotive force is dependent on the composition of the solution in all the cells having stable solid phases, it should be noted that at the transition points the composition is fixed when both solid phases are present. Eight cells were made with the two hydrated solid phases in equilibrium with the saturated solution. The solutions did not have the composition of the transition point when first prepared but approached it gradually after the cells were set up. The cells were not constant at first and did not agree until constancy was attained.

TABLE IV

CELLS WITH BOTH $Pb(C_2H_3O_2)_2 \cdot 3H_2O$ AND $Pb(C_2H_3O_2)_2 \cdot 0.5H_2O$ AS SOLID PHASES, 25°

Cells	Initial v.	7 Days v.	1 Month v.	6 v.	12 v.
27	*0.72994*	*0.72974*	*0.73002*	*0.73033*	*0.73031*
28	.72994	.72922	.72956	.73018	.73032
36	.72929[a]	.72992[a]	.73011[a]	....	....
37	.72937[a]	.73001[a]	.73019[a]	.73018	.73017
50	.73098	,73055	.73015	....	....
51	.73068	.73047	.73017	....	....
52	.73088[a]	.73078[a]	.73072[a]	.73044[b]	....
53	.73090[a]	.73078[a]	.73073[a]	.73044[b]	....

[a] Calculated from measurement at 30°. [b] Three months.

It can be considered that the reaction for the cells of Table IV does not involve the electrolyte. The anhydrous lead acetate produced by reaction of lead with mercurous acetate must become hydrated at the expense of the trihydrate present, since the composition of the solution cannot change. The reaction, therefore, is

$$5\text{Pb(amalgam)} + 5\text{Hg}_2(\text{C}_2\text{H}_3\text{O}_2)_2 + \text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2\cdot 3\text{H}_2\text{O} \longrightarrow 6\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2\cdot 0.5\text{H}_2\text{O} + 10\text{Hg} \quad (1)$$

The change of electromotive force with temperature was therefore determined in order to calculate the heat of reaction.

TABLE V

CHANGE OF ELECTROMOTIVE FORCE WITH TEMPERATURE

	$E_t - E_{25}$						
Cells	t = 16° mv.	20° mv.	30° mv.	35° mv.	40° mv.	45° mv.	50° mv.
27–28	−1.02	−0.59	0.20	0.50	0.77	0.97	0.76
36–37	−0.63	− .18	.20	.53	.70	0.82	.91
Calcd.	− .45	− .25	.25	.50	.75	1.00	. .

The variation with temperature is linear within the limits of error and follows the relationship

$$E_t = E_{25} + 0.000050(t - 25)$$

as shown in the table.

For the cell Pb(Solid)/Pb^{++}/Pb(Hg) Gerke[11] found the value $E = 0.0057 + 0.000016\ (t - 25)$. Combining the two cells gives the electromotive force of the lead–mercurous acetate cell with a solid lead electrode, of which the electromotive force is $E = 0.7359 + 0.000066\ (t - 25)$. Application of the Gibbs–Helmholtz equation gives $\Delta H = -165.26$ kg. cal. with an uncertainty of not more than 0.2 kg. cal. If this is substituted in Equation 1 along with the values for the heats of formation of lead acetate trihydrate and mercurous acetate, namely, 446.12 and 203.34 kg. cal., respectively,[12] the heat of formation of $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2\cdot 0.5\text{H}_2\text{O}$ is found to be 271.35 kg. cal. The precision of this value depends mainly on that of the heats of formation of lead acetate trihydrate and mercurous acetate.

The temperature coefficients of the other cells were determined also. The cells with the higher water concentrations had negative temperature coefficients. The temperature coefficient approached zero as the ratio of acetic acid to water increased, and was positive for the cells with the higher ratios. It is interesting to note that a cell with the trihydrate as the solid phase and a ratio of acetic acid to water a little larger than that of cells 21–22 should have a zero temperature coefficient.

In connection with the temperature coefficient measurements, during which the cells were heated to 52°, no tendency of any of the solid phases to change to a more stable form was noted.

Summary

Lead–mercurous acetate voltaic cells have been set up with solvents covering a wide range of acetic acid–water mixtures and including nearly anhydrous acetic acid, and with three different solid phases.

[11] Gerke, THIS JOURNAL, 44, 1684 (1922).

[12] "International Critical Tables," Vol. V, pp. 184, 187

Duplicate cells with nearly pure acetic acid as the solvent could be reproduced to within 0.1 mv. and were constant in electromotive force for several months at least.

A cell containing two solid phases in equilibrium with the saturated solution was prepared.

The heat of formation of the compound $Pb(C_2H_3O_2)_2 \cdot 0.5H_2O$ was determined.

The Viscosity of Aqueous Solutions as a Function of the Concentration

BY GRINNELL JONES AND SAMUEL K. TALLEY

It has long been known that the viscosity of aqueous solutions is approximately a linear function of the concentration. In 1876 Sprung[1] published measurements on many salts at many temperatures. His viscosity–concentration curves are approximately linear but have an upward trend at higher concentrations which indicates an increasing deviation from a linear limiting law. Arrhenius[2] also found that the linear relationship holds approximately over the lower part of the concentration range but that the viscosity increases more rapidly than the concentration at high concentrations. He proposed an equation which is reducible to the form $\eta = A^c$, η is the relative viscosity compared to that of water at the same temperature and A is an empirical constant for any salt and temperature. This equation has been much used by later experimenters although it is only a rough approximation.

Most salts give solutions with viscosity greater than that of water at all concentrations. Some salts (including most but not all of the iodides, bromides, chlorides, bromates, chlorates, nitrates and thiocyanides, of cesium, rubidium, potassium, ammonium, thallium and hydrogen) give solutions having a viscosity less than that of water.[3] In such cases it is usual for the viscosity–concentration curve to go through a minimum and for some salts at sufficiently high concentrations the viscosity may become greater than that of water. This type of curve cannot be reproduced by the Arrhenius equation.

(2) S. Arrhenius, Z. *physik. Chem* , *1*, 285 (1887).

(3) A. I. Rabinovich, THIS JOURNAL, 44. 954 (1922), discusses the hypotheses which have been suggested to account for this phenomenon An interesting suggestion has recently been made by Z. W. Wolkowa and W. S. Titow [*Z. physik. Chem* , **A155**, 53 (1931)], who say "We may therefore suspect (vermuten) that an aqueous solution can only have a greater fluidity than water if the heat of dilution is negative."

Einstein[4] in **1906** deduced from the principles of hydrodynamics that if the solute could be regarded as made up of spherical incompressible uncharged particles which are large in comparison with the molecules of the water the viscosity of the solution would be $\eta = 1 + 2.5\,\Theta$, where Θ is the total volume of the solute particles per unit volume of solution. This equation obviously connotes a linear relationship between viscosity and concentration.

Finkelstein[5] extended Einstein's treatment to solutions of binary electrolytes in polar solvents. He investigated mathematically the effect on the viscosity of the relaxation time of the solvent dipoles and concluded that the electric influence of the ions on the polar solvent will increase the viscosity proportionally to the concentration. Neither Einstein nor Finkelstein account for the fact that some solutes diminish the viscosity of water.

Grüneisen,[6] who improved the experimental technique and extended his measurements to greater dilution than his predecessors, found that for sucrose the linear relationship is valid; but that for salts, deviations from the linear law became more pronounced at low concentrations instead of disappearing. Griineisen made the deviation from linearity evident by plotting $(\eta - 1)/c$ against c (or some root of c for the sake of spreading out the points at the lower concentrations). This method of plotting would give a horizontal straight line if the linear relationship held. His curves, however, show a pronounced negative slope at low concentrations, pass through a minimum at about **0.2** normal and then have a slight positive slope and positive curvature at higher concentrations. We shall call the departure of the viscosity–concentration curves from linearity at high dilutions the Griineisen effect. However, Griineisen's attempts to give a theoretical explanation of the failure of the linear law at high dilutions, on the basis of Arrhenius' theory of electrolytic dissociation, and to derive an equation expressing the viscosity as a function of the concentration were unsuccessful.

Later workers, especially Schneider, Applebey and Merton,[7] found the Grüneisen effect with other salts, but they did not give a satisfactory interpretation or derive a valid equation for the variation of the viscosity with the concentration.

Measurements of the viscosity of solutions of barium chloride were undertaken in this Laboratory by the senior author and Malcolm Dole[8] on account of their interest in these data in connection with the phenomena

(8) Grinnell Jones and Malcolm Dole, THIS JOURNAL, 51, 2950 (1929). This paper contains a more detailed discussion of the Gruneisen effect

of electrolytic conductance and for this purpose were carried to a high dilution (0.005 molal). These measurements showed that the Grüneisen effect is magnified at great dilution. Analysis showed that in this case the fluidity-concentration curve has a simpler form than the viscosity–concentration curve. It was pointed out that, although the principal effect of the dissolved salts on viscosity is proportional to the concentration, the curvature (discovered by Grüneisen) in the dilute end of the viscosity–concentration (or fluidity–concentration) curves proves that there is another effect of the dissolved salt which is of relatively greater importance in dilute solutions. The Grüneisen effect always tends to increase the viscosity regardless of whether the sum of all of the effects of the salts is to increase or decrease the viscosity.

It then occurred to Jones and Dole that the Debye–Hückel theory of interionic attraction might be extended by applying it to this problem. The electric forces between the ions tend to establish and maintain a preferred arrangement of the ions and resist any distortion of the preferred arrangement and thus stiffen the solution or increase its viscosity. Although they did not succeed in deriving an equation for the viscosity as a function of the concentration which makes adequate allowance for the Grüneisen effect by rigid deduction from fundamental postulates of the Debye–Hückel theory, they inferred that the effect would be proportional to the square root of the concentration. This idea together with the knowledge that, for salts which increase the viscosity of water, the fluidity is approximately a linear function of the concentration suggested an equation of the form $\varphi = 1 + A\sqrt{c} + Bc$; where φ is the fluidity (*i. e.*, the reciprocal of the relative viscosity) and A would be expected to be negative for all electrolytes but zero for non-electrolytes. The value of B may be either positive or negative in different cases. The equation $\varphi = 1 - 0.02013\sqrt{c} - 0.20087\,c$, was found to fit their data for barium chloride over the whole range from 0.005 to 1 molal. It was furthermore found that the equation is consistent with the best data on other salts available in the literature, although the scarcity of precise measurements at low concentrations hindered a rigid test of the general validity of the equation.

The manuscript of the paper by Jones and Dole was then taken to Debye by Dole during the summer of 1929. Debye suggested that the problem could be attacked by modifying the fundamental differential equation of Onsager to allow for the viscous flow. With the inspiration of Debye's interest and suggestions, Falkenhagen and Dole[9] then attacked the problem deductively and found a partial solution. In order to simplify the problem it was at first assumed that only a binary salt is present and that the anion and the cation have the same mobility. The result was an equation,

(9) H Falkenhagen and M Dole, *Z physik. Chem.*, [B] 6, 159 (1929); *Physik. Z.*, 30, 611 (1929)

$\eta = 1 + A\sqrt{c}$, which was, however, regarded only as a limiting law for extreme dilution. It is obvious that A in this equation is the same as the A in the Jones and Dole fluidity equation with a reversed sign. Later the mathematical difficulties of a more general treatment were overcome by Falkenhagen,[10] who derived an equation of the same form, but with a more explicit evaluation of the coefficient A, applicable to any salt with ions of any valence and any mobility.

The deductive treatment of Falkenhagen is a substantial advance over the inductive treatment of Jones and Dole in that the coefficient A is given as a complicated but explicit function of the mobilities and valences of the ions, the temperature, and the universal constants which commonly appear in the equations derived from the Debye-Hückel theory. Falkenhagen and Vernon have computed the value of A for a number of salts. However, the deductive reasoning of Falkenhagen did not give the linear term, which is numerically greater than the square root term except at extreme dilutions. On the other hand, the inductive reasoning of Jones and Dole has given a new law for the relationship of viscosity to concentration which appears to be valid over a substantial range of concentration.

The original paper of Jones and Dole contains the following statement: "It may be predicted from our equation that at very low concentrations the viscosity of solutions of all strong electrolytes will be greater than that of water, including salts which at moderate concentrations show diminished viscosity. So far as we are aware, the only published measurement which shows that even those salts which cause diminished viscosity at moderate concentrations will give an increase in viscosity at extreme dilutions is by Schneider, who reports a relative viscosity of 1.0008 for 0.05 *N* potassium chlorate, and a viscosity of less than 1 for solutions of 0.1 to 0.5 *N* potassium chlorate. We expect to test this prediction experimentally in the near future."

Schneider makes no comment on the significance of his recorded observation that 0.05 *N* potassium chlorate has a viscosity greater than 1 whereas stronger solutions have a viscosity less than that of water.

Since the publication of the prediction by Jones and Dole quoted above, Joy and Wolfenden[11] have tested this prediction by means of new data on potassium chloride, rubidium nitrate, potassium chlorate, and nitric acid at both 18 and 35°. They have confirmed the prediction for the three salts at 18° and for rubidium nitrate at 35°, but have found that nitric acid increases the viscosity at all concentrations at both of these temperatures, and potassium chloride and chlorate behave likewise at 35°. Incidentally they found that Schneider's figure of 1.0008 for the viscosity

of 0.05 N potassium chlorate at 18° is an experimental error. Their measurements show that at this concentration and temperature the viscosity is really less than that of water and that a viscosity greater than that of water is only found at concentrations less than 0.008 N.

The primary object of the present investigation was to test the validity of the prediction of Jones and Dole that all salts will give solutions which have a viscosity greater than that of water if measured at sufficiently great dilution, even including those salts whose solutions exhibit diminished viscosity at moderate concentrations. Secondary objects were to collect additional data to test the general validity of the Jones and Dole equation, to compare the values of A found experimentally with the value computed by the formula of Falkenhagen and Vernon, and to test more rigorously the conclusion drawn from existing data that the square root term is absent for non-electrolytes.

In order to accomplish our primary object it was evidently necessary to measure the relative viscosity of extremely dilute solutions with high precision. The analysis of the meager existing data on salts which give solutions having a viscosity less than that of water indicated that the maximum in the viscosity–concentration curves would probably be less than 0.1% greater than that of water. Therefore data reliable to 0.01% or better are needed.

The earlier measurements on viscosity in this Laboratory had been carried out by observing the movement of a meniscus past a mark on the viscometer and tapping a key with the hand to record the instant of transit on the moving tape of a chronograph. Our experience with this method made it clear that the greatest source of error was that due to an inexact coordination of the eye and hand. We therefore undertook to eliminate this psychological error entirely by substituting a photoelectric cell and its amplifier and other accessories for the human eye, brain, nerves and hand, in the hope that a more precise record of the time of transit of the meniscus in the viscometer could be obtained.

Experimental

A new viscometer of quartz of the Ostwald type was made for this investigation at the Lynn Works of the General Electric Company. The workmanship is extraordinarily good and our exacting specifications were met with astonishing precision. It is shown in Fig. 1.

In order to avoid any surface irregularities which might cause irregular drainage the tube from which the bulb, B, was made was ground and polished internally before being drawn down and sealed to the tubes C_1 and C_2. Care was taken that the end portions of the bulb connecting the side walls of the bulb and the constriction should have sufficiently steep slopes at all points to give good drainage over the entire surface.

The time of flow was determined by timing the transit of the meniscus past fixed points in the upper and lower constrictions C_1 and C_2. The diameter of these tubes is an important detail. By making them narrow the rate of motion of the meniscus is increased and therefore the event to be timed is made more definite. On the other hand, if the tube C_1 is made too narrow the liquid draining from the upper wall after the passage of the meniscus will bridge across the tube and will obstruct the entrance of air into the bulb. Of course this obstruction will soon be broken by the suction of the receding liquid, but the drop of liquid will immediately be drawn back into the capillary tube by its surface tension. This process repeats itself indefinitely. The result is an extra irregular back pressure which gives erratic and erroneous results. The tube C_1 must, therefore, be wide enough to remain free of drops after the meniscus has passed. After some preliminary trials with tubes of various diameters we specified a diameter of 10 mm. for this tube with satisfactory results. The lower tube C_2 should be of the same diameter so that the two transits which are to be timed shall be as nearly identical as possible. The tubes C_1 and C_2 were therefore made from the same piece of tubing. The ground joints connecting the upper Pyrex cross piece with the viscometer were placed on the outside of the viscometer because this construction minimizes the danger that ground glass or grease will get into the viscometer. The more important dimensions are the average hydrostatic head, 22.8 cm.; the volume of the upper bulb, 10.063 ml.; the length of the capillary, 18.5 cm.; the diameter of the capillary, 0.0476 cm. The period with water at 25° is approximately 618 seconds.

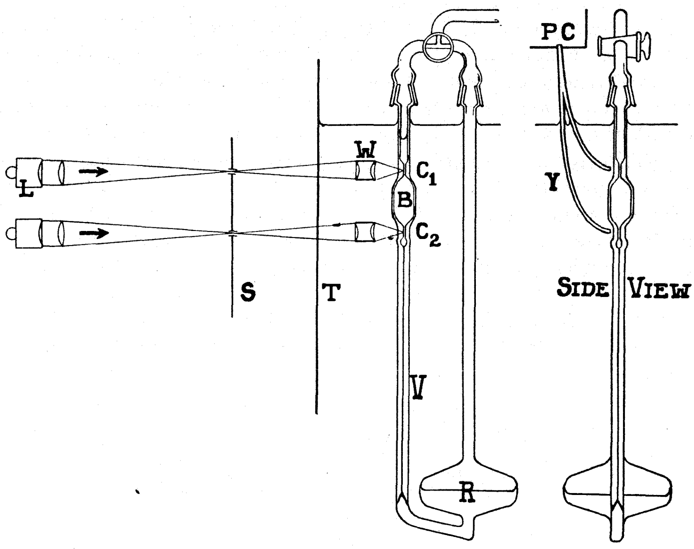

Fig. 1.—Viscometer and optical system.

The viscometer was mounted permanently in a stout brass frame and was always handled in its frame. It is important that after the instrument is removed from the thermostat for cleaning and refilling it shall always be put back in a definite reproducible position so that the hydrostatic head shall be constant. The frame was therefore held at only three points against a strong well-braced support which was designed to give mechanical stability with minimum of interference with the circulation of the water of the thermostat.

Since the viscosity of water changes about 2% per degree, the thermostat used must be of high quality. Our thermostat apparently maintained its temperature within 0.001° but the means used to obtain this constancy need not be described in detail since they are not novel. Our thermostat was set at 25.00° for all of the measurements recorded in this paper. Since the temperature coefficient of a dilute solution will not vary greatly from that of water the absolute value of the temperature does not have to be known with great precision.

The most novel feature of our viscometric procedure was the development and use of automatic timing of the transit of the meniscus by means of a photoelectric cell. The method of timing finally adopted was based on the total internal reflection of a beam of light at the quartz-air interface which is formed in the constriction at the instant of the transit of the meniscus. This method requires a beam of light which is as narrow as possible vertically but broad enough horizontally to cover at least half of the tube C_1 and which can be focused at a definite reproducible height on the tube C_1. The source of light was an automobile head-light bulb (6 candle power, 6 volts) with a straight tungsten filament which was mounted so that the filament would be horizontal. In order to secure more intense illumination the bulb was operated with 10 volts instead of its rated 6 volts. The light passed through a condensing-projecting lens, L (a Bausch and Lomb, series II Cinephor with an effective focal length of five inches and a relative aperture of 3.5) and was brought to a primary focus outside the thermostat, as shown in Fig. 1. A screen with a horizontal slit was placed at this focus. This helped greatly in obtaining a beam which was narrow vertically at the viscometer. The diverging beam from the slit passed through a plate glass window in the side of the thermostat and then through a double lens, W, which brought the beam to a focus on the viscometer at C_1. In order to increase the relative aperture without increasing the aberrations the parts of the final double lens were mounted in a water-tight cell so that their more refractive inner surfaces were in contact with the enclosed air and the outer surfaces were in contact with the water of the thermostat This lens when mounted as described in water had an effective focal length of 75 millimeters and a relative aperture of 2.5. A single lamp and projecting lens, L, served for both the upper and lower meniscus by mounting them in an elevator provided with suitable stops. The final double lenses, W, and slit in the screen, S, were duplicated so that each constriction C_1 and C_2 had its own lens and slit which remained in a fixed position. The double lenses were especially made for us by the firm of Pinkham and Smith of Boston We wish to thank Mr. John A. Seaverns of this firm for his help in the construction of this optical system.

The optical effect which forms the basis of our new method of timing is shown diagrammatically in Fig. 2.

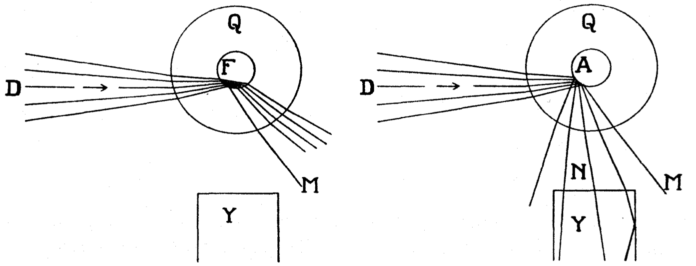

Fig. 2.—Principle of optical effect at meniscus transit.

When the narrow horizontal beam of light, D, strikes the quartz–water interface at the capillary tube inside C_1 most of the light will pass into the water, F, inside the capillary and finally emerge into the water of the thermostat nearly opposite where it entered the quartz. A small portion of the light beam which strikes the interface at a sufficiently acute angle will suffer total internal reflection as shown (M) but will miss the collecting rod of quartz, Y. However, as soon as the meniscus has passed below the light beam the water inside the capillary will be replaced by air, A, and as a consequence the critical angle for total internal reflection will be greatly changed, and therefore a much larger portion of the beam will suffer a total internal reflection to the side as shown at N in Fig. 2 and will emerge from the quartz tube into the water of the thermostat at an angle from the entering beam. The light thus diverted sideways enters the end of a quartz collecting rod, Y, which is suitably mounted near C_1 and C_2, and passes through the rod lengthwise to the photoelectric cell. The light cannot emerge into the water of the thermostat owing to total internal reflection provided the curves in the rod are not too sharp.

The two quartz collecting rods from the two constrictions were joined together in the form of a Y as shown in Fig. 1. The upper end of the quartz rod entered a light-tight box where the photoelectric cell was mounted. The invention of this method of producing a side-wise reflection of the light at the moment of transit of the meniscus and the device of leading this reflected light out of the water of the thermostat to the photoelectric cell by means of a quartz rod are the essential novel features of our method of timing. It was developed only after patient experimentation and adopted after critical comparison with other procedures which proved to be less satisfactory. The development of the rest of the apparatus to record the time accurately, although laborious and expensive, was comparatively speaking a routine matter. We used the photoelectric cell made by the General Electric Company and designated by them as type PJ-23. It is more sensitive than any other cell which we tried. Dr. R. F. Field and Mr. Horatio Lamson of the General Radio Company kindly brought their new type of stretched wire oscillograph to our laboratory and made some measurements on the current given by the photoelectric cell both when using the optical effect described above and when using other effects which proved to be less useful and are therefore not described here. These oscillographic tests showed that, when operating as described above, about 0.05 second was required from the time when the current from the photoelectric cell could be first detected until it reached its maximum value. This presumably measured the total time of transit of the meniscus through the height of the beam of light. This does not mean, however, that there is an error or uncertainty of this magnitude in our final results because the electromagnetic recording device operated when the current attained a definite value less than the maximum. We are measuring the difference in time between two very similar transits and the recording device operated at the corresponding stage of the two transits and thus gave the interval correctly. Moreover, we always compared the time of flow of a dilute solution with that of water so that any constant errors would be canceled out of the results.

The power output from a photoelectric cell is too small to operate the chronograph needle directly and must therefore be amplified. There are difficulties in amplifying a current which takes 0.05 second to build up from zero to its maximum, which corresponds to a frequency of 5 cycles per second, but they can be overcome. The amplifier finally built uses three audion tubes with resistance–capacitance coupling and a minimum of inductance. It is shown diagrammatically in Fig. 3. The types of tubes and the voltages used are shown in the figure. The best values for the resistances and capacitances indicated in the diagram will depend to some extent on the individual tubes. In our apparatus R_1 was 20 megohms, R_2 and R_4 were each 2 megohms, and R_3 and R_5 were 1 megohm each, C_1 and C_2 were 2 microfarads. When the meniscus transit occurs the electric impulse from the amplifier through the chronograph was about 20 milliamperes. The photoelectric cell and entire amplifier, except the batteries, was contained in an electrostatically shielded box mounted immediately over the thermostat. We do not claim that this amplifier is the best possible design but merely that it worked satisfactorily. Figure 3 also shows a switch, CK, which when closed connected the clock to the chronograph and recorded seconds on the tape; and a tapping key, IK, which permitted the operator to make a mark on the tape at will to identify or call attention to any particular signal from the clock or photoelectric cell.

Our timing depended on a pendulum clock of good quality made by the Gaertner Scientific Company of Chicago and described in their catalog under Number *L1013*. The invar pendulum carried a platinum tip which swung through a small trough of mercury, thus closing, once every second, an electric circuit including a battery and the chronograph. It seems improbable that the rate of this clock varied sufficiently during any day to cause an error of 0.01 second in 618 seconds.

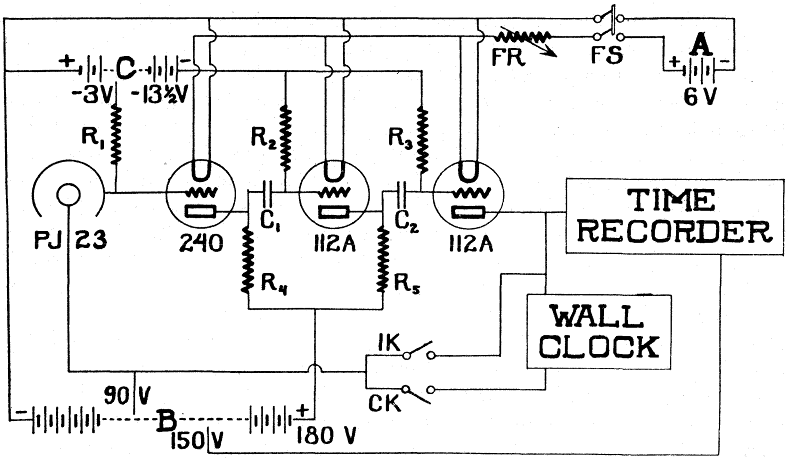

Fig. 3.—Photoelectric cell, amplifier and electrical connections

The chronograph used was a Duplex Syphon Recorder made by the General Radio Company of Cambridge and designated by them as type 456. It had a moving paper tape (stock market ticker tape) which had an idling speed of 2.5 cm. per second and a recording speed of 30 cm. per second. It had two independent siphon pens operated by electromagnets which required about 5 milliamperes more or less dependent on the adjustment of the spring of the armature. It is estimated that the lag in these pens was not more than 0 001 second. One pen recorded the transits of the meniscus, the seconds given by the pendulum clock, and the marks manually impressed by the key, IK, to identify the seconds of the clock. The other pen recorded the seconds and tenths of seconds given by another clock driven by a synchronous electric motor. This electric clock was made by the General Radio Company and is their type 511S. The rate of this clock depended on the frequency of alternations of the power supplied by the Cambridge Electric Light Company. The records of this clock were only used to subdivide the full seconds given by the pendulum clock. Unless the rate of this electric clock varied by more than 1% within the second in which the transit of the meniscus occurred, its records are reliable to within 0.01 second for the purpose of subdividing the full seconds. With this arrangement the velocity of the paper tape would have to vary by 10% within the 0.1 second in which the transit occurred to cause an error of 0.01 second. It seems probable that the timing mechanism was reliable to within 0.01 second.

After many months of apparently fruitless effort and disappointments following changes in the equipment, the eventful day arrived when seven successive runs with water gave results for the time of flow which differed by only 0.01 second between the highest and lowest of the seven, out of a total of 618 seconds. This demonstrated that the optical effect of the passage of the meniscus was sufficiently definite and that the timing mechanism and temperature control were adequate. But these observations were made on one filling of the viscometer. The problem of cleaning ahd refilling the viscometer without changing the period still gave us much trouble and indeed has not yet been completely solved. Absolute cleanliness is essential as a trace of grease or dust will give erratic results. Cleansing reagents can make as much trouble as the more obvious forms of dirt. Indeed on one occasion the period increased from one filling to the next by nearly a second and the new high value for the period persisted for about two months in spite of drastic cleaning and then suddenly and inexplicably returned to its old value. The most plausible hypothesis to account for such a large change is that a speck of dust had become lodged in the capillary although it was not revealed by careful inspection. We have found it essential that every thing which enters the viscometer (water, solutions, cleansing reagents, and the air used to dry the instrument) should be filtered through a sintered glass filter or a platinum sponge filter. The sintered glass filter was made for us of Pyrex glass by H. E. Bent.[12]

If the volume of the working liquid is varied the hydrostatic head will change and this will influence the period. Therefore we filled the viscometer by means of a special pipet with a goose-neck delivery tube designed to deliver as definite a volume as possible each time and yet permit the actual volume delivered in each experiment to be determined by weighing the pipet to milligrams before and after filling the viscometer. If the amount actually delivered differed by a significant amount from the standard volume (about 60 ml.) a correction to the measured time was applied, based on the results of special experiments showing that a surplus of 0.013 ml, caused the time of flow to be increased by 0.01 second. After skill in the manipulation of the pipet had been acquired by practice the volume correction averaged less than 0.01 second. The delivery tube was broken accidentally twice during the experiments and after being repaired delivered a slightly different standard volume which caused a corresponding difference in the water value. The water value was also changed by slight but significant amounts in the course of the work by adjustments in the optical system, by remounting the viscometer in its frame, and by a redetermination of the 25° mark on the Beckmann thermometer after it had been lost by overheating. All of these changes, however, affect the solutions to the same extent as the water. Since we could not be sure that the water value would remain unaltered it was our invariable practice to measure water and a solution alternately and always measure the water at least once on the same day that the solutions were measured. After the technique had been perfected successive measurements of the time of flow without refilling rarely differed by more than 0.02 second and different fillings made on different days usually agreed within 0.03 second although occasionally much greater variations occurred for the reasons explained above. The viscosity of the solutions is computed with a water value determined within four hours of the time of measuring the solution instead of an average (or standard value) and the results for the relative viscosity of the solutions thus obtained are more consistent than can be obtained by assuming the water value to be unchanged.

The kinetic energy correction was applied to the results in all cases in which it amounted to 0.001% or more, in accordance with a method suggested by Bingham.[13] The greatest correction which needed to be applied was only 0.00013 in the case of 0.02 molal sucrose solution.

The density of the solutions enters into the calculations of the relative viscosity as a direct factor and therefore needs to be known with the same precision as the time of flow. For this reason the density of all of the solutions was determined by the use of pycnometers of about 50 cc. capacity. The densities were determined with greater precision than the time of flow could be determined.

Materials.—The water used both for making up the solutions and to determine the period of the viscometer was conductivity water, collected in contact with the laboratory

[13] E. C. Bingham, "Fluidity and Plasticity," McGraw-Hill Book Co., Inc., New York, 1922, p. 18.

air and kept in large Non-Sol bottles. Its conductivity was determined before it was used and if the conductivity was found to be abnormally high the water was rejected. The average conductivity was 1.0×10^{-6} at 25°. All of the materials used are believed to have contained no impurities in sufficient amounts to affect the results measurably. The most dangerous impurity would be specks of dust. The purest salts available by purchase were dissolved, filtered through sintered glass filters, crystallized, drained and washed in platinum Gooch crucibles in a centrifuge. This entire process was repeated several times for some salts, but not in all cases, depending on the purity of the salts as judged by the color in the flame or other tests. Potassium chloride was fused and the other salts subjected to prolonged drying in vacuum desiccators. The cesium nitrate was kindly prepared for us from the mineral pollucite by Professor Brainerd Mears of Williams College. Spectroscopic and chemical tests showed that this material was of the highest quality.

Two non-electrolytes, sucrose and urea, were studied in order to test the theoretical prediction that the viscosity-concentration curves for electrolytes and for non-electrolytes would have an essentially different shape at low concentrations. It was, therefore. especially important to ensure that these materials should be as free as possible from electrolytes. This was, of course, easily tested by measuring the conductivity of the solutions. The sample of sucrose was estimated by conductimetric analysis to contain about 0.001% of electrolytes which could not influence the viscosity measurably. Since dilute sucrose solutions are liable to change by inversion or fermentation, the solutions were measured as promptly as possible after they were prepared. A special experiment showed no measurable change in viscosity after standing for forty-eight hours.

Sterling's C. P. urea was treated twice by the procedure described above for salts. Solutions of urea may be slowly hydrolyzed to form ammonium carbonate, and this change was easily detected by a slow change in the conductivity.

The conductivity of our freshly prepared solution indicated that it had hydrolyzed to the extent of nearly 0.002%, which increased to nearly 0.02% after standing for twenty-four hours in the conductance cell (in contact with the platinum electrodes which may have catalyzed the reaction). The strongest urea solution measured was 0.2 molal and even assuming 0.02% hydrolysis, which is probably an overestimate since the viscosity measurements were made promptly after preparing the solution, the concentration of the ammonium carbonate would have been only 0.00004 molal and therefore could not have influenced the viscosity measurably.

The solutions were prepared by weighing out the solute and making up the solution to 1 liter in a volumetric flask at 25°.

The data on the solution of 0.1 *N* potassium chlorate are given in considerable detail in Table I in order to show the concordance of the data obtainable with our new procedure.

The first line gives the concentration, *c*, of the solution in moles per liter at 25° and the date of the experiment; the second line gives the density at 25°, based on 0.997074 for the density of water at the same temperature with the letters B, C, D designating the different pycnometers used and av. the average. The numbers 1, 2, 3, designate the successive measurements of the time of flow on the same filling of the viscometer. The viscometer was filled with solution giving the results shown in the second column, then washed and dried and filled with water giving the results shown in the third column and again filled with another portion of the same solution giving the results shown in the fourth column. The figures designated by wt. are the weights of water or solution delivered by the filling pipet. The next line gives the volume correction (v. c.) in seconds to correct for the influence on the measured time of the variations in average hydrostatic head. The next line gives the average time of transit, t, with the volume correction applied. The next line gives the apparent viscosity, d_ct_c/d_0t_0, before the kinetic energy correction has been applied, and the last line gives the corrected relative viscosity, η, after applying the kinetic energy correction.

which they are based show that the prediction of Jones and Dole that even those salts which decrease the viscosity of water at moderate concentration will give an increased viscosity at sufficiently low concentration has been confirmed experimentally at 25° for five salts, potassium chlorate, potassium chloride, ammonium chloride, potassium nitrate and cesium nitrate.

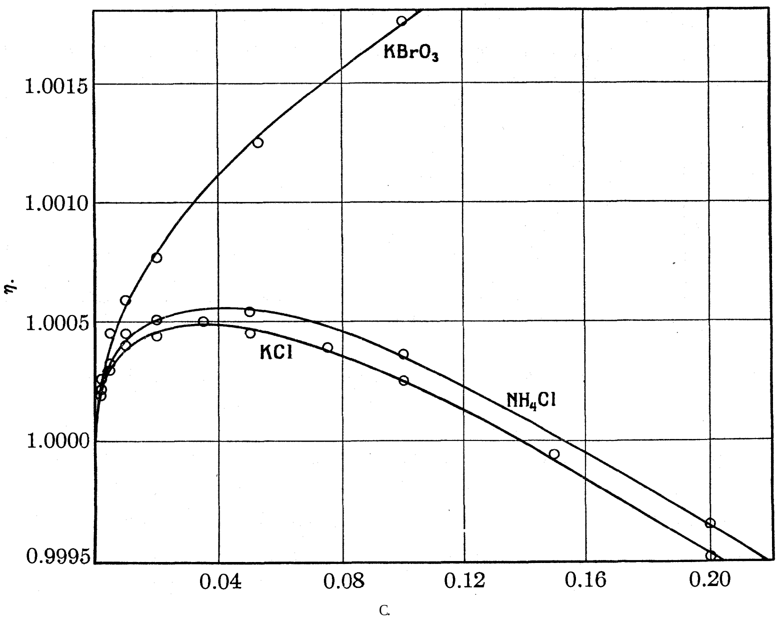

Fig. 4.—Relative viscosity-concentration curve for potassium bromide, ammonium chloride and potassium chloride.

In addition, the prediction has been confirmed by Joy and Wolfenden for potassium chloride, potassium chlorate, and rubidium nitrate at 18° and for rubidium nitrate at 35°. In the case of potassium bromate the viscosity remains greater than that of water throughout the range of concentration covered by our experiments (up to 0.1 molal).

Jones and Dole demonstrated that for barium chloride, which is presumably typical of the salts which increase the viscosity of water, the fluidity–concentration curves have a simpler form than the viscosity–concentration curves and that the equation $\varphi = 1 + A\sqrt{c} + Bc$ is valid up to 1 molal.

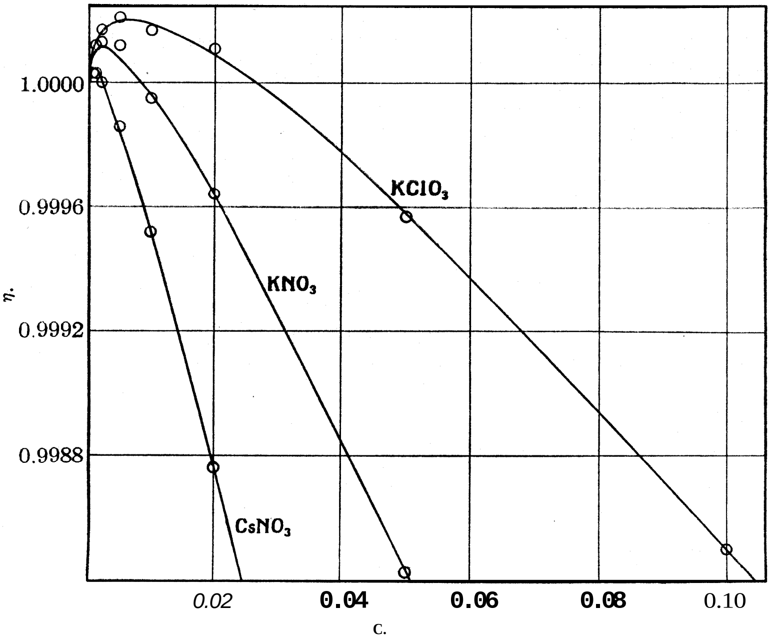

Fig. 5.—Relative viscosity–concentration curve for potassium chlorate, potassium nitrate and cesium nitrate.

In this equation A is expected to have a negative value for all salts and B may be either positive or negative, depending on the salt and temperature. On the other hand, for salts which diminish the viscosity of water this equation is probably not generally valid beyond 0.2 molal. For such salts it will probably be better to use an equation of similar form in terms of viscosity, namely, $\eta = 1 + A\sqrt{c} + Bc$, where the A is the same as the A in the fluidity equation except for a reversed sign, and the B will also be reversed in sign and identical in value within the limit of error to which B has yet been determined. The substantial equivalency of the two forms for dilute solutions ($c << 1$) will be apparent by replacing φ by $1/\eta$ and taking the reciprocal of both sides of the equation, making due allowance for the fact that *A* and B are much smaller than unity for all salts yet studied. When the equation is stated in terms of viscosity *A* is expected to be positive for all salts and zero for non-electrolytes. *B* may have either a positive or negative value depending on the salt and the temperature.

The equation $\eta = 1 + A\sqrt{c} \pm Bc$ may be readily transformed into $(\eta - 1)/\sqrt{c} = A \pm B\sqrt{c}$. This equation may therefore be most conveniently tested by plotting $(\eta - 1)/\sqrt{c}$ against $\sqrt{c}$ which should give a straight line whose intercept on the vertical axis is *A* and whose slope is ***B*****.**

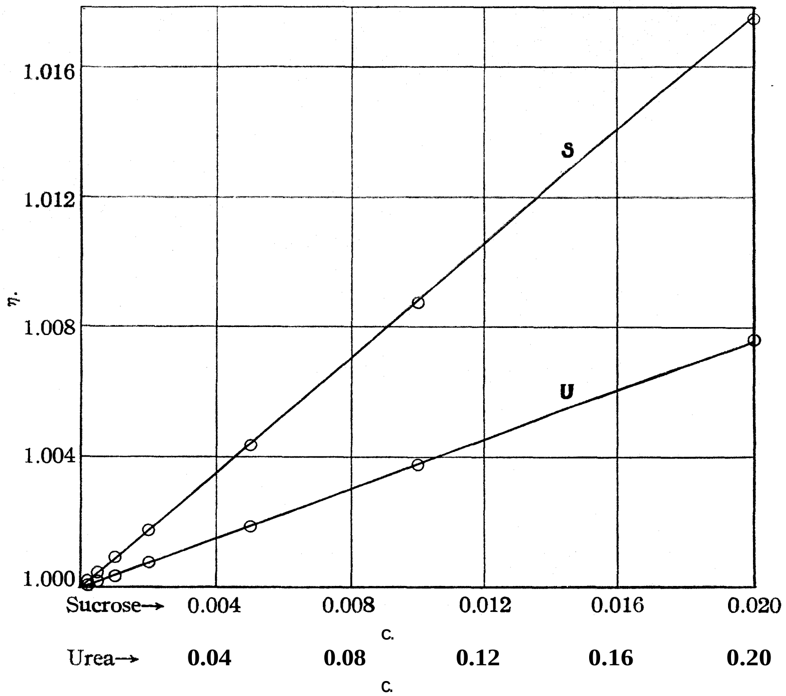

Fig. 6.—Relative viscosity-concentration curves for sucrose and urea.

As will be seen from Pigs. 7 and 8 the plotted data lie on a straight line and the value for *A* is positive for all the salts and zero for sucrose and urea. The values for *A* and *B* were selected by the use of the method of least squares instead of by plotting because the algebraic procedure is more precise and entirely objective. In the last column of Table III are given the differences between the observed viscosity and the viscosity computed by this equation with the values of coefficients *A* and *B* given in Table IV below. The average deviation, disregarding the sign, is 0.0015% which corresponds to an error in the time of flow of only 0.01 second. The maximum deviation for any of the forty-two solutions measured is 0.005% which corresponds to an error in the time of flow of 0.03 second.

This maximum deviation is probably accounted for by the fact that this particular measurement was made during a period of hot weather when the temperature of the room was above 25° which makes the control of the temperature less satisfactory than during cooler weather. The Jones and Dole equation is therefore confirmed for these six salts within the limit of error of the experiments.

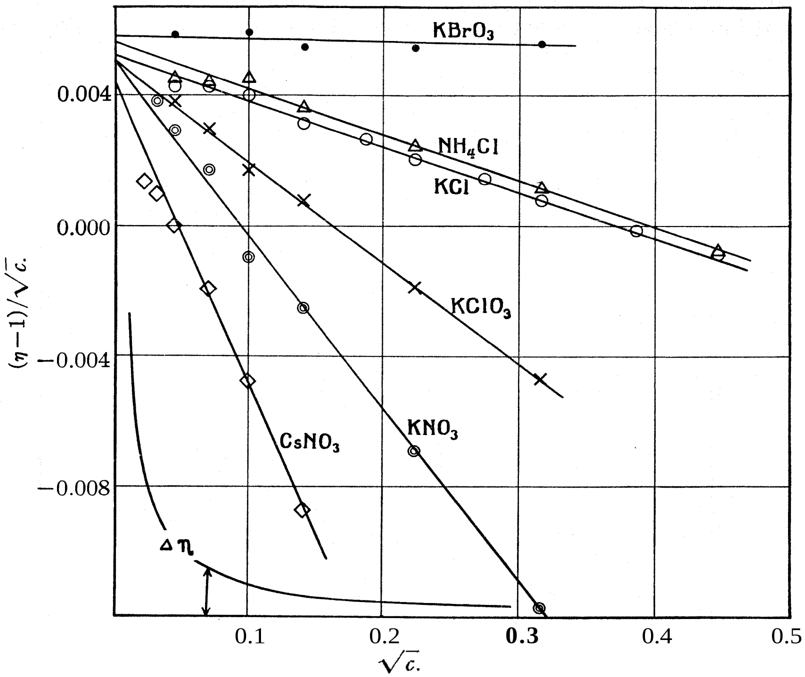

Fig. 7.—$(\eta-1)/\sqrt{c}$ against $\sqrt{c}$ for electrolytes: the curve $\Delta\eta$ shows graphically how a variation of 0.01% in η affects the data as plotted above.

The experimental values of A and B, computed by the method of least squares from the data above to fit the Jones and Dole equation, are shown in the following table and compared with the theoretical values of A computed by the Falkenhagen and Vernon equation. This equation reduces to the following form for the case of a uni-univalent salt

$$A = \frac{1.45}{\eta_0\sqrt{2D_0T}}\left[\frac{l_1 + l_2}{4l_1\,l_2} - \frac{(l_1 - l_2)^2}{(3+\sqrt{2})l_1\,l_2\,(l_1+l_2)}\right]$$

where η_0 and D_0 are the absolute viscosity and dielectric constant of water at the temperature T and l_1 and l_2 are the equivalent conductances of the two ions at zero concentration.

The coefficient of the linear term (B) varies much more from salt to salt and has a greater temperature coefficient than the coefficient of the square root term (A). For most salts the sign of B will be positive in the viscosity

TABLE IV

equation (or negative in the fluidity equation). Little is known as yet in regard to the factors which influence the sign and value of this coefficient.

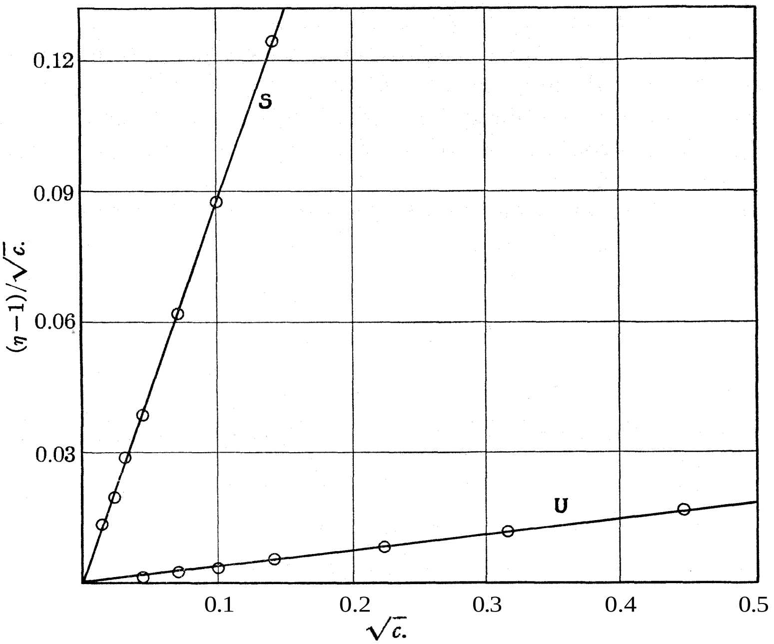

Fig. 8.—$(\eta-1)/\sqrt{c}$ against $\sqrt{c}$ for the non-electrolytes sucrose and urea.

The agreement between the observed and computed values is good and supports the Falkenhagen and Vernon equation for A. According to the Falkenhagen and Vernon equation the value of A for any given salt, solvent, and temperature will depend mainly on the valence type of the salt and to a less extent on the mobilities of the ions concerned. The results obtained up to the present time are in harmony with these conclusions as far as they go.

The results on extremely dilute solutions of sucrose and urea confirm the theoretical prediction that square root term will be absent for non-electrolytes.

It is planned to continue the work in this Laboratory by measurements on other salts, at other temperatures, and in other solvents.

Grateful acknowledgment is made for an appropriation from the Milton Fund of Harvard University for the expenses of this investigation.

Summary

1. A new method for the automatic measurement of the time of flow of the liquid in a viscometer of the Ostwald type by means of a photoelectric cell is described. The elimination of the psychological errors inherent in the older technique permits greater precision.
2. The viscosities of dilute aqueous solutions of six salts and two non-electrolytes have been measured at 25°.
3. The results confirm the prediction made by Jones and Dole based on the Debye theory of interionic attraction that all salts will increase the viscosity of water if measured at sufficiently low concentration, including those salts which give a diminished viscosity at moderate concentrations.
4. The results confirm the Jones and Dole equation for the viscosity of solutions of electrolytes.
5. The results also confirm the Falkenhagen and Vernon equation for the computation of the influence of interionic attraction on the viscosity

The Solubility of Nitrates in Anhydrous Acetic Acid

BY ARTHUR W. DAVIDSON AND HARRIET A. GEER

Introduction

Although several investigations have recently been carried out upon various properties of solutions of salts in anhydrous acetic acid, quantitative solubility data for such solutions are still very meager. Aside from some early work on halides of mercury,(1) calcium and magnesium,(2) and antimony,(3) and the studies of acetates (bases in this solvent) reported from this Laboratory,(4) the only accurate solubility measurements have been those of Seward and Hamblet(5) on potassium perchlorate and potassium nitrate, at a single temperature, in the presence of varying amounts of added salts.

It was mentioned in a previous paper[6] that a large number of nitrates are appreciably soluble in acetic acid. In the present investigation, solubility data were determined over a wide range of temperature for the nitrates of silver, sodium and ammonium, and for barium nitrate at a single temperature. In the case of ammonium nitrate the determinations were continued to the melting point of the pure salt, so as to cover the entire range of concentrations; the freezing point curve thus obtained presents several interesting features.

Method

Preparation of Materials.—Pure anhydrous acetic acid was prepared as described previously.[7] The freezing point of the acid used in this work was from 16.55 to 16.60°. The salts were purified by recrystallization and thoroughly dried under suitable conditions; the purity of the silver nitrate and the ammonium nitrate was checked by analysis.

Determination of Solubility.—In the case of the silver, sodium and ammonium salts. the synthetic or freezing point method was used;[8] the determinations were carried out in large stoppered test-tubes provided with thermometer and stirrer as previously described. The thermometers were carefully calibrated before use. and each saturation temperature was determined at least twice. The measurements for sodium and silver nitrate were not continued beyond 100°, because of the inconveniently high vapor pressure of acetic acid at higher temperatures; ammonium nitrate, however, was so much more soluble at 100° that the vapor pressure was lowered sufficiently for the determinations to be continued up to the melting point, without change of method.

The accuracy of the determinations varies considerably with the rate of change of solubility with temperature. For the sodium and ammonium nitrate solutions, the equilibrium temperatures reported are believed to be correct to within 0.5°, a considerable portion of the ammonium nitrate data being more accurate than this. In the case of silver nitrate, a very faint turbidity, which persisted up to the boiling point, and may have been brought about by a slight solvolysis, was observed in all the solutions. Because of this fact, together with the extreme steepness of the freezing point curve, the equilibrium temperatures are less accurate; they are believed to be correct to within 1°.

The solubility of the barium nitrate proved to be so small that it could not be determined by the synthetic method. Instead, the concentration of solute in a solution saturated at a fixed temperature was determined by analysis. An excess of the salt was heated with 100 cc. of acid to 100° for forty-five minutes in a stoppered flask. The mixture was then cooled to room temperature, placed in a thermostat and allowed to remain at 30° for two days, with frequent stirring. The concentration of the solution was then determined by precipitation of the barium as sulfate. Because of the extremely small solubility, no high degree of accuracy is claimed for the result; it is correct to within 10%.

Analysis of Solid Phases.—Samples of the solid phases present at equilibrium were obtained by filtration, followed by rapid drying between porous tiles. The products so obtained were then analyzed to determine whether or not acetic acid of solvation was present. In the case of the silver nitrate solution, the solid was analyzed both for its silver content, by precipitation as chloride, and for acidity, by titration with sodium hydroxide solution; a rough colorimetric determination of nitrate, by means of phenoldisulfonic acid, was made also. The sodium nitrate was tested merely by titration

(8) A detailed discussion of the factors affecting the accuracy of this method has been given in a recent article by Sunier, *J. Phys. Chem.*, 34, 2582 (1930).

for acidity. In the case of the ammonium nitrate, the ammonia was determined by addition of excess of sodium hydroxide solution, followed by distillation into standard hydrochloric acid.

Results

The data obtained are tabulated below, and are represented also in the accompanying diagrams. Concentrations are expressed throughout in mole percentage of solute; T denotes the equilibrium temperature in °C.

I. Silver Nitrate–Acetic Acid

Solid phase silver nitrate

$AgNO_3$, %	0.0274	0.0398	0.0439	0.0708
T	30	36	40	54
$AgNO_3$, %	0.1035	0.1332	0.1361	0.1940
T	64	78	81	93

The solubility curve is shown in Fig. 1. The solid phase showed no measurable acidity; analysis for silver gave 62.30% (calcd. for $AgNO_3$, 63.49%). It is evident that the compound is unsolvated silver nitrate.

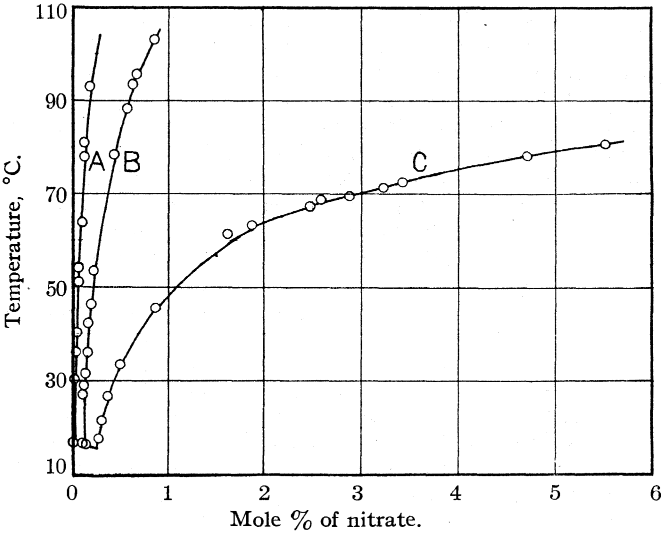

Fig. 1.—Solubility curves for $AgNO_3$ (A), $NaNO_3$ (B) and NH_4NO_3 (C) in anhydrous acetic acid.

A colorimetric test for nitrate gave results in accord with this conclusion. It has been reported[9] that when silver nitrate was treated with an excess of boiling acetic acid, colorless needles of a substance having the formula $(C_2H_3O_2)_2NOH(OAg)_2$ separated on cooling. This formula might equally well be written $Ag_2(C_2H_3O_2)NO_3.HC_2H_3O_2$, and the compound might be regarded as a solvated product of partial solvolysis (a basic salt of the acetic

(b) Solid phase sodium nitrate

$NaNO_3$, %	0.122	0.139	0.150	0.166	0.173	0.183	
T	27.0	29.0	31.5	36.0	40.0	42.5	
$NaNO_3$, %	0.202	00.46	0.448	0.573	0.641	0.677	0.854
T	46.5	53.7	78.5	88.3	93.4	95.7	103.0

The solubility curve is shown in Fig. 1. The solid phase (b) showed no appreciable acidity, and is therefore unsolvated sodium nitrate.

III. AMMONIUM NITRATE–ACETIC ACID

(a) Solid phase acetic acid

NH_4NO_3, %	0.0	0.0741	0.1287
T	16.60	16.57	16.47

(b) Solid phase ammonium nitrate

NH_4NO_3, %	0.2832	0.3249	0.3916	0.5143	0.8745	1.634
T	17.7	21.4	27.0	33.6	45.8	61.2
NH_4NO_3, %	1.887	2.468	2.636	3.239	3.447	4.710
T	63.5	67.6	69.0	71.4	72.8	78.3
NH_4NO_3, %	5.508	7.255	8.620	13.68	17.15	19.36
T	80.9	85.7	89.0	97.1	101.0	102.6
NH_4NO_3, %	23.30	27.64	31.25	37.98	43.31	47.56
T	106.3	108.9	110.6	113.1	115.8	117.0
NH_4NO_3, %	51.67	55.5	60.1	63.1	66.8	71.6
T	118.3	120.0	121.4	122.9	124.8	128.9
NH_4NO_3, %	75.0	78.6	82.3	86.3	89.6	100.0
T	131.4	136.9	143.1	149.7	157.8	167.5

A small portion of the solubility curve is shown in Fig. 1, and the entire curve, on a smaller scale, in Fig. 2. Analysis of the solid phase (b) in equilibrium with solution at about 30° showed 20.00% of ammonia (calcd. for NH_4NO_3, 21.27%); since the upper portion of the curve terminates at the melting point of ammonium nitrate, the solid phase is evidently unsolvated salt throughout the entire range of concentrations.

Since ammonium nitrate is known to exist in four different crystalline modifications, at ordinary pressure, between −18° and its melting point,[10] the solubility curve might have been expected to exhibit sudden changes in slope at the transition temperatures, namely, 32.3, 84.2 and 125.2°; such discontinuities have, in fact, been observed in the solubility curve for this

---

[10] The most recent discussion of the polymorphism of ammonium nitrate is given by Hendricks, Posnjak and Kracek, THIS JOURNAL, **54**, 2766 (1932).

salt in water.[11] In the acetic acid curve, however, these discontinuous changes must be much less marked, those at the two lower temperatures not being detectable at all in Fig. 2. A slight "break," however, may be observed at a temperature of 125°, corresponding to the change from the tetragonal (II) to the cubic (I) modification; this change, incidentally, is accompanied by a far greater heat of inversion than any of the others.

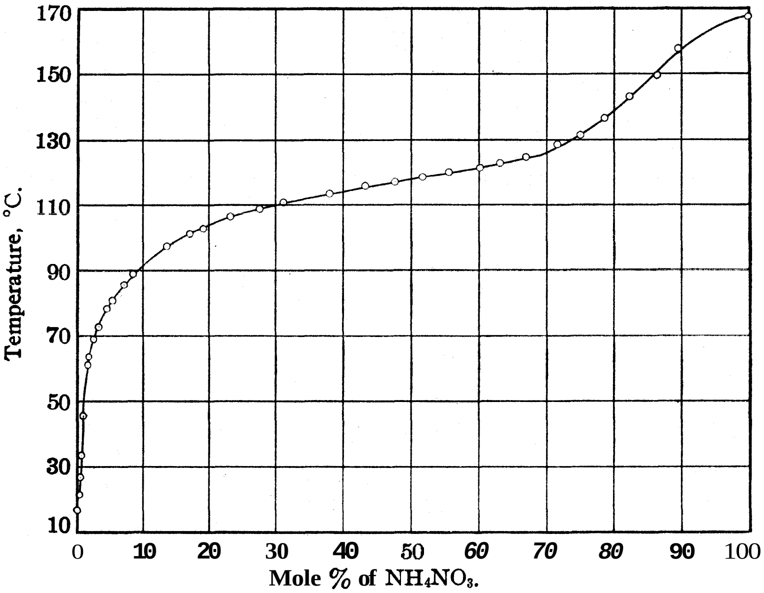

Fig. 2.—System NH_4NO_3–$HC_2H_3O_2$.

The form of the ammonium nitrate–acetic acid curve will be further discussed below.

IV. BARIUM NITRATE–ACETIC ACID

Solid phase $Ba(NO_3)_2$; solubility at 30°, 0.0005%

It was previously reported[12] that this salt was very slightly soluble and could be obtained as a precipitate upon mixing acetic acid solutions of barium iodide and sodium nitrate.

Discussion

The solubilities at 25° of the four salts here studied, together with that of potassium nitrate,[13] are shown in Table I; their solubilities in water[14] are included for purposes of comparison. In both solvents the solid phase is in every case the unsolvated salt.

(12) Ref. 6, p. 1893.

(13) Seward and Hamblet, Ref. 5, p. 568. (In the heading of the second column of Table II "$KClO_4$" appears, evidently as a typographical error, instead of "KNO_3").

(14) Ref. 11, pp. 217–240.

TABLE I

SOLUBILITY OF UNSOLVATED NITRATES IN ACETIC ACID AND IN WATER AT 25°

Salt	Solubility in acetic acid Mole, %	Solubility in acetic acid Moles per 1000 g. solvent	Solubility in water Moles per 1000 g. solvent
$Ba(NO_3)_2$	0.0005	0.00008	0.400
KNO_3	.105	.0175	3.74
$NaNO_3$	.121	.0202	10.80
$AgNO_3$	.020	.0033	14.00
NH_4NO_3	.370	.0619	26.98

The fact that interionic forces are much greater in acetic acid than in water makes the former a poorer "salt solvent."[15] Except for silver nitrate, solubility in acetic acid, in this series of salts, increases in the same order as in water; which, incidentally, corresponds to the order of decreasing melting points.

The discontinuous change in slope of the freezing point curve for ammonium nitrate at 125° has been mentioned above. Even aside from this "break," however, the entire course of the curve—steep in its initial portion, flattening out to a long central section of small slope, and becoming steeper again at a high concentration of salt—is of a decidedly unusual character. It resembles somewhat the curve observed for salicylic acid in water by Alexejew,[16] and that for silver perchlorate in benzene discussed by Hill,[17] each of which shows a point of inflection; but in the ammonium nitrate curve there are two distinct points of inflection, at 60% and at 85% of solute, respectively.

It is often of interest, in the study of solubility data, to plot them in the manner suggested by Hildebrand,[18] using as coördinates log N (where N is the mole fraction of solute) and $1/T$, the reciprocal of the absolute temperature at which solution and solute are in equilibrium. In the ideal case (for a solution obeying Raoult's law at all temperatures and pressures) this method of plotting yields a straight line whose slope is $-L_f/4.58$, where L_f is the molal heat of fusion of the solute.[19] In the case under consideration, since both components are polar to different degrees, and since they doubtless also differ considerably in internal pressure, wide and as yet unpredictable deviations from ideal behavior might be anticipated.[20] Nevertheless, it appeared to be worth while to plot the data, at least for that portion of the curve in the vicinity of the melting point of the solute, in the manner just described.

The molecular state of acetic acid in solution is not definitely known.

(19) If the heat of fusion varies with the temperature, there is a corresponding deviation from a linear relationship.

(20) Ref. 18, chapters VIII and IX. This system would not fall in the class of "regular" solutions, discussed at length by Hildebrand, THIS JOURNAL, 61, 66 (1929).

This compound is undoubtedly associated in the liquid state, both alone and in solution in many solvents,[21] and association is considerable in the vapor state also,[22] persisting even to temperatures well above the boiling point.[23] On this account, several writers,[24] in discussing systems containing acetic acid as one component, have considered it as having the formula $(C_2H_4O_2)_2$. While it is probable, in the present instance, that a considerable fraction of the acetic acid is in this form in solutions containing a large proportion of the solvent, at low temperatures, it is doubtful that such association would persist in solutions dilute in acetic acid, or at high temperatures. However, mole fractions have been calculated on the basis both of single and of double molecules (molar weight 120) of acetic acid, for purposes of comparison, and the resulting curves have been plotted in Fig. **3.** Each of these curves, it will be noticed, shows a slight "break" at a point corresponding to the transition temperature, 125°.

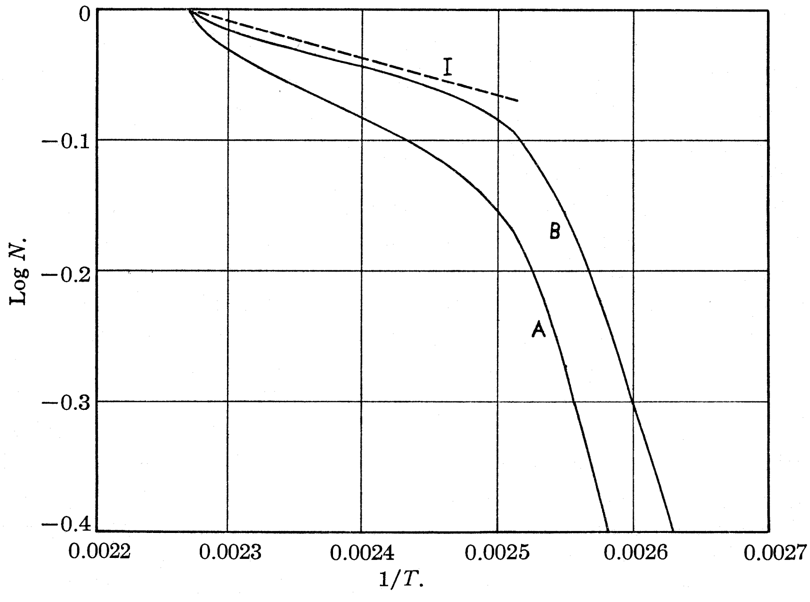

Fig. 3.—Solubility of ammonium nitrate in acetic acid: A, curve based on usual formula for acetic acid; B, curve based on formula $(C_2H_4O_2)_2$; I, approximate course of ideal curve.

The heat of fusion of ammonium nitrate has apparently never been determined by direct calorimetric measurement. However, Bridgman,[25]

in a study of the effect of pressure upon the polymorphism of this substance, calculated the heat of fusion, by means of the Clapeyron equation, from the rate of change of melting point with pressure, obtaining the value 6.9 kilogram-meters per gram, which is equivalent to the remarkably low value of 1300 calories per gram mole. Due to the difficulty in determining the increase in volume accompanying fusion, this value is probably not very accurate. In such an approximation, the unknown difference in heat capacity between the solid and liquid forms may be neglected, and the heat of fusion may be regarded as constant over a short temperature range.[26] Using the value of 1300 for L_f, we get -284 as the slope of the ideal curve between the melting point and 125°. This is represented in Fig. 3 by the broken line, the equation for which is $\log N = 0.644 - 284/T$.

It is evident that the experimental curve plotted on the basis of the usual formula for acetic acid deviates very widely from the ideal, even at low concentrations of acid, in the direction of smaller solubility. On the other hand, the curve plotted on the basis of double molecules of acetic acid approaches the ideal position rather closely at temperatures within 35° of the melting point; it is nearly linear over most of this range and has, in fact, practically the slope calculated from the approximate heat of fusion found by Bridgman. In the present state of our knowledge of this system, however, this approach to the ideal curve must be regarded as hardly more than fortuitous.[27] At lower temperatures the solubility appears to fall far below the ideal value; solvation presumably occurs only to a slight extent, if at all.

Summary

1. Quantitative solubility data have been obtained for ammonium, sodium and silver nitrates in acetic acid over a wide range of temperatures, and for barium nitrate at 30°. The solubility of these salts decreases in the order named. No solvates were isolated from any of the solutions.

2. A "break" occurs in the solubility curve of ammonium nitrate at 125°, due to the change in crystalline form which occurs at this temperature.

3. A plot of the logarithm of the mole fraction of ammonium nitrate against the reciprocal of the absolute temperature of equilibrium shows that the solution deviates widely from Raoult's law, as would be expected from the character of the components.

(26) A further complication arises from the probable ionization of the ammonium nitrate, which, if complete, would result in a linear relationship between log $(2N/(N + 1))^2$, instead of log N, and $1/T$ (Ref. 18, p. 165). But the deviation produced by this factor is very small at high concentrations of solute—probably less, in this case, than the uncertainty of the heat of fusion—and has therefore been neglected in locating the ideal curve.

(27) Certainly we should not be justified in concluding that acetic acid was present entirely as double molecules under these conditions. The danger in drawing such conclusions as to the molecular state of substances in solution from the deviation of the solutions from Raoult's law has been repeatedly emphasized by Hildebrand (see, for instance, Ref. 18, pp. 83–84).

Solubility Studies. IV. The Solubilities of Certain Slightly Soluble Organic Compounds in Water[1]

BY PAUL M. GROSS, JOHN H. SAYLOR AND MARY A. GORMAN

In continuing a general program of research on the solubility in water and aqueous salt solutions of organic compounds in relation to their polar character,[2] the solubilities of an additional number of slightly soluble organic compounds in water have been measured. Since solubilities for most of these compounds are not in the literature, the value for the solubilities we have found are published now. The theoretical significance of these and other experimental values will be considered in a later paper.

Method.—The saturated solutions of the substances were prepared in thin-walled cylindrical flasks in a large water thermostat. The thermostat was kept at 30 ± 0.02°. The saturated solutions were analyzed by means of a Zeiss combination liquid and gas interferometer. The procedure has been previously described in detail.[2a]

Materials

Purification of Materials.—All of the organic chemicals were Eastman Kodak Company best grade with the exception of the cinnamic acid, which was a sample prepared in this Laboratory by Mr. William Miller, Jr. Solids were further purified by repeated recrystallization from an appropriate solvent until the melting points from two successive recrystallizations were the same. Liquids were purified by fractional distillation using for fractionations at atmospheric pressure a 25-cm. all-glass Widmer still and a small all-glass still with a 105-cm. column of the type previously described.3 A Hickman still, designed for a moderate vacuum with a barostat operated by a vacuum tube relay was used for distillations under reduced pressure. The thermometers used were a set of small two-tenth degree thermometers with a fifty degree range, calibrated by the Bureau of Standards; a set of fiftieth degree Goetze thermometers with a twelve degree range, calibrated by the Physikalische Technische Reichsanstalt; and for 1,3-dibromopropane, an uncalibrated tenth degree thermometer of good quality. Melting points down to −10° were determined with a tenth degree thermometer calibrated by the Bureau of Standards. For lower temperatures a pentane-filled degree thermometer with a range of 0 to −200°, calibrated by the Physikalische Technische Reichsanstalt was used. For distillations at atmospheric pressure the boiling points were corrected to 760 mm. by means of Craft's rule, whenever the value of dT/dp could not be found in the literature. Distilled water of good quality from the laboratory supply was used for the solubility determinations.

Table I summarizes the boiling point and melting point data for the samples used for the solubility determinations. The pressures during the vacuum distillations were maintained by the barostat within ±0.5 mm. of the values listed in column three.

Results

The solubilities of all of the substances measured and the estimated percentage errors are also given in Table I. The error was estimated from the concordance of duplicate determinations.

We have included ethyl adipate in the list of compounds measured, as a paper by Sobotka and Kahn[10] has recently appeared describing a rapid and simple solubility method applicable to certain liquids in which the solubilities of ethyl adipate and similar compounds were given. Our value at 30° of 4.26 g. per 1000 g. of water is in good agreement with the value found by the above authors which is 4.23 g. per 1000 cc. of water at 20°. Our results confirm the accuracy of their method.

Values for the solubilities of four of the compounds we have measured are given in the literature as follows, the temperature in all cases being 25° instead of 30".

Cinnamic acid, 0.546 g. per 1000 g. of water,'' 1.3-dichloropropane, 2.73 g. per 1000 g. of **water,**[2b] ***o*-nitroaniline,** 1.212 g. per 1000 g. of water, m-nitroaniline, 0.910 **g.** per 1000 g. of **water.**[12]

Allowing for the difference in the temperature of 5° our results are in

The Dissociation Constant of Acetic Acid from 0 to 60° Centigrade[1]

BY HERBERT S. HARNED AND RUSSELL W. EHLERS

In a recent communication,[2] we showed that it was possible to determine the dissociation constant of a weak acid with very high accuracy from electromotive force measurements of the cells

$$H_2 \mid HAc\ (m_1),\ NaAc\ (m_2),\ NaCl\ (m_3) \mid AgCl \mid Ag$$

Values of the dissociation constants were determined from 0 to 35° inclusive at 5° intervals. More recently, we have obtained data from which this important constant may be obtained from 0 to 60° at 5° intervals. This determination involves values of the normal potential of the silver–silver chloride electrode through this temperature range. The values of this quantity which we shall employ have been revised slightly by us between 0 and 35° and determined between 35 and 60°.[3]

The method of calculation of K is described fully in our earlier contribution and was adhered to in all its detail. The equation for the electromotive force, E, of the cell is

$$E - E_0 + \frac{RT}{F}\ln\frac{m_{\mathrm{HAc}}m_{\mathrm{Cl}}}{m_{\mathrm{Ac}}} = -\frac{RT}{F}\ln\frac{\gamma_{\mathrm{H}}\gamma_{\mathrm{Cl}}\gamma_{\mathrm{HAc}}}{\gamma_{\mathrm{H}}\gamma_{\mathrm{Ac}}} - \frac{RT}{F}\ln K \qquad (1)$$

E_0 is the normal potential of the cell, K, the dissociation constant, and the "m's" and "γ's" are the molalities and activity coefficients of the species denoted by subscripts. m_{HAc} and m_{Ac} were evaluated as previously described. As before, we let the right side of the equation equal $-RT/F \ln K'$, and then plot this quantity against μ. At zero μ, K' equals K. The extrapolation is easily carried out accurately as indicated by Fig. 1 of the former investigation. The value of K at 35° was redetermined and the

One further refinement has been carried out. By the method of least squares, we have computed E_0 as a function of the temperature.[3] Its value is given by the equation

$$E_0 = 0.22239 - 645.52 \times 10^{6} (t - 25) - 3.284 \times 10^{-6} (t - 25)^2 + 9.948 \times 10^{-9} (t - 25)^3 \quad (2)$$

If we employ the values computed by this equation which are given in column two of Table II, we obtain the values of K in the third column. These we regard as our final values. At 25° our result of 1.754×10^{-5} checks very closely that of 1.753×10^{-5} recently determined by MacInnes and Shedlovsky[4] from conductance measurements. We have no accurate values with which to compare our results at other temperatures. In Fig. 1 we have plotted K against the temperature. All points except that at 30°

(4) MacInnes and Shedlovsky, THIS JOURNAL, **54**, 1429 (1932).

fall on the smooth curve to within ±2 in the third decimal place which corresponds to an error of ±0.03 of a millivolt. It is apparent that K increases, reaches a maximum at about 23° and then decreases with increasing temperature.

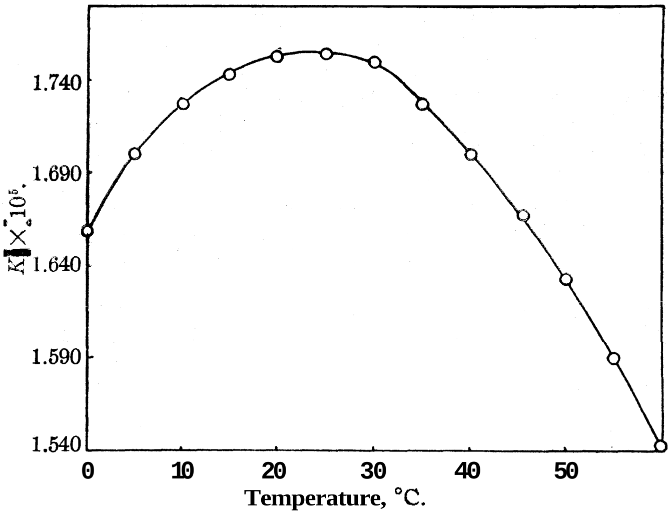

Fig. 1. —The dissociation constant of acetic acid as a function of the temperature.

To determine the heat content of ionization of the acid, we employed the equation

$$\frac{d \ln K}{dT} = \frac{\Delta H}{RT^2} \quad \text{or} \tag{3}$$

$$\frac{d \ln K}{d\,(1/T)} = -\Delta H \tag{4}$$

ln K was plotted against $1/T$, and A H was evaluated from the slope. A plot of these values of A H against T revealed that A H varied approximately linearly with the temperature. This suggested that the problem could be treated in the usual way. A H was taken to vary with the temperature according to

$$A\,H = a + bT + cT^2 \tag{5}$$

Upon substituting this value of ΔH in equation (3) and performing the integration

$$\log K = -\frac{a}{2.303\,RT} + \frac{b}{R}\log T + \frac{c}{2.303\,R}\,T + d \tag{6}$$

is obtained in which a, b, c and d are empirical constants. By substitution of the known values of K and T in equation (6), thirteen equations were obtained from which the constants were evaluated by the method of least squares. The equation with the empirical constants was

$$\log K = -\frac{1500.65}{T} - 6.50923 \log T - 0.0076792\,T + 18.67257 \tag{7}$$

Values of K computed by this equation are given in the fourth column of Table II. The differences between the observed and calculated results are given in the fifth column. At the higher and lower temperatures the calculated values are slightly higher than the observed, while in the middle range of temperature they are somewhat lower. We have previously noted this behavior when dealing with **a** similar calculation and function,[3] and found that another term, dT^3, is necessary in equation (5) in order to represent the results within the experimental error throughout the entire concentration raoge. In the present treatment, we have not resorted to this refinement. On the whole the agreement is good. The mean deviation is ±**0.003,** which corresponds to about ±**0.04** millivolt.

The equation for the change in heat content of the dissociation of acetic acid derived from equation (7) is

$$A\ H = 6871.0 - 12.94361' - 0.0351611'' \qquad (8)$$

Values of A H computed by this equation are given in the sixth column of Table II. In column seven, ΔC_p, the differences in specific heat of the ions and the undissociated molecule of acetic acid computed from the equation

$$\Delta C_p = -12.9436 - 0.070322T \qquad (9)$$

are compiled.

Summary

1. Measurements of the cells

$$H_2 \mid HAc\ (m_1),\ NaAc\ (m_2),\ NaCl\ (ma) \mid AgCl \mid Ag$$

have been made from **35** to 60° at 5° intervals.

2. By a method previously described by us, the dissociation constant of acetic acid has been computed from **35** to 60° at 5° intervals from these results. Our earlier results from 0 to 35° have been recomputed by the use of more recently determined values of the normal potential of the silver–

silver chloride electrode. Final values of the dissociation constant of acetic acid from 0 to 60° at 5° intervals have been tabulated. Our value of **1.754** $\times 10^{-5}$ agrees excellently with the value, **1.753** $\times 10^{-5}$, determined from the conductance measurements by MacInnes and Shedlovsky.

3. The dissociation constant is given by the equation

$$\log K = -\frac{1500.65}{T} - 6.50923 \log T - 0.0076792T^2 + 18.67257$$

4. The heat of dissociation is given by the equation

$$AH = 6871.0 - 12.9436T - 0.035?61T^2$$

Types of Chemical Reactions

BY WILLIAM ALBERT NOYES

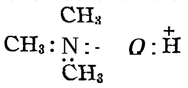
A study of the interaction of nitrogen trichloride with nitric oxide and with nitrogen tetroxide has given results from which, in conjunction with other experimental evidence and with current electronic theories, it is possible to define accurately, with a high degree of probability, the electronic course of several types of reactions.

The discussion which follows applies, primarily, to elements with atomic weights of 40 or below. For elements of higher atomic weights the outer shell of valence electrons seems to be less sharply defined.

Three principles are used. (1) On account of their "spin" and for other reasons, the electrons of the valence shell of an atom are usually, not always, associated in pairs, octets or sextets. (2) Every atom must have the positive charge of its nucleus balanced by the electrons immediately associated with it, or it must be an ion or form part of a complex ion, which is held to or in the neighborhood of another ion of the opposite sign, by static attraction. (3) In balancing the positive charge of the nucleus of an atom the pair of electrons of a covalence is equivalent to a single unshared electron.

1. Formation of Ions

A. Permanent ions, formed with an outer shell of electrons (usually an octet) for some atom, in such a manner that the positive charge of the kernel or nucleus is overbalanced or underbalanced by the electrons surrounding it: (a) by the gain or loss of one or more electrons, as for sodium, calcium, chlorine or sulfur; (b) by the addition of a positive hydrogen or methyl ion to ammonia or to a tertiary amine, a positive hydroxyl group to a tertiary amine,



$\mathrm{CH_3:\overset{CH_3}{\underset{\ddot{C}H_3}{N}}:\cdot\ \mathit{O}:\overset{+}{H}}$

or a positive methyl to dimethyl

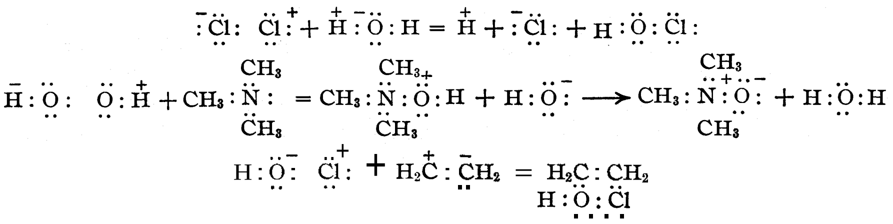
sulfide,  $CH_3:\overset{CH_3+}{\underset{CH_3}{\ddot{S}}}:$. In these cases the positive charge of the kernel of the nitrogen or sulfur atom is underbalanced because the sum of the covalence and unshared electrons is less than the number of their valence electrons. (c) By the removal of a positive ion from a covalence, as when the removal of a hydrogen ion from water gives an hydroxide ion, $H:\ddot{\underset{..}{O}}:^-$, in which the oxygen atom causes the ion to be negative because it has one covalence and six unshared electrons. The nitrogen and oxygen atoms of trimethylamine oxide,  $CH_3:\overset{CH_3}{\underset{CH_3}{\overset{+}{N}}}:\underset{..}{O}:^-$, and the two oxygen and the sulfur atom of dimethyl sulfate,  $CH_3:\ddot{\underset{..}{O}}:\overset{:\ddot{O}:^-}{\underset{:\underset{..}{O}:^-}{\overset{+}{\underset{+}{S}}}}:\ddot{\underset{..}{O}}:CH_3$, are held by one covalence and one ionic valence because the positive charges of the kernels of the nitrogen and sulfur atoms are underbalanced as they are in the ammonium and sulfonium ions, and because the positive charges of the kernels of the oxygen atoms are overbalanced as they are in the hydroxide ion.

Hydrogen ions are unique because they have no electrons. In general, hydrogen ions held by covalences ionize slightly, and since it is probable that hydrogen ions may be held by static attraction to atoms or molecules having complete octets it is often difficult to determine whether the atom is held in this manner or by a covalence. Physical methods are most suitable for an answer to this question.

For these reasons reactions in which hydrogen ions are involved have an intermediate position between the ordinary ionic reactions and covalence reactions. The hydrogen ionization of water, of ammonia, of ethyl alcohol, of hypochlorous acid and of hydrogen atoms held by a covalence to carbon, is trifling, but it has been demonstrated by conductivity measurements in the first four cases. The ionization of hydrogen attached to carbon is important for an understanding of nitration and sulfonation reactions, the tautomerism of actoacetic ester and similar compounds, the Perkin, Kolbe and other condensation reactions involving the ionization of hydrogen atoms which are alpha to a carbon atom combined with oxygen, and many molecular rearrangements.

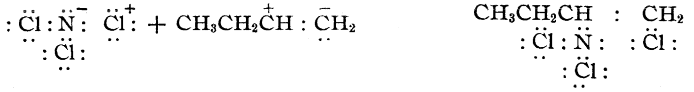
Some chemists have assumed negative hydrogen ions. It is doubtful if these ever occur in organic reactions.

B. Six-electron-ephemeral ions are formed by the separation of two atoms held by a covalence in such a manner as to form a negative ion with a complete octet of electrons and a positive ion with only six electrons in the outer shell of the other atom. This is illustrated by the following equations



In this case both the hypochlorous acid and the ethylene form six-electron ions.

This is the first step in the formation of chloric acid from hypochlorous acid.



Because of the ephemeral character of positive, six-electron ions the evidence for their existence is indirect and similar to the evidence for organic radicals long used so successfully by organic chemists. In addition to the list given, they furnish a very simple explanation of nitration and sulfonation (the first step may be an addition), of the transfer and interchange of positive chlorine and hydrogen between nitrogen and carbon, of the interchange of methyl or phenyl groups and hydroxyl in other rearrangements, and of many intramolecular shifts of atomic attachments.

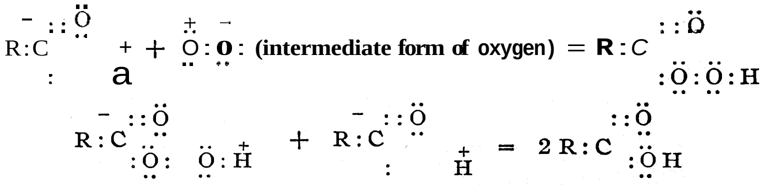
Because the evidence is indirect, we cannot expect complete agreement in the explanations given by different chemists. The situation is quite like that of tautomerism thirty to fifty years ago. We should be very careful to avoid dogmatism and should look diligently for experimental evidence for one view or another.

2. Ionic Reactions

A. Permanent Ions with Full Octets.—These are reversible and so rapid that the speed can rarely be measured. Three causes may make them nearly complete and may often reverse their direction: (a) formation of an insoluble or difficultly soluble product; (b) formation of a volatile product or of a compound which dissociates, giving a volatile product; (c) formation of a product which ionizes slightly, such as water, or which rearranges to a compound which ionizes slightly. Organic indicators belong to this class.

B. Covalence Reactions; Six-Electron Ions.—Such reactions are, superficially considered, very similar to the reactions of permanent ions, but there are important differences. One at least of the compounds reacting must be held together by a covalence; the number of six-electron ions is always very small and the speed of the reaction is frequently of such a rate that it can be measured; the covalence compounds formed may separate less readily than the original compounds and the reaction may be practically irreversible; covalence compounds may separate at different points and in different ways, causing different reactions to proceed at the same time—this is particularly true of organic compounds. Covalence compounds may also dissociate to electrically neutral parts with odd electrons and these free radicals (see below) may react in a different manner. Very often one of the reacting compounds and one of the products consist of permanent ions, as when methyl iodide reacts with silver nitrate. The same factors which cause reactions of permanent ions to become nearly complete are often important in covalent reactions.

The oxidation of aldehydes and ketones, recently discussed by Haber and Willstatter[1] and previously by Wieland, is probably of the covalence type



$$\underset{:\quad a}{\overset{-\,::\ddot{O}}{R:C}}\ {}^{+} + \overset{+\;\;-}{\ddot{O}:\ddot{O}:}\ \text{(intermediate form of oxygen)} = \underset{:\ddot{O}:\ddot{O}:H}{\overset{::\ddot{O}}{R:C}}$$

$$\underset{:\ddot{O}:}{\overset{-\,::\ddot{O}}{R:C}}\ \overset{+}{\ddot{O}:H} + \underset{:}{\overset{-\,::\ddot{O}}{R:C}}\ \overset{+}{H} = 2\,\underset{:\ddot{O}H}{\overset{::\ddot{O}}{R:C}}$$

In the last reaction positive hydroxyl and positive hydrogen exchange places. Wieland has shown that acid peroxides are formed in some of these reactions.

3. Dissociation and Reactions of Free Radicals

The term "electrolytic dissociation" was originally used for ionization. It helps to clearer thinking if we use the word dissociation to designate separations which give electrically neutral atoms or molecules, and ionization to designate all cases where the positive charge of the kernel or nucleus of some atom is not balanced by the electrons immediately associated with it. Such ions, or the groups which contain them, may separate from the ions of opposite sign in solutions, or may be held to them by static attraction while retaining their ionic character as sodium and chlorine are held together in crystals and probably in the gaseous state, as the ammonium and carboxyl ions are held together in aminolauronic acid, , and as atoms are held together in the semipolar unions of sulfuric acid and other compounds.

Dissociation is usually caused by heat, photochemical action or electrolysis. Typical examples are the dissociation of chlorine molecules to two chlorine atoms with seven electrons each; and the removal of an elec-

---

(1) Haber and Willstätter, Ber., 64, 2849 (1931).

tron from the acetate ion in the electrolysis of sodium acetate. This is followed by the formation of a covalence between the oxygen atom which has lost the electron and the carbon of the carboxyl group, the other electron being taken from the covalence with the methyl. Carbon dioxide then separates in an electrically neutral state and the methyl, which is also electrically neutral, with its odd electron, immediately unites with another methyl radical to form ethane. Paneth and Rice have shown that similar free radicals may be formed by thermal dissociation and that such radicals are extremely reactive. Triphenylmethyl and similar compounds and the free radicals of nitrogen discovered by Wieland are more stable. Nitric oxide, an electrically neutral molecule with an odd electron takes an electrically neutral chlorine atom from nitrogen trichloride. The nitrogen dichloride unites with another mole of nitric oxide to form dichlorodinitrogen oxide. At −150° a third mole of nitric oxide takes an electrically neutral atom of chlorine from this compound.

Two atoms of sodium give their odd electrons to electrically neutral chlorine atoms, forming sodium chloride

$$2\mathrm{Na}. + :\ddot{\mathrm{Cl}}:\ddot{\mathrm{Cl}}: = 2\overset{+}{\mathrm{Na}} + 2:\underset{\cdot\cdot}{\ddot{\mathrm{Cl}}}\overset{-}{:}$$

In a similar manner two atoms of sodium give their electrons to a molecule of oxygen, forming sodium peroxide

$$\mathrm{Na}.\ \cdot\underset{\cdot\cdot}{\ddot{\mathrm{O}}}:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}\cdot\ .\mathrm{Na} \longrightarrow \mathrm{Na}:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}:\mathrm{Na}$$

The reaction of sulfite ions with cupric ions giving cuprous ions and dithionate ions, recently discussed by Haber and Willstätter,[2] is probably of this type

$$2(\mathrm{Cu}^{\underset{\cdot}{+}+}\cdot\mathrm{SO}_3^{=}) = 2\mathrm{Cu}^{+} + (\mathrm{O_3S{:}SO_3})^{=}$$

An electron is transferred from each sulfur atom to a cupric ion, reducing it to a cuprous ion. Then the sulfur atoms with odd electrons unite.

The decomposition of nitrogen trichloride and of acetylene and the chain reactions between hydrogen and chlorine and between hydrogen and oxygen, are almost certainly of this, class. When such reactions are strongly exothermic they will be explosive.

The catalytic hydrogenation reactions are very probably due to hydrogen atoms with odd electrons.

I wish to express my thanks to a number of my friends, who have kindly read this paper and whose criticisms have been very helpful.

Summary

Reactions are classified, in accordance with their electronic character, under three heads: (1) formation of ions; A, with complete octets; B, from covalences, one with eight electrons, one with six; (2) ionic reactions;

---

(2) Haber and Willstatter. Ber.. 64, 2844 (1931).

A, ions with complete octets; B, ions formed from covalences; **(3)** dissociation and reactions of electrically neutral atoms and molecules.

The following principles, which the space allowed does not permit me to discuss, give a satisfactory explanation of the inorganic complexes: 4. Atoms may form covalence groups with a larger number of covalences than the number of valence electrons of the central atom. **5. A** valence electron may be transferred, either to form a negative ion which enters the complex or one that is exterior to the complex. **6. If** the "donor" (Sidgwick) is an electrically neutral molecule (ammonia or water), it becomes a positive ion in the complex; if it is a negative ion (Cl^-, NO_2^-), it becomes electrically neutral in the complex. **7.** The "acceptor," in every case, develops a negative charge for each covalence, which may be balanced by the positive charge of the "kernel" (Lewis), by the positive ions of the complex or by positive ions exterior to the complex.

The Linear Thermal Expansion of a Single Crystal of Sodium Nitrate

BY J. B. AUSTIN AND R. H. H. PIERCE, JR.

The results of a recent series of studies of the physical properties of sodium nitrate conducted by Kracek[1] and his colleagues[2] have firmly established the existence of a gradual transition in the crystalline salt between 150 and 280°. The transition appears to be practically completed at 275° but abnormal changes in the heat capacity and volume are distributed over an extended temperature interval below this critical point.

The basis for a satisfactory explanation of the phenomenon seems to have been found in the theoretical treatment by Pauling[3] of the problem of the diatomic homopolar molecule free to rotate in an axially symmetrical field of force. His analysis together with the available x-ray evidence[2] makes it seem almost certain that during the transition interval the rotational degree of freedom of the nitrate ion about an axis normal to the plane of the group becomes excited. At the critical temperature this degree of freedom is fully excited and the nitrate ion begins to rotate about the trigonal axis of the crystal unit. The transition corresponds, therefore, to a change from oscillational to rotational motion for the nitrate ion.

One of the properties studied in detail by Kracek was the volume ex-

pansion of the salt. While his results serve admirably to demonstrate the existence of the transition they do not elucidate the very interesting question of the anisotropic expansion in various directions in the crystal. Such information is of considerable value in analyzing the nature of the changes which take place during the transition, and since a knowledge of the mechanism of these changes is of great importance in the theory of the solid state, we have undertaken a series of measurements of the expansion in several directions of known orientation in the crystal.

Material.—The sodium nitrate used in the experiments was recrystallized three times starting with the best material commercially available. It crystallizes easily so that single crystals of considerable size can be readily secured. A number of crystals were prepared and the clearest and most perfect ones were selected for use.

Apparatus.—The Pulfrich–Fizeau interference method as modified by the U. S. Bureau of Standards was employed in making the measurements. The principles of, and apparatus for, this method are described in the publications of the Bureau.[4] The only departure from the equipment therein specified was in the design of the furnace which is shown in Fig. 1. A porcelain tube, F, wound with a helical nichrome coil, K, is mounted vertically in a sheet iron jacket and is surrounded with Sil-O-Cel. A smaller tube, E, supports the porcelain cup, C, which contains the interferometer plates, S. A small bore porcelain tube holding the platinum–platinrhodium thermocouple passes through the bottom of the cup. C, the junction being so adjusted that it nearly touches the lower interferometer plate. The upper end of the furnace is closed by another porcelain tube containing the fused silica windows W_1 and W_2; W_3 is a glass window.

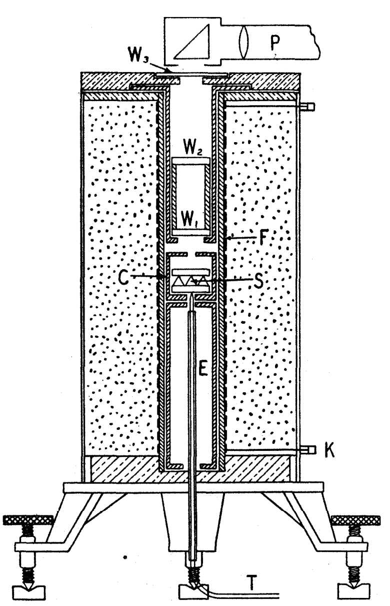

Fig. 1.—Apparatus for measuring linear thermal expansion.

The viewing apparatus is shown at P. The helium line at **5875.6 Å.** was used as a monochromatic source of illumination. With this light a change in length of $\pm 3 \times 10^{-6}$ cm. could be easily detected.

The thermocouple was checked in position in the furnace on the melting points of tin, aluminum and silver, and on the α-β inversion of quartz; it was also checked against a carefully calibrated refraction thermometer of fused silica. Temperatures were read on a Leeds and Northrup wall-type potentiometer which had been checked at the Bureau of Standards and are probably good to ±1° or better.

With this apparatus it is necessary to have three small specimens very nearly the same height. Preliminary experiments showed that the results obtained with a set of three small pyramids cut from one large crystal were more satisfactory than those obtained with specimens cut from three small crystals; hence for the final measurements a small slab was cut from a large crystal so that the normal to the surface of the slab co-

[4] Peters and Cragoe, *Bur. Standards Sci. Papers* (No. 393), 16, 449 (1920); Peters and Boyd, *ibid.*, (No. 436), 11,677 (1922); Merritt, ibid., (No. 485) 19,357 (1924).

incided with the direction in the crystal along which the expansion was to be determined. Three small pyramids were then cut from this slab. Although this method of preparation does not orient the specimens with great accuracy it proved to be quite satisfactory for the present purpose.

Results

The expansion was measured in three different directions: parallel to the *a* axis, parallel to the *c* axis and perpendicular to the rhombohedral faces $(10\bar{1}1)$ and $(\bar{1}01\bar{1})$. For the first two directions two sets of specimens were examined; for the last direction but one was used.

The results obtained are given in Table I in the form of the increase in length per unit length and the true linear expansion coefficient; these values were taken from a smoothed curve drawn through the experimental points for all the determinations in a given direction. This procedure was rendered advisable by the fact that the curves for any single determination showed curious undulations, apparently connected with the efflorescence of the salt on heating, which were not reproducible and could be largely balanced out by combining the data for two runs. The curves themselves and the experimental points are shown in Fig. 2.

295	2.80	29.0	47.0	10.0	540	660

The variation of the expansion coefficients with temperature is shown in Fig. 3a.

Aside from the slight irregularities mentioned the results were, with one exception, strictly reproducible, not only on heating and cooling but also from sample to sample. Such variations as do appear are well within the possible error arising from the uncertainty of the orientation and the measurement of the expansion.

The one exception is the contraction of the crystal above the critical temperature in the direction of the a axis, which was not reproducible even for the same sample on heating and cooling.

Unfortunately the set of specimens for the direction perpendicular to the $10\bar{1}1$ face suffered some irregular behavior in passing through the critical point at 275° and the fringes were lost, hence no measurements above this temperature are available for this direction.

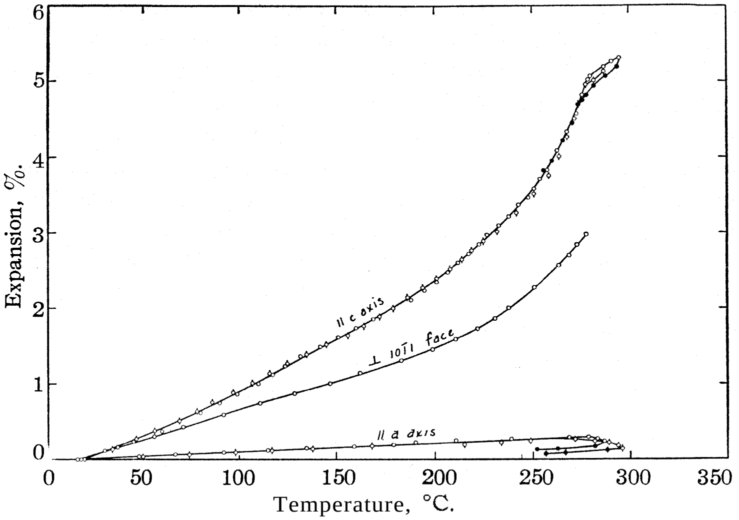

Fig. 2.—Linear expansion of single-crystal sodium nitrate in various directions in the crystal. O, first set of specimens; ϕ, second set of specimens; e, points obtained on cooling.

Discussion

The most striking feature of the data presented is the very large difference in expansion in the directions of the crystallographic axes. In the direction of the *a* axis the total expansion at 275° is only 0.3%, while perpendicular to this direction (parallel to *c* axis) it is 5% or 17 times as great. Anisotropy of this magnitude is extremely unusual, at least among the substances thus far described in the literature, and is to be accounted for by the abnormal increase in length along the *c* axis during the transition. It will be interesting to see whether, when other substances having the same type of transition are discovered, they will possess a similar behavior.

It is important to note that the effect of the transition along the *a* axis is extremely slight, if indeed it exists at all, since the expansion coefficient actually decreases slightly in the transition range. This fact together with the abnormal increase in length along the *c* axis leads to some important conclusions regarding the mechanism of the change.

In order to picture the relative motions of the various parts of the lattice it is necessary to have the structure of the lattice clearly defined. It appears to be well established that a number of nitrates, including sodium nitrate, owe their strong double refraction to the arrangement of the nitrate groups in parallel planes. It also appears that the metal ions lie in planes parallel to, and alternating with, the planes of the NO_3 group.

If the interpretation of the x-ray data by Kracek, Posnjak and Hendricks is correct the abnormal expansion between 150 and 280° is indicative of an increasing amplitude of oscillation of the NO_3 ions in the plane of the group and perpendicular to this plane, that is, the oscillation is about the trigonal axis of the crystal unit. It is also probable that actual rotation is present for a small number of ions during the transition interval, the proportion of such ions increasing with temperature.

Applying these concepts to the expansion data one is led to conclude that the increasing amplitude of oscillation results in a marked separation of the planes of the nitrate ions and metal ions without any abnormal increase in the dimensions in the plane of the group. In other words the intermolecular forces which are affected are those acting between the alternate layers of nitrate and metal ions whereas the forces acting in those planes remain substantially unchanged.

A more exact description can be made along the lines of Pauling's theoretical treatment. As the temperature is increased the energy level, *n*, of the nitrate ion will also change. When $n + 1$ becomes greater than a certain critical value, which depends upon the moment of inertia and the constant of the potential function (V_0), the motion becomes rotational. As n approaches the transition value the eigenfunctions change completely in nature, becoming more nearly constant This change increases the repulsive forces between alternate layers of nitrate ions and possibly between the layers of nitrate and metal ions resulting in a tendency to spread the crystal lattice as soon as an appreciable number of molecules have begun to rotate. But spreading the lattice decreases the forces between the layers and decreases V_0. This permits more molecules to rotate and the effect builds up to give increasingly greater expansion

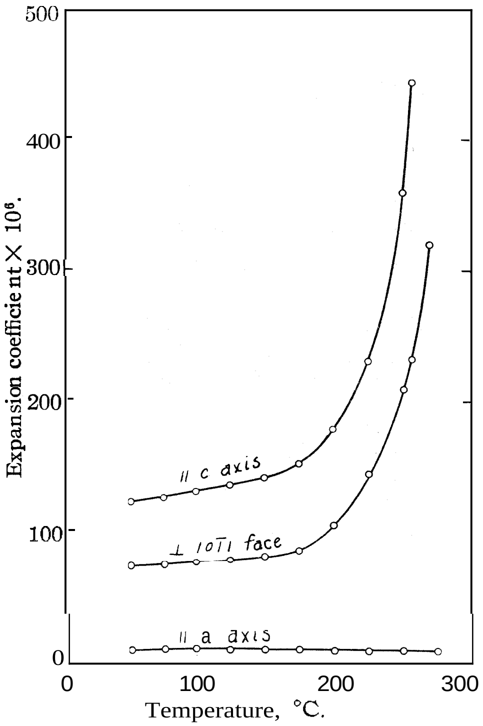

Fig. 3a.—True linear expansion coefficient of sodium nitrate in various directions in the crystals.

perpendicular to the planes of the NO_3 ions. When all the nitrate groups are rotating the effect is no longer observed.

So far rotation about an axis normal to the plane of the NO_3 group has been considered The ion has two other rotational degrees of freedom about axes in the plane of the group but these are apparently degenerate, as pointed out by Kracek, Posnjak and Hendricks, and hence will not be considered.

Attention should also be called to the irreversible contraction observed in the direction of the a axis when the critical point is passed. This effect may be due to an actual contraction of the specimen but it is also possible that in this region the crystal becomes so soft that it can no longer support the weight of the upper plate of the interferometer. While no definite choice can be made at present between these explanations, the fact that the contraction was not reproducible with different specimens renders the latter hypothesis slightly more acceptable.

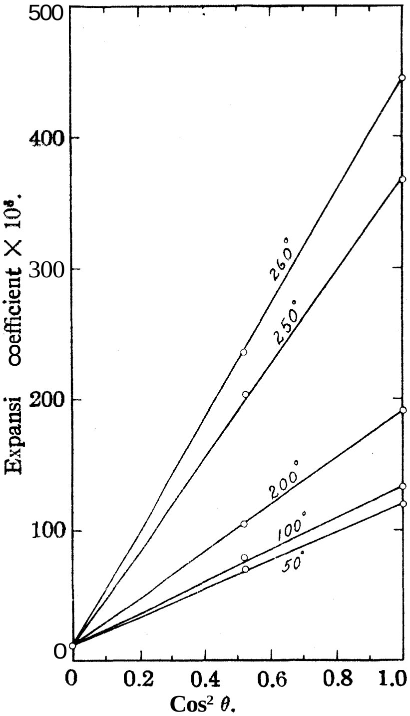

Fig. 3b.—True expansion coefficient a plotted as a function of cos² θ.

The abnormal increase in length along the c axis also leads to an appreciable decrease in α, that is, the angle between the axes of the true structural unit[5] as Kracek, Posnjak and Hendricks have already noted. Specifically they found that α decreased from 47°14' at 25° to 45°35' at 280°. If we assume for 25° the axial ratio a:c = 1:0.8297 which corresponds to $\alpha = 47°14'$, values of the axial ratio and of α for 280° can also be obtained from the expansion data. The axial ratio so computed is 0.8662, corresponding to an angle of 45°34', which is only one minute smaller than the angle calculated from the x-ray data. This agreement is most satisfactory.

As mentioned above the data for successive runs on the same set of samples and measurements on different sets gave results which showed that the effects observed were unquestionably reproducible. It can further be shown that the data for the three directions measured are consistent within themselves. The simplest manner of comparing the data for this purpose

(5) Cf. Wyckoff, *Phys. Rev.*, **16**, 149 (1920).

is by means of the cosine-square law which states that in a crystal having hexagonal symmetry the expansion coefficient is a linear function of the square of the cosine of the angle between the direction of measurement and the principal axis of the crystal.

The expansion coefficients at a number of temperatures for the three directions studied are plotted against $\cos^2\theta$ in Fig. 3b. In plotting these curves no correction has been made for the change in the angle θ with temperature but for the set of measurements in the direction perpendicular to the rhombohedral faces it has been assumed to be 43°46′, the value at 25°, throughout. The neglect of this change is justified by the fact that it is quite small and introduces an uncertainty less than that in the orientations of the specimens along the a and c axes. It is obvious, however, from the figure that the results are consistent among themselves within the limit of experimental error.

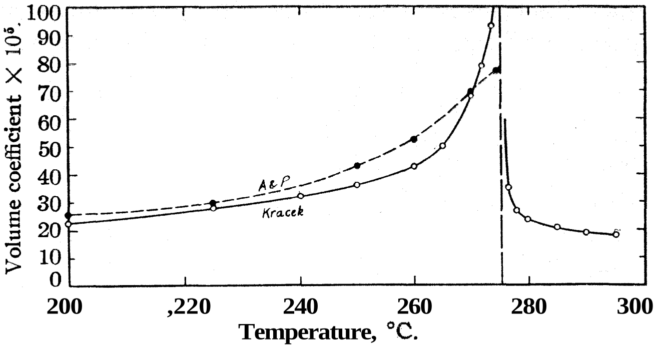

Fig. 4.—Volume expansion coefficient of sodium nitrate: O, Kracek direct determination; ●, Austin and Pierce, calculated from linear expansion coefficients along the crystallographic axes.

It is also possible to calculate the volume expansion of the crystal from the expansions along the directions of the crystallographic axes. Thus the coefficient of cubical expansion β is equal to $\alpha_3 + 2\alpha_1$ where α_3 and α_1 are the linear coefficients in the c direction and *a* directions, respectively. The values of β so calculated are shown by the dotted line in Fig. 4 where they are compared with the direct determinations of Kracek (solid line). The agreement is satisfactory considering the uncertainties inherent in each curve.

It may be worth mentioning in conclusion that our measurements of the temperature at which the transition is completed appeared to be nearer 278° than 275.5° as reported by Kracek. The difference is not serious and may arise from the fact that our temperature measurements were not so precise as his or may possibly be due to different definitions of the completion of the change.

Summary

It has been shown by means of linear expansion measurements in different directions in single crystals of sodium nitrate that the gradual transition occurring between **150** and 278° is most marked in the direction of the *c* axis and was not detected along the a axis. This is interpreted as indicating a separation of the layers of nitrate ions resulting from the change in the eigenfunctions caused by the rotation of the ion. The angle a is calculated to be **45'34'** at 280° as compared with a = **45'35'** obtained from the x-ray data by Kracek, Posnjak and Hendricks.

Anomalous Electrolytes. I. The Electrical Conductivity of Solutions of Iodine and Cyanogen Iodide in Pyridine[1]

BY L. F. AUDRIETH[2] AND E. J. BIRR

It has often been shown that substances which are usually designated as non-electrolytes, with reference to water as solvent, may in suitable media exhibit salt-like properties and yield conducting solutions. This anomalous behavior has been ascribed either to (1) a transformation of a pseudo-salt into a true salt, or (2) to reaction of the solute with the solvent with the resultant formation of solvated compounds of greater or lesser stability which conduct the electric current. Thus nitro compounds have been found to yield conducting solutions in ammonia[3] and in hydrazine,[4] whereas iodine and the cyanogen halides have been found to act as electrolytes in such solvents as liquid sulfur dioxide, arsenious chloride and sulfuryl chloride.[5]

In the first paper of this series the results of a preliminary investigation concerning the nature of solutions of iodine and cyanogen iodide in pyridine, as revealed by a study of their electrical conductivity, are presented.

Experimental

Materials.—The solvent, Pyridin purissimum Kahlbaum, was dried over solid potassium hydroxide and then distilled repeatedly from a solution of cadmium per-

chlorate in an atmosphere free from carbon dioxide and water vapor. The first and final fractions were always rejected. This procedure sufficed to give a highly purified arid anhydrous pyridine whose specific conductivity varied from $\kappa_{25°} = 2.0$ to 7.0×10^{-8}.

Iodine was purified by sublimation from a mixture of pure and dry sodium iodide and iodine. Cyanogen iodide was also purified by sublimation.

Apparatus.—For details of the apparatus employed in carrying out the conductivity measurements reference is made to the original articles.[6] All measurements were carried out at 25°. The conductivity cell which had been employed previously in a study of the conductivity of salts in pyridine[7] was used in the present investigation. The cell constant, $K_c = 0.0824$, was found to have remained unchanged as indicated by a recheck against standard potassium chloride solutions and by comparison with other cells.

(a) Iodine in **Pyridine.**—Iodine dissolves in pyridine to give a brown solution. Addition of water to such a solution, either immediately or after the solution has stood for some time, results in the precipitation of a rather unstable complex compound possessing the formula, $C_5H_5N \cdot I_2$.[8] Since iodine solutions in pyridine are brown, pyridine has been designated as an "active" solvent and one in which "the reactivity (of iodine) is increased by virtue of its coordinative linkage."[9] Thus, iodine in pyridine reacts with silver saccharide to precipitate silver iodide, a reaction which does not take place, or only very slowly, in solvents in which iodine dissolves to give a violet solution.[9]

Both freshly prepared solutions and those which have aged are decolorized by shaking with mercury.

An investigation of such solutions with respect to their electrical conductivity[10] revealed the fact that these undergo rapid change with time. The conductivity increases rapidly during the first hour and then very slowly over a time interval of 100–150 hours. To follow this change more carefully, accurately weighed amounts of iodine were dissolved in pyridine and the change in conductivity with respect to time investigated. Several typical runs are noted in Table I. The concentrations in moles per liter, C, and the dilutions in liters per mole, V, are noted. κ represents the specific conductivity, λ the molecular conductivity calculated on the basis of iodine dissolved as I_2. All values were corrected for the specific conductivity of the solvent, $\kappa_{\text{solv.}}$, which was measured each time before the addition of the iodine. The time in hours is noted.

It is clearly evident from the data in Table I that the character of iodine solutions in pyridine changes profoundly on standing. This fact had already been surmised by Ley and Engelhardt,[11] also by Getman,[12] who

observed a difference in the absorption spectrum of freshly prepared and older solutions of iodine in pyridine.

Since the X-values obtained were extraordinarily high it was deemed advisable to carry out several series of measurements at higher dilutions in order to determine the character of the conductivity curve. The following method was employed.

Stock solutions of iodine in 100 cc. of pyridine were prepared and then kept in a thermostat at 25° for one hundred hours to permit the reaction to come to equilibrium. Fifty cc. of pyridine was then pipetted into the conductivity cell and the specific conductivity of the solvent determined. The various concentrations were then prepared by the addition of definite volumes of stock iodine solution to the solution in the cell. The results of three such series of measurements are presented in Table II in which the molar conductivities, X, and the concentrations, C, are noted.

TABLE II

MOLAR CONDUCTIVITIES OF IODINE SOLUTIONS IN PYRIDINE, $t = 25°$

$C \times 10^{-5}$	λ	$C \times 10^{-5}$	λ
0.0000	132.0	34.38	62.0
4.059	103.5	36.94	59.6
7.814	91.1	42.36	60.7
8.71	90.9	52.9	61.1
16.02	77.1	104.5	53.9
16.77	76.9	224.2	48.4
18.01	73.0	240.8	47.8
22.95	70.5		

At high dilutions a constant conductivity value was quickly attained, but at higher concentrations the solutions revealed a gradual increase toward a constant maximum value. Above dilutions of 5000 liters excellent agreement between the various series of runs was obtained, but with increasing concentrations the final values often showed considerable divergence. The more dilute the original stock solution, the more rapidly were the equilibrium values approached.

By plotting the experimentally determined λ_v-values against the square root of the concentration and extrapolating to infinite dilution (which is permissible since values above 5000 liters lie on a straight line), the surprising value of approximately 130–2 is obtained. This value for the limiting conductivity is about twice as great as might be expected on the basis of a simple dissociation of the iodine molecule into a positive and a negative ion. Such a value might have appeared logical had chemical interaction between solvent and solute resulted in the formation of two molecules of pyridonium iodide, $C_5H_5N{\cdot}HI$, from one molecule of iodine. However, pyridine solutions of iodine, even after standing for a month, still precipitate the insoluble complex, $C_5H_5N{\cdot}I_2$, on the addition of water, and are still largely decolorized by shaking with mercury. Such a reaction can, therefore, not be considered as an explanation for the observed phenomena.

There is only one other possibility and this involves the formation of a ternary electrolyte. In order to explain the experimental findings the following equilibrium must be set up:

$$\mathrm{Py} + \mathrm{I_2} \rightleftharpoons \underset{(\mathrm{A})}{\mathrm{Py{\cdot}I_2}} \rightleftharpoons \underset{(\mathrm{B})}{\mathrm{IPy^+}} + \mathrm{I^-} \rightleftharpoons \underset{(\mathrm{C})}{\mathrm{Py^{++}}} + 2\mathrm{I^-} \qquad (1)$$

$$2[\mathrm{Py{\cdot}I_2}] \rightleftharpoons \underset{(\mathrm{D})}{\mathrm{IPy^+}} + \mathrm{I{\cdot}PyI_2^-} \qquad (2)$$

Equation (I) explains satisfactorily (1), the transformation of the pyridine–iodine complex, a non-electrolyte, into a true salt, *iodipyridonium iodide*[13] (A to B); (2), the extremely labile character of the equilibrium in that the addition of water, and of mercury, drives the reaction to the left with the removal of iodine; (3), the extremely high value for the limiting conductivity, λ_∞, which can only be explained by the formation of a ternary electrolyte (C); (4), the displacement of the equilibrium to the right with decreasing concentration of iodine. Since electrophoresis of such iodine-pyridine solutions (0.02–0.03 *M*) results in the migration of the colored ion to the anode, it is very probable that the transformation of the pseudo-salt involves the intermediate formation of polyiodides, that is, the reaction is a stepwise process as indicated by Equation (2). It is therefore highly probable that solutions of iodine in pyridine contain in equilibrium with one another the various forms A, B, C and D. Dilution shifts this equilibrium to the right with formation of the ternary electrolyte (C), whereas the forms A, B and D predominate in more concentrated solutions.

(b) Cyanogen Iodide in **Pyridine.**—Clark and Streight[14] have already

---

(13) In a publication entitled "Über eine neue Klasse von Verbindungen des positiv einwertigen Jods" (Verlag Hirzel, Leipzig, 1932), which has just come to the attention of the authors, Carlsohn describes the preparation and properties of a whole series of salts of the two hypotheticl bases, I(Py)OH and I(Py)OH. Our theory that the rapid change in conductivity of solutions of iodine and cyanogen iodide in pyridine is due to the formation of quaternary iodipyridonium salts is further substantiated by these findings of Carlsohn.

(14) Clark and Streight, Trans. *Roy. Soc. Canada,* [3] **22**, 323 (1928).

shown that solutions of cyanogen iodide in pyridine conduct the electric current. Electrolyses of 0.1 M solutions result in the discharge of cathodic iodine. They ascribe the conductivity of the cyanogen halides to the formation of quaternary pyridonium salts.[14]

An investigation of solutions of cyanogen iodide in pyridine with respect to their electrical conductivity revealed the fact that these too, like the iodine–pyridine solutions, suffered an increase in conductivity on standing. Dilute solutions of cyanogen iodide are at first colorless, but become on standing successively yellow, orange, red-brown and finally deep red-brown. The results of three series of measurements, in which the change in conductivity was observed, are given in Table III.

TABLE III

CHANGE IN CONDUCTIVITY OF SOLUTIONS OF CYANOGEN IODIDE IN PYRIDINE WITH TIME, $t = 25°$

32.00	8.897			47.00	9.48
50.08	9.74			54.43	9.90
98.83	10.8			72.50	10.81
119.00	11.26			77.70	11.02
				126.00	11.77

The change in conductivity again is due to the formation of an electrolyte. It seems quite probable that a similar sort of reaction mechanism may be postulated for solutions of cyanogen iodide in pyridine as in the case of iodine. However, the transformation of the pseudo-salt into an electrolyte proceeds much more slowly and is further-complicated by side reactions.[15] It is of interest to note that the conductivity values for solutions of cyanogen iodide in pyridine are much lower than those of corresponding concentrations of iodine in this solvent. This fact further supports the formation of an iodipyridonium cyanide,[16] possibly also of a corresponding

---

(15) Interaction of pyridine with an ethereal solution of cyanogen bromide results in the formation of an extremely unstable addition compound which can be obtained in crystalline form This substance breaks down rapidly to give a variety of ill-defined decomposition products [Shimidzu. *Chem. Zentr.*, I, **2202** (1927)].

(16) Iodine monochloride also dissolves in pyridine to give a solution whose conductivity increases rapidly upon standing The process of solution is, however, accompanied by very apparent decomposition. It is highly probable that the rapid increase in conductivity may here also be ascribed to the formation of a quaternary pyridonium salt. This assumption is further supported by the fact that the addition of pyridine to a solution of iodine monochloride in ether results in the formation of a crystalline compound, $C_5H_5N\ ClI$ [see Pictet and Krafft, ***Bull. soc.*** chim., [3] 7, **73** (1892)].

ternary electrolyte. Cyanides are much weaker salts in pyridine than are iodides?

Summary

Both iodine and cyanogen iodide dissolve in pyridine to give solutions whose electrical conductivity increases with time to give maximum values The experimental evidence indicates that reaction between solvent and solute results in the primary formation of a non-conducting addition compound which in time changes over to a true quaternary pyridonium salt. In the case of iodine the extraordinarily high value for the molecular conductivity at infinite solution can only be explained by the formation of a ternary salt.

Electric Moments of Hydrazine and its Derivatives[1]

BY L. F. AUDRIETH,[2] W. NESPITAL AND H. ULICH

In a discussion of the structure of azo compounds as revealed by the measurement of their dipole moments, Bergmann, Engel and Sandor[3] arrive at the conclusion that hydrazo compounds probably also possess a trans-configuration, first, because azotoluene and hydrazotoluene form mixed crystals, and, second, because the former has a zero electric moment and must therefore possess a structure of highest symmetry. While their statement "that only similarly constituted substances can form mixed crystals" is not a question for dispute, it nevertheless seemed highly improbable that a definite comparison between the structures of these two classes of compounds, based on this one observation, was permissible. That hydrazo compounds might easily assume the trans-configuration in solid mixtures in which this form is forced upon it by the symmetry of the other component is very probable. That they should prefer this structure exclusively, say in dilute benzene solution, seemed questionable in view of the fact that the $>$N—N$<$ linkage in hydrazo compounds permits free rotation, that is, theoretically allows a variety of positions of the substituents with respect to each other, whereas the positions of groups in azo compounds with —N=N— linkage is presumably fixed.

That this objection to Bergmann's postulation is correct is conclusively

proved by our experimental results. Hydrazobenzene possesses an appreciable electric moment, whereas it should have zero moment if it assumed only the trans-configuration, that is, if the substituents were fixed in a position of highest symmetry.

We have also measured the dielectric constants of dilute benzene solutions of hydrazine and several of its derivatives in order to determine the effect of substitution upon the dipole moment of the parent hydronitrogen.

Experimental

Apparatus and Method.—The dielectric constants of the various binary solutions were measured in the apparatus designed and used by Ulich and Nespital,[4] based on the resonance principle and employing a crystal controlled oscillator. For a detailed description of the apparatus and its operation reference is made to the original articles.[4]

The various concentrations were prepared either by the direct addition of the solute to the benzene solution in the condenser cell, or by the preparation of standardized stock solutions in benzene which were pipetted to the solution in the cell. In the latter case an equal amount of solution was always removed from the cell before the addition of the standard solution, so that the volume of liquid remained constant throughout a single series of measurements.

Benzene was used exclusively as the non-polar solvent. Carbon disulfide and carbon tetrachloride had to be eliminated from consideration because of the interaction of these solvents with hydrazine and its derivatives.

All substances were carefully purified either by recrystallization from appropriate solvents, or by distillation under reduced pressure.

Evaluation of the Experimental Data.—The polarization of a binary liquid mixture may be calculated in accordance with Debye[5] from the equation

$$P_{1,2} = P_1X_1 + P_2X_2 = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{M_1X_1 + M_2X_2}{d} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{M_{1,2}}{d}$$

in which $P_{1,2}$ is *the* molar polarization of the binary liquid mixture; P_1 and P_2, X_1 and X_2, M_1 and M_2, the molar polarizations, mole fractions and molecular weights of the solvent and solute, respectively; ϵ, the dielectric constant of the solution; d, the density of the solution; $M_{1,2}/d$, the average molecular volume of the solution.

The density of the most concentrated solution of each series of measurements was determined and $M_{1,2}/d$ calculated for this concentration. The values for the less concentrated solutions were obtained by interpolation, Only in the case of hydrazine were all $M_{1,2}/d$ values determined by interpo-

---

[4] Ulich and Nespital, *Z. physik. Chem.*, **16B**, 227 (1932).

[5] "Polar Molecules," The Chemical Catalog Co., Inc., New York, 1929. See also C. P. Smyth, "Dielectric Constant and Molecular Structure," A. C. S. Monograph, No. 55, The Chemical Catalog Co., Inc., New York, 1931.

lation between the molecular volumes of pure hydrazine and of pure benzene, assuming a linear variance of $M_{1,2}/d$ with X_2. Where the densities of the pure substances were available, theoretical values for $M_{1,2}/d$ were calculated in the same way and for control compared with those found by direct density measurements.

The molar polarization of the solute, P_2, was calculated on the basis of the above equation in the following form: $P_2 = (P_{1,2} + P_1X_2 - P_1)/X_2$. P_∞ was obtained by extrapolation of the P_2 values to infinite dilution (where $X_2 = 0$). The electric moments were then calculated on the basis of the equation, $\mu = 0.01273 \times 10^{-18} \sqrt{P_M T}$, in which P_M is the polarization due to the permanent moment of the molecule and T, the absolute temperature. P_M was obtained by correcting P_∞ for the induced polarization, $P_E + P_A$, due to deformation of the molecule by the applied electric field. P_E was obtained either by adding together the individual atomic refractivities (D-line) with suitable allowance for variance in type of linkage or, where density and refractive index were available, by application of the Lorenz–Lorentz expression. P_A was arbitrarily taken as 15% of P_E in accordance with the suggestion of K. L. Wolf.[6]

The experimental data[7] are summarized in the tables.

TABLE I

HYDRAZINE,[8] N_2H_4, $t = 18°$

18°	2.286	88.64	26.597
20°	2.282	88.86	26.605

[8] The anhydrous hydrazine employed had been prepared for use in making conductivity measurements by Dr. H. Hilgert (Thesis, Rostock, 1932). Its specific conductivity was $\kappa_{25°} = 1 \times 10^{-6}$. Due to its slight solubility in benzene, only very dilute solutions could be prepared. The presence of a trace of moisture in the solvent, or exposure of the benzene solution to the air, rapidly caused the solution to become cloudy. In Table I each concentration, X_2, represents a separately prepared stock solution of hydrazine in benzene. Each ϵ-value represents an average of several measurements, each time with fresh portions of the same stock solution.

Discussion.—Our values for phenylhydrazine vary somewhat, but if the upper limit is considered as being more nearly the correct one, it is evident that the moments of (2), **(3)** and (4) do not vary greatly from one another and are practically identical with that of hydrazine itself. This result is not at all surprising if one considers that free rotation around the axis of the N—N linkage is possible in hydrazine and those of its derivatives where such rotation is not hampered by the size of the substituent groups. The observed differences may rest in part with the manner in which the P_A values have been approximated. There is reason to assume that hydrocarbon groups give a relatively smaller P_A contribution than has arbitrarily been assigned to them in the above table on the basis of Wolf's suggestion. Consequently, the differences in the dipole moments of the first four substances lie within the limits of the experimental and calculative errors of our method.

That benzaldehyde phenylhydrazone should have a higher moment might also be expected, since it undoubtedly possesses a less symmetrical structure than any of the above substances. If the moment for benzalazine is assumed to be due to the relative positions of the $C_6H_5CH=$ groups, the low moment may be explained as resulting from the fact that the two substituent groups oscillate preferentially in a sector around the trans-position and that, because of the size of these groups, complete rotation around the N—N axis is prevented.[12]

Synthetic Glycerides. IV. Esters of Aromatic and Aliphatic Acids

BY DONALD T. JACKSON AND C. G. KING

The general purpose of our investigation has been stated in previous communications.[1] The structural relationships found for fatty acid esters of glycerol have been in agreement with Fischer's[2] findings which showed that methods of preparation which were expected to yield β-monoglycerides gave a-monoglycerides, and that methods which were thought to yield a,β-diglycerides produced a,α'-diglycerides. However, Abderhalden and Eichwald[3] and Bergmann[4] apparently succeeded in preparing α,β-diglycerides of aromatic acids by an indirect and difficult method using propylamines.

Several investigators[6] have continued to use methods which give compounds of different structure than that assigned.[6]

Helferich and Sieber,[7] by the use of triphenylmethyl (trityl) ethers of glycerol, prepared the β-mono-(p-nitrobenzoate) and the β-monobenzoate (probably the first true β-esters of glycerol), and the α,β-dibenzoate.

Bergmann and Carter[8] prepared β-monopalmitin, the first fatty acid ester of this type, by the catalytic reduction of β-palmito-α,α'-benzylidene glycerol.

In the present investigation the β-mono-(p-nitrobenzoate) and the α,β-dibenzoate of glycerol were prepared by the method of Helferich and Sieber and their identity established by their ready conversion, when

treated with acyl chlorides, into the β-mono-(*p*-nitrobenzoate)-α,α′-dihenzoate (melting point 87°) and the α-mono-(*p*-nitrobenzoate)-α′,β-dibenzoate of glycerol (melting point 113°), respectively. These compounds, to our surprise, were identical with those prepared by Fischer's method (from acetone glycerol). Apparently there was no molecular rearrangement involving the migration of an acyl group in these glycerol esters of aromatic acids. However, when the same reactions were followed through for the preparation of 8-monopalmitin, β-monostearin, α,β-dipalmitin and α,β-distearin, the only products which could be identified were the a-monoglycerides in the first case, and the symmetrical diglycerides in the second case. The symmetrical aromatic ester also melted lower than the unsymmetrical isomer, reversing the order for aliphatic esters. This peculiarity appears to be characteristic of the esters with one *p*-nitrobenzoate group.[9]

Experimental

The α,α′-ditrityl and a!-monotrityl ethers of glycerol were prepared essentially as described by Helferich and co-workers, having melting points of 176° and 108–110°, respectively.

Preparation of **α,α′-Ditrityl** Ether of **β-Monopalmitin.**—To a solution of 5 7 g. of symmetrical ditrityl ether of glycerol dissolved in 20 cc. of dry benzene and 3 cc. of quinoline, there was added a mixture of 3 g. of palmityl chloride and 3 cc. of quinoline. This mixture was kept at 40° for eighty-four hours, by which time a heavy white precipitate of quinoline hydrochloride had settled out. The mixture was taken up in 50 cc. of benzene and 50 cc. of half-normal sulfuric acid, washed several times with half-normal sulfuric acid, then with 10% potassium bicarbonate solution and finally with water. After drying over sodium sulfate, the benzene was evaporated at room temperature. The sirup which remained was taken up in acetone and poured into anhydrous alcohol. A precipitate formed which, after several recrystallizations from acetone and alcohol, melted at 71.5°, yield 5.6 g.

The α,α′-ditrityl ethers of 6-monostearin, m. p. 78.5–79.5°, β-mono-(*p*-nitrobenzoate), m. p. 187.5" and β-monolaurin, m. p. 47°, were prepared in a similar manner.

Preparation of Monotrityl Derivatives.—The α-monotrityl ethers of a, β-dipalmitin, melting point 40.5–41.5°, of α,β-distearin, melting point 46–48°, and of α,β-dibenzoate of glycerol, melting point 92–94°, were prepared according to the method which is described for the preparation of the a-monotrityl ether of α,β-dipalmitin. A mixture of 11.2 g. of palmityl chloride and 5 cc. of quinoline was added to a solution of 6.7 g. of glycerol monotrityl ether dissolved in 20 cc. of benzene and 5 cc. of quinoline. The reaction mixture, after standing at 35–40' for twenty-four hours, was taken up in benzene, washed with cold half-normal sulfuric acid, then with 10% potassium bicarbonate solution and dried over sodium sulfate. The product was crystallized by evaporation of the benzene and recrystallized from acetone–alcohol mixture; melting point 40.5–41.5°; yield 40%.

Removal of Trityl Groups.—The following procedure for the removal of the trityl groups from α,α′-ditrityl ether of β-monopalmitin was used for all compounds of this type. A solution of 5 g. of the ditrityl ether of β-monopalmitin was shaken for one hour at 0° with 15 cc. of a chloroform solution saturated at 0° with hydrogen bromide. Any triphenylmethyl bromide which separated was filtered off. The filtrate was washed with

---

(9) *Ber.*, **53**, 1596 (1920); *ibid.*, 54, 936 (1921).

potassium bicarbonate solution and with water, dried over sodium sulfate, and the solvent evaporated. The residue was taken up in acetone, petroleum ether was added and the solution allowed to stand. Crystals of triphenylcarbinol (from the hydrolysis of triphenylmethyl bromide) soon appeared and were filtered off. The a-monopalmitin crystallized out after evaporating part of the solvent and cooling.

Molecular weights were determined for all of the new compounds and most of the intermediates used in their preparation, using the method of Menzies and Wright,[10] with ethyl acetate as the solvent.

Summary

The β-mono-(*p*-nitrobenzoate) and the α,β-dibenzoate of glycerol have been prepared from glycerol trityl ethers and found to correspond to the compounds previously prepared by Helferich and Sieber. These compounds, when thus prepared, apparently do not undergo a rearrangement involving the migration of the aromatic acyl group. The same procedures when used for the preparation of β-monopalmitin, β-monostearin, α,β-dipalmitin and α,β-distearin resulted in the migration of the aliphatic acyl groups and the production of the isomeric a-monoglycerides and α,α′-diglycerides.

The synthesis and identification of the following compounds has been described: the α,α′-ditrityl ether of β-monostearin, the a,α′-ditrityl ether of β-monolaurin, the a-monotrityl ether of α,β-dipalmitin, the a-monotrityl ether of α,β-distearin, and the a-monotrityl ether of acetoneglycerol.

The Number of Structurally Isomeric Hydrocarbons of the Ethylene Series[1]

BY HENRY R. HENZE AND CHARLES M. BLAIR

The method for calculating the number of structural isomers by establishing a unique relationship between the number of structurally isomeric hydrocarbons of the methane series and of the acetylene series and the alkyl groups of which these may be considered to be composed may also be utilized successfully in calculating the number of structurally isomeric hydrocarbons of the ethylene series.

The homologs of ethylene are divided into four groups: A, consisting of those hydrocarbons which may be formed, theoretically, by replacing one hydrogen atom of ethylene by an alkyl radical; B, in which two hydrogen atoms are replaced by alkyl groups; C, in which three hydrogen atoms are replaced by alkyls; and D, in which all four hydrogen atoms are replaced.

---

[1] This paper was presented before the Central Texas Section of the American Chemical Society at its annual meeting in Waco, Texas, on April 23, 1932. Previous contributions in this series are Henze and Blair, THIS JOURNAL, 53, 3042–3046, 3077–3085 (1931); 54, 1098-1106, 1538–1545 (1932); Coffman, Blair with Henze, *ibid.*, 55, 252-253 (1933).

Group A.—The total number of structural formulas of olefin hydrocarbons of N carbon atom content included in Group A, $CH_2{=}CHR$, and formed by replacing one hydrogen atom in ethylene by an alkyl radical of $N - 2$ carbon atom content, will equal the total number of such alkyl radicals[2] or $T_{(N-2)}$.

$$A_N = T_{(N-2)} \tag{A}$$

Group **B.**—The structural formulas of the hydrocarbons of Group B are theoretically of two types: (1), those in which the alkyl radicals, R- and R'- (the carbon content of R- plus R'- always equaling $N-2$), are of unequal carbon content; and (2), in which the alkyls are of equal carbon content. Type (2) is actually impossible with hydrocarbons of uneven carbon content for in this type N—2 should be divisible by two. Each of the types (1) and (2) may be further divided into two subtypes: (a), in which the two alkyl radicals are attached to the same carbon atom of the ethylene group, $H_2C{=}CRR'$; and (b), in which the alkyls are not attached to the same carbon atom, $RHC{=}CHR'$. Derivation of (finite) recursion formulas for calculating the number of isomeric hydrocarbons of odd carbon atom content included, respectively, in subtypes (a) and (b) leads to identical expressions Hence twice the number calculated by means of that formula equals the total number of isomeric homologs of ethylene included in Group B. An analogous relationship exists between subtypes (a) and (b) of the hydrocarbons of even carbon atom content. The following represent such formulas for odd and even carbon atom contents, respectively

Odd:

$$B_N = 2[T_1{\cdot}T_{(N-3)} + T_2{\cdot}T_{(N-4)} + \dots T_{(N-3)/2}{\cdot}T_{(N-1)/2}] \tag{B$_o$}$$

Even:

$$B_N = 2\left[T_1{\cdot}T_{(N-3)} + T_2{\cdot}T_{(N-4)} + \dots T_{(N-4)/2}{\cdot}T_{N/2} + \frac{T_{(N-2)/2}{\cdot}(1 + T_{(N-2)/2})}{2}\right] \tag{B$_e$}$$

Note that the subscripts in each term add up to N—2, and that the number of terms is $(N-3)/2$ for odd carbon content and $(N-2)/2$ for even.

Group C.—The structural formulas of the hydrocarbons included in Group C are theoretically of three types: (1), those in which the alkyl radicals, R-, R′- and R″- (the carbon content of R- plus R′- plus R″- always equaling N—2), are of different carbon content; (2), those in which two of the alkyl radicals, R- and R′- are of equal carbon content and different from that of the third, R″-; and (3), those in which all three alkyls are of the same carbon content. Type (3) is actually possible only when $(N-2)/3$ is an integer.

Type (1) may be further divided into three subtypes: (a), in which the alkyl radicals R- and R'- are attached to the same carbon atom of the ethylene group, $RR'C{=}CHR''$; (b), in which R- and R″- are attached

---

[2] For the total number of alkyl radicals, which are, of course numerically equal to the number of structurally isomeric alcohols of the methanol series, through C_{20} see THIS JOURNAL, 63, 3045 (1931).

to the same carbon atom, $RR''C{=}CHR^1$; and (c), in which R'- and R''- are attached to the same carbon atom, $R'R''C{=}CHR$. Derivation of (finite) recursion formulas for calculating the number of isomeric hydrocarbons included in subtypes (a), (b) and (c) leads to identical expressions. Hence the total number of isomers included in type (1) will equal three times the number calculated by that expression for each subtype or

$$3\Sigma T_i \cdot T_j \cdot T_k \tag{C$_1$}$$

where i, j and k are integers, distinct, and greater than zero; $i + j + k = N - 2$; $i > j > k$.

Type (2) may be further divided into two subtypes: (a), in which the two alkyl radicals of equal carbon content are attached to the same carbon atom of the ethylene group, $RRC{=}CHR^1$; and (b), in which the two alkyls of equal carbon content are not attached to the same carbon atom, $RR'C{=}CHR$. The number of isomers included in subtype (a) equals $1/2\Sigma T_i \cdot T_j \cdot (1 + T_i)$. The number of isomers in subtype (b) equals $\Sigma(T_i)^2 \cdot T_j$. Hence, the total number of isomeric homologs of ethylene included in type (2) may be calculated by use of a summation of these two expressions, or

$$1/2\Sigma T_i \cdot T_j \cdot (1 + 3T_i) \tag{C$_2$}$$

where i and j are integers, distinct, and greater than zero, and $2i + j = N - 2$.

The total number of isomers of type (3) is given by the expression

$$1/2\Sigma (T_i)^2 \cdot (1 + T_i) \tag{C$_3$}$$

where i is an integer greater than zero, and $3i = N - 2$.

Group D.—The structural formulas of the hydrocarbons included in group D are theoretically of five types: (1), those in which the four alkyls R-, R'-, R''- and R'''- are of different carbon content; (2), those in which two of the alkyl radicals are of equal carbon content and each of the others, R'- and R''-, of different carbon content; (3), those in which three of the alkyl radicals are of the same carbon content and different from that of the fourth, R'-; (4), those in which all four alkyls are of the same carbon content; and (5), those in which the four alkyl radicals can be divided into two sets of two each, the individual members of each set being of the same carbon content but differing in carbon content from the members of the other set. It will be seen that types (4) and (5), though theoretically possible for hydrocarbons of both odd and even carbon content, are actually possible only for the latter, for in type (4) $N-2$ should be divisible by four, and in type (5) $N-2$ should be divisible by two.

Type (1) may be further divided into three subtypes: (a), in which the alkyl radicals R- and R'- are attached to the same carbon atom of the ethylene group, $RR'C{=}CR''R'''$; (b), in which R- and R''- are attached to the same carbon atom, $RR''C{=}CR'R'''$; and (c), in which R- and R'''- are attached to the same carbon atom, $RR'''C{=}CR'R''$. Here, again, the expression for the number of isomers in subtype (a) is identical with that for (b) and for (c), hence the total number of isomeric homologs of ethylene of type (1) is given by the formula

$$3\Sigma T_h\cdot T_i\cdot T_j\cdot T_k \tag{D$_1$}$$

where h, i, j and k are integers, distinct, and greater than zero; $h + i + j + k = N - 2$; and $h > i > j > k$.

Type (2) may be further divided into two subtypes: (a), in which the two alkyl radicals of equal carbon content are attached to the same carbon atom of the ethylene group, RRC═CR′R″; and (b), in which the two alkyl radicals of equal carbon content are not attached to the same carbon atom, RR′C═CR″R. The number of isomers included in subtype (a) equals $1/2\Sigma T_i\cdot T_j\cdot T_k\cdot(1 + T_i)$. The number of isomers in subtype (b) equals $\Sigma(T_i)^2\cdot T_j\cdot T_k$. Hence, the total number of isomeric homologs of ethylene included in type (2) is equal to the sum of these expressions, or

$$1/2\Sigma T_i\cdot T_j\cdot T_k\cdot(1 + 3T_i) \tag{D$_2$}$$

where i, j and k are integers, distinct, and greater than zero; $2i + j + k = N - 2$; and $j > k$.

The total number of isomers of type (3) is given by the expression

$$1/2\Sigma(T_i)^2\cdot T_j\cdot(1 + T_i) \tag{D$_3$}$$

where i and j are integers, distinct, and greater than zero; and $3i + j = N - 2$.

The number of isomers of type (4) may be calculated by use of the formula

$$1/8\,[T_i\cdot(1 + T_i)][2 + T_i\cdot(1 + T_i)] \tag{D$_4$}$$

where i is an integer greater than zero, and $4i = N - 2$.

Type (5) may be further divided into two subtypes: (a), in which the two alkyl radicals of equal carbon content are attached to the same carbon atom, RRC═CR′R′, and (b), in which the two alkyl radicals of equal carbon content are not so attached, RR′C═CR′R. The total number of homologs of ethylene of type (5), including both subtypes (a) and (b), may be calculated by the following (finite) recursion formula

$$1/4\Sigma T_i\cdot T_j\cdot(3T_i\cdot T_j + 3 + T_i + T_j) \tag{D$_5$}$$

where i and j are integers, distinct, and greater than zero; $2i + 2j = N - 2$; $i > j$.

In Table I is to be found a summary of the number of terms actually present in all theoretically possible cases of Groups A, B, C and D through a carbon content of forty. Since the number of alkyl groups through C_{20} is recorded in a previous contribution, it is now possible to calculate the number of structurally isomeric hydrocarbons of the ethylene series through a-carbon content of twenty-two. Hence, to calculate the total number of structurally isomeric hydrocarbons of this series of higher carbon content it would be necessary to make a preliminary calculation of the total number of alkyl radicals (structurally isomeric monosubstitution products of the paraffins) of N—2 and all lesser carbon contents.

The total number of structurally isomeric alkenes of N carbon atoms may be obtained by a summation of the numbers calculated in Groups A, B, C and D. The actual meaning and use of these recursion type formulas may be illustrated in the calculation of the number of structurally isomeric tetradecylenes, since the hydrocarbons corresponding to $C_{14}H_{28}$ represent the simplest homologs of ethylene in which all structural types are represented.

SAMPLE CALCULATION

Group A. $N = 14;\ N - 2 = 12$

$T_{(N-2)} = 3057$

Group B. Even carbon content; number of terms is $(N - 2)/2 = 6$

$$2 \cdot T_1 \cdot T_{11} = 2 \cdot 1 \cdot 1238 = 2476$$
$$2 \cdot T_2 \cdot T_{10} = 2 \cdot 1 \cdot 507 = 1014$$
$$2 \cdot T_3 \cdot T_9 = 2 \cdot 2 \cdot 211 = 844$$
$$2 \cdot T_4 \cdot T_8 = 2 \cdot 4 \cdot 89 = 712$$
$$2 \cdot T_5 \cdot T_7 = 2 \cdot 8 \cdot 39 = 624$$
$$2 \cdot \frac{T_6 \cdot (1 + T_6)}{2} = 2 \cdot \frac{17 \cdot 18}{2} = 306$$

$$1/8\,T_3\,(1 + T_3)\cdot[2 + T_3\,(1 + T_3)] = 1/8\cdot 2\,(1 + 2)\,[2 + 2\,(1 + 2)] = 6$$

Type (5)

$$1/4\,T_5\cdot T_1\cdot(3\cdot T_5\,T_1 + T_5 + T_1 + 3) = 1/4\cdot 8\cdot 1\,(3\cdot 8\cdot 1 + 8 + 1 + 3) = 72$$
$$1/4\cdot T_4\cdot T_2\,(3\,T_4\cdot T_2 + T_4 + T_2 + 3) = 1/4\cdot 4\cdot 1\cdot(3\cdot 4\cdot 1 + 4 + 1 + 3) = 20$$

Thus, of the tetradecylenes there are 14,497 structural isomers. The totals of such structural isomers, as obtained by the use of these recursion formulas, through a carbon content of twenty are shown in Table II.[3]

TABLE II

NUMBER OF STRUCTURALLY ISOMERIC HYDROCARBONS OF THE ETHYLENE SERIES

Carbon content	Number of isomers	Carbon content	Number of isomers	Carbon content	Number of isomers
2	1	9	153	15	36,564
3	1	10	377	16	93,650
4	3	11	914	17	240,916
5	5	12	2,281	18	623,338
6	13	13	5,690	19	1,619,346
7	27	14	14,497	20	4,224,993
8	66				

---

(3) The structural formulas of the homologs of ethylene, inclusive of a carbon content of eleven, were written in connection with the derivation of these recursion formulas. The totals obtained from actual count of these structural formulas agreed exactly with those derived by use of the recursion formulas

Summary

By means of a separation of the isomeric hydrocarbons of the ethylene series of each specified carbon content into types, arbitrarily chosen upon the basis of their structural formulas, a relationship may be established between the number of structurally isomeric homologs of ethylene and the alkyl groups which may be considered to be attached to the $>C=C<$ grouping. Mathematical formulas of the (finite) recursion type are advanced which permit of the calculation, from their carbon content, of the number of isomers in each of these structural types. In using these recursion formulas to calculate the total number of such structurally isomeric hydrocarbons of any given carbon content, the total number of alkyl groups (*i. e.*, the total number of structurally isomeric monosubstitution products of the paraffins) of N—2 and all lesser carbon contents must be known.

Naphthol Studies. II. The Chlorination of 1,5-Dihydroxynaphthalene

BY ALVIN S. WHEELER AND W. J. MATTOX[1]

The studies of Wheeler and Ergle[2] have shown that one, two or three atoms of bromine may be introduced into 1,5-dihydroxynaphthalene. In the present study we have prepared dichloro and trichloro derivatives but no tetrachloro compound was obtained. A similar relation was noted in the juglone studies of Wheeler and co-workers,[3,4] more bromine being taken up than chlorine. Willstatter and Schuler[5] chlorinated dihydroxynaphthalene in acetic acid solution but for the purposes of this study we found it better to chlorinate the diacetate in carbon tetrachloride. The description of our compounds C and G does not agree with that of Willstatter and Schuler. This will be re-examined, In chlorinating the diacetate at room temperature two atoms of chlorine are taken up whereas at 80° three atoms are introduced. In each case one acetyl group is hydrolyzed. We tried to prove that OH and O in compound I are ortho to each other by Dimroth's pyroboroacetate ester method. We obtained the characteristic reddish purple color but no solid product. The first two chlorine atoms are put in positions 4 and 8 and the third also in 4 since one

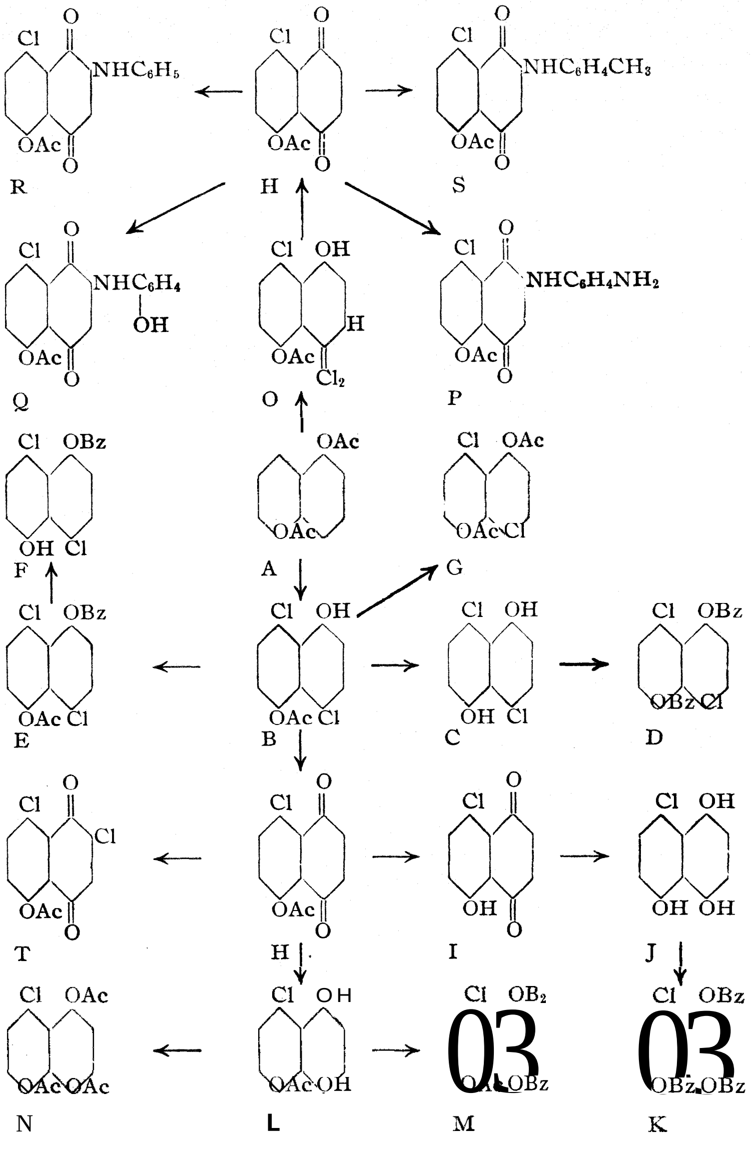
O replaces 2Cl in the production of compound H. This is in harmony with the observed instability of compound O. Quinone H gave characteristic reactions with several aromatic amines. The nitroanilines, sulfanilic acid, *p*-aminobenzoic acid and 2,4-dichloroaniline did not react.



Experimental

4,8-Dichloro-1-hydroxy-5-acetoxynaphthalene (B).—Five grams of the diacetate of 1.5-dihydroxynaphthalene (m. p. 159°) was suspended in 40 cc. of carbon **tetra-**

chloride, a small crystal of iodine was added and a slow stream of chlorine passed at room temperature until solution took place. The solution after treatment with charcoal was reduced one-half in volume in a vacuum desiccator. Petroleum ether was then added until a cloudiness remained after stirring. The colorless needles which soon separated were recrystallized from a small amount of glacial acetic acid. On heating the substance it turned green at 158–160° and then effervesced vigorously. If recrystallized from alcohol yellow impurities clung tenaciously to the crystals. The product was soluble in acetone, chloroform and ether.

Anal. Calcd. for $C_{12}H_8O_3Cl_2$: Cl, 26.19. Found: Cl, 26.34.

4,8-Dichloro-1,5-dihydroxynaphthalene (C).—Compound B may be hydrolyzed in alkaline or acid solution, but the acid hydrolysis is to be preferred. The alkaline solution is purple in color and acidification gives a greenish product. The acid hydrolysis gives at once a white product. Two grams was dissolved in 100 cc. of warm alcohol and 30 cc. of concd. hydrochloric acid was added. The solution after standing four to five hours was poured into 200 cc. of water. The white precipitate was recrystallized from glacial acetic acid as fine, colorless needles, m. p. 194". Willstatter and Schuler give 188–189° for a pale yellow product. The compound is soluble in alcohol, ether, chloroform, hot benzene and carbon tetrachloride. It darkens slowly on exposure to light and air.

Anal. Calcd. for $C_{10}H_6O_2Cl_2$: Cl, 31.00. Found: Cl, 30.75.

8-Chloro-5-acetoxy-1,4-naphthoquinone (H).—Two grams of B was dissolved in 40 cc. of glacial acetic acid at 50° and a solution of 4 g. of chromic acid in 10 cc. of water was added. After standing for two to three hours the solution was poured into several volumes of water. The precipitated quinone was dissolved in acetone and warmed with charcoal. The filtered solution was mixed with water, giving fine yellow needles, m. p. 143". It can be recrystallized from alcohol in a yield 45%. This quinone was also obtained by the oxidation of the trichloro compound O. It is stable and sublimes without decomposition.

Anal. Calcd. for $C_{12}H_7O_4Cl$: Cl, 14.17. Found: Cl, 14.32

4,4,8-Trichloro-1-hydroxy-5-acetoxynaphthalene (O).—Five grams of A was dissolved in 25 cc. of glacial acetic acid. Chlorine was passed into the solution at 50° for two and one-half hours. The solution became red and on cooling with ice the trichloro compound crystallized out. Sometimes seeding was necessary. The color of the crystals was largely removed by washing with petroleum ether. Kccrystallization from hot glacial acetic acid gave colorless needles, m. p. 174°, yield 2.5 g.; soluble in acetone, hot alcohol, ether and benzene. The substance darkens in a few days when exposed to sunlight. It is readily decomposed by dilute alkali. Boiling for several hours with absolute alcohol does not remove any chlorine. Oxidation in glacial acetic acid with chromic acid gives the quinone H as does also the compound B.

Anal. Calcd. for $C_{12}H_9O_3Cl_3$: Cl, 34.75. Found: Cl, 34.72.

The dichloro compound B also takes up chlorine at 80° giving the same compound O. Analysis for Cl gave 34.69.

2,8-Dichloro-5-acetoxy-1,4-naphthoquinone (T).—One-half gram of H was dissolved in 10 cc. of glacial acetic acid and an excess of chlorine passed into the solution Water was added until a faint cloudiness appeared The product crystallized out on standing. It was recrystallized from alcohol as pale yellow needles, m. p. 158–159°. It is noteworthy that only one atom of chlorine is taken up.

Anal. Calcd. for $C_{12}H_6O_4Cl_2$: Cl, 24.91. Found: Cl, 24.37.

In the table other derivatives are indicated.

Summary

1. 1,5-Diacetoxynaphthalene suspended in carbon tetrachloride yields with chlorine in the sunlight or with iodine as a catalyst a dichloro substitution product and at 80° a trichloro product.

2. The chloro compounds yield the same quinone when oxidized with chromic acid.

3. The quinone gave mono, di and trihydroxy naphthols.

The Reaction between Alpha, Beta-Unsaturated Ketones and Organic Magnesium Compounds. Unsaturated Mesitylenic Ketones

BY E. P. KOHLER AND CARL E. BARNES

Earlier papers on this subject contain a description of the reaction between organic magnesium compounds and every member of the series of alpha, beta-unsaturated ketones which could be formed by replacing the hydrogen atoms in acrolein one by one with phenyl groups. Not one of these ketones under any conditions formed a product containing more than two phenyl groups in the beta position. In the case of tetraphenyl propenone, from which such a product was most to be expected, the reaction took an entirely unexpected direction involving addition to a phenyl group.[1]

$$(C_6H_5)_2C{=}C(C_6H_5)COC_6H_5 + C_6H_5MgBr \longrightarrow (C_6H_5)_2C{=}C(C_6H_5)COC_6H_4C_6H_5(o)$$

In view of this result it now became a matter of interest to study the reaction with unsaturated mesitylenic ketones which are so constituted that the hindrance to 1,2 addition would be prohibitive, and that any type of 1,4 addition would inevitably lead to substances with three hydrocarbon residues in the β-position. With this end in view we decided to investigate the behavior of beta phenyl benzalacetomesitylene. The reaction between phenylmagnesium bromide and this ketone had been briefly examined many years ago with negative results,[2] but with the experience gained since then in working with highly phenylated compounds this outcome no longer seemed inevitable.

We have now found that by operating under favorable conditions and with sufficient persistence it is possible to add both phenylmagnesium bromide and ethylmagnesium bromide to this ketone in ether. In the case of methylmagnesium iodide the highly colored intermediate complex product is so nearly insoluble in ether that a reaction in this solvent is impossible but even here it is possible to secure reaction by operating at a

[1] Kohler and Nygaard, THIS JOURNAL, **52**, 4128 (1930).

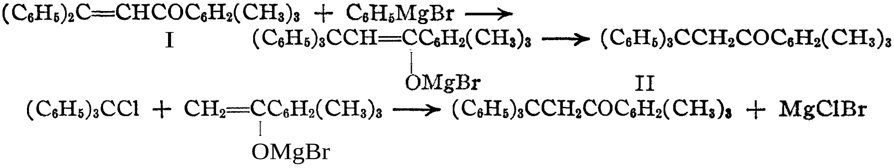
[2] Kohler, Am. *Chem.* J., 38, 560 (1907).

higher temperature in benzene. In all three cases the products are saturated ketones.

These highly substituted saturated ketones are exceedingly unreactive; most reagents that attack them at all degrade them to the point where the results are no longer significant. Their structure therefore had to be established by independent syntheses. An attempt to synthesize the product that had been obtained with phenylmagnesium bromide by a Friedel and Crafts reaction was balked at the outset by the ease with which triphenyl propionyl chloride was converted into an indene derivative. Another attempt to synthesize it by the interaction of sodium triphenyl methane and α-chloro acetomesitylene in liquid ammonia was equally unsuccessful, the ketone merely exchanging one of its hydrogen atoms for sodium

$$(C_6H_5)_3CNa + ClCH_2COC_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_3CH + ClCH{=}C(ONa)C_6H_2(CH_3)_3$$

The synthesis of the saturated ketone was, however, readily accomplished by taking advantage of the fact that when acetomesitylene is treated with a Grignard reagent it forms a halomagnesium enolate which reacts essentially like the metallic derivatives of acetoacetic ester.[3] Under proper conditions this enolate reacted with triphenylmethyl chloride to form the same substance that was obtained by the action of phenylmagnesium bromide an the unsaturated ketone



$$(C_6H_5)_2C{=}CHCOC_6H_2(CH_3)_3 + C_6H_5MgBr \longrightarrow$$
$$\underset{\text{I}}{} \quad (C_6H_5)_3CCH{=}\underset{\underset{\text{OMgBr}}{|}}{C}C_6H_2(CH_3)_3 \longrightarrow \underset{\text{II}}{(C_6H_5)_3CCH_2COC_6H_2(CH_3)_3}$$
$$(C_6H_5)_3CCl + CH_2{=}\underset{\underset{\text{OMgBr}}{|}}{C}C_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_3CCH_2COC_6H_2(CH_3)_3 + MgClBr$$

Owing to the difficulty of preparing pure methyl diphenyl chloro methane this device could not be used for establishing the structure of the product obtained with methylmagnesium iodide, but equally conclusive evidence was secured in a different manner. By analogy with the reaction of phenylmagnesium bromide, methylmagnesium iodide would be expected to form methyl diphenyl propionyl mesitylene and this same ketone should be formed by the action of phenylmagnesium bromide on β-methyl benzalacetomesitylene. This was found to be the case.

$$\text{A.}\quad \underset{\text{I}}{(C_6H_5)_2C{=}CHCOC_6H_2(CH_3)_3} + CH_3MgI \longrightarrow$$

$$\text{B.}\quad \underset{\text{IV}}{(C_6H_5)(CH_3)C{=}CHCOC_6H_2(CH_3)_3} + C_6H_5MgBr \longrightarrow$$
$$(C_6H_5)_2(CH_3)CCH{=}C(OMgBr)\,C_6H_2(CH_3)_3 \longrightarrow \underset{\text{III}}{(C_6H_5)_2(CH_3)CCH_2COC_6H_2(CH_3)_3}$$

---

(3) Kohler and Baltzly, THIS JOURNAL, 54, 4015 (1932).

These results show that, though difficult, it is not impossible to add Grignard reagents to β-phenyl benzalacetomesitylene and analogous compounds—the hydrocarbon residues as usual going into the beta position. The difference in the speed with which the several addition reactions occur is surprising. Thus, although the two reactions represented by A and B result in the formation of the same magnesium derivative, the first requires for completion at least three hours at the boiling point of benzene, while the second proceeds almost as fast as the reactants are brought together at the ordinary temperature. This great difference in rate appears to be due largely to a difference in the quality of the conjugated system, because methylmagnesium iodide can be substituted for phenylmagnesium bromide in the second reaction without materially altering its speed.

$$CH_3C(C_6H_5){=}CHCOC_6H_2(CH_3)_3 + CH_3MgI \longrightarrow$$
$$(CH_3)_2C(C_6H_5)CH{=}C(OMgI)C_6H_2(CH_3)_3 \longrightarrow (CH_3)_2C(C_6H_5)CH_2COC_6H_2(CH_3)_3$$

Experimental Part

β-Phenyl benzalacetomesitylene has been obtained heretofore by means of a series of reactions that are not well adapted for making larger quantities of the substance. We therefore devised a new method of preparation which is modeled after the best method for obtaining β-phenyl benzalacetophenone and which is indicated by the following series of compounds

$$\underset{A}{C_6H_5CH{=}CHCOC_6H_2(CH_3)_3} \longrightarrow \underset{B}{C_6H_5CHBrCHBrCOC_6H_2(CH_3)_3} \longrightarrow$$
$$\underset{C}{C_6H_5COCH_2COC_6H_2(CH_3)_3} \longrightarrow \underset{D}{(C_6H_5)_2COHCH_2COC_6H_2(CH_3)_3} \longrightarrow$$
$$\underset{I}{(C_6H_5)_2C{=}CHCOC_6H_2(CH_3)_3}$$

Benzalacetomesitylene, the first substance in the series, was originally prepared by the action of cinnamoyl chloride on mesitylene. It is much more easily obtained in quantity by the usual condensation of an aldehyde with a methyl ketone. Our procedure was as follows

To a solution of 62 g. of sodium hydroxide in 540 cc. of water, and 270 g. of alcohol was added, first 200 g. of acetomesitylene and then, gradually, with vigorous stirring, 146 g. of freshly distilled benzaldehyde. After stirring for six hours the mixture was cooled with ice and salt and inoculated, the stirring being continued to produce small crystals. The mixture crystallized rapidly and completely. The solid was washed with water until free from base and then with 25% alcohol to remove organic impurities. The yield of crude dry product was 290 g. or 94%. The crude product is sufficiently pure for the next step.

From the unsaturated ketone the dibromide (B) was obtained in the usual manner. In working with large quantities of material it is essential that the bromine be added slowly and with vigorous stirring, and also that it be not added in excess, otherwise some of it enters the mesitylene group and it is impossible to get bromine-free products in subsequent operations. From 290 g. of crude unsaturated ketone we obtained 357 g. of pure recrystallized product melting at 126–127°—a yield of 76%.

In a flask provided with a stirrer, a reflux condenser and a dropping funnel, 357 g. of the pure dibromide was mixed with 250 cc. of dry methyl alcohol. From the dropping funnel a solution of 39 g. of sodium in 380 cc. of dry methyl alcohol was added gradually while the flask was cooled with running water, the stirrer being started as soon as the mixture became sufficiently fluid. After all the methylate had been added, the mixture was boiled for three hours, then diluted with enough water to dissolve the sodium bromide and acidified with hydrochloric acid. The acidified solution was boiled for three hours, then cooled in ice water while it was stirred vigorously to prevent the formation of large lumps. It deposited a solid which after washing with water and with 50% alcohol yielded 219 g. of crude dry product. On recrystallization from methyl alcohol 20–30% of the material was left in the filtrates, the yield of pure product being 70–80%.

Anal. Calcd. for $C_{18}H_{81}O_2$: C, 81.2; H, 6.8. Found: C, 80.9; H, 6.8.

Benzoylacetomesitylene (C) is moderately soluble in all common organic solvents except petroleum ether in which it dissolves but sparingly. It crystallizes in colorless prisms and melts at 79°. A bromine titration by the Kurt Meyer method showed that like other aromatic diketones it is completely enolic. and in a quantitative examination with methylmagnesium iodide it reacted with two moles of reagent and liberated one mole of gas.

The diketone was converted into the β-hydroxy ketone (D) in the following manner. A solution of 50 g. of the substance in dry ether was added gradually to a similar solution of phenylmagnesium bromide. The mixture was boiled until the purple-red color which developed in the solution disappeared—usually five to six hours. At this stage the solution contained a dimagnesium compound which is stable but in order to isolate the carbinol, which readily loses water, it was necessary to proceed with great caution. The mixture was added slowly with efficient stirring to ice and hydrochloric acid, the ethereal layer washed with sodium carbonate, dried and allowed to evaporate spontaneously. It left a yellow oil which solidified when its solution in methyl alcohol was cooled in a freezing mixture. The solid was purified by recrystallization from methyl alcohol.

Anal. Calcd. for $C_{24}H_{24}O_2$: C, 83.7; H, 7.0. Found: C, 83.6; H, 7.2.

The carbinol is moderately soluble in ether, in benzene and in petroleum ether. It crystallizes in thick colorless plates and it melts at 75°.

β-Phenyl Benzalacetomesitylene, I.—From the carbinol the unsaturated ketone is readily obtained by warming it with aqueous hydrochloric acid but since it is easier to isolate and purify the ketone than the carbinol it is best to prepare it directly from the dimagnesium compound. This was accomplished by adding an equal volume of constant boiling hydrochloric acid to the ethereal layer obtained by decomposing the magnesium derivative, distilling off the ether, and warming the residue on a steam-bath for half an hour. The yellow oil solidified on cooling. The solid was recrystallized from methyl alcohol, from which it separated in thin plates melting at 104°. The yield was 82%.

β-Methyl Benzalacetomesitylene, IV.—By a slight modification of the method which has just been described it was also comparatively easy to prepare the methyl ketone which was needed for the structural work, the steps being represented as

$$C_6H_5COCH_2COC_6H_2(CH_3)_3 \longrightarrow (C_6H_5)(CH_3)C(OH)CH_2COC_6H_2(CH_3)_3 \longrightarrow$$

$$(C_6H_5)(CH_3)C{=}CHCOC_6H_2(CH_3)_3$$

IV

The procedure was as follows. A solution of methylmagnesium iodide made from 2.3 g. of magnesium was added gradually to a solution of 25 g. of benzoyl acetomesitylene in 150 cc. of ether. The mixture, which had developed a purple color during the addition of the reagent, was boiled for seven hours, and then decomposed with iced acid in the usual manner. The ethereal layer, on evaporation, left a yellow oil which solidified when it was heated for half an hour with dilute hydrochloric acid. The solid was purified by recrystallization from petroleum ether from which it separated in large yellow prisms melting at 84°. The yield was 92.4%.

Anal. Calcd. for $C_{19}H_{20}O$: C, 86.4; H, 7.6. Found: C, 85.8; H, 7.6.

The unsaturated ketone is moderately soluble in the common organic solvents Its structure was established by ozonization, the ozonide yielding acetophenone, identified as m-nitro benzalacetophenone, and mesitylene carboxylic acid, which was identified by comparison with a specimen on hand.

Action of **Phenylmagnesium** Bromide on Phenyl Benzalacetomesitylene, **β,β,β-Triphenyl Propiomesitylene (II).**—The unsaturated ketone combines with phenylmagnesium bromide to form a red intermediate complex compound which is sparingly soluble in ether, and which regenerates the ketone when it is acidified. In order to carry the reaction beyond this preliminary stage it is necessary to use dilute solutions and to add the ketone at such a slow rate that the intermediate never crystallizes from the solution. Our best results were obtained as follows. A solution of **5** g. of the ketone in **125** cc. of dry ether was added during a period of three to four hours to a solution of the reagent which had been prepared from **1.6** g. of magnesium. The mixture was boiled for five hours more, or until the red color of the solution disappeared completely. After the usual manipulation, the mixture yielded a solid product which was recrystallized from glacial acetic acid.

Anal. Calcd. for $C_{30}H_{28}O$: C, **89.1;** H, **6.7.** Found: C, **89.0;** H, **7.0.**

The saturated ketone is sparingly soluble in alcohol and ether. From glacial acetic acid it crystallizes in needles melting at 194–195°. The yield was only 60% but no other product was formed. By distilling the filtrates with steam and crystallizing the residue enough unsaturated ketone was recovered to account for all the material that had been used.

Structure of the Addition Product.—A solution of the bromomagnesium enolate of acetomesitylene was prepared by adding **16.2** g. of acetomesitylene to a solution of ethylmagnesium bromide made from **2.6** g. of magnesium and boiling the mixture for ten minutes. To this solution was added an ethereal solution of **28** g. of triphenylmethyl chloride. After a few minutes' boiling the mixture solidified. The solid, washed with water and recrystallized from glacial acetic acid, yielded **21.5** g. of the same product that had been obtained from β-phenyl benzalacetomesitylene.

Reaction with Methylmagnesium Iodide, **β,β-Diphenyl Butyrylmesitylene (III).**—After a number of fruitless attempts to carry out the reaction in ether, the following procedure was found to be effective. **A** solution of **5** g. of the ketone in **75** cc. of benzene was added in the course of half an hour to a boiling ethereal solution of methylmagnesium iodide prepared from **1.6** g. of magnesium. The resulting red solution was boiled for three hours and then decomposed in the usual manner. The benzene, on evaporation, left an oil, but when a solution of the oil in petroleum ether was cooled in a freezing mixture it deposited **3.6** g. of solid. Another gram of the same solid was obtained by distilling the filtrate with steam and treating this residue also with petroleum ether. The total yield, therefore, was **82%.**

Anal. Calcd. for $C_{25}H_{26}O$: C, **87.7;** H, **7.6.** Found: C, **87.4;** H, **7.8.**

The product is soluble in all common organic solvents including petroleum ether. It crystallizes in needles and it melts at **87°.** Its structure was established in the following manner. **A** solution of **5 g.** of 8-methyl benzalacetomesitylene in **75** cc of ether was added in the course of five minutes to a solution of phenylmagnesium bromide prepared from **2** g. of magnesium. Since the color of the red intermediate addition product disappeared rapidly, the mixture was decomposed with iced acid a few minutes after all of the ketone had been added. It yielded **4.0** g. of the same product which had been obtained by the action of methylmagnesium iodide on phenyl benzalacetomesitylene. The reaction was evidently incomplete, because the yield was only 62% and nearly a fourth of the unsaturated ketone was recovered, but the yield was diminished when the mixture was boiled for several hours before it was acidified.

Reaction with Ethylmagnesium Bromide, β,β-Diphenyl Valerylmesitylene C_2H_5C-$(C_6H_5)_2CH_2COC_6H_2(CH_3)_3$.—A solution of 6 g. of phenyl benzalacetomesitylene in 250 cc. of dry ether was added in the course of three hours to a solution of ethylmagnesium bromide prepared from 1.2 g. of magnesium. The color of the red intermediate compound was very persistent but it gradually faded to a light pink when the mixture was boiled for four hours. By decomposition with iced hydrochloric acid, and the usual manipulation of the ethereal layer, the mixture yielded a solid which separated from petroleum ether in needles and which melted at 106°.

Anal. Calcd. for $C_{26}H_{28}O$: C.87.6; H, 7.9. Found: C, 87.4; H, 7.7.

β-Methyl Benzalacetomesitylene and Methylmagnesium Iodide, $(C_6H_5)(CH_3)_2$-$CCH_2COC_6H_2(CH_3)_3$.—An ethereal solution of 5 g. of methyl benzalacetomesitylene was added in the course of a few minutes to an ethereal solution of methylmagnesium iodide which had been prepared from 1.8 g. of magnesium. The orange-colored solution soon began to deposit a colorless magnesium derivative. After ten minutes at the ordinary temperature it was decomposed with ice and acid in the usual manner. It yielded a solid which crystallized from acetic acid in colorless needles and which melted at 184–185°.

Anal. Calcd. for $C_{20}H_{24}O$: C, 85 8; H, 8.6. Found: C, 86.0; H, 8.8.

Summary

The former statement that β-phenyl benzalacetomesitylene does not add phenylmagnesium bromide is incorrect. Both β-phenyl and β-methyl benzalacetomesitylene add Grignard reagents, forming enolates of the corresponding saturated ketones.

The Number of Stereoisomeric and Non-Stereoisomeric Alkines

BY DONALD D. COFFMAN

Since the number of structurally isomeric alkines[1] can be readily deduced from the number of structurally isomeric mono-substitution products of the paraffins,[2] an attempt has been made to calculate the number of stereoisomeric alkines.

Blair and Henze have advanced recursion formulas which[3] permit the calculation from their carbon content of the number of stereoisomeric and non-stereoisomeric primary, secondary and tertiary mono-substitution products of the paraffins. The use of these formulas depends upon the knowledge of the total number of stereoisomeric and non-stereoisomeric mono-substituted paraffins of every lower carbon content. By employing the published data of Blair and Henze, it is possible to calculate the number of stereoisomeric and non-stereoisomeric mono-substituted and

---

(2) Henze and Blair, *ibid.*, 53, 3042–3046 (1931).

(3) Blair and Henze, *ibid.*, 54, 1098–1106 (1932).

di-substituted alkines of the formulas RC≡CH and RC≡CR′. The calculation depends upon the classification of the alkines into simple types whose number of stereoisomers may be estimated.

Mono-substituted **Alkines.**—The structural formulas of the mono-substituted alkines RC≡CH of N total carbon content may be formed by attaching to the residue —C≡CH each alkyl group R of $N-2$ carbon atoms. It is therefore apparent that the number of stereoisomeric mono-substituted alkines of N total carbon content formed in this way will equal the total number of stereoisomeric mono-substituted paraffins of all types containing $N-2$ carbon atoms. For these same reasons the number of non-stereoisomeric mono-substituted alkines of N total carbon content will equal the total number of non-stereoisomeric mono-substituted paraffins of all types containing $N-2$ carbon atoms. These values may be obtained from the tables of Blair and Henze.

Di-substituted **Alkines.**—The structural formulas of the di-substituted alkines RC≡CR′ of N total carbon content may be formed by attaching to the residue —C≡C— the alkyl groups R and R' (the sum of the carbon atoms in R and R' must always equal N—2). The total number of isomers that may be formed in this manner will be determined by the number of possibilities of combining with the residue —C≡C— complementary values of R and R . These combinations may be divisible into two types: (1) in which R and R' may be of[4] unequal carbon content, and *(2)* in which R and R' may be of equal content. As a matter of fact, type (2) is impossible for RC≡CR′ of an odd number of carbon atoms since $(N-2)/2$ must be an integer, greater than zero.

Type I.—When R and R' are of unequal carbon content, the number of possibilities of combining stereoisomeric and non-stereoisomeric values of R and R' with the residue —C≡C— may be represented by the expression $A_{s_i} \cdot A_{s_j} + A_{s_i} \cdot A_{n_j} + A_{n_i} \cdot A_{s_j}$ in which A, and A_{s_j} represent the total number of all types of stereoisomeric mono-substituted paraffins RX and R X each of carbon contents i and j, and in which A_{n_i} and An, represent the total number of all types of non-stereoisomeric mono-substituted paraffins RX and R'X each of carbon contents i and **j.** Here i and j are integers, distinct, and greater than zero, $i > j$, and $i + j = N-2$. By defining $T_i = A_{s_i} + A_{n_i}$ and $T_j = A_{s_j} + A_{n_j}$, substitution in and simplification of the above expression yields a formula representing the total number of stereoisomeric alkines RC≡CR′ of type 1

$$\Sigma(T_iT_j - A_{n_i}A_{n_j}) \qquad (\mathrm{I_s})$$

When N is even, the number of $T_i \cdot T_j - A_{n_i} \cdot A_{n_j}$ terms in the summation will be $(N-4)/2$; when N is odd, the number of terms will be $(N-3)/2$.

---

(4) These types are analogous to those of the secondary mono-substitution products of the paraffins as classified by Blair and Henze.

The number of non-stereoisomeric alkines RC≡CR′ of type 1 will be equal to

$$\Sigma A_{n_i} . An, \qquad (I_n)$$

requiring $(N-4)/2$ terms when N is even, and $(N-3/2)$ terms when N is odd.

Type 11.—When R and R' are of equal carbon content, it is convenient to subdivide the isomers further into two groups: (a) in which R and R' are structurally and stereoisomerically identical, and (b) in which R and R′ are not identical.

Group (a).—The number of possibilities of combining identical stereoisomeric values of R and R' with the residue —C≡C— will equal the number of stereoisomers of this subdivision, or A_{s_i}. By the combination of identical non-stereoisomeric values of R and R′ with the residue —C≡C—, no stereoisomers can result.

Group (b).—When non-identical complementary values of R and R′, both stereoisomeric and non-stereoisomeric, are combined with the residue —C≡C—, the number of such possibilities may be represented by the expression $A_{s_i} . A_{n_i} + A_{s_i}(A, -1)/2$. The sum of the expressions in group (a) and group (b) gives a formula representing the total number of stereoisomers of type II.

$$A_{s_i}(2A_{n_i} + A_{s_i} + 1)/2 \qquad (II.)$$

in which i is an integer greater than zero, and $i = (N-2)/2$.

TABLE I

ISOMERIC ALKINES

Carbon content	RC≡CH Stereo	RC≡CH Non-stereo	RC≡CR′ Stereo	RC≡CR′ Non-stereo	RC≡CH and RC≡CR′ Total stereo	RC≡CH and RC≡CR′ Total Non-stereo	Total isomers
3	0	I	0	0	0	1	1
4	0	1	0	1	0	2	2
5	0	2	0	1	0	3	3
6	2	3	0	3	2	6	8

16	109,980	520	79,980	1,393	189,960	1,913	191,873
17	327,216	876	240,590	2,487	567,806	3,363	571,169
18	979,020	1,471	726,238	4,460	1,705,258	5,931	1,711,189
19	2,944,414	2,475	2,199,070	7,924	5,143,484	10,399	5,153,883
20	8,897,732	4,159	6,683,108	14,095	15,580,840	18,254	15,599,094
21	27,004,290	6,996	20,378,720	24,925	47,383,010	31,921	47,414,931
22	82,287,516	11,759	62,347,546	44,065	144,635,062	55,824	144,690,886

The number of possibilities of combining non-stereoisomeric values of R and R' (type II) with the residue —C≡C— may be represented by the expression $A_{n_i} + A_{n_i}(A_{n_i} - 1)/2$ which on simplification yields

$$A_{n_i}(A_{n_i} + 1)/2 \qquad (\mathrm{II_n})$$

representing the number of non-stereoisomeric alkines RC≡CR' of type II.

The finite formulas $\mathrm{I_s}$, $\mathrm{I_n}$, $\mathrm{II_s}$ and $\mathrm{II_n}$ permit the calculation of the number of stereoisomeric and non-stereoisomeric di-substituted alkines RC≡CR' of N total carbon content when the number of stereoisomeric and non-stereoisomeric mono-substitution products of the paraffins of all types of $N - 3$ and every lower carbon content is known. In applying these formulas the values for the stereoisomeric and non-stereoisomeric mono-substitution products of the paraffins, as calculated by Blair and Henze, have been employed. The table indicates the calculated number of stereoisomeric and non-stereoisomeric alkines containing from three to twenty-two carbon atoms inclusive.6

Summary

The number of stereoisomeric and non-stereoisomeric mono-substituted alkines RC≡CH of N total carbon content has been deduced from the number of stereoisomeric and non-stereoisomeric mono-substitution products of the paraffins.

The number of stereoisomeric and non-stereoisomeric di-substituted alkines RC≡CR' of N total carbon content has been calculated employing finite recursion formulas. The use of these formulas is dependent upon the knowledge of the number of stereoisomeric and non-stereoisomeric mono-substitution products of the paraffins of $N - 3$ and every lower carbon content. The number of isomers so obtained agrees with the number required by theory through the decines as shown by writing the formulas and counting the stereoisomeric and non-stereoisomeric alkines RC≡CR'.

The Pyrolysis of Alpha Unsaturated Hydrocarbons[1]

BY CHARLES D. HURD[2] AND HARRY T. BOLLMAN[3]

To extend our knowledge of the pyrolysis of olefins beyond the C_5 members, these unsaturated hydrocarbons were chosen for study: diallyl, 4-methyl-1-pentene, allylcyclohexane and 4-phenyl-1-butene. All possess the general structure $R—CH_2CH=CH_2$, wherein R is a radical of low electron attraction. In contrast to propylene and isobutylene,[4] which required temperatures of 700° or above for extensive decomposition, these olefins decomposed considerably in the 425–500° range. Both types possess a $C\overset{\alpha}{—}C=C$ skeleton but the former has no $C\overset{\beta}{—}C\overset{\alpha}{—}C=C$ skeleton. This difference suggests that pyrolysis produces a rupture of the $C\overset{\beta}{—}C$ bond more readily than the $C\overset{\alpha}{—}C$.

Confirmation was found in the fact that propylene predominated throughout in the gases. The ethylene content was small, indicating an inconsiderable $C\overset{\alpha}{—}C$ scission. Saturated hydrocarbons and hydrogen comprised most of the remainder of the gas. Allene was sought for but not found.

In the lower boiling liquid products, materials were encountered which possessed slightly higher distillation ranges than the original hydrocarbon. They gave higher n_D values and, in the case of the liquid from diallyl, showed a different behavior toward tetranitromethane reagent. These facts suggest the presence of isomeric unsaturated hydrocarbons (such as 1,4- or 2,4-hexadiene from diallyl; 4-phenyl-2-butene from 4-phenyl-1-butene; etc.) or dehydrogenated compounds (such as 1,3,5-hexatriene from diallyl; phenylbutadiene or naphthalene from 4-phenyl-1-butene; etc.). Naphthalene was isolated in quantity from the phenylbutene liquids.

To compensate for the propylene found in the gas, much toluene (and some benzene) was formed from the phenylbutene. Similarly, cyclohexane, benzene and cyclohexene were indicated in the liquids from allylcyclohexane. Polymerization products were formed in every case, as shown by the high boiling material and tars which were encountered.

Mechanism.—The facts are best explained by assuming that these α-olefins undergo a preliminary scission into radicals at the allyl bond:

$R—C_3H_5 \longrightarrow R— + C_3H_5—$. These radicals acquire hydrogen atoms from some source, presumably largely from the original hydrocarbon, and escape as $RH + C_3H_6$. The dehydrogenated material may escape as $R'CH{=}CH—CH{=}CH_2$ or, in common with the original unsaturated hydrocarbon, it may undergo polymerization.

The formation of propylene without allene from diallyl resembles the analogous formation of aniline without allene from allylaniline[5] and of methane without allene from isobutylene.[6] A compound analogous to diallyl, namely, tetraphenylhexadiene, $(Ph_2C{=}CH—CH_2—)_2$, has been reported[7] to pyrolyze into α,α-diphenylpropylene and tar. The tar was regarded as polymerized diphenylallene but this position now becomes untenable.

A conclusion may be drawn from the present work regarding the pyrolysis of hydrocarbons in general, namely, that simple scission into two compounds should not be considered the primary effect even though each of the two products may be among the products of the reaction (as in the case of ethane + ethylene, or methane + propylene, from n-butane).

Experimental Part

Preparation of Hydrocarbons.—The compounds studied were synthesized by the general method:[8] $RMgX + BrCH_2CH{=}CH_2 \longrightarrow RCH_2CH{=}CH_2 + MgBr$. In the synthesis of diallyl it was found convenient to use much less ether than Cortese recommended and to add the allyl bromide slowly. The *diallyl* used boiled at 58–60'. For the *allylcyclohexane*, b p. 148–150°, these new constants were determined: d_4 = 20°/0.8160; 28.5°/0.8117; 41.5°/0.8010; n_D = 15°/1.4528; 25°/1 4483 The *dibromide of allylcyclohexane* gave these constants: b. p. 129–131 (11 mm.); n_D = 15°/1.5293, 20°/1 5271, 25°/1.5251. To synthesize *4-phenyl-1-butene*, benzylmagnesium chloride was used rather than the bromide. The hydrocarbon boiled at 175–178°; n_D^{20} 1.5090.

4-Methyl-1-pentene has not been made previously by this method. It was prepared from 24 g. of magnesium, 123 g. of isopropyl bromide in 150 cc. of dry ether, and 110 g. pf allyl bromide in 250 cc. of ether. It was converted[g] (in ether solution) into the dibromide and the latter dehalogenated with zinc and alcohol. The weight of olefin, b. p. 52.5–54.5°, was 33 g. Based on the allyl bromide, this represents a 43% yield.

Method of Heating.—Except for the manner of introducing the liquid hydrocarbons at a uniform rate into the unpacked Pyrex reaction tube, namely, by displacement with mercury, the method of heating and of collecting the products was very similar to that described for isobutylene.[10] The data from some representative experiments are summarized in Table I.

In several experiments with diallyl, the gases were passed through bromine in carbon tetrachloride. In a typical case, 21.5 g. of liquid, b. p. 139–140°, n_D^{20} 1.5206, was formed. These data characterized the liquid as 90% propylene bromide and 10% ethylene bromide There was about a gram of residue, 0.9 g. of which was butadiene tetrabromide, m. p. 114". Allene tetrabromide was not formed.

[a] Magnesium turnings in the tube about half filling the tube. [b] Quartz tube of small diameter used; Pyrex used elsewhere. [c] In experiments in which carbon dioxide was used, a steady flow of the gas was maintained throughout the experiment. This item was considered in calculating the contact time: Contact time = (vol. tube × time in sec. × 273)/$T°$ Abs. (((22400 × wt.)/mol. wt.) + vol. CO_2).

Some gas from a 500° run was cooled by liquid air. The condensate was distilled, the first fraction including everything from −190 to −80° (200 cc.) and the second from −80° to room temperature (300 cc.). Propylene, ethylene, methane and ethane (n in C_nH_{2n+2} was 1.23) were found in the first fraction. The last fraction contained much more propylene and a little ethane (n = 2.04). Propane and butane were not indicated.

A trace of butadiene (but no allene) was also found by brominating the gases from 4-methyl-1-pentene or allylcyclohexane. The saturated hydrocarbons from 4-methyl-1-pentene were methane and ethane. No liquid (propane or butane) condensed from it at −80°.

Liquid Products.—The extent of the decomposition was determined by distilling off the unused hydrocarbon from the condensed liquids. Obviously this method lacked the precision which was possible in work with gaseous hydrocarbons. From a 500° run with diallyl, the 16.1 g. of liquid gave these fractions: (°C., g, n^{22}_D) 58–60, 4.4, 1.406; 60–65, 3.7, 1.414; 65–75, 2.7, 1.440; above 75, 1.2, 1.465; and 4.2 g. of residue. In another run (485°), 8.97 g. in a 58–67" fraction was mixed with aniline and refractionated: (b. p., n^{20}_D) 58–60, 1.401; 60–63, 1.416; 63–69, 1.423. The 58–60" fraction was almost pure diallyl. A little of it, added to a mixture of 4 cc. of an ether solution of tetranitromethane and 2–3 drops of pyridine, caused no immediate coloration but in fifteen minutes a yellow-green color developed.[11] In contrast, the other fractions produced an almost immediate brown coloration. This may point to a conjugated hexadiene.

The high boiling residue from diallyl gave a solid, m. p. 47°, on bromination. Its bromine content was 66.3% and its molecular weight 476. This would be satisfactory for $C_{12}H_{20}Br_4$, $C_{12}H_{18}Br_4$ or $C_{12}H_{16}Br_4$.[12] The liquid and gaseous products were not markedly affected by the presence of magnesium[13] in the reaction tube.

Distillation of the liquids from allylcyclohexane gave volatile hydrocarbons (b. p. 70–145°), then recovered allylcyclohexane (145–150°), finally a tarry residue which was 4–5 times heavier than the volatile portion. The latter contained[14] aromatics, cycloalkanes and lesser amounts of cycloalkenes. The refractive index (20°) of the 78–85" fraction was 1.463, suggesting about equal parts of benzene and cyclohexene.

Fractionation of the liquids from the 550° run with 4-phenyl-1-butene gave 9.7 g. of benzene and toluene; 6 g. between 115–170°; 6.7 g., 170–178° (n^{20}_D 1.5225); 5 g., 178–185° (n^{20}_D 1.5268); 19.2 g. of residue about half of which was naphthalene. Some stilbene was also isolated from the residue. The 170–178° fraction contained the phenylbutene, but its high refractive index denoted a contaminant.

Summary

The pyrolysis of diallyl, 4-methyl-1-pentene, allylcyclohexane and 4-phenyl-1-butene was studied. All of these gave a predominating quantity of propylene as a gaseous product and none gave any allene. Liquid products were formed which pointed to isomerization, dehydrogenation and polymerization processes. A mechanism for these observations is outlined which also incorporates facts of other varied experiments on pyrolysis.

The Grignard Reaction in the Synthesis of Ketones. I. A New Method of Preparing Desoxybenzoins

BY SANFORD S. JENKINS

In order to facilitate certain studies, some of which have been published,[1a,b] dealing with desoxybenzoins a general method of synthesizing this interesting class of ketones was sought.

The object of this report is to describe a method that is more generally applicable than the usual ones and which appears to be entirely reliable in its indication of structure. Briefly, the method, which is an adaptation with certain improvements of that of Béis[2] for preparing aliphatic ketones, consists in condensing primary benzamides with benzylmagnesium halides. In order to obtain the maximum yields, however, there are two conditions to be observed: three to four equivalents of the halide to one of the amide must be used and long heating of the reactants is necessary.

In this manner benzyl phenyl, benzyl *m*-chlorophenyl, benzyl p-methoxyphenyl, o-chlorobenzyl p-methoxyphenyl and *p*-chlorobenzyl p-methoxyphenyl ketones were obtained in satisfactory yields.

Although rearrangements are known to take place when benzylmagnesium halides are condensed with certain substances,[3] no evidence of any abnormal product was obtained in this work. Where possible the products were compared directly with the desoxy ketones obtained in the reduction of the corresponding benzoins but since most of the latter compounds were either not available or have not been described, this procedure was supplemented by the Beckmann rearrangement of the ketoximes.[4] The structures of the resulting anilides were then established by comparison with authentic samples. When prepared according to the directions given below the oximes are all of the anti-benzyl type.

Experimental

Preparation of Ketones

Apparatus and Method.—A 500-cc. three-necked, round-bottomed flask is fitted with a mechanical stirring apparatus, a dropping funnel, and a condenser to which is attached a drying tube. A very satisfactory heater may be made by inserting an electric bulb in the apex of an inverted cone of asbestos paper the base of which is placed under the flask. When mounted on a single ringstand the apparatus is compact and convenient.

After placing the required amount of thin, bright magnesium turnings and a small crystal of iodine in the flask and connecting the various parts, the apparatus is swept out with dry hydrogen. A solution of the benzyl halide in 100 to 125 cc. of ether is

p-$CH_3OC_6H_4CONH_2$	*p*-$ClC_6H_4CH_2MgBr$	E	*p*-$CH_3OC_6H_4COCH_2C_6H_4Cl$-*p*	66	137.5	260.5	266	$C_{15}H_{13}ClO_2$	13.60	13.81

The reactants were employed in the ratio of 0.050 mole of amide to 0.20 mole of Grignard reagent and were heated for forty to forty-eight hours. Ketones **A,** B, and C were obtained as white plates, D as white cubes and E as white diamond-shaped plates.

The yields are based on the amides and represent material that was crystallized once from alcohol. Ketone B is soluble in ether and benzene, fairly soluble in 80% alcohol and may be conveniently crystallized from ligroin (Skelly Solve "C"). E is sparingly soluble in ether and alcohol and is best purified by crystallization from benzene-petroleum ether solution.

The amides were obtained in the usual manner from the corresponding acids. "Baker's C. P. Analysed" benzyl chloride and Eastman best grade of o- and *p*-chlorobenzyl bromides were used in this work.

Ketone A was found to be authentic by comparison with desoxybenzoin obtained in the reduction of benzoin. Ketone C proved to be identical with one of the reduction products of benzanisoin.[1b]

The molecular weights were obtained by means of the Rast method using borneol instead of camphor.

placed in the dropping funnel and a small portion (10–15 cc.) added to the magnesium. The flask is now heated until the reaction is under way, after which the heat is cut off and the stirrer started. The solution is added at such a rate that gentle refluxing of the ether is maintained. After the addition the stirring is continued until the solution cools. The dropping funnel is now replaced by a ctak and by means of a long-handled spatula the dry, finely-powdered amide is added in portions, the rate of addition being determined by the vigor of the reaction. The heat is now turned on and the solution allowed to reflux with occasional stirring for the required time.

The complexes were decomposed by pouring the solutions into 200 g. of a slush of ice and water containing 20 g. of sulfuric acid. After standing at room temperature for an hour the ether was separated. The water layer was heated on the hot-plate for half an hour, cooled and extracted with ether. In this way an additional portion of ketone was obtained. The ether extracts were then combined and steam distilled. On cooling the yellow residue solidified and was crystallized from alcohol.

Ketones C, D and E, not being very soluble in ether, usually separated in part when the complexes were hydrolyzed.

Preparation of **Oximes.**—The oximes were prepared by mixing 2.00 g. each of ketone and hydrovylamine hydrochloride, 3.20 g. of potassium acetate and 40 cc. of alcohol. After standing overnight at room temperature the mixture was heated on the water-bath under reflux for three hours. Hot water was then added until a clear solution was obtained and a faint opalescence appeared. The solution was then set aside in a cool place and after several hours the crystals were filtered. Further crops were obtained by adding cold water to the filtrates.

The oximes of ketones C and E were also prepared by using 20 cc. of pyridine instead of the alcohol and potassium acetate, with identical results.

Preparation of Anilides

1. By Rearrangement of the **Oximes.**—To 1.00 g. of oxime dissolved in 30 cc. of absolute ether about 1.50 g. of powdered phosphorus pentachloride was added portionwise. The solution was shaken and kept cold during the addition. After standing at room temperature for half an hour the mixture was poured into 100 cc. of cold water and the ether driven off by means of a stream of air. The crude anilide was then separated and washed with water.

2. By Synthesis from the Acids or Acid Chlorides **and** the Corresponding **Anilines.**—(a) Anilides A, B and C were prepared in the Schotten–Baumann manner by mixing phenylacetyl chloride and the corresponding anilines.

(b) Anilides D and E were obtained from o- and p-chlorophenylacetic acids[6] and *p*-anisidine by heating the mixture in an oil-bath at 180–200° for two hours

The anilides as obtained by either method (1 or 2) were recrystallized from dilute alcohol until pure. Their identity was established by their mixed melting points and crystalline structures.

Acknowledgments

I wish to thank Prof. E. Emmet Reid for his interest and many valuable suggestions in this work, Messrs. J. R. Meadow and E. M. Richardson for making the molecular weight determinations and Mr. Richardson for assistance in the analyses.

Summary

A new method of synthesizing desoxybenzoins which appears to be of wide application has been described.

---

(6) Mehner, *J. prakt. Chem.*, 62, 554 (1900).

From the appropriate primary benzamides and benzylmagnesium halides benzyl phenyl, benzyl m-chlorophenyl, benzyl p-methoxyphenyl, *o*-chlorobenzyl *p*-methoxyphenyl and *p*-chlorobenzyl p-methoxyphenyl ketones have been obtained in satisfactory yields.

No evidence of rearrangements has been obtained in this type of Grignard reaction.

Six new compounds were prepared and characterized.

Stereochemistry of Diphenyls. XXVII.[1] Comparison of the Racemization of 2,2'-Difluoro-6,6'-dicarboxydiphenyl and 2,2'-Dimethoxy-6,6'-dicarboxydiphenyl

BY W. M. STANLEY, EDWARD MCMAHON[2] AND ROGER ADAMS

The methoxyl group has been shown in previous researches to have a smaller interference effect when substituted in the 2,2',6,6' positions than had at first been predicted. It was found impossible to resolve 2,2'-difluoro-6,6'-dimethoxy-3,3'-dicarboxydiphenyl[3] and the active 2-nitro-&carboxy-2'-methoxydiphenyl was very readily racemized.[4] The relative interference value of the methoxyl was thus revised from 1.56, as at first estimated, to 1.45. The latter value would conform to all the facts thus far assembled in connection with various hydroxylated and methoxylated diphenyls; the interconversion of the cis to the trans isomers of di-(3-bromo-2,4,6-trimethy1phenyl)2-5-dihydroxybenzoqinone[6] (interference on each side 0.135 Å.), the non-existence of two isomers in di-(2,4-dimethylphenyl)-2,5-dihydroxybenzoquinone[6] (interference on each side, —0.265 Å.) and in 2,2'6,6'-tetramethoxy-3,3'-dicarboxydiphenyl (interference on each side, 0.00 Å.).[7]

A more direct comparison of the methoxyl group and fluorine atom has now been made by the study of 2,2'-difluoro-6,6'-dicarboxydiphenyl (VI) and 2,2'-dimethoxy-6,6'-dicarboxydiphenyl. The two diastereoisomeric salts of each compound were isolated and from these the two active acids of each of the two diphenyls.

The active 2,2'-difluoro-6,6'-dicarboxydiphenyl was completely race-

(7) Unpublished results of M. C. Cupery.

mized when heated on a steam cone for eight minutes in 0.1 *N* sodium hydroxide and a marked diminution in rotation occurred when allowed to stand for one week at 2b° in 0.1 N sodium hydroxide. Complete racemization occurred in boiling alcohol in about two hours and in boiling acetic anhydride in ten minutes, and partial racemization was caused by boiling in glacial acetic acid for five minutes and by standing for one week at 25° in absolute ethyl alcohol containing 40% hydrochloric acid.

On the other hand, the active 2,2′-dimethoxy-6,6′-dicarboxydiphenyl racemized much more slowly, giving the following half-life periods: in boiling 0.1 *N* sodium hydroxide, seven hours and fifty minutes; in boiling sodium ethylate, eleven hours; in boiling glacial acetic acid, seventy-eight minutes; and in boiling alcohol about sixty hours.

The fluorine therefore is a considerably smaller interfering group than the methoxyl. On the basis of calculated values previously used, the interference in the 2,2′-difluoro would be 0.05 Å.; in the 2,2′-dimethoxy, 0.11 Å. on each side of the molecule if the value of 1.45 Å. for the methoxyl is adopted.

The discrepancy between the racemization rates of active 2,2′-dimethoxy-6,6′-dicarboxydiphenyl and of active 2-nitro-6-carboxy-2′-methoxydiphenyl[4] corresponds to the observed fact that for the same interference value, the rate of racemization of a 2,2′,6-trisubstituted compound is more rapid than that of a 2,2′,6,6′-tetrasubstituted compound.[1,4]

The active esters and amides of 2,2′-dimethoxy-6,6′-dicarboxydiphenyl were prepared and their rates of racemization determined. In glacial acetic acid, the half-life period values of the acid, ester and amide were seventy-eight, eighty-eight, and two hundred and forty minutes, respectively. The atom or group combined to the atom which is attached to the ring thus plays an appreciable part in the interference value of the whole group. A comparison is now being made of various esters and substituted amides of 2,2′-dimethoxy-6,6′-dicarboxydiphenyl to determine the relative effects of these groups.

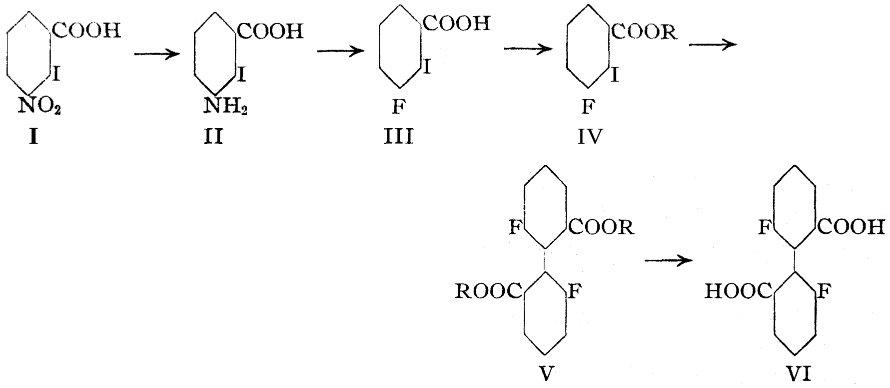
Experimental

The difluoro acids was prepared from 1-nitro-2-iodo-3-carboxybenzene (III) by a series of reactions of which the stages are shown by the accompanying formulas.

Certain steps in this procedure are of particular interest. Kenner reported that acid reducing agents could not be used on (I) on account of the activity of the iodine atom. Nevertheless, it was found that the reduction could be accomplished by the action of stannous chloride and hydrochloric acid either with or without a little alcohol. The amino group could not be replaced by fluorine using the usual procedure through treatment of the diazonium chloride or diazonium fluoride with hydrofluoric or hydro-

---

(8) Kenner and Turner [*Chem. & Ind.*, **46**, **218** (1927)] mentioned their intention of preparing 2,2′-difluoro-6,6′-dicarboxydiphenyl but as no description has appeared to date, it has been assumed that this particular research has been abandoned. See also Stanley and Adams, THIS JOURNAL, **52**, 1200 (1930).



borofluoric acid. Only by diazotization of the amino acid in 48% hydrofluoric acid and by then allowing the diazonium fluoride to stand for a considerable time at room temperature was the fluorine introduced.

1-Methoxy-2-nitro-3-carboxybenzene.—In a 3-liter three-necked flask, equipped with a stirrer and a reflux condenser, were placed 50 g. of 1-methyl-2-nitro-3-methoxybenzene and a solution of 160 g. of potassium permanganate in 2 liters of water. The mixture was refluxed, with stirring, for twelve hours. The manganese dioxide was removed by filtration and the filtrate concentrated to about 500 cc. The unoxidized material steam distilled during this process. Upon cooling and acidifying with 10% sulfuric acid 1-methoxy-2-nitro-3-carboxybenzene precipitated and was purified from 400 cc. of 95% alcohol. The yield was 26 g. (58%) of a product melting at 256–257° (corr.). Rieche[10] reports a m. p. of 251°.

1-Methoxy-2-amino-3-carboxybenzene.—A solution of 4 g. of the nitro acid in 100 cc. of hot 95% alcohol was reduced with 0.2 g. of platinum oxide and hydrogen at 2.5 atm. pressure in five minutes. A total of twenty-five such reductions was made, six to a single sample of catalyst. The alcoholic solution of all the 1-methoxy-2-amino-3-carboxybenzene thus obtained was filtered from the platinum and the alcohol distilled until the volume of the residual solution was about 600 cc. Upon cooling, 66 g. of tan-colored amino acid separated. Recrystallization from 95% alcohol raised the melting point to 171–172° (corr.). The mother liquor was evaporated to 300 cc. and cooled and a second crop of crystals obtained. The total yield was 71.5 g. (84%). Pschorr[11] reports m. p. 169–170°.

1-Methoxy-2-iodo-3-carboxybenzene.—To an ice-cold suspension of 60 g. of 1-methoxy-2-amino-3-carboxybenzene in 500 cc. of water containing 51 cc. of concentrated sulfuric acid was added, with stirring, a solution of 24.8 g. of sodium nitrite in 60 cc. of water. Stirring was continued in the cold for thirty minutes and the solution was then added, with stirring, to a boiling solution of 60 g. of potassium iodide in 200 cc. of water in a 3-liter three-necked flask equipped with a reflux condenser and a mechanical stirrer. The mixture was refluxed with stirring for thirty minutes while the evolution of nitrogen was vigorous and then allowed to cool (stirring continued) to room temperature. The product separated and was crystallized from 95% alcohol. The yield was 68 g. (68%) of a product melting at 148–149° (corr.). Kenner and Turner[9] report a melting point of 150–151°.

1-Methoxy-2-iodo-3-carbomethoxybenzene.—The acid was esterified with absolute

---

[9] Kenner and Turner, J. *Chem Soc.*, 2340 (1928).

[10] Rieche, *Ber.*, 22,2352 (1889).

[11] Pschorr, Ann., 391, 27 (1912).

methanol containing a little concentrated sulfuric acid. The yield was 44.5 g. (96%). Upon recrystallization from 95% alcohol, white crystals melting at 56–57° were formed. (Kenner and Turners report a melting point of 57°.) The ester was used without recrystallization for the preparation of 2,2′-dimethoxy-6,6′-dicarbomethoxydiphenyl.

2,2′-Dimethoxy-6,6′-dicarbomethoxydiphenyl.—By heating 5 g. of 1-methoxy-2-iodo-3-carbomethoxybenzene and 10 g. of copper powder in a metal bath at 205–215° for one hour, extracting with boiling benzene and ether and evaporating, the product was obtained; yield, 16 g. from seven runs. It was purified by crystallization from benzene, m. p. 136–137° (corr.).

2,2′-Dimethoxy-6,6′-dicarboxydiphenyl.—The acid was obtained by the action of alcoholic potassium hydroxide on the ester. It was recrystallized from 95% alcohol. The yield was 12.3 g. (90%) of product melting at 293–294°. Kenner and Turner[8] report a melting point of 288–290 .

Resolution of 2,2′-Dimethoxy-6,6′-dicarboxydiphenyl

Monobrucine Salt.—To a hot solution of 1.305 g. of anhydrous brucine in 30 cc. of dry ethyl acetate was added a hot solution of 0.500 g. of 2,2′-dimethoxy-6,6′-dicarboxydiphenyl in 25 cc. of absolute methyl alcohol. Upon cooling for five hours a crop of fine white crystals weighing 0.96 g. separated. After recrystallization from absolute methyl alcohol the salt melted at 198–199° (corr.).

Rotation. 0.2000 g. made up to 20 cc. in chloroform at 20° gave α, +0.235°; 1 = 2; $[\alpha]^{20}_{D}$ +11.7°. Recrystallization from absolute methyl alcohol did not raise the melting point or change the rotation.

Kenner and Turner report the preparation of this compound and give a melting point of 268° but do not report its rotation.

Anal. Calcd. for $C_{39}H_{40}O_{10}N_2$: N, 4.02. Found: N, 4 02.

The remaining material which separated upon further evaporation of the solvent was found to be a mixture of the salt with unchanged brucine.

Diquinine Salt.—To a hot solution of 12.88 g. of anhydrous quinine in 80 cc. of absolute methyl alcohol was added a hot solution of 6 g. of 2,2′-dimethoxy-6,6′-dicarboxydiphenyl in 170 cc. of absolute methyl alcohol. Upon evaporation *in vacuo* at room temperature a dry residue was obtained which was heated to boiling with 200 cc. of dry acetone. Upon cooling, 9.79 g. of white crystals separated. After recrystallization from dry acetone, the salt melted at 178–179° (corr.).

Rotation. 0.2045 g. made up to 20 cc. in chloroform at 20° gave α, +2.27°; l = 2; $[\alpha]^{20}_{D}$ +111.0°. The salt, upon recrystallization from dry acetone, was not changed in melting point or rotation. Kenner and Turner[8] report a melting point of 172–173° and an $[\alpha]_D$ in chloroform of +126°.

Anal. Calcd. for $C_{56}H_{62}O_{10}N_4$: N, 5.90. Found: N, 5.80.

The mother liquor from the first crop of crystals was evaporated to 50 cc. by bubbling nitrogen through the solution. Upon cooling, 0.30 g. of salt separated. This was removed by filtration. The mother liquor was evaporated to dryness. The residue consisted of a resin which, when the last traces of solvent were removed, formed a white powder. The salt could be dissolved in acetone or ethyl acetate and precipitated as a white, flocculent mass by addition of petroleum ether (b. p. 20–40°). Upon filtration, however, this solid turned to a gummy mass which reverted to a white powder when all traces of the solvent were removed. The salt melted at 98–100° (corr.). The weight of salt thus obtained was 8.5 g.

Rotation. 0.1550 g. made up to 20 cc. in chloroform at 20° gave α_D −0.93°; l = 2; $[\alpha]^{20}_{D}$ −60°.

Anal. Calcd. for $C_{56}H_{62}O_{10}N_4$: N, 5.90. Found: N, 5.93.

Kenner and Turner[8] report that the more soluble salt melts at about 60° with decomposition and has an $[\alpha]_D$ in chloroform of −68°.

l-2,2'-Dimethoxy-6,6'-dicarboxydiphenyl.—A mixture of 3 g. of the less soluble salt and 40 cc. of 5% sodium hydroxide solution was ground in a mortar. This mixture was extracted with four 15-cc. portions of cold chloroform. The alkaline solution was then acidified with 6 N hydrochloric acid. The 1-acid precipitated as a white spongy mass which was filtered and dried. After drying, the compound was crystalline and melted at 291–292°.

Rotation. 0.0766 g. made up to 20 cc. in dry acetone at 20° gave α_D −0.88°; 1 = 2; $[\alpha]^{20}_D$ −114.9'.

Kenner and Turner[9] report a melting point of 294–295° and an [a], −115°.

The active acid was recrystallized from boiling chloroform, but apparently racemized somewhat during the procedure.

Rotation. 0.0785 g. made up to 20 cc. in dry acetone at 20' gave α_D −0.70°; 1 = 2; $[\alpha]^{20}_D$ −89.5'.

If the l-acid was dissolved in dry acetone and excess petroleum ether (b. p. 20–40°) was added, feathery crystals separated after standing in the cold for two hours. The melting point and rotation were unchanged by this treatment.

Anal. Calcd. for $C_{16}H_{14}O_6$: C, 63.6; H, 4.64. Found: C, 63.7; H, 4.57.

d-2,2'-Dimethoxy-6,6'-dicarboxydiphenyl.—Three grams of the more soluble salt was decomposed by the procedure used for the less soluble salt. The d-acid obtained in this way melted at 291–292''.

Rotation. 0.0737 g. made up to 20 cc. in dry acetone at 20° gave a,, +0.80°; l = 2; $[\alpha]^{20}_D$ +108.5°.

The d-acid was recrystallized from boiling chloroform. Partial racemization took place.

Rotation. 0.0717 g. made up to 20 cc. in dry acetone at 20° gave α_D +0.62°; *1* = 2; $[\alpha]^{20}_D$ +86.5°.

The d-acid was then purified by dissolving in dry acetone and adding excess petroleum ether. The product had the same melting point and rotation.

Anal. Calcd. for $C_{16}H_{14}O_6$: C, 63.6; H, 4.64. Found: C, 63.61; H, 4.77.

Racemization Experiments.—Only a few of the readings taken during the racemization experiments are given. Many more were recorded and from all of them the half-life periods were calculated.

In Sodium Hydroxide

Rotation. 0.0967 g. made up to 20 cc. in 0.1 N sodium hydroxide at 20° gave α_D −2.60'; l = 2; $[\alpha]^{20}_D$ −269°. After refluxing for fifty-five minutes the rotation was −256°; after eight hours, −137.5'; after twenty-three hours. −16.6°; after twenty-six hours, −10.3°; and after twenty-nine hours the rotation was zero. The half-life period was seven hours and fifty minutes.

In Sodium Ethylate

A solution of sodium ethylate was prepared by dissolving 0.50 g. of sodium in 100 cc. of absolute alcohol.

Rotation. 0.0678 *g.* of 1-acid made up to 20 cc. in sodium ethylate solution at 20° gave α_D −0.83°; 1 = 2; $[\alpha]^{20}_D$ −121.8'. After refluxing for two hours the rotation was −108'; after nine hours and thirty minutes, −67.8'; after twenty-three hours and thirty minutes, −36.9'; and after forty-four hours and thirty minutes, −3.9'. The half-life period was eleven hours.

In Ethanol

Rotation. 0.0880 g. made up to 20 cc. in 95% alcohol at 20° gave α −1.19°; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ −135.5°. After refluxing for forty-five minutes the rotation was −133°; after eight hours and twenty-five minutes, −125°; after twenty-nine hours and thirty minutes, −99°. The half-life period was sixty-one hours and thirty minutes.

In Glacial Acetic Acid

Rotation. 0.0670 g. made up to 20 cc. in glacial acetic acid at 20° gave α_{D} −1.13°; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ −168.5°. After refluxing for two hours and thirty minutes the rotation was −49.2°; after four hours, −20.9°; after five hours and forty-five minutes, −5.5°; and after seven hours and fifteen minutes the rotation was zero. The half-life period was seventy-eight minutes.

Unfortunately racemization tests in chloroform could not be performed since the active acids were soluble only in boiling solvent. The recrystallization of the active acids from chloroform indicated a more rapid racemization than in the other solvents.

l-2,2′-Dimethoxy-6,6′-dicarbomethoxydiphenyl.—In a side-arm test-tube was placed 1 cc. of thionyl chloride and 0.2 g. of l-2,2′-dimethoxy-6,6′-dicarboxydiphenyl having a rotation of −114.9'. The tube was stoppered and after standing at room temperature for two and one-half hours, the excess thionyl chloride was removed by suction. The residual acid chloride was treated with 3 cc. of absolute methyl alcohol and allowed to stand for two hours. The methyl alcohol was then evaporated and the crystalline ester was washed with 0.1 N sodium hydroxide and then with water. The I-ester melted at 101-102°.

Rotation. 0.0560 g. made up to 20 cc. in absolute methyl alcohol at 20° gave α −0.78°; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ −139". The solution was evaporated to the appearance of crystals. The material which separated had the same melting point and rotation.

Anal. Calcd. for $C_{18}H_{18}O_6$: C, 65.5; H, 5.45. Found: C, 65.7; H, 5.67.

d-2,2′-Dimethoxy-6,6′-dicarbomethoxydiphenyl.—The d-ester was prepared in a similar manner from a sample of d-acid having a rotation of +86.5°. The d-ester thus obtained melted at 98-99°.

Rotation. 0.0530 g. made up to 20 cc. in absolute methyl alcohol at 20° gave α_{D} +0.70°; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ +132°. The methyl alcohol was evaporated to the appearance of crystals. The material thus obtained had the same melting point and rotation.

Anal. Calcd. for $C_{18}H_{18}O_6$: C, 65.5; H, 5.45. Found: C, 65.64; H, 5.72.

Racemization Experiment

Rotation. 0.0508 g. made up to 20 cc. in glacial acetic acid at 20° gave α_{D} −0.886°; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ −174.5°. After refluxing for forty-five minutes the rotation was −122.5°; after three hours and fifty minutes, −27.6°; after five hours and fifty minutes, −11.8". Refluxing was then continued overnight to complete the racemization. The acetic acid was then evaporated and the ester thus obtained melted at 135–136° (the m. p. of the racemic ester). The half-life period was eighty-eight minutes.

l-2,2′-Dimethoxydiphenyl-6,6′-dicarboxylic Acid Amide.—The acid chloride prepared as described under the ester was poured slowly into 5 cc. of ice-cold aqueous ammonia (sp. gr. 0.9). Upon standing in the cold for six hours the amide separated as long needles which were filtered and dried. The l-amide melted at 230-231° (corr.).

Rotation. 0.0338 g. made up to 20 cc. in absolute methyl alcohol at 20" gave α −0.185"; l = 2; $[\alpha]^{20}_{\mathrm{D}}$ −54.8".

The amide was recrystallized from absolute methyl alcohol. The melting point and rotation were unchanged.

Anal. Calcd. for $C_{16}H_{16}O_4N_2$: N, 9.33. Found: N, 9.33.

The d-amide obtained by a similar procedure melted at 230–231° (corr.).

Rotation. 0.0190 g. made up to 20 cc. in absolute methyl alcohol at 20° gave α_D $+0.102'$; $l = 2$; $[\alpha]^{20}_D$ $+53.6°$. The amide was recrystallized from absolute methyl alcohol. The melting point and rotation were unchanged.

Anal. Calcd. for $C_{16}H_{16}O_4N_2$: N, 9.33. Found: N, 9.31.

Racemization Experiment

Rotation. 0.0582 g. of the I-amide made up to 20 cc. in glacial acetic acid at 20° gave α_D $-0.38''$; $l = 2$; $[\alpha]^{20}_D$ $-65.3'$. After refluxing for one hour and fifteen minutes the rotation was $-51.5''$; after four hours and fifteen minutes, $-29.2''$; after nine hours, $-17.2'$. Refluxing was then continued overnight, after which time the rotation was zero. The half-life period was four hours. The solvent was evaporated and the racemic amide thus obtained melted at 271–272°. A mixed melting point determination with racemic amide prepared from the racemic acid showed no depression.

2,2'-Dimethoxydiphenyl-6,6'-dicarboxylic Acid Amide.—The racemic amide was prepared from racemic 2,2'-dimethoxy-6,6'-dicarboxydiphenyl as described for the active acids, except that refluxing was necessary to form the acid chloride readily. The amide was recrystallized from 50% alcohol using norite. The melting point was 273–274°.

Anal. Calcd. for $C_{16}H_{16}O_4N_2$: N, 9.33. Found: N, 9.48.

I-Nitro-2-iodo-3-carboxybenzene (I).[12]—This compound was produced by the method of Culhane and Whitmore in 65–75% yields.

I-Amino-2-iodo-3-carboxybenzene (II).—A solution of 320 g. of stannous chloride in 320 cc. of concentrated hydrochloric acid was warmed to 60°, and 40 g. of powdered 1-nitro-2-iodo-3-carboxybenzene was added with stirring. Sufficient ethyl alcohol (about 40 cc.) may be added with stirring if the reduction does not start (much larger amounts of alcohol caused diminution in yield). The mixture was stirred continuously and cooled sufficiently to maintain the temperature between 60 and 75°. After standing for an hour the mixture was cooled and the precipitated tin salt was removed by filtration with suction. The yield of double tin salt was 80 g. The run was repeated twice and the total 240 g. of double tin salt was treated with 750 cc. of water and sufficient aqueous ammonia to obtain an alkaline reaction. The mixture was heated to boiling, cooled and the curdy white precipitate of stannic oxide was removed by filtration with suction. The precipitate was washed with dilute aqueous ammonia and finally with water. The washings were added to the main portion and heated to boiling, cooled and filtered. The filtrate was made barely neutral with concentrated hydrochloric acid. The precipitated amino acid was filtered with suction and dried. The yield was 70.5 g. (68%). The crude product was purified by recrystallizing twice from 20% ethyl alcohol and formed purplish-gray needles, m. p. 133° (corr.). The amino acid was insoluble in cold but soluble in hot concentrated hydrochloric acid. On cooling, the hydrochloride of 1-amino-2-iodo-3-carboxybenzene crystallized out as fine granules which, when pure, start to decompose under 100" and finally melt with decomposition at 263–264°. The hydrochloride was readily soluble in water

Various attempts to reduce 1-nitro-2-iodo-3-carboxybenzene with ammoniacal ferrous sulfate were unsuccessful. The catalytic reductions with platinum black in hot and cold alcohol, ethyl acetate and glacial acetic acid all resulted in the formation of reddish, insoluble material. Catalytic reduction of the ethyl ester gave negative results. Reductions using zinc dust and acetic acid, and zinc dust and hydrochloric acid, were unsuccessful.

I-Fluoro-2-iodo-3-carboxybenzene (III).—To a solution of 100 cc. of 48% hydrofluoric acid at 25° in a platinum dish was added 42 g. of 1-amino-2-iodo-3-carboxy-

---

(12) "Organic Syntheses," Collective Vol. I, 1932, p. 121.

benzene. After solution, the mixture was cooled to 0° by a salt–ice bath. This caused the formation of a gray pasty mass of the amine hydrofluoride. Then 11.5 g. of powdered sodium nitrite was added very slowly with continuous stirring. The precipitate dissolved with the formation of the diazonium fluoride, which was readily soluble. Diazotization was shown to be complete by a positive reaction with starch–potassium iodide paper five minutes after the addition of the last portion of sodium nitrite The diazotized solution was allowed to come to 30 ± 2° and remain at that temperature for two days. During this period bubbles of nitrogen were continually evolved from the solution and a precipitate slowly formed on the sides and bottom of the platinum vessel. The evolution of bubbles ceased after two days and the precipitate which had formed was removed by filtration with suction and washed with water. The yield was 28 g. (62.5%) of 1-fluoro-2-iodo-3-carboxybenzene which melted at 152–153° (corr.) after two crystallizations from water.

Anal. Calcd. for $C_7H_4O_2IF$: I, 47.76. Found: I, 47 37.

Diazotization of the amine in varying dilutions of hydrochloric acid solution with subsequent treatment with varying amounts of hydrofluoric acid or hydroborofluoric acid, or diazotization in hydrofluoric acid with subsequent addition of hydroborofluoric acid or diazotization in hydrofluoric acid with subsequent boiling with water gave a product soluble in alcohol or water, melting at 144–145" (corr.). This product was readily acetylated with acetic anhydride (whereas the fluoro compound melting at 152–153° was [illegible] similar treatment) to give a product insoluble in alcohol and water and melting at 144°. It is evident that the original compound is 1-hydroxy-2-iodo-3-carboxybenzene and the second the corresponding acetate.

1-Fluoro-2-iodo-3-carbomethoxybenzene (IV).—A mixture of 28 g of 1-fluoro-2-iodo-3-carboxybenzene and 19 g. of thionyl chloride was refluxed for ten hours. The excess of thionyl chloride was removed by distillation, 50 cc. of absolute methyl alcohol was added slowly and the mixture then refluxed for five hours. The excess alcohol was removed and the ester distilled under reduced pressure. The yield was 25 g. (85%) of a product boiling at 127–128° (4 mm.).

Anal. Calcd. for $C_8H_6O_2IF$: I, 45.33. Found: I, 44.93.

1-Fluoro-2-iodo-3-carboethoxybenzene.—A sample of 7 g. of 1-fluoro-2-iodo-3-carboxybenzene was similarly treated using absolute ethyl alcohol instead of methyl alcohol. The yield of ethyl ester was 6 g.; the boiling point was 148–150° (6 mm.).

Anal. Calcd. for $C_9H_8O_2IF$: I, 43.16. Found: I, 42.85.

2,2′-Difluoro-6,6′-dicarbomethoxydiphenyl (V).—To 28 g. of 1-fluoro-2-iodo-3-carbomethoxybenzene heated to 180° in a 100-cc. three-necked flask fitted with a stirrer and reflux condenser was added slowly with stirring 56 g. of copper powder. A vigorous exothermic reaction occurred after the addition of about half of the copper powder. The reaction mixture was heated at 240° for one hour. It was then cooled and the reaction mixture extracted five times with 50 cc. of ether The yield was 8.5 g. (57%). The product was crystallized from *p*-cymene and benzene to a constant melting point of 116–117°.

Anal. Calcd. for $C_{16}H_{12}O_4F_2$: C, 62.72; H, 3.95. Found: C, 62.45; H, 3.88.

2,2′-Difluoro-6,6′-dicarboethoxydiphenyl.—The diethyl ester was prepared similarly by the action of copper powder on 1-fluoro-2-iodo-3-carboethoxybenzene. Crystallization of the diethyl ester from *p*-cymene and then from absolute ethyl alcohol gave a product melting at 105–107°.

Anal. Calcd for $C_{18}H_{14}O_4F_2$: C, 64.64; H, 4.82. Found: C, 64.31; H, 4.64.

2,2′-Difluoro-6,6′-dicarboxydiphenyl (VI).—A mixture of 7.6 g. of dimethyl ester was saponified with an absolute ethyl alcohol solution of potassium hydroxide. Recrystallization from 95% ethyl alcohol raised the melting point to a constant value of 308–311° (corr.). The acid begins to shrink about 50" below the melting point recorded, softens noticeably about 10° below and melts sharply at the point given, forming a meniscus.

Anal. Calcd. for $C_{14}H_8O_4F_2$: C, 60.42; H, 2.90. Found: C, 60.18; H, 2.99. Neut. equiv.: calcd., 278.1. Found: 280.0.

Resolution **of 2,2′-Difluoro-6,6′-dicarboxydiphenyl.**—To a hot solution of 2.5 g. of 2,2′-difluoro-6,6′-dicarboxydiphenyl in 75 cc. of 95% ethyl alcohol was added with stirring a hot solution of 3.0 g. of anhydrous quinine in 45 cc. of 95% ethyl alcohol. The solution was evaporated to 95 cc. and allowed to cool. A crop of white flaky crystals separated, which was essentially pure salt, as shown by rotation and melting point as compared with recrystallized material. The crystals of pure less soluble salt were removed by filtration with suction, washed with 95% alcohol and dried; weight 2.5 g. Recrystallization from 95% ethyl alcohol gave a pure product of melting point 221–222° (corr.).

Rotation. 0.1695 g. made up to 15 cc. with absolute ethyl alcohol at 20° gave α_D +0.44°; $l = 1$; [a]: +38.9°. Recrystallization from 95% ethyl alcohol did not change the melting point or rotation.

Anal. Calcd. for $C_{34}H_{32}O_6F_2N_2$: N, 4.65. Found: N, 4.52.

The mother liquor from the first crop of crystals was further evaporated to 50 cc. Upon cooling, 0.32 g. of salt crystallized out, which was by rotation shown to be impure less soluble salt. The filtrate was evaporated to dryness and the residue of more soluble salt washed once with 25 cc. of a 10% solution of ethyl alcohol in water. After drying, the weight was 2.5 g. and the melting point was 159–160" (corr.).

Rotation. 0.1755 g. made up to 15 cc. with absolute ethyl alcohol at 20° gave α_D −1.18°; $l = 1$; [a]: −101°. The more soluble salt was dissolved in ethyl alcohol and precipitated by the addition of water into two fractions. The melting point was unchanged and the rotation of the two fractions identical with that of the original material.

Anal. Calcd. for $C_{34}H_{36}O_6F_2N_2$: N, 4.65. Found: N, 4.32.

l-2,2′-Difluoro-6,6′-dicarboxydiphenyl.—The pure less soluble salt was hydrolyzed by two procedures, both giving practically the same results. The first procedure consisted in digesting 1.0 g. of salt three times for ten minutes each in the cold with 10 cc. of 2 N hydrochloric acid. The pasty mass which first formed changed to white flakes on' continued stirring. The active l-acid so obtained was then washed on a filter with another 10-cc. portion of 2 N hydrochloric acid, then with water, and finally crystallized from 95% ethyl alcohol. The melting point was 305–306° (corr.), with a melting behavior similar to that of the racemic acid. A mixed melting point with the racemic acid gave 302–304° (corr.).

Rotation. (a) 0.1535 g. made up to 15 cc. with 95% ethyl alcohol at 20° gave α_D −0.23"; $l = 1$; $[\alpha]^{20}_D$ −22.5'. (b) 0.1008 g. made up to 15 cc. with 0.1 N sodium hydroxide at 20° gave α_D −0.835'; $l = 1$; $[\alpha]^{20}_D$ −124°.

The second procedure consisted in digesting 1.2 g. of pure less soluble salt with 10 cc. of cold 2 N hydrochloric acid for five minutes. The acid was decanted and the white flakes which were obtained from the pasty mass by stirring were washed with water and dissolved in 2 N sodium hydroxide solution. The solution was warmed to 80°, immediately cooled, and extracted three times with 4 cc. each of chloroform. The alkaline solution was then acidified with concentrated hydrochloric acid. The l-acid precipitated and was washed with water and dried. After crystallization from 95% ethyl alcohol, the melting point was 305–306° (corr.).

Rotation. 0.0945 g. made up to 15 cc. with 0.1 N sodium hydroxide at 20° gave α_D −0.8'; $l = 1$; $[\alpha]^{20}_D$ −127.0".

Anal. Neut equiv., calcd., 278.1. Found: 280.

d-**2,2'-Difluoro-6,6'-dicarboxydiphenyl.**—The d-acid was obtained from 2 2 g. of the more soluble salt by the second procedure given above. After recrystallization from 95% ethyl alcohol the melting point was 305–306° (corr).

Rotation. (a) 0.1387 g. made up to 15 cc. with 0.1 *N* sodium hydroxide at 20° gave α_D +0.94°; 1 = 1; $[\alpha]^{20}_D$ +101.8°. (b) 0 1071 g. made up to 15 cc. with 95% ethyl alcohol at 20° gave α_D +0.12"; *l* = 1; $[\alpha]^{20}_D$ +16.8°.

Synthesis of More Soluble Salt.—An alcohol solution of 0 1071 g. of d-acid having a rotation in alcohol of +16.8° was treated with 0.125 g. of quinine. The salt obtained upon evaporation of the alcohol to 2 cc. and precipitation with water was washed with water and dried. The melting point was 163–165° (corr.).

Rotation. 0.0860 g. made up to 15 cc. with absolute ethyl alcohol at 20° gave α_D −0.435°; *l* = 1; $[\alpha]^{20}_D$ −76.0°.

Racemization Experiments

In Sodium Hydroxide—Hot.—The rotation was taken on an alkaline solution of the I-acid. *Rotation.* 0.0945 g. made up to 15 cc. with 0.1 N sodium hydroxide at 20° gave α_D −0.8"; *l* = 1; $[\alpha]^{20}_D$ −127°. The alkaline solution was heated in a closed container on a steam cone for eight minutes. The rotation was again taken and the acid was found to be completely racemized.

In Sodium Hydroxide—Cold.—The rotation was taken on an alkaline solution of partially active 1-acid. *Rotation.* 0.0870 g. made up to 15 cc. with 0.1 N sodium hydroxide at 20° gave α_D −0.38°; *l* = 1; $[\alpha]^{20}_D$ −66.5°. After standing for one day at room temperature (25°) the rotation was −60°, after two days, −54°, after three days, −45°, after five days, −24°, and after one week the rotation was −18°. A solution of d-acid in 0.1 N sodium hydroxide racemized from a rotation of +62.3° to +15° after standing at 25° for one week.

In Ethanol.—A solution of I-acid was made in 95% ethyl alcohol. *Rotation.* 0.0892 g. made up to 15 cc. with 95% ethyl alcohol at 20° gave α_D −0.12"; *l* = 1; $[\alpha]^{20}_D$ −20.2". The alcoholic solution was refluxed for one hour and the rotation was then −11.7°. The solution was refluxed an additional hour and a half and the rotation was zero.

In Acetic Anhydride.—A sample of 0.1014 g. of acid having a rotation of −127° in 0.1 N sodium hydroxide was dissolved in 15 cc. of acetic anhydride. Warming to 50° for three minutes was required to effect solution. The rotation in acetic anhydride was taken and found to be zero. The solution was boiled for ten minutes and the acetic anhydride removed in a vacuum. The residue was dissolved in 0.1 N sodium hydroxide. It was necessary to bring the mixture to boiling to effect solution as the residue went into solution very slowly. The solution was immediately cooled and the rotation in 0.1 N alkali was zero.

In Acetic Acid.—A 0.1281-g. portion of acid having a rotation of −66.5° in 0.1 *N* alkali was dissolved in 15 cc. of glacial acetic acid. Solution took place readily in the cold and the rotation was found to be zero. The acetic acid solution was refluxed for five minutes and the acetic acid removed in a vacuum. The residue dissolved readily in cold 0.1 N sodium hydroxide. The rotation in 0.1 N alkali was found to be −36.6". Refluxing with glacial acetic acid, therefore, caused partial racemization.

In Alcoholic Hydrochloric Acid.—A solution of d-acid was prepared with absolute ethyl alcohol containing 40% concentrated hydrochloric acid. *Rotation.* 0.1181 g. made up to 15 cc. with absolute ethyl alcohol containing 40% of hydrochloric acid at 20° gave α_D +0.09°; 1 = 1; $[\alpha]^{20}_D$ +11.4°. After standing for one week the rotation was +6.6°.

Summary

1 2,2′-Difluoro-6,6′-dicarboxydiphenyl has been prepared from 1-methoxy-2-iodo-3-carboxybenzeneby reduction to the amine, diazotization and replacement of the amino group by fluorine, and coupling by means of copper powder.

2. The compound has been resolved into optical isomers through the quinine salt. The active forms of 2,2′-difluoro-6,6′-dicarboxydiphenyl racemize rapidly in hot dilute alkali, fairly readily in hot alcohol, hot acetic anhydride or hot glacial acetic acid, and slowly in cold dilute alkali or in a 40% solution of concentrated hydrochloric acid in absolute alcohol.

3. 2,2′-Dimethoxy-6,6′-dicarboxydiphenyl has been prepared and resolved according to the outlined procedure of Kenner and Turner. The active acids racemized much more slowly than the difluoro compounds.

4. The active 2,2′-dimethoxy-6,6′-dicarbomethoxydiphenyl and the corresponding methyl ester racemized at about the same rate. The active diamide racemized much more slowly.

Stereochemistry of Diphenyl. XXVIII.[1] Preparation and Properties of 2,2′-Difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl

BY E. C. KLEIDERER[2] AND ROGER ADAMS

Diphenyls containing fluorine in one or more of the 2,2′,6,6′-positions are of especial interest in connection with the stereochemistry of the diphenyls, since fluorine is the smallest substituent which can be introduced in place of a hydrogen. The compounds of this type thus far prepared are the non-resolvable 2,2′-difluoro-3,3′-dicarboxy-6,6′-dimethoxydiphenyl[3] (I), the extremely unstable brucine salt of 2-nitro-6-carboxy-2'-fluorodiphenyl[4] (11), the easily racemized 2,2′-difluoro-3,5,3′,5′-tetramethyl-6,6′-diaminodiphenyl[5] (III) and 2,2′-difluoro-6,6′-dicarboxydiphenyl[1] (IV). Although the properties of these compounds agree satisfactorily with those predicted for such structures, nevertheless, it might appear that the mobility of these compounds may be due to some specific property of the fluorine, other than its small size. A compound has, therefore, been

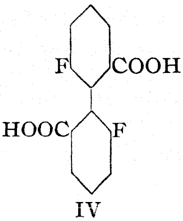
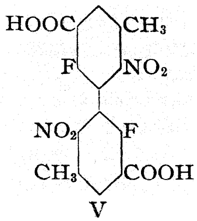
111



IV



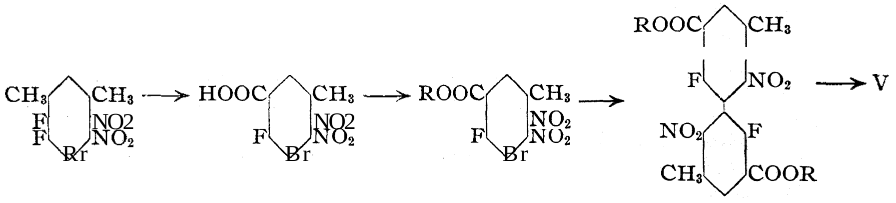
V

This should be resistant to racemization if the size of the groups is the primary influence, and it, indeed, proved to be so. This is satisfactory evidence that the lability of all the previously studied fluorodiphenyls is due, primarily, to the size rather than to any other specific property of the fluorine atom.

The compound prepared was 2,2′-difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl (IX). The l-form showed no appreciable racemization after several hours of boiling in ethyl alcohol, glacial acetic acid, cyclohexanone and 0.1 N sodium hydroxide. The alkaline solution, however, became colored on standing and an extended experiment in this solvent was impossible.

Experimental

The dinitro-difluoro compound was prepared by the following series of reactions



VI VII VIII

1-Bromo-2-fluoro-3-carboxy-5-methyl-6-nitrobenzene (VI).—A mixture of 5 g. of 1-bromo-2-fluoro-3,5-dimethyl-6-nitrobenzene[5] (V) and 20 cc. of concentrated nitric acid (sp. gr. 1.42) diluted with 40 cc. of water, was placed in a sealed tube and heated in a horizontal position for eight hours at 150" (Longer than eight hours gave considerable decomposition with evolution of carbon dioxide.) Upon cooling, the reaction mixture was made alkaline, filtered and extracted once with ether. Upon acidification with dilute sulfuric acid, the acid precipitated as a light yellow curd. The crude acid was crystallized from dilute alcohol. It formed light yellow needles melting at 249–251" (corr.). In no case was a mixture of acids obtained. The yield was 2 g. (36% of the theoretical).

Anal. Calcd. for $C_8H_5O_4BrFN$: N, 5.04; Br, 28.80; neut. equiv., 278. Found: (micro Dumas) N, 5.34; Br, 28.89; neut. equiv , 275.3.

The evidence that the methyl group adjacent to the fluorine was oxidized and not that adjacent to the nitro was indirect. By the same concentration of nitric acid and under the same conditions used in the oxidation just described, it was found that in 1-

nitro-2,4-dimethylbenzene, the 4-methyl group oxidized exclusively. The methyl ortho to the nitro apparently was unaffected by this reagent.

1-Bromo-2-fluoro-3-carbomethoxy-5-methyl-6-nitrobenzene (VII).—VI was heated with excess of thionyl chloride for five minutes to convert it to the acid chloride. The crude acid chloride was treated with absolute methyl alcohol and refluxed for thirty minutes. The ester was isolated by pouring the methyl alcohol mixture onto ice. It was purified by crystallization from 50% methyl alcohol, from which it crystallized in white needles melting at 88–89" (corn.). The yield was quantitative.

Anal. Calcd. for $C_9H_7O_4BrFN$: N, 4.80. Found: (micro Dumas) N, 4.73.

1-Bromo-2-fluoro-3-carboethoxy-5-methyl-6-nitrobenzene (VII).—The ethyl ester was prepared in the same way as the methyl ester. The ester was purified from 50% ethyl alcohol, from which it crystallized in white needles melting at 65–66° (corr.). The yield was quantitative.

Anal. Calcd. for $C_{10}H_9O_4BrFN$: N, 4 58. Found: (micro Dumas) N, 4.46.

2,2′-Difluoro-3,3′-dicarbomethoxy-5,5′-dimethyl-6,6′-dinitrodiphenyl (VIII).—In a large Pyrex test-tube a mixture of 4.8 g. of (VII) and 5 g. of copper bronze was heated to 225°, when the reaction began as evidenced by the change in color of the copper. The reaction was allowed to continue at 220" for one hour. The melt was extracted with acetone and the solution treated with activated carbon (norite). The essentially colorless acetone was evaporated slowly and absolute methyl alcohol added. After most of the acetone had evaporated the diphenyl compound crystallized in needles, melting upon recrystallization from methyl alcohol at 191–193° (corr.). The yield was 2.26 g. (65%).

Anal. Calcd. for $C_{18}H_{14}O_8F_2N_2$: N, 6.60. Found: (micro Dumas) N, 6.79.

2,2′-Difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl (V).—A mixture of the ester (VIII), 50% methyl alcohol and a slight excess of sodium hydroxide over that necessary for hydrolysis, was refluxed for thirty minutes, at which time the diester had dissolved and the solution had changed from colorless to light yellow. After cooling, acidifying, evaporating to half volume and again cooling the acid crystallized in short colorless needles. These were recrystallized from 50% ethyl alcohol. They melted at 301–304" (uncorr.) on the bloc Maquenne, 318–320° (corr.) with decomposition in a melting-point tube.

Anal. Calcd. for $C_{16}H_{10}O_8F_2N_2$: N, 7.07; neut. equiv., 198. Found: (micro Dumas) N, 7.15; neut. equiv., 196.5.

Resolution **of 2,2′-Difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl** (V.) Strychnine Salt.—To a solution of 2.1 g. of strychnine dissolved in 300 cc. of absolute methyl alcohol was added 1.23 g. of the acid (V). The solution was evaporated to 210 ce. and allowed to stand overnight in a'desiccator. At the end of this time 1.5 g. of salt had crystallized.

The salt for purification was dissolved in 150 cc. of absolute methyl alcohol and allowed to stand overnight. At the end of this time the salt had crystallized out in small cubes. The melting point was 224–228° (corr), with decomposition.

Rotation. 0.1000 g. made up to 10 cc. with pyridine at 20° gave α_D −0.75°, l = 1; $[\alpha]^{20}_D$ −75°. Further recrystallization brought no change in rotation.

Anal. Calcd. for $C_{16}H_{10}O_8F_2N_2 \cdot 2C_{21}H_{22}O_2N_2$: N, 7.89. Found: (micro Dumas) N, 7.83.

The mother liquor from the first crop of crystals was evaporated to 150 cc., when 0.35 g. of needle-like crystals came down. These were filtered off and the filtrate was evaporated to 80 cc. and allowed to stand overnight. At the end of this time 1 g. of needle-like crystals had separated. This last fraction was recrystallized from absolute methyl alcohol, m. p. 190–193° (corr.) with decomposition.

Rotation. 0.1000 g. made up to 10 cc. with pyridine at 20° gave α_D −0.50, 1 = 1; $[\alpha]^{20}_{D}$ −50.0°. Further recrystallization gave no change in rotation.

Anal. Calcd. for $C_{16}H_{10}O_8F_2N_2 \cdot 2C_{21}H_{22}O_2N_2$: N, 7.89. Found: (micro Dumas) N, 7.56.

As the nitrogen analysis will not distinguish the mono- and distrychnine salts, a portion of salt was decomposed quantitatively and acid and base isolated. The salt proved to be dibasic.

0.2230 g. of salt yielded 0.0830 g. of acid and 0.1350 g. of strychnine. For 0.0830 g of acid, there is required 0.1400 g. of strychnine for a dibasic salt.

***l*-2,2′-Difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl.**—The less soluble salt was treated in the cold with 5% aqueous sodium hydroxide for about thirty minutes. At the end of this time the precipitated strychnine was filtered off. The acid was precipitated with dilute hydrochloric acid and purified from 50% alcohol, from which it crystallized in white needles. The melting point (tube) was 298–300° (corr.) with decomposition.

Rotations. 0.1000 g. made up to 10 cc. at 20° with methyl alcohol gave α_D −0.17°, l = 1; $[\alpha]^{20}_{D}$ −17.0°.

Further recrystallization did not change the rotation.

0.0750 g. made up to 10 cc. at 20° with pyridine gave α_D −0 18°, 1 = 1; $[\alpha]^{20}_{D}$ −24 0°.

0.1000 g. made up to 10 cc. at 25° with cyclohexanol gave α_D −0.12°, l = 1; $[\alpha]^{20}_{D}$ −12.0°.

0.1000 g. made up to 10 cc. at 20° with glacial acetic acid gave a, −0.15°, 1 = 1; $[\alpha]^{20}_{D}$ −15.0'.

0.1068 g. made up to 10 cc. at 20° with cyclohexanone gave a, −0.154°, 1 = 1; $[\alpha]^{20}_{D}$ −14 4°.

0.1000 g. made up to 10 cc. at 20° with 0.1 Nsodium hydroxide gave a, −0.135°, l = 1; $[\alpha]^{20}_{D}$ −13.5°.

Anal. Calcd. for $C_{16}H_{10}O_8F_2N_2$: N, 7.07. Found: (micro Dumas) N, 7.17.

***d*-2,2′-Difluoro-3,3′-dicarboxy-5,5′-dimethyl-6,6′-dinitrodiphenyl.**—The d-acid was prepared in the same way as the 1-isomer. After crystallization from 50% alcohol it melted at 297–301° (corr.) with decomposition.

Rotation. 0.1000 g. made up to 10 cc. at 20° with methyl alcohol gave a, +0.15°, l = 1; $[\alpha]^{20}_{D}$ +15.0°.

Anal. Calcd. for $C_{16}H_{10}O_8F_2N_2$: N, 7.07. Found: (micro Dumas) N, 7.11.

Racemization Experiments.—Refluxing in 95% ethyl alcohol for five hours; in glacial acetic acid for seven hours; in cyclohexanone for three hours; in 0.1 N sodium hydroxide for three hours resulted in no appreciable change in rotation.

Summary

1. 2,2′ - Difluoro - 3,3′ - dicarboxy - 5,5′ - dimethyl - 6,6′ - dinitrodiphenyl has been synthesized and resolved. The probable presence of the two carboxyl groups as 3,3′ and not 5,5′ was determined only by indirect evidence.

2. The active forms are stable to racemization under the conditions used. This is evidence that the mobility of previously prepared fluoro derivatives is due not to any peculiar property of the fluorine atom but probably primarily to its size.

The Coupling Action of the Grignard Reagent. IV. Benzal Chloride and Benzotrichloride

BY REYNOLD C. FUSON AND WM. E. ROSS

It has been shown previously that the benzyl halides when treated with methylmagnesium iodide are converted into dibenzyl according to the equation: $2C_6H_5CH_2X + 2CH_3MgI = CH_3CH_3 + C_6H_5CH_2CH_2C_6H_5 + 2MgIX$.[1] This type of reaction has been reported by several investigators and appears to be applicable to a rather wide variety of types of halogen compounds. An examination of these various compounds, however, reveals the striking fact that the most conspicuous examples contain the skeletal grouping, $Ar-\overset{|}{\underset{|}{C}}-X$, characteristic of arylmethyl halides. Thus, for example, the methoxybenzyl halides,[2] di-α-naphthylmethylchloromethane,[3] diphenylbromoethane,[2] ethylphenylbromomethane,[2] α - chlorophenylacetic acid[4] and the cyanobenzyl halides[5] give the coupling reaction and all of them possess the structural grouping in question.

On the other hand, benzal chloride and benzotrichloride—compounds which contain this structural unit—have not been found to undergo coupling. Reychler[6] examined the behavior of these two compounds toward phenylmagnesium bromide. In the case of benzotrichloride, he was unable to isolate any definite products. Benzal chloride gave a large amount of triphenylmethane and a small quantity of s-tetraphenylethane. Reychler attributed the formation of the latter to the action of metallic magnesium on diphenylchloromethane formed as an intermediate. In the light of Spath's work on diphenylbromomethane, we would now explain Reychler's result as due to the coupling of diphenylchloromethane by the action of the Grignard reagent.

In view of the fact, already pointed out, that benzal chloride and benzotrichloride possess the structural grouping which seems to be most effective in promoting the coupling tendency, the behavior of these two compounds toward the Grignard reagent has been reëxamined. The present paper is a report of this investigation.

Benzal Chloride.—In the case of benzal chloride methylmagnesium iodide was chosen as the reagent because of the high yields of coupling products which this reagent was found to give when used with the benzyl halides and with the cyanobenzyl halides. The results obtained were altogether unlike those reported by Reychler for phenylmagnesium

bromide and benzal chloride. It was found that methylmagnesium iodide effected direct coupling just as it did in the case of benzyl chloride, the second chlorine atom apparently having no influence upon the course of the reaction. The product was α-stilbene dichloride and the equation representing the reaction is

$$2C_6H_5CHCl_2 + 2CH_3MgI \longrightarrow C_6H_5CHClCHClC_6H_5 + CH_3CH_3 + 2MgICl$$

No evidence was obtained of the formation of cumene or of *s*-dimethyldiphenylethane—the products which would have been predicted in analogy with Reychler's results.[7] In view of this fact the reaction between benzal chloride and phenylmagnesium bromide has been reexamined. As in Reychler's work, triphenylmethane was obtained, but no *s*-tetraphenylethane was isolated. Instead, considerable amounts of diphenyl and α-stilbene dichloride were found. These products evidently arise from the following reaction—a typical example of coupling

$$2C_6H_5CHCl_2 + 2C_6H_5MgBr = C_6H_5CHClCHClC_6H_5 + C_6H_5-C_6H_5 + 2MgBrCl$$

Benzotrichloride.—The Grignard reagent used in connection with the study of benzotrichloride was methylmagnesium chloride. Experiments were carried out with dilute solutions (0.2 molal) and with concentrated solutions (2 molal). In the presence of the dilute reagent benzotrichloride underwent coupling to yield tolane tetrachloride as shown by the equation

$$2C_6H_5CCl_3 + 2CH_3MgCl = C_6H_5CCl_2CCl_2C_6H_5 + CH_3CH_3 + 2MgCl_2$$

The reaction between benzotrichloride and the concentrated solution of methylmagnesium chloride gave an entirely different result. No tolane tetrachloride was isolated and instead there was obtained a mixture of the cis and *trans* forms of tolane dichlorides. The total yield of these isomers was about 22% of the theoretical; the proportion of the *trans* form to the cis was approximately 5 to 1.

It seemed probable that the effect of the concentration of the reagent was due not to a difference in the initial coupling reaction but to a difference in the stability of the initial product, tolane tetrachloride, toward the two solutions of the reagent. If this surmise were correct the tetrachloro compound which was stable in the dilute solution of the reagent should be attacked by the concentrated solution. Experiment has verified this hypothesis In the 2 molal solution of methylmagnesium chloride tolane tetrachloride was found to react to give a mixture of the two geometrically isomeric tolane dichlorides.

Experimental

The Reaction of Benzal Chloride with Methylmagnesium Iodide.—To an approximately 2 molal solution of methylmagnesium iodide (prepared from 60 g. of methyl io-

---

[7] Since this work was done experiments have been carried out with benzal chloride and methylmagnesium chloride with results which are somewhat more in accord with those of Reychler. Evidence is now available which indicates that the halogen involved in the Grignard reagent used has a profound influence on the course of the reaction. A report of this work will appear in the near future.

dide and 10 g. of magnesium) was added over a period of two hours with continuous stirring 25 g. of benzal chloride. The reaction was very vigorous and caused the ether solution to boil steadily throughout the time of reaction. The stirring was discontinued and the reaction mixture was then heated externally and the boiling was maintained for two hours longer. Following this, the mixture was decomposed with concentrated hydrochloric acid and ice.

The supernatant ether layer was then separated and washed with a solution of sodium thiosulfate to remove any free iodine, and the ether was then evaporated by drawing a stream of air over the surface of the solution. The semi-solid residue which remained was separated by means of a suction filter into a colorless crystalline solid and a brown viscous oil. The yield of the solid before recrystallization was 4.3 g.

After three recrystallizations from glacial acetic acid the solid was obtained in large, colorless prisms melting at 189–190°. A mixture of this compound with α-dichlorostilbene (melting point 190°)[8] melted at 190°.

The brown, viscous oil did not crystallize and could not be distilled even at 200° at 10 mm. No evidence was obtained of the presence of cumene.

The Reaction of Benzal Chloride with Phenylmagnesium Bromide.—A mixture of 150 cc. of a 1.6 molal solution of phenylmagnesium bromide and 32 g. of benzal chloride was heated under reflux. A crystalline precipitate began to separate almost immediately and at the end of three hours the liquid contained a large amount of suspended solid. Water and hydrochloric acid were added until two clear layers resulted. The ether layer was separated and the ether was removed on the steam-bath. The residue was a brown, lachrymatory oil which when cooled in an ice-bath deposited crystals melting at 190–192° after one recrystallization from glacial acetic acid. A mixture of these crystals with α-stilbene dichloride melted at 190–192°.

The remainder of the oily material was subjected to distillation. Ten grams of unchanged benzal chloride was recovered. A considerable amount of diphenyl was also removed during the distillation. The tarry residue deposited crystals which were filtered and recrystallized from ethyl alcohol. A mixed melting point determination showed this compound to be triphenylmethane (melting point 92°).

The Reaction of Benzotrichloride with Methylmagnesium Chloride in Dilute Solution.—To 500 cc. of an approximately 0.2 molal solution of methylmagnesium chloride in ether was added slowly 19.5 g. of benzotrichloride in 50 cc. of anhydrous ether. There was no evidence of a reaction. The mixture was then heated under reflux with continued stirring for three hours. Decomposition of the reaction mixture with water and hydrochloric acid and subsequent distillation of the ether from the ether layer gave a brown oil. This material was placed in a 10% solution of sodium hydroxide and subjected to steam distillation. About 3 cc. of unchanged benzotrichloride was recovered in the distillate. A crystalline substance was left in the distilling flask. After six recrystallizations from glacial acetic acid this compound melted at 161–162°. One gram of the pure compound was obtained in the form of a fine, white powder. A mixture of this compound with an authentic specimen of tolane tetrachloride (melting point, 161–162°)[9] showed no depression in the melting point.

The Reaction of Benzotrichloride and Methylmagnesium Chloride in Concentrated Solution.—To 200 cc. of an approximately 2 molal solution of methylmagnesium chloride was slowly added[10] 39 g. of benzotrichloride. Although the addition was carried out in a dropwise manner it caused the ether to boil vigorously. After the addition was complete and the reaction had apparently ceased, the mixture was heated under

---

(8) Zincke, Ber., 10, 1002 (1877).

(9) Zinin, Ann., 34, 188 (1840).

(10) This as well as other solutions of methylmagnesium chloride used in these experiments was analyzed by titration with acid.

reflux for an hour. The mixture was decomposed in the manner described for the experiment which was carried out in dilute solution. Also, the steam distillation was conducted in the way described for the preceding experiment. However, the distillate in this case came over very slowly. In addition to a few cc. of oil the distillate contained a waxy solid which was collected over a period of eighteen hours of continued distillation. This material was a mixture of *cis* and *trans* tolane dichlorides. The two isomers were separated by fractional crystallization from alcohol. The *trans* isomer melted at **63"** and the *cis* form at **138–139°**. In several experiments there was obtained an average yield of 22% of that theoretically possible for the two dichlorides. The proportion of *cis* to *trans* was about **1** to **5.**

Anal. Calcd. for $C_{14}H_{10}Cl_2$: C, *28.5*. Found for the *cis* isomer: Cl, *28.5*. Found for the *trans* isomer: Cl, *28.6*.

The Reaction between Methylmagnesium Chloride and **Tolane Tetrachloride.**—Seven-tenths gram of tolane tetrachloride was heated under reflux for four hours with an excess of a 2 molal solution of methylmagnesium chloride. Decomposition of the reaction mixture in the usual manner gave a solid melting from *63* to 80° which proved to be a mixture of the isomeric tolane dichlorides. The yield was *0.2* g.

Summary

Methylmagnesium iodide has been shown to exert a coupling action on benzal chloride. The product, α-stilbene dichloride (C_6H_5CHCl-$CHClC_6H_5$), was likewise obtained when phenylmagnesium bromide was allowed to react with benzal chloride.

A similar coupling was observed with benzotrichloride. When treated with a dilute solution of methylmagnesium chloride it gave tolane tetrachloride ($C_6H_5CCl_2CCl_2C_6H_5$).

In concentrated solutions of methylmagnesium chloride benzotrichloride has been found to yield a mixture of the cis and *trans* forms of **tolane dichloride** ($C_6H_5CCl{=}CClC_6H_5$).

The same mixture of isomers was obtained when tolane tetrachloride was treated with the concentrated solution of methylmagnesium chloride.

The latter result has been interpreted to mean that tolane tetrachloride is produced alike by dilute and by concentrated solutions of the reagent but that in the latter case it is subsequently transformed into the tolane dichlorides.

Reduction Studies of Schiff Bases. III. The Condensations of Certain Secondary Aromatic Amines with Formaldehyde in Acid Solution; Nuclear or N-Methylations by Means of Formaldehyde

BY E. C. WAGNER

Condensations of formaldehyde and other aldehydes with aromatic amines in neutral or alkaline media yield compounds of either the azomethine or the di-imine type. A similarly simple statement cannot be made regarding condensations in acid media. There is scattered evidence, mostly for negatively substituted aldehydes or amines,[1] that in any case the initial step is the additive union of aldehyde and amine, but the actual existence of intermediate addition compounds has been demonstrated in only a few instances, owing to the ease with which the condensation is usually completed by loss of a molecule of water. From acid media the azomethine or di-imine is obtained in some cases,[2] but in general, though a trace of acid may catalyze condensation,[3] presence of mineral acid may promote the reverse hydrolysis, or, especially in the case of formaldehyde, may lead to further changes, with the result that the first isolable product is of secondary origin. Such secondary products may be designated as of (1) the anhydro-aminobenzyl alcohol type, (2) the less important intermediate aminobenzylaniline type[4] and (3) the diaminodiphenylmethane type, the last representing the final stage, since compounds of this type are obtainable not only from the first two,[4,5] but from the azomethines, the di-imines,[6] or without the appearance of intermediate stages, from the amines.[7] Of the three types whose formation is peculiar to condensations in acid media it seems probable that the anhydro-aminobenzyl alcohol type forms first.[6e,4c] The mechanism of its formation is therefore important in a study of condensations of formaldehyde and aromatic amines in acid media, and several investigations have been made of this matter.

A mechanism proposed in a Kalle and Co. patent[8] is represented thus:

$$C_6H_5NH_2HCl + CH_2O \longrightarrow \boxed{H}C_6H_4NHCH_2\boxed{Cl} \xrightarrow{\text{alkali}} \underbrace{CH_2C_6H_4NH}_{} \text{ (polymerized)}$$

Green and Saunders[9] suggested a similar course, the chloromethyl compound yielding momentarily the corresponding hydroxymethyl compound. The actuality of the chloromethyl compounds does not seem to be established, though analogous compounds such as $C_6H_5NHCH_2CN$, etc., are known. The crystalline and definite compounds obtained from methylaniline and ethylaniline, and represented[10] to be chloromethyl compounds, *e. g.*,  $C_6H_5N\begin{smallmatrix}CH_3\\CH_2Cl\end{smallmatrix}$, were shown by Friedländer[11] to be hydrochlorides of the dimeric anhydro-alkylaminobenzyl alcohols, the structure being proved, in the case of the methyl compound, by reduction to *p*-toluidine. Friedlander concluded that formaldehyde first unites at the para-position to yield the carbinol $CH_3NHC_6H_4CH_2OH$, of which two molecules condense with loss of water to yield the dimeric base  $\begin{matrix}CH_3NC_6H_4CH_2\\ | \qquad\quad |\\ H_2CC_6H_4NCH_3\end{matrix}$ whose dihydrochloride appears as product.

This view seems to be inconsistent with the ready formation of the anhydro-aminobenzyl alcohols from azomethines or di-imines, and with the claims of several patents[12] on N-alkylation of aromatic amines by condensation with homologs of formaldehyde, with concurrent reduction, in acid solution, indicating that the primary point of attack is the nitrogen atom. This is also the basis for the mechanism recently proposed for similar condensations by v. Braun and co-workers,[13] involving the assumed primary formation of a N-hydroxyalkyl compound, *e.* g., $C_6H_5NR_2Cl$ $CH(OH)R$, which rearranges to the form $\underbrace{RCHC_6H_4NR_2Cl}_{}$.

The present study deals with the condensations of five alkylanilines (methyl, ethyl, n-propyl, n-butyl and isoamyl) with formaldehyde in dilute hydrochloric or sulfuric acid solution. Two series of experiments were made. In one series the initial product of the condensation was reduced promptly, before secondary changes could much interfere; this procedure led in every case to ***N-methylation,*** yielding tertiary bases. In the other series the amines were condensed with formaldehyde in dilute hydrochloric acid solution, and the solid hydrochlorides of the resulting bases allowed to precipitate. They were isolated, analyzed and submitted to vigorous reduction; in every case the corresponding alkyl-*p*-toluidine was obtained in quantity, the net result being ***nuclear*** *methylation*

of the original amine. These results confirm the opinion that condensation in acid solution involves initially the nitrogen atom, yielding a compound which contains the unit  $C_6H_5N{<}\begin{matrix}R\\ CH_2-\end{matrix}$, and they show the separated hydrochlorides to have the same essential structure as Friedländer's dimeric anhydro-*p*-methylaminobenzyl alcohol, *i. e.*, to contain the unit  $\underset{|}{R}NC_6H_4\underset{|}{C}H_2$, which clearly is obtained from the first by a secondary rearrangement or condensation.

Experimental

General.—The alkylanilines used were Kahlbaum or Eastman products. In the analyses reported below, nitrogen was determined by the Kjeldahl method, using the boric acid modification, with methyl red as indicator, and halogen was determined by the sodium peroxide bomb method, the silver halide being weighed. Melting points were determined in an apparatus of the Anthes type,[14] provided with a mechanical stirrer in the bulb, and with the elongated neck vacuum-jacketed to permit more accurate stem corrections. Boiling points were determined in a small side-arm flask, using short-scale thermometers, the apparatus being that recommended by Mulliken.[15] Boiling points stated are substantially "corrected," though with several of the higher-boiling bases the entire mercury column, while within the flask, was not completely immersed in the vapors. All thermometers used had been calibrated.

N-Methylations of Alkylanilines by Reduction of the Initial Condensation Products with Formaldehyde in Acid Solution.—The procedure for methyl-, ethyl-, propyl- and butylanilines was as follows. The base was dissolved in dilute hydrochloric acid, the solution cooled to 20° or below in an ice-bath, and slightly more than one equivalent of formaldehyde added as a 35% solution. Within five minutes an excess of zinc dust was introduced as rapidly as possible without causing the temperature to exceed 25°, the mixture being vigorously stirred mechanically; more hydrochloric acid was added at intervals to maintain a brisk action. In a typical experiment there were used 15 g. of methylaniline dissolved in 75 cc of water and 20 cc. of concd. hydrochloric acid; the chilled solution was treated with 12 cc. of 35% formaldehyde, 25 g. of zinc dust added and 80 cc. of concd. hydrochloric acid introduced gradually, the temperature being kept around 25°. The liquid was finally colorless and clear except for some undissolved metal.

With isoamylaniline the above procedure yielded an intermediate semi-solid material which trapped the zinc dust. To effect reduction it was necessary to raise the temperature to 70° or above, and to make further additions of zinc and acid. The liquid was finally clear, and the yield of methylisoamylaniline fairly good

The reduction liquid was made alkaline with sodium hydroxide and the dialkylaniline distilled out with steam, extracted in ether, dried with sodium sulfate, the extract filtered and the product obtained by evaporation of the ether; it was purified by careful redistillation and then identified. The tertiary bases made in this way were all of good quality, boiling when crude within ranges of 4–5°, readily narrowed to 1–2° upon redistillation. The best yields varied, for the several amines, from 55 to 88%. There seemed to be no secondary amine finally present, indicating that the condensa-

tions with formaldehyde were rapid and complete. In experiments conducted at higher temperatures there was increased formation of material not volatile with steam, shown in one case to be the *p,p'*-bis-(dialkylamino)-diphenylmethane.

Data for individual experiments are given in Table I.

TABLE I

REDUCTION OF THE INITIAL CONDENSATION PRODUCTS OF SOME ALKYLANILINES WITH FORMALDEHYDE IN ACID SOLUTION

Product, dialkyl-aniline	Best yield crude, %	B. p. redist., °C.	Identification		
			Nitrogen, %		
			Found	Calcd.	Derivative
Dimethyl	79.6	194–195	...	...	*p*-Nitroso compound, m. p. 87°
Methylethyl	87.8	207–209"	10.17	10.37	Picrate,[b] m. p. 129–129.5°
Methyl-n-propyl	75.5	222–224	9.42	9.39	Picrate,[c] m. p. 110.5°. Hydrochloride, see below
Methyl-n-butyl	54.9	241–242.4	...	...	Note[d]
Methylisoamyl	60.5	253–255[e]	7.75	7.91	Picrate,[f] m. p. 89.5"

[a] This value probably better than the b. p. 201° reported by Claus and Howitz [*Ber.*, 17, 1325 (1884)] for methylethylaniline not specially purified.

[b] Komatsu [*Mem. Coll. Sci.* Eng. *Kyoto Imp. Univ.*, *3*, 371 (1912); *Chem. Abstracts*, 7, 1021 (1913)] reported the value 121–122°. A number of Komatsu's constants are incorrect; see Reilly and Hickinbottom, note *d*, and also notes c and f.

[c] Meisenheimer [Ann., 449, 196 (1926)] reported 109°; Komatsu's value was 103–104°.

[d] Boiling point in good agreement with value 242.5" reported for the pure base by Reilly and Hickinbottom [*J. Chem. Soc.*, 117, 109 (1920)].

[e] Previous values, for speamens made by two distinct methods and not specially purified: 257° (Claus and Rautenberg) and 246–248° (Thomas and Jones).

[f] This picrate separated as oil from ordinary or aqueous alcohol, but crystallized from hot absolute alcohol. Komatsu reported m. p. 93–94°.

In the first preparation of dimethylaoiline (Table I), using higher temperature (70–75°) for condensation and reduction, the main product was a solid not volatile with steam. It was crystallized several times from alcohol, and the melting point thus raised from 72 to 82°, with indications that the substance was still impure. It was eventually identified as *p,p'*-bis-(dimethylamino)-diphenylmethane by means of the picrate, which melted at 178°, and by its nitrogen content of 11.05% (calcd., 10.90%). A mixed melting point test of the picrate with a specimen (m. p. 179° corr.), made from the base prepared in the usual way, gave the result 178.5° corr.. and confirmed the identification.

As an additional identifying derivative for methyl-n-propylaniline the hydrochloride was prepared (in dry ether). It melted 120–122° uncorr., and analyzed satisfactorily: nitrogen, 7.47% (calcd., 7.55%), chlorine, 18.84% (calcd. 19.11%) The melting point 106°, reported by Claus and Hirzel[16] for an impure specimen prepared from an impure base (b. p. 212") is therefore incorrect.

In the preparation of methylisoamylaniline there was formed an oily product not volatile with steam. This was distilled in *vacuo*, and after three distillations yielded a main fraction boiling at 275–280" at 10 mm. (282–287° corr.). Analysis for nitrogen gave 7.50, 7.51%, indicating the compound to be probably *p,p'*-bis-(methylisoamylamino)-diphenylmethane (nitrogen, calcd., 7.65%), formed by side reaction during the hot reduction.

Nuclear Methylations of Alkylanilines by Reduction of the Anhydro-*p*-alkylaminobenzyl Alcohol Salts

(a) Preparation of the Anhydro-*p*-alkylaminobenzyl Alcohol Salts.—The conditions approximated those given in references previously cited[10,11] The amine was dissolved in four to five parts of water by addition of slightly more than one equivalent of hydrochloric acid. The solution was chilled in ice, and treated with a small excess of formaldehyde, added as a 35% solution. After about an hour the mixture was allowed to come to room temperature, when there separated after a time the solid amine salt, the liquid generally "setting" The product was filtered off the following day, and the filtrate allowed to stand a further time. from one to several smaller crops of product being thus frequently obtained. The salt was washed with cold water containing hydrochloric acid. The methyl, ethyl and propyl compounds were highly crystalline and white. They were washed finally with alcohol, then with ether and were dried in *vacuo.* The butyl and amyl compounds were yellowish and granular. Attempted washing with alcohol rendered them slimy and unfilterable, so these compounds were dried thoroughly in *vacuo* after washing with water containing hydrochloric acid.

The methyl, ethyl and propyl compounds are soluble in water, and are reprecipitated by addition of hydrochloric acid; the corresponding bases are precipitated by alkali or sodium acetate. The butyl and amyl compounds are not appreciably soluble in water. All five compounds dissolve in dilute sulfuric acid. The n-propyl, n-butyl, and isoamyl compounds appear to be new. Yields and analytical data are given in Table II.

TABLE II

PREPARATION OF SOME ANHYDRO-*p*-ALKYLAMINOBENZYL ALCOHOL SALTS

Product $\mathrm{RNC_6H_4CH_2(HCl)}$ R =	Best yield, %	Nitrogen, % Found	Nitrogen, % Calcd [a]	Chlorine, % Found	Chlorine, % Calcd [a]	No. of specimens anal

Isoamyl	96.4	6.26	6.62	1587	16.76	3

[a] Yields and elementary percentages are calculated from the formula at the head of the first column.

[b] Prepared from methylaniline, formaldehyde and hydrobromic acid; *cf.* Goldschmidt *Chem.-Ztg.*, 26, 967 (1902).

For the ethyl and n-propyl compounds (Table II) the analytical results support the formula $\mathrm{CH_2C_6H_4NR(HCl)}$. For the methyl compound Friedlander's results could not be duplicated.[17] The averaged values for four specimens indicate a molecular weight of 161.6 per atom of chlorine, or 164.2 per atom of nitrogen, *i.* e., 6 and 8.6 units higher than required by formula, and suggest possible presence of a molecule of water for each dimeric molecule of the salt. The butyl and isoamyl compounds likewise yielded results for nitrogen and chlorine lower than those required by formula, but these compounds were probably less pure than the first three. All these compounds, however, were reproducible within rather narrow limits of composition and their identity in essential structure was shown by their reducibility to the corresponding alkyl-p-toluidines.

There was a noticeable delay in the precipitation of these salts. Their separation

---

[17] Friedlander determined only chlorine (by direct precipitation with silver nitrate from aqueous solution acidified with nitric acid) and obtained 22.74%.

was much retarded if the reaction mixture was kept cold. At room temperature precipitation usually began only after an hour or more, and in some cases continued for days. As was shown by the experiments on N-methylation above, the condensation of amine and formaldehyde is rapid; further, the anhydro-*p*-alkylaminobenzyl alcohol hydrochlorides when dissolved in water are promptly precipitated by hydrochloric acid. It is therefore obvious that the delay noticed in every case was not due to a slow amine-aldehyde condensation, nor to a lag in precipitation of the amine-salt, but that it represented the interval during which there occurred the secondary change by which the first-formed unit  $C_6H_5N\underset{\text{<H}_2\text{—}}{}$ assumed the structure —$CH_2C_6H_4NR$—. It seems that a kinetic study of one of these reactions should be feasible.

(b) Reduction of **Anhydro-*p*-alkylaminobenzyl** Alcohol Salts to **Alkyl-*p*-toluidines.**—Reduction was most successful using zinc dust and dilute sulfuric acid at 70–85°. Cold reduction was ineffective, and hydrochloric acid was unsatisfactory because of its salting-out action. For the reductions two procedures were used. (1) The methyl, ethyl and propyl compounds were dissolved or suspended in 10–20 parts of 3 *N* sulfuric acid, the mixture stirred mechanically, some zinc dust added, and the temperature raised quickly to 70–85°. As rapidly as possible the rest of the zinc dust (in all about twice the weight of the compound to be reduced) was added, and the reduction temperature was maintained, with vigorous stirring, until action ceased. (2) The butyl and isoamyl compounds were ground with twice their weight of zinc dust, and the mixture added in small portions, but rapidly, to the hot acid. In either case reduction was rapid, with usually not more than moderate frothing, and the liquid was finally colorless and clear except for some undissolved metal. It was found advisable to reduce not more than 5 or 10 g. of the anhydro-alkylaminobenzyl alcohol salts at a time, the operations outlined then requiring about thirty minutes.

The reduction liquid was made alkaline with sodium hydroxide and was steam-distilled until no more oil passed over. The oil was extracted in ether, the solution dried with sodium sulfate and filtered, and the product obtained as a residue or by distillation after removal of the ether. The best yields of the alkyl-*p*-toluidines ranged from 54 to 80%. The products, as obtained by steam distillation, seemed to be substantially pure, boiling within narrow ranges; on redistillation the widest boiling range observed for any main fraction was 1.5". The alkyl-*p*-toluidines were fully identified; isoamyl-*p*-toluidine has apparently not been prepared hitherto

In all these experiments there remained in the steam distilling flask an oil not volatile with steam. This was examined in several cases and found to consist largely of the corresponding *p,p'*-bis-(alkylamino)-diphenylmethane.

In preliminary experiments it was found that anhydro-*p*-methylaminobenzyl alcohol was not hydrolyzed under the conditions of reduction, no steam volatile product resulting. The anhydromethylaminobenzyl alcohol itself was found to be non-volatile with steam. The steam volatile oils obtained by reduction of the methyl and ethyl compounds were examined for primary ortertiary amines, but no such products could be isolated, nor was there any indication that some of the original alkylaniline contaminated the alkyl-*p*-toluidine.

Data as to yields and identification of products obtained in these reductions are given in Table III.

In the first preparation of methyl-*p*-toluidine (Table III) the oil not volatile with steam was distilled *in vacuo*, and identified as *p,p'*-bis-(methylamino)-diphenylmethane. It yielded a nitrosamine of m. p. 97–97.5' uncorr., identical with a specimen (m. p. 97–98" corr.)[18] made from the base prepared as described by v. Braun,[19] as shown by

			Hydrochloride, m. p. 146°; from dil. HCl	6.52	6.56	16.69	16.60

[a] In every case the material reduced was the corresponding anhydro-*p*-alkylaminobenzyl alcohol salt.

[b] Yields are calculated from the ideal formulas for the salts, and for the methyl, butyl and amyl compounds are therefore slightly lower than if based upon analysis (Table II).

[c] Identification verified by mixed melting point test with the same derivative prepared from Eastman Co. alkyl-p-toluidine.

[d] The picrate obtained from Eastman Co. ethyl-p-toluidine melted at 140°.

[e] Reilly and Hickinbottom [J. Chem. *Soc.*, 113, 977 (1918)] found the boiling point of carefully purified *n*-butyl-*p*-toluidine to be 264–265° (766 mm.).

mixed melting point test. The preparation of ethyl-*p*-toluidine yielded a similar by-product, whose nitrosamine (from alcohol and ether) melted at 81° uncorr., close to the value (83°) found by v. Braun[20] for the nitrosamine of *p,p'*-bis-(ethylamino)-diphenylmethane.

Summary

1. The secondary aromatic amines methyl-, ethyl-, n-propyl-, *n*-butyl- and isoamylanilines, when condensed with formaldehyde in aqueous solution in presence of hydrochloric acid, yield solid products which have, or approximate, the composition $[\mathrm{R\underset{|}{N}C_6H_4\underset{|}{C}H_2(HCl)}]_n$, and are to be considered the hydrochlorides of the anhydro-*p*-alkylaminobenzyl alcohols. This essential structure was shown by reduction of these compounds to the corresponding alkyl-*p*-toluidines.

2. When the same secondary amines are condensed with formaldehyde in acid solution, with prompt reduction of the initial condensation product, they are methylated to yield the corresponding tertiary amines.

3. It is concluded that condensation of these monoalkylanilines with formaldehyde in acid solution involves primarily the nitrogen atom, and

---

[20] V. Braun, Ref. 19, p. 2151.

yields first a compound which contains the unit  $C_6H_5N{<}^{R}_{CH_2-}$, reducible to methylalkylaniline. The formation of the anhydro-*p*-alkylaminobenzyl alcohol salts, which eventually occurs under the same conditions but in absence of reducing agent, is therefore not the result of a special primary condensation, but of a secondary intra- or intermolecular action, probably a coupling of the units shown in (1).

4. By the procedures described either nuclear or N-methylation of alkylanilines can be effected by means of formaldehyde.

Alkyl-Nitroguanidines. Dearrangement and Preparation by Nitration[1]

BY TENNEY L. DAVIS AND ROBERT C. ELDERFIELD

Nitroguanidine dearranges in two modes and may be used for synthesis in two ways by taking advantage of the products which result from its dearrangement in one manner or the other. Thus, with ammonium carbonate it yields guanidine carbonate, and with primary aliphatic amines it gives N-alkyl-N′-nitroguanidines.[2] These alkyl-nitroguanidines, having a hydrogen atom attached to each of the guanidine nitrogens, are capable of dearrangement in two modes, as follows.

$$\text{RNH—C(NH)—NH—NO}_2 \rightleftharpoons \begin{cases} \text{RNH}_2 + \text{HNCN—NO}_2 & \text{(I)} \\ \text{RNCNH (or RNHCN)} + \text{NH}_2\text{—NO}_2 & \text{(II)} \end{cases}$$

The first of these modes corresponds to the method by which the substances have been synthesized from nitroguanidine; the second opens new possibilities of synthesis. We have therefore wished to determine whether the alkyl-nitroguanidines dearrange in the predicted manner and to investigate their usefulness for the easy preparation of monoalkyl- and N,N′-dialkyl-guanidines by reaction with ammonia and with primary amines, respectively.[3]

As no alkyl-nitroguanidines have heretofore been prepared by the nitration of alkyl-guanidines, we have studied that reaction in an effort to gain a further insight into the mechanism of the nitration of amines, and have found that the only alkyl-nitroguanidines which we have been able to
