Bromonitrothiophene

BY V. S. BABASINIAN

Although iodonitrothiophene has been prepared by the earliest workers in the thiophene series,[1] the corresponding bromine compound has scarcely been mentioned in the literature.[2] After describing the nitration of iodothiophene, Kreis[1] (pp. 2073–2075) stated that due to difficulties encountered in the preparation of bromothiophene its nitration was not attempted.

At the present time the preparation of bromothiophene does not present insurmountable difficulties. Although the yield of the costly product is under the most favorable conditions barely over one-half of that required by theory, a number of convenient methods are available for its preparation.[3] The bromothiophene used in this investigation was prepared from thiophene and acetbromamide, the method of Steinkopf and Otto[3b] (p. 69) being employed with certain modifications.

The Nitration of Bromothiophene.—The nitration of negatively substituted thiophene derivatives has been possible in a number of instances with the usually employed nitric–sulfuric acid mixture.[4] Contrary to expectation, the presence of the strongly negative bromine atom in bromothiophene does not inhibit undesirable side reactions when the compound is treated with this nitrating mixture. Töhl and Schultz[5] have shown that concentrated sulfuric acid reacts very readily with bromothiophene at the ordinary temperature, converting it into dibromothiophene, dithienyl derivatives, and two isomeric sulfonic acids. Moreover, observations made in this Laboratory support the conclusion that the nitric acid in the nitrating mixture oxidizes a part of the bromothiophene into open chain decomposition products. With pure nitric acid the reaction proceeds with almost explosive violence, yielding a dark oil in which sulfuric acid may be identified. It may also be added that by the action of fuming nitric acid Angeli and Ciamician[6] have almost completely converted the more stable tetrabromothiophene into dibromomaleic anhydride and sulfuric acid; and the study of other brominated compounds in the thiophene series has led the authors to the conclusion that these halogen derivatives oxidize into products in which the atomic grouping  $-\underset{\underset{\displaystyle O}{\|}}{C}-C{=}C-\underset{\underset{\displaystyle O}{\|}}{C}-$ may in general be recognized[6b] (p. 1347).

It is clear that while the presence of bromine tends to make the thiophene ring more resistant to oxidation, the formation of by-products in

large quantities can hardly be prevented if an attempt is made to nitrate bromothiophene with pure nitric acid or a mixture of nitric and sulfuric acids.

Nitration in Acetic Anhydride and Glacial Acetic Acid.—Side reactions are checked to a great extent when bromothiophene dissolved in acetic anhydride is nitrated with a solution of nitric acid in the same solvent. Under these conditions there is a decided increase in the yield of bromonitrothiophene if a reaction temperature of -5 to 0° is maintained during nitration.

An acetic anhydride solution of bromothiophene may also be nitrated at 5° with a solution of nitric acid in glacial acetic acid. Moreover, nitration takes place at 50° when acetic acid alone is employed as a solvent. However, the yield of bromonitrothiophene is always poor when the anhydride is either diluted with glacial acetic acid or is entirely replaced by it. The use of pure acetic anhydride is therefore suggested for the nitration of bromothiophene.

Experimental

Twenty-five grams of bromothiophene (b. p. 149.5–150.5°) dissolved in 50 cc. of acetic anhydride was introduced into a half-liter round flask, provided with a stirrer and a cooling device. At -5° the liquid was treated, during rapid stirring, with a solution of 25 g. of nitric acid (sp. gr. 1.51) dissolved in 50 cc. of ice-cold acetic anhydride. The acid was added dropwise within a period of forty-five minutes and the temperature was not permitted to rise above 0°. In the earlier phases of the reaction a faint yellow color developed in the mixture. This was followed by the formation of a lemon-yellow precipitate weighing less than a gram. The color of the precipitate and its quantity remained practically unchanged during the nitration. At the end of the forty-five-minute period the stirring was continued for half an hour. The nitrating flask was then surrounded with ice and kept in a refrigerator for twenty-four hours. It was poured, with stirring, into finely crushed ice. The yellow-brown crystalline solid formed in this way was dried in a brown desiccator over sulfuric acid. It was dissolved in a large volume of hot ligroin, decolorized with darco and concentrated to crystallization at the room temperature. The first fraction of crystals consisted of long faint-yellow prisms. From the mother liquor three additional fractions were obtained, the last and smallest fraction being darker in color. The acid filtrate was found to contain a very small quantity of the product upon neutralization with sodium carbonate and distillation with steam. The total yield of the crude product was 21.3 g., or 66% of that required by theory. This was purified by distillation with steam; weight of the pure product 19.5 g., or 61% of the theoretical quantity.

Anal. Calcd. for $C_4H_2S(NO_2)Br$: S, 15.41; Br, 38.42. Found: S, 15.39; Br, 38.37.

Properties.—Bromonitrothiophene is a pale yellow solid, usually crystallizing in fine prisms. It melts at 45–46° and distils at 235–237° (750 mm.) with only slight decomposition. It has a sweetish taste, developing an extremely astringent after-taste. The compound is very volatile with steam. The steam distillate forms snow-white fine prisms. In a very short time the product assumes a yellow color. The same changes in color are noticed upon crystallization from solvents. It is very soluble in ether, methanol, chloroform, carbon tetrachloride, methyl formate, ethyl alcohol and benzene. It dissolves sparingly in petroleum ether. By slow crystallization it separates out from this solvent in beautiful transparent needles.

Bromonitrothiophene is assumed to be the 2,5-derivative of thiophene. Its provisional formula  remains to be established.

Summary

1. Bromothiophene may be nitrated into bromonitrothiophene in pure acetic anhydride. The yield of the product is over 60% when a reaction temperature of -5 to 0° is maintained.

2. The yield is not satisfactory when nitration is carried out in a mixture of acetic anhydride and glacial acetic acid at 5°, or in pure acetic acid at 50°.

3. The properties of bromonitrothiophene are described. The compound is assumed to be the 2,5-derivative of thiophene.

Chemical Studies on Toad Poisons. VII. Bufo arenarum, Bufo regularis and Xenopus laevis[1]

BY H. JENSEN

As further chemical evidence for the correctness of the formulas assigned to arenobufagin ($C_{25}H_{34}O_6$) and arenobufotoxin ($C_{39}H_{60}O_{11}N_4$), which were isolated by Chen, Jensen and Chen from the secretion of Bufo arenarum,[2] several derivatives of arenobufagin have been prepared and analyzed. From the secretion of the South African toad, *Bufo regularis,* which has been studied pharmacologically by Epstein and Gunn,[3] two analogous physiologically active compounds, regularobufagin and regularobufotoxin were isolated by Chen and Chen, in amounts sufficient only for pharmacological study.[4] It seemed desirable therefore to prepare these principles in somewhat larger amounts for chemical identification. On the basis of several analyses of these principles as well as certain of their derivatives, the following empirical formulas have been assigned to regularobufagin, $C_{25}H_{34}O_6$, and to regularobufotoxin, $C_{39}H_{60}O_{11}N_4$.

The isomeric arenobufagin and regularobufagin are both lactones, forming hydroxy acids by the action of alcoholic sodium hydroxide. Simultaneously with the hydrolysis of the lactone ring, one molecule of acetic acid (identified as the silver salt) is liberated, presumably from an acetoxy group. Oxidation with chromic acid gives the corresponding monoketones, indicating the presence of a secondary hydroxy group. On treatment of arenobufagin with acetic anhydride, acetylarenobufagin, $C_{27}H_{36}O_7$, is formed. On treatment of regularobufagin under the same conditions, it was found that one molecule of acetic acid is split off (probably from a tertiary acetoxy group) giving a product $C_{25}H_{32}O_5$. There are certain known examples of an intramolecular loss of water by similar treatment, notably the dehydration of ouabain to anhydroouabainheptaacetate,[5] and of ergostadienetriol to dehydroergosteryl acetate[6] by acetic anhydride. Neither the acetyl derivative of arenobufagin nor the compound $C_{25}H_{32}O_5$ obtained from regularobufagin gives a ketone on oxidation with chromic acid, which indicates that acetylation of the secondary hydroxy groups has taken place. Arenobufagin and regularobufagin are C_{23}-derivatives (after splitting off the acetyl radical which is attached to a tertiary hydroxy group), and can be considered as acetyl derivatives of a doubly unsaturated trihydroxy lactone $C_{23}H_{32}O_5$. It is of interest to note that the analytical data for arenobufagin and regularobufagin closely agree with those reported for bufotalin (the bufagin of *Bufo vulgaris*) by Wieland and co-workers,[7] and to which they assigned the empirical formula $C_{26}H_{36}O_6$. The bufagins probably possess a ring structure identical with that of the aglucones of certain plant glucosides. They likewise are C_{23}-derivatives and recently have been shown to contain a ring structure identical with that of the sterols.[8] Further investigation is required to confirm these possibilities.

Pharmacological investigation has indicated the presence of epinephrine in the secretion of *Bufo arenarum* and *Bufo regularis*[2,3,4,9] and this has been substantiated by the isolation and identification of the base from both secretions. Bufothionine, a sulfur-containing compound which has been obtained by Wieland and co-workers from the secretion of the Japanese toad,[10] and from an alcoholic extract of the dried skin secretion of *Bufo arenarum,*[11] was found to be present in small quantities in the secretion of *Bufo arenarum.* From the secretion of *Bufo regularis,* there has been isolated as a flavianate, a basic constituent which is identical with that obtained by Jensen and Chen from the secretion of *Bufo valliceps.*[12]

From the skin secretion of the South African clawed toad, *Xenopus laevis,* which is biologically more closely related to *Rana* than to *Bufo,*

the following constituents have been isolated: cholesterol, fatty acids, and a basic compound as the flavianate. The base was found to be identical with bufotenidine, which is present in Ch'an Su and in the secretion of certain other toads, and the constitution of which has recently been determined.[11,12] No evidence of the presence of any bufagin-like substance in this secretion has been thus far obtained. The chemical findings are in agreement with the results of the pharmacological study of this secretion by Gunn.[13]

Most of the analyses reported in this paper were carried out by Dr. Ing. A. Schoeller, Berlin-Schmargendorf, Germany.

Experimental

Secretion of Bufo arenarum

The usual methods were employed for the isolation of arenobufagin.[2,14]

Acetylarenobufagin, $C_{27}H_{36}O_7$.—Fifty milligrams of arenobufagin was heated with 1 cc. of acetic anhydride for two hours in a boiling water-bath. The acetyl compound was isolated in the usual manner, and crystallized from alcohol. The fine white needles melted at 162–163°.

Anal. Calcd. for $C_{27}H_{36}O_7$: C, 68.64; H, 7.63. Found: C, 68.51, 68.46; H, 7.85, 7.77.

Arenobufagone, $C_{25}H_{32}O_6$.—Eighty milligrams of arenobufagin was dissolved in 2 cc. of glacial acetic acid, and 0.15 cc. of chromic acid solution (40 g. of water, 8 g. of sulfuric acid, and 5.3 g. of chromium trioxide) was added with thorough stirring. The solution was allowed to stand for fifteen minutes and then diluted with water. After standing overnight the precipitate was filtered off and recrystallized from dilute ethyl alcohol. The ketone consisted of faintly yellow rhombohedric leaflets, melting at 219–220°.

Anal. Calcd. for $C_{25}H_{32}O_6$: C, 70.09; H, 7.41. Found: C, 69.82, 69.84; H, 7.25, 7.22.

Arenobufaginic Acid, $C_{23}H_{34}O_6$.—Three-tenths gram of arenobufagin was refluxed with 25 cc. of 1 *N* alcoholic sodium hydroxide for three hours. After cooling, the solution was diluted with water and allowed to stand overnight. The small amount of flocculent precipitate which might have formed was filtered off, and the filtrate made slightly acid with hydrochloric acid. After standing for several days, the precipitate was filtered off and dried at room temperature. The acid, however, could not be obtained in crystalline form. For further purification it was dissolved in ethyl alcohol and water added until a permanent turbidity resulted. The next day a pale yellow amorphous precipitate had settled out. This was filtered off and the filtrate further diluted with water. The precipitate thus obtained was filtered off, washed with water, and dried at room temperature. The product was an amorphous white powder; the analytical data indicated a considerable degree of purity. The acid began to decompose at 220°, and became progressively darker until it was completely melted at 235°. Water is probably eliminated at the higher temperature.

Anal. Calcd. for $C_{23}H_{34}O_6$: C, 67.98; H, 8.37. Found: C, 67.70, 67.68; H, 7.92, 7.98.

Detection of an Acetyl Group in Arenobufagin.—The filtrate from the bufaginic acid was distilled from an oil-bath. The distillate (acid toward litmus) was shaken with silver oxide and allowed to stand for one day. The silver oxide was then filtered off and the filtrate evaporated *in vacuo* over sulfuric acid. The silver acetate was recrystallized from dilute alcohol.

Anal. Calcd. for CH_3COOAg: Ag, 64.61. Found: Ag, 64.31, 64.29.

Bufothionine, $C_{12}H_{14}O_4N_2S$.—In working up the alcoholic extract of the secretion of *Bufo arenarum*, the cholesterol fraction, which crystallizes out on evaporation, was found to be accompanied by a foreign crystalline substance. After filtration, the cholesterol was removed by extraction with petroleum ether, and the insoluble residue purified from 96% ethyl alcohol. The compound crystallized as prisms, darkening at 240°, and melting at 250° with decomposition. The properties of this substance were identical with those described for bufothionine by Wieland and his co-workers.[10,11]

Anal. Calcd. for $C_{12}H_{14}O_4N_2S$: C, 51.06; H, 5.00; N, 9.93; S, 11.34. Found (average of several analyses): C, 50.93; H, 4.97; N, 8.80; S, 11.10.

Epinephrine, $C_9H_{13}O_3N$.—Epinephrine was isolated from about 10 g. of the dried secretion, which had been extracted twice with alcohol in accordance with the procedure of Jensen and Chen.[15] Approximately 40 mg. of the substance was obtained. It melted at 211° with decomposition and showed no depression of the melting point when mixed with epinephrine.

Anal. Calcd. for $C_9H_{13}O_3N$: C, 59.01; H, 7.18; N, 7.65. Found: C, 58.73; H, 7.42; N, 7.97.

Secretion of Bufo Regularis.—Regularobufagin and regularobufotoxin were obtained from the secretion according to methods previously described.[4,14] The derivatives of regularobufagin were prepared similarly to those of arenobufagin.

Regularobufotoxin, $C_{39}H_{60}O_{11}N_4$.—The principle was repeatedly crystallized from 96% ethyl alcohol and finally from acetone. It crystallized in colorless spheroids, which soften at 190° and melt at 205°. Like the bufotoxins of other species of toads, it gives a positive Sakaguchi reaction indicating the presence of arginine.

Anal. Calcd. for $C_{39}H_{60}O_{11}N_4$: C, 61.69; H, 7.97; N, 7.39. Found: C, 61.82, 61.88; H, 8.28, 8.37; N, 7.58, 7.50.

Regularobufagin, $C_{25}H_{34}O_6$.—The compound was purified from either dilute alcohol, or from a chloroform–ether–petroleum ether solution. It crystallizes in prisms melting at 235–236°. Its color reactions are similar to those of the other bufagins.[16]

(13) Gunn, *Quart. J. Expt. Physiol.*, **20**, 1 (1930).

(14) Jensen and Chen, *J. Biol. Chem.*, **87**, 741 and 755 (1930).

(15) Jensen and Chen, *ibid.*, **82**, 397 (1929).

(16) The melting point and the analytical data for regularobufagin agree closely with the results given by Chen and Chen for this principle. However, they assigned a different empirical formula to it.[4]

Anal. Calcd. for $C_{25}H_{34}O_6$: C, 69.71; H, 7.94. Found: C, 69.88, 69.95; H, 8.18, 8.20.

Acetylation of Regularobufagin, $C_{25}H_{32}O_5$.—White needles crystallized from dilute methyl alcohol, melting at 224–225°.

Anal. Calcd. for $C_{25}H_{32}O_5$: C, 72.81; H, 7.77. Found: C, 72.95, 73.00; H, 8.02, 7.92.

Regularobufagone, $C_{25}H_{32}O_6$.—Recrystallizes from dilute methyl alcohol in rhombohedric leaflets, faintly yellow, melting at 210–211°.

Anal. Calcd. for $C_{25}H_{32}O_6$: C, 70.09; H, 7.41. Found: C, 69.72, 69.80; H, 7.21, 7.51.

Regularobufaginic Acid, $C_{23}H_{34}O_6$.—The acid begins to decompose at 125°, and becomes more and more colored until it is completely melted. Water is probably split off at the higher temperatures. For analysis, the substance was dried *in vacuo* over calcium chloride.

Anal. Calcd. for $C_{23}H_{34}O_6$: C, 67.98; H, 8.37. Found: C, 67.62, 67.58; H, 7.91, 7.90.

Detection of the Acetyl Group in Regularobufagin.—*Anal.* Calcd. for CH_3COOAg: Ag, 64.61. Found: Ag, 64.28, 64.25.

Epinephrine, $C_9H_{13}O_3N$.—The base was isolated from about 10 g. of the dried secretion, after it had been extracted twice with alcohol. Approximately 30 mg. of the compound was obtained, which melted at 210° with decomposition and showed no depression of the melting point when mixed with epinephrine.

Anal. Calcd. for $C_9H_{13}O_3N$: C, 58.01; H, 7.18; N, 7.65. Found: C, 58.71; H, 7.46; N, 7.90.

Regularobufotenine.—This compound was isolated as the flavianate from an aqueous solution of the material, obtained by evaporation of the alcoholic extract of the secretion. The procedure was similar to that employed by Jensen and Chen in the preparation of the flavianates of the different basic constituents present in the secretions of the various species of toads.[12] The flavianate was recrystallized several times from water, and it then melted at 264° with decomposition. It showed no depression of the melting point when mixed with the flavianate of *Bufo valliceps*.

Anal. Calcd. for $C_{11}H_{12}O_2N_2 \cdot C_{10}H_6O_8N_2S$: C, 48.65; H, 3.48; N, 10.81; S, 6.18. Found: C, 48.82, 48.91; H, 3.82, 3.77; N, 11.11, 11.15; S, 6.48.

The flavianate was converted into the picrate by decomposing the salt with barium acetate according to the procedure of Wieland and co-workers.[11] The picrate crystallized from water as red clusters of needles melting at 203–204°. The picrate contains one molecule of water of crystallization, and showed no depression of the melting point when mixed with the picrate of *Bufo valliceps*.

Anal. Calcd. for $C_{11}H_{12}O_2N_2 \cdot C_6H_3O_7N_3 \cdot H_2O$: C, 45.23; H, 3.77; N, 15.52. Found: C, 45.20, 45.32; H, 4.11, 3.92; N, 16.2, 15.92.

Secretion of Xenopus laevis

The procedure was similar to that for the secretions of other species of toads. Fifty grams of the dried skin secretion was extracted twice with 300 cc. of 96% ethyl alcohol. The crystalline matter which separated out on concentration of the alcoholic solution was identified as cholesterol. The filtrate from the cholesterol fraction was evaporated to dryness *in vacuo*, and extracted twice with 100 cc. of water. Most of the material went into solution, the insoluble part consisting mostly of protein material and higher fatty acids. The aqueous solution was shaken out twice with chloroform, flavianic acid was added and the precipitate recrystallized several times from water. The flavianate crystallized in long needles melting at 200°, and showed no depression in melting point when mixed with the flavianate of bufotenidine obtained from Ch'an Su and certain other species of toads.[11,12]

Anal. Calcd. for $C_{13}H_{18}ON_2 \cdot C_{10}H_6O_8N_2S \cdot H_2O$: C, 50.18; H, 4.73; S, 5.82. Found: C, 49.88, 49.94; H, 5.12, 4.99; S, 5.74.

The flavianate was converted into the picrate and also into the hydriodide salt following the method of Wieland and his co-workers.[12] The derivatives showed the same melting points as the corresponding salts of bufotenidine, and mixed melting points showed no depression. The chemical analysis of these salts also supports the view that the base is identical with bufotenidine. The picrate crystallized from ethyl alcohol in red needles melting at 197°.

Anal. Calcd. for $C_{13}H_{18}ON_2 \cdot C_6H_3O_7N_3$: C, 51.01; H, 4.70; N, 15.67. Found: C, 51.21, 51.11; H, 5.10, 4.94; N, 16.01, 15.92.

The hydroiodide salt crystallized from methyl alcohol in prisms, melting at 208–209°.

Anal. Calcd. for $C_{13}H_{18}ON_2 \cdot HI$: C, 45.09; H, 5.50; N, 8.08. Found: C, 45.21, 45.06; H, 5.82, 5.71; N, 7.8.

The author is greatly indebted to Professor J. W. C. Gunn of the University of Cape Town, South Africa, for the supply of the secretions of *Bufo regularis* and *Xenopus laevis*, and to Professor B. A. Houssay, University of Buenos Aires, Argentina, for the supply of the secretion of *Bufo arenarum*.

Summary

Various derivatives of arenobufagin and regularobufagin have been prepared. The analytical data obtained for these compounds substantiate the empirical formula $C_{25}H_{36}O_6$ assigned to these principles. The two compounds are isomers and are C_{23}-derivatives after removing the acetyl radical which is attached to a hydroxy group. Regularobufotoxin has been isolated in pure form from the secretion of *Bufo regularis*. Epinephrine has been isolated and identified as such from the secretions of both *Bufo arenarum* and *Bufo regularis*.

Cholesterol, fatty acids and a basic principle have been obtained from the secretion of the South African clawed toad. The base was obtained as the flavianate, which was found to be

identical with that of bufotenidine. No evidence for the presence of any bufagin-like substance in this secretion has been obtained.

BALTIMORE, MARYLAND RECEIVED JULY 1, 1935

The Action of Perthiocyanic Acid on Amines

BY H. G. UNDERWOOD AND F. B. DAINS

In preparing dithiobiurets for another investigation, the action of perthiocyanic acid on various substances containing the amino group has been investigated. Glutz[1] has shown that perthiocyanic acid unites with aniline to form phenyldithiobiuret and Fromm[2] has pointed out that in the formation of phenyldithiobiuret an excess of aniline tends to increase the amount of thiocarbanilide formed along with the dithiobiuret. The reactions for the formation of dithiobiurets and dithioureas occur as follows

$$RNH_2 + C_2H_2N_2S_3 \longrightarrow RNHCSNHCSNH_2 + S \quad (I)$$
$$4RNH_2 + C_2H_2N_2S_3 \longrightarrow 2(RNH)_2CS + 2NH_3 + S \quad (II)$$

In this work fusions were carried out first at water-bath temperature and if no reaction was evident higher temperatures were employed. The ratio of the amine to perthiocyanic acid was usually 2:1. The results indicate that the nature of the reaction product depends upon the amine employed; thus there were formed (a) normal dithiobiurets, (b) thioureas, (c) fused side rings with certain substituted amines or (d) no reaction occurred.

Experimental

Synthesis of Dithiobiurets (I–VIII).—The new dithiobiurets listed in Table I (I–VIII) were prepared by fusing the amine (2 moles) with perthiocyanic acid (1 mole) on the water-bath. Di-*p*-bromophenylthiourea (IV) was obtained as a by-product in the preparation of *p*-bromophenyldithiobiuret. It is probable that dithioureas are also formed along with the other dithiobiurets but the small amounts formed did not warrant their separation.

TABLE I

Text no.	Compound	Formula	M. p., °C.	Nitrogen, % Calcd.	Nitrogen, % Found

[a] Only one amino group of *m*-diaminobenzene reacted.

Synthesis of Thioureas

α,β-Di-*p*-xenylthiourea (IX).—*p*-Xenylamine (0.1 mole) and perthiocyanic acid (0.05 mole) were heated for one hour at 150°. Only a small quantity of the reaction product was soluble in base. The main product insoluble in alkali was the thiourea which on recrystallization from hot water formed plate-like crystals melting at 228°,[3,4] yield 13 g.

α,β-Dibenzylthiourea (X).—The reaction was spontaneous on mixing benzylamine (0.05 mole) and perthiocyanic acid (0.05 mole), ammonia being evolved. The reaction mixture almost completely liquefied and then resolidified. To ensure complete reaction the product was warmed on the water-bath for one hour. Large plate-like crystals of dibenzylthiourea melting at 147–148°[5,6] were obtained from alcohol.

Reaction of Secondary Butylamine with Perthiocyanic Acid.—Secondary butylamine at room temperature gave an oily product which on distillation yielded secondary butyl thiourea and secondary butyl isothiocyanate.

Fused Ring Compounds

$\overline{C_6H_4NHCSNHCO}$, **4-Keto-2-thiotetrahydroquinazoline (XI).**—This product resulted when anthranilic acid or methyl anthranilate was heated at 180° for two hours. The reaction product was extracted with sodium hy-

droxide solution (10%) and filtered. Neutralization gave the quinazoline which was recrystallized from glacial acetic acid (m. p. 285°).[7]

***o*-Phenylenethiourea (XII).**—*o*-Phenylenediamine and perthiocyanic acid were heated for two hours at 180° with evolution of ammonia. An extraction was made of the fusion mixture with dilute sodium hydroxide solution. The basic product, obtained on acidifying the alkaline filtrate, gave light yellow, almost colorless leaflets from alcohol melting at 298–299°.[8,9]

Fusion of *o*-Aminophenol with Perthiocyanic Acid (XIII).—*o*-Aminophenol was fused with perthiocyanic acid at 180° for one hour with evolution of hydrogen sulfide. Light orange colored leaflets, melting at 205°, were obtained on acidifying the sodium hydroxide extraction solution of the fusion product. The analyses and properties correspond to a benzoxazole thiourea, $\underline{C_6H_4—N=C}O$-$(NHCSNH_2.)$[10]

No Reaction.—Perthiocyanic acid failed to react to form dithiobiurets or dithioureas with *p*-nitroaniline, 2,6-dibromo-3-methylaniline, 2,5-dichloroaniline, glycine, phenylglycine, benzanilide and glutamic acid.

Summary

Perthiocyanic acid reacted with amines to form (a) normal dithiobiurets, (b) thioureas, (c) fused rings or (d) no reaction occurred, depending upon the nature of the amine employed.

Some Dithiazane Rings

BY H. G. UNDERWOOD AND F. B. DAINS

The formation of thiazolidines and of *m*-thiazanes from thioureas and ethylene dibromide or trimethylene dibromide has been fully investigated. With the methylene dihalides and thioureas the only ring compound listed is one described by Foerster[1] as the methylene ether of thiocarbanilide, $\underline{SCNH_2NC_6H_5C}=NC_6H_5$ (from methylene iodide and diphenyl thiourea). Further examples of such ethers are described later in our paper. It has been shown in our work, however, that six-membered rings of the type 1,3,5-dithiazanes, $\underline{\overset{1}{S}\overset{2}{C}HR\overset{3}{S}\overset{4}{C}(NR)\overset{5}{N}H\overset{6}{C}}(NR)$ can be formed by the action of methylene halides on thiourea, monoaryl thiourea or 1,5-diaryldithiobiurets. To date derivatives of the dithiazanes have been confined to the thialdine, $\underline{SCHRSCHRNHC}HR$, the 2,4,6-trimethyldithiazane formed by the action of hydrogen sulfide on aldehyde ammonia, or an N-methyl derivative from methylamine and thioacetic aldehyde.[2,3,4] The structure of these thialdins has not been confirmed by direct experiment.

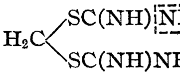
The following work shows that such rings can be synthesized by methods that give some definite proof of their constitution.

Experimental

4,6-Diimino-1,3,5-dithiazane Hydroiodide.—Dixon and Taylor[5] had heated methylene diiodide in alcohol solution with thiourea. The free base (m. p. 198°) from the salt was assumed to be the methylene ether of dithiourea, $CH_2(SC=NHNH_2)_2$, on the basis of a sulfur determination. In repeating this work the methylene iodide (1 mole) was heated in alcohol solution with thiourea (2 moles) for two hours and filtered hot; the salt that separated was purified by crystallization from hot water. Since the free base (m. p. 202–209°) failed to give concordant results on analysis for nitrogen, due seemingly to hydrolysis and loss of ammonia, the stable hydriodide salt was examined.

Anal. Calcd. for $C_3H_5N_3S_2·HI$: N, 15.27. Found: N, 15.08, 15.22, 15.16.

The results correspond to the dithiazane structure and not to the monohydriodide salt of methylene dithiourea (N, 19.16) or the dihydroiodide salt (N, 13.37). The mechanism of this reaction is evidently as follows; a mol of ammonia is lost from the methylene thiourea,



, thus closing the ring which in the form of a salt is stable.

Benzal Chloride and Thiourea, 4,6-Imino-2-phenyl-1,3,5-dithiazane.—Abel[6] heated benzal chloride with thiourea and obtained a compound $C_9H_{10}ClN_3S_2$ for which he gives no structural formula or melting point. In this work thiourea and benzal chloride in excess were heated in an oil-bath, the temperature not being allowed to rise above 150°. Unless care is used the temperature goes to 190° and a resin results. The solid residue was difficultly soluble in hot water and was further purified by solution in alcohol and precipitation with ether. The salt melted at 236° and was formed as follows

$$C_6H_5CHCl_2 + 2CS(NH_2)_2 \longrightarrow C_9H_9N_3S_2·HCl + NH_4Cl$$

Anal. Calcd. for $C_9H_{10}ClN_3S_2$: N, 16.15; S, 24.69; Cl, 13.65. Found: N, 16.23, 15.95; S, 24.45, 24.25; Cl, 13.11, 13.22.

[6] Abel, *Am. Chem. J.*, **13**, 118 (1891).

The free base was not isolated in a pure condition. Excess alkali decomposes the salt yielding benzaldehyde, hydrogen sulfide and ammonia, while neutralization with 0.1 *N* alkali gave mixtures in which part of the nitrogen had been lost. The imino group was easily hydrolyzed to ammonia.

Phenylthiourea Derivative, 4,6-Diphenylimino-1,3,5-dithiazane.—The stability of the dithiazane ring is greatly increased by the presence of phenylimino rather than imino groupings. Phenylthiourea and methylene iodide were refluxed in alcoholic solution for four hours. The difficultly soluble hydroiodide salt when crystallized from hot water melted at 263°.

Anal. Calcd. for $C_{15}H_{14}IN_3S_2$: N, 9.83; S, 14.98. Found: N, 9.90; S, 15.04.

The Hydrobromide Salt.—A mixture of methylene bromide and phenyl thiourea was heated in an oil-bath at 120–130° for one-half hour. The mixture was treated with alcohol and the precipitated salt crystallized from hot water (m. p. 268°). The free base was obtained on neutralizing hot dilute solutions of the bromide or iodide salts with alkali. It crystallized from alcohol in the form of a light yellow powder of m. p. 107°.

Anal. Calcd. for $C_{15}H_{13}N_3S_2$: N, 14.04; S, 21.46; mol. wt., 299. Found: N, 13.98; S, 21.92; mol. wt., 297.

The dithiazane was decomposed by boiling with 15% potassium hydroxide, yielding hydrogen sulfide, phenyl isothiocyanate and aniline.

Thiazanes from Dithiobiurets.—Final proof of the dithiazane structure was shown as follows. 1,5-Diphenyldithiobiuret and methylene bromide were heated at 120°, giving a hydrobromide salt that melted at 263°. The free base was insoluble in alkali, melted at 109° and was shown by analysis and mixed melting point to be identical with the compound from phenylthiourea. Ring closure evidently occurred as follows, , thus confirming the structure.

Benzoyl Derivative (5- or 6-Benzoyl).—The diphenyliminodithiazane was readily benzoylated in pyridine solution, yielding a product of m. p. 120–121°.

Anal. Calcd. for $C_{28}H_{22}N_3OS_2$: N, 8.77. Found: N, 8.71.

4,6-Di-*p*-tolylimino-1,3,5-dithiazane Hydrobromide.—*p*-Tolyl thiourea was heated with methylene dibromide at 130° for one-half hour. From the melt on crystallization from hot water was isolated a yellow salt, m. p. 283°.

Anal. Calcd. for $C_{17}H_{18}BrN_3S_2$: N, 10.29. Found: N, 10.18, 10.98.

The free base melted at 175°.

Anal. Calcd. for $C_{17}H_{17}N_3S_2$: N, 12.83. Found: N, 12.47, 12.58.

4,6-Di-*o*-tolylimino-1,3,5-dithiazane Hydrobromide.—The yellow hydrobromide salt melted at 236°.

Anal. Calcd. for $C_{17}H_{18}BrN_3S_2$: N, 10.29. Found: N, 10.29, 10.04.

The free base melted at 174°.

Anal. Calcd. for $C_{17}H_{17}N_3S_2$: N, 12.83. Found: N, 12.31, 12.35.

Ethylidene Dibromide and Monophenyl Thiourea: 2-Methyl-4,6-diphenylimino-1,3,5-dithiazane Hydrobromide.—Molar quantities of ethylidene dibromide and monophenyl thiourea were heated at 160° for four hours. From the reaction product was isolated and purified by crystallization from hot water the hydrobromide salt of 2-methyl-4,6-diphenylimino-1,3,5-dithiazane melting at 248°.

Anal. Calcd. for $C_{16}H_{16}BrN_3S_2$: N, 10.66. Found: N, 10.60, 10.52.

The free base melted at 181°.

Anal. Calcd. for $C_{16}H_{15}N_3S_2$: N, 13.48. Found: N, 13.37, 13.30.

2-Phenyl-4,6-phenylimino-1,3,5-dithiazane.—Monophenyl thiourea (35 g.) and benzal chloride (30 g.) were heated on a paraffin bath. The reaction began at 100° and the flask was removed from the bath, the temperature rising to 150°. The solid residue was crystallized from water–alcohol and melted at 232°.

Anal. Calcd. for $C_{21}H_{18}ClN_3S_2$: N, 10.21; S, 15.57; Cl, 8.61. Found: N, 10.22; S, 15.60; Cl, 8.52.

The free base melted at 145°.

Anal. Calcd. for $C_{21}H_{17}N_3S_2$: N, 11.19; mol. wt., 375. Found: N, 10.69; mol. wt., 368.

Further evidence as to the dithiazane structure was shown by its synthesis from 1,5-diphenyldithiobiuret which was heated with benzal chloride at 150° until evolution of hydrogen chloride ceased. A hydrochloride was obtained melting at 232°, which by mixed melting point and analysis proved to be identical with the product from benzal chloride and monophenyl thiourea.

Anal. Calcd. for $C_{21}H_{18}ClN_3S_2$: N, 10.21. Found: N, 9.91, 10.02.

2-Phenyl-4,6-di-*p*-tolylimino-1,3,5-dithiazane Hydrochloride.—Benzal chloride and *p*-tolyl thiourea gave the corresponding 2-phenyl-4,6-di-*p*-tolylimino-1,3,5-dithiazane hydrochloride which was obtained as a light yellow powder melting at 222°.

Anal. Calcd. for $C_{23}H_{22}ClN_3S_2$: N, 9.55. Found: N, 9.46.

The Action of Methylene Iodide on Disubstituted Thioureas.—This was tried in order to see whether a dithiazane ring could be made with the loss of a RNH_2. The results show that not to be the case, but instead evidence was obtained of the formation of the methylene ethers of the thioureas. Foerster[1] heated methylene iodide with thiocarbanilide in alcoholic solution and obtained a base (m. p. 68°). It was analyzed as the platinum salt which gave figures corresponding to the methylene ether of diphenylthiourea. On repeating his work a gummy base was obtained which gave an impure platinum salt and a product melting at 68–69°, which proved to be phenyl thiourethan.

Methylene Ether of Di-*p*-tolyl Thiourea.—Molar quantities of di-*p*-tolyl thiourea and methylene iodide were heated in acetone solution for a period of four hours. The reaction product was found to contain unchanged thiourea, tolyl mustard oil, toluidine and a basic compound that melted at 151° when crystallized from alcohol.

Anal. Calcd. for $C_{16}H_{16}N_2S$: N, 10.41; mol. wt., 268. Found: N, 10.77, 10.83; mol. wt., 271.

These results point to a methylene ether and not a dithiazane derivative or a methylene dithio ether, $CH_2(SC{=}NC_6H_5NHC_6H_5)_2$, which has nearly the same percentage composition but a molar weight of 468.

1,5 - Diphenyl - 2 - thiolmethyl - 4 - thiolmethylenedipseudodithiobiuret Hydroiodide and Base.—A corresponding methylene ether was obtained from 1,5-diphenyl-2-thiolmethylpseudodithiobiuret ($C_6H_5N{=}C(SCH_3)NHCSNHC_6H_5$) when heated with methylene iodide alone at 120° or in alcoholic solution. This was obtained as the difficultly soluble hydroiodide salt (m. p. 275°) together with phenyl mustard oil.

Anal. Calcd. for $C_{16}H_{16}IN_3S_2$: N, 9.52. Found: N, 9.53, 9.58.

The light yellow base melted at 125°.

Anal. Calcd. for $C_{16}H_{15}N_3S_2$: N, 13.48. Found: N, 13.44.

Benzal chloride failed to give ethers of this type. Heated with thiocarbanilide or di-*p*-tolyl thiourea at 160° it gave only the triphenyl or tritolyl guanidine.

2 - Phenylimino - 3 - thioformanil - tetrahydrothiazole.—While 1,5-diphenyldithiobiuret with methylene iodide gave a dithiazane ring, with ethylene dibromide, a thiazole is formed. An alcoholic solution of the thiobiuret and ethylene dibromide with an excess of ammonium hydroxide was allowed to stand for several days, when light yellow crystals of the thiazole separated (m. p. 165°).

Anal. Calcd. for $C_{16}H_{15}N_3S_2$: N, 13.41. Found: N, 13.39.

Hydrolysis with alcoholic potassium hydroxide gave phenyl mustard oil and 2-phenylaminothiazolidine.

Thiazolidone Synthesis.—The action of chloroethyl acetate on 1,5-diphenyl-2-thiolmethylpseudodithiobiuret was studied in order to note the influence of the two groups upon the constitution of the possible thiazolidone. Heating the two components in alcoholic solution gave a thiazolidone $\underline{SC(NCSCH_3NC_6H_5)NC_6H_5COCH_2}$, melting at 127° with the structure phenyl-4-thiazolidone-thiolmethylpseudothiourea. This was shown by the fact that the 5-benzal derivative melting at 157° (N, calcd. 9.79; found, 9.86) on hydrolysis yielded the known 5-benzal-3-phenyl thiazoledione identified by melting point and analysis.

Anal. Calcd. for $C_{17}H_{15}N_3OS_2$: N, 12.26. Found: N, 12.17.

α,α-Phenylmethyl-β-thiazolidone Thiourea.—This compound was readily formed by heating the phenylmethyldithiobiuret with chloroethyl acetate or chloroacetyl chloride with one mol of pyridine in acetone solution for four hours (m. p. 222°).

Anal. Calcd. for $C_{11}H_{11}N_3OS_2$: N, 15.85. Found: N, 15.92, 15.95.

Hydrolysis of the 5-benzal derivative (m. p. 274°) with 50% sulfuric acid gave 5-benzal-2,4-thiazoledione, thus proving that the thiourea grouping was at position 2.

Anal. Calcd. for $C_{18}H_{16}N_3OS_2$: N, 11.86. Found: N, 11.37, 11.38.

Summary

Methylene dihalides reacted with thiourea, monoaryl thioureas and 1,5-diaryldithiobiurets to form dithiazanes while α,β-diaryl thioureas formed methylene ethers or products of hydrolysis.

Densities of Adsorbed Gases. I. Carbon Dioxide on Charcoal[1]

BY THOS. DE VRIES

It is possible, by the use of Polanyi's theory,[2] to calculate from an adsorption isotherm the isotherms for other temperatures. It is also possible to calculate the average density of the adsorbed layer. An experimental method was developed to determine the density of adsorbed carbon dioxide, and the agreement between observed and calculated densities lends confirmation to the reasonableness of the underlying assumptions. The density of water on silica gel at 25° has been determined by Ewing and Spurway.[3] No other densities of adsorbed vapors have been recorded in the literature. In this paper an apparatus and technique are described which gave results with a precision of 3 to 5% for the density of carbon dioxide adsorbed on activated coconut charcoal. In brief the method consisted in using helium as the displaced fluid to determine, before and after carbon dioxide adsorption, the unoccupied volume in a tube containing charcoal. A temperature of 30.00° was chosen which is just under the critical temperature of carbon dioxide.

Experimental

Carbon dioxide was prepared according to the method of Lowe and Guthmann,[4] and thoroughly dried by passing over anhydrous magnesium perchlorate. Helium was

---

purified by passing over hot copper oxide and over activated charcoal cooled with liquid air. It was stored in glass flasks sealed to the apparatus. When used the helium was again passed over charcoal cooled with liquid air. No rubber connections were used, and all possible precautions were taken to prevent contamination of the gases with stopcock grease, moisture or traces of air. For the experiments, ash-free coconut charcoal was used.

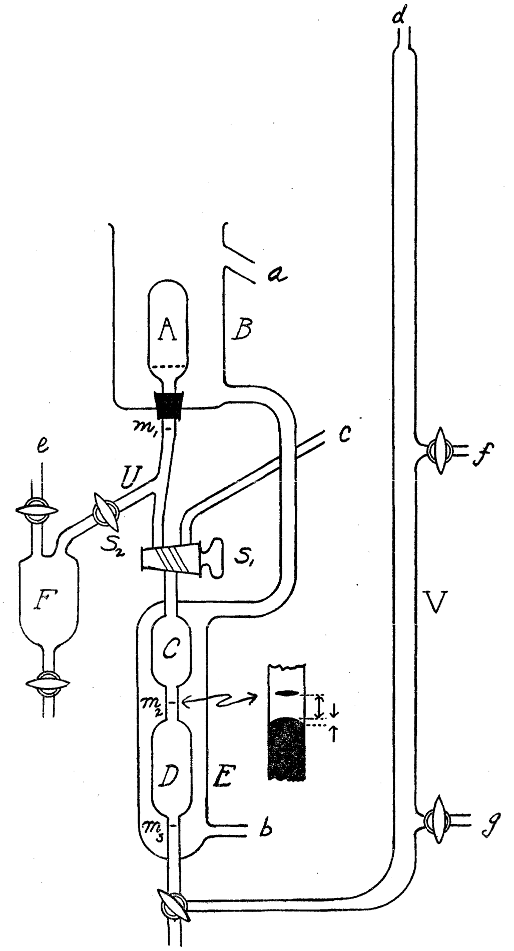

Fig. 1.—a, Return to thermostat; b, from thermostat via pump; c, to carbon dioxide and helium supply, and vacuum; d, e, to vacuum; f, g, to leveling bulbs; other symbols described in the text.

A diagrammatic sketch of the apparatus is given in Fig. 1. Water from a thermostat was circulated by pump around bulbs C and D (55.158 and 78.024 ml., respectively) in which the gases were measured and into the can surrounding the charcoal bulb, A. The temperature was read at this point and was kept constant to within 0.01°. The charcoal was supported by an iron washer covered with iron gauze. This made it possible to fill the tube with charcoal and move the washer in position with a magnet before inverting the tube and sealing it on to the apparatus.

The successive steps for a typical determination were as follows. The charcoal was degassed at 375° by slipping an electric heater over the charcoal tube. The time varied from twelve to forty-eight hours. A high-capacity double-stage mercury vapor pump of special design was used, backed by a Cenco Hyvac. There was a slow change in the volume of the bulb when a higher temperature was used for degassing. Bore 1 of stopcock S_1 was filled with mercury before the volume of carbon dioxide was measured in bulb C. The pressure on the gas was measured with a Gaertner cathetometer reading to 0.005 cm. By the use of an auxiliary lens the cathetometer could be brought close to the menisci and thus a more precise setting was obtainable. A thermometer, reading to 0.1°, was used to determine the temperature of the mercury columns and the appropriate corrections were made to 30° as standard. Corrections were also made for capillary depression in the tubes m_1, m_2, m_3 and V. These corrections were taken from "International Critical Tables,"[5] for mercury menisci of different heights and were checked experimentally to eliminate any error arising from the refraction of light as it passed through the outer glass wall and the intervening water. The optimum size for tubes m and V was 6 and 12 mm., respectively. A third important factor which added materially to the precision of the results was to bring the mercury meniscus up to but not opposite the reference mark (see Fig. 1), and then from the cathetometer readings and with the aid of an alignment chart, the volume was determined of the space between the mark and the curved mercury surface. The variability in the curvature of the mercury surface introduced errors of sufficient magnitude to make this correction necessary when volumes of gas must be measured with precision. The pressure on the gas was given directly from the difference in height of the two mercury menisci since the tube F was evacuated.

When the carbon dioxide was admitted into the charcoal bulb, mercury floating over into tube U would completely prevent leakage of air into the apparatus or loss of helium when it was used. When the pressure of the carbon dioxide in equilibrium with the charcoal became steady or changed very slowly at a constant rate, a known amount of helium was admitted to the charcoal bulb. The mercury between the mark m_1 and stopcock S_2 was first drawn down into the reservoir F, and the helium was admitted slowly so that the mercury might not be carried up into the bulb above the mark m_1. After about an hour, when the helium had diffused through the carbon dioxide, the pressure was constant and was measured. The same kind of corrections were applied as when the gases were measured in bulb C. After subtracting the partial pressure of the carbon dioxide from the total pressure, the volume of space occupied by the helium was easily calculated by using the gas law (V in Table II). Several determinations at different times with the carbon dioxide omitted gave values for the volume when no carbon dioxide was adsorbed. These values are recorded in Table I as V_0. The difference was the volume of the adsorbed layer into which the helium could not penetrate. The calculations with Polanyi's theory showed that the helium did not penetrate very far into the adsorbed layer. The weight of adsorbed gas was calculated from the amount measured in the bulb C, allowing for the amount left unadsorbed in the charcoal

Lowry and Olmstead's[6] method of calculation was followed in applying Polanyi's condensed film theory to the experimental data. Their notation is also used in this paper. These authors showed that the work of compressing carbon dioxide at 303.1°K. from a molal volume,[7] $V = 1$ to a molal volume V_{δ_i}, is given by

$$\epsilon_i = 4.5767T\left[\frac{0.4343(b_g)_T}{V\delta_i - (b_0)_T} - \frac{237.213\ a_T}{TV\delta_i} - \log V\delta_i - \frac{(b_g)_T}{(b_0)_T}\log\left(1 - \frac{(b_0)T}{V\delta_i}\right)\right]$$

If the original pressure is such that V is not equal to 1, then a $\Delta\epsilon$ is calculated by $\Delta\epsilon = 4.5767\ T \log V_{\delta_x}$. The values given by this equation (see Table III) are needed to calculate the curve. The values given in Table IV and calculated from the experimental results are also needed. The resulting ϵ–φ curve (see Table V and Fig. 2) was used to calculate the milligrams of carbon dioxide adsorbed per gram of charcoal (see last column in Table IV). The calculations for one of the experimental values are given in Table VI, which shows how the average density can vary with the adsorption volume, φ.

TABLE III

VALUES OF ϵ_i FOR DIFFERENT DENSITIES δ_i

$V_{\delta_i} = 84.337/P$(cm. of Hg): $\epsilon_s = \Delta\epsilon + 2321$.

TABLE V

ADSORPTION POTENTIAL, ϵ, AND VOLUME OF ADSORPTION, φ

ϵ, cal.	7250	6000	5000	4606	3982	3702
φ, cu. mm.	0	0.50	1.80	2.84	7.50	10.90
ϵ, cal.	3153	2500	2000	1500	1000	500
φ, cu. mm.	22.90	50.0	85.0	120	139	149

It is also possible to calculate how far the helium penetrated into the layer of adsorbed carbon dioxide by using the ϵ–φ curve. The experiments gave the volume of the adsorbed layer (see Table II). The boundary of this layer is characterized by an "adsorption potential" which corresponds to the work required to compress the gas from the density at the equilibrium pressure to the density at the boundary of the adsorbed layer. Hence when $\Delta\epsilon$ is subtracted from ϵ, values of ϵ_i are obtained from which densities of carbon dioxide can be determined with the use of the data in Table III. The results of the calculation are given in

---

[6] Lowry and Olmstead, *J. Phys. Chem.*, **31,** 1601 (1927).

[7] In Lowry and Olmstead's notation, $V = 1$ represents a volume of 22,416 ml. and $V\delta_i$ a molal volume corresponding to the density δ_i g. per ml.

Table VII. It is evident that the helium did not penetrate appreciably into the layer of adsorbed carbon dioxide when the density was larger than 0.09 g. per ml.

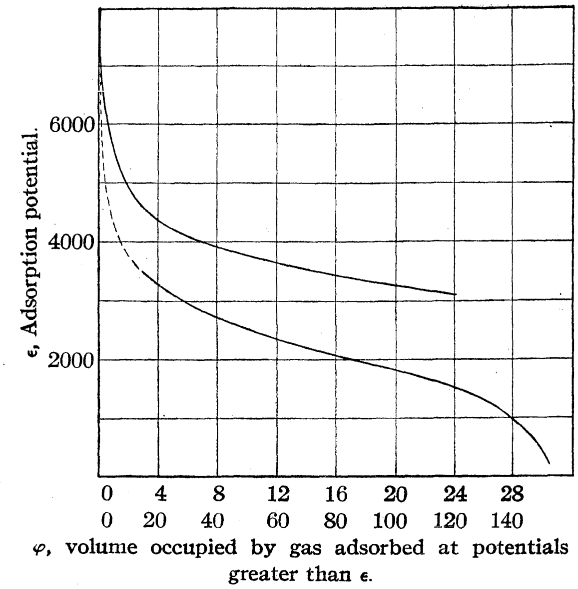

Fig. 2.—Upper curve is a five-fold extension of the dotted section. See Table V for values of the complete lower graph.

TABLE VI

CALCULATION OF AMOUNT OF CARBON DIOXIDE ADSORBED

				Average	0.091

When the application of Polanyi's theory to the experimental data is considered from the viewpoint of how much of the adsorption volume, φ, must be included to obtain an average density equal to that observed experimentally, then it is evident, as can be seen from one of the calculations given in Table VI, that the experimental values agree well with the densities which can be calculated with the aid of Polanyi's theory, and that less than 10% of the carbon dioxide, which can still be considered as under the attractive influence of the charcoal, mixes with the helium.

The author acknowledges with gratitude a Grant-in-Aid from the National Research Council for this research project which is being continued.

Summary

1. By using helium as an inert gas the density of adsorbed carbon dioxide on charcoal was determined at 30°.

2. By using Lowry and Olmstead's modification of Polanyi's theory, an ϵ–φ curve was calculated. From the experimental results and this curve, it was shown that helium did not penetrate the carbon dioxide layer when its density was more than 0.09 g. per ml.

3. Polanyi's theory gives densities for the adsorbed layer equal to those observed if the assumption is made that the helium penetrates the outer portion of the adsorbed layer.

The Photo-oxidation of Hydrogen and Deuterium Iodides[1]

BY G. A. COOK AND J. R. BATES

Many investigations[2] have been made of the reaction of hydrogen atoms with oxygen molecules. One such study was that of Bates and Lavin,[3] who obtained the hydrogen atoms for the reaction by the photo-dissociation of hydrogen iodide. It was pointed out by Bodenstein and Schenk[4] that the results of Bates and Lavin might be equally well explained on the assumption that the reaction $H+O_2$ occurred as either a two-body or a three-body process. The present work represents an attempt to differentiate between these two alternatives by studying the same reaction with improved experimental accuracy and under much more widely varied conditions. The problem is of theoretical importance in connection with the interpretation of a number of different reactions[2] such as the explosion limits of hydrogen and oxygen,[5] the effect of oxygen on the photochemical hydrogen–chlorine reaction,[4] etc. The general theoretical implications of the problem have been discussed by Kassel.[6]

A similar study was also made on the reaction of deuterium iodide with oxygen. A comparison of the results for hydrogen and deuterium iodides is of interest in connection with the effect of mass and zero point energy on chemical reactions.[7]

Method and Apparatus

The method used was similar to that of Bates and Lavin.[3] A mixture of hydrogen (or deuterium) iodide with oxygen (and also in a few cases with nitrogen) in a quartz reaction vessel of 277.1 cc. effective volume, was illuminated, the pressure change was noted and the products analyzed for hydrogen and iodine. The reaction vessel was kept at 0° except in two 20° runs. The source of light was a low-voltage mercury–argon quartz lamp designed by Duffendack and Owens.[8] It used a nickel cathode activated by a coating of barium and strontium oxides.

The hydrogen iodide was synthesized by passing a mixture of hydrogen and iodine vapor through a tube containing two glowing platinum spirals, the first spiral being kept hotter than the second. Deuterium iodide was made in a similar way, using deuterium obtained by electrolysis of 99.9% D_2O.

No stopcocks were employed in connection with the reaction vessel or the storage tube for hydrogen iodide; instead, two greaseless valves were employed. These made use of a glass bellows similar to that of Bodenstein,[9] but substituting for his glass-in-glass seat a fused silver chloride seat as described by Ramsperger.[10]

The hydrogen was analyzed by a method suggested by Professor H. N. Alyea of Princeton. It made use of a sensitive slanting mercury manometer, calibrated for the purpose, to measure the decrease in both pressure and volume resulting from the combustion of hydrogen in a sample of known volume.

The rest of the apparatus was essentially the same as that described by Bates and Lavin.[3]

Experimental Results

Results of the runs are incorporated in the tables.

[a] Assuming that $k_4/k_3 = 0$.

In general these data confirm the experimental results of Bates and Lavin, and in addition it is immediately evident that the following qualitative statements are true: (1) in any two runs, if all conditions are the same except that hydrogen iodide is used in one and deuterium iodide in the other, more of the deuterium is always oxidized than of the hydrogen; and (2) in any two runs, if all conditions are the same except that nitrogen is added in one case and not in the other, a great deal more of the hydrogen is oxidized when the nitrogen is added than when it is absent. In other words, the presence of an inert gas greatly speeds up the reaction of hydrogen atoms with oxygen molecules. This is true whether hydrogen or deuterium is used.

Products of the Oxidation

No experimental test was made for hydrogen peroxide in the presence of the hydrogen iodide; instead, the pressure of hydrogen that should have been formed was calculated from the observed decrease in pressure[3] (page 86) under two assumptions: (1) that only hydrogen peroxide formed; (2) that only water formed. These calculated results were then compared with the actual pressure of hydrogen formed as determined by the gas analysis. Results showed that assumption (1) gave about twice as good results as (2), the two hydrogen pressures always lying between the values calculated on each of the two assumptions. Thus apparently about one-third of the hydrogen peroxide formed[11] decomposed to water during the run. Most of the runs lasted ten minutes; a few of them fifteen minutes.

Theoretical Discussion

The two mechanisms to be compared were as follows.

MECHANISM I

(A)	$HI + E \longrightarrow H + I$	A
(1)	$H + HI \longrightarrow H_2 + I$	k_1
(2)	$H + O_2 \longrightarrow HO_2$	k_2
(3)	$HO_2 + HI \longrightarrow H_2O_2 + I$	k_3
(4)	$HO_2 \longrightarrow H + O_2$	k_4

leading to the integrated expression

$$[H_2] = -\frac{1}{2}\left[HI_F - HI_0 + ([O_2]k_2/k_1) \ln \frac{HI_0 + [O_2]k_2/k_1 + k_4/k_3}{HI_F + [O_2]k_2/k_1 + k_4/k_3}\right] \qquad (I)$$

in which $[H_2]$ = the pressure of hydrogen formed during the reaction; HI_0 = the initial pressure of hydrogen iodide; HI_F = the final pressure of hydrogen iodide; $[O_2]$ = the average pressure of oxygen; all pressures being measured in millimeters.

MECHANISM II

(A)	$HI + E \longrightarrow H + I$	A
(1)	$H + HI \longrightarrow H_2 + I$	k_1
(5)	$H + O_2 + M \longrightarrow HO_2 + M'$	k_5
(3)	$HO_2 + HI \longrightarrow H_2O_2 + I$	k_3

leading to the integrated expression

$$[H_2] = -\frac{1}{2}\left[HI_F - HI_0 + ([O_2][M]\,k_5/k_1) \ln \frac{HI_0 + [O_2]\,[M]\,k_5/k_1}{HI_F + [O_2]\,[M]\,k_5/k_1}\right] \qquad (II)$$

in which $[M]$ = the average total pressure.

From equation (I) values of k_2/k_1 may be calculated for any assumed value of k_4/k_3. From equation II values of k_5/k_1 may be calculated directly. Results of these calculations are given in Tables I, II and III.

---

[11] Bates and Salley, THIS JOURNAL, **55**, 110 (1933).

It is seen that for pairs of runs in which the only difference is the presence or absence of nitrogen (Table III) the value of k_5/k_1 remains fairly constant, whereas the value of k_2/k_1 (assuming $k_4 = 0$) is not constant. k_2/k_1 values were calculated also for values of k_4/k_3 up to 10^6, but the values of k_2/k_1 did not stay constant under any conditions. The evidence seems to show, therefore, that Mechanism II is much to be preferred to Mechanism I, and hence that the action of hydrogen atoms on oxygen molecules is a trimolecular process.

The values of k_5/k_1 show a slight variation with the O_2:HI ratio employed. This particular variation can be eliminated by using a more complicated mechanism, replacing the step $H + O_2 + M$ with the steps:

$$\begin{array}{lll} (6) & H + O_2 + O_2 \longrightarrow HO_2 + O_2' & k_6 \\ (7) & H + O_2 + N_2 \longrightarrow HO_2 + N_2' & k_7 \\ (8) & H + O_2 + HI \longrightarrow H_2O_2 + I & k_8 \end{array}$$

For this the integrated expression is found to be

$$\frac{1}{K} = \frac{1}{(HI_0 - HI_F - 2[H_2])\,(1 + [O_2]k_8/k_1)} \ln \frac{HI_0 + K}{HI_F + K}$$

$$\text{Where } K = \frac{[O_2]\,k_6/k_1 + [O_2]\,[N_2]\,k_7/k_1}{1 + [O_2]\,k_8/k_1}$$

To simplify the calculations, it was assumed that $k_6 = k_7$. Various values of k_6/k_1 were assumed and the corresponding values of k_8/k_1 calculated. For both hydrogen and deuterium it was found that $k_8/k_1 \cong 2k_6/k_1$; hence $k_8 \cong 2k_6$.

The mean values found experimentally were as follows, the errors indicated being mean deviations.

(1) From Table I, hydrogen iodide plus oxygen
$k_5/k_1 = (1.24 \pm 0.17) \times 10^{-4}\,\text{mm.}^{-1} = (2.11 \pm 0.29) \times 10^3\,\text{cc. mol.}^{-1}$

(2) From Table II, deuterium iodide plus oxygen,
$k_5/k_1 = (2.34 \pm 0.44) \times 10^{-4}\,\text{mm.}^{-1} = (3.98 \pm 0.75) \times 10^3\,\text{cc. mol.}^{-1}$

The rate k_5 of the reaction $H + O_2 + M$ varies somewhat with the nature of the third body.[12] In the present work, the third body was chiefly either oxygen or hydrogen iodide.

Moreover, the value to be assigned to k_5 depends on the value assumed for k_1, since experiment gave only the ratio of k_5 to k_1. It is known from the work of Bonhoeffer and Farkas[13] that $(k_{H + I_2})/(k_{H + HI}) \cong 100$. The reaction $H + I_2$ should go on every collision since the reaction has zero activation energy and there is no reason to ascribe to it a steric factor which would materially differ from unity.[14] However, the value 100 is only approximate and can be trusted only to an order of magnitude.

The constant $k_{H + HI}$ may be calculated, using the usual equation given for the number of collisions per cubic centimeter per second between the molecules of two different gases. The result is $k_{H + I_2} = 2.699 \times 10^{14}$ cc.^{2} moles^{-1} sec.$^{-1}$. Then $k_{H + HI} = 2.699 \times 10^{12}$, and $k_{H + O_2 + M} = 5.7 \times 10^{15}$. That k_5 is probably smaller than this value may be seen from the following considerations. It was shown above that $k_{H + O_2 + HI} \cong 2k_{H + O_2 + O_2}$. If the reaction $H + O_2 + HI$ goes on every collision, then its specific reaction rate as calculated by the method outlined by Bates[2a] (p. 460) using $\tilde{\nu} = 3804$ cm.$^{-1}$, is $k_8 = 2.4 \times 10^{14}$ cc.^{3} moles^{-2} sec.$^{-1}$. This would give $k_6 \cong k_8/2 \cong 1.2 \times 10^{14}$. There are two other reasons for choosing this value rather than the maximum value of 5.7×10^{15} calculated above for $H + O_2 + M$.

(1) Calculation shows that if the reaction $H + O_2 + O$ goes on every trimolecular collision, k_6 would be only 3.0×10^{14}. This makes the high value ot 5.7×10^{15} seem improbable.

(2) In a study of the rate of recombination of hydrogen atoms and of the reaction $H + O_2$, Farkas and Sachsse[2b] found that $k_{H + H + H_2} \cong 3.4 \times 10^{16}$ cc.^{3} moles^{-2} sec.$^{-1}$, and that $k_{H + H + H_2}/k_{H + O_2 + H_2} \cong 500$. If their value for $k_{H + H + H_2}$ is used together with the value of 1.2×10^{14} for $k_{H + O_2 + O_2}$, it is seen that $k_{H + H + H_2}/k_{H + O_2 + O_2} = 283$, which is in remarkably good agreement with their ratio of 500 mentioned above. If Steiner's best value[15] for $k_{H + H + H_2} = 1.1 \times 10^{16}$ is used, $1.1 \times 10^{16}/1.2 \times 10^{14} = 91$, which is still in fair agreement with the ratio found by Farkas and Sachsse. But if Smallwood's value[16] of $k_{H + H + H_2} = 3.4 \times 10^{14}$ is used, the ratio is 3, in disagreement by a factor of over 150 with the findings of Farkas and Sachsse. Extremely poor agreement is found if the maximum value of 5.7×10^{15} for $k_{H + O_2 + M}$ is used, the ratios with the same three values of $k_{H + H + H_2}$ mentioned above being 6, 2 and 0.06, respectively.

If the value of $k_{H + O_2 + O_2}$ is taken, therefore, as 1.2×10^{14}, and compared with the calculated value for the same reaction if it went on every collision, namely, 3.0×10^{14}, it is seen that the reaction goes on at least one out of every two or

three trimolecular collisions, a result that is not at all in bad agreement with the conclusion of Bodenstein and Schenk[4] that $H + O_2 + M$ goes on every trimolecular collision. Their third body was in part oxygen, but also largely hydrogen and chlorine.

The results of the present study together with that of Farkas and Sachsse[2b] may be taken as evidence that Steiner's value[15] for the rate of recombination of hydrogen atoms is much to be preferred to Smallwood's latest value.[16] In this connection it is interesting to note that Senftleben in his most recent work[12] completely reverses his previous stand[17] with regard to the relative efficiencies of hydrogen atoms and molecules as the third body in the recombination of hydrogen atoms, bringing his latest findings in this regard into line with those of Steiner[15] and Farkas and Sachsse.[2b] This is doubly confusing in that Smallwood's method, of all those used, seems to offer the least possibility of experimental difficulty. In addition, Amdur[18] in a recent publication claims to have as yet unpublished data which confirm the results of Smallwood.

It may also be shown in this connection that if the trimolecular recombination of hydrogen atoms takes place almost wholly with hydrogen *atoms* as third body, as Smallwood[16] believes, the thermal decomposition of the molecules must proceed through activation by collision with atoms: $H + H_2 \longrightarrow 3H$. This would mean that activation by an atomic collision must be about 100 times more effective than a similar collision involving molecules. Why this should be is not at present immediately evident.

There are several reasons why an exact agreement between the values of $k_{H + O_2 + M}$ as determined by Farkas and Sachsse and ourselves should not be obtained. The third bodies (M) are different, and in addition, the re-formation of hydrogen atoms by the reaction $HO_2 + H_2$ might take place to a large extent at low oxygen pressures[2a] (p. 461). It is apparent that for a better comparison between our work and that of Farkas and Sachsse the large discrepancy between the results of Smallwood and Steiner's work on the rate of recombination of hydrogen atoms should be cleared up, and an investigation of the inhibiting effect of iodine on the reaction $H + HI$ should be included in our program of photoreaction studies.

Deuterium Atoms

The experimental results yield the relationship $\frac{k_{D + O_2 + M}}{k_{H + O_2 + M}} \times \frac{k_{H + HI}}{k_{D + DI}} = 1.89$. Kinetic theory leads to the conclusion that the rates of the two trimolecular reactions should not be a function of the masses of the hydrogen and deuterium atoms, since the increased number of collisions between the H and O_2 would be just compensated by the smaller lifetime of HO_2. On the other hand, if the full zero point energy difference (936 calories) were operative, the reaction $H + HI$ should be 7.8 times as fast as the reaction $D + DI$. Thus we are led to the belief that the zero point energies of the respective activated complexes[7] are of the same magnitude as those of the halide molecules. If this is so, the frequencies of the complex must be fairly high, calling for a dependence of the reaction rates upon mass lying between $(\mu_1/\mu_2)^{1/2}$ and $(\mu_1/\mu_2)^{3/2}$, where the μ's are reduced masses. This is in agreement with the results found.

Summary

1. Definite evidence has been given to show that the reaction between hydrogen atoms and oxygen molecules is a three-body process.

2. The experimental data yielded the following mean values (with mean errors). $k_{H + O_2 + M}/k_{H + HI} = (2.11 \pm 0.29) \times 10^3$ cc. × mole^{-1}, and $k_{D + O_2 + M}/k_{D + DI} = (3.98 \pm 0.75) \times 10^3$ cc. × mole^{-1}.

3. Evidence has been given to show that Steiner's value[15] for $k_{H + H + H_2}$ is to be preferred to the very different one given by Smallwood.[16]

4. Calculation shows that $k_{H + O_2 + O_2} \cong k_{D + O_2 + O_2} \cong 1.2 \times 10^{14}$ cm.^{2} moles^{-2} sec.$^{-1}$.

The Kinetics of Absorption of Oxygen by Catechol

BY M. A. JOSLYN AND G. E. K. BRANCH

The absorption of oxygen by polyhydric phenols and its catalysis by ferric and manganous ions, by alkali, and by plant phenolases is well known. However, the kinetics of the reaction in absence of any other catalyst but alkali have not been systematically investigated, except in the case of hydroquinone for which the results as to order of the reaction with respect to OH^- have been rather contradictory.[1,2,3,4,5,6,7]

In this paper we are reporting a study of the kinetics of the auto-oxidation of catechol in absence of any catalyst but alkali and in the absence of light.

A fairly stable *p*-quinone is formed in the oxidation of hydroquinone so that the kinetics of its auto-oxidation may be studied either by determining the rate of absorption of oxygen or the rate of formation of quinone. However, the *o*-quinone is much more unstable[8] and the auto-oxidation of catechol is more complex, yielding intensely dark brown products which are evidently compounds of considerable complexity.

Auto-oxidations in general involve a preliminary absorption of oxygen with the formation of peroxides, followed by secondary reactions. The initial rate of absorption of oxygen is a measure of the rate of the primary reaction. When the subsequent reactions do not involve oxygen gas, or are slow with respect to the primary reaction, and when no catalyst or inhibitor is produced during the reaction, the initial rate of absorption of oxygen remains constant over a measurable time during which absorption of appreciable quantities of gas occurs, and the rate of the primary reaction can be measured. It is evident that the primary reaction as defined above is not necessarily the first step in the reaction. For instance, it cannot be the formation of active chain continuing molecules, for the time taken to reach a steady state of such active molecules is too short to be measured. It is probably the formation of peroxides no longer capable of continuing a chain leading to the absorption of oxygen.

In the auto-oxidation of catechol in buffered alkaline solution, easily measured quantities of oxygen are absorbed at a constant rate (see Fig. 2). Further evidence that this constant rate of absorption of oxygen is a measure of the rate of the primary reaction was given by the fact that the rate was unaltered in the presence of about 10% of freshly oxidized catechol. It was found also that the rate of the primary reaction could be measured in alkaline solutions even in absence of buffer.

The dependence of the primary reaction on such variables as H^+-ion concentration, catechol concentration, partial pressure of oxygen, temperature and surface was studied, both in buffered and unbuffered solutions.

Experimental Part

Reagents.—A fresh stock of Eastman catechol was used without further purification. The crystals were perfectly colorless, gave a colorless solution, and melted sharply at 105°. The other chemicals used were of the purest commercial grade obtainable, either Eastman or analytical reagent grade.

Apparatus.—The rate of oxygen absorption was followed by measuring the rate of decrease in pressure, at practically constant volume, occurring when definite quantities of catechol dissolved in water, phosphate buffers or sodium hydroxide solutions, were rapidly shaken in an atmosphere of oxygen. The apparatus consisted essentially of two flasks, each connected to one arm of a manometer, to each other, and to an oxygen supply and a vacuum pump so that they could be at will flushed out and filled with oxygen at the desired pressure. Both flasks were connected to a metal swing and immersed in a darkened thermostat at 25 ± 0.03°. The manometer liquid was Brodies' solution[9] and the volume of the manometer was small, less than 0.1% of the volume of the flasks. During each individual experiment the concentration of catechol and the pressure of oxygen were practically constant as the total amount of oxygen absorbed was small with respect to both the oxygen and the catechol in the reaction vessel.

The rates are expressed in cc. of oxygen at 25° and 1 atmosphere absorbed by 125 cc. of solution.

The experiments were performed by introducing 100 cc. of the buffer solution or other substrate into one of the flasks, and 25 cc. of freshly prepared aqueous catechol solution (usually 0.5 *M*) into a small tube supported in the flask by a glass rod. Both flasks were evacuated and filled with oxygen. The system was then cut off from the oxygen supply and allowed to stand until temperature equilibrium was reached, usually one hour. The stopcocks connecting the two flasks were turned, the glass rod lifted to precipitate the catechol into the buffer solution and the shaker started. The shaking was sufficiently violent to shatter the tube, to cause practically immediate mixing, and to keep the solution in a state of froth. The empty thermostated flask attached to one arm of the manometer was found to effectively prevent movements of the manometer liquid other than those caused by the reaction.[10]

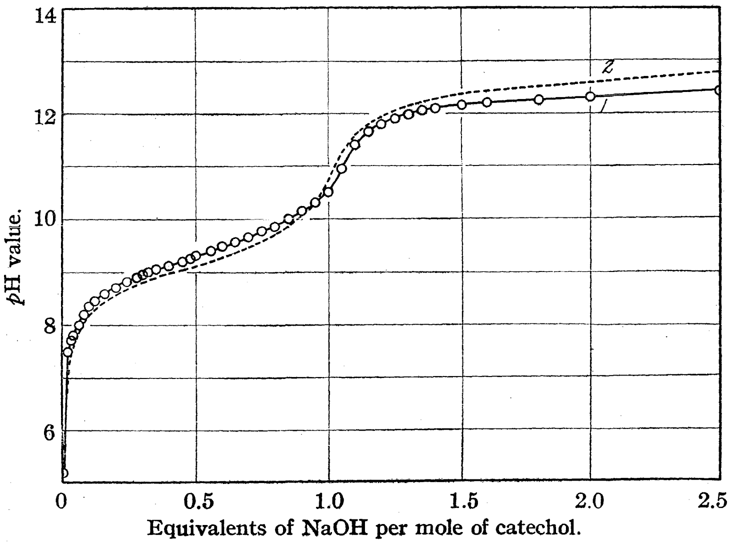

Fig. 1.—Titration curve: 1, pure catechol; 2, in presence 0.8 *M* KCl.

Measurement of pH.—The actual hydrogen-ion concentrations of the alkaline solutions of catechol used were measured by means of a Leeds and Northrup large bulb type glass electrode No. 7685 using an L and N saturated calomel electrode No. 7724, a type K potentiometer, and a 2500-f type R galvanometer. The glass electrode was used in preference to the hydrogen electrode, because of the difficulty of determining the *p*H of the alkaline catechol solutions by the latter, particularly in presence of the products of oxidation. However, by saturating the catechol solution with hydrogen and making the measurements in an atmosphere of hydrogen, it was found possible to measure *p*H values of unoxidized catechol solutions. The glass electrode was calibrated from *p*H 4 to 9 against buffers whose *p*H value was measured by a hydrogen electrode. The *p*H values above 9 were taken from an electrometric titration curve for unoxidized catechol determined in an atmosphere of hydrogen.

Accuracy.—Except in the most acid or most alkaline regions studied, the rates were readily reproducible to well within an error of 5%, particularly in buffered solutions. The results for the rates lower than 0.02 or higher than 20 cc. per minute were less accurate. The *p*H values were reproducible to less than ±0.05 unit except in the most alkaline range, where the limit of error is probably 0.1 unit. The internal evidence of the accuracy of the measurements indicates an average error of 7%, most of which is due to error in *p*H measurement.

Data and Discussion

Titration Curve.—Catechol is capable of existing in alkaline solutions in three forms—undissociated molecule, monovalent ion, and divalent ion—and it is necessary to know the proportions in which these various substances are present in a given solution. The dissociation constant of 3.2×10^{-10} given in the "International Critical Tables" (Vol. VI, p. 259) is corrected for salt effect and it was desirable to determine this value under our conditions in sodium hydroxide solutions and in the presence of added potassium chloride. The electrometric titration curve (at t = 23°) constructed in part from data obtained by glass electrode and in part by hydrogen electrode, both in absence and presence of 0.8 *M* potassium chloride for 0.1 *M* catechol is shown in Fig. 1. The pK value of the first dissociation is 9.3 without added salt and 9.1 in presence of 0.8 *M* potassium chloride. These values neglecting the slight temperature correction[11] are in fair agreement with the value given in the literature ($pK = 9.5$). The difference of these results from each other and from the accepted pK value of 9.5 is evidently due largely to a salt effect. The titration curve does not show a break for the second dissociation. This is in agreement with the results obtained by Kolthoff, who found that the conductivity curve for catechol shows only one break.[12] The lack of a second break indicates a pK value greater than 12.5 for the second dissociation. Sheppard[13] gives 1.75×10^{-10} and 3.97×10^{-12} as the two dissociation constants for hydroquinone.

---

[10] The necessity for a thermobarometer to serve as a control is clearly pointed out by R. Siebeck, see reference 9, page 30.

[11] Following the procedure of Euler and Brunius[3] the temperature correction was made by comparison with Lundén's values for phenol at various temperatures [*Z. physik. Chem.*, **70**, 249 (1910)]. The values for k decrease with decrease in temperature but the pK values increase. The correction in our case amounts to about −0.03 pK units which is within the limits of experimental error.

[13] S. E. Sheppard, *Trans. Am. Electrochem. Soc.*, **39**, 429–440 (1922).

Homogeneity of the Reaction.—The addition of large amounts of powdered Pyrex or soft glass had no appreciable effect on the rate of oxygen absorption; the reaction is thus homogeneous and free of wall effects.

Difference between Buffered and Unbuffered Solutions.—When the reaction is carried out in a well buffered solution, whether an external buffer is used or the concentration of sodium hydroxide is sufficient to nearly half neutralize the catechol present, more than 10 cc. of oxygen can be absorbed without any noticeable change in the rate. But when no external buffer and only a small amount of sodium hydroxide is used the rate decreases after the absorption of but little oxygen, and the initial rates must be obtained by extrapolation. Typical runs obtained in phosphate buffers prepared by mixing 1 *M* dipotassium phosphate and 1 *M* monopotassium phosphate and in sodium hydroxide solutions, shown in Fig. 2, illustrate this behavior. This is nothing but the usual phenomenon that is shown by any reaction whose rate depends on the concentration of hydrogen ion and in which the hydrogen-ion concentration changes. That it occurs in this reaction shows that the products of the auto-oxidation of catechol include an acid or acids stronger than catechol.

We have tested for other factors causing a reduction in rate in unbuffered solutions. No gas was formed in the reaction for the residual oxygen was found to contain no impurity.[14] No inhibitor was formed during the reaction. This was shown by oxidizing an alkaline solution 0.01 *N* with respect to catechol and then using the resulting solution as a substrate for a new experiment. Both in unbuffered and buffered solutions these new experiments gave the same rate of oxygen absorption as in experiments with clean substrate and pure catechol at the same *p*H value. These experiments also show that no catalyst is formed in the reaction.

Confirmation of the production of an acid or acids in the auto-oxidation was obtained by measuring the *p*H values present after reactions in which the rate had changed considerably. In these cases the observed decrease in *p*H was more than sufficient to account for the change in rate.[15]

A similar decrease in rate was observed in the auto-oxidation of hydroquinone in unbuffered or slightly buffered solutions.[1,2,5] Dubrisay and Saint-Maxen[5] found that in presence of small amounts of sodium hydroxide the rate of oxygen absorption by hydroquinone rapidly decreases and finally tends to be practically zero, while the solution changes from alkaline to slightly acid.

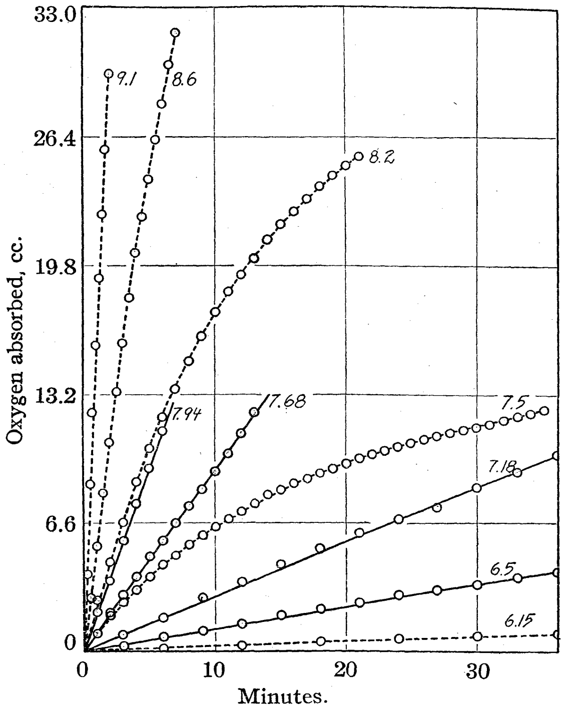

Fig. 2.—Rate of oxygen absorption at the *p*H values indicated on the curves: ——, in buffered solutions; ----, in NaOH solutions.

Variation of Rate with *p*H.—The results obtained for rates of oxygen absorption by a 0.1 *M* catechol solution in buffered solutions, and in sodium hydroxide solutions with and without added potassium chloride, at 1 atmosphere pressure of oxygen are shown in Tables I to V. The values of *K* were calculated on the assumption that the rate was directly proportional to the concentration of hydroxyl ions. It is seen that in all cases *K* is sensibly constant over a wide range of concentration. The average value of *K* in 0.8 *M* phosphate buffer solution is 1.46×10^6 in the range *p*H 6.5 to 8.25; in sodium hydroxide solutions it is 1.07×10^6 in the range *p*H 6.6 to 8.2; in sodium hydroxide solutions containing 0.8 *M* potassium chloride it is 1.89×10^6 in the range, *p*H 6.68 to 8.74; in sodium hydroxide solutions containing 1.6 *M* potassium chloride it

TABLE V

RATE IN SODIUM HYDROXIDE SOLUTIONS IN PRESENCE OF 2.4 *M* POTASSIUM CHLORIDE

*p*H	K = rate (cc./min.)/ OH$^-$ $\times 10^{-6}$	*p*H	K = rate (cc./min.)/ OH$^-$ $\times 10^{-6}$
4.84	6.35	8.0	2.64
5.72	5.45	8.1	2.67
6.12	2.67	8.2	2.75
6.63	2.00	8.34	2.69
6.95	2.17	8.44	2.69
7.22	2.77	8.55	2.54
7.65	2.36	8.81	1.91
7.85	2.53	8.95	1.73

Average K in *p*H range 6.12–8.55 = 2.54×10^6..

At the higher *p*H values, particularly in the two cases carried into the strongly alkaline range, K rapidly decreases with increase in *p*H. But this decrease in K is to be expected in the reaction of an acid in the range where the alkali concentration is sufficiently large to neutralize an appreciable fraction of the acid. If we assume that the rate of oxygen absorption, V, is proportional to the concentration of the monovalent catechol ion (cat.$^-$), the rate law can be expressed as

$$V = K' \frac{k_a C}{k_a + (\mathrm{H}+)}$$

where K' is the specific rate constant for the oxidation of cat.$^-$, k_a the first dissociation constant of catechol, and C the concentration of total catechol (= 0.1 *M*). The values of K' calculated from the above expression are shown in column 3 of Tables II and III. It can be seen that these values are practically constant almost throughout the entire range from slightly acid to strongly alkaline solutions. The average value of K' in absence of added salt is 221 and in presence of 0.8 M potassium chloride it is 270.

The constancy of K and K' suggests that the monovalent ion of catechol is the oxygen absorbing species. This is not strictly warranted because the product of (cat.) by (OH^-) is proportional to the concentration of (cat.$^-$) and the reaction may be one in which the OH ion acts as a basic catalyst for the oxidation of undissociated catechol.

In this case the negative ions of the phosphate buffer are also basic catalysts and the rate in buffered solution should be faster than in solutions in which the same pH values and ionic strength are obtained with sodium hydroxide and potassium chloride. This is contrary to the facts. It is, therefore, best to attribute the effect of alkali to the formation of the more reactive catechol ion from the less reactive undissociated catechol.

The constancy of K' from pH 6 to 10, shows that in this range absorption by the second ion of catechol is negligible, but in more alkaline solution there is a definite upward trend of the values of K' indicating that absorption of oxygen by the second ion has a greater specific rate than that by the first. If we assume that the absorption of oxygen by the second ion is first order with respect to its concentration, the rate in strongly alkaline solution ($p\text{H} > 10$) is given by the expression $V = K'(\text{cat.}^-) + K''(\text{cat.}^{--})$. On this assumption the rates in strongly alkaline solutions in the absence of potassium chloride correspond to values for K'' and the second dissociation constant of catechol having the orders of magnitude of 10^3 and 10^{-13}, respectively.

At low pH values, particularly below pH 6, K (and also K') is considerably higher than the average. This indicates that not only the ions but the undissociated catechol itself must be able to absorb oxygen. However, the rate of absorption of oxygen by the undissociated catechol molecule is very much less than that by the monovalent ion, since it only interferes with the constancy of K on the acid side of neutrality, that is, when the concentration of the monovalent ion is exceedingly small compared to that of catechol.

Salt Effect.—In the range pH 6 to 10, the rate of absorption of oxygen increases with added salts. The salt effect is not entirely determined by the ionic strength. for the rate in phosphate buffers is less than that in potassium chloride solutions of similar ionic strength. A large part of this salt effect is due to the influence of salt on the acidic strength of catechol. Thus K in 0.8 M potassium chloride is 77% greater than K in absence of extraneous salt, but K' which is independent of the strength of catechol is only 22% greater in 0.8 M potassium chloride than in 0.0 M potassium chloride.

Potassium chloride decreases the rate of absorption of oxygen by the second ion of catechol. This is shown by the fact that in strongly alkaline solutions the rate in the presence of potassium chloride falls below that in its absence.

Variation of Rate with Concentration of Oxygen.—Measurements of the rate of oxygen absorption by 0.1 M catechol solution in phosphate buffers at pH 8.40 were made at varying partial pressures of oxygen. These were produced both by making the runs in partially evacuated system and in presence of air at atmospheric pressure. The results obtained are shown in Table VI.

TABLE VI

RATE OF OXYGEN ABSORPTION AT VARYING PARTIAL PRESSURES OF OXYGEN

Partial press. of O_2, atm.[a]	Rate	$K = \text{rate}/(P_{O_2})$
0.082	0.220	2.78
.097	.260	2.68
.206[b]	.53	2.57
.206[b]	.56	2.72
.272	.790	2.90
.423	1.15	2.72
.439	1.38	3.14
.627	1.63	2.60
.792	2.07	2.61
.969	2.55	2.63
	Average K =	2.72

[a] Corrected for vapor pressure of water. [b] In air.

The constancy of the values of K calculated on the assumption that the rate of oxidation is proportional to the partial pressure of oxygen shows that over a more than tenfold range of oxygen pressure the reaction is directly proportional to the pressure of oxygen.

Variation of Rate with Concentration of Catechol.—To determine the effect of varying the catechol concentration at constant pH, the rate of oxygen absorption was measured at varying concentrations of catechol in a strongly buffered phosphate solution at pH 6.5 and in sodium hydroxide solutions in which the equivalence of sodium hydroxide added per mole of catechol was maintained at 0.08 mole of sodium hydroxide per mole of catechol. The *p*H value of the sodium hydroxide solutions was practically constant at 8.20. The results obtained are shown in Table VII.

TABLE VII

RATE OF OXYGEN ABSORPTION AT VARYING CONCENTRATIONS OF CATECHOL

Concn. of catechol, M	Rate in phosphate buffer	Rate in NaOH	K_1 Buffer	K_1 NaOH	K_2 Buffer	K_2 NaOH
0.025	..	0.345	..	13.8	..	24.8
.05	0.0253	.782	0.506	15.6	7.08	21.9
.075	.041	..	.547	..	6.92	..
.10	.051	1.885	.510	18.9	6.12	22.7
.125	.071	..	.568	..	6.60	..
.15	.098	2.91	.652	19.4	7.42	22.1
.175	.107	..	.610	..	6.80	..
.20	.123	3.75	.614	18.8	6.77	20.7
.30	.202	..	.673	..	7.20	..
.40	..	8.00	..	20.0	..	28.7
				Average K_2 =	6.86	23.5

K_1 = rate/(concentration).
K_2 = rate × (concn. + 0.02)/(concn.)^2.

The rate is approximately first order with respect to catechol but it is slower than would be expected from this law at low concentrations of catechol. Thus, the values of K_1 calculated on the assumption that the reaction is first order with respect to catechol are over 30% lower at concentrations of catechol below 0.1 M. The rate obeys more exactly the law: rate = $K_2 (C)^2/(C + A)$, where C is concentration of catechol and A some constant. The K_2 values shown in Table VII were calculated using the same value of A, namely, 0.02 for both solutions.

By combining the results obtained by separately varying the *p*H value, the pressure of oxygen, and the total concentration of catechol, the rate of oxygen absorption in the range *p*H 6 to 10 is given by the expression

$$V\alpha(\text{Cat.}^-)(\text{O}_2) \times C/(C + A)$$

In view of the facts that A is approximately the same at two very different concentrations of hydroxide ion, and that the values of K' given in Tables II and III are constant over wide degrees of neutralization of the catechol, the concentration represented by C is to be taken as that of the sum of the concentrations of the undissociated catechol and of its first ion. The proportionality constant in the above expression is $K' \times (0.1 + 0.02)/0.1$. This is 266 expressed in the units cc. of oxygen × atm.$^{-1}$ × mole^{-1} × liter × min.$^{-1}$, for solutions containing no extraneous salts.

Variation of Rate with Temperature.—The rates of oxygen absorption by 0.1 M catechol solution in phosphate buffers at *p*H 8.35 and in sodium hydroxide at *p*H 8.20 were measured at 20, 25, 30 and 35°. The results are shown in Table VIII. It is seen that the values for the phosphate buffer are somewhat more consistent. The average heat of activation is 12,900 calories for the phosphate solutions and 9400 calories for the sodium hydroxide solution. The temperature coefficient V_{35}/V_{25} is 2.16 for the phosphate solutions and 1.68 (corr.) for the sodium hydroxide solutions. These heats of activation include not only the heat of activation of the oxygen absorbing species but also the heats of neutralization of catechol by $HPO_4^=$ and OH^-, respectively. The difference in these heats of neutralization largely accounts for the higher heat of activation in the buffered solution.

TABLE VIII

EFFECT OF TEMPERATURE ON RATE OF OXYGEN ABSORPTION

Temp., °C.	Rate Phosphate	Rate NaOH
20.0	1.76	1.35
25.0	2.51	1.70
30.0	3.74	2.22
35.0	5.22	3.00

Acknowledgment.—Leo A. Joslyn is to be thanked for his aid in making the runs, and Professor J. P. Bennett for making available to us the thermostat and other equipment.

Summary and Conclusions

The rate of oxygen absorption by catechol solutions has been studied under various conditions.

1. In the range of *p*H value 6.5 to 10, $V\alpha \times (\text{Cat.}^-) \times O_2 \times C/C + A$.

2. In more acid solutions absorption of oxygen by the undissociated molecule is appreciable; and in more alkaline solutions, the divalent ions also absorb oxygen.

3. In moderately alkaline solutions potassium chloride increases the rate of absorption, chiefly through a positive salt effect on the dissociation constant of catechol. In strongly alkaline solutions salt retards the reaction.

4. The heats of activation in sodium hydroxide solutions and in phosphate buffers were measured over the range 20 to 35°. The apparent heat of activation is higher in the phosphate buffer.

This difference can be accounted for by the difference between the heats of neutralization of catechol by $HPO_4^=$ and OH^-, respectively.

The Adsorption of Methane by Coal[1]

BY J. BARTLETT SUTTON AND EARL C. H. DAVIES

Introduction

To determine the adsorption equilibrium between a highly adsorptive coal and methane, we have recently used an apparatus which contains a variable volume unit, by means of which the total system volume can be varied through four stages, enabling one to obtain adsorption values for four pressures with each gas sample and to check such values on both the adsorption and desorption side of the equilibrium point. The fact that approximately twenty-four hours were required for equilibrium conditions to be attained led us to enclose, in an electric refrigerator at constant temperature (± 0.1°), not only the adsorption bulb but the entire apparatus.

Materials and Apparatus

The coal was obtained from the Carreta, West Virginia, mine of the Carter Coal Company, which is the most gassy mine in the world. It was of semibituminous rank and from the Pocahontas No. 4 seam. A ton sample, collected from all over the mine, was passed through a jaw crusher and then quartered several times to obtain a representative sample of fifty pounds. A portion of this was then ground in a "coffee mill" to approximately 100-mesh average size.

The analysis of this coal[2] as given by the Bureau of Mines was H, 4.4; C, 88.7; N, 1.3; O, 2.2; S, 0.5; H_2O, 0.4 and ash, 2.9. After refluxing with water for two weeks, we found the average density (nine determinations) to be 1.3521. The range of particle sizes, in the coal sample, as determined by the application of Stokes' equation to sedimentation data, was: 63.0%, 0.132 mm.; 10.0%, 0.045 mm.; 10.8%, 0.030 mm.; 10.2%, 0.021 mm.; 1.7%, 0.016 mm. and 4.3%, 0.007 mm. The coal received no preliminary heat treatment but was evacuated to 10^{-4} mm. for a period of seventy-two hours.

The methane was obtained from the Bureau of Mines at Pittsburgh, Pennsylvania. The higher hydrocarbons[3] had been removed from natural gas by passing it through 117 cm. of activated coconut charcoal.

The analysis of the methane[4] supplied by the Bureau of Mines was: CH_4, 97.8–98.0%; C_2H_6, 0.05%; O, 0.10% and N, 1.85%. The density found by the Regnault method was 0.7196. Traces of moisture were removed from the methane, before it was admitted to the system, by passing through a coil submerged in an ether–solid carbon dioxide mixture.

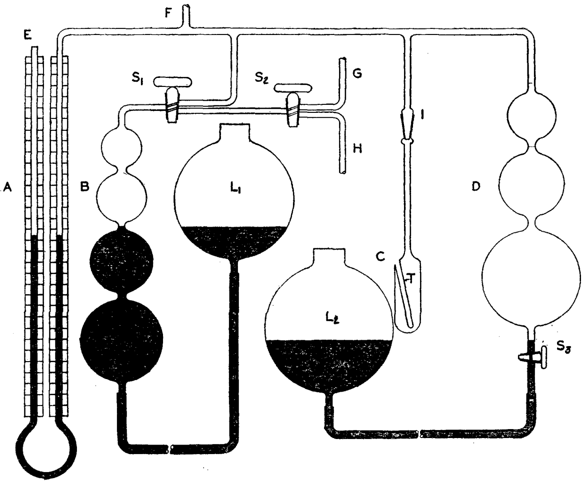

Fig. 1.—Adsorption apparatus with variable volume unit.

The apparatus (Fig. 1), designed and constructed in this Laboratory, consists essentially of the four units, A, B, C and D. A is the manometer, B the gasometer, C the adsorption bulb and D the variable volume unit. The volumes, between constricted portions, of both the gasometer and variable volume unit, as well as the total system volume, were accurately measured by the use of mercury. The temperature was determined by means of two ten-junction copper–constantan thermocouples, the hot junctions of which were en-

---

closed in a paraffin-filled glass tube, embedded in the adsorbing material, while the cold junctions were enclosed in a glass tube immersed in a water–ice mixture, contained in a Dewar flask.

Experimental Procedure

By means of blank determinations, we found that the glass and mercury surfaces within the apparatus did not adsorb a measurable amount of methane. The procedure followed was similar to that used in other investigations of the same nature except for the use of the variable volume unit, by means of which the pressure was varied through four stages by changing the mercury level within the unit.

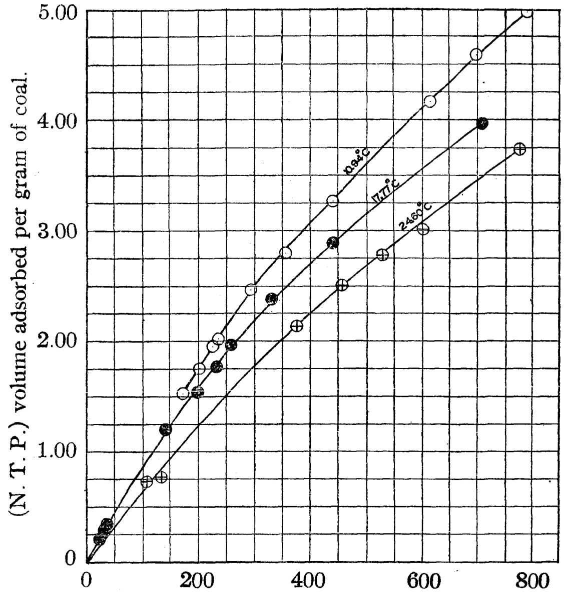

Fig. 2.—Adsorption isotherms.

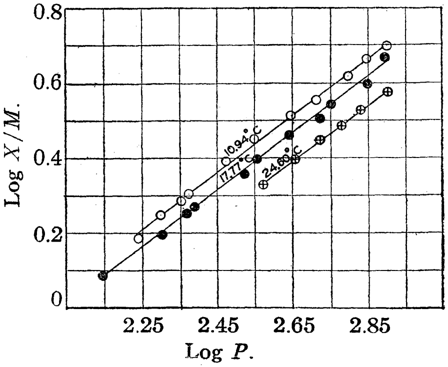

Fig. 3.—Log isotherms.

A weighed sample of coal was then placed in C and the manipulations carried out as before. After adsorption values had been determined and checked at four different pressures, more gas was then added and the above procedure repeated. The volume of gas adsorbed is $V_a = (273/760\ T_1)(P_1V_1 - P_2V_2)$, where T_1 is the temperature of the system, V_1 the volume of gas introduced, P_1 the atmospheric pressure, V_2 the volume of the system and P_2 the pressure produced by the gas introduced into the system.

Data and Graphical Interpretations

The relationships between adsorption and pressure for temperatures of 10.94, 17.77 and 24.60° are represented graphically in Fig. 2.

The Freundlich equation has been found to be applicable to the data, as shown by the straight line curves in Fig. 3. Here the log of x/m has been plotted against the log of P. A straight line is obtained, because the Freundlich equation in the form $\log x/m = \log k + 1/n \log P$ yields a straight line if it is applicable to the data. The slope of this line is equal to $1/n$ and its intercept with the $\log x/m$ axis is equal to $\log k$.

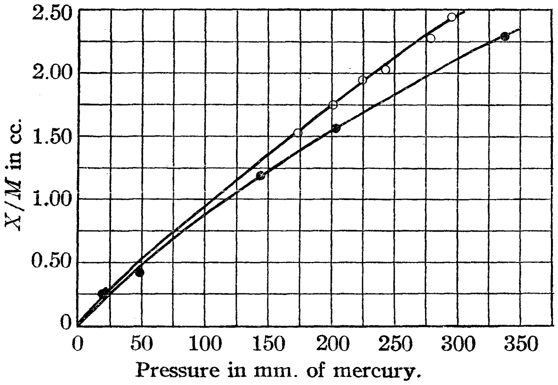

Fig. 4.—Effect of moisture in decreasing adsorption.

The effect of traces of moisture in lowering the adsorption of methane is shown in Fig. 4. The data for these curves were obtained at 10.94°.

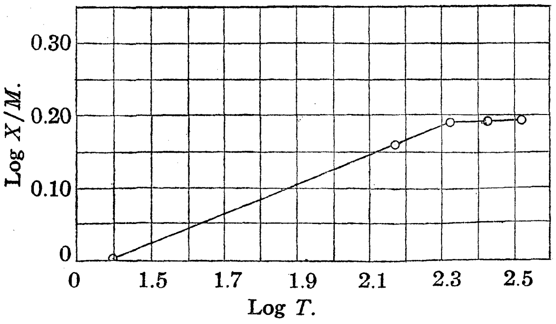

Fig. 5.—Log rate curve.

Figure 5 gives a log rate curve, the values for which were obtained at 17.77°.

The heats evolved per mole of gas adsorbed, as obtained by the application of the Clausius–Clapeyron equation to pressure and temperature readings taken from adsorption isosteres (Fig. 6), are plotted against amounts of gas adsorbed in Fig. 7.

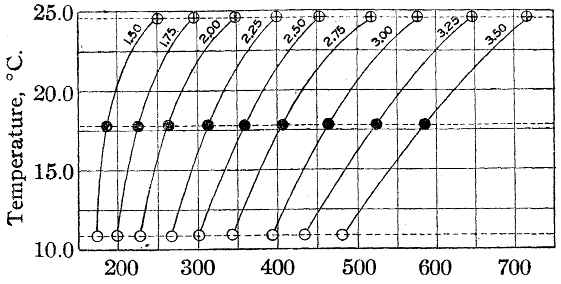

Fig. 6.—Adsorption isosteres.

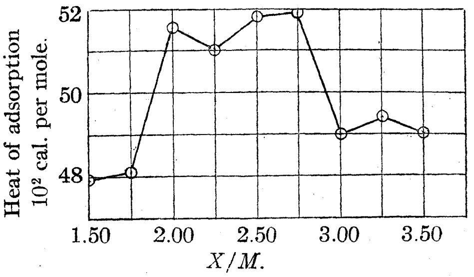

Fig. 7.—Heats of adsorption of methane on coal at 17.77°.

Summary

1. It has been shown that an apparatus equipped with a variable volume unit offers an accurate means of checking adsorption equilibrium on both the adsorption and desorption side of the equilibrium point.

2. The maintenance of the total adsorption system at constant temperature has been found to offer advantages of accuracy of measurement and simplicity of calculation.

3. A successful application of the Freundlich equation, to data found for the adsorption of methane by coal, has been made.

4. The calculated heats of adsorption of methane on coal have been found to be between 4700 and 5200 calories per mole for *x/m* values between 1.5 and 3.5.

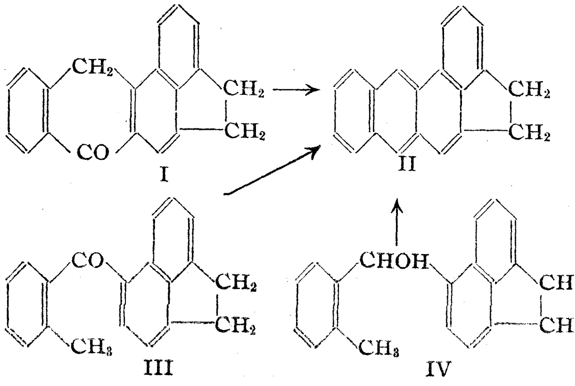
A Pyrolytic Synthesis of 2,3-(Naphtho-2',3')-acenaphthene[1]

BY BRADFORD P. GEYER AND SAVERIO ZUFFANTI

2,3-(Naphtho-2',3')-acenaphthene (II) has been synthesized by Cook[2] by reduction of the anthrone (I), and, according to the statements in some patents,[3] the hydrocarbon also can be obtained by the pyrolysis of 3-*o*-toluylacenaphthene (III) or 3-acenaphthyl-*o*-tolylcarbinol (IV) in the presence of a dehydrating catalyst. These intermediates have not been described in the literature, however, and there is no evidence to indicate that a catalyst is required in their pyrolysis. It appeared a matter of interest, therefore, to synthesize 3-*o*-toluylacenaphthene and then, by subjecting this ketone to the conditions ordinarily employed for effecting the Elbs reaction, to prepare the hydrocarbon II.

The ketone III was obtained from *o*-toluyl chloride and acenaphthene by the Friedel–Crafts reaction. When pyrolyzed at 400–410°, it was converted smoothly into a hydrocarbon having the composition and the properties of the substance described by Cook.[2]



The authors are greatly indebted to Professor Louis F. Fieser of Harvard University for much helpful advice.

Experimental Part[4]

The *o*-toluyl chloride used in this work was made from the acid by the use of thionyl chloride; yield, 89%; b. p. 212°, corr.

3-*o*-Toluylacenaphthene (III).—Anhydrous aluminum chloride (30 g.) was added slowly, a little at a time, to an ice-cold mixture of 30 g. of pure acenaphthene and 30 g. of *o*-toluyl chloride in 75 cc. of carbon disulfide. After six hours at 0–5° the mixture was allowed to warm gradually to room temperature and then carefully treated with water and cracked ice. The solvent and some unchanged acenaphthene were removed from the crude, dark brown ketone by steam distillation, first in the presence of dilute hydrochloric acid, and then dilute sodium hydroxide, and the product was extracted with ethyl alcohol from a considerable amount of tarry residue. After three crystallizations from ethyl alcohol and a final recrystallization from methyl ethyl ketone, 3-*o*-toluylacenaphthene was obtained in the form of glistening, pale yellow, rhombic plates, m. p. 139–140°; yield, 12 g. (23%). The solution of the ketone in concentrated sulfuric acid is of a deep yellow-orange color.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92. Found: C, 88.11; H, 5.89.

2,3-(Naphtho-2′,3′)-acenaphthene (II) was prepared by the pyrolysis of 0.7 g. of 3-*o*-toluylacenaphthene under an atmosphere of carbon dioxide in a two-bulb distilling flask at a bath temperature of 400–410° for forty minutes. At the conclusion of this time the elimination of water seemed to be complete. The crude product was then submitted to distillation in vacuum at a pressure of 2 mm., whereupon a golden-yellow crystalline solid was obtained. This material, when treated with an equal quantity of picric acid in benzene, formed a picrate which crystallized in clusters of slender, short, dark red-brown needles, m. p. 182.5–183.0°, corr. Decomposition of this picrate with ammonia and recrystallization of the regenerated hydrocarbon from ligroin (b. p. 90–120°) gave 2,3-(naphtho-2′,3′)-acenaphthene, very pale yellow leaflets, m. p. 192.5–193.5°, corr.; yield, 0.15 g. (23%). A benzene solution of this hydrocarbon possesses a yellow-green fluorescence, and the concentrated sulfuric acid solution has a red-violet color with an exceedingly strong, deep red fluorescence.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.50; H, 5.50. Found: C, 94.37; H, 5.80. Calcd. for $C_{26}H_{17}O_7N_3$: N, 8.70. Found: N, 9.00.

Summary

2,3-(Naphtho-2′,3′)-acenaphthene has been synthesized by the Elbs condensation of 3-*o*-toluylacenaphthene.

Derivatives of Piperazine. VI. Alkylation by Means of Aldehydes

BY W. T. FORSEE, JR., AND C. B. POLLARD

Some secondary amines have been alkylated by using aldehydes in the presence of a reducing agent.[1–5] However, the possibilities of the reaction seem to have attracted little attention.

Piperazine and N-monophenylpiperazine were quite readily alkylated by this method. In most cases products were obtained in better yields and were more easily purified than when prepared by other methods. N,N′-Dimethylpiperazine and N,N′-diethylpiperazine were prepared by the action of formaldehyde and acetaldehyde, respectively, on piperazine in the presence of powdered zinc and hydrochloric acid. N-Phenyl-N′-methylpiperazine and N-phenyl-N′-ethylpiperazine were prepared by the respective action of formaldehyde and acetaldehyde on N-monophenylpiperazine in the presence of zinc and hydrochloric acid. With one exception, good yields were obtained and in some cases one distillation served to give a pure product. This method was not satisfactory for aldehydes which are insoluble in hydrochloric acid even when sufficient alcohol was added to keep them in solution.

Formic acid was used as the reducing agent for those aldehydes which are insoluble in hydrochloric acid. Where aliphatic aldehydes were involved the reaction required from one to three hours. With aromatic aldehydes the reaction velocities were very slow, requiring as much as five days of refluxing. All products were easily purified. The solid derivatives were crystallized from 60% alcohol.

The yields, properties and analyses of these compounds are shown in Table I.

Experimental

Using Zinc and Hydrochloric Acid as Reducing Agent.—To a water solution of the amine hydrochloride were added, for each equivalent of secondary nitrogen, one

[a] Prepared from N,N′-dimethylpiperazine by passing dry hydrogen chloride into the anhydrous ether solution of the free base. [b] Prepared by using zinc and hydrochloric acid as the reducing agent. [c] Prepared by using formic acid as the reducing agent.

mole of the aldehyde and two moles (twice the calculated amount) of powdered zinc. A quantity of concentrated hydrochloric acid sufficient to react with the zinc was added gradually with stirring and cooling. After the zinc had all reacted, the mixture was made alkaline and the free base was extracted with ether. The ether solution was dried over anhydrous sodium carbonate, filtered and the ether evaporated. The free base was purified by distillation.

Using Formic Acid as Reducing Agent.—A mixture of 0.1 equivalent of the secondary amine and 0.1 mole of the aldehyde was refluxed with 40 cc. of formic acid (90%) until the evolution of carbon dioxide had ceased. The excess formic acid was evaporated on a water-bath and the residue made alkaline. The free base was extracted with ether, dried, filtered and the ether evaporated. The derivative was purified by recrystallization or distillation.

Summary

Satisfactory methods are described for the preparation of alkyl piperazines by the condensation of piperazine or N-monophenylpiperazine with aldehydes in the presence of a reducing agent.

The Free Energy Change that Accompanies Hydrogenation of Pyridine to Piperidine[1]

BY GEORGE H. BURROWS AND LOUIS A. KING, JR.

That pyridine is readily hydrogenated to piperidine, and that the reaction is reversible, has been shown by Zelinski and Borisov.[2] The purpose of the present investigation is to determine the free energy change of the reaction, through direct determination in the vapor phase of the equilibrium involved at each of several temperatures.

Attempts to achieve this equilibrium through initial use of hydrogen and pure pyridine or of hydrogen and pure piperidine did not lead to the desired results, and substantiated the conclusion of Sadikov and Mikhailow[3] that side products are extensively formed. It was also our experience that the active life of the platinum or nickel catalyst was short.

On these accounts experiments were devised to apply the use of trial mixtures of the several components, that mixture being deemed of equilibrium composition which underwent no appreciable change on being passed over the active catalyst at the selected temperature.

Materials and Experimental Details

Pyridine and piperidine of high quality were obtained from the Eastman Kodak Company. The pyridine was refluxed over solid potassium hydroxide and distilled. Its boiling point was 115.2–115.4°, its index of refraction $n^{25}\text{D}$ was 1.50682. In some instances the piperidine was given this same treatment, in others no treatment was necessary, as shown by its refractive index. This had the value $n^{25}\text{D}$ 1.45036.

The hydrogen, a commercial electrolytic product of high purity, was freed from possible oxygen contamination by palladinized asbestos and thoroughly dried before use.

The compositions of pyridine–piperidine mixtures were determined through their refractive

[1] Grateful acknowledgment is made to the Elizabeth Thompson Science Fund for aid in financing this research.

[2] Zelinski and Borisov, *Ber.*, **57**, 150 (1924).

[3] Sadikov and Mikhailow, *J. Russ. Phys.-Chem. Soc.*, **58**, 527 (1927).

indices. The data for synthetic mixtures of known composition are shown in Table I.

TABLE I

% pyridine	% piperidine	n^{25}_D
0.00	100.00	1.45036
26.92	73.08	1.46394
53.03	46.97	1.47840
74.79	25.21	1.49134
100.00	00.00	1.50682

The composition–refractive index curve is almost linear, but is slightly concave toward the composition axis. The data of Table I may be expressed by the equation, $n_D = 1.45036 + 0.0_349$ (% pyridine) $+ 0.0_673$ (% pyridine),^{2} with an average deviation of 0.0001. Precision of analysis is favored by the wide difference between the indices of the pure components.

The nickel used as catalyst in the final experiments was prepared from oxide reduced in place by hydrogen and on an unglazed porcelain support. Complete reduction and removal of moisture is necessary and was indicated by ultimate constancy in weight of a drying tube through which the effluent gas was passed.

The experimental procedure was as follows. A bubbler system immersed in a constant temperature bath contained a mixture of pyridine and piperidine. It was provided with tubes through which this mixture could be withdrawn and replaced for the purpose of change of composition. Hydrogen entering the bubbler at constant rate of flow passed with the vapors of pyridine and piperidine in constant ratio either through the catalyst chamber or through the by-pass. Both catalyst chamber and by-pass were supported in a furnace that maintained the temperature constant within 0.5°. The catalyst chamber or the by-pass, as the case might be, led to a weighed condensing tube immersed in a freezing mixture; beyond this the hydrogen was collected and measured. The condensed mixture of pyridine and piperidine was weighed and analyzed.

Through systematic change in composition of the bubbler mixture and alternate use of catalyst chamber and by-pass, it proved not difficult to fix upon a mixture that remained essentially unchanged by the catalyst.

Sadikov and Mikhailow[3] noted that use of nickel as catalyst led to opening of the pyridine ring, with formation of amylamine. Under the conditions of the present work, this side product could not have been present in other than relatively small amounts, for the condensate from the catalyst chamber gave negative results when subjected to the Van Slyke method of analysis for amines. Absence of significant amounts of this side product was deemed sufficient evidence that other side products were not formed in sufficient quantities to necessitate consideration, under the existing condition of brief contact with the catalyst, and at the temperatures of the experiments used in our calculations.

The indices of refraction and compositions of the final equilibrium mixtures at the several furnace temperatures used, and the partial pressures and equilibrium constants calculated from these are shown in Tables II and III.

TABLE II

Furnace temp., °C.	n_D catalyst condensate	n_D by-pass condensate	Wt. of catalyst condensate, g.	Vol. H_2, cc. (reduced)
150	1.45627	1.45627	1.3586	257.3
170	1.47948	1.47967	0.9924	250.5
180	1.48113	1.48142	.6848	255.3
180	1.48500	1.48568	.5984	258.7

TABLE III

Temp., °C.	Composition catalyst condensate		Partial pressures (atm.)			K_p
	% pyridine	% piperidine	H_2	C_5H_5N	$C_5H_{11}N$	
150	11.75	88.25	0.415	0.073	0.509	97.4
170	54.88	45.12	.486	.288	.220	7.45
180	57.70	42.30	.573	.251	.171	3.6
180	64.20	35.80	.607	.256	.132	2.3

Greater difficulty was experienced at 180° in gaining close agreement between the compositions of mixtures that passed over the catalyst and through the by-pass, than at the lower temperatures. This is thought to be due to increased formation of side products at the higher temperature. The results at this temperature, therefore, are not used in the free energy calculations. The equilibrium constant at 180° calculated from the values at 150 and 170° is 2.25.

From the constants at 150 and 170°, the free energy changes at these temperatures are $F^\circ_{423} = -3835$ cal. and $F^\circ_{443} = -1760$ cal., respectively, corresponding in each case to the reaction

$$C_5H_5N(g) + 3H_2 = C_5H_{11}N(g)$$

Heat capacity data for pyridine and for piperidine in the gaseous state are not available and cannot be estimated reliably; consequently reduction of the free energy change to that at 25° is not attempted.

The equilibrium constants at 150 and 170° give as the heat of reaction between these temperatures, $H = -47{,}680$ cal. Approximate reduction to 25° and pyridine and piperidine in liquid state gives for these conditions $H = -45{,}000$ cal. The corresponding value calculated from thermochemical data ("International Critical Tables") is −38,600 cal.

Summary

The equilibrium between pyridine, hydrogen and piperidine has been measured at 150 and at 170°, and more approximately at 180°. The heat of reaction and the accompanying free energy changes have been calculated.

Diffusion Coefficients in Alcohol–Water Mixtures

BY H. MOUQUIN AND W. H. CATHCART

The diffusion coefficients of a number of organic dyes dissolved in water–ethyl alcohol mixtures of varying composition were studied by Ostwald and Quast.[1] Their method, which essentially involves a continuously varying diffusion layer, seemed to contain some experimental difficulties. In view of this fact and the rather unusual nature of their results, the present authors attempted to repeat the original experiments with the intention of extending the work in this field. In spite of every effort to duplicate the conditions described in the original paper, the method proved too unreliable to permit verification of the previous findings.

The Ostwald method contained two obvious limitations: first, the solutions were placed in an unsealed vessel and were thus very sensitive to any disturbances capable of bringing about mass flow; second, the arrangement of the apparatus was such that it necessarily involved the tacit assumption that the density of the solution was greater than that of the solvent.

Testing the relative densities of crystal violet solutions and corresponding solvents at varying alcohol concentrations by means of the "schlieren" method, it was soon discovered that at least in the region between 25 to 50% (by weight) of alcohol the density of the 0.1% dye solution was actually less than that of the corresponding solvents. This no doubt is the major difficulty involved in the Ostwald method.

In recent years, a method first used for the measurement of diffusion coefficients by Northrup and Anson,[2] and greatly extended by McBain and co-workers, has become available. We refer to the so-called fritted glass membrane method, involving a constant diffusion-layer thickness. In two recent papers, McBain and Dawson[3] have pointed out the advantage of using a closed system. In a previous paper,[4] the disadvantages of stirring had been mentioned, but this was attempted only in an open cell.

The major requirements in the membrane cells not only include the existence of an undisturbed diffusion gradient in the membrane, but also adequate stirring in the bulk of the solutions right up to the surface of the fritted glass disk. If this last condition is not fulfilled, secondary diffusion layers build up beyond the strict confines of the membrane and this introduces a variable and unknown factor.

In the original technique, density difference between solvent and solution must be depended upon entirely for adequate mixing. Variations in viscosity must certainly affect the efficiency of this gravitational streaming, but, besides this, the density differences can vary over a wide range from case to case.

In the case at hand where the density differences may become vanishingly small, it is obvious that the traditional technique is impossible. In fact the formation of vague secondary diffusion layers beyond the physical boundaries of the membrane could easily be seen in the case of the more highly colored solutions.

The cell shown in Fig. 1 was designed to overcome the above difficulties and has been in use in this Laboratory for more than a year. First, it is entirely enclosed;[3] this effectively prevents any mass flow, outside of the most violent agitation. Second, the entire cell is slowly rotated at a speed somewhat under one r. p. m. by means of a wheel and belt drive placed in the thermostat. This motion coupled with the rise and fall of the en-

closed glass balls brings about gentle but sufficient mechanical stirring right up to the membrane surface.

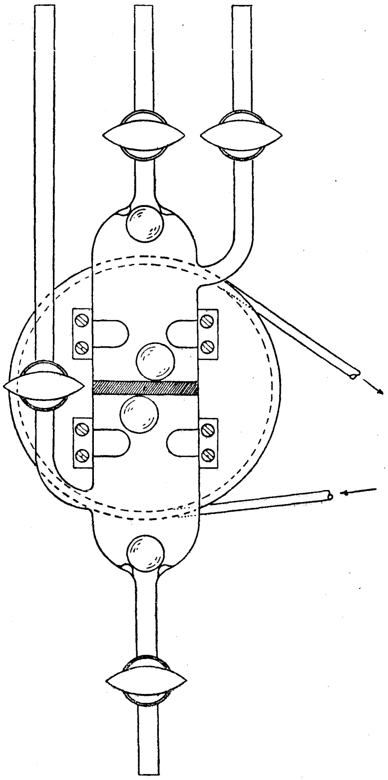

Fig. 1.

A few more practical details may be useful to other workers. One of each pair of glass balls is light enough to float, while the other sinks. The relative buoyancy of these, as well as the rate of rotation, should not be exaggerated, since the resultant excessive wear and tear tends to form a groove on the friable glass disk. Attempts to substitute mercury globules for the glass spheres have yielded unsatisfactory results. Indentations in the cell walls, near the ends, prevent the balls from blocking the end-tubes while the solutions are being removed. If sufficiently large stopcocks are used (6 mm. or more) and the solutions are of ordinary viscosity, the side tubes shown may be dispensed with. As in former methods, one end of the cell and the membrane are first filled by suction and the usual routine of refilling, etc., carried out before starting the rotation.

The effect of the stirring is at once evident when the cell constant of the rotating cell is compared with the same cell in a stationary position. As determined according to McBain, with 0.1 N hydrochloric acid, the constant in the cell used here showed an increase of nearly 5% when adequate stirring was maintained.

The data given in Table I show the diffusion coefficients of crystal violet taken over the whole range of water–alcohol mixtures, as obtained by this method. Curve II on Fig. 2 shows the data plotted graphically. Curve I is taken from Ostwald's data for comparison. The crystal violet was a very pure sample obtained from Grübler which has proved satisfactory in other research carried out in this Laboratory. The original solutions contained 0.1 g. of the monohydrate dye in 100 cc. of the solvent mixtures; the changes in concentration were measured by known dilution of the original solution until a close match was obtained in the colorimeter. The thermostat was kept at 25° and the viscosity corrections were made relative to water at that temperature. In verifying the fact that there is no appreciable difference in the viscosities of solvent and corresponding solution, the results seemed to be in bet-

ter agreement with those published by Butler[5] than with the data given in the "International Critical Tables;" accordingly, the former were used to make the corrections.

Compositions of the water–alcohol mixtures were checked by determining the density by means of a pycnometer and tables given in "I. C. T."

The most interesting region of the curve consists of a definite "break" observable in the vicinity of 65 wt. % alcohol. Robinson and co-workers[6] have shown that it is seldom justifiable to interpret data for electrolytes such as given above, in terms of particle sizes. In any case some primary cause for the sharp break would have to be accounted for.

Since the days of Mendeléjeff attempts to furnish evidence of compound formation in alcohol–water mixtures have not been very successful. If we now take the break at 65 wt. % of ethyl alcohol as such evidence we are immediately confronted with the fact that this composition does not correspond to a one-to-one or any other whole number ratio of the traditional molecular weights. This criticism becomes less destructive when it is realized that the ratio of the two molecular weights in the liquid state of such compounds is not definitely known. If we assume the molecular weight of the alcohol to be normal, and that 65% corresponds to a one-to-one compound tendency it is necessary to assume an average molecular weight for water of about 25. A fairly reliable and independent substantiation of this value is to be found in the calculations made by Murray[7] based on the vapor pressure data obtained by Makowiecki for acetone–water mixtures.

Further search revealed a considerable quantity of evidence suggestive of the peculiar significance of the 65% region. If we restrict ourselves to the mixtures (neglect values for pure water and 100% alcohol), plotting various sorts of physical properties against the weight percentage very frequently demonstrates an abrupt change in the character of the solvents at this particular composition. In some cases, this is best revealed by a logarithm plot.

TABLE II

A. C. RESISTANCES OF THE ORIGINAL SOLUTIONS (CELL CONSTANT 1.3943)

% alcohol by wt.	$R \times 10^{-3}$ resistance (ohms)	$\eta^{25°}$ compared to H_2O	$R/\eta^{25°} \times 10^{-3}$
15.48	11.30	1.75	6.47
30.50	14.36	2.45	5.86
40.58	18.20	2.66	6.84
49.61	19.17	2.64	7.25
55.30	19.00	2.57	7.39
61.84	19.77	2.47	8.00
67.50	19.37	2.33	8.31
71.16	19.57	2.22	8.82
80.62	20.00	1.92	10.41
94.75	19.76	1.43	13.80

Figure 3 shows the plot of Table II, which is the electrical resistances, corrected for viscosity, of the crystal violet solutions used in the diffusion experiments. (The dye contains less than 0.5% sodium chloride.) A "break" around 65% is noticeable. A similar effect can be seen by making a log plot of the conductivity data (viscosity correction) published[5] for zinc chloride and potassium iodide solutions.

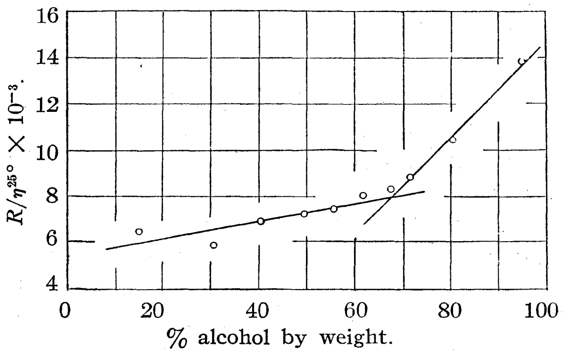

Fig. 3.

Other data which show irregularities in the 65% region are (1) log plot of the solubilities of zinc valerate, phenyl salicylate, ammonium benzoate, lithium benzoate and others (data from "I. C. T."); (2) log plot of % deviation of kinematic viscosity from a linear additivity rule (data from "I. C. T."); (3) dielectric constant for water–ethyl alcohol mixtures (plot on large scale).[8]

From the above evidence it seems fairly clear that the observed break in the diffusion coefficient must be caused by a peculiar condition characteristic of this solvent mixture.

Summary

1. The inadequacies of some former diffusion measurements are pointed out.

Studies in the Physical Chemistry of Amino Acids, Peptides and Related Substances. V. Influence of Amino Acids, Urea and Alcohol upon the Velocity Constants of Chemical Reactions[1]

BY DANELLA STRAUP AND EDWIN J. COHN

The velocity constants of most chemical reactions are not independent of changes in the medium but vary with the ionic strength and the dielectric constant. The variation with change in salt concentration appears to be explained adequately by Brönsted's[2] theory of reaction rates, which considers the rate proportional to the activity coefficients of the reactants and inversely proportional to the activity coefficient of the critical complex. In the present communication we are concerned with the influence of alcohol, urea and amino acids upon reaction rates. All of these substances profoundly influence the dielectric constant of the medium and their activity coefficients vary in a very different manner from those of electrolytes.

In dilute electrolyte solution activity coefficients, and therefore changes in reaction rate, may be estimated by means of the Debye limiting law. The effect of more concentrated electrolytes or of non-electrolytes may be calculated by the method of Christiansen.[3] This method has been recently discussed by Harned and Samaras,[4] La Mer[5] and Scatchard.[6] The Brönsted–Christiansen and Debye–Hückel theories yield[6]

$$\log \frac{k}{k_0} = \frac{\epsilon^2 Z_A Z_B}{2.303\ DKT} \frac{\kappa}{1 + \kappa a} \tag{1}$$

in which k is the velocity constant in the salt solution, k_0 that in the absence of salt, K is the Boltzmann constant, κ the reciprocal distance proportional to the square root of the ionic strength, and a the distance of closest approach of the ions. The velocity constant should vary, according to equation (1), not only with the valence, Z, and ionic strength, μ, of the electrolytes, but with any change in the dielectric constant[7] of the solution, D, from its value in the standard state, D_0. Signifying by k' the velocity constant at zero ionic strength in a medium having a dielectric constant other than that of the standard state, equation (1) may be written

$$\log \frac{k}{k'} = \frac{Z_A Z_B\ (D_0/D)\ \sqrt{(D_0/D)\mu}}{1 + (a/3)\ \sqrt{(D_0/D)\mu}} \tag{2}$$

When D is equal to D_0, k' is equal to k_0.

The effect of changing dielectric constant on reactions between ions at zero ionic strength has been calculated[6] as

$$\log \frac{k'}{k_0} = \frac{\epsilon^2 Z_A Z_B}{2.303\ KTa}\left(\frac{1}{D} - \frac{1}{D_0}\right) = \frac{242.3\ Z_A Z_B}{a}\left(\frac{1}{D} - \frac{1}{D_0}\right) \tag{3}$$

This equation is analogous to the Born–Fajans equation for equilibrium relations.

Amino acids, due to their zwitterionic structure, exert electrostatic forces in solution. Since they do not contribute to the ionic strength, Debye's equation does not apply even in dilute solution. Solutions of amino acids have high dielectric constants and attempts have been made to describe the effect of amino acids on activity coefficients[8] in terms of the Born–Fajans equation. Another treatment of the effect of amino acids is described later on in this paper.

Two types of reactions have been studied: (1) a reaction between a non-electrolyte and an ion, and (2) a reaction between two ions. The thio-

(7) The dielectric constants of the solvents employed have been determined by Wyman [THIS JOURNAL, **53**, 3292 (1931); *ibid*, **55**, 4116 (1933)]. In dilute solution they have been estimated by the equation: $D = D_0 + \delta C$, where D_0 is 78.54 at 25°, δ is 2.8 for urea, 22.7 for α-, and 36 for β-amino acids [Wyman and McMeekin, *ibid.*, p. 908].

(8) Failey, *ibid.*, **54**, 576 (1932).

sulfate ion was employed in both reactions; in the one type in the reaction with uncharged alkyl iodide molecules, in the other with bromoacetate ions, for which there is a positive salt catalysis. Both types of reactions have previously been shown to be bimolecular.

Materials and Methods.—All solutions were made up immediately before starting each experimental run.

Thiosulfate solutions were made from a stock solution of 0.1 *N* sodium thiosulfate which was standardized with weighed samples of resublimed iodine, dried over calcium chloride. A tenth dilution of this solution was titrated against standard iodine. These two standardizations agreed within 0.1%. 0.01 *N* iodine solutions were standardized with arsenic trioxide obtained from the U. S. Bureau of Standards, according to the method of Washburn.[9]

The glycine used was three times recrystallized from water. The urea obtained from the Eastman Kodak Co. was once recrystallized. Methyl iodide of Eastman Kodak and also of Kahlbaum, and ethyl iodide of Kahlbaum were used without further purification. Both preparations of methyl iodide gave the same results.

Reactions were carried out at 25 ± 0.03°. In the reaction with alkyl iodide and thiosulfate, the methyl iodide or ethyl iodide was added to the thiosulfate solutions containing the additional component at 25° from a weight buret. The reaction was carried out in special flasks to allow of pipetting without loss of alkyl halide by volatilization. Some of the experiments with these reactions were repeated using a separate flask for each determination. In these cases a saturated solution of ethyl iodide or a half saturated solution of methyl iodide was added to the thiosulfate solution, taking precaution to avoid loss by volatilization during the transfer of the solutions.

Bromoacetate solutions were made from weighed samples of bromoacetic acid, obtained from Eastman Kodak Co., and dried over sulfuric acid, and titrated with standard sodium hydroxide using phenolphthalein as indicator. The concentration of the sodium bromoacetate was checked by allowing it to react with a three-fold excess of thiosulfate and determining the concentration of thiosulfate remaining when the reaction was completed. The concentration of the sodium bromoacetate solution as determined by weighing, titration with sodium hydroxide and reaction with thiosulfate agreed within 0.5%.

Reaction between Thiosulfate and Alkyl Iodides.—Both salts and amino acids increase the rate of reaction between the bromoacetate and thiosulfate ions, and diminish that between the latter and uncharged alkyl iodides. The experimental error in determining the velocity constant of the latter reaction is greater, due to the tendency toward volatilization of the non-electrolyte.[10] The values of *k* for this reaction, given in Table I, are the averages of at least three determinations during the run. They are accurate only to two significant figures.

	1.00	.08	− .138

The addition of glycine to the solution brings about a decrease in the velocity constant for both the reaction of methyl iodide and of ethyl iodide with thiosulfate ion (Fig. 1). The effect of amino acids is less than that of electrolytes, but is of the same order of magnitude, whereas urea has only a slight effect on these reactions. Ethyl alcohol on the other hand brings about a large increase in the velocity constant for both reactions.

In order to test the influence of the dielectric constant upon reaction rates, solutions have been prepared, having the same dielectric constant as water, but different compositions. The values of the velocity constant for the alkyl iodide–thiosulfate reaction in solutions isodielectric with water are given in Table II. The addition of glycine or urea to alcoholic solutions yields lower

---

[9] Washburn, THIS JOURNAL, **30**, 31 (1908).

[10] The initial concentration of thiosulfate in these experiments was 0.01 *N*, the initial concentration of alkyl iodide varied from 0.005 to 0.010 *N*.

velocity constants than in the alcohol solutions alone, but the decrease is far smaller than that expected on the basis of proportionality between change in velocity constant and change in dielectric constant.

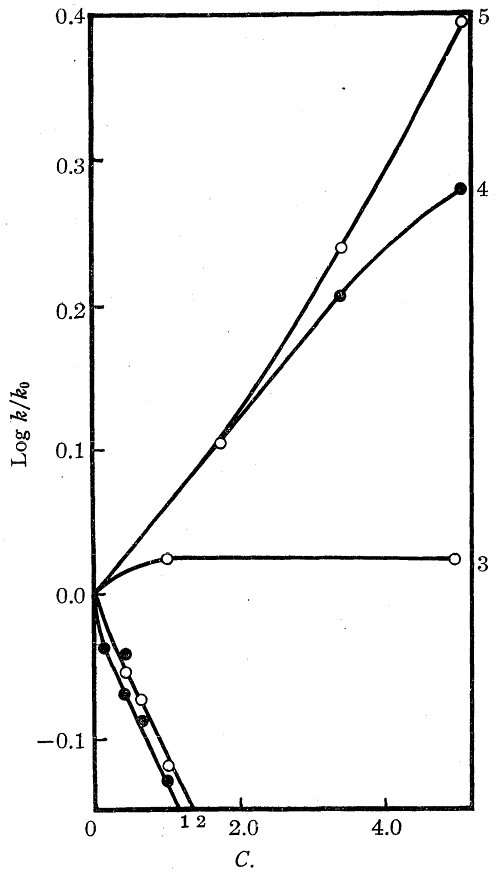

Fig. 1.—Hollow circles represent methyl iodide, solid circles ethyl iodide, in media containing (1) potassium chloride; (2) glycine; (3) urea; (4) and (5) ethanol.

Indeed the effect of glycine or of urea in diminishing the velocity constant is not very different in 20 or 30% alcohol from that in water. The rate of reaction in mixtures of glycine or urea and alcohol appears to depend rather upon specific properties of solute molecules than upon the dielectric constant of the solution.

TABLE II

[a] The urea concentrations were calculated on the basis of $\delta = 2.82$.

Reaction between Thiosulfate and Bromoacetate Ions.—The reaction between bromoacetate and thiosulfate ions has repeatedly been studied. Recently La Mer,[11] La Mer and Fessenden,[12] and Kappanna[13] have shown that the velocity constant of this reaction is influenced by the ionic strength according to the expectation from the theory of Debye and Hückel. On the basis of linear extrapolation in the presence of monovalent cations, La Mer and Fessenden[12] estimate log k_0 to be $\bar{1}.396$. Kilpatrick[14] has employed equation (1) to describe several reaction rates, putting a, for convenience, equal to 3 Å. Accepting La Mer and Fessenden's value for k_0 for the bromoacetate reaction, our measurements yield values of a of 5.30, 5.19, 5.89, 5.67. The intermediate value of 5.6 Å. is employed in subsequent calculations.[15]

Effect of Alcohol.—In striking contrast to its effect upon the reaction between the alkyl iodides and thiosulfate, ethyl alcohol has very little influence on the reaction between thiosulfate and bromoacetate ions. Alcohol produces a very marked change in the dielectric constant of the solution, however, and one might therefore anticipate a large change in velocity constant of the basis of equation (3). The change in the logarithm of the velocity constant of these solu-

[14] Kilpatrick, THIS JOURNAL, **56**, 2326 (1934).

[15] La Mer and Fessenden's measurements as well as ours are better described by a still higher value of a, 6.2 Å., and of log k_0, $\bar{1}.398$. On the other hand, Kappanna's measurements in dilute solutions yield $\bar{1}.376$ for log k_0. It is probable that an equation more complicated than (1) should be employed in concentrated salt solutions.

tions with change in the dielectric constant is calculated in Table III, where k^* is the velocity constant of a solution of the same ionic strength, but with no additional component. So considered, the result bears no relation to the expectation.

[a] Equal concentrations of the materials were employed in the experiments of $\sqrt{\mu} = 0.204$ and 0.289. In those of $\sqrt{\mu} = 0.228$ the concentration of thiosulfate was double and that of $\sqrt{\mu} = 0.270$ half that of the bromoacetate.

Both our measurements and conclusions regarding the influence of alcohol in this reaction are consistent with those of Kappanna,[13] whose measurements extend up to 80% alcohol and over a wide range of ionic strengths. We have attempted to correct both his measurements and ours for the increased electrostatic forces in media of low dielectric constant by means of equation (2). The estimated values of k' substituted in equation (3) yield values which vary from 53 to approximately 35 in our measurements and to 22 in Kappanna's measurements in 80% alcohol.[16] The expectation, according to equation (3), is 86.6 if a is equal to 5.6 Å. It is perhaps not surprising that the agreement is no better, for other effects than those due to electrostatic forces should unquestionably be considered.

Effect of Urea.—Whereas urea has no appreciable effect upon the velocity constant of the reaction between thiosulfate and an uncharged molecule, it greatly increases the rate of reaction with the bromoacetate ions.[17] Values of log k/k^* for the bromoacetate reaction are negative

---

(16) Kappanna's measurements are most satisfactorily studied by plotting D/D_0 log k against $\sqrt{(D_0/D)\mu}$. The curve for 80% alcohol is superimposable throughout its length with that for water, but the other curves, especially that for 20% alcohol, are very different.

(17) The dissertation of Mildred Elsie Kamner, Columbia University 1934, has been received since this was written. Miss Kamner has also studied urea, as well as sucrose, glycerol and dioxane. She reports that all of these increase the rate of this reaction, and concludes that "there is no simple relation between the dielectric constant of the solvent and the velocity constant." The ratio log k/k^* calculated from her result with urea at approximately the ionic strengths studied by us, is in excellent agreement with those in Table III. The velocity constant in the presence of dioxane, 0.567, is very close to that reported by Kappanna for the same ionic strength in 80% alcohol, 0.589, and the solutions are approximately isodielectric. The influence of the other substances studied is far smaller even than that of urea, and of a different order than that of the amino acids.

in ethyl alcohol and positive in urea. Since $(1/D - 1/D_0)$ is positive in alcohol, but negative in urea, the ratios have the same sign (Table III). Moreover, the ratios in the case of urea are approximately those predicted by equation (3). Substituting values of k/k^* in this equation yields estimates of a from 6.3 to 7.5 Å., whereas correcting for diminished electrostatic forces at higher dielectric constants by means of equation (2) (k'/k_0) yields values of a from 4.4 to 5.1 Å. The influence of urea upon this reaction is in the direction and of the order to be expected from its effect on the dielectric constant.

Effect of Amino Acids.—The effects of glycine and α-alanine upon the dielectric constant of solutions, and upon the velocity constant of the bromoacetate–thiosulfate reaction are almost identical. Where they have been studied at the same concentration and ionic strength, the influence of α-alanine appears to be slightly smaller than that of glycine, but the effect of β-alanine with its higher dipole moment is very much greater. The changes in velocity constant with changes in dielectric constant are, moreover, of the same order for urea and the amino acids (Table III), though there is a tendency for them to increase with concentration in the presence of urea and generally to decrease in the presence of glycine. The greater influence of β-alanine on the dielectric constant is reflected in a somewhat smaller value of the ratio in the calculations in the third, though not those in the fourth column, which are corrected for the diminished electrostatic forces at higher dielectric constants. The influence of amino acids and urea upon the velocity constant of this ionic reaction thus appears, as a first approximation, to depend upon their influence on the dielectric constant of the solution.

Isodielectric Solutions.—If the rate of the thiosulfate bromoacetate reaction depended only upon change in ionic strength and dielectric constant, k should be the same in mixtures however constituted, having the same dielectric constant as water. The experiments reported in Table IV demonstrate that this is too simple a postulate in reactions between ions, as well as in reactions between ions and uncharged molecules (Table II).

A slight difference in the effect of urea and glycine on the bromoacetate reactions may be mentioned. The velocity constants are smaller in alcoholic than in aqueous solutions containing the same concentration of urea, but are greater for glycine in alcohol than in water, an effect interpretable in terms of increased electrostatic forces in alcoholic solutions.

TABLE IV

[a] These solutions may have had slightly lower dielectric constants. Urea concentrations were calculated on the basis of δ = 2.82.

The effect of amino acids on the velocity constant of this reaction is less than that of electrolytes, but is of the same order of magnitude. In order to facilitate comparison the values of k in the presence of electrolytes estimated by La Mer and Fessenden[12] and by Kiss[18] have been plotted in Fig. 2 against the concentration beyond $\sqrt{\mu}$ equal to 0.2, at which k^* equals 0.486.[19] Although the influence of amino acids and of salts is of the same order of magnitude, the influence of electrolytes varies as the square root of the ionic strength, whereas that of urea and of amino acids varies as the first power of the concentration. The influence of amino acids is therefore described by the ratio (log k/k^*)/C. All our measurements are so calculated in Table III and show that the change in velocity constant with change in amino acid concentration increases (1) with decreasing values of C, (2) of μ, and (3) with increasing values of the dipole moment of the amino acid.

The Kirkwood Equation.—The lack of agreement between change in velocity constant and

---

[18] Kiss, *Z. anorg. allgem. Chem.*, **209**, 236 (1932).

[19] The data of Kiss (18) on the effect of electrolytes of high concentrations do not give the actual concentration of the reactants, and the ionic strength due to the reactants is not taken into account here.

change in dielectric constant is not limited to rates of reactions but occurs in any consideration of activity coefficients. Kirkwood has recently developed a theoretical equation for the activity coefficients of amino acids[20] in terms of the distance, R, separating the positive and negative charges of the zwitterion, the mean distance of closest approach of zwitterion and ion, a, the concentration of the former, C, and the ionic strength of the latter, μ. Assuming that the relative distributions of the ions of valence Z_A and Z_B is determined by electrostatic forces, both in the presence and absence of zwitterions, Kirkwood has developed equations[21] relating change in velocity constant to amino acid concentration. Ignoring multipole moments of higher order than the dipole, his equation valid only at low zwitterion concentration becomes

$$\frac{\log k/k^*}{C} = \frac{3\pi N\epsilon^4 Z_A Z_B}{2303\ (DKT)^2}\,\frac{R^2}{a}\,\frac{1 + \kappa a/2}{(1 + \kappa a + \kappa^2 a^2/3)^2} \qquad (4)$$

Substituting numerical values at 25° yields

$$\frac{D/D_0 \log k/k^*}{(D_0/D)\ C} = 0.125 Z_A Z_B\,\frac{R^2}{a} \times$$
$$\frac{1 + 0.165a\sqrt{(D_0/D)\mu}}{(1 + 0.329a\sqrt{(D_0/D)\mu} + 0.036a^2\,(D_0/D)\mu)^2} \qquad (5)$$

Glycine.—The value of R for glycine has been estimated to be 3.17 Å. by Kirkwood[20] on the basis of our measurements upon the solvent action of lithium chloride on glycine in alcohol–water mixtures[22] and to be 3.1 Å. by Scatchard and Prentiss[23] on the basis of freezing point measurements. The distance of closest approach, a, may be taken as the sum of the radius of the glycine, 2.82, estimated from its molal volume[24] and one-half the value of a for the ions estimated by equation (1). The valence of the reacting ions being two and one, the expression $0.125\ Z_A Z_B R^2/a$ becomes 0.44 if a for the ions be taken as 5.6 Å. and the influence of amino acids on the rate of reaction at the ionic strengths becomes

$\sqrt{\mu}$	$\left(\frac{\text{Log } k/k^*}{C}\right)$ Obs.	$\left(\frac{0.44\ (1 + 0.93\sqrt{\mu})}{(1 + 1.85\sqrt{\mu} + 1.14\ \mu)^2}\right)$ Calcd.
0.204	0.26	0.26
.228	.24	.24
.270	.23	.22
.289	.21	.21

The agreement with the highest results recorded in Table III is considerably greater than is warranted by the simplifying assumptions on which the theory and calculations are based. A larger value for a, or a smaller value of R, would render the agreement less satisfactory.

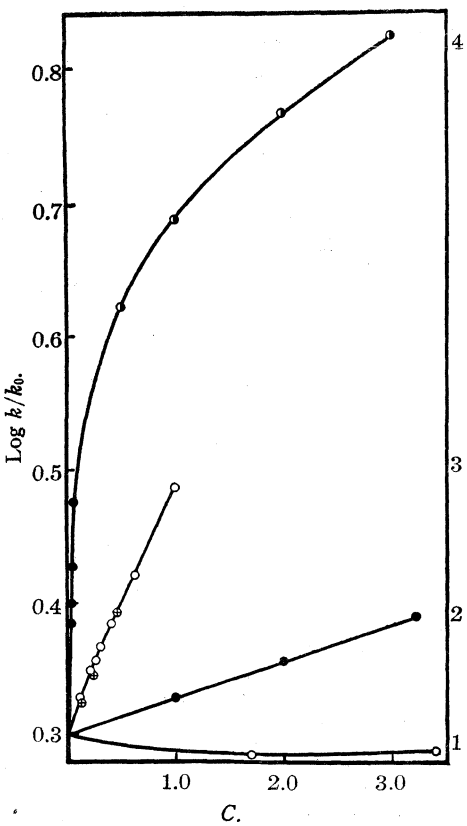

Fig. 2.—Concentration of reactants, $a = b = 0.010$: (1) ethanol, ○; (2) urea, ●; (3) glycine, ○ and α-alanine, ⊕; (4) sodium salts, La Mer and Fessenden, ●; and Kiss, ◑.

Alanine.—The radius of both α- and β-alanine is somewhat greater than that of glycine, 3.08 Å.[24] and so is the dipole moment of the β-alanine. Assuming the amino acids to be rods leads to a value of R of 4.4 Å., whereas the assumption that the increment in dielectric constant, δ, increases as the square of R[25] leads to 3.9 Å. for this constant when the amino group is in the β-position.

---

(20) Kirkwood, *J. Chem. Physics*, **2**, 351 (1934).

(21) We are indebted to Dr. Kirkwood for developing this very interesting consequence of his theory. On the basis of the Brönsted–Christiansen theory (with the assumption that the distance of closest approach of the ions in the so-called critical complex is the same as the mean distance of closest approach of the zwitterion to the ions) he obtains for low amino acid concentrations

$$\log_{10}\frac{k}{k^*} = \frac{2\pi N Z_A Z_B \epsilon^2}{2303\ (DKT)^2}\, C \sum_{n=1}^{\infty}$$
$$\frac{(2n+1)\ Q_n}{(2n-1)(n+1)^2\, a^{2n-1}}\,\frac{(2n+1)K_{n-1}\,K_{n+1} - (2n-1)K_n{}^2}{K_{n+1}{}^2}$$

the symbols having the same significance as in his paper (20).

(22) Cohn, *Naturwissenschaften*, **20**, 663 (1932).

(23) Scatchard and Prentiss, THIS JOURNAL, **54**, 2696 (1932).

(24) Cohn, McMeekin, Edsall and Blanchard, *ibid.*, **56**, 784 (1934).

(25) Wyman, *ibid.*, **56**, 536 (1934).

$$\left(\frac{0.0425\ R^2\ (1 + 0.97\ \sqrt{\mu})}{(1 + 1.93\ \sqrt{\mu} + 1.25\ \mu)^2}\right)$$

	α-Alanine	β-Alanine	
$\sqrt{\mu}$	$R = 3.1$	$R = 3.9$	$R = 4.4$
0.228	0.22	0.35	0.44

The observed values for α-alanine (Table III) are 0.21 and for β-alanine 0.31 at this ionic strength and the lowest amino acid concentration.

Kirkwood's equation should hold only for very dilute solutions, whereas the concentrations of the glycine studied in alcohol–water mixtures were appreciable (Table IV). None the less the following comparison can be made with aqueous solution containing the same glycine concentration, and having the same ionic strength (Table III).

Volume fraction alcohol, v_2	$\sqrt{\mu}$	Amino acid concn., C	$\left(\frac{\text{Log}\ k/k^*}{C}\right)$	$\left(\frac{D/D_0 \log k/k^*}{(D_0/D)C}\right)$
0.0	0.204	0.40	0.21	0.26
.2	.204	.40	.24	.24
.0	.289	.40	.19	.24
.2	.289	.40	.25	.25
.0	.204	.62	.19	.27
.3	.204	.62	.26	.26

The right-hand expression of equation (2) changes very little with change in dielectric constant. Thus the calculated value at infinite dilution of glycine at $\sqrt{\mu} = 0.204$ is 0.25 for 20% alcohol as compared with 0.26 for water.

Urea.—Whether or not urea is a zwitterion remains a controversial question and is considered elsewhere.[26] On the assumption[25] that the increment in dielectric constant, δ, increases as the square of the dipole distance, and that the radius of urea is 2.6 Å.[24] a becomes 5.4 Å. and the right-hand side of equation (5) yields 0.033 at the ionic strength at which urea has been studied. The observed ratio was 0.028 (Table III). The calculated effect of urea in 20 and 30% alcohol is 0.031. The observed values are 0.023 and 0.015.

Kirkwood's equation was developed on the assumption that the dipole moment is large relative to that of a solvent molecule, and this condition does not obtain for urea. In the cases for which it was intended the Kirkwood equation appears to describe the effect of zwitterions as satisfactorily as does the Debye equation that of ions.

Summary

1. The rates of reaction of thiosulfate with uncharged alkyl iodide molecules and with bromoacetate ions have been studied.

2. The rates of reaction with the uncharged molecule are increased with alcohol and to a small extent by urea, and decreased by ions and by amino acids.

3. The rate of reaction with ions is increased by salts, amino acids and urea and but slightly influenced by alcohol.

4. Whereas salts increase the logarithms of the velocity constant proportionately with the square root of the concentration, the effect of amino acids and urea varies with the concentration.

5. Both urea and the amino acids increase the dielectric constant of water proportionately with the concentration. That the influence upon the rate of reaction is not due merely to change in dielectric constant is indicated by the effect of alcohol, and of urea and glycine in alcoholic solutions isodielectric with water.

6. Kirkwood's equation for the activity coefficients of the amino acids extended to apply to rates of reaction satisfactorily describes the observed results in terms of the valence of the reactants, the dimensions of ions and amino acids and the dipole moments of the amino acids.

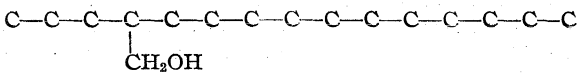
Some Isomeric Branched Hexadecanols

BY WARREN M. COX, JR., AND E. EMMET REID

In a previous paper[1] we were led to the provisional view that certain aliphatic alcohols, such as cetyl alcohol, might possess mild purgative properties. On the basis of this hypothesis we have prepared all the eight primary hexadecanols which are theoretically possible when a —CH_2OH group is successively attached to each carbon in pentadecane.



$$\underset{\substack{|\\ CH_2OH}}{\text{C—C—C—C}}\text{—C—C—C—C—C—C—C—C—C—C—C}$$

Only the first member of this series, cetyl alcohol had been previously prepared.

Preparation

The correct conditions for the simplest method of preparation, *i. e.*, reduction of the branched chain aldehyde obtained by heating the glycidic ester condensation product of the corresponding ketone and chloroethyl acetate,[2] could not be found. Consequently, the branched chain acid[3] corresponding to the alcohol was prepared by means of the malonic ester synthesis, and the ethyl ester of this substituted acetic acid reduced by the method of Bouveault and Blanc.[4]

The required thirteen normal halides, from methyl to tridecyl, were prepared in the usual way[5] from the corresponding alcohols. The alcohols above butyl, with the exception of heptyl, were made from ethyl esters of the corresponding acids by reduction with metallic sodium in butyl alcohol.[4] Heptanol was prepared according to the method of Clarke and Dreger.[6] With the exception of undecylic acid the odd acids were prepared by the malonic ester synthesis or the nitrile reaction. *Ethyl Undecylate.* The crude undecylenic acid was distilled, esterified, and the ethyl ester cut 185–190° (100 mm.),[7] iodine no. 113. The ester was hydrogenated with a nickel catalyst, and reduced to the alcohol in the usual way.[4] The resultant undecyl alcohol, iodine no. 5.1, was dissolved in absolute ethyl alcohol and hydrogenated (Adams platinum oxide) to an iodine no. of 1.0.

Substitution of the Halides in Malonic Ester

One of the most annoying factors involved in the use of the malonic ester synthesis is the large volumes of anhydrous ethyl alcohol required. This difficulty has been overcome by the use of butyl alcohol, which is obtained anhydrous by mere distillation. The ethyl malonate should first be converted to the butyl ester[8] but in the present work ethyl malonate was used in butyl alcohol solution, with a resultant formation of ethyl butyl, diethyl and dibutyl esters of the mono-substituted malonic ester. Fortunately, the dibutyl ester predominated. Substitution of halides was in the usual way.

Saponification.—The disubstituted ester was refluxed for three hours with 25% alcoholic potassium hydroxide (with occasional addition of a little water to prevent separation of potassium malonate). The ethyl and butyl alcohols were steam distilled.[9] The remaining dipotassium-disubstituted-malonate was refluxed with concentrated hydrochloric acid in 100% excess until the fatty acid layer was clear. The disubstituted acid was separated, and heated to 190° in an oil-bath.

Esterification of α,α' Dialkyl Acetic Acids.—The branched chain acids are more difficult to esterify than are normal acids. The usual procedure (refluxing with 95% ethyl alcohol containing 3% hydrochloric acid), was modified by the addition of anhydrous calcium chloride, 1.5 mols for 4 mols of water. After refluxing for twenty-four hrs., the aqueous layer was removed, and the procedure repeated. This procedure applied to a straight chain acid (as palmitic) gives 98–99% esterification, but

[a] Prepared by refluxing with acetic anhydride and sodium acetate, and distilling directly under reduced pressure. [b] Analyzed by Dr. Ing. A Schoeller, Berlin, Germany. Calculated for $C_{16}H_{34}O$: C, 79.26; H, 14.14. [c] Readings approximate. Alcohols supercool to glassy solids. [d] "I. C. T." $n^{78.9}D$ $d^{78.9}_4$. [e] Calculated saponification no. 197.5. [f] This was reacetylated and the product redistilled but without essential change. The densities of the other acetates are 0.0222 greater than those of the alcohols according to which the density of this acetate is 0.0015 low which indicates 6.8% of unchanged alcohol. The saponification number found indicates 93.2% ester. According to this the true density is 0.8542.

with the substituted acids, much poorer yields were obtained (see Table I).

Reduction.—Reduction of the distilled esters was accomplished by the Bouveault–Blanc reaction. With the exception of the α-methylpentadecylate, the reaction was very sluggish, and instead of cooling the reaction flask, it had to be heated. The yields were poor (Table I). Separation of unreduced acid from the alcohol formed by the reaction could not be accomplished in the usual way, *i. e.*, by taking advantage of the insolubility of the calcium soaps in toluene. This method of separation was effective only in the case of the α-methylpentadecylate. The calcium salts of the other branched chain acids are soluble in toluene. To effect this separation it was necessary to convert the unreduced acid into the zinc salt, during steam distillation of the solvent butyl alcohol, and then to distil the branched chain alcohol, directly, under reduced pressure. The zinc salt remains liquid, and apparently undergoes no decomposition at moderately high temperatures. It may be removed from the still, after distillation of the alcohol, and converted to the ester by refluxing with ethyl alcohol containing hydrochloric acid.

The properties of the seven branched chain hexadecanols and their acetates are compiled in Table II. The purgative qualities of the alcohols and acetates was not marked. 2-Ethyl-2-dodecylethanol-1 and 2-hexyl-2-octylethanol-1 were reported by Macht and Barba-Gosè[10] as stimulating intestinal peristalsis in rats.

Acknowledgment.—The authors wish to express their appreciation to Dr. Marie Josefa Barba-Gosè for assistance in the preparation of these materials.

Summary

Substituted ethanols of the type  $\begin{matrix}R\\R_1\end{matrix}\!\!>\!CHCH_2OH$, where R and R_1 are straight chain aliphatic residues and total 14 carbon atoms, have been synthesized and their physical properties studied.

A New Synthesis of Benzoins. 2′,4′,6′-Trimethylbenzoin

BY REYNOLD C. FUSON, H. H. WEINSTOCK, JR., AND G. E. ULLYOT

The great reactivity of the aldehyde group in α-ketoaldehydes suggested that, in the presence of aluminum chloride, these compounds might condense with aromatic hydrocarbons to give benzoins, according to the equation

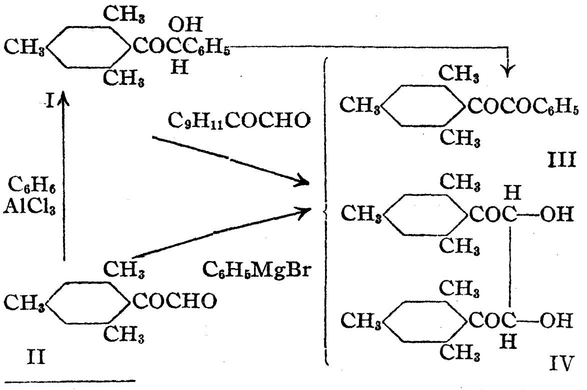
$$RCOCHO + ArH \xrightarrow{AlCl_3} RCOCH(OH)Ar$$

We have been able to show that this is a general method for the synthesis of benzoins of the type indicated. In view of the fact that the selenium dioxide oxidation method[1] has made α-keto aldehydes readily available, it is felt that the new method of preparing benzoins will prove in many instances to be superior to older methods. A detailed report of the work on this method will be published separately. The work presently reported makes use of the new synthesis in a study of the benzoin, 2′,4′,6′-trimethylbenzoin (I).

2′,4′,6′-Trimethylbenzoin (I) was not obtained when mesitylglyoxal (II) was condensed with phenylmagnesium bromide; instead, there resulted a mixture of mesityl phenyl diketone (III) and 1,2-di-(2,4,6-trimethylbenzoyl)-ethylene glycol (IV).[2] To account for this result it was suggested that the bromomagnesium alkoxide may have been oxidized to the diketone by the keto aldehyde, the latter being reduced to the bromomagnesium derivative of the glycol.

$$C_9H_{11}COCH(OMgBr)C_6H_5 + 2C_9H_{11}COCHO \longrightarrow C_9H_{11}COCOC_6H_5 + C_9H_{11}COCH(OMgBr)CH(OH)COC_9H_{11}$$

The present work has been carried out in an effort to test this hypothesis.



The benzoin is easily prepared by condensing mesitylglyoxal with benzene in the presence of aluminum chloride. It is very readily converted to the diketone by the action of oxidizing agents. In particular, it is rapidly oxidized in solution by the oxygen of the air. This ease of oxidation seems to offer a satisfactory explanation for the fact that in many attempts to synthesize the benzoin the product was the oxidation product.

Of especial interest, of course, was the action of mesitylglyoxal on the benzoin. It was found that when the benzoin is treated with mesitylglyoxal in benzene solution, reaction occurs and the diketone and the glycol are formed. This result provides an explanation of the fact that the benzoin could not be obtained from mesitylglyoxal and phenylmagnesium bromide.

Another method which was tried in the early attempts to prepare the benzoin was the action of alkali on mesityl phenyl triketone (V). De Neufville and von Pechmann[3] had found that diphenyl triketone was decomposed by alkali to give benzoin, together with benzoic acid, mandelic acid and carbon dioxide. Since we happened to have some mesityl phenyl triketone, it occurred to us that it might react with alkali to give the desired benzoin. As a matter of fact, the products which were isloated were the diketone (VI), 2,4,6-trimethylbenzoic acid (VII) and carbon dioxide.

$$\underset{V}{C_9H_{11}COCOCOC_6H_5} \xrightarrow{NaOH}$$

$$\underset{VI}{C_9H_{11}COCOC_6H_5} + CO_2 + \underset{VII}{C_9H_{11}COOH}$$

Experimental

Phenyl Mesityl Triketone.—The triketone was made by oxidation of 2,4,6-trimethyldibenzoylmethane, which was prepared by the method of Kohler and Barnes.[4] Ten grams of the diketone was dissolved in 200 cc. of commercial dioxane, and 8.2 g. of selenium dioxide was added. After eight hours of refluxing, the mixture was allowed to cool to room temperature. Hydrogen sulfide was bubbled through the reaction mixture for three hours, and then it was allowed to stand for two hours. The precipitated selenium and sulfur were removed by filtration, and a clear orange-colored solution was obtained. The dioxane was

(2) Gray and Fuson, THIS JOURNAL, **56**, 739 (1934).

(3) De Neufville and von Pechmann, *Ber.*, **23**, 3375 (1890).

(4) Kohler and Barnes, THIS JOURNAL, **55**, 690 (1933).

removed by distillation under diminished pressure; the red oil which remained underwent partial crystallization when treated with a small amount of ligroin. Fractional crystallization (from ligroin) of this material gave 2.6 g. of mesityl phenyl triketone, which is a yellow solid, melting at 90–91°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.1; H, 5.71. Found: C, 76.73, 77.04; H, 5.7, 5.96.

In addition to the triketone and a large amount of the red oil (which did not solidify and which could not be distilled) there was obtained 1 g. of an orange-yellow solid, melting at 169–170°. It contained selenium. *Anal.* Found: C, 70.84, 70.87; H, 5.39, 5.77. This compound has not yet been identified.

The Action of Alkali on Mesityl Phenyl Triketone.—Two grams of the triketone was added to 10 cc. of a 10% solution of sodium hydroxide; a reaction occurred and the solution became opaque. The triketone disintegrated, and a new solid formed which melted at 134.5–135.5°, and proved to be mesityl phenyl diketone. The alkaline filtrate was allowed to stand overnight; during this time additional small amounts of the diketone separated. These were removed by filtration, and the solution was acidified by hydrochloric acid. Carbon dioxide was identified by passing the evolved gas into a solution of calcium hydroxide. The acidification of the solution caused the precipitation of an acid which melted at 151–152°, and proved to be 2,4,6-trimethylbenzoic acid.

2 - Phenyl - 3 - (2,4,6 - trimethylbenzoyl) - quinazoline.—Five-tenths of a gram of mesityl phenyl triketone and 0.21 g. of *o*-phenylenediamine were dissolved in 4.5 cc. of hot alcohol. The orange color of the solution faded to a pale yellow, and a colorless crystalline compound separated. The product, after recrystallization from alcohol, was light yellow in color, and melted at 134–134.5°.

Anal. Calcd. for $C_{24}H_{20}ON_2$: N, 7.95. Found: N, 8.07.

2′,4′,6′-Trimethylbenzoin.—To a mixture of 26.6 g. of anhydrous aluminum chloride and 100 cc. of dry benzene contained in a 500-cc., three-necked flask immersed in water at a temperature of 10° was added 17.6 g. of mesitylglyoxal[5] dissolved in 100 cc. of dry benzene. The addition was carried out, with stirring, over a period of two hours. Stirring was continued an additional five hours at room temperature. The mixture was poured slowly into ice and concentrated hydrochloric acid. The benzene layer, containing the benzoin, was removed. The aqueous layer was extracted once with a small amount of benzene. The benzene solution was added to the main portion of the solution. The benzene was removed at 50° by evaporation at diminished pressure. Because of the ease of oxidation of the benzoin, nitrogen instead of air was admitted through the ebulliator tube. The residual yellow liquid was crystallized from 100 cc. of ethyl alcohol. There was obtained 16.1 g. of a colorless substance, melting at 97–99°. The pure compound melted sharply at 102°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.3; H, 7.08. Found: C, 79.9; H, 7.10.

Urethan Derivative.—One cubic centimeter of phenyl isocyanate was added to 0.5 g. of 2′,4′,6′-trimethylbenzoin dissolved in 20 cc. of high-boiling petroleum ether. The solution was refluxed for four hours, cooled, and filtered. There was obtained a good yield of a white crystalline substance, which, after recrystallization from petroleum ether, melted at 158.5–159°.

Anal. Calcd. for $C_{24}H_{23}O_3N$: C, 77.62; H, 6.20. Found: C, 77.33; H, 6.20.

Oxidation.—One gram of 2′,4′,6′-trimethylbenzoin was added to 40 cc. of glacial acetic acid. Dry air was bubbled through the solution for eight hours at a temperature of 50°. The solution was reduced by evaporation under diminished pressure to a volume of 5 cc., cooled, and the bright yellow solid which crystallized was collected on a filter. The yield of mesityl phenyl diketone (m. p. 133–134.5°) was 0.72 g. A mixed melting point with a known sample of mesityl phenyl diketone showed no depression.

The Action of 2′,4′,6′-Trimethylbenzoin on Mesitylglyoxal.—Five grams of 2′,4′,6′-trimethylbenzoin and 5.6 g. of mesitylglyoxal in 150 cc. of dry benzene were refluxed for four hours. The benzene was removed at 50° under diminished pressure, no ebulliator tube being used. The yellow oil remaining was dissolved in 50 cc. of ethyl alcohol, cooled, and filtered. The crude product melted at 122–127°. Treatment of this with hot, high-boiling petroleum ether left 0.35 g. of a white, insoluble substance, melting at 155–157°. Cooling of the petroleum ether solution yielded 3.6 g. of a bright yellow substance (m. p. 129–132°) which, on purification, was shown (by the mixed melting point method) to be mesityl phenyl diketone. By the same method, the white solid was found to be identical with 1,2-di-(2,4,6-trimethylbenzoyl)-ethylene glycol.

Summary

2′,4′,6′-Trimethylbenzoin was prepared by condensing mesitylglyoxal with benzene in the presence of aluminum chloride. This is a general method for making benzoins.

Attempts to prepare the benzoin by condensing mesitylglyoxal with phenylmagnesium bromide, and by decomposition of mesityl phenyl triketone with alkali, failed; in each case the product was mesityl phenyl diketone.

2′,4′,6′-Trimethylbenzoin is readily converted to the diketone by oxidizing agents.

Mesitylglyoxal oxidizes the benzoin to the benzil, being itself reduced to the pinacol.

URBANA, ILLINOIS RECEIVED JULY 29, 1935

---

(5) The mesitylglyoxal was prepared by the method of Gray and Fuson [THIS JOURNAL, **56**, 739 (1934)], who report it to be a liquid boiling at 118–119° at 12 mm. It has now been found to have a melting point of 45°.

The Application of Equations for the Chemical Potentials to Partially Miscible Solutions

BY GEORGE SCATCHARD AND WALTER J. HAMER

It has been shown[1] that an analytical expression for the thermodynamic functions is extremely valuable for the treatment of solutions containing more than two components. The method is equally valuable when the temperature varies with the composition, and is essential when one equilibrium relation is calculated from a quite different one. In the present paper this method is applied to the equilibrium between the two liquid or two solid phases of partially miscible solutions, and the results are used to calculate the liquid–vapor equilibrium when there are experimental measurements of the latter to serve as a check.

The liquid solutions which we discuss have at least one polar component, and should not be expected to obey the simple expression derived for non-polar mixtures,[2] that the free energy of mixing per mole, F_x^M, of a binary mixture is

$$F_x^M = RT\,(x_1 \ln x_1 + x_2 \ln x_2) + \beta V z_1 z_2 \qquad (1)$$

in which x_1 and x_2 are the mole fractions of the two components, V is the volume of one mole of the mixture or $x_1V_1 + x_2V_2$, the z's are the volume fractions, $z_1 = x_1V_1/V$, and β is a parameter expressing the deviations from ideality, with the further relation that βV is independent of the temperature. However, the concentrations of the two phases in equilibrium, or the fact that the chemical potential of each component must have a horizontal inflection at the critical mixing point, permit the calculation of two parameters at each temperature. We have calculated them for equations of the form

$$F_x^M - RT(x_1 \ln x_1 + x_2 \ln x_2) = F_x^E = \beta V z_1 z_2 + \gamma z_1^2 z_2 = V z_1 z_2[(\beta + \gamma/2) + \gamma(z - 1/2)] \qquad (2)$$

and also of the form to which equation 2 reduces for components of equal molal volumes

$$F_x^E = Bx_1x_2 + Cx_1^2x_2 = x_1x_2[(B + C/2) + C(x - 1/2)] \qquad (3)$$

F_x^E may be termed the excess free energy of mixing per mole.

The equations for the changes in chemical potential on mixing, μ_1^M and μ_2^M, and the excess chemical potentials, μ_1^E and μ_2^E, corresponding to equation 2 are

$$\mu_1^E = \mu_1^M - RT \ln x_1 = V_1(\beta + 2\gamma)z_2^2 - 2V_1\gamma z_2^3 \qquad (4)$$

$$\mu_2^E = \mu_2^M - RT \ln x_2 = V_2(\beta - \gamma)z_1^2 + 2V_2\gamma z_1^3 \qquad (5)$$

Those corresponding to equation 3 are

$$\mu_1^E = (B + 2C)x_2^2 - 2Cx_2^3 \qquad (6)$$

$$\mu_2^E = (B - C)x_1^2 + 2Cx_1^3 \qquad (7)$$

It will be noted that μ_1^M is RT times the natural logarithm of the activity of the first component, and μ_1^E is RT times the natural logarithm of the activity coefficient of that component.

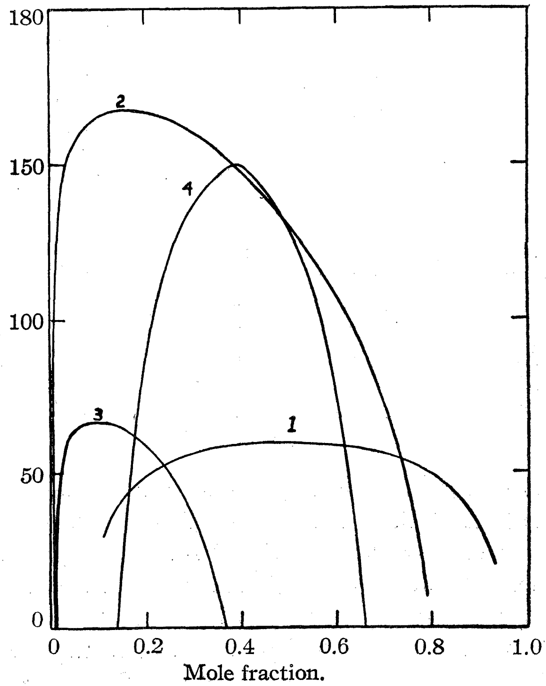

Fig. 1.—Equilibrium compositions: 1, aniline–hexane; 2, water–aniline; 3, water–phenol; 4, platinum–gold (add 1000° to t).

The magnitude of γ relative to $(\beta + \gamma/2)$ indicates the extent of the failure of equation 1 to represent the dependence on the concentration; and the change of $(\beta + \gamma/2)$ with the temperature

shows how far the solution is from regular in the sense of Hildebrand.[3] Figure 1 shows the equilibrium compositions for liquid solutions of aniline–hexane,[4] water–aniline[4] and water–phenol,[4] and for solid solutions of platinum–gold[5] (for which 1000° must be added to the temperature scale). Table I gives the mole fractions and volume fractions of the larger component in the two equilibrium solutions, and the parameters computed from them. The figures in parentheses after the names of the substances are the molal volumes in cubic centimeters at 20 or at 25°, the values used in equations 2, 4 and 5.

For aniline–hexane, equation 3 gives a much smaller asymmetry term than equation 2, but for the solutions containing water, equation 3 leads to so great asymmetry that the excess free energy of mixing is negative over a large part of the range even though the solutions are not completely miscible. Equation 2 gives about the same degree of asymmetry for each of the three liquid solutions, and the constants decrease with increasing temperature as should be expected with polar components. For platinum–gold solid solutions, the volumes are so nearly equal and are

---

[3] J. H. Hildebrand, THIS JOURNAL, **51**, 66 (1929).

[4] "I. C. T.," Vol. III, pp. 397, 389.

[5] C. H. Johansson and J. O. Linde, *Ann. Physik*, [5], **5**, 762 (1930).

measured at a temperature so far from those of the equilibrium measurements that no attempt was made to use equation 2. We note that its use would reduce the asymmetry, but by only a small amount. For this system $(B + C/2)$ is independent of the temperature over a large range, and the change at lower temperatures may well be within the experimental error. The simple theory would predict this behavior for non-polar components. Equation 3 might be expected to give the variation with composition for two isomorphous solids. The asymmetry may arise from the fact that a foreign molecule which is too large distorts a crystal lattice more than one which is too small.

Keyes and Hildebrand[6] obtain 290 mm. for the vapor pressure of hexane and 277 mm. for the vapor pressure of the two-liquid system at 40°. Using the former figure and 1 mm. for the vapor pressure of aniline, we obtain 262 mm. for the two-liquid system by equation 2, and 263 mm. by equation 3, assuming the vapors to be perfect gases. Since the vapor pressure of hexane is 15 mm. higher than that accepted for the "International Critical Tables," it is not certain that the discrepancy should be attributed to our calculations.

For water–aniline, the "International Critical Tables" give values for the composition of the vapor in equilibrium with two liquid phases from 40 to 90°, and the vapor composition and pressure for several compositions of the water-rich phase at 75°. Figure 2 shows the comparison of the first (circles) with calculations from equation 2 (full line) and from equation 3 (broken line), using the parameters determined from the liquid–liquid equilibrium. For equation 2 the discrepancy varies from 50% at 41.5° to 7% at 90°; for equation 3 the discrepancies are somewhat larger.

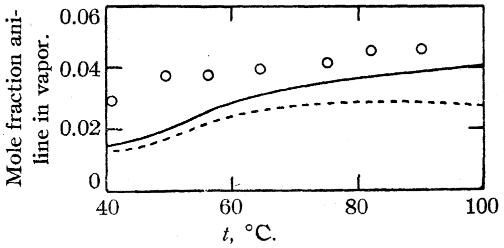

Fig. 2.—Water–aniline, two liquids: full line, equation 2; broken line, equation 3; circles, observed.

Figure 3 shows the vapor pressure and the vapor composition at 75° as a function of the liquid composition, with calculations from equation 2 only. The agreement of the vapor compositions is excellent, except for the saturated solution. The calculated pressures are consistently 2% lower than the measured values. It should be noted that the condensate is two-phase in almost all these measurements, and that the experimenter (Schreinemakers) claimed no great accuracy.

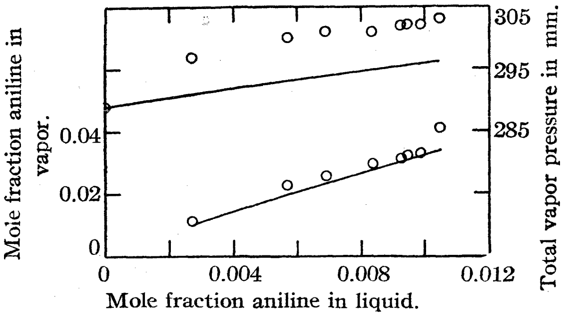

Fig. 3.—Water–aniline, 75°: above, total vapor pressure; below, mole fraction aniline in vapor.

For water–phenol there are measurements of the composition and pressure of the vapor in equilibrium with two liquid phases from 15 to 68.5°, and measurements over the whole composition range at 56.3[7] and at 58.4°.[8] The calculations require the vapor pressure of liquid phenol (supercooled through much of the range) and no measurements were found. The values found were obtained by extrapolating the "I. C. T." equation valid from 116 to 180°. Figure 4 shows the vapor composition and pressure of the two-liquid system as a function of the temperature. The agreement of equation 2 is apparently well within the uncertainty in the vapor pressure of phenol. Equation 3 leads, however, to absurd results for this system, as might be expected from the large values of the parameters.

The vapor compositions and pressures were calculated at 57.5°, and compared with the measured values at the two neighboring temperatures. For this comparison the measured pressures were multiplied by the ratio of the vapor pressure of water at 57.5° to its vapor pressure at the temperature of the measurements. The vapor composition is shown as the logarithm of the "relative volatility," α.

$$\log \alpha = \log (y_2x_1/y_1x_2) = \frac{(\mu_2^E - \mu_1^E)}{2.3RT} + \log (P_2/P_1) \quad (8)$$

in which y_1 and y_2 are the mole fractions in the vapor, and P_1 and P_2 the vapor pressures of the pure components. The comparison is shown in Fig. 5, with the liquid composition expressed as weight fraction, rather than mole fraction, to give a better distribution of the points. The broken line for log α is that obtained by increasing log P_2 by 0.1. The agreement with the experiments appears to be within this range, which is probably smaller than the experimental error.

Recently Guggenheim[9] has criticized the use of such equations, particularly that to which equation 1 reduces when the molal volumes are equal

$$F_x^E = Bx_1x_2 \tag{9}$$

for solutions which deviate so widely from ideality as to be only partially miscible on the ground that these equations neglect the deviations from random distribution. There is no doubt about the basis of his criticism, but there is reason to believe that the equations used in this paper agree better with the behavior of actual systems than the approximate treatment offered by Guggenheim (equation 21). We may compare this equation with equation 9 if we assume that each molecule is in contact with twelve others, as in closely packed crystals. The upper curves in Fig. 6 show the equilibrium temperature divided by the critical mixing temperature as a function of the composition for a regular solution obeying equation 9 (B independent of the temperature) as a full line, and for Guggenheim's equation 21 as a broken line. The lower curves in this figure show, as functions of the composition, $-[x_1 \ln x_1 + x_2 \ln x_2]$; $F_x^E = H_x^M$ for the critical mixing isotherm according to equation 9; F_x^E according to Guggenheim; and H_x^M according to Guggenheim.

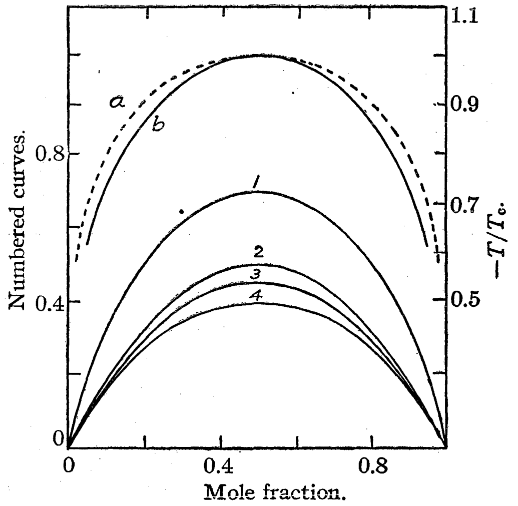

Fig. 6.—Comparison with Guggenheim's equation: a, equilibrium compositions by Guggenheim's Equation 21; b, equilibrium compositions by Equation 9; (1) $-[x_1 \ln x_1 + x_2 \ln x_2]$; (2) $F_x^E = H_x^M$ at T_c, Equation 9; (3) F_x^E at T_c, Guggenheim's Equation 21; (4) H_x^M at T_c, Guggenheim's Equation 21.

---

[9] E. A. Guggenheim, *Proc. Roy. Soc.*, (London), **A148**, 304 (1935).

F_x^M is given by the difference between the second, or third, curve and the first.

From the upper curves we see that Guggenheim's equation fits most partially miscible liquids better than equation 9 in that it is somewhat flatter, but there is no assurance that this is not a coincidence and that B should not actually decrease with increasing temperature because of polarity, giving rise to a flatter curve than that corresponding to equation 9. The platinum–gold system, which should correspond closely to the model used by Guggenheim, shows little or no flattening. In any case most systems deviate from equation 9 much more seriously through their lack of symmetry than through their flatter maxima.

The lower curves show that the difference between the two treatments is not very great, and that the modification introduced by Guggenheim is probably in the wrong direction, for the second curve is independent of the temperature but the third and fourth increase with increasing temperature with the second curve as limit at infinite temperature. Experimentally it is found, even with non-polar mixtures, that when any variation of F_x^E with temperature can be detected it is a decrease and not an increase, and that whenever F_x^E and H_x^M have both been measured the second is larger than the first. We believe that Guggenheim's approximation, in addition to its failure to represent the asymmetry of most real systems, gives much too large an effect of the deviation from random distribution.

Summary

Equations for the free energy of mixing are computed from the mutual solubilities of partially miscible substances, and the vapor compositions and pressures computed from these equations are compared with the experimental measurements with good agreement.

Guggenheim's treatment is discussed and found less satisfactory than the simpler one given here.

The Application of Equations for the Chemical Potentials to Equilibria between Solid Solution and Liquid Solution

BY GEORGE SCATCHARD AND WALTER J. HAMER

The method of determining the composition of liquid and solid phases in equilibrium at each temperature from the melting points and heats of fusion of the components when both solutions are ideal, or when the activity coefficients are known, has been developed by Seltz.[1] His treatment of the activity coefficients is, however, completely qualitative. Analytical expressions for the chemical potentials[2] permit a consistent treatment of such equilibria. From the compositions of the two phases at equilibrium it is possible to calculate two parameters, one of which may be attributed to each solution. The accuracy of the experimental measurements, which are carried out at constant composition and not at constant temperature, does not warrant the calculation of these constants at each temperature, but the solutions may be treated as regular and the parameters calculated at one temperature may be used to compute the equilibrium compositions at other temperatures. Since the molal volumes of the metals at the equilibrium temperatures are not well known and are not very different, we have expressed the excess free energies of mixing in terms of mole fractions rather than volume fractions.

For the liquid solution the changes on mixing of the free energy per mole and of the molal chemical potentials are

$$F_x^M = RT(x_1 \ln x_1 + x_2 \ln x_2) + Bx_1x_2 \quad (1)$$

$$\mu_1^M = RT \ln x_1 + Bx_2^2 \quad (2)$$

$$\mu_2^M = RT \ln x_2 + Bx_1^2 \quad (3)$$

Similar equations would apply to the solid solutions, but we need the change in these functions in going from the two liquid components to the solid solutions, which functions we shall designate with primes.

$$F_x^{M'} = x_1L_1(T/T_1 - 1) + x_2L_2(T/T_2 - 1) + RT(x_1 \ln x_1 + x_2 \ln x_2) + B'x_1x_2 \quad (4)$$

$$\mu_1^{M'} = L_1(T/T_1 - 1) + RT \ln x_1 + B'x_2^2 \quad (5)$$

$$\mu_2^{M'} = L_2(T/T_2 - 1) + RT \ln x_2 + B'x_1^2 \quad (6)$$

---

(2) G. Scatchard and W. J. Hamer, *ibid.*, **57**, 1805 (1935).

For approximate work we have found the method of Gibbs[3] more convenient than that of Seltz, although the latter would be preferable for exact calculations. Gibbs' method is to plot F_x^M and $F_x^{M'}$ against x_2 at each temperature, draw the common tangent and read the points of tangency as the composition of the respective phases. It is necessary to determine the two parameters by trial and error, so that some general conclusions may be noted. If $B = B'$ the liquidus and solidus will each approach asymptotically at each end the corresponding curve for ideal solutions, but they will deviate from the ideal curves in the middle unless B and B' are zero: if the parameters are positive the curves will spread outside (liquidus above, solidus below) the ideal curves; if the parameters are negative both curves will lie between the two ideal curves. If the parameters are unequal both curves will be displaced from the ideal toward the region which has the more positive parameter: if B' is more positive than B, the curves will be lowered and may give a minimum if the difference is great enough; if B' is more negative both curves will be raised and may give a maximum. The separation of the two curves will increase as the average of B and B' becomes more positive. The application of the method is illustrated for two systems.

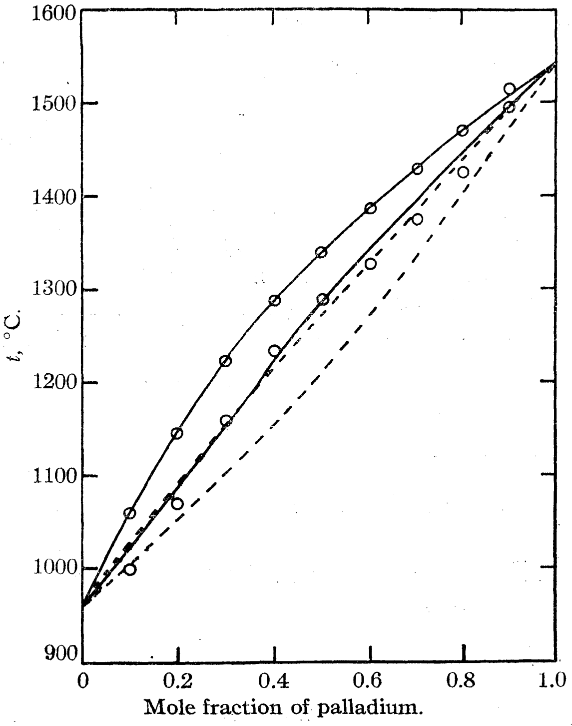

Fig. 1.—Silver–palladium equilibrium compositions: broken line, ideal; full line, equations 1 and 4; circles, observed.

Figure 1 shows the silver–palladium system, calculated with 2628 and 3822 cal. per mole for the heats of fusion of silver and palladium, respectively, and $B/2.3R = +83.93$; $B'/2.3R = -52.85$. The agreement with the liquidus is excellent. The parameters were chosen to fit the solidus near the middle of the temperature range, and miss some of the points as much as 25°. They obviously could have been chosen to give a better average fit over the whole curve, but it is not at all certain that the solidus curve is determined experimentally any more accurately than the present agreement. The figure shows definitely that a much more complicated equation would be required to give as pronounced a hump in the solidus curve as the experimental results indicate. The broken lines are the ideal curves.

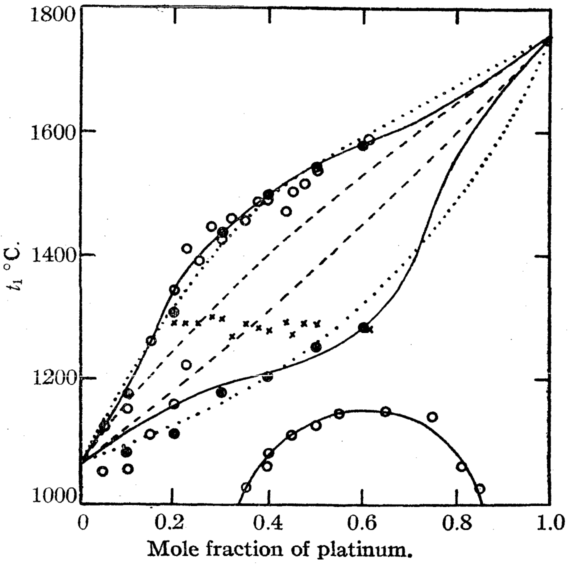

Fig. 2.—Gold–platinum equilibrium compositions: – – –, ideal; . . . . , customary curves ——, equations 1 and 4; ●, Doerinckel; ○, Grigorjew (liquidus and solidus); ×, Grigorjew (three phase); lower curve and circles, solid–solid equilibrium.

Figure 2 shows the gold–platinum system, calculated with 3130 and 5250 cal. per mole for the latent heats of fusion of gold and platinum, respectively, and $B/2.3R = +1155.5$; $B'/2.3R = +1164.6$. The top of the solid–solid equilibrium curve is also shown. The broken lines are those calculated for ideal solutions, and the dotted lines are the lens shaped pair usually drawn

---

(3) J. W. Gibbs, "Collected Works," Longmans, Green, and Co., New York, 1906, p. 118.

from the measurements of Doerinckel,[4] which are represented by the black circles. The open circles represent the measurements of Grigorjew[5] of the liquidus and solidus, and the crosses represent his supposed equilibrium between two solids and a liquid. Our curves (full line) fit the liquidus and solidus at least as well as the usual curves. (Failure to obtain equilibrium should give too low a solidus.) They probably explain also the observations of Grigorjew, whose own explanation is certainly wrong.[6] The solidus curve is so flat from 1300 to 1200° that most of the remaining liquid solidifies in so small a temperature range that he interpreted it as an isothermal transition.

Since $B'/2R = 1340$, it indicates partial miscibility below 1340°A. or 1067°C., with the critical mixing composition fixed at the equimolal mixture by the nature of the equation. The experimentally observed critical mixing point is at 1150° and 60 mole per cent. platinum. Those forces, neglected in our equations, which displace this point from 50 to 60 mole per cent., might well raise the temperature 5 or 6%. The agreement may be considered a very good confirmation of the approximate accuracy of our treatment.

We attempted to apply the same method to the manganese–cobalt system, which shows a minimum melting point. In equilibria between two different states of aggregation, the temperature of a minimum or maximum gives only the difference between B and B', and the composition at the minimum or maximum is determined from the transition temperatures and heats of the components. Unless the heats of fusion in the literature are in error by more than their rather wide scattering, B–B' for this system decreases rapidly with increasing temperature, or with increasing cobalt concentration, and our equations are quite inadequate.

Seltz believed that "A phase diagram with liquidus curve displaced above the ideal and with solidus displaced below is shown to require the existence of very unusual activity curves," but we have reproduced such a diagram for the gold–platinum system accurately with equations corresponding to the simplest form of non-ideal curves. The discrepancy arises because Seltz makes the comparison between the deviations of the two components in each solution rather than between the deviations of each component in the two solutions. Such a phase diagram may result if the deviation of the higher melting component is more positive in the liquid than in the solid, and the deviation of the lower melting component is more positive in the solid than in the liquid. Since the solid solution is at every temperature richer in the higher melting component and poorer in the lower melting component than the liquid, this criterion is not hard to satisfy if the deviations are all positive.

Summary

Simple equations for the change in chemical potentials on mixing are applied to the equilibria between solid and liquid solutions of the silver–palladium and the gold–platinum systems, and some general conclusions are noted.

The Catalytic Decomposition of Nitramide in Acid and Salt Solutions[1]

BY CHARLES A. MARLIES AND VICTOR K. LA MER

Introduction

Brönsted developed his important theory of generalized basic catalysis from his kinetic studies of the reaction

$$NH_2NO_2 \text{ (nitramide)} \longrightarrow H_2O + N_2O^2$$

The reaction proceeds to completion without the complications of side reactions or any change in environment in aqueous systems[2b,3,4,5,6,7,8] and may be followed by physical means. The simplicity of the products and the sensitivity of the reaction to catalytic influence renders it particularly valuable for elucidating the theory of chemical kinetics in its various aspects, especially protolytic reactions. However, the difficulties of preparation and storage of nitramide have prevented the exhaustive investigation which the reaction deserves. A study of the preparation and the measurement of the decomposition of nitramide was accordingly undertaken to render this desirable reaction more conveniently available for kinetic investigations.

When this study was begun in 1929, the published work of Brönsted and his students[2b,4,5] showed that the decomposition of nitramide exhibited only generalized base catalysis, without appreciable primary salt effect. On the other hand, the other two well-established examples of generalized base catalysis, namely, the mutarotation of glucose[9] and the acetone–iodine reaction,[10] exhibited generalized acid catalysis as well. Other objectives were consequently the search for and the exact investigation of an acid catalysis and a salt effect for the nitramide reaction.

Using ordinary technique and methods of purification, an acid catalysis was quickly discovered, but the velocity constants obtained in duplicate experiments showed wide variations (5–10%). This same range of values was obtained by Brönsted and his students in their work on nitramide, but was by no means precise enough for the purpose, due to the small magnitudes of the acid and salt constants. By refining the technique the deviation from the mean was reduced to less than 1%. The first group of experiments (42 in number) in which the precision technique was not used and for which the variation in results was considerable are not reported.

Surprisingly few reactions even in solution have been measured within 1%. Furthermore, in practically all these cases a chemical method of following the reaction was used, which is surprising in view of the many advantages of physical methods.

A few experiments were made in low concentration of deuterium oxide (heavy water) and a marked decrease in rate was found (February, 1934). Further investigation in heavy water should throw light on the mechanism of the decomposition, which is still not certain, and the catalytic action of deuterium.

Materials

Nitramide.—Several modifications were made of the synthesis described by the discoverers, Thiele and Lachman.[3] The most important involves the manner of extraction of the nitramide from the aqueous solution in which it is made.[11] Other attempted methods of preparation, such as addition of silver nitrite to chloramine (explosion occurred) or addition of hydrogen chloride to an ether suspension of potassium nitrocarbamate, resulted in little or no yield of nitramide.

Further purification[5] of the nitramide produced no change in the velocity constants. The nitramide was stored in an open vessel in a desiccator over phosphorus pentoxide in the refrigerator. The desiccator was always brought to room temperature before opening to prevent condensation of moisture on the inside. The nitramide was handled exclusively in glass or bright platinum, as it attacks brass and other base metals.

Water.—Conductance water, prepared so as to ensure the absence as far as possible of all bases, *e. g.*, carbonates, silicates, etc., was used. In the last two distillations scrap platinum was used to prevent bumping, and the distillate was collected hot, a large proportion being allowed to escape as steam. The final distillation was from a quartz still.

Hydrochloric Acid.—Constant boiling hydrochloric acid was prepared from specially purified reagents. The con-

centrations of acid were calculated from Bonner and Wallace's tables.[12]

Potassium and sodium chlorides were recrystallized from laboratory distilled water, constant boiling hydrochloric acid and conductance water. The dried salt was fused in a platinum crucible, the melt poured onto a wide platinum dish, broken up and bottled while hot.

Nitrous oxide, stated by the manufacturers[13] to contain 2% nitrogen as the only significant impurity, was passed in succession through sodium hydroxide solution, ferrous sulfate–sulfuric acid solution, water and a dense cotton plug.

Solutions.—Solutions were made up by weight to avoid contact with soft glass (ordinary calibrated) volumetric containers, using such precautions that the error in the concentration of the solutions was probably less than 0.01%. In most cases, at least one dilution of each solution was made. Analyses of the diluted solutions showed a maximum error of 0.1%, always in the direction of greater concentration, which is ascribed to evaporation during handling. Purified nitrous oxide was passed into the solutions through a quartz delivery tube.

Solutions more acid than 0.05 *M* were stored in quartz, and the more dilute in non-sol bottles, which were proved satisfactory for the purpose.

Apparatus and Experimental Procedure

The apparatus and method were similar to those used by Brönsted and his students[4,14] with some changes in design and procedure. The solution was shaken in a flask of about 200 ml. capacity and the rate of shaking was adjusted to the resonance period to give maximum agitation; for the same reason the flask was half filled with solution. The flask was closed by a ground glass stopper with a mercury seal. By regrinding the surfaces with levigated alumina and rubbing with Acheson graphite (99.9%), the ungreased joint held a vacuum of less than 1 mm. for several weeks.

The spiral connecting the flask to the manometer system was 3-mm. o. d. Pyrex tubing bent to permit a 2–3 cm. horizontal displacement of the flask. The manometer capillary, made of 1 mm. i. d. tubing, was not graduated itself, since Pyrex cannot be etched accurately, but was surrounded by a soft glass jacket, graduated from 0 to 18 cm. in 0.1 with a maximum error of 0.01 cm. The space between the jacket and the manometer tube was filled with very dilute hydrochloric acid to magnify the meniscus, the acid keeping the glass bright. The mercury reservoir was 5 cm. in diameter so that the maximum movement of the mercury in the manometer produced a fall in level in the reservoir of 0.01 cm. A mercury lubricant composed of dibutyl phthalate saturated with mercury-*p*-ditolyl[15] prevented sticking of the mercury column. The manometer and a very small part of the adjacent gas space were the only portions of the apparatus not immersed. No distillation into this space was observed at any time.

The space over the mercury column was evacuated to the lowest pressure possible with a Hy-Vac pump, because an appreciable pressure in this space would have necessitated a correction for change of room temperature during the run. No leakage into this space occurred over a period of months.

After introduction of the solution, the system was evacuated for two minutes while shaking, then carbon dioxide-free air admitted through a soda lime tower to the flask, the charge of nitramide (approximately 130 mg. = 0.002 mol.) added and the evacuation repeated. The procedure of double evacuation was followed, so that the entire system could be checked before the nitramide was introduced, and to ensure complete removal of the carbon dioxide. After five minutes of the second evacuation, the stopcock to the pump was closed and readings of pressure taken at ten-minute intervals.

In the absence of pretreatment with nitrous oxide, it was found that one to two hours were necessary before the readings could be used, probably due to the expulsion of dissolved air and traces of carbon dioxide by the nitrous oxide being formed. Using solutions containing nitrous oxide reduced this period to twenty or thirty minutes.

Occasionally the manometer temperature during the end-point reading or during the second set of readings (Guggenheim method) was sufficiently different to necessitate a correction for the expansion of the mercury, which never exceeded 0.01 cm. The Beckmann thermometer was compared with a platinum resistance thermometer calibrated by the Bureau of Standards, and with a *verre dur* thermometer calibrated by the International Bureau of Weights and Measures. The temperature of the thermostat[16] was controlled to within 0.01°. During the summer months artificial cooling was obtained by an electric fan directed on the surface of the bath and thrown into circuit on the cooling cycle, by means of a four pole Mercoid switch mounted on the relay of the regulator.

Calculations and Precision

The decomposition follows accurately the unimolecular law

$$k = (1/t) \ln (C_0/C) \qquad (1)$$

The final pressure measures the initial concentration of nitramide C_0. Since

$$C \sim (p_\infty - p);\ \ln (p_\infty - p) = \text{Const.} - kt \qquad (2)$$

or

$$\log (p_\infty - p) = \text{Const.}^* - k^*t \qquad (3)$$
$$\text{where } k^* = 0.4343k$$

Duplicate experiments under various conditions showed that this equation applies accurately. They also indicate that large indeterminate errors, such as effect of dissolved glass, etc., were absent.

Methods of Calculation.—In equation (3) the error in p_∞ exerts a greater influence than do the errors in the various p's. Guggenheim[17] avoids this source of error by taking two complete series of readings, separated by a constant time. However, the Guggenheim method need only be

used when the end-point reading is known with no more, or even less, accuracy than the other readings. In the present experiments, the end-point reading was observed over a long period of time (two to three hours), the reading being sometimes repeated on successive days; consequently it was more precise than any other observation. In check experiments the two methods gave the same results and the same deviation in k; consequently the one chosen for any particular experiment was dictated by convenience.

Guggenheim[17] suggests plotting log $(p'-p)$ against t, where p' refers to the reading in the second set corresponding to the reading p in the first set of observations. However, as Birge[18] has pointed out, graphical methods "give no objective criterion for the error. . . .They are never as accurate as an analytic method, and have no unique solution. . . .One of the most fundamental rules of computing is that the error introduced by the calculation itself shall be negligibly small, compared to the probable experimental error. A graphical solution obviously fails to satisfy this criterion." Although a direct plot and deviation line may be used as directed by Goodwin,[19] this involves considerable work with no certainty that the best solution has been obtained, unless several deviation plots are made.

An especially simple analytic method, if the observations are separated by equal time intervals, has been suggested by Roeser.[20] Applying this method to equation (3)

Let r = log $(p_\infty - p)$
m = number of values of r
i = interval between successive values of r (10 min.)

$$\text{Therefore } k^* = \frac{6}{im(m+1)\,(m-1)}\Sigma \qquad (4)$$

where $\Sigma = (m-1)\,(r_m - r_1) + (m-3)\,(r_{m-1} - r_2) + \ldots$

This method is based on the principles of least squares, where all the values r are of equal weight. It is of striking mathematical simplicity in contrast to other schemes.[21]

Errors.—In the construction of the apparatus and calculation of results, the following sources of errors received consideration: (1) assumptions in equation (2) leading to non-linearity of relationship between pressure change and concentration—(a) deviations from Henry's law; (b) deviation from Boyle's law; (c) change in volume of the gas space due to movement of mercury into manometer; (2) errors of apparatus and measurement—(a) non-uniformity of manometer bore; (b) temperature of manometer; (c) error in reading pressure; (d) supersaturation; (e) timing; (f) temperature of thermostat; (3) concentration of the solutions; (4) equality of the weights of the different points r.

Nitrous oxide[22] follows Henry's law in aqueous solution within the error of measurement, which was 0.25%. The assumption that this is the maximum deviation from Henry's law leads to only 0.07% error in equation (2) for the present apparatus. The error increases with increasing ratio of liquid to gas space and equals $(3.9 + 6.7\ V_g/V_1)^{-1}\%$. In the present case this ratio was 1.5. Nitrous oxide deviates from Boyle's law but in the low pressure range pV is a linear function of the pressure. This corrects equation (2) to

$$C \sim (p_\infty - p)/[1 - A(p_\infty + p)] \qquad (5)$$

where A = 0.0055/atm. at 25°.[23] The maximum correction amounted to 0.07% $(r_m - r_1)$ and was smaller for the succeeding terms of the series Σ.

On correction for error 1 c, eq. (2) becomes

$$C \sim (p_\infty - p)\ [1 + (p_\infty + p - p_1)\pi D^2/4V_g] \quad (6)$$

where p_1 is first reading used in the calculation and D is diameter of manometer capillary. The maximum correction was 0.04% $(r_m - r_1)$ and was smaller for the succeeding terms of the series Σ

Errors 2a, b and c produced a probable effect of 0.02 cm. This resulted in an error of about 0.5% $(r_m - r_1)$ which was about the same for all the terms of the series Σ. The error changed but slightly with the individual values of r, ranging from *ca.* 0.2% for r_1, to *ca.* 0.3% for r_m.

Pedersen[24] has shown that supersaturation merely invalidates the early readings; after a sufficient induction period, the usual graph of log $(p_\infty - p)$ has the same slope as though supersaturation were absent, provided the rate of stirring is kept constant. Experiments showed the maximum induction period to be four minutes. Error 2d is not present.

Error 2e was 0.02%, the maximum deviation of the watch from a frequency controlled standard. Error 2f amounted to 0.12% of k, based on E_{act} equal to 190 × 10^2 cal. Even at the highest concentration of salt used (2.9 M sodium chloride), error 3 was less than 0.1% k.

[23] Cawood and Patterson, *ibid.*, 619 (1933).

[24] Pedersen, THIS JOURNAL, **49**, 2681 (1927).

The various errors discussed above have different effects on the weights of the various r's. However, the only significant error is in the measurement of pressure and it has about the same effect on the various r's, the range being 0.2–0.3%. Therefore, all the points have about the same weight, justifying the above application of the method of least squares (*cf.* Roseveare[25] and Luten[26]).

Precision of the Data.—Since the various errors are present to the same extent in all experiments the deviation from the mean can be obtained by an analysis of the results of a large set of duplicate experiments. The results are given in Table I for 0.01 M hydrochloric acid (k^* is given in min.$^{-1}$, M in mole/kg. and C in mole/liter).

TABLE I

Expt.	$k^*_{obs.}$	Wt.	d
95	0.001187	16	0.000051
97	1243	13	5
144	1239	10	1
148	1234	14	4
189	1249	14	11
191	1235	11	3
220	1233	20	5
222	1236	18	2

Discarding the first value, the weighted mean is 0.001238, the weighted a. d. is 0.000005 and the % d. is 0.4; the maximum variation of the individual values is 1.3%. In 0.5 M hydrochloric acid a greater variation (2.2%) was obtained: $k^* = 0.001251$; a. d. = 0.000009; % d. = 0.7; $n = 7$ (number of duplicate experiments). Since this a. d. was the largest observed, the diameters of the circles in Figs. 1 and 2 were chosen equal to $0.000009/\sqrt{n}$. In averaging experiments the rate constants were given weights equal to the number of observations used for their calculation.

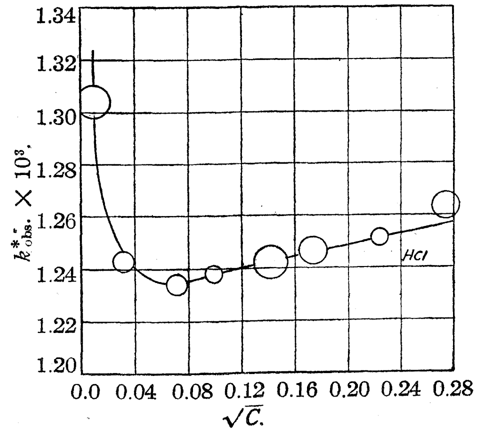

Fig. 1.

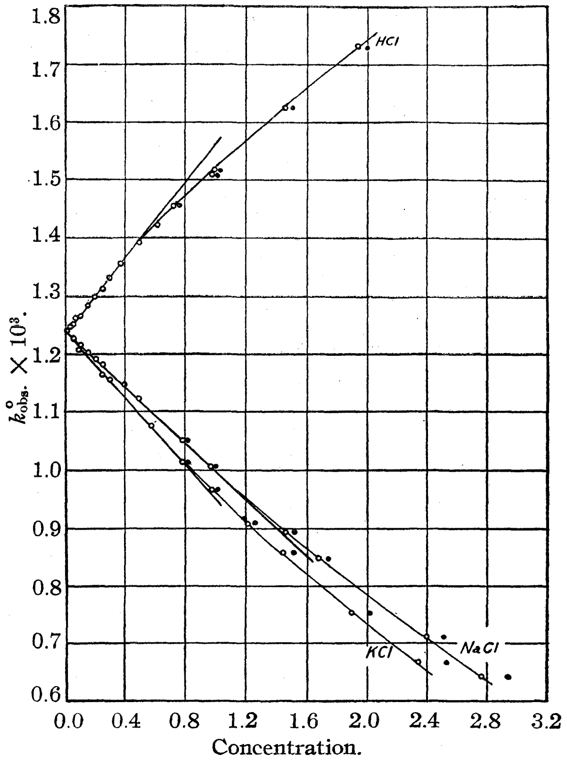

Fig. 2.—Above 0.7 molar: ○, molarity; ●, molality.

After adoption of the precision technique, only 9 values of k in some 180 were rejected and in *all* cases the rejected k's were *lower* than the means of their duplicates, which would be the case if there were a slight leak into the apparatus during the experiment. Since two stopcocks had to be turned to start any experiment and since the apparatus was under vacuum during the entire time (six days in some cases) the occasional occurrence of slight leaks is not surprising. The value of k is sensitive to leaks, as the deviation from the mean of the rejected experiment (No. 95) on 0.01 molal hydrochloric acid can be accounted for by the admission of sufficient air to increase p_∞ by 0.15 cm.

Suggested Improvements in Design.—1. Lengthened manometer tube. This will decrease the effect of the most important error—measurement of pressure. 2. Elimination of all stopcocks in the gas phase. 3. Immersion of the manometer into the thermostat to obviate correction for its temperature change. 4. Decrease of the gas to liquid ratio to enable the use of

---

(25) Roseveare, THIS JOURNAL, **53**, 1651 (1931).

(26) Luten, *J. Phys. Chem.*, **39**, 199 (1935).

smaller charges of nitramide, thus compensating for the lengthened manometer tube, which would require larger charges of nitramide.

Data

A typical experiment is given in Table II.

TABLE II

EXPT. NO. 191, HCl 0.01000 M, $p_\infty = 15.47$

t	p	$p_\infty - p$	Log $(p_\infty - p)$	k^*
10	4.59	11.18	1.0484	0.00122
20	4.60	10.87	1.0362	121
30	4.90	10.57	1.0241	121
40	5.19	10.28	1.0120	124
50	5.48	9.99	0.9996	124
60	5.76	9.71	.9872	122
70	6.03	9.44	.9750	122

The results of sets of experiments at various concentrations are given in Tables III, IV, V and VI. The densities required for the conversion from molality to molarity were taken from "International Critical Tables"[27] or calculated by the rule of mixtures which has been shown to hold for aqueous solutions of hydrochloric acid, sodium chloride and potassium chloride.[28]

In the hydrochloric acid solutions (Fig. 1) the velocity constant reaches a minimum between 0.001 and 0.005 M. The square root of the concentration has been used to magnify the scale at very low concentrations. The values for the extremely dilute acid solution (10^{-5} M hydrochloric acid) drifted continuously during the course of the experiments from an initial value of 0.0013 to 0.0015 when half completed, the average value being about 10% greater than that for 0.01 M hydrochloric acid, which is identical with the 10% increase found by Brönsted and King[5] for the velocity of decomposition in "pure water" over that in "acid" solution at 15°. However, their claim that the deviations from the unimolecular course were not measurable if the observations were confined to the first two-thirds of the reaction was not confirmed, due we believe to the greater precision of our measurements.

The observed k^*'s of Tables III, IV, and V at concentrations greater than 0.005 M are plotted in Fig. 2 against both molarity and molality, the differences being greater than the experimental error above 0.7 molar. For simplicity the curves connecting the molality values have not been drawn. Similarly, to avoid confusion, points and curves of $k^*_{\text{obs.}}$ *vs.* mole fraction have not been added; they lie between the molarity and molality points but nearer the molarity values. It appears that for this reaction a linear relation holds to a slightly higher concentration for the molarity scale.

The velocity constant may be considered as composite: $k = k_0 + k_s C_s$ (7) where k_0 = spontaneous velocity constant (water reaction), k_s = velocity constant for S (acid or salt), and C_s = concentration of S. Extrapolating the hydrochloric acid curve to zero concentration

$$k^*_0 = 1.235 \times 10^{-3}$$

The limiting slopes in Fig. 2 and the concentrations over which they are valid

$k^*_{\text{HCl, obs.}} = + 0.328 \times 10^{-3}$ from 0 to 0.4 molar

$k^*_{\text{NaCl, obs.}} = - 0.245 \times 10^{-3}$ from 0 to 1.0 molar

$k^*_{\text{KCl, obs.}} = - 0.291 \times 10^{-3}$ from 0 to 0.8 molar

Water Correction

k_0 is the velocity constant due to the catalysis by water and equals $k_w C_w$. At 24.84° the molar catalytic constant for water is $k^*_w = 0.02231 \times 10^{-3}$. For high concentrations of acid and salt it cannot be assumed that C_w has a constant value of 55.51 m./l. Accordingly, equation (7) is more properly written $k = k_w C_w + k_s C_s$ and correction should be made for the reduced concentration of water as acid and salt are added. Furthermore, in the hydrochloric acid solutions, the proton exists as H_3O^+, still further decreasing the water concentration. Accordingly

$k_{\text{corr.}} = k_{\text{obs.}} - k_w C_w$ for the HCl solutions

$k_{\text{corr.}} = k_{\text{obs.}} - k_w C_w - k_{\text{H}_3\text{OCl}} C_{\text{H}_3\text{OCl}}$ for the NaCl and KCl in 0.01 M HCl solutions

The recalculated results are given in the last columns of Tables III, IV and V; the corrected k's have been plotted against the molarities. The limiting slopes and the concentrations over which they are valid

$k^*_{\text{H}_3\text{OCl, corr.}} = +0.367 \times 10^{-3}$ from 0 to 0.4 molar

$k^*_{\text{NaCl, corr.}} = -0.213 \times 10^{-3}$ from 0 to 1.4 molar

$k^*_{\text{KCl, corr.}} = -0.251 \times 10^{-3}$ from 0 to 0.8 molar

Miscellaneous Experiments

Heavy Water.—Some experiments were conducted with a solution of heavy water containing 4.72 mole per cent. of D_2O (d_{25} 1.00213 g./ml.). To ensure proper purification, a specimen of ordinary water purposely contaminated with potassium hydroxide, rubber and laboratory sweepings was purified at the same time and concurrent experiments carried out with both specimens. In the distillations the liquids were heated to dryness in the stills and the sprayhead and condenser flamed to remove the last traces of water, which was necessary to avoid waste and isotopic separation during the purification. The receivers were kept in freezing mixtures during the distillations. The samples were redistilled five times at atmospheric pressure from various purifying agents and finally in a special two-flask apparatus by vaporization *in vacuo*. The vacuum was broken with purified nitrous oxide and the distillates poured into tared non-sol bottles. By means of a micro weighing buret, a few drops of constant boiling hydrochloric acid was added to make the solutions 0.01 *M* in hydrochloric acid. After one experiment, without withdrawing the solution, an additional charge of nitramide was added and a second experiment carried out. Then the proper amount of potassium chloride was added to make the solutions 1 *M* in potassium chloride and two more experiments performed. The results are given in Table VII.

TABLE VII

Solution	Expt.	$k^*_{\text{obs.}}$	Wt.	Mean
0.00982 *M* HCl in 4.72% D_2O	181	1.174×10^{-3}	35	1.176×10^{-3}
	183	1.178	29	
0.00976 *M* HCl in H_2O	182	1.246	35	1.249
	184	1.252	29	
0.00982 *M* HCl + 1.000 *M* KCl in 4.72% D_2O	185	0.923	29	0.919
	187	.915	26	
0.00976 *M* HCl + 1.000 *M* KCl in H_2O	186	.976	29	0.971
	188	.966	26	

It is evident that the method of purification was adequate. The mean for the 0.01 *M* HCl in H_2O is 0.9% higher, and the mean for the 0.01 *M* HCl + 1 *M* KCl in H_2O is but 0.4% higher than those for the corresponding solutions made up by the usual method.

The velocity constant for 0.01 *M* HCl in 4.7% D_2O is 5.8% lower, and the velocity constant for 0.01 *M* HCl + 1 *M* KCl in 4.7% D_2O is 5.2% lower than those for the corresponding H_2O solutions. An investigation of this striking result is in progress.

Mercuric Chloride.—While studying the effect on the reaction velocity of all possible substances in the system, mercury, mercurous chloride and mercuric chloride were tried. The first two had no effect, but the last showed a marked positive catalysis. In 0.01 *M* HCl + *ca.* 10^{-5} *M* $HgCl_2$, k^* was 2×10^{-3}, an increase of 75% over that in the same solution without the mercuric chloride. This effect is probably related to the molecular rather than ionic nature of mercuric chloride in solution and merits further investigation.

Discussion

Comparison with Previous Work.—Contrary to the earlier published findings from Brönsted's laboratory, a marked primary salt effect and an appreciable acid catalysis were found. On communication of these results, Professor Brönsted disclosed the following values of the velocity constant[29] obtained at 15° in potassium chloride solutions containing a little hydrochloric acid.

C_{KCl}, m./l.	1.00	1.50	2.00
k^*	31.85	27.90	24.50×10^{-5}

They show the same negative salt effects reported here.

After this study was initiated in 1929, Brönsted and Vance[7] reported an acid catalysis in isoamyl alcohol. The molar catalytic constant found was approximately the same for both hydrochloric and hydrobromic acids, which they ascribe to the ion $C_5H_{11}OH_2^+$. For 0.1 *M* this acid effect was about 100 times larger than the spontaneous reaction. Brönsted and his students have not found an acid catalysis in aqueous solution due to the restricted acid range in which they worked, the lower precision of their measurements and the relatively small magnitude of the effect.

Salt Effect.—The action of added salt on the decomposition of nitramide is undoubtedly a primary salt effect upon the catalysis by water. The effect is large amounting to an 18% decrease for 1 molar sodium chloride and 22% for 1 molar potassium chloride.

Of the reactions subject to generalized base catalysis, only one other, the enolization of acetoacetic ethyl ester, has been studied in concentrated salt solutions. For the spontaneous reaction in water Pedersen[30] has found a large linear negative salt effect amounting to 18% in 1 molar sodium chloride and 22% in 1 molar potassium chloride at 18°. This exact agreement with the nitramide results, which can hardly be fortuitous since the temperature effect is very small, points to the same cause operating in the two cases, which is the effect of the salts on the basic proper-

---

[29] Brönsted, private communication; experiments made in 1926–27.

[30] Pedersen, *J. Phys. Chem.*, **37**, 751 (1933).

ties of water. (The acid catalysis by water of both reactions must be vanishingly small compared to the base catalysis.) This salt effect is probably due to hydration, since thereby water is removed. Indeed, it is even possible to calculate the average hydration of the ions required to produce the decrease, the values obtained being similar to those given by other methods.

Using Brönsted's results at 15° and the corresponding values at 24.84° interpolated from the curve in Fig. 2, the constants in the integrated form of the Arrhenius equation, $\log k^* = B - E/2.3026RT$ are

C_{KCl}, m./l.	1.00	1.50	2.00
B	10.90	10.71	10.72
E	189.8	187.6	188.9 × 10^2 cal.

The minor variation is within the precision of the data.

Acid Effect.—The positive effect of hydrochloric acid on the decomposition of nitramide is small, being of the same order of magnitude as the salt effects. The increase in reaction velocity is only 2.6% in 0.1 molar hydrochloric acid. Pedersen found a similar increase (3.8%) for the enolization of acetoacetic ethyl ester and was uncertain as to whether it represented primary salt effect or hydrogen ion catalysis. For the nitramide reaction there is little doubt that the effect is acid catalysis, because of the existence of acid catalysis in isoamyl alcohol.[7] The much smaller value of the acid catalysis in water is to be expected from the leveling effect of the base water on strong acids.

Another and better proof of acid catalysis is given by Fig. 3, in which $\log k^*_{\text{corr.}}$ for the hydrochloric acid effect is plotted against the acidity function, $H_0 = -\log a_{H^+}(f_B/f_{BH^+})$, using for the latter the values of Hammett and Paul.[31] With the exception of the value in 2 M hydrochloric acid, all the points agree with the straight line within the experimental error. (The error is large for the first two points because $k^*_{\text{corr.}}$ is obtained as the difference of two quantities which are almost equal.)

Although there may also be a primary salt effect of the hydrochloric acid on the water catalysis, it must be quite small because it is extremely unlikely, as Fig. 3 shows, that this salt effect would follow the same mathematical relationship as the acid catalysis.

Mechanism of the Decomposition.—Pedersen[32] has suggested a plausible mechanism for the decomposition by bases. He assumes that the following equilibria are attained practically instantaneously

$$H_2N\cdot NO_2 \rightleftarrows HN{=}NO_2^- + H^+ \rightleftarrows HN{=}NOOH$$

and that there is present at all times a constant, but very small, fraction of the undissociated nitramide in the form HN=NOOH. He explains the decomposition as taking place when bases remove the last proton bound to the nitrogen. Since HN=NOOH is a neutral molecule, this explanation is in conformity with the absence of appreciable salt effect in dilute solution, as found by Brönsted and his students for all their experiments no matter what the charge type of the base. It should be pointed out that the assumption of a very small fraction of the undissociated nitramide present as HN=NOOH is not necessary, since the decomposition can just as well be explained by assuming that *all* the undissociated nitramide is present in this form and that a very *small* percentage of the collisions by bases is fruitful. Indeed Hantzsch[33] maintains that the nitramide ordinarily exists in the form HN=NOOH rather than $H_2N\cdot NO_2$.

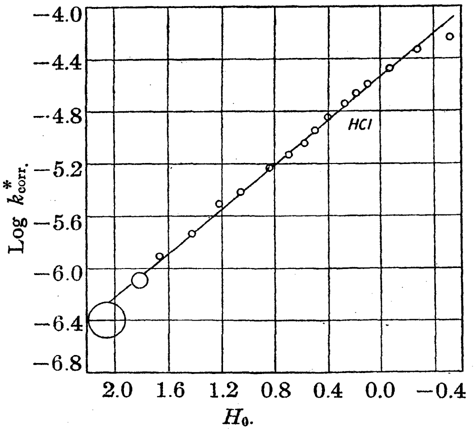

Fig. 3.

It is difficult to see why Pedersen accepts the mechanism proposed by Brönsted to explain the rise in reaction velocity in solutions of very low acidity (pure water). Brönsted postulated[6] that the nitramide ion decomposes about twenty times more rapidly than the undissociated nitramide, so that the increased dissociation as the acidity is decreased causes a more rapid decom-

---

(31) Hammett and Paul, THIS JOURNAL, **56**, 827 (1934).

(32) Pedersen, *J. Phys. Chem.*, **38**, 581 (1934). *Vide*, p. 589.

(33) Hantzsch, *Ber.*, **66B**, 1566 (1933).

position. However, the results are just as well explained by assuming catalysis of the undissociated nitramide by OH^-, which increases in concentration as the acidity is decreased. Brönsted mentioned this possibility in an earlier paper.[5] Indeed, because of the equilibrium

$$H_2N_2O_2 + OH^- \rightleftarrows HN_2O_2^- + H_2O$$

it is impossible to differentiate kinetically between the two such conceptions. However, equivalence of the interpretation is not a sufficient reason for a departure from the first mechanism of the nitramide decomposition as a basic catalysis of the molecule.

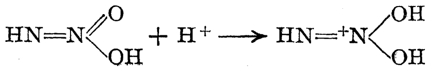
Assuming catalysis of the molecule by OH^-, the molar velocity constant was calculated from the measurements made below 0.005 *M* HCl, in which range the velocity constant increases (see Fig. 1). In calculating the OH^- concentration, correction was made for the influence of the nitramide present for which the dissociation constant of nitramide was taken to be 2.55×10^{-7}, the value for 15°.[5] The results are given in Table VIII.

TABLE VIII

C_{HCl}	C_{OH^-}	$k^*_{obs.}$	$(k^*_{obs.} - k^*_{0,\ corr.})/C_{OH^-}$
0.001000	1×10^{-11}	1.243×10^{-3}	$0.8 \times 10^{+6}$
.0001000	0.8×10^{-10}	1.304	$0.9 \times 10^{+5}$
.0000100	0.2×10^{-9}	*ca.* 1.45	*ca.* $1.1 \times 10^{+6}$

The agreement is within the precision of the data. This molar velocity constant is about 2000 times the most rapid hitherto measured for the nitramide decomposition. A very long and probably unjustified extrapolation of the Brönsted and Pedersen formula[2b] indicates about 10^9 for k_{OH^-} at 15°.

We advance the following mechanism to explain the acid catalysis



$$HN{=}N\begin{smallmatrix}{\nearrow}O\\ {\searrow}OH\end{smallmatrix} + H^+ \longrightarrow HN{=}{}^+N\begin{smallmatrix}{\nearrow}OH\\ {\searrow}OH\end{smallmatrix}$$

The substance formed should be unstable, since two OH groups have never been known to be bound to one nitrogen atom, and therefore the compound should decompose into nitrous oxide and oxonium ion.

Acknowledgment is made to the College of the City of New York for the use of some of the apparatus for this investigation.

Summary and Conclusions

1. The preparation and the measurement of the decomposition of nitramide was studied to render this desirable reaction more conveniently available for kinetic investigations.

2. An improved method of preparation of nitramide is outlined.

3. The rate of decomposition of nitramide has been measured in aqueous acid and salt solutions over a wide range of concentrations with an error of about 1%.

4. A detailed analysis of the errors has been presented.

5. Suggestions have been advanced for an improved apparatus, so as to make the measurement of the velocity of a chemical reaction proceeding by gas evolution more precise.

6. A negative primary salt effect has been found which is ascribed to the effect of salt on the catalytic properties of the base water. The constants of the Arrhenius equation have been calculated.

7. An acid catalysis has been found which is closely correlated with the acidity function H_0.

8. Pedersen's mechanism for the basic catalysis has been discussed and simplified. The catalytic constant for hydroxyl ion is about 2000 times greater than that of any other base measured previously.

9. A mechanism for the acid catalysis has been advanced.

10. Heavy water decreases the velocity of the decomposition as compared to ordinary water.

11. Mercuric chloride has a marked positive effect on the reaction velocity.

Hydrous Thoria Hydrosols Considered as Polynuclear Basic Thorium Complexes

BY ARTHUR W. THOMAS AND CHESTER B. KREMER

The purpose of this paper is to submit evidence in support of the view that hydrous thoria hydrosols (more accurately, thorium oxychloride or basic thorium chloride hydrosols) may be regarded as polyolated and/or oxolated complexes, differing from thorium chloride crystalloidal solutions of low basicity in degree rather than in kind. This chemical point of view of the so-called metallic oxide hydrosols has been previously proposed for aluminum[1] and chromium oxysalt hydrosols.[2] In the present investigation, twelve basic thorium chloride hydrosols were studied, the results obtained with three of them ("C," "E," "F") being submitted here as typical.

Preparation and Description of Hydrosols.—Hydrosol "C" was prepared as follows. Portions of 3 *N* ammonium hydroxide (redistilled) were added to an aqueous solution of pure thorium chloride at room temperature with mechanical stirring. The addition of ammonium hydroxide was continued until the liquid became decidedly turbid, whereupon the stirring was continued for twenty-four hours. Then the liquid was dialyzed at room temperature against a highly permeable nitrocellulose membrane for five days using running distilled water.

Hydrosols "E" and "F" were prepared by the action of hydrochloric acid ("E") and of thorium chloride ("F") upon hydrous thoria at room temperature as follows. Hydrous thoria was precipitated from a thorium chloride solution by addition of ammonium hydroxide. Centrifugal washings and decantations were then applied until chloride ion had been removed. The hydrous oxide was then suspended in a small amount of distilled water and the desired amount of hydrochloric acid or thorium chloride dissolved in about 1500 cc. of water, was slowly added accompanied by vigorous stirring. After standing for twenty-four hours, the systems were dialyzed for six days as described above.

In all cases, at the conclusion of dialysis the hydrosols were centrifuged for one hour (1200 r. p. m., 42 cm. radius) and the supernatant liquid was siphoned into water-resistant glass bottles.

These three hydrosols which were turbid in appearance are described quantitatively in Table I. The micelles were positively charged.

TABLE I

COMPOSITION OF HYDROSOLS

Sol	Thorium milliequiv. per liter	Chloride milliequiv. per liter	Eq. Th/Eq. Cl	*p*H[a]
C	81.3	12.4	6.6	3.95
E	63.9	5.7	11	3.97
F	100.9	13.1	8	4.16

[a] The *p*H values are those measured immediately at the completion of dialysis.

Action of Neutral Salts.—The hydrosols were titrated with various potassium salts in the following manner. To 10-cc. portions of hydrosol in 30 cc. volume glass-stoppered bottles were added 10 cc. portions of salt solution. The bottles were rotated (7 r. p. m.) for 12 ± 3 hours at 25 ± 0.2° and the *p*H values were then measured. The quinhydrone electrode was used in cases where the *p*H value was below 8, the platinized-platinum hydrogen gas electrode being employed for systems with *p*H values near to or greater than 8.

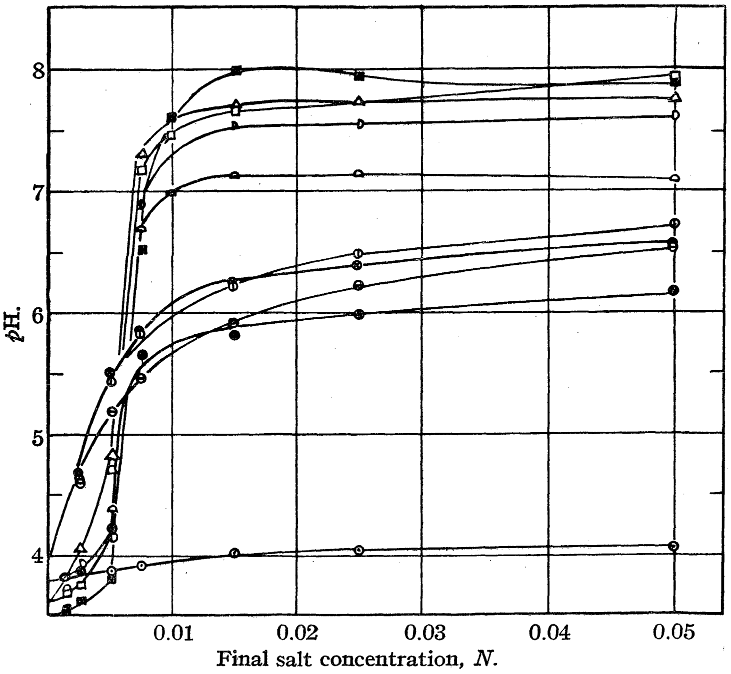

Fig. 1.—Effect of potassium salts on the *p*H value of Sol C: ⦶, acetate; ⊙, chloride (also nitrate); ■, citrate; ⊖, formate; △, malate; ⌓, malonate; □, oxalate; ⊗, propionate; ●, sulfate; D, tartrate.

In the case of the hydrogen electrode, the mixture was filtered to remove precipitate when oxalate was the added salt. No other salt caused precipitation when the *p*H value exceeded 8.

(2) A. W. Thomas and F. C. von Wicklen, *ibid.*, **56**, 794 (1934).

The *p*H values of the 0.1 *N* potassium salt solutions were adjusted to *p*H = 6.4 ± 0.3[3] by the addition of potassium hydroxide in the case of the chloride, nitrate and sulfate and by addition of the proper 0.1 *N* acid to the other solutions. These values are given in Table II.

TABLE II

*p*H VALUES OF 0.1 *N* POTASSIUM SALT SOLUTIONS

Acetate	6.6	Nitrate	6.3
Chloride	6.2	Oxalate	6.4
Citrate	6.8	Propionate	6.4
Formate	6.4	Succinate	6.4
Malate	6.3	Sulfate	6.3
Malonate	6.4	Tartrate	6.5

The reaction time of twelve hours was well beyond that required for a "practical equilibrium" to be established.

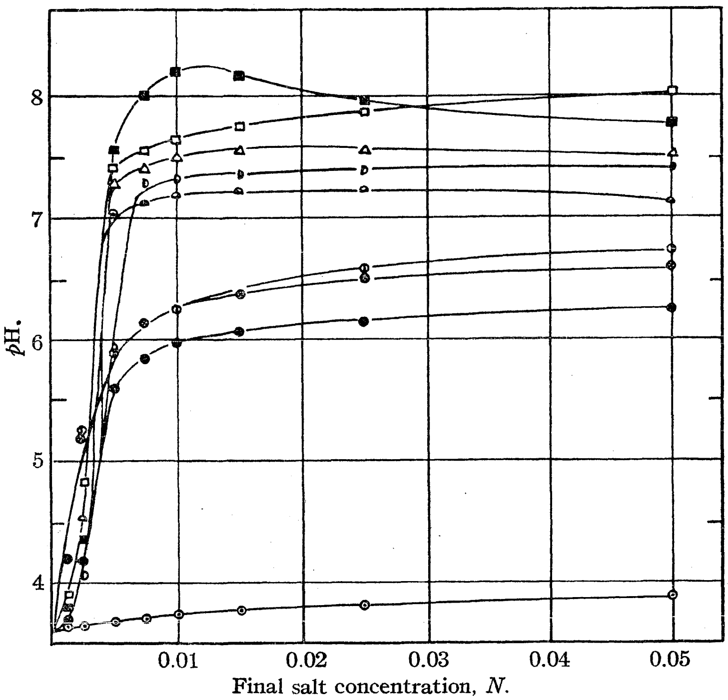

Fig. 2.—Effect of potassium salts on the *p*H value of Sol E: ⦶, acetate; ⊙, chloride (also nitrate); ■, citrate; △, malate; ⌓, malonate; □, oxalate; ⊗, propionate; ●, sulfate; D, tartrate.

The results of the *p*H-salt titrations are shown in Figs. 1, 2 and 3.[4] It is seen that the *p*H raising order is in general: citrate > oxalate > malate > tartrate > malonate > succinate > acetate > propionate > formate > sulfate > chloride = nitrate. This series is similar to those obtained with basic aluminum[1] and chromic[2] salt hydrosols in so far as the above salts were studied with the latter named sols.

As pointed out in previous publications from this Laboratory, these increases in *p*H values are ascribed to the displacement of the coördinatively bound hydroxo (and possibly ol) groups from the thorium atom by the anions of the added salt. Salts producing a marked increase in *p*H value contain anions which have a stronger coördinative binding tendency than those producing smaller *p*H increases. This occurs whether the central metallic atom is part of a colloidal micelle or is a simple crystalloid ion.

Aquo and chlorido groups should likewise be displaced by the added anions. That the latter takes place is evidenced by increased chloride ion activity caused by the addition of salts to other oxide hydrosols.[5] The displacement of aquo groups by the added anions should lead to reversal of the sign of charge of the micelles. In certain instances this happens and the subject will be discussed in a subsequent paper.

Effect of Age.—Basic thorium chloride hydrosols stored at room temperature rapidly become more acid in reaction (to about *p*H 3) as shown in Fig. 4. This may be accounted for by three mechanisms: (1) aquo groups are converted to hydroxo groups and free hydrogen ion, (2) olation removing a product of reaction (1) favors (1) and, (3) oxolation of ol groups liberates hydrogen ion. At room temperature (3) would not be expected to proceed to any great extent. All of these reactions are favored by rise in temperature. Portions of the hydrosols which were boiled in a ground glass joined Pyrex glass reflux apparatus decreased in *p*H to the range of 2.1–2.5 depending upon the concentration of the sol. A typical example of the rate of change is shown in Fig. 5. When these heated sols were allowed to stand at room temperature, partial reversal of the reactions was noted as shown in Fig. 4. Conflicting statements are found in the literature concerning

---

(3) With the exception of citrate where the *p*H value was adjusted only to 6.80.

(4) Basic thorium chloride hydrosols "age" rapidly, *i. e.*, they olate and/or oxolate rapidly at room temperature. For example, when dialysis of sol "E" was concluded it had a *p*H value of 3.97; three days later its *p*H value was 3.65 and in five days it was 3.45. This behavior accounts for the *p*H values at zero salt concentration not being identical inasmuch as one could not perform all the salt titrations in one day. The decrease in *p*H on "aging" is, of course, reflected also in the *p*H values attained upon addition of neutral salts.

(5) (a) H. B. Weiser, *J. Phys. Chem.*, **35**, 1, 1368 (1931); (b) S. Roychoudhury, A. Sen and A. Chatterjee, *J. Indian Chem. Soc.*, **11**, 23 (1934).

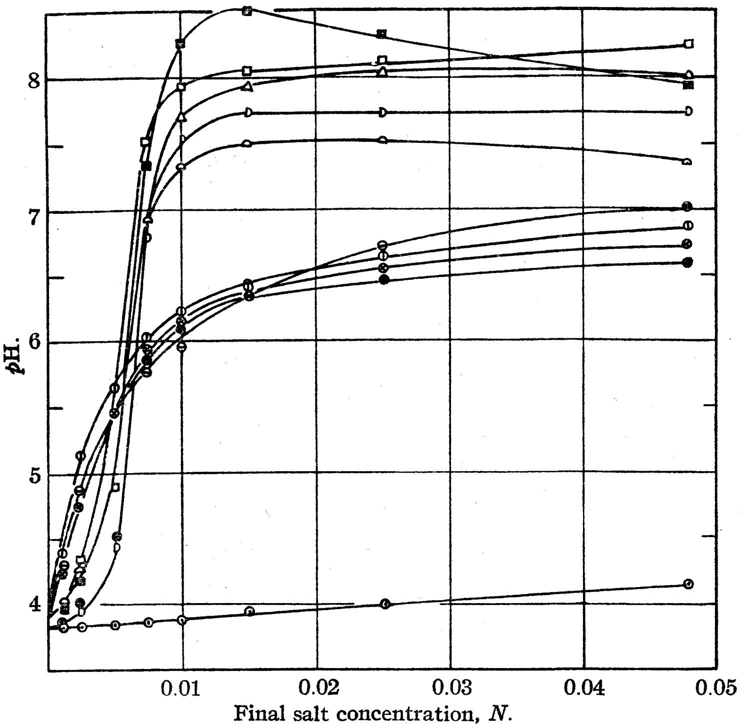

Fig. 3.—Effect of potassium salts on the pH value of Sol F: ⦶, acetate; ⊙, chloride; ■, citrate; ⊖, formate; △, malate; ◓, malonate; □, oxalate; ⊗, propionate; ●, sulfate; D, tartrate.

pH changes in "oxide" hydrosols. That the pH may increase or decrease is explained by the present theory. A metallic "oxide" hydrosol which has been boiled, or which has not been sufficiently dialyzed, becomes less acid on standing due to hydrogen ion reacting with OH groups in the complex and also to partial deolation. A well dialyzed sol, on the other hand, becomes more acid upon aging due to conversion of aquo to hydroxo groups, to olation and to oxolation.

The conversion of hydroxo to ol groups should render a sol less responsive to the pH increasing action of added neutral salts since one would suspect ol groups to be more firmly held by the thorium atoms than hydroxo groups. Oxo groups would, of course, be unaffected by neutral salt additions.

The effect of previous heating on the pH raising effect of neutral salt additions is shown in Fig. 6. This behavior is the same as that noted in the case of basic aluminum[1b] and basic chromium[2] salt hydrosols.

Conductance Titrations.—Conductivity titrations of basic aluminum and basic chromium salt hydrosols with silver salts have revealed that the drop in conductivity is the greater, the stronger the tendency is for the anion to become coördinatively bound to the central metallic atom.[1b,2] Employing a technique essentially the same as that previously described, the data plotted in Fig. 7 were obtained.[6] The relatively effective coördinative binding ions, sulfate and acetate, produce steep drops in the conductivity. To be sure, part of the conductivity drop is due to combination between the chloride ions in the sol and the added silver ions, but the steep drop cannot be attributed entirely to this reaction, as previously stated.

The coördinative binding of the anion results in its being without effect upon the conductivity of the system and, further, if it is bound by replacement of aquo groups, it thereby lowers the positive charge upon the micelle and thus another conductivity lowering factor enters the picture. Silver nitrate produced a slight fall in conductivity in the case of sol "C" while in sol "F" it produced a slight increase in conductivity. Thus nitrate, known in general as a weak coördinative binding ion and in particular as regards thorium,

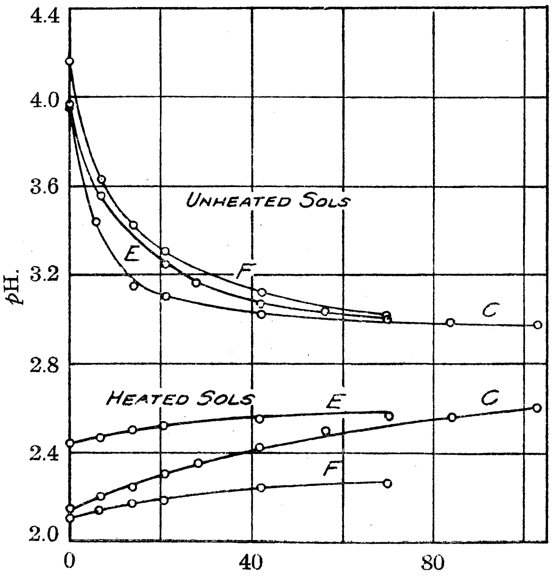

Fig. 4.—Change in the pH values of unheated and of boiled sols upon standing at room temperature.

---

[6] The abscissas represent milliequivalents of solid silver salt added to 50 cc. of hydrosol.

shows some coördinative tendency in the case of sol "C" but not with sol "F."

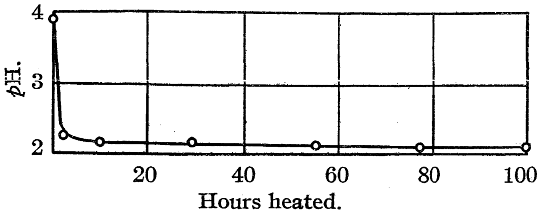

Fig. 5.—Change in *p*H value produced by boiling sol F.

Inasmuch as sols "C" and "F" had approximately the same ratio of Th:Cl, then the difference might be ascribed to the fact that they were prepared by different methods, inasmuch as one would hardly expect the 25% difference in concentration between the two sols to produce the divergence in nitrate penetration.

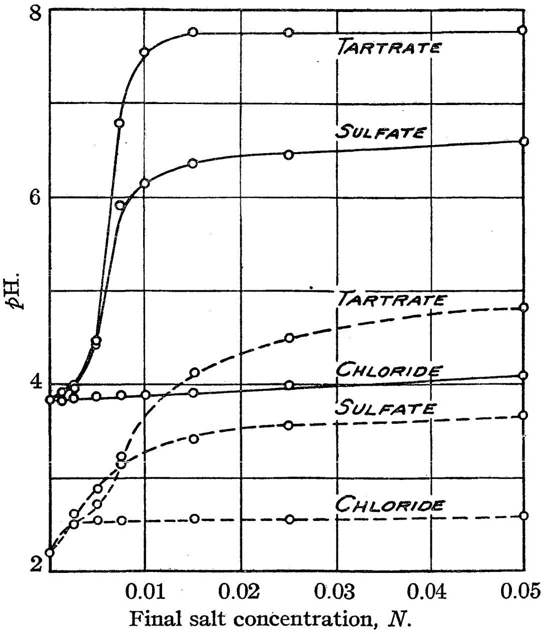

Fig. 6.—Effect of potassium salts on the *p*H value of sol F before and after boiling: ———— unheated sol; – – – – – boiled sol.

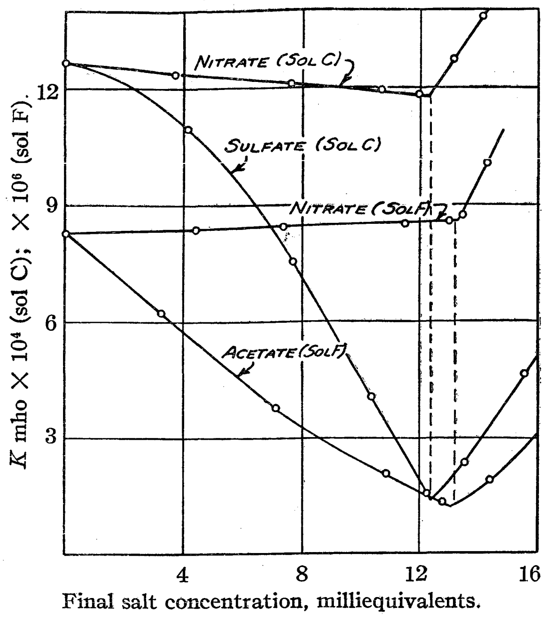

Fig. 7.—Effect of silver salts upon the specific conductivities of sols C and F.

Summary

The *p*H values of basic thorium chloride (so-called "thorium oxide") hydrosols are raised by the addition of potassium salts. The order of effectiveness in general, similar to that found with certain other "oxide" hydrosols, is: citrate > oxalate > malate > tartrate > malonate > succinate > acetate > propionate > formate > sulfate > chloride = nitrate, the first named markedly increasing the *p*H value while the last named exerted very slight effect. The effect is ascribed to displacement of coördinatively bound OH groups by the anion of the added salt, the anion then becoming coördinatively bound. Dialyzed basic thorium chloride hydrosols rapidly become more acid on standing at room temperature; the rate increases upon heating and the reactions producing this effect show partial (or extremely slow) reversal. Heated basic thorium chloride hydrosols are less responsive to the *p*H increasing effect of added neutral salts. The interpretation of these behaviors can be made on the assumption of a polyolated and/or oxolated structure of the micelle, an extension to colloidal dispersions of the postulates which Werner and Pfeiffer applied to crystalloid basic salts.

Basic Zirconium Chloride Hydrosols

BY ARTHUR W. THOMAS AND HARRY S. OWENS

Studies upon metallic "oxide" hydrosols previously reported from this Laboratory[1,2,3] have been extended to include basic zirconium chloride hydrosols (generally known as "zirconium oxide" hydrosols).

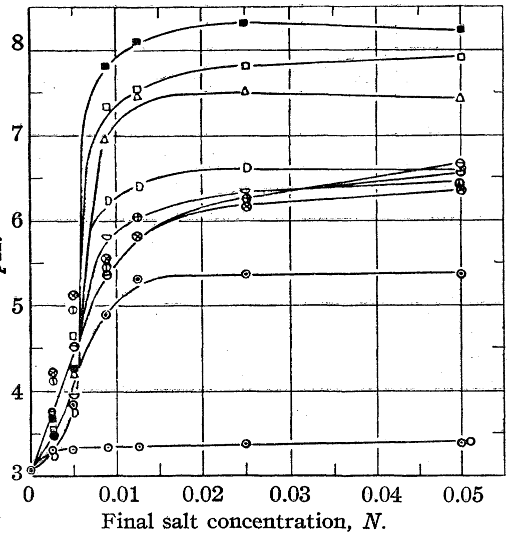

Fig. 1.—Effect of potassium salts on the *p*H value of Sol B; sol one day old: ⦶, acetate; ⊙, chloride; ■, citrate; ⊖, formate; ▽, glycolate; △, malate; ○, nitrate; □, oxalate; ⊗, propionate; ●, sulfate; D, tartrate.

The behavior of fifteen different basic zirconium chloride hydrosols was investigated, the results obtained with three which were typical of all being submitted here.

Preparation and Description of Hydrosols.—Hydrosols "B" and "F" were prepared in the following manner. Hydrous zirconium oxide precipitated from an aqueous solution of pure zirconyl chloride by redistilled ammonium hydroxide was washed by centrifugal decantations to the absence of a test for chloride ion. Portions of this oxide were rotated in contact with a 0.4 *M* zirconyl chloride solution at 25° for twenty-four hours in water-resistant glass-stoppered bottles. They were then dialyzed as previously described,[3] "B" for twenty hours and "F" for one hundred hours. Hydrosol "D" was prepared by boiling a 0.6 *M* aqueous zirconyl chloride solution in a glass-joined Pyrex reflux apparatus for twenty-four hours when it was dialyzed for one hundred and four hours. All sols were then centrifuged for one hour at 120 r. p. m. and a 42-cm. rotating diameter.

These hydrosols were turbid in reflected light, "D" exhibiting a bluish cast. To transmitted light "B" and "F" were colorless and clear while "D" was clear but orange-red in color. The micelles were positively charged in each case. Quantitative data are given in Table I.

TABLE I

COMPOSITION OF HYDROSOLS

The *p*H values are those obtained immediately at the completion of dialysis.

Sol	Zirconium milliequiv. per liter	Chloride milliequiv. per liter	Eq. Zr/Eq. Cl	*p*H
B	89.1	11.2	8.1	3.22
D	136.7	9.0	15	3.50
F	38.5	2.3	17	3.92

Action of Neutral Salts.—The effect of additions of potassium salts upon the *p*H values of the hydrosols was measured as previously described.[3] All of the potassium salt solutions were adjusted to *p*H 6.5 ± 0.3 as listed in Table II. The results obtained are plotted in Figs. 1, 2 and 3. It is seen that the *p*H values were raised in every case, alkaline solutions resulting with citrate, oxalate, malate and tartrate. The order of effectiveness of the anions is, citrate > oxalate > malate > tartrate > glycolate > succinate = malonate = maleinate > propionate = acetate = fumarate = formate > sulfate > chloride = nitrate.

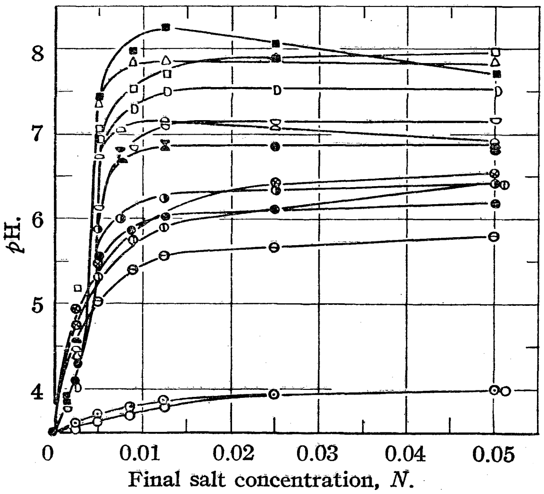

Fig. 2.—Effect of potassium salts on the *p*H value of Sol D; sol four days old: ⦶, acetate; ⊙, chloride; ■, citrate; ⊖, formate; ◑, fumarate; ▽, glycolate; △, malate; ▾, maleinate; ⌓, malonate; ○, nitrate; □, oxalate; ⊗, propionate; ▴, succinate; ●, sulfate; D, tartrate.

TABLE II

*p*H VALUES OF 0.1 *N* POTASSIUM SALT SOLUTIONS

Salt	*p*H	Salt	*p*H
Acetate	6.6	Maleinate	6.8
Chloride	6.6	Nitrate	6.4
Citrate	6.8	Oxalate	6.6
Formate	6.5	Propionate	6.6
Fumarate	6.3	Sulfate	6.5
Glycolate	6.5	Tartrate	6.6
Malate	6.3		

In general this is similar to the order found with the other basic metalli-salt hydrosols studied in this Laboratory.[1,2,3] Such an order might be expected from the present incomplete knowledge of the crystalloidal chemistry of zirconium.[4] De Boer,[5] for example, has found the following order for the tendency of anions to become coördinatively bound to zirconium: $OH > F > PO_4 > C_2O_4 > SO_4 > NO_3 > Cl$. Although the OH group seems to be one of the most strongly coördinatively bound (which would indicate difficultly in displacing it), conditions in the experiments performed favored its displacement because the hydroxyl ion concentration in the body of the solution was low while the concentration of the added anion was comparatively high. However, as the hydroxyl ion concentration of the solution increases owing to the displacement of hydroxo groups by the added anion, much greater amounts of salt are required for the reaction to proceed. The equilibria among hydroxo (and ol), hydroxy, aniono, and anion groups accounts for the shape of the curves in Figs. 1–3.

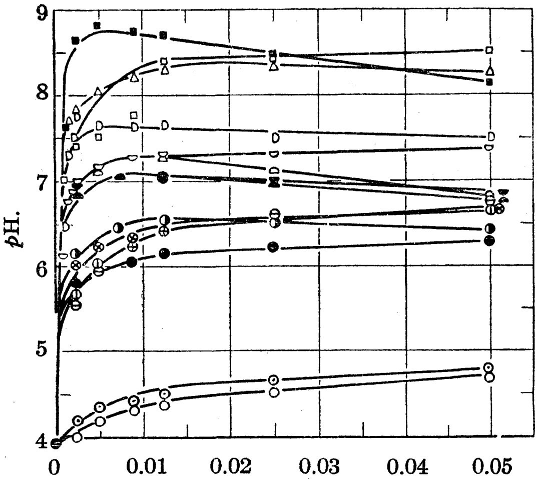

Fig. 3.—Effect of potassium salts on the *p*H value of Sol F; sol four days old: ⦶, acetate; ⊙, chloride; ■, citrate; ⊖, formate; ◑, fumarate; ▽, glycolate; △, malate; ▾, maleinate; ⌓, malonate; ○, nitrate; □, oxalate; ⊗, propionate; ▴, succinate; ●, sulfate; D, tartrate.

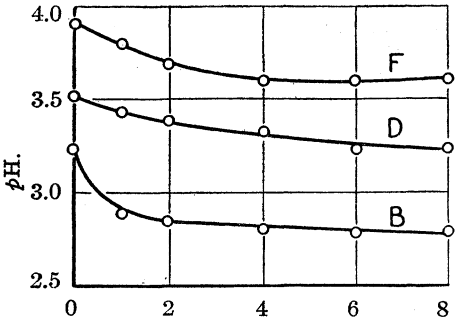

Fig. 4.—Change in *p*H of sols upon standing at room temperature.

Effect of Aging and Heating.—Representative results of the change in the *p*H values of basic zirconium chloride hydrosols stored in water-resistant glass bottles at room temperature are given in Fig. 4. It will be noted that the *p*H values decrease on aging in every case although not so rapidly as reported for basic thorium chloride sols.[3] This decrease is believed to be due to olation, and to a smaller extent oxolation. Olation though not changing the hydrogen ion activity itself, removes the primary hydrolytic

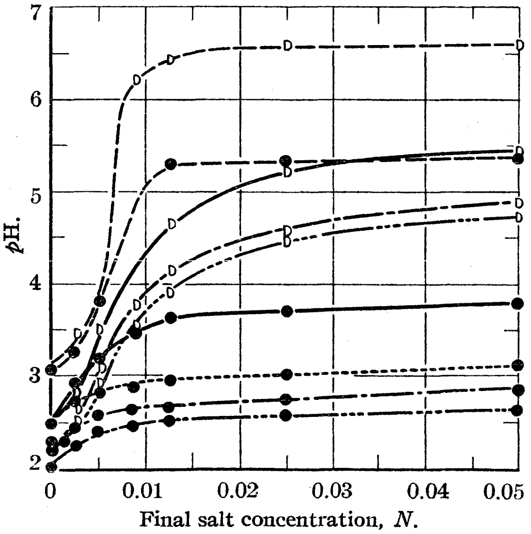

Fig. 5.—The effect of boiling of Sol B upon its reaction to the addition of potassium salts: D, tartrate; ●, sulfate; — — —, not heated; ———, boiled 8 hr.; - - - - - - - -, boiled 96 hr.; — - —, boiled 192 hr.; — - - - —, boiled 240 hr.

products favoring further hydrolysis and production of hydrogen ions.

Upon boiling, the *p*H of basic zirconium chloride sols decreases as in the case of other "oxide" sols reported from this Laboratory but, upon standing at room temperature after being boiled, the reaction showed no tendency to reverse. In this respect basic zirconium chloride sols differ from those of aluminum, chromium and thorium. Typical results are given in Table III. Among the group of elements named, zirconium is unique in that the normal ion in crystalloidal solution is a basic one. The stability of the zirconyl radical is well known, powerful coördinators being required to decompose it. The inertness of ignited zirconium oxide to nearly all ordinary reagents also typifies the stability of oxygen bridges between zirconium atoms. For these reasons it is believed that boiling a basic zirconium chloride hydrosol produces a high degree of oxolation.[6] The oxygen bridges thus formed are stable to the acid produced during the boiling and consequently little change in the *p*H values of the sols standing at room temperature would be expected.

In view of the shift of the reactions, hydroxo compounds $\rightleftarrows$ ol complexes $\rightleftarrows$ oxo complexes to the right upon heating, one would expect added neutral salts to exert less *p*H raising effects. A typical series of measurements is plotted in Fig. 5.

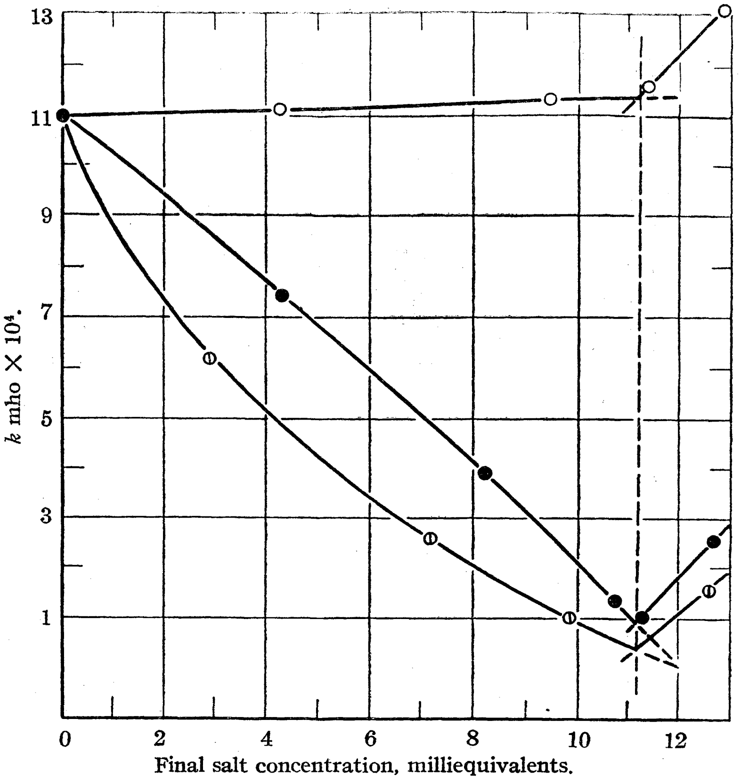

Fig. 6.—The effect of silver salts upon the specific conductivity of Sol B: ◐, silver acetate; ○, silver nitrate; ●, silver sulfate.

TABLE III

DECREASE OF *p*H OF HYDROSOLS UPON BOILING

Sol	*p*H before boiling	Hours boiled	*p*H after boiling	*p*H 6 months later[a]
B	3.11	8	2.50	2.45
	2.80	96	2.40	
	2.80	192	2.22	2.22
	2.80	240	2.04	2.09
D	3.50	72	2.50	2.44
F	3.90	72	3.19	3.12
	3.90	120	3.12	
	3.90	190	2.91	
	3.90	240	2.84	
	3.90	288	2.72	

[a] Kept at 25° for six months after cessation of boiling.

Conductance Titrations.—Conductance titrations with silver salts performed by means of a technique previously described[1b,2,3] produced the values plotted in Fig. 6. Here again the silver salt containing the more strongly coördinative binding anion was the more effective in lowering the conductivity. Nitrate shows little or no such tendency and as a result silver nitrate produced an increase in conductivity just as in the case of a basic chromium[2] and of a basic thorium[3] chloride hydrosol. Interpretations of these behaviors have been published.[1b,2,3] Similar curves for "thorium oxide" and "aluminum oxide" hydrosols have been obtained by Pauli.[7]

Summary

The *p*H values of basic zirconium chloride (so-called "zirconium oxide") hydrosols are raised by the addition of potassium salts. The order of effectiveness in general similar to that found with

---

(6) x-Ray investigations made by Böhm and Niclassen [*Z. anorg. allgem. Chem.*, **132**, 1 (1924)] upon the gel obtained by ultrafiltration of a freshly prepared basic zirconium nitrate hydrosol showed it to be amorphous. The gel ultrafiltered from such a hydrosol which had been boiled for many hours showed a few bright rings which, considering their location, were probably those of zirconium oxide. After heating the precipitate from an evaporated sol at a higher temperature, the x-ray diagram for zirconium oxide was obtained.

(7) Wo. Pauli and E. Valkó, "Elektrochemie der Kolloide," Verlag Julius Springer, Vienna, 1929, pp. 552, 554.

other hydrosols is citrate > oxalate > malate > tartrate > glycolate > succinate = malonate = maleinate > propionate = acetate = fumarate = formate > sulfate > chloride = nitrate, the first named markedly increasing the *p*H value while the last named exerted very slight effect. This effect is ascribed to displacement of coördinatively bound OH groups by the anion of the added salt, the anion then becoming coördinatively bound to zirconium atoms in the micelle. Dialyzed basic zirconium chloride sols become more acid upon standing at room temperature although not so rapidly as basic thorium chloride sols. The decrease in *p*H is hastened by heating and the reactions show no sign of reversal after six months of storage at 25°. In the latter respect, basic zirconium hydrosols differ from those of thorium. As in the cases of other basic metalli-salt hydrosols, the heated sols are less responsive, in so far as *p*H changes, to the action of added neutral salts.

It may be said that "zirconium oxide" hydrosols show a very strong tendency to oxolate.

By application of the ideas which Werner and Pfeiffer suggested for crystalloid basic salts, and assuming that the micelles in basic zirconium chloride hydrosols are polyolated and/or oxolated structures, their behaviors can be readily interpreted.

The Extraction of Germanium and Gallium from Germanite. I. The Removal of Germanium by the Distillation of Germanous Sulfide

BY WARREN C. JOHNSON,[1] LAURENCE S. FOSTER AND CHARLES A. KRAUS

Germanite is a sulfide ore containing chiefly copper, iron, arsenic, germanium, zinc, lead, gallium, and aluminum as well as minute amounts of several other elements. It was discovered in 1920 at Tsumeb, South West Africa, by Schneiderhöhn.[2] An analysis by Pufahl[3] showed the presence of germanium, and further analyses by Kriesel,[4] Lunt,[5] and Thomas and Pugh[6] not only verified the germanium but, in addition, showed gallium to be present in appreciable quantities.

Several methods of extraction of germanium from germanite have been reported[7] in which the ore is either roasted or subjected to oxidation with a mixture of nitric and sulfuric acids, leading eventually to the separation of the germanium from aqueous solutions containing the other elements of the ore. The procedures are tedious and require the handling of relatively large quantities of solutions. Patnode and Work[8] chlorinated the ore at 350° and then fractionally distilled the anhydrous chlorides produced. The fraction containing the germanium was hydrolyzed to precipitate the dioxide. After this product had been dissolved in hydrochloric acid, germanium tetrachloride was distilled from the solution in the presence of chlorine, according to the very useful method of Buchanan.[9]

In the present paper, a process is reported for the complete removal of germanium from germanite as germanous sulfide in the vapor phase. The method eliminates the handling of large volumes of solutions, the distillation of liquids, and leaves a residue from which the gallium can be removed very readily. The simplicity of the process will be evident from a description of the operations required for the removal of germanous sulfide.

Operation I.—Finely ground germanite is heated in a stream of dry, oxygen-free, nitrogen gas at 800° with the removal of arsenious sulfide and sulfur.

Operation II.—Ammonia gas is passed over the residue from (I) at 825° whereby the germanic sulfide of the ore is reduced to germanous sulfide, which, in turn, distils from the ore mass to collect in cooler regions of the apparatus. If the arsenious sulfide is completely removed in (I), germanous sulfide is the only substance to leave the ore in (II).

For the preliminary experiments, we are greatly indebted to the late Professor Charles James of

the University of New Hampshire for a 50-g. sample of germanite. In addition, ore was purchased during the course of the work from the Otavi Minen und Eisenbahn Gesellschaft, Berlin, Germany. Analyses showed the germanium content of the several lots to range from 4.5 to 7%.

Apparatus

A diagram of the apparatus used in the two stages of the process is shown in Fig. 1. A large furnace A was constructed to take care of considerable quantities of the ore, 600–700 g. in *Operation I* and about twice this quantity in *Operation II*. For this furnace, a threaded Vitreosil tube, 56 cm. in length and 7.6 cm. in diameter, wound with number 14 Chromel A wire in two coils of equal length, was placed in a sheet iron container 20 cm. in diameter. The furnace was insulated with Sil-o-Cel. This arrangement permitted use of the coils either in series or in parallel and provided a satisfactory means for controlling the rate of heating and the temperature. The furnace was arranged so that it could be moved horizontally on two steel rods about 1.5 meters in length which were supported at the ends by steel plates. The furnace and carrier were mounted on a bench (not shown in figure).

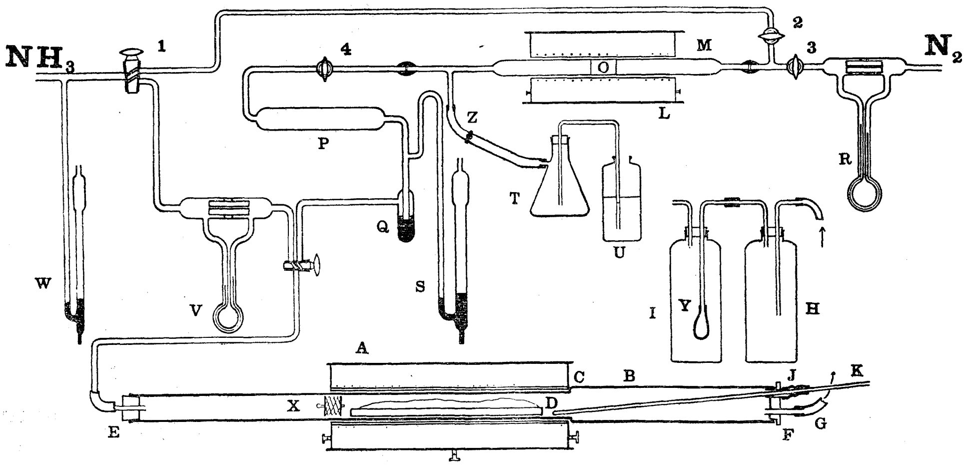

Fig. 1.

The germanite was placed in a cylindrical Alundum boat D, 50 cm. long, 4.5 cm. in diameter and 0.5 cm. thick. The Vitreosil furnace tube B (shown in the figure for *Operation II*) was constructed by fusing a tube, 100 × 5 cm., to a second section, 50 × 10 cm. in dimensions. The joint of the seal at C was made as nearly a right angle as possible. The ends of B were closed with rubber stoppers, E and F; the former being fitted with a glass tube 6 mm. in diameter to permit the entrance of nitrogen or ammonia, while the latter was equipped with a tube G, 15 mm. in diameter, leading to the dust bottles, H and I. A cheesecloth bag, tied at Y, served to remove finely divided material suspended in the gas stream. A large rubber tube led from I to the hood. Through a glass tube J was slipped a loosely fitting Vitreosil tube K, sealed at the inner end and fastened in position with rubber tubing. With this tube it was possible to scrape germanous sulfide crystals from the wall of the large Vitreosil tube B near C to prevent plugging of the apparatus.

For *Operation I*, tube B was replaced by a second Vitreosil tube (not shown in the figure) about 75 mm. long to which was attached by means of an asbestos packed, brass gland an iron tube of the same dimensions. This joint was placed immediately beyond the end of the furnace so that the greater part of the arsenious sulfide condensed in the iron section.

In order to obtain nitrogen free from oxygen, ordinary tank nitrogen was passed over copper wire in the Vitreosil tube M, which was heated to about 600° by an electric furnace L. This tube was provided with a transparent section at O through which one might observe the condition of the copper. After *Operation I*, it was found necessary to reduce the copper oxide in M; ammonia gas was used for this purpose. By proper adjustment of stopcocks 1, 2, 3 and 4, and the screw clamp at Z, the gas stream, which also contained water from the reduction of the copper oxide, was allowed to pass through the trap T and into the bottle U where the excess ammonia was absorbed. A tube P, filled with phosphorus pentoxide, was placed beyond the furnace to dry the nitrogen. The rate of flow of the gas was indicated and regulated by a mercury bubbler Q and a flowmeter R. The apparatus was provided with a mercury safety-trap S which served as an outlet in case of plugging.

The ammonia used in *Operation II* was transferred from commercial cylinders into steel tanks of approximately 10 kg. capacity. The latter contained metallic sodium as drying agent. The ammonia was allowed to escape from these tanks as a gas and to enter the apparatus at a point indicated in the diagram. Its rate of flow was determined by the flowmeter V. A safety-trap W was connected ahead of the furnace tubes. A plug X, made from shredded asbestos held between Chromel wire gauze, was inserted in the furnace tube to prevent heating of the exposed length of quartz tube and circulation of the gases in a direction opposed to the main gas stream. Without this plug considerable material was found to deposit in the cooler regions of the tube in the direction toward E.

Procedure and Results

Operation I.—Between 600 and 700 g. of the ore ground so as to pass through a 100-mesh, but not a 180-mesh, screen was placed in the Alundum boat which was then inserted in the Vitreosil tube. After the air in the apparatus had been expelled by the passage of approximately 50 liters of dry, oxygen-free nitrogen, the furnace was heated to 800° as rapidly as possible, and maintained at this temperature for four and one-half hours with a nitrogen flow of 30 liters per hour. The furnace was allowed to cool and the boat was removed and weighed. After the arsenious sulfide had been scraped from the Vitreosil and iron tubes, another sample was prepared and the above procedure repeated. The resulting slugs were removed from the boat, labeled, and set aside for *Operation II.* The loss in weight for the different lots of ore is recorded in Table I.

TABLE I

LOSS IN WEIGHT OF GERMANITE IN THE TWO OPERATIONS

Ore (lot no.)	Ore, kg.	% loss Operation I	Operation II	Total loss, %
1	8.19	13.6	12.9	26.5
2	17.44	13.6	12.6	26.2
3	24.69	11.9	16.4	28.3
4	19.10	13.2	12.1	25.3
4	4.05	12.6	13.6	26.2
5	16.56	14.0		
5	26.56	15.3	11.1	26.4

Operation II.—Two slugs from (I), equivalent to 1200–1400 g. of the original ore, were placed in the Alundum boat for the second stage of the process. After the plug X was in position, pure nitrogen was passed through the apparatus for fifteen minutes at a rate approaching 60 liters per hour. The furnace was then heated rapidly to a temperature of 825° and kept at this point. Ammonia gas was then admitted at a rate of 50 liters per hour. After a short time, germanous sulfide began to collect at C. Twelve hours of heating was found sufficient to remove all of the germanium. The furnace was allowed to cool, the boat was removed and weighed, and the ore residue was set aside and saved for its gallium content.[10] Tube B was removed from the furnace, the germanous sulfide and metallic germanium were scraped from the walls and separated by hand-picking and screening, and then another charge of the product of *Operation I* was carried through the same procedure.

The loss in weight during *Operation II* is given in Table I. All slugs of ore residue from (I) were numbered and followed through (II) so that the total loss in weight might be known. The loss given in the table for (II) is calculated on the basis of the weight of the original ore.

A complete account of the germanium-containing residues and products and the total amount of germanium found is given in Table II for one lot of ore.

The germanium-containing products were divided into six lots; (1) germanous sulfide crystals, (2) impure germanous sulfide (the chief impurity being metallic germanium), (3) very impure germanous sulfide, (4) germanium-containing dusts, and (5) germanium metal (containing some germanous sulfide as an impurity). All of these products were analyzed for germanium by the usual methods. The impure germanium sulfide shows a higher germanium content than the pure product; this is due to the presence of finely divided metallic germanium, which could not be separated. Analyses of the ore residues (after completion of II) showed the germanium content to range from only 0.04 to 0.05%. On the other hand, the arsenious sulfide distillate, usually amounting to about 10% of the ore, was found to contain between 4 and 5% of germanium. Thus, about 10% of the germanium content of the ore must be recovered from that product.[11]

In the run reported here, product (3) is the largest, but this is accidental; the crystals of pure germanous sulfide were not so coherent and went through the screen in larger percentage. In some runs nearly one-half of the germanium was collected as well crystallized germanous sulfide (1), containing a small amount of metallic germanium, only, as an impurity.

TABLE II

THE AMOUNT OF GERMANIUM OBTAINED FROM GERMANITE (ORE NO. 4, 4.05 KG.)

Type of product	Weight, g.	% Ge	Ge, g.
GeS crystals	68.1	68.1	44.6
Impure GeS	61.2	71.3	43.6
Very impure GeS	157.9	48.8	77.1
GeS in dust bottles	18.3	42.3	7.7
Ge metal	12.8	91.9	11.8
Ge from the tube walls	1.8	69.4	1.3
Ge in As_2S_3 residues	428	4.15	17.8
Ge left in ore	2988.4	0.04	1.2
Total germanium			206.9
% Ge in germanite (based on Ge recovered)		5.11	
% Ge in germanite (based on analysis of 25 g.)		5.13	

Discussion

Attention is called to the fact that the total loss in weight for the combined operations is approximately the same for the different lots of ore, and, in general, it appears that the sum of the germanium and arsenic contents of germanite is very nearly constant. When insufficient time is allotted for (I) more arsenic appears in the products of (II) than would otherwise be the case. With the apparatus described herein, for *Operation I* a nitrogen gas flow of 30 liters per hour, operating for four and one-half hours, was found to be uniformly satisfactory. It is necessary, however, to determine these conditions empirically when working with different lots of ore, since the ratio of the germanium to arsenic varies considerably from lot to lot.

---

(10) The recovery of gallium from this residue is described in the following article.

(11) For methods of separating arsenic and germanium, refer to Abrahams and Müller, THIS JOURNAL, **54**, 86 (1932).

In *Operation I* it is essential that the oxygen be removed from the nitrogen. At the temperature of the process, oxygen reacts with germanic sulfide to give germanic oxide. In *Operation II* any germanic oxide in the ore mass would be reduced by the ammonia to metallic germanium which would not be carried out with the gas stream, since its vapor pressure at 825° is exceedingly low. Another precaution which must be observed in (I) is that the temperature should not be permitted to rise much above 800°, as at temperatures ranging from 850–900°, the major portion of germanic sulfide would distil directly from the ore[12] and would be carried along with the arsenious sulfide. Undoubtedly, the germanium found in the arsenious sulfide residues (Table II), even when the temperature is maintained in the neighborhood of 800°, is the result of some distillation of germanic sulfide.

It is apparent that in *Operation II* the germanium leaves the ore mass as germanous sulfide. The presence of a small amount of metallic germanium in the cooler regions of the quartz tube may be attributed to the reduction of germanous sulfide with ammonia in the region of C.

When the furnace has reached the desired temperature, the flow of ammonia gas must be very rapid. If it is too slow, reduction of the sulfide to metallic germanium takes place within the ore before it has an opportunity to get out into the cooler regions. Once the germanium is left in the ore in this condition, its removal can be accomplished only through dissolution with strong oxidizing acids and subsequent distillation of germanium tetrachloride. An ammonia gas flow of 50 liters per hour was found sufficient for the success of (II) with the apparatus described herein.

The only impurity found with the different products of distillation is arsenic, provided all particles of germanite are kept within the region occupied by the furnace. The amount of germanium left in the ore, after the completion of (II), is surprisingly small, approximately 0.5% of the total germanium content. When all of the germanium products and residues are taken into account, the total amount of germanium recovered agrees well with that found by direct analysis.

The procedure described in this article has been used for the extraction of germanium from more than 100 kg. of germanite. The method ensures the removal of at least 99% of the total germanium content. Since only germanium and arsenic in combination with sulfur are removed in the two stages of the process, the ore residues contain all of the gallium.

An advantage of the process is its production of large amounts of nearly pure germanous sulfide, a starting material for the preparation of many compounds of germanium in the lower valence state.[13]

In addition, germanous sulfide is easily oxidized to germanic oxide, which serves as a source for the preparation of germanic compounds. The less pure products are readily converted to pure germanic oxide by the usual methods.

Summary

A method is described which removes at least 99% of the germanium in germanite ore. The procedure is carried out entirely in the dry condition, whereby most of the objectionable features of the usual methods of extraction are eliminated.

The Extraction of Germanium and Gallium from Germanite. II. The Acid Extraction of Gallium

BY LAURENCE S. FOSTER, WARREN C. JOHNSON[1] AND CHARLES A. KRAUS

The methods of recovery of germanium from germanite developed by Thomas and Pugh[2] and Keil[3] involve the complete dissolution of the ore and the subsequent volatilization of germanium tetrachloride. The extraction of gallium from the residual germanium-free solution requires the handling of large volumes of liquids and the carrying out of numerous tedious separations of the remaining elements of the ore. A superior method was introduced by Berg and Keil,[4] who recover the gallium by extracting gallium trichloride from an acid solution by means of ether, but when this method is applied to kilogram lots of the ore, it has the disadvantage of being costly both in time and materials.

The pyrogenetic method of removal of germanium from germanite, described in the preceding article, leaves a black, partially-sintered residue, consisting chiefly of copper sulfide and amounting to about 75% by weight of the original ore. If these residues are boiled with hydrochloric acid, the gallium is removed completely, although only about 25% of the material is dissolved. The removal of the gallium from the extract is accomplished in six further operations involving neither special apparatus nor expensive chemicals. This method has the following advantages: (1) the necessity of completely dissolving the ore residue is eliminated; (2) the volumes of the solutions to be handled are markedly reduced; (3) the number of operations required to reach the final separation of metallic gallium is decreased; (4) loss of gallium through adsorption is minimized, eliminating reprecipitations; (5) the methods used in carrying out the precipitations lead to the formation of granular rather than flocculent and gelatinous masses, making it possible to use suction filtration in each step; and (6) all the gallium present is precipitated in one lot, making it unnecessary to recover traces of the element from many types of residues.

The Extraction Procedures

The Boiling Process.—The partially sintered residue, resulting from the removal of arsenic and germanium from germanite, is broken up and ground to pass a 100-mesh screen. One kilogram of the powder is placed in a 5-liter round-bottomed Pyrex flask, fitted with a rubber stopper carrying a small still-head. A water-cooled condenser and a large filter flask for the distillate are attached. One liter of 6 *N* hydrochloric acid is added to the flask and the mixture is refluxed for a total of twenty-two hours. Twice during this period, 150 cc. of concentrated hydrochloric acid is added to restore the acid concentration to approximately its original value. After heating for twenty-two hours, the rate of boiling is increased until distillation occurs and about 800 cc. of the acid is removed.[5] If during this process caking occurs, 500 cc. of water is added to the residue, the cake is loosened mechanically, and distillation continued until the amount of liquid left in the flask has again been reduced to a small volume.

The removal of hydrochloric acid by distillation minimizes the amount of alkali required for the subsequent neutralization, yet leaves the solution sufficiently acid to prevent hydrolysis of the dissolved salts. The cooled mixture, which contains some crystallized lead chloride, is suction-filtered. The sludge collected is washed by decantation at least five times with 200-cc. lots of 1% hydrochloric acid. The final volume of the filtrate, combined with the wash solution, need not be over 1500 cc.

The insoluble portion of the ore residue is returned to the boiling flask with 750 cc. of 6 *N* hydrochloric acid and refluxed again for five hours. After distilling off part of the acid, the mixture is filtered, the sludge is washed with a small amount of dilute acid, and the filtrate is added to the first extract. Besides gallium, the solution contains relatively large quantities of copper, lead, iron, aluminum and zinc, together with traces of many other elements.

The Efficiency of the Extraction.—The second hydrochloric acid extracts from two different lots of germanite were analyzed for gallium by a determination of the x-ray emission spectra, which gave $K\alpha_1$, $K\alpha_2$ and $K\beta_1$ lines.[6] A semi-quantitative check on the concentration of gallium was obtained by comparison with a known sample prepared to contain 0.5% of gallium oxide thoroughly mixed with ferric oxide. The intensities of the lines from the known and unknown samples showed the latter to contain about 1% of gallium in each case. Calculations made from these results indicate that the first hydrochloric acid extract contains between 99.0 and 99.8% of the total extractable gallium. Taking into account the amounts of

[5] In case the germanium has not been removed completely in the earlier operations, much of the residuum will be found in the distillate.

[6] We are greatly indebted to Mr. C. M. Olson and Professor W. C. Pierce, of the University of Chicago, for these results. They carried out the experiments with an x-ray spectrograph constructed by them.

gallium reported in the ore by various workers,[7] which average around 0.5%, we may conclude further that the extraction process removes the gallium practically quantitatively. Since such a high percentage of the gallium does appear in the first extract, this conclusion appears reasonable, and certainly indicates that no more than two extractions are profitable.

Treatment of the Extract with Hydrogen Sulfide.—The combined extracts are first treated with strong sodium hydroxide solution until a small amount of a permanent green precipitate is observed (not to be confused with the crystals of lead chloride which appear as neutralization proceeds). Then enough hydrochloric acid is added to dissolve the green precipitate and to render the solution at least 0.2 N in excess acid. Hydrogen sulfide is introduced, the black precipitate which forms is allowed to settle and the mixture is suction-filtered. Finally, the precipitate is pressed dry with a spatula and then washed several times with small amounts of acidified water.

After the removal of the sulfides, the filtrate is tested for complete precipitation of the lead and copper. If shown necessary, the treatment with hydrogen sulfide is repeated, after the acidity of the solution has again been reduced to only 0.2 N in excess acid by the method outlined above.

If the acid concentration is kept at the recommended value, very little gallium is adsorbed on the sulfide precipitate, and, in general, reprecipitation is unnecessary.

The weight of the oven-dried sulfide is about 25 g. If the wash solution is concentrated by boiling before being mixed with the original filtrate, the volume of the combined solutions is kept below 2500 cc.

The Precipitation of Crude Hydrated Gallium Oxide.—As major components, the solution now contains between 4 and 8 g. of gallium, about 40 g. of iron, 30 g. of zinc, and 3–4 g. of aluminum. It is not feasible to precipitate the iron as hydroxide and the zinc as sulfide from an alkaline solution because in these processes a large percentage of the gallium is carried down by adsorption,[8] necessitating many reprecipitations. The extraction of gallium chloride by means of ether, as described by Berg and Keil,[4,9] is very convenient on a small scale, but when kilogram lots of ore residues are used, the method becomes very laborious and wasteful. A method was sought whereby gallium could be precipitated from solutions containing large quantities of iron and zinc. Thomas and Pugh[2] accomplished a similar separation by boiling the solution (containing gallium iron, copper and zinc) with a limited amount of ammonium hydroxide until a permanent precipitate was formed which contained the gallium, a small amount of iron and, in their case, all of the copper. The disadvantage of using ammonium hydroxide is that the precipitate formed is flocculent, making rapid filtration impossible. Dennis and Bridgman[10] found that a granular precipitate of hydrated gallium oxide is formed by boiling the gallium solution in the presence of sodium sulfite, sodium hydrogen sulfite or ammonium hydrogen sulfite. Porter and Browning[11] precipitated gallium quantitatively in the presence of zinc by this method. Following these suggestions it was found possible to separate the gallium and the aluminum from the iron as well as the zinc. The precipitate produced is readily filtered and washed. The small amount of iron present as impurity is subsequently removed without danger of adsorption.

Procedure.—The filtrate resulting from the removal of sulfides is boiled to expel hydrogen sulfide and treated while still warm with ammonium hydroxide until a small amount of permanent precipitate appears. The precipitate is redissolved by the addition of a few drops of hydrochloric acid. The solution is then brought to a boil and ammonium hydrogen sulfite solution, prepared by saturating 5 N ammonium hydroxide with sulfur dioxide, is slowly added. The amount of reagent must be determined by trial; if too large a quantity is used, the precipitate is contaminated with large quantities of basic ferrous sulfite. After the addition of the sulfite reagent, boiling is continued until sulfur dioxide is no longer being rapidly expelled. The granular precipitate settles rapidly and is removed by suction filtration and washed with hot water.

The process must be repeated to guard against incomplete precipitation. Before this is done, the film of gallium oxide, adhering to the walls of the beaker, is dissolved in a few drops of concentrated hydrochloric acid. The filtrate is returned to the beaker, 5 cc. of a 0.1% aqueous solution of sodium alizarin sulfonate added to serve as an indicator, and hydrochloric acid is added until the solution becomes distinctly yellow. The acidified solution is heated to boiling and a limited quantity of ammonium hydrogen sulfite solution is again introduced. During the evolution of sulfur dioxide which ensues, the color of the indicator turns from yellow to pink and, when the pH has become sufficiently high, the remaining traces of gallium and aluminum hydroxides are slowly precipitated. It may be necessary to repeat this process once more before only negligible quantities of precipitate are obtained. Gallium hydroxide is concentrated largely in the first two precipitations, since it is more acidic than aluminum hydroxide.[12]

Analyses.—In two instances, the combined precipitates prepared as described above from equal volumes of solution were analyzed. The results, reproduced in Table I,

TABLE I

ANALYSIS OF CRUDE GALLIUM OXIDE SEPARATED FROM GERMANITE

No.[a]	Vol. of soln., cc.	Ga_2O_3, g.	Al_2O_3, g.	Fe_2O_3, g.
A-1	1365	2.01	1.70	0.103
A-2	1365	2.02	1.60	.206
B-1	400	0.436	0.562	.021
B-2	400	.438	.590	.055

[a] The two solutions, A and B, do not contain comparable amounts of gallium. In case of solution A, the separation of gallium and aluminum was made by precipitating $AlCl_3 \cdot 6H_2O$; in case of solution B, by the extraction of $GaCl_3$ with ether.

show that the procedure outlined is capable of yielding quantities of gallium oxide in good agreement, while the amount of aluminum varies. The table shows, in addition, that the precipitate is contaminated with only a small amount of iron.

The Separation of Gallium and Aluminum.—Of the various methods proposed to separate gallium and aluminum, the most satisfactory is that used by Dennis and Bridgman[10] and Ato[13] in which aluminum chloride hexahydrate, $AlCl_3 \cdot 6H_2O$, is precipitated from an ether–water mixture saturated with hydrogen chloride. In adapting it to the large scale extraction of gallium, the procedure described below was followed.

Procedure.—The precipitates containing the hydrated oxides of gallium, aluminum and iron are dissolved in concentrated hydrochloric acid. To the strongly acid solution produced, an equal volume of ether is added slowly with cooling and agitation. The resulting mixture, in two layers, is saturated with hydrogen chloride, care being exercised to keep the contents of the flask thoroughly mixed and cooled. During this process, the ether layer disappears and fine, white crystals of aluminum chloride hexahydrate settle out. The precipitate is filtered off, using a sintered glass Büchner type funnel (Jena 17, G-3), and is washed with a 50–50 mixture of ether and water saturated with hydrogen chloride. The filtrate is transferred to a large beaker and, after the addition of some dilute sulfuric acid, the ether and excess acid are removed by evaporation of the solution to a small volume. The residue is diluted with distilled water to make about 300 cc. of solution in preparation for the removal of traces of iron.

The aluminum precipitate is tested for gallium before being discarded. The separation is usually found to be very satisfactory.

The Separation of Gallium and Iron.—The gallium solution, containing a small amount of iron, but no aluminum, is brought to the boiling point and hydrogen peroxide is added to oxidize the iron. Sodium hydroxide solution, 6 *N*, is then added slowly to the boiling solution until the gallium hydroxide, which at first precipitates, is redissolved, leaving the brick-red hydrated ferric oxide suspended in a clear, colorless solution. Continuing the boiling, for a few minutes, dehydrates the ferric oxide more thoroughly and makes filtration easier. The hot solution is filtered on a suction filter, with only a slight difference in pressure, and the precipitate is washed thoroughly with hot water. The amount of iron oxide precipitated is usually so small that reprecipitation is unnecessary. The filtrate contains all the gallium but only traces of other metallic elements.

The Precipitation of Pure Gallium Hydroxide.—The alkaline filtrate from which the iron has been removed is neutralized and made slightly acid with hydrochloric acid; excess ammonium hydrogen sulfite is added and the solution is boiled vigorously to expel sulfur dioxide. A copious pure white precipitate of hydrated gallium oxide appears. When the evolution of sulfur dioxide is no longer rapid, boiling is discontinued, the precipitate is allowed to settle and is removed by suction filtration. The precipitate is washed with hot water until free from chloride ion. The filtrate may be reboiled to test for completeness of precipitation, but usually there is so little gallium left in solution that it may be collected conveniently by means of tannin, following the directions of Moser and Brukl.[14] The presence of sulfite does not interfere with this procedure.

To indicate the quantities of material that can be handled at one time, we cite an instance in which 10 g. of gallium oxide, dissolved in 1500 cc. of solution, contained in a 2-liter Pyrex beaker, was precipitated by this method so completely that only a few hundredths of a gram of gallium oxide was recovered through the treatment with tannin.

The Preparation of Pure Gallium.—To prepare pure gallium from the hydrated oxide obtained in the above procedure, the latter is dissolved, while still moist, in a slight excess of potassium hydroxide solution and then electrolyzed. The metal may be converted to the volatile chloride, $GaCl_3$, which is readily sublimed *in vacuo*.[15]

Gallium Content of Germanite.—Published analyses[7] of different lots of germanite show the gallium content to range from 0.3 to 0.8%. Table II summarizes the results of the extraction of germanium and gallium from several kilograms of germanite.

TABLE II

RECOVERY OF GERMANIUM AND GALLIUM FROM GERMANITE

Ore lot no.	3	4
Ge recovered, %	6.88	5.13
Ga recovered, %	0.59	0.34

Observations on a large number of different samples of germanite have shown that when the germanium content is high, the gallium content is likewise high. The amount of gallium found is in substantial agreement with the value given by previous workers,[7] but we have observed that the ore contains a much higher percentage of aluminum than is given in their analyses. (Table I shows that with our ores, the gallium and aluminum contents are approximately the same.) It is possible that some of the very high values for gallium which have been published were the result of the failure to effect a complete separation of these elements. The ore is, nevertheless, the richest source of gallium yet discovered.

Summary

Gallium, occurring in germanite, is extracted after the removal of arsenic and germanium, by boiling the residues with hydrochloric acid.

After the precipitation of the sulfides of the heavy metals, the gallium and aluminum are separated from large quantities of iron and zinc by boiling the solution containing them with am-

monium hydrogen sulfite, leaving the iron and zinc in solution.

Aluminum is separated as $AlCl_3 \cdot 6H_2O$ from a hydrogen chloride saturated ether–water mixture in which gallium and traces of iron remain dissolved.

After the remaining iron has been removed, the gallium is precipitated as the hydrated oxide. The metal is obtained by electrolysis from a solution of the oxide in potassium hydroxide solution.

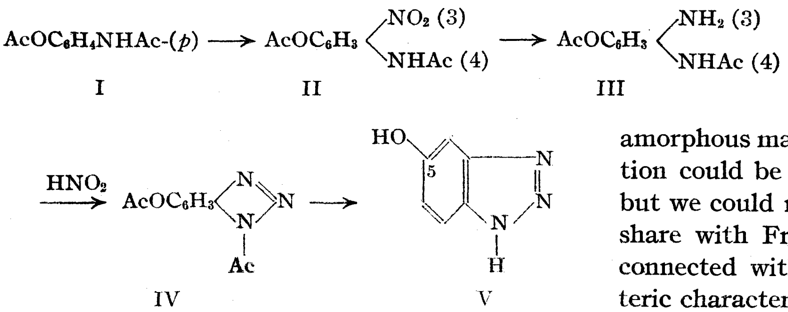
A Comparison of Heterocyclic Systems with Benzene. V. The Benzotriazole (Azimidobenzene) Series

BY LOUIS F. FIESER AND ELMORE L. MARTIN

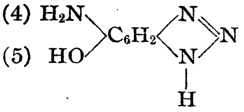
Since only one, rather unfavorable, example of a quinone containing the 1,2,3-triazole nucleus has been studied potentiometrically,[1] the synthesis of simple ortho or para quinones derived from benzotriazole was undertaken in order that a direct comparison might be made with the naphthoquinones. Although it was found that the benzotriazole quinones are unusually elusive substances, we were able to produce one member of the series in solution and to obtain from it the pure, crystalline hydroquinone. This was well suited to the purpose at hand.

The starting point for the preparation was 5-hydroxybenzotriazole, V, a compound which was unknown at the beginning of our investigation, but which has been described by Fries, Güterbock and Kühn[2] in a paper published since the completion of this part of our work. The Fries group prepared the hydroxy compound from the amine, the starting point for the preparation of which is 2,4-dinitroaniline. From the statements in the literature, supplemented by observations of our own, it is estimated that the over-all yield by this method is about 18%. We selected for the synthesis the series of transformations I → V.

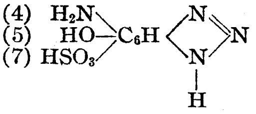


Reduction of the nitro compound II could not be accomplished with stannous chloride or sodium hydrosulfite without hydrolysis, but catalytic hydrogenation to the amine III proceeded smoothly, with a small amount of the hydrazo compound as the only by-product. The remaining steps were nearly quantitative, and the yield from p-aminophenol was 53%.

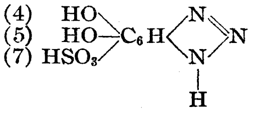
As a means of introducing an amino group in the 4-position, the reduction of the arylazo, nitro, and nitroso derivatives of 5-hydroxybenzotriazole was studied under various conditions. All of these substances gave the same reduction product, VI, but the only satisfactory preparative method consisted in the reduction of the nitroso compound with sodium hydrosulfite in a neutral, aqueous suspension. Like Fries and collaborators, who were the first to prepare 4-amino-5-hydroxybenzotriazole, we were unable to isolate a quinone on oxidation of the substance. Under ordinary conditions only black, amorphous material was obtained. A red coloration could be produced in very dilute solutions, but we could not isolate the red substance. We share with Fries the view that the difficulty is connected with the water solubility and amphoteric character of the unknown quinone.



VI



VII



VIII

From the 4-nitroso derivative we obtained with bisulfite 4-amino-5-hydroxy-7-sulfonic acid,

---

[1] Fieser and Ames, THIS JOURNAL, **49**, 2604 (1927).

[2] Fries, Güterbock and Kühn, *Ann.*, **511**, 213 (1934).

VII, and the oxidation of this substance was somewhat more successful. Clear orange-red solutions could be obtained which responded to the usual tests (with aniline, alkali, etc.) for an ortho quinone sulfonate, but the substance appears to be extremely soluble in water and rather sensitive, and we were unable to isolate it. To prepare the hydroquinone, VIII, the sulfonate VII was oxidized with bromine water and the red solution was decolorized with sulfur dioxide. 4,5-Dihydroxybenzotriazole-7-sulfonic acid (VIII) was obtained as colorless crystals of the potassium salt.

As a possible route to a quinone of the para series, we investigated Gattermann's method of preparing *p*-aminophenols by the electrolytic reduction of nitro compounds in concentrated sulfuric acid solution. Benzotriazole, the required starting material, usually is prepared by the action of nitrous acid on *o*-phenylenediamine. A more economical method, which has advantages with respect both to the yield and the quality of the product, consists in diazotizing *o*-aminoacetanilide and hydrolyzing the resulting acetate. To obtain *o*-aminoacetanilide, *o*-nitroaniline was acetylated in benzene solution by a method similar to that of Kaufmann,[3] and the nitro compound was reduced catalytically. In each of the five operations involved in the new synthesis of benzotriazole the yield was 90% or better, and pure products were easily obtained at each step. In the hydrogenation of *o*-nitroacetanilide, small amounts of the hydrazo compound and of 2-methylbenzimidazole were formed, but these substances are easily eliminated. Fries and collaborators[2] showed that the nitration of benzotriazole yields the 4-nitro compound. We were able to transform this substance into 4-amino-7-hydroxybenzotriazole, but all attempts to isolate a quinone by the oxidation of the compound were unsuccessful. No better results were obtained with the known methylated nitrobenzotriazoles. With 1-methyl-4-nitrobenzotriazole the Gattermann reaction was successful, but no quinone could be obtained on oxidation. No pure product was isolated from the electrolytic reduction of 1-methyl-7-nitrobenzotriazole.

Potential Measurements

Solutions of benzotriazole-4,5-quinone-7-sulfonate (XI) prepared by the oxidation of the pure hydroquinone VIII in dilute aqueous solution were found to be quite stable at 25° except in strongly alkaline solutions. The results of a series of electrometric titrations of the reductant, carried out by the method previously described,[4] and under the same conditions, are summarized in Table I. Bromine water proved to be an excellent titrating agent for the acid and neutral range, electrode equilibrium being attained very rapidly.

TABLE I

POTENTIALS OF THE SYSTEM FROM POTASSIUM BENZOTRIAZOLE-4,5-QUINONE-7-SULFONATE (25°)

$E_0 = 0.6721$ v. $K_o^b = 1.04 \times 10^{-5}$. $K_r^b = 1.57 \times 10^{-6}$. $E_n = E_0 + E_h + 0.02956 \log [1 + [H^+]/K_r^b] - 0.02956 \log [1 + [H^+]/K_o^b]$.

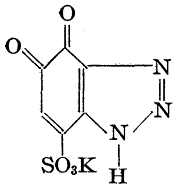
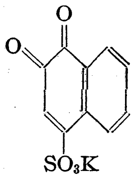
The normal potential (E_0) for the system of which the heterocyclic quinone XI is the oxidant is 42 mv. higher than that for the carbocyclic quinone XII. This comparison is regarded as more accurate than that between α,β-naphthotriazole-4,5-quinone and phenanthrenequinone (difference of 23 mv.),[1] for the factor of dissociation could not be taken into account in the earlier work. According to the present results there is a difference of nearly one *p*K unit in the constants for the basic ionization of the triazole nucleus in the quinone and in the hydroquinone, the latter



$E_0 = 0.672$ v.

XI



$E_0 = 0.630$ v.

(4) Fieser and Fieser, THIS JOURNAL, **56**, 1565 (1934).

substance being the more strongly basic. The normal potential (E_0) reported refers to conditions under which there is no basic ionization of either the oxidant or the reductant. The value is intermediate between those for the quinones containing a benzene ring and a thiophene ring[5] in place of the triazole nucleus. If the comparison is strictly valid, this would indicate an intermediate degree of aromaticity for the triazole system, this ring being less aromatic than benzene.

Experimental Part

1. Synthesis of 5-Hydroxybenzotriazole (V)

1 - Acetylamino - 2 - nitro - 4 - acetoxybenzene.[6]—1 - Acetylamino-4-acetoxybenzene, m. p. 150–151°, was obtained from *p*-aminophenol hydrochloride in 90% yield. For the nitration, 100 g. of the diacetate was added in small portions to 200 cc. of fuming nitric acid (sp. gr. 1.5) which was mechanically stirred in a freezing mixture. The temperature was kept at 0–5° throughout the addition which, with efficient cooling, required fifteen to twenty minutes. The temperature was allowed to rise to 12–15° and maintained there for twenty to twenty-five minutes, when the solution was poured onto ice. The yellow product was washed entirely free from acid and crystallized from alcohol, when it formed stout yellow needles, m. p. 144–145°; yield, 110 g. (89%).

1-Acetylamino-2-amino-4-acetoxybenzene (III).—The hydrogenation was carried out in the low pressure apparatus, using 30 g. of the nitro compound dissolved in 300 cc. of hot alcohol and 0.1 g. of Adams catalyst. With a good catalyst the temperature rose and the reduction was complete in ten to fifteen minutes. The colorless solution was filtered and the solvent was distilled in vacuum, giving a slightly yellow crude product melting at 172–174°; yield from a total of 120 g., 98 g. (93%). This contained as a by-product the orange azo compound, which was left as a residue on dissolving the crude amine in hot water. On decolorizing the solution and cooling, the amine was obtained as colorless plates, m. p. 175–177°; yield 79 g. (75%). The pure compound crystallizes from water in fine needles, from alcohol as square plates, m. p. 178–179° (Analysis No. 1, Table II).

The following derivatives were obtained in somewhat purer form than by previous methods. 1,2-Di-(acetylamino)-4-acetoxybenzene was prepared by acetylating III in aqueous solution and crystallized from water (No. 2): fine needles, m. p. 187–188° (lit., 184–185°).[7] 3,4-Di-(acetylamino)-phenol was obtained by treatment of the triacetate with cold, dilute alkali for one hour and acidifying the resulting solution (No. 3): stout needles from water, m. p. 214–215° (lit., 205–207°).[7]

2,2′ - Di - (acetylamino) - 5,5′ - diacetoxyazobenzene (No. 4) appeared in amounts of 0.1–1.0 g. in each hydrogenation of 30 g. of the nitro compound, the quantity being greatest when the catalyst was poor and the reduction slow. The substance is not present as such at the end of the hydrogenation but as the hydrazo compound, which becomes oxidized after exposure to the air. The azo compound is insoluble in acids or alkalies and it crystallizes from glacial acetic acid (sparingly soluble) as fine orange needles decomposing at 280–285°.

1-Acetyl-5-acetoxybenzotriazole, IV (No. 5).—To a solution at 0° of 62.4 g. of the pure amine III in 53 cc. of concentrated hydrochloric acid and 750 cc. of water, a solution of 20.7 g. of sodium nitrite in 200 cc. of water was slowly added. The triazole separated at once to give a crystalline paste and it was collected and washed; m. p. 125°; yield, 64 g. (98%). The substance was obtained from benzene–ligroin or from dilute acetone as fine, colorless needles, m. p. 125–126°. From 5-hydroxybenzotriazole and acetyl chloride in pyridine Fries, *et al.*[2] obtained a diacetate which sintered at 115° and melted at 127°. With acetic anhydride and sodium acetate we obtained a sample identical with the above. Unlike the case of 5-methylbenzotriazole[8] the acetylation gives only one of the two possible isomers.

5-Hydroxybenzotriazole Hydrochloride (No. 6).—The moist diacetate obtained as above (64 g., dry) was warmed with 200 cc. of concentrated hydrochloric acid until solution was complete (a slight yellow color was discharged if necessary by the addition of a trace of stannous chloride). On cooling to 0° 43 g. of colorless crystals separated, and 4 g. more was obtained by concentrating the mother liquor; yield, 90%. For analysis the compound was recrystallized from dilute acid, when it formed stout, colorless needles decomposing at about 225°.

5-Hydroxybenzotriazole, V (No. 7).—On mixing aqueous solutions of 5.15 g. of the above hydrochloride and of 2.6 g. of sodium bicarbonate a white, crystalline precipitate began to form after a few minutes; m. p. 232–234°; yield, 3.6 g. (90%). The compound crystallized from water as colorless micro-needles, m. p. 234–235°, with some decomposition. Fries, *et al.*,[2] obtained a slightly yellow product, m. p. 228° dec.

2. Derivatives of 5-Hydroxybenzotriazole

The **4-benzeneazo** derivative (No. 8), orange needles from alcohol, m. p. 230–232°, dec., the **4-*p*-tolueneazo** compound (No. 9), reddish-orange needles from alcohol, m. p. 224–225°, and the **4-*o*-tolueneazo** compound (No. 10), bright red needles from alcohol, m. p. 243–244° dec., were prepared in the usual way. The dyes are insoluble in dilute hydrochloric acid but soluble in alkali (probably because of the acidic character of the triazole nucleus).

4-Nitro-5-hydroxybenzotriazole (No. 11).—To a solution of 10.8 g. of III in 40 cc. of concentrated sulfuric acid at 15–20° 4 cc. of nitric acid (sp. gr. 1.4) was added by drops. After one-half hour at 15–20° and one hour at 50°, the solution was poured onto ice, and the product was crystallized from dilute acetic acid; m. p. 262–263°; yield, 9 g. (63%). Fries, *et al.*,[2] prepared the compound by another method and give the melting point as 236° dec. This probably is a typographical error.

4-Nitroso-5-hydroxybenzotriazole (No. 12) was prepared by a method similar to that of Fries, *et al.*:[2] sodium nitrite solution was added to a solution of 5-hydroxybenzotriazole hydrochloride in water; yield, 97%.

---

[5] Fieser and Kennelly, This Journal, **57**, 1611 (1935).

[6] Hähle, *J. prakt. Chem.*, **43**, 63 (1891), prepared this compound but recorded few details of the procedure.

[8] Morgan and Micklethwait, *J. Chem. Soc.*, **103**, 1396 (1913).

4 - Amino - 5 - hydroxybenzotriazole - 7 - sulfonic Acid (VII).—The moist nitroso compound from 5.16 g. of 5-hydroxybenzotriazole was stirred for one hour with a solution of 8.8 g. of sodium bisulfite in 200 cc. of water, when it all dissolved. The filtered, yellow solution was treated with 10 cc. of concentrated sulfuric acid and maintained at 40° for three and a half hours. The solution had become red and a yellow, crystalline product had separated. This was dissolved in a hot solution of 10 g. of sodium bisulfite in 50 cc. of water, the solution was decolorized with Norite and acidified while still hot. The product was pale yellow and weighed 4.8 g. (70%). The color was removed completely by crystallization from water, in which the substance is only sparingly soluble. The compound separates slowly in long, colorless needles; it dissolves in alkali or soda with a green coloration.

Anal. Calcd. for $C_6H_6O_4NS$: S, 13.92. Found: S, 13.94, 14.01.

Potassium Benzotriazole-4,5-hydroquinone-7-sulfonate (VIII).—Of various oxidizing agents tried for the preparation from VII of solutions of the triazolequinone sulfonate, bromine water was the most satisfactory. In the presence of an excess of bromine the orange solution is fairly stable. Treated with alkali, the solution becomes dark and then clear red. With aniline a red anilino quinone is precipitated, but the compound was not obtained in a crystalline condition. The hydroquinone was obtained as follows. A small part of 3.3 g. of VII was suspended in 10 cc. of water and shaken with a small part of 1 cc. of bromine. The material soon dissolved to give an orange solution, and further small quantities of the aminohydroxy compound and of bromine were added with shaking until all had been used. To the filtered quinone solution 10 cc. of saturated potassium chloride solution was added, and the solution was decolorized with sulfur dioxide. The potassium salt VIII began to separate at once as colorless crystals. When crystallized from water containing a little sulfur dioxide the substance formed stout, glistening needles of the tetrahydrate; yield, 2.6 g. (55%).

Anal. Calcd. for $C_6H_4O_5N_3SK \cdot 4H_2O$: S, 9.67. Found: S, 9.62, 9.65.

4-Amino-5-hydroxybenzotriazole.—(a) To a saturated aqueous solution of 10.5 g. of sodium hydrosulfite 3.28 g. of 4-nitroso-5-hydroxybenzotriazole was added slowly with stirring. The mixture became warm and the yellow solid soon was transformed to the colorless, crystalline reduction product. Crystallized from hot water containing a trace of hydrosulfite, this gave 2.5 g. (83%) of the free amine, m. p. 210–214° dec., and from it 3 g. of the pure, colorless dihydrochloride was obtained.

(b) The 4-benzeneazo compound was reduced with stannous chloride and the tin double compound was decomposed with hydrogen sulfide. The dihydrochloride was obtained by evaporation in vacuum; yield, 22%.

(c) Electrolytic reduction of the 4-nitro compound (7 g.) in concentrated sulfuric acid gave 10 g. of the aminohydroxybenzotriazole as the sparingly soluble sulfate.

That these three methods give the same product was shown by a comparison of samples of the free base, which is best prepared from the pure dihydrochloride by the addition of sodium bicarbonate, followed at once by a trace of hydrosulfite, to the aqueous solution of the salt. 4-Amino-5-hydroxybenzotriazole (No. 13) crystallizes from water as long, colorless needles, m. p. 216–217° dec. Fries, *et al.*,[2] report the m. p. 217°. The substance soon darkens when exposed to the air in a moist condition. The **dihydrochloride (No. 14)** was obtained as completely colorless, stout needles, decomposing at about 225°; it does not deteriorate on storage.

3. Preparation of Benzotriazole

2-Nitroacetanilide.—To a solution of 69 g. of *o*-nitroaniline in 75 cc. of warm benzene 75 cc. of acetic anhydride was added, along with 3–5 drops of concentrated sulfuric acid. The latter reagent initiated a vigorous reaction and a part of the benzene distilled. After heating on the steam-bath for thirty minutes, the solvent was removed by evaporation in a dish on the steam-bath, and on cooling the light yellow melt solidified. One crystallization from dilute alcohol gave 84 g. (93%) of yellow needles, m. p. 92–93°.

2-Aminoacetanilide.—Hydrogenation of the nitro compound (30 g. in 200 cc. of hot alcohol, with 0.1 g. of Adams catalyst) proceeded smoothly (ten to fifteen minutes), and on evaporation of the filtered, initially colorless solution in vacuum the crude amine was obtained as a slightly yellow product, m. p. 130–132°. From 120 g. of nitro compound the yield was 97 g. (97%). The main portion dissolved readily in hot water, leaving a yellow residue which, when crystallized from glacial acetic acid, formed orange needles, m. p. 270–271°, having the properties of 2,2′-di-[acetylamino]-azobenzene.[9] On clarifying and cooling the aqueous solution, 2-aminoacetanilide (75 g.) separated as colorless plates, m. p. 132–133°, and an additional crop was obtained by concentrating the mother liquor under reduced pressure; yield, 90 g. (90%). A second concentration of the mother liquor gave 3 g. of another substance which, when recrystallized from water, melted at 174–175°, corresponding with the description of 2-methylbenzimidazole.[10]

1-Acetylbenzotriazole.—A solution at 0° of 100 g. of pure 2-aminoacetanilide in 500 cc. of water and 120 cc. of concentrated hydrochloric acid was treated with a solution of 46 g. of sodium nitrite in 200 cc. of water, added dropwise with stirring. A colorless precipitate separated at once; washed and dried it weighed 102 g. (95%) and melted at 49–51° (recrystallized, 50–51°).

Benzotriazole.—The crude acetate (100 g.) was dissolved by warming in 150 cc. of concentrated hydrochloric acid, a small crystal of stannous chloride being added to remove a slight yellow coloration. On cooling, colorless needles of the hydrochloride separated (82 g.), and a further crop was obtained by concentration of the mother liquor; yield, 89 g. (92%). A solution of 46.7 g. of the pure salt in 200 cc. of water was carefully neutralized with a solution of 26 g. of sodium bicarbonate. Benzotriazole separated as colorless crystals, m. p. 97–98°; yield, 33 g. (92%). Recrystallization from benzene gave long, colorless needles, m. p. 98–99°.

The preparation of benzotriazole by the action of nitrous acid on *o*-phenylenediamine was found to be quite tedious in comparison with the above method. After three treat-

---

[9] Willstätter and Pfannenstiel, *Ber.*, **38**, 2351 (1905).

[10] Hübner, *Ann.*, **209**, 353 (1881).

ments with Norite we obtained a light gray product, m. p. 94–96°, in 67% yield.

4. Electrolytic Reduction of the Nitro Compounds

4-Amino-7-hydroxybenzotriazole (No. 15).—4-Nitrobenzotriazole was prepared by nitration essentially as described by Fries, *et al.*,[2] the yield of recrystallized material, m. p. 229–230°, being 68%. A solution of 10 g. of the nitro compound in 100 g. of concentrated sulfuric acid was subjected to electrolytic reduction according to Gattermann,[11] using a 5 × 9 cm. porous clay cell resting in a beaker of 80–90% of sulfuric acid. The current, taken from a 6-v. line, increased from 1–1.5 amp. to about 3 amp. as the temperature rose to the maximum value of 70–80°. The reaction was complete in about twenty hours and a part of the amine sulfate separated during this period and the remainder was obtained by diluting the acid liquor with an equal volume of water and allowing the solution to stand at 0° for two days; yield, 10 g.

The sulfate is sparingly soluble in water and it does not crystallize well. The free base was liberated from the salt with sodium bicarbonate and crystallized from water in the presence of a trace of sodium hydrosulfite. The colorless needles were collected, washed with alcohol and ether, and quickly dried in vacuum. The substance decomposes at about 225–230°, and it is sensitive to air oxidation. It is moderately soluble in water, sparingly soluble in ether. Oxidizing agents added to a solution of the hydrochloride produce a red coloration, but no quinone could be isolated.

1-Methyl-4-nitrobenzotriazole.—Following the method of Fries, *et al.*,[2] 4-nitrobenzotriazole was methylated with dimethyl sulfate. Like their material, our product softened at 163° and melted at 173° even after several crystallizations from alcohol, but after a single crystallization from dilute acetic acid the substance melted sharply at 181–182° and this value remained unchanged on further crystallization. The yield of the pure isomer was 30%.

1-Methyl-4-amino-7-hydroxybenzotriazole was obtained in good yield by reduction of the 4-nitro compound by the Gattermann method. The sulfate forms colorless micro crystals and is moderately soluble in water. The free base is very sensitive to oxidation and was not obtained entirely pure. The **dibenzoate** (No. 16) forms colorless needles from alcohol, m. p. 262–263°.

1-Methyl-7-nitrobenzotriazole.—The **methylation** of benzotriazole by Reissert's[12] method gave the 1-methyl derivative in less than 10% yield. The nitro compound[2] gave no clean products when submitted to electrolytic reduction in sulfuric acid solution.

Summary

Methods of obtaining ortho and para quinones or hydroquinones of the benzotriazole series have been investigated and one compound of the type desired has been prepared and studied potentiometrically. The oxido-reduction potential of a bicyclic quinone containing the triazole nucleus is appreciably higher than that of the corresponding naphthoquinone.

CONVERSE MEMORIAL LABORATORY
CAMBRIDGE, MASSACHUSETTS
RECEIVED JULY 5, 1935

---

[11] Gattermann, *Ber.*, **26**, 1846 (1893).

[12] Reissert, *ibid.*, **47**, 677 (1914).

[13] The semimicrocombustion of some of these compounds, particularly those containing the stable triazole nucleus and having a high nitrogen content, presented considerable difficulty. The method found most satisfactory was to mix the sample with fine copper oxide and to conduct the combustion with air in a very hot tube.

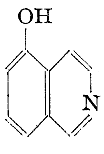
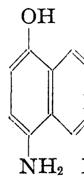
A Comparison of Heterocyclic Systems with Benzene. VI. Quinones of the Quinoline and Isoquinoline Series

BY LOUIS F. FIESER AND ELMORE L. MARTIN

It was desired to obtain for potentiometric study quinones or hydroquinones derived from quinoline and isoquinoline. In the case of the former heterocycle no preparative problem was involved, for 5,8-quinolinequinone is a known compound[1] and Matsumura and Sone[2] have developed a very convenient method for the preparation of the corresponding hydroquinone. In the isoquinoline series, however, compounds of the desired type do not appear to have been described. The three known Bz-hydroxyisoquinolines were first considered as possible starting materials. The only isomer whose structure is fully established, 7-hydroxyisoquinoline, has been prepared by a rather tedious synthesis.[3] The other two compounds have been obtained from the products of high-temperature and low-temperature sulfonation.[4] In analogy with naphthalene, the first of these probably is a β-derivative, and since it differs from the 7-isomer, it probably is 6-hydroxyisoquinoline. The hydroxy compound derived from the other sulfonate has been obtained also from nitroisoquinoline, and since both the sulfonate and the nitro compound are known to be Bz-alpha derivatives[5] the substance is either 5- or 8-hydroxyisoquinoline. The former structure perhaps is the more probable, and we shall refer to the compound as the 5(8)-derivative and formulate it as the 5-isomer, I. Although this compound is not easily obtained, it appeared to be more readily available than the other isomers and a small quantity was prepared and investigated. It was found possible to convert the substance through the benzeneazo derivative into the 5,8 (or 8,5)-hydroxyamino compound II, but the entire process was so unsatisfactory with respect to yields that a better method was sought.

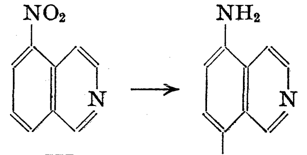


I



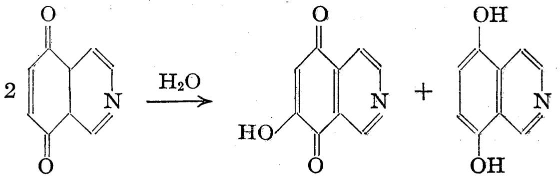
II

Such a method was found in the electrolytic reduction by Gattermann's method of the readily available 5(8)-nitroisoquinoline, III, for this gave in good yield the isomeric 8,5(5,8)-hydroxyamino compound IV. It was expected that the two *p*-hydroxyamino compounds II and IV would yield on oxidation the same *p*-isoquinolinequinone.



III IV

The same yellow product was indeed obtained in each reaction, but instead of being the expected quinone it had the properties of the corresponding hydroquinone. It was observed that the yield was less than half of the expected amount, that mother liquor was deep red whereas solutions of the pure hydroquinone (salt) are yellow, and that the yield decreased as the amount of oxidizing agent was increased. From these facts it appears very probable that the hydroquinone (VI) results from a disproportionation of the quinone first formed.



V (or isomer) VI

Such a reaction has been well established in the *o*-quinone series.[6] The red mother liquor probably contained a mixture of hydroxyquinones, but no pure product could be isolated. The quinone V could be produced in solution from pure VI, but we were unable to isolate it. The two methods of preparing the hydroquinone establish the structure of 5,8-dihydroxyisoquinoline, VI, and the substance was also obtained by the action of iron and hydrochloric acid on the nitroso

derivative of the 5(8)-hydroxy compound (method of Matsumura and Sone[2]).

An ortho quinone of the series was obtained starting with the readily available IV, which was converted through the monoacetate VII and its *p*-sulfobenzeneazo compound into the amine VIII. Oxidation yielded an ortho quinone which may have either of the alternate structures: 5-acetylamino-7,8-isoquinolinequinone (IX) or 8-acetylamino-5,6-isoquinolinequinone.

IX

Potential Measurements

Titrations of the reductants were carried out as indicated in the fifth paper.[7] Both the quinoline- and isoquinoline-quinone were too sparingly soluble in solutions more alkaline than about *p*H 7 to permit an extension of the data of Tables I and II. The normal potentials for the two systems under such conditions that there is no ionization (E_0) are very nearly identical. The difference in the basic dissociation constants of the oxidant and of the reductant is in each case about four *pK* units, the quinone being the weaker base. Quinolinequinone is so weakly basic that the value reported for K^b_0 is in this case only a rough approximation. The isoquinoline compounds are distinctly more basic (one *pK* unit) than the corresponding quinoline derivatives.

TABLE I

POTENTIALS OF THE SYSTEM FROM 5,8-QUINOLINEQUINONE (25°)[8]

Titrations of the reductant with $K_3Mo(CN)_8$. E_0 = 0.5570 v. $K^b_r = 1.76 \times 10^{-5}$. $K^b_0 = 1.10 \times 10^{-1}$. $E_n = E_0 + E_h + 0.0295 \log [1 + [H^+]/K^b_r] - 0.0295 \log [1 + [H^+]/K^b_0]$.

5-Acetylaminoisoquinoline-7,8-quinone, IX (or 8,6,5), is so sparingly soluble in water that satisfactory results were obtained only in the strongly acid region. In titrations of the hydroquinone with potassium dichromate at *p*H 0.40–0.50, the difference between the oxido-reduction electrode at half-oxidation and a hydrogen electrode in the same buffer was found to be 0.7573 v. (av.). As nearly as can be judged from available data, this substituted ortho quinone bears the normal relationship in potential to the para quinone of the isoquinoline series.

Discussion

A sufficient number of heterocyclic systems have been studied in this series of investigations to warrant a brief analysis of the main results. In initiating the work it was pointed out[9] that the lowering in the potential of a benzoquinone resulting from the fusing on of a benzene ring to produce a naphthoquinone probably gives a measure of the inertness or aromaticity of the benzene nucleus. The reactivity of one of the quinonoid ethylenic linkages is dampened when it becomes at the same time an integral part of an aromatic ring. If this premise is correct, the lowering in potential produced by a heterocycle, in comparison with the effect of a benzene ring, might give a measure of the relative degree of aromaticity of the heterocyclic ring. The ring systems for

---

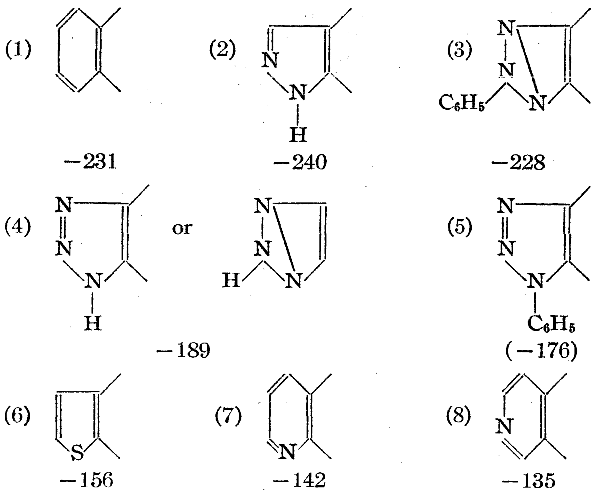
which reliable data are now available are indicated in the accompanying chart.



EFFECT OF AROMATIC RINGS ON THE POTENTIAL OF A QUINONE (IN MV.).

The question of prime importance is whether or not the diminished degree of unsaturation characteristic of the aromatic state is the only factor involved in determining the effect of the different heterocyclic rings. Were this the case the results would indicate that the pyrazole ring (2) is strongly aromatic, that the pyridine ring in the condition of either (7) or (8) is weakly so, and that the thiophene ring occupies a somewhat intermediate position. It is not easy to decide on the basis of other data if this is a reasonable relationship. The ease of substitution is hardly a valid criterion, because it is so likely to be determined, in part at least, by the character of the hetero atom. The ease of substitution of thiophene and furan may be connected with the presence in the ring of a key atom which when joined to a benzene ring facilitates substitution. The reluctance of the pyridine ring to react with many substituting reagents may be because the reaction is conducted in an acidic medium where the hetero atom forms an ionic, positive pole, so that it functions as a meta-directing group and retards substitution. The fact that Py-hydroxyquinolines and isoquinolines, unlike the naphthols, exist to a large extent in the ketonized forms points to a weakened condition of aromaticity of the pyridine ring, for the tendency to retain the completely aromatic type is an important characteristic of the benzene ring. On the other hand, the pyridine ring is remarkably resistant to attack by oxidizing agents, even under conditions such that there is no stabilization of the ring by salt-formation, and indeed it surpasses benzene in this respect. The thiophene ring is much more susceptible to oxidation. Although the different lines of evidence are conflicting, the relative positions of thiophene and pyridine indicated by the electrochemical results appear dubious. On the whole pyridine seems to possess more of the attributes of the truly aromatic type.

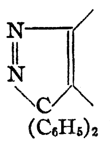
That some factor other than the aromaticity may be of influence in determining the potentials of the heterocyclic quinones has been recognized from the outset,[9] and it has been suggested[9,10] that the hetero atom may function as a part of a substituent group, independently of the stability of the ring. A group containing bivalent sulfur would shift the potential of a quinone to a more negative level, while a substituent containing the —N=C or the —C=N linkage of quinoline or isoquinoline probably would have the opposite effect. If the figures given above could be corrected for these possible effects, the value representing the aromaticity of the thiophene ring would become less negative and that for the pyridine rings would become more negative. These changes would be such as to bring the results into better accord with the general inferences from chemical observations, and we are inclined to believe that until such corrections can be made, or until they can be proved to be negligible, the results of the electrochemical comparisons should be viewed with caution.

While a revision may be required along the lines indicated, it is also possible that the results are essentially valid as they stand. It may be noted that the results of different comparisons of the same heterocycle have been remarkably concordant, and that the influence of a pyridine ring is practically the same whether the nitrogen atom is in the α- or the β-position with respect to the quinonoid nucleus. One other observation may be made which strongly indicates that the potential-lowering effects defined above reflect in some measure a property fundamentally connected with the aromatic character of the heterocycles. As judged by the general criteria of stability and lack of chemical reactivity, the 1-phenyltriazole ring system (5) certainly is to be classed as aromatic, and, like the benzene ring, it produces a decided lowering in the potential of a quinonoid nucleus to which it is joined. While formally

[10] Fieser and Kennelly, THIS JOURNAL, **57**, 1611 (1935).

similar to (5), the diphenyl pseudopyrazole ring (9) has entirely different properties.[11] The azo linkage is very reactive, the ring can be cleaved with great ease, and the system is distinctly unstable and in no sense aromatic. The difference is adequately reflected in the potentials, for the effect of fusing this truly unsaturated ring to *p*-benzoquinone is to raise the potential by the substantial amount of 110 mv. From the potentials above it would be concluded that (5) and (9) are fundamentally different, and that the azo group of (5), if indeed it exists as such, has a modified or dampened character quite distinct from an ordinary center of unsaturation, for in the latter case the effect upon the potential would be in the positive direction.

(9)



Experimental Part

5(8)-Hydroxyisoquinoline.—Isoquinoline sulfate (0.2 mole) was sulfonated essentially according to Weissgerber[12] (with 110 g. of fuming acid, 50% sulfur trioxide, at 20–25° for forty-eight hours), the solution was poured onto 500 g. of a mixture of ice and water and the solution was allowed to stand undisturbed. Long, colorless needles soon separated, and the pure α-sulfonic acid was easily obtained by recrystallization of this material from water; yield, 30 g. (72%). We consider the tedious separation through the barium salt unnecessary. No improvement could be made in the alkali fusion and the best yield was 17% (m. p. 228–230°).

5(8)-Hydroxy-8(5)-aminoisoquinoline (II).—The hydroxy compound (1.45 g.) was coupled with diazotized aniline in alkaline solution and the azo compound was reduced with sodium hydrosulfite. The yellow amine which separated was dissolved with a trace of stannous chloride in 3 cc. of concentrated hydrochloric acid and 5 cc. of water. After clarification, 20 cc. of concentrated acid was added to the hot, yellow filtrate. On cooling, the product separated as stout, bright yellow needles of the dihydrochloride; yield, 1 g. (43%).

Anal. Calcd. for $C_9H_{10}ON_2Cl_2$: C, 46.35; H, 4.33. Found: C, 46.07; H, 4.47.

5(8)-Amino-8(5)-hydroxyisoquinoline (IV).—5(8)-Nitroisoquinoline was prepared as described by Claus and Hoffmann,[13] the yield of crude material, m. p. 104–108°, being 74%. The electrolytic reduction of the nitro compound (12 g.) in sulfuric acid solution (120 cc.) was carried out as described in the fifth paper.[7] After twenty-four hours the yellow solution was filtered from calcium sulfate through asbestos, diluted with an equal volume of water, and allowed to stand for several days in the ice box. Fine yellow needles of the amine sulfate separated and were collected on an asbestos filter; yield, 20 g. This salt probably contains two molecules of sulfuric acid; it dissolves readily in water and presently the solution deposits fine yellow needles of the **monosulfate**, which is very sparingly soluble in water.

Anal. Calcd. for $C_9H_8ON_2 \cdot H_2SO_4$: C, 41.83; H, 3.90; S, 12.42. Found: C, 41.89; H, 4.30; S, 12.57.

The dihydrochloride, which is considerably more soluble in water, was prepared as follows. The crude sulfate from 12 g. of the nitro compound was suspended in 100 cc. of water, covered with a layer of ether to prevent oxidation, and the acid was neutralized with solid sodium bicarbonate. The solid became bright red and then yellow, as the neutral point was reached. The yellow amine was collected, washed with water and quickly dissolved with a trace of stannous chloride in 18 cc. of concentrated hydrochloric acid and 50 cc. of water. After heating the solution and filtering it through charcoal, 200 cc. of concentrated hydrochloric acid was added. The stout yellow needles which separated on cooling were washed with dilute acid, alcohol and ether; yield, 13.3 g. (83%). The salt is readily soluble in water and it dissolves in alkali with a green coloration.

Anal. Calcd. for $C_9H_8ON_2 \cdot 2HCl$: C, 46.35; H, 4.33; Cl, 30.44. Found: C, 46.25; H, 4.34; Cl, 30.61.

The dibenzoyl derivative was prepared by shaking an aqueous suspension of the sulfate with benzoyl chloride and alkali. An oil formed and soon solidified. The substance crystallized from alcohol as fine, colorless needles, m. p. 223–224°.

Anal. Calcd. for $C_{23}H_{16}O_3N_2$: C, 74.98; H, 4.38. Found: C, 74.96; H, 4.42.

Isoquinoline-5,8-hydroquinone Hydrochloride (VI).—(a) A suspension of 5.16 g. of crude 5(8)-amino-8(5)-hydroxyisoquinoline sulfate in 25 cc. of water was treated at 5° with 24 cc. of cold 20% ferric chloride solution. The solid material soon dissolved to give a deep red solution and after standing for a time a fine, yellow precipitate began to separate. After cooling in ice for one hour, this was collected and washed free of red mother liquor with ice water. The crude product was dissolved in 40 cc. of hot water and 10 cc. of concentrated hydrochloric acid and brought down with 75 cc. of concentrated acid, when it gave no test for sulfate ion. After a further crystallization from dilute acid the hydrochloride was obtained as fine, yellow leaflets; yield, 0.73 g. It darkens at about 260° and has no melting point. The substance gives no coloration with ferric chloride, it rapidly darkens in alkali and it gives a very sparingly soluble sulfate.

Anal. Calcd. for $C_9H_7O_2N \cdot HCl$: C, 54.71; H, 4.09; Cl, 17.95; N, 7.18. Found: C, 54.76; H, 4.20; Cl, 18.05; N, 7.16.

(b) The preparation from 5(8)-hydroxy-8(5)-aminoisoquinoline was similar and gave an identical product.

(c) 5(8)-Hydroxyisoquinoline (1.45 g.) was converted into the nitroso derivative by slowly acidifying an alkaline solution of the substance containing sodium nitrite. The crude, moist nitroso compound was dissolved quickly in 400 cc. of hot water containing 12 cc. of concentrated hydrochloric acid and the filtered solution was treated at 95° with 3 g. of iron powder, added in one hour with stirring. The solution was filtered, concentrated in vacuum, and treated with 10 cc. of concentrated hydrochloric acid.

Yellow crystals of the hydroquinone hydrochloride separated on cooling; yield, 0.2 g. (10%).

Dibenzoyl isoquinoline-5,8-hydroquinone formed colorless needles from alcohol, m. p. 162–163°.

Anal. Calcd. for $C_{23}H_{15}O_4N$: C, 74.78; H, 4.10. Found: C, 74.80; H, 4.28.

Diacetyl 5(8)-amino-8(5)-hydroxyisoquinoline.—This derivative was obtained from the dihydrochloride of the aminohydroxy compound with acetic anhydride and sodium acetate either in an aqueous solution (60% yield) or without a solvent (69% yield). It crystallizes from dilute alcohol as long, colorless needles, m. p. 208–209°.

Anal. Calcd. for $C_{13}H_{12}O_3N_2$: C, 63.91; H, 4.96. Found: C, 64.02; H, 5.13.

5-Acetylamino-7-(*p*-sulfobenzeneazo)-8-hydroxyisoquinoline (or 8,6,5).—The above diacetyl compound (2.41 g.) was dissolved in a cold solution of 1 g. of sodium hydroxide in 25 cc. of water (hydrolysis of the O-acetyl group) and the solution was treated at 0° with a suspension of the diazo compound from 2.09 g. of sulfanilic acid. A portion of the deep purple-red solution after being diluted yielded a brown, crystalline precipitate of the azo compound on acidification.

Anal. Calcd. for $C_{17}H_{14}O_5N_4S$: C, 52.82; H, 3.65. Found: C, 52.40; H, 3.99.

5-Acetylamino-7-amino-8-hydroxyisoquinoline Dihydrochloride, VIII (or 8,6,5).—The remainder of the solution of the azo compound was treated with sodium hydrosulfite and warmed gently until the color was discharged. The crystalline, yellow precipitate was dissolved in 20 cc. of water and 4 cc. of concentrated hydrochloric acid, and the clarified solution was saturated with hydrogen chloride at 0°, when fine yellow needles of the dihydrochloride soon separated; yield, 1.3 g. (43%). The salt is only moderately soluble in water but it is slow to crystallize.

Anal. Calcd. for $C_{11}H_{11}O_2N_3 \cdot 2HCl$: C, 45.52; H, 4.52. Found: C, 45.12; H, 4.70.

5-Acetylaminoisoquinoline-7,8-quinone Hydrochloride, IX (or 8,6,5).—A solution of 0.29 g. of VIII in 4 cc. of water and 0.5 cc. of concentrated hydrochloric acid was treated at 10° with 2 cc. of 20% ferric chloride solution added in one portion. The solution became red and fine, yellow needles soon separated. The product was washed free of dark mother liquor with concentrated acid, dissolved in 10 cc. of water, and 1 cc. of concentrated acid was added to the clarified solution. Golden yellow needles soon separated in 51% yield. Without isolating any of the intermediates, the yield from diacetyl aminohydroxyisoquinoline was 38%.

Anal. Calcd. for $C_{11}H_8O_3N_2 \cdot HCl$: Cl, 14.03. Found: 13.93, 13.94.

Summary

Isoquinoline-5,8-hydroquinone has been prepared by three methods, and the oxido-reduction systems from this reductant and from the known quinoline-5,8-hydroquinone have been studied potentiometrically. An analysis is presented of the results obtained in this series of investigations of the degree of aromaticity of various heterocyclic rings.

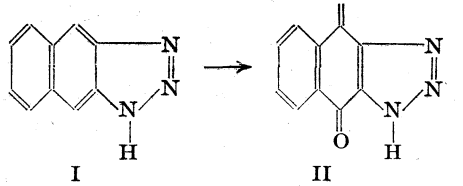
A Comparison of Heterocyclic Systems with Benzene. VII. Isologs of Anthraquinone Containing One and Two Triazole Rings

BY LOUIS F. FIESER AND ELMORE L. MARTIN

When this work was undertaken no unsubstituted quinones of the type indicated in the title were known, but in a paper published in March of this year Fries, Walter and Schilling[1] described the preparation of *lin*-naphthotriazole-8,9-quinone (II) by the oxidation of *lin*-naphthotriazole (I) with chromic anhydride. We had at the time performed a similar experiment, but the succession of steps leading to II was so generally unsatisfactory that a better method was developed.



I II

Ullmann and Ettisch[2] worked out an excellent method of preparing 2,3-dichloro-1,4-naphthoquinone from α-naphthol and found that one of the two chlorine atoms is easily replaced by reaction with ammonia. The halogen atom of the amino compound (III) is resistant to attack by amines under comparable conditions, but Fries and Ochwat[3] found that the acetyl derivative IV reacts normally with aromatic amines to give arylamino derivatives. On treating the acetyl compound IV with dry ammonia in nitrobenzene solution, we found that the substance is converted

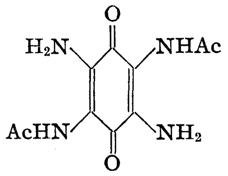
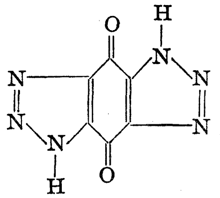
III IV V

smoothly into the amine V. We were at first unable to bring about a reaction of this substance with nitrous acid although the structure assigned was confirmed by the preparation of various derivatives. It was found that the difficulty is connected with the sparing solubility of the amine. When a solution of the colorless hydroquinone of V in dilute acid was treated with excess nitrous acid, a red precipitate of the quinone was produced in fine suspension, and in this condition it slowly reacted with the reagent with the formation of the desired *lin*-naphthotriazole-8,9-quinone, II, the acetyl group being hydrolyzed either during the reaction or in working up the product. On methylating the quinone II by the method described by Fries and co-workers,[1] we obtained a product identical with the 1-methyl-*lin*-naphthotriazole-8,9-quinone synthesized by Hartwell[4] by a method which establishes the structure.

Following the method described above, it was possible to prepare a *lin*-bis-triazoloquinone. Two of the halogen atoms of chloranil are easily replaced by amino groups, and it was found that after acetylation of these groups the remaining halogens can be caused to react with ammonia, giving VI. This substance is very sparingly soluble in most solvents and no reaction with nitrous acid could be brought about in an aqueous medium, even through the expedient found serviceable in the other series. The desired result was achieved by adding sodium nitrite to a suspension of VI in glacial acetic acid at 100°. The red diacetate gradually was transformed to a yellow, crystalline solid which proved to be the monosodium salt of 2,3,5,6-bis-triazolo-1,4-benzoquinone, VII. The quinone, which evidently is a very strongly acidic substance, was obtained by acidifying an aqueous solution of the salt with mineral acid. It decomposes explosively at a high temperature, and gives a characteristic anthraquinone vat test. The pure quinone is completely colorless, a remarkable property for substances of this class.[5]



VI



VII

Attempts to obtain the angular isomer of VII by the oxidation of 1,2,3,4-bis-triazolobenzene met with no success, but some improvements were made in the synthesis of the tricyclic compound and the details are recorded in the experimental part.

Unfortunately the two tricyclic quinones reported above do not dissolve to any appreciable extent in water, and a complete electrochemical characterization could not be made. In the case of *lin*-naphthotriazole-8,9-quinone it was possible to perform titrations of the reductant in alcoholic solutions, the potentials at half-oxidation against a hydrogen electrode in the same buffer at 25° being as follows: 0.4345 v. in 50% alcohol, 0.1 *N* in hydrochloric acid and 0.2 *N* in lithium chloride; 0.3450 v. in 37% alcohol, 0.047 *M* in monopotassium phosphate and 0.047 *M* in disodium phosphate. The difference between these two figures is in the direction which would be expected in a system whose oxidant has a strongly acidic group and whose reductant is basic.

Discussion

Although the results are very meager, an interesting inference can be drawn from a comparison of the potential of *lir*-naphthotriazole-8,9-quinone in alcoholic hydrochloric acid (0.435 v.) with that of other tricyclic quinones in the same solvent. Since *lin*-naphthindazolequinone (E_0 = 0.155 v.) has practically the same potential as its 1-methyl ether VIII,[4] it would be safe to predict that the hydrogen compound corresponding to IX would have a potential close to that of IX. The fact that the value found for *lin*-naphthotriazole-8,9-quinone is so decidedly different, suggests that the structure may be represented more accurately by formula X.[6]

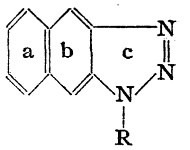
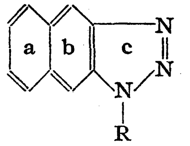
As for the fine structure of the isologs of anthrahydroquinone or of anthracene containing a triazole nucleus, the electrochemical results favor the formulation XI, which indicates that Ring c, being less aromatic than Ring a, is the one which assumes the *o*-quinonoid or dihydride structure.

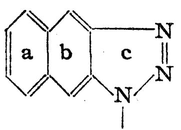


XI



XII

Fries,[1] on the basis of hydrogenation experiments, writes the alternate structure XII, in which Ring a is quinonoid, and the question is still open. We are in complete agreement with this author with regard to the principle involved, and indeed this was discussed previously by one of us with Ames.[6] At that time we failed to recognize a second principle set forth in the important paper by Fries, Walter and Schilling[1] to the effect that every ring of a polynuclear aromatic compound strives to approach as nearly as possible the condition of a true benzoid ring. According to this principle, to which we now subscribe, a structure such as XIII (or a similar structure for anthracene) is highly improbable, for two of the rings (b, c) have the dihydride structure.



XIII

From a consideration of both of the influences determining the positions of the bonds, the formula for naphthacene XIV previously discussed[7] should be revised as in XV. In each formula two rings are quinonoid, but in XIV they are combined to form a highly unstable 2,3-naphthoquinonoid grouping (Rings a and b), while in XV two isolated and less reactive *o*-benzoquinonoid rings (a and d) are present. The fine structure previously written for naphthacenequinone[7] accords with the principle of greatest stability and it is similar to that assigned by Fries to pentacenequinone, XVI. Fries has expressed the view that, because of the special bond structure of the central nucleus, XVI is no *p*-quinone, and he considers that this explains the failure of the substance to form a vat. We do not share this view, but believe, rather, that the reluctance of XVI to undergo reduction is conditioned by a very low reduction potential. This is determined, not by the special structure of the quinone, but by the reactive quinonoid bond structure of the hydroquinone. This explanation has been advanced to account for a similar property of naphthacenequinone.[7] Clar's "2,3-phthaloylphenanthrene,"[8] which can be assigned the structure XVII, does not contain an ordinary *p*-quinone ring but it nevertheless gives the vat test (because the angular ring stabilizes the anthracene structure of the hydroquinone, giving a higher oxido-reduction potential).[9] Arguments have been advanced[10] for attributing to 1,4-anthraquinone the structure of XVIII, and the substance has all the properties of a true *p*-quinone in spite of the tetraketonic structure of the terminal ring.

in alcoholic alkali with a deep red-purple coloration and is precipitated unchanged by acids; the solution in concentrated sulfuric acid has a light orange color.

Anal. Calcd. for $C_{12}H_{10}O_3N_2$: C, 62.58; H, 4.38; N, 12.2. Found: C, 62.19; H, 4.38; N, 11.9.

2,3 - Di - (acetylamino) - 1,4 - naphthohydroquinone.—An aqueous suspension of the quinone V was treated with sodium hydrosulfite and stirred until the red crystals disappeared and the colorless hydroquinone separated. This substance was dissolved in dilute hydrochloric acid, and one equivalent of acetic anhydride was added, followed by sodium acetate solution. The diacetyl derivative soon separated and it was recrystallized from dilute alcohol, forming colorless crystals, m. p. 255° dec., which turned yellow on storage.

Anal. Calcd. for $C_{14}H_{14}O_4N_2$: C, 61.29; H, 5.15. Found: C, 60.96; H, 5.19.

***lin*-Naphthotriazole-8,9-quinone (II).**—2-Acetylamino-3-amino-1,4-naphthoquinone (1.5 g.) was reduced as above and the nearly colorless product was collected and dissolved in 25 cc. of water and 3 cc. of concentrated hydrochloric acid. The slightly yellow solution was completely decolorized by filtration through a layer of Norite, and the filtrate, diluted to 50 cc., was treated at 0° with 10 cc. of 10% sodium nitrite solution. A fine, bright red precipitate separated immediately (collected at once, it was found to be the pure starting material), but on standing at 10–20° for two to three hours with the occasional addition of nitrite solution the color faded and finally a nearly colorless product resulted. This was collected, clarified in a dilute solution in alkali, and reprecipitated from the yellow filtrate. A solution of the faintly yellow material in hot acetone was decolorized with Norite, diluted with two volumes of warm water, and allowed to cool, when thin, glistening plates separated; yield 0.6 g. (46%). These crystals have a barely visible yellow tinge and they contain one molecule of water of crystallization which is lost on heating slightly above room temperature. The anhydrous compound decomposes at 240–245°. It does not dissolve in dilute acids. With alkaline hydrosulfite it forms a light red vat with an intensely green intermediate stage (quinhydrone).

Anal. Calcd. for $C_{10}H_5O_2N_3$: C, 60.28; H, 2.53. Found: C, 60.24; H, 2.82.

Fries, Walter and Schilling[1] state that their sample of this quinone was yellow and that the solution in dilute alkali was nearly colorless. Our quinone was nearly colorless and gave a faintly yellow solution in alkali. We obtained the same compound by the oxidation of *lin*-naphthotriazole in glacial acetic acid with chromic anhydride, but the yield was poor and the product was not obtained in a nearly colorless condition.

The N-methyl derivative, prepared by alkylation with dimethyl sulfate and alkali, formed colorless crystals from benzene, m. p. 248–250°. A mixture with Hartwell's sample[4] melted at 250–251°.

2. *lin*-bis-Triazoloquinone

2,5-Diamino-3,6-dichloroquinone.—The method of von Knapp and Schultz[11] was improved considerably by passing dry ammonia into a suspension of 12.3 g. of finely powdered chloranil in 150 cc. of boiling alcohol until the yellow crystals had dissolved. Dark red crystals of the diamine separated along with the ammonium chloride. After cooling, the solid was washed with water, alcohol, and ether, leaving 7.8 g. (75%) of deep red needles. Finding no suitable recrystallizing solvent, the material was purified as follows. A suspension of 1 g. of the quinone in aqueous hydrosulfite solution was warmed slightly to effect reduction. The nearly colorless hydroquinone was dissolved in dilute hydrochloric acid and the solution was decolorized by filtration through a layer of Norite, diluted to 200 cc., and treated at 90° with excess ferric chloride solution. The quinone separated slowly as long fine, deep red needles (0.8 g.).

2,5-Di-(acetylamino)-3,6-dichloroquinone.—A suspension of 8.2 g. of the diaminoquinone in 25 cc. of acetic anhydride was treated with ten drops of concentrated sulfuric acid and stirred at room temperature until conversion to bright yellow crystals of the diacetyl compound was complete. Alcohol was added to the cooled mixture and the product was collected; yield, 8.7 g. (75%); m. p. 240–245°. The substance is moderately soluble in glacial acetic acid and slightly soluble in alcohol. It crystallizes well from either solvent as yellow needles, m. p. 253–254°.

Anal. Calcd. for $C_{10}H_8O_4N_2Cl_2$: C, 41.24; H, 2.77. Found: C, 41.36; H, 2.95.

2,5-Di-(acetylamino)-3,6-diaminoquinone (VI).—The reaction of the diacetylaminodichloroquinone with ammonia did not proceed well in boiling nitrobenzene solution, the material being largely destroyed. A better method consisted in passing dry ammonia into a suspension of 8.2 g. of the finely powdered material in 100 cc. of boiling alcohol and allowing most of the alcohol to evaporate as the reaction progressed. A reddish-brown product separated, and after cooling this was collected and washed with water, alcohol and ether, giving 5.6 g. (79%) of material suitable for the next step. The quinone is sparingly soluble in most solvents and no recrystallizing solvent was found. A purification was accomplished by dissolving the brown-red material (0.25 g.) in a mixture of 25 cc. each of alcohol and water containing 1 cc. of 10% alkali, filtering the purple-red solution, and acidifying. Fine, dark red needles separated slowly. The substance has no characteristic point of decomposition; the solution in concentrated sulfuric acid is deep red and becomes yellow on the addition of a small amount of water. Carbon–hydrogen analyses were unsatisfactory.

2,3,5,6-Bistriazolo-1,4-benzoquinone (VII).—A suspension of 0.5 g. of the crude quinone VI in 20 cc. of glacial acetic acid was warmed on the steam-bath and treated with 20 cc. of 10% sodium nitrite solution, added slowly in portions. The dark starting material slowly dissolved and the color of the solution faded to a light red. Solid sodium nitrite was added until the color changed to a light yellow and yellow crystals of the sodium salt of the reaction product separated. After cooling, the crystals were washed with cold water, alcohol and ether. The substance crystallized from water as stout, bright yellow needles of the monosodium salt dihydrate; yield, 0.2 g.

Anal. Calcd. for $C_6HN_6O_2Na \cdot 2H_2O$: N, 33.9. Found: N, 34.0.

---

(11) Von Knapp and Schultz, *Ann.*, **210**, 183 (1881).

The quinone itself separated as completely colorless microcrystals on acidifying a hot, clarified, aqueous solution of the sodium salt; yield, 0.15 g. (40%). The substance is insoluble in the usual solvents and it could not be recrystallized, but the above material appeared to be pure.

Anal. Calcd. for $C_6H_2O_2N_4$: C, 37.89; H, 1.06. Found: C, 38.12; H, 1.20.

The colorless quinone gives a yellow vat with alkaline hydrosulfite solution, and on shaking with air the solution acquires a beautiful blue color, probably as the result of quinhydrone formation. In the presence of excess reducing agent the color fades to yellow on standing, and the test can be repeated until the reagent is exhausted, when the sparingly soluble sodium salt of the quinone separates. The quinone is unaffected at temperatures up to 300°; when heated on a spatula it decomposes with explosive violence.

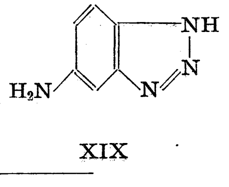
3. Preparation of *lin*-Naphthotriazole (I)

As the procedure of Friedländer and v. Zakrzewski[12] for preparing **potassium 2,3-dihydroxynaphthalene-6-sulfonate** gave very poor results, the following method was developed. Technical 2-naphthol-3,6-disulfonic acid (120 g.) was added rapidly with stirring to a melt at 200° from 460 g. of potassium hydroxide, 20 g. of sodium hydroxide, and 6 cc. of water. In the course of twenty minutes the temperature was raised to 250°, when the yellow melt changed to an even paste. The melt while hot was transferred in portions to 1 kg. of ice and 730 cc. of concentrated hydrochloric acid, and the red-brown solution was treated with active charcoal, filtered and acidified. The slightly colored salt which separated on cooling was dissolved in hot water saturated with sulfur dioxide and after clarifying the solution with active charcoal, the colorless filtrate deposited 50 g. (52%) of glistening, colorless plates. The addition of ferric chloride to the aqueous solution produces a beautiful intense blue-violet coloration.

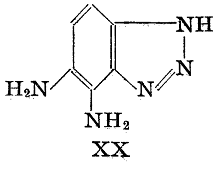
2,3-Dihydroxynaphthalene[12] was obtained by heating 30 g. of the above sulfonate with 240 cc. of water and 45 cc. of concentrated sulfuric acid for twelve hours in an autoclave at 150–160°; yield, 13 g. (65%); m. p. 158–159°. This was converted into 2,3-diaminonaphthalene by the method of Morgan and Godden.[13] The conversion was nearly quantitative in successful experiments, but few tubes withstood the drastic conditions. The method of the above authors was used for closing the triazole ring.

4. Preparation of 1,2,3,4-bis-Triazolobenzene

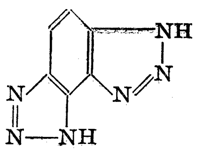
This compound (XXI) has been obtained[14] from 5-aminobenzotriazole (XIX) through the diamino compound XX.



XIX

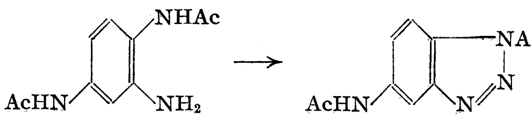


XX



XXI

An improved method of preparing XIX was found in nitrating diacetyl *p*-phenylenediamine, reducing the nitro compound catalytically, converting the amine XXII with nitrous acid into the diacetyl compound XXIII and hydrolyzing the latter compound.



XXII XXIII

2,5-Di-(acetylamino)-aniline (XXII).—2,5-Di-(acetylamino)-nitrobenzene, m. p. 186–188°, was obtained in 83% yield by Ladenburg's method,[15] and 19.7 g. of this material dissolved in 300 cc. of hot alcohol was hydrogenated in the presence of 0.1 g. of Adams catalyst. The amino compound (XXII) was collected and a solution of the material in dilute acid was clarified with Norite. On neutralization the substance separated in a colorless condition; yield, 15 g. (87%); m. p. 235–237° (recrystallized from alcohol, m. p. 236–237°).[16]

5-Aminobenzotriazole Dihydrochloride.—The slow addition of 70 cc. of 10% sodium nitrite solution to a cold solution of 20.7 g. of XXII in 150 cc. of water and 17.7 cc. of concentrated hydrochloric acid gave 20.6 g. (95%) of 5-aminobenzotriazole diacetate, m. p. 182–184° (recrystallized from acetone–water, m. p. 184–185°, literature,[17] 184°). For the hydrolysis, 4.36 g. of the diacetate was boiled with 10 cc. of concentrated hydrochloric acid for one hour, adding a trace of stannous chloride to discharge a faint yellow color. On cooling at 0°, stout colorless needles of the dihydrochloride separated; yield, 4 g. (90%).

4,5-Diaminobenzotriazole (XX) was prepared from XIX through the benzeneazo compound. The latter substance was obtained by coupling in the presence of sodium acetate according to Fries, Güterbock and Kühn,[17] but it was more conveniently collected as the hydrochloride. This was obtained as a mass of fine, bright red needles by adding dilute acid to the orange, gelatinous precipitate of the azo compound, yield 95%. The substance dissolves in dilute alkali and an excess of reagent precipitates the orange sodium salt. For the reduction, 5.49 g. of the hydrochloride was stirred at room temperature with a solution of 9 g. of stannous chloride crystals in 50 cc. of concentrated hydrochloric acid. After gentle warming the resultant yellow mixture was cooled and the precipitated material was recrystallized twice from hydrochloric acid solution; fine yellow needles, 3.2 g. (69%).

1,2,3,4-bis-Triazolobenzene (XXI).—On treating XX with nitrous acid according to Nietzki and Prinz,[14] most of the material was destroyed by oxidation. This was

prevented to some extent by protecting one of the amino groups by acetylation.

A solution of 1.16 g. of 4,5-diaminobenzotriazole dihydrochloride and 0.6 cc. of acetic anhydride in 100 cc. of water was treated quickly with a solution of 1 g. of fused sodium acetate in water. The light yellow solution was clarified with charcoal, cooled to 0°, and treated slowly with 4 cc. of 10% sodium nitrite solution. The nearly colorless precipitate (acetate) was dissolved in warm 2% sodium hydroxide solution and precipitated with dilute acid, giving 0.2 g. (25%) of the almost colorless bis-triazolobenzene.

Summary

Methods have been developed for the synthesis of isologs of anthraquinone with either one or two of the benzene rings replaced by a triazole ring. Unfortunately these compounds proved to be so sparingly soluble that only a very limited potentiometric characterization was possible, but the results obtained have some bearing on the problem of the fine structure of the triazole nucleus. This paper includes also a comparison with the views of Fries concerning the bond structure of polynuclear hydrocarbons and quinones.

Studies of Crystalline Vitamin B_1.[1] X. Sulfite Cleavage. III. Chemistry of the Basic Product

BY EDWIN R. BUCHMAN, ROBERT R. WILLIAMS AND JOHN C. KERESZTESY

By cleavage of vitamin B_1 with sulfite Williams[2] obtained a basic substance C_6H_9NSO (II), easily isolated as the crystalline hydrochloride in yields up to 97%. The free base is a colorless, rather viscous oil with a characteristic faint basic odor, easily soluble in water, alcohol and chloroform and less readily in ether. It is a mono acid base giving well-defined crystalline derivatives with chloroplatinic, picric and picrolonic acids.

The evidence[3] points to the presence of a free hydroxyl group in the vitamin. Since the oxygen in (II) is evidently derived directly from the vitamin, attempts were made to demonstrate an hydroxyl in (II). With concentrated hydrochloric acid at 150° it was found, as expected, that —OH is replaced by non-ionic chlorine

$$C_6H_9NSO\ (II) \xrightarrow{HCl} C_6H_8NSCl\ (V)$$

(V), obtained in good yield in the form of its crystalline hydrochloride, closely resembles the oxy base (II); the ultraviolet absorption spectra are nearly identical.[4]

When treated with excess *p*-nitrobenzoyl chloride in pyridine, (II) gave a crystalline mononitrobenzoate which still exhibited basic properties. Evidently only the —OH group reacts with acyl chlorides and it may be assumed that the nitrogen in (II) is tertiary in character.

The action on (II) of nitrous acid and of methyl iodide was studied to secure further evidence on this point. With nitrous acid a crystalline product was obtained in good yield, but its analysis and properties showed it to be the nitrate of the original base, $C_6H_9NSO \cdot HNO_3$. With methyl iodide a typical quaternary salt was obtained by allowing the two components to combine slowly at room temperature.

$$C_6H_9NSO\ (II) \xrightarrow{CH_3I} C_6H_9NSO \cdot CH_3I\ (VI)$$

Treatment of the salt (VI) with alkali regenerated no ether-soluble base. In striking contrast to (II) which after heating with 20% alkali at 100° can be recovered unchanged, (VI) under the same conditions was completely destroyed with formation of alkali sulfide. The vitamin itself is readily attacked by hot alkali, also splitting out sulfide.[5] This analogy is consistent with the view that the vitamin is a quaternary salt of (II).[6]

While this investigation was in progress there appeared an article[7] by Windaus, Tschesche and Grewe describing the splitting of the vitamin with nitric acid and the isolation of two well-characterized degradation products, one a sulfur-containing acid $C_5H_5NSO_2$. Oxidation of (II) with nitric acid at 40° gave sulfuric acid and 30% of an acid (VII).

$$\underset{\text{(II)}}{(C_4H_4NS)\text{—}C_2H_4OH} \xrightarrow{HNO_3} \underset{\text{(VII)}}{(C_4H_4NS)\text{—}COOH}$$

A comparison of the properties of (VII) with those listed[7] by Windaus for his acid showed that the two substances are identical. The similarity in ultraviolet absorption spectra[4,7] of (II) and (VII) strengthens the view that these substances have a common heterocyclic nucleus C_4H_4NS—.[8] The side chain —C_2H_4OH may be written —$CHOHCH_3$ or —CH_2CH_2OH. The optical inactivity of the vitamin argues against the first formulation. When treated with iodine and alkali (II) gave no iodoform,[9] further indicating that the —OH is in the β position.

Experimental

Basic Cleavage Product C_6H_9NSO (II).—The hydrochloride[2] was available for this work in amounts equivalent to approximately 2 g. of vitamin. It is the salt of a weak[10] base crystallizing in thin bars, readily soluble in water and alcohol, practically insoluble in ether, chloroform and acetone and subliming essentially unchanged at 50° *in vacuo*. Due to its extreme hygroscopicity, great care was necessary in the handling of this substance.

The free base was liberated by making alkaline the aqueous solution of the hydrochloride, shaking out with ether or chloroform and evaporating off the solvent. There was obtained a colorless oil miscible with water but almost insoluble in 20% sodium hydroxide.

An aqueous solution of the hydrochloride gave with phosphotungstic acid an immediate white microcrystalline precipitate. The picrolonate was made by treating an aqueous solution of the hydrochloride with picrolonic acid in methanol. After standing for two days, well-formed yellow crystals had deposited, m. p. 184°[11] (dec.). *Anal.* Calcd. for $C_6H_9NSO{\cdot}C_{10}H_8N_4O_5$: S, 7.87. Found: S, 8.09. With chloroplatinic acid in alcoholic solution, there was an immediate orange-yellow crystalline precipitate of m. p. 181° (dec.). Under similar conditions with gold chloride, an oil was obtained. The addition of ethereal picric acid to an ether solution of the free base threw down a picrate, m. p. 162–163°, difficultly soluble in ether and in alcohol but moderately soluble in water.

A few crystals of the hydrochloride were subjected to pyrolysis and a pine splinter moistened with hydrochloric acid introduced into the vapors. There was no color formed; the vitamin under the same conditions also gave a negative test. However, the characteristic color which the vitamin develops with diazotized sulfanilic acid was not given by (II). Also, unlike the vitamin, the basic cleavage product was found to be quite stable to hot alkali. A weighed amount (*circa* 20 mg.) of the crystalline hydrochloride was heated at 100° for three-fourths of an hour with 1 cc. of 20% sodium hydroxide. The reaction mixture gave a definitely negative test with nitroprusside[12] solution. A recovery of 90% of the starting material was effected by extraction of the base with ether and conversion into the hydrochloride.

Action of Concentrated Hydrochloric Acid on (II).—26.0 mg. of the hydrochloride of the basic cleavage product was heated in a sealed tube for three hours at 145° with 0.5 cc. of concentrated hydrochloric acid (d. 1.19). The contents of the tube were evaporated to dryness *in vacuo* and taken up in absolute alcohol, yield 27.4 mg. Recrystallization was effected by adding dry ether to the alcoholic solution. After standing overnight 14.5 mg. of cube-like crystals had formed. *Anal.* Calcd. for $C_6H_8NSCl{\cdot}HCl$: Cl, 35.81; Cl^-, 17.91; N, 7.07; S, 16.19. Found: Cl, 35.47; Cl^-, 18.29; N (Dumas), 7.06; S, 16.36. The substance is much like the hydrochloride of (II) in its solubilities, but it is decidedly less hygroscopic. Also it is noticeably more volatile. *Circa* 10 mg. was dried for analysis at room temperature in a phosphorus pentoxide desiccator connected to a water pump and after twenty-four hours it was found that the entire sample had been volatilized. The free base has a pyridine-like odor. The nitroprusside test was negative.

Action of *p*-Nitrobenzoyl Chloride on (II).—79.4 mg. of the hydrochloride was refluxed for one-half hour in pyridine solution with excess of *p*-nitrobenzoyl chloride. The reaction mixture was diluted with water and sodium carbonate was added. Extraction with ether and subsequent evaporation of solvent yielded 41.5 mg. of crystalline product (low yield indicative of side reaction). The 41.5 mg. was purified by dissolving in alcohol and adding water. Fine nearly white needles melting sharply at 131° were obtained and dried *in vacuo* at 55° for analysis; yield 22.7 mg. *Anal.* Calcd. for $C_{13}H_{12}N_2SO_4$: S, 10.97; N, 9.59. Found: S, 11.06; N (Dumas), 9.44. The *p*-nitrobenzoate is practically insoluble in water but soluble in ether, in alcohol, and readily in dilute hydrochloric acid. A crystalline hydrochloride was obtained by evaporating the hydrochloric acid solution.

Action of Nitrous Acid on (II).—A portion of the hydrochloride was treated in aqueous solution with sodium nitrite and the mixture extracted with ether. On evaporation of the ether an oil was obtained which in a few minutes changed to an ether-insoluble[13] crystalline mass. After crystallization from ethanol–ether the substance was dried at 55° *in vacuo*. *Anal.* Calcd. for $C_6H_9NSO{\cdot}HNO_3$: N, 13.59; S, 15.55. Found: N (Dumas), 13.33; S, 15.75. The above product is hygroscopic, sublimes when heated *in vacuo*, is almost insoluble in ether and chloroform, soluble in acetone and readily soluble in alcohol and water. The aqueous solution was found to have a strong acid reaction and to give a copious precipitate with nitron reagent. The nitrate of (II), prepared from the hydrochloride and the theoretical amount of silver nitrate, behaved in a similar fashion.

Action of Methyl Iodide on (II).—65.3 mg. of the hydrochloride was converted into the free base, which was then allowed to stand for two days at room temperature with excess methyl iodide. After removal of excess methyl

[10] R. R. Williams and A. E. Ruehle, THIS JOURNAL, **57**, 1856 (1935).

[11] All melting points in this paper are uncorrected.

[12] All nitroprusside tests in this paper were performed in a like manner except that much less substance was usually used.

[13] A somewhat similar phenomenon is described by Pummerer, *Ber.*, **43**, 1405 (1910).

iodide *in vacuo* the partly crystalline colored residue weighed 94.8 mg. This was purified by taking up in alcohol (acetone may be used) and precipitating with dry ether; 59.6 mg. of not quite colorless leaf-like crystals was obtained and a portion dried for analysis *in vacuo* at room temperature. *Anal.* Calcd. for $C_7H_{12}NSOI$: N, 4.91; S, 11.25. Found: N (Dumas), 4.70; S, 11.25. The methiodide is hygroscopic, quite insoluble in ether and chloroform, soluble in acetone and alcohol and readily soluble in water. It is extremely unstable toward alkali. A portion treated with 20% sodium hydroxide liberated no ether-soluble base but on standing at room temperature a dark tar was formed, insoluble in water and acid. The nitroprusside test was strongly positive. The methiodide as well as the other compounds described here has no vitamin B_1 activity.

Action of Nitric Acid on (II).—The hydrochloride of (II) was first converted into the nitrate or better into the free base and then oxidized with nitric acid (d. 1.42); 101 mg. of the hydrochloride gave with silver nitrate 115.7 mg. of the nitrate which was dissolved in 1 cc. of nitric acid. After short heating at 40° the reaction started, as evidenced by the darkening of the solution and the evolution of nitrogen oxides. The solution was kept at about 40° until no more gas bubbles formed and then most of the nitric acid was removed *in vacuo*. Quantitative removal of sulfate with baryta gave 50.2 mg. of barium sulfate. The remaining solution was evaporated to dryness, the residue suspended in water and extracted repeatedly with ether. Evaporation of the ether gave 42.0 mg. of white crystalline material which crystallized from methanol in cubes; yield 20.7 mg. After drying at 55° *in vacuo* it was analyzed. *Anal.* Calcd. for $C_5H_5NSO_2$: C, 41.93; H, 3.52; N, 9.79; S, 22.40. Found: C, 41.70; H, 3.51; N (Dumas), 9.20; S, 22.99. In later experiments it was found more convenient, instead of extracting the substance from its aqueous suspension with ether, to dissolve it in alkali and reprecipitate it by bringing to neutrality with acid. The properties of the substance are identical with those given by Windaus[7] for an acid of the same constitution obtained from the vitamin. It sublimes *in vacuo* at about 160°; on heating in a capillary tube it becomes colored above 200° and decomposes at about 250° with gas evolution. It is rather difficultly soluble in hot water and ether, soluble in alcohol and readily soluble in acids and in alkali. It gave a weak positive nitroprusside reaction. When heated with concentrated nitric acid no sulfate was formed. With ethereal diazomethane the methyl ester of m. p. 74° described by Windaus was obtained.

Action of Iodine and Alkali on (II).—The reaction was carried out on a 10-mg. portion of the hydrochloride according to the technique described by Mulliken.[14] No iodoform was formed.

We wish to acknowledge our indebtedness to Drs. H. T. Clarke and O. Wintersteiner for securing the microanalyses and to the Carnegie Corporation for a grant of funds through the Carnegie Institution of Washington.

Summary

1. The basic cleavage product (II) gives on oxidation an acid $C_4H_4NS—COOH$ identical with the product obtained by Windaus directly from the vitamin.

2. Evidence is presented for regarding (II) as a tertiary heterocyclic base with a β-hydroxyethyl side chain $C_4H_4NS—CH_2CH_2OH$.

3. Evidence is presented consistent with the view that the vitamin is a quaternary salt of the base (II).

The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. I. The Bougault Reaction

BY LOUIS F. FIESER AND EMANUEL B. HERSHBERG

In recent years γ-arylbutyric acids have acquired a position of considerable importance in the synthesis of polynuclear hydrocarbons, and several excellent methods have been developed for the preparation of these acids. Butyric acids of the benzene, naphthalene, phenanthrene, anthracene, and pyrene series are readily available as starting materials, as are many of their derivatives substituted in either the nucleus or the side-chain.[1] It occurred to us to submit some of these acids in the form of the esters to a special cyclization procedure which hitherto has been applied only to the simplest member of the series.

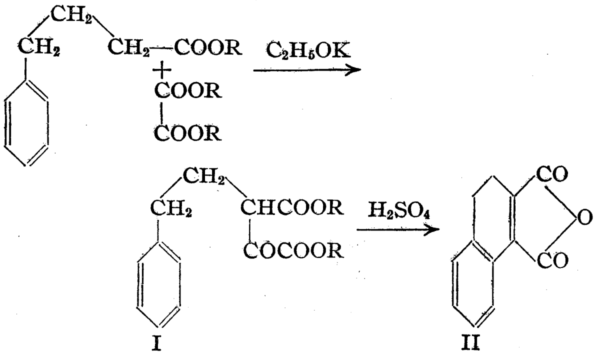
Bougault[2] discovered that the condensation product from β-phenylpropionic ester and oxalic ester is converted by concentrated sulfuric acid into the diester of indene-1,2-dicarboxylic acid,

---

Soc.*, 1125, 1784, 2248, 2717, 2720 (1932); 1012 (1933); 454 (1934); Cook and Hewett, *ibid.*, 398 (1933); Cook and Haslewood, *ibid.*, 767 (1935); Fieser and Peters, THIS JOURNAL, **54**, 4347, 4373 (1932).

[2] Bougault, *Compt. rend.*, **159**, 745 (1915).

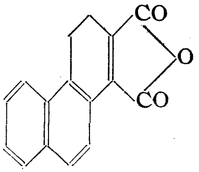
and von Auwers and Möller[3] applied the Bougault cyclization reaction to the next higher homolog. α-Oxalyl-γ-phenylbutyric acid (I) was prepared by these investigators in excellent yield by the condensation of phenylbutyric ester and oxalic ester with potassium ethylate.



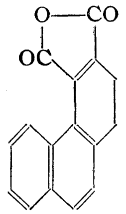
I II

At −15° the ester (I) was converted by sulfuric acid into the diethyl ester of 3,4-dihydronaphthalene-1,2-dicarboxylic acid, while at room temperature the reaction product was obtained in the form of the corresponding anhydride, II, in nearly quantitative yield. In repeating the work of von Auwers and Möller it has been found that the ester condensation can be carried out with equally satisfactory results using sodium ethylate.

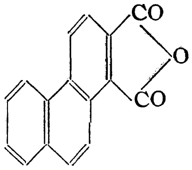
Starting with γ-(1-naphthyl)-butyric ester and γ-(2-naphthyl)-butyric ester we prepared the oxalic ester condensation products and submitted them to the Bougault reaction. With concentrated sulfuric acid there was extensive sulfonation, but the esters were converted smoothly by 80% acid into the cyclic anhydrides III and IV.[3a]



III



IV



V

The structure of III is established by the method of synthesis and the fact that the new ring can be aromatized, 3,4-dihydrophenanthrene-1,2-dicarboxylic acid anhydride (III) being converted in good yield into phenanthrene-1,2-dicarboxylic acid anhydride (V) on treatment with sulfur. This method was applied with equally good results to the dihydronaphthalene derivative, II, whereas von Auwers and Möller found that dehydrogenation with bromine proceeds very poorly. The anhydride of naphthalene-1,2-dicarboxylic acid may now be classed as a readily available compound.

The new phenanthrene and hydrophenanthrene derivatives substituted in the 1,2-positions (III and V) offer many interesting possibilities for further synthesis, and we are investigating particularly the synthesis of substances related to the oestrogenic hormones and their transformation products. Preliminary results indicate that both phenanthrene-1,2-dicarboxylic acid anhydride and the 3,4-dihydro derivative have oestrogenic activity.

We are indebted to Dr. G. Pincus of the Harvard Biological Laboratory for studying the physiological activity of the compounds. He reports that the anhydrides produced prolonged oestrus in mice, the effect lasting over a period of as much as two weeks. Cornification resulted in every case after the administration of as little as 0.05 mg. of either compound. The completely aromatic anhydride V acts slightly more rapidly than the dihydro compound III. Because of the protracted action it is difficult to make a direct comparison with the follicular hormone, but on the basis of the ordinary method of assay the minimum activity of both phenanthrene-1,2-dicarboxylic acid anhydride and the 3,4-dihydro compound is approximately 20,000 mouse units per gram.

The investigation of various substitution products and derivatives of the above compounds and related substances is in progress.

Experimental Part[4]

3,4-Dihydronaphthalene-1,2-dicarboxylic Acid Anhydride.—After several experiments on the ester condensation, the procedure of von Auwers and Möller[3] was modified in certain respects. The proportions of reagents found most satisfactory were as follows: 50 g. of ethyl phenylbutyrate, 57 g. of diethyl oxalate (1.5 equiv.), 10.4 g. of potassium (1.02 equiv.) and 12.6 g. of absolute ethyl alcohol (1.05 equiv.). The amount of alcohol is about one-third that specified,[3] and to promote a rapid reaction it was necessary to use powdered potassium. The metal was cleaned by melting it under toluene and powdered in the same solvent in an all-glass apparatus. After cooling, the metal powder was washed by decantation with ether in an atmosphere of nitrogen. After the completion of the condensation reaction the mixture containing

(3) Von Auwers and Möller, *J. prakt. Chem.*, **217**, 124 (1925).

(3a) Bardhan, *Nature*, **134**, 217 (1934), has reported the synthesis of a dihydrophenanthrene derivative by a similar cyclization.

(4) All melting points are corrected. Analyses by Mrs. G. M. Wellwood, Dr. R. G. Larsen and Mr. E. L. Martin. For a part of the synthetical work we are indebted to Mary Fieser.

the potassium salt was decomposed with dilute acid and the ethereal solution of the oxalyl ester and excess oxalic ester was washed, dried with sodium sulfate and the solvent was evaporated in vacuum. In our experience the separation of the potassium salt from the mixture is incomplete.

In other experiments an equivalent amount of sodium ethylate, prepared as above, was found equally satisfactory, the only difference being that it was necessary to reflux the mixture for twenty-four hours in order to bring the reaction to completion.

For the cyclization the residual light yellow oil (containing oxalic ester) was dissolved in 500 cc. of concentrated sulfuric acid, keeping the temperature below 25°. After one and one-half hours the deep red solution was poured onto ice and the crude anhydride (m. p. 117–122°) was collected and washed. One distillation in vacuum gave 42–44 g. (81–85%) of light yellow material, m. p. 122–124°, b. p. 227–230° at 23 mm. The distillate exhibits triboluminescence. Once crystallized from benzene–ligroin the product melted at 126–127°.

Naphthalene-1,2-dicarboxylic Acid Anhydride.—A mixture of 17.8 g. of the dihydro compound and 2.85 g. of sulfur was heated with shaking in a nitrate bath at 230° until the sulfur had dissolved, and the bath temperature was then raised to 240–250° until the evolution of hydrogen sulfide was at an end (about thirty minutes). The residue was then distilled (b. p. 211–214° at 11 mm.) and crystallized from benzene–ligroin, giving 13.3 g. (76%) of pale yellow needles, m. p. 164–165°.

Condensation with β-Methoxynaphthalene.—The reaction of naphthalene-1,2-dicarboxylic acid anhydride with this ether was investigated in preliminary work which was later abandoned. The Friedel and Crafts reaction in warm tetrachloroethane solution gave, as in the case of phthalic anhydride,[5] a lactone: pale yellow prisms, m. p. 238–239°.

Anal. Calcd. for $C_{22}H_{12}O_3$: C, 81.49; H, 3.71. Found: C, 81.85; H, 3.98.

Heated in tetrachloroethane solution with aluminum chloride for three hours on the steam-bath, the lactone was isomerized to a naphthaloylnaphthol; thick yellow prisms from toluene, m. p. 264–265°.

Anal. Calcd. for $C_{22}H_{12}O_3$: C, 81.49; H, 3.71. Found: C, 81.91; H, 3.52.

3,4-Dihydrophenanthrene-1,2-dicarboxylic Acid Anhydride.—Ethyl γ-(1-naphthyl)-butyrate was prepared in 91% yield by esterification with alcohol and hydrogen chloride; b. p. 210–211° at 14 mm. The condensation with oxalic ester was carried out by the original procedure of von Auwers and Möller,[3] using excess alcohol and lumps of potassium. The potassium salt of the oxalyl ester in this case separated very completely from the ethereal solution, and it was collected, washed with ether and decomposed with ice-cold, dilute sulfuric acid. The oil which separated was collected and dried in ether, and after distillation of the solvent at diminished pressure, the product was obtained as a viscous yellow oil in 80% yield.

The oxalyl ester was warmed with 7–10 parts by volume of 80% sulfuric acid on the steam-bath with vigorous shaking, when it was soon converted into a bright yellow, granular solid. The product was collected after diluting the mixture with water. This material was practically pure and the yield of the anhydride was quantitative.

The anhydride is sparingly soluble in glacial acetic acid or benzene and moderately soluble in dioxane. The solutions exhibit a brilliant greenish-yellow fluorescence. Crystallized from dioxane or acetic anhydride it formed golden yellow needles, m. p. 263.5–264.5°.

Anal. Calcd. for $C_{16}H_{10}O_3$: C, 76.77; H, 4.04. Found: C, 76.83; H, 4.37.

A solution of the anhydride in acetone, diluted with water, neutralized only one equivalent of methyl alcoholic potassium hydroxide, probably because of the formation of a mono-ester; neutralization equivalent found, 239; molecular weight 250.

Phenanthrene-1,2-dicarboxylic Acid Anhydride.—For the dehydrogenation, 5.7 g. of the above anhydride was heated with 0.73 g. of sulfur at 320–325° for ten minutes, and the residue was distilled at 15 mm. pressure directly from the bath. The yellow solid was crystallized from acetic anhydride, when it formed long yellow needles of m. p. 311–312°; yield, 5.1 g. (91%). The substance is only sparingly soluble in dioxane or acetic anhydride; it gives a phthalein test with resorcinol and sulfuric acid.

Anal. Calcd. for $C_{16}H_8O_3$: mol. wt., 248; C, 77.39; H, 3.25. Found: C, 77.55; H, 3.62; neutralization equivalent, 245.

1,2-Dihydrophenanthrene-3,4-dicarboxylic Acid Anhydride.—Ethyl γ-(2-naphthyl)-butyric ester (b. p. 227–228° at 25 mm.) was condensed with oxalic ester in the presence of potassium ethylate, exactly as described above for ethyl γ-phenylbutyrate. The potassium salt of the product remained dissolved in the ethereal reaction mixture, and the oil obtained on shaking the solution with dilute acid, drying and removing the solvent, contained ethyl oxalate. The crude oil from 19.6 g. of the arylbutyric ester was mechanically stirred with 125 cc. of 80% sulfuric acid at 80–90° for one hour. The oil partially dissolved at the start and after about ten minutes a yellow solid separated from the dark acid liquor. After cooling, the solid was collected on a glass funnel, washed with 80% sulfuric acid and, after thorough draining, with a liberal quantity of alcohol. The product was bright yellow and nearly pure; yield, 16.5 g. (81%). The anhydride is readily soluble in benzene; it dissolves only slowly in boiling alcohol or glacial acetic acid and tends to remain in solution. It crystallizes well from benzene–ligroin as bright greenish-yellow needles, m. p. 151–152°. The solution in concentrated sulfuric acid is bright red.

Anal. Calcd. for $C_{16}H_{10}O_3$: C, 76.77; H, 4.04. Found: C, 76.68, 76.65; H, 4.22, 4.28.

Summary

The anhydrides of dihydrophenanthrene-*o*-dicarboxylic acids can be prepared in good yield by extending an adaptation of the cyclization reaction of Bougault to α-oxalyl-γ-arylbutyric esters of the naphthalene series. These and other similar substances are being investigated both for use in the synthesis described in the

---

[5] Fieser, THIS JOURNAL, **53**, 3546 (1931).

second paper of this series, and because the Bougault reaction provides a convenient route to 1,2-substituted phenanthrenes of a type which may prove useful in the synthesis of compounds related to the sex hormones. It has been found that the anhydrides of both 3,4-dihydrophenanthrene-1,2-dicarboxylic acid and phenanthrene-1,2-dicarboxylic acid have oestrogenic properties.

Cerin and Friedelin. II. Some Functional Derivatives[1]

BY NATHAN L. DRAKE AND STERL A. SHRADER

Earlier investigation has shown[2] that cerin and friedelin possess the same polycyclic nucleus of thirty carbon atoms. It is the purpose of this paper to describe certain functional derivatives of these substances, thereby confirming the carbonyl nature of friedelin and demonstrating that cerin is an hydroxy ketone.

In keeping with its carbonyl nature friedelin reacts with hydroxylamine, with *p*-nitrophenylhydrazine, and with 2,4-dinitrophenylhydrazine, yielding the corresponding derivatives of the carbonyl group. Friedelin oxime is converted by treatment with phosphorus pentachloride into an isomeric substance which is no longer an oxime. This rearrangement product is not at all altered by any hydrolytic agent which does not decompose it, does not form an acetate with acetic anhydride and cannot be reconverted to friedelin by any method that we have been able to discover. The oxime, on the other hand, can be hydrolyzed readily to friedelin, and gives an acetate with acetic anhydride.

Cerin, like friedelin, can be converted into an oxime and a 2,4-dinitrophenylhydrazone. When treated with Purdie's reagents, cerin yields a monomethyl ether. An oxime or a 2,4-dinitrophenylhydrazone can be prepared from this ether without removal of the methyl group. When reduced in *n*-amyl alcohol by means of sodium, cerin yields a dihydroxy derivative which is characterized by the formation of a diacetate. It is apparent, therefore, that cerin must contain a carbonyl and an hydroxyl group. Whether the hydroxyl or the carbonyl of cerin occupies the same position in the nucleus as the carbonyl group of friedelin we do not know, for all attempts to obtain friedelin from cerin have failed.

Experimental

Friedelin Oxime.—Ten grams of friedelin was dissolved in 200 ml. of benzene containing 50 ml. of alcohol, and 3.5 g. of hydroxylamine hydrochloride, dissolved in 25 ml. of alcohol, was added. Three grams of potassium hydroxide dissolved in 25 ml. of alcohol was added to the reaction mixture through the reflux condenser and the mixture was refluxed for one hour, cooled and poured into 400 ml. of water. The resulting solution was acidified with sulfuric acid, and the product filtered, washed and recrystallized from a 2 to 1 mixture of benzene–ethyl acetate; 7.9 g. of oxime was obtained. The substance melts at 290–294° and crystallizes in thin hexagonal plates.

Anal. Calcd. for $C_{30}H_{51}ON$: C, 81.56; H, 11.65; N, 3.17. Found: C, 81.29, 81.25; H, 11.57, 11.71; N, 3.32, 3.25.[3]

Hydrolysis of Friedelin Oxime.—One-half gram of friedelin oxime was dissolved in 90 ml. of *n*-amyl alcohol and 6 ml. of 50% phosphoric acid was added. The mixture was refluxed for seven hours, and 50 ml. of alcohol was removed by distillation. The crystals which separated overnight were recrystallized from an ethyl acetate–benzene mixture, and melted at 257–262°. No change in the melting range was observed when this material was melted mixed with friedelin.

Anal. Calcd. for $C_{30}H_{50}O$: C, 84.43; H, 11.82. Found: C, 84.26, 84.00; H, 11.88, 11.71.

Friedelin Oxime Acetate.—0.6 g. of friedelin oxime was dissolved in 20 ml. of acetic anhydride and refluxed for one-half hour. The acetate which separated from the cold solution was recrystallized from ethyl acetate from which it separates in the form of hexagonal plates. The product melted at 237–239°.

Anal. Calcd. for $C_{32}H_{53}NO_2$: C, 79.28; H, 11.23. Found: C, 79.52; H, 10.97.

The Beckmann Rearrangement of Friedelin Oxime.—7.5 g. of friedelin oxime was dissolved in 2500 ml. of dry chloroform, the solution was cooled to −5°, and 4.5 g. of phosphorus pentachloride added in small portions during the course of fifteen minutes. The mixture was allowed to stand in an ice- and salt-bath for twelve hours, and then allowed to warm up to room temperature; 80% of the

[1] From the Ph.D. dissertation of Sterl A. Shrader.

[2] Drake and Jacobsen, THIS JOURNAL, **57**, 1570 (1935).

[3] We are indebted to Dr. T. B. Smith for the nitrogen determinations.

chloroform was distilled off and the remainder poured into ice water. After neutralization of the acid with 10% potassium hydroxide solution, the chloroform was removed by distillation, and the solid filtered and recrystallized from benzene containing one-fourth its volume of alcohol; 6.5 g. of product was obtained. Recrystallization from ethyl acetate–chloroform–ethyl alcohol, and finally from dioxane yielded a product which melted at 316–318°. The substance crystallizes in the form of hexagonal plates.

Anal. Calcd. for $C_{30}H_{51}ON$: C, 81.56; H, 11.65; N, 3.17. Found: C, 81.32, 81.38; H, 11.87, 11.67; N, 3.34, 3.32.[4]

Attempts to Hydrolyze the Rearrangement Product.—Many attempts were made to hydrolyze the product obtained by the action of phosphorus pentachloride on friedelin oxime, but none were successful. Alkali or acid in aqueous *n*-amyl alcohol under reflux or in a sealed tube at 200–250° did not effect a cleavage of the substance. Aqueous ethylene glycol and phosphoric acid at the reflux temperature were without effect. Phenol containing some water and hydriodic acid had no effect under reflux. Likewise, acetic acid and phosphoric acid containing water did not effect hydrolysis. Sulfuric acid and sodium nitrite in *n*-amyl alcohol were similarly without effect. In all but one of these experiments the original substance was recovered; phenol, hydriodic acid and the material heated in a sealed tube produced a tar.

Friedelin-2,4-dinitrophenylhydrazone.—One-half gram of friedelin was dissolved in 60 ml. of hot methyl cellosolve, and 0.3 g. of 2,4-dinitrophenylhydrazine added. The mixture was warmed until homogeneous. Two drops of concentrated hydrochloric acid were added and the mixture boiled for five to ten minutes. On cooling, the solution deposited narrow orange-colored lath-like crystals which were recrystallized from benzene. The product melted with decomposition at 297–299°.

Anal. Calcd. for $C_{36}H_{54}N_4O_4$: C, 71.24; H, 8.98; N, 9.23. Found: C, 71.50, 71.24; H, 9.05, 8.92; N, 9.26, 9.27.

Friedelin *p*-nitrophenylhydrazone was prepared by a method similar to that described above for the 2,4-dinitrophenylhydrazone; the *p*-nitrophenylhydrazone melted with decomposition at 277–279°.

Anal. Calcd. for $C_{36}H_{55}N_3O_2$: C, 76.95; H, 9.85; N, 7.47. Found: C, 77.41, 77.58, 77.42; H, 9.95, 9.78, 9.89; N, 7.58, 7.52.

We are unable to account for the poor carbon determinations. Further crystallization from dioxane, benzene and ethyl acetate–benzene results in a product whose percentage composition is essentially that recorded above. This substance crystallizes in the form of narrow hexagonal laths.

Cerin Methyl Ether.—Ten grams of cerin was dissolved in 500 ml. of dry dioxane, and treated with 50 g. of methyl iodide and 4 g. of silver oxide. The mixture was refluxed for nine hours with the addition of a gram of fresh silver oxide every two hours. The solution was then freed of silver oxide and iodide by filtration, and concentrated to about 50 ml.; 4.5 g. of methylated product separated from the cold solution. This substance melted at 235–245°. An additional gram of product which melted at 204–230° was obtained by concentrating the solution to about 30 ml. The remainder of the material would not crystallize, and was obtained as an amorphous white precipitate by adding water. We were unable to obtain this material in crystalline form by use of any of the usual solvents or solvent combinations. The two crystalline fractions were combined and again treated with methyl iodide and silver oxide using dioxane as a solvent; 3.5 g. of a product melting at 259–262° and 2 g. melting at 200–215° were obtained from this methylation. Recrystallization of the high melting product from benzene–acetone yielded a substance that crystallized in narrow laths and melted at 265–270°. Extensive recrystallizations did not serve to raise the melting point of the low-melting fraction very much and analysis indicated it to be considerably deficient in methoxyl content.

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.58; H, 11.48; OCH_3, 6.80. Found: C, 81.55, 81.47; H, 11.44, 11.28; OCH_3, 6.81, 6.84, 6.82, 6.73.

The specific rotation of cerin methyl ether in chloroform solution is $[\alpha]^{26}_{5461}$ $-58.9°$ ($C = 2.76$).

The Oxime of Cerin Methyl Ether.—Cerin methyl ether (0.5 g.), dissolved in a 2 to 1 mixture of benzene and alcohol, was converted by refluxing for an hour with hydroxylamine hydrochloride (0.2 g.) and potassium hydroxide (0.5 g.) into an oxime. The product crystallized in narrow laths and melted at 258–262°.

Anal. Calcd. for $C_{31}H_{54}NO_2$: C, 78.71; H, 11.52; N, 3.06; OCH_3, 6.57. Found: C, 78.72, 78.93; H, 11.29, 11.24; N, 3.37, 3.17; OCH_3, 6.66, 6.83, 6.79.

2,4-Dinitrophenylhydrazone of Cerin Methyl Ether.—The method employed was identical with the one described above for preparing the 2,4-dinitrophenylhydrazone of friedelin. The product crystallizes in narrow laths, almost needle-like, and melts with decomposition at 284–285°.

Anal. Calcd. for $C_{37}H_{56}N_4O_5$: C, 69.82; H, 8.86; N, 8.80. Found: C, 69.81, 69.83; H, 8.78, 8.89; N, 8.87, 8.90.

2,4-Dinitrophenylhydrazone of Cerin.—Prepared as above, this product crystallized from a benzene–alcohol mixture in the form of orange laths with a pronounced tendency to form spherulites and melted with decomposition at 253–255°.

Anal. Calcd. for $C_{36}H_{54}N_4O_5$: C, 69.42; H, 8.74; N, 9.00. Found: C, 69.50, 69.53; H, 8.78, 8.86; N, 9.04, 9.36.

Cerin Oxime.—One and nine-tenths grams of cerin dissolved in a mixture of 150 ml. of benzene and 100 ml. of ethyl alcohol was heated under reflux for three hours with hydroxylamine hydrochloride (0.8 g.) and potassium hydroxide (1 g.). Water was then added and the mixture made acid to Congo red. The benzene was removed by steam distillation and the crude product recrystallized from benzene–ethyl acetate. A final recrystallization from ethyl alcohol yielded a product which crystallized in lath-like plates and melted at 266–272°.

Anal. Calcd. for $C_{30}H_{51}NO_2$: C, 78.71; H, 11.24. Found: C, 78.56, 78.57; H, 11.62, 11.35.

---

[4] We wish to thank Dr. J. R. Spies for these analyses.

Dihydrocerin (Cerinol).—One and one-half grams of cerin in 100 ml. of *n*-amyl alcohol was reduced by adding 3 g. of sodium to the hot solution over a period of fifteen minutes. After the sodium had dissolved completely, the alcohol was removed by steam distillation and the product recrystallized from dioxane. The dicarbinol, for which we propose the name *cerinol*, crystallized from dioxane in narrow white laths, which melted at 293–295°; $[\alpha]^{25}_{5461}$ +9.4 (C = 0.48).

Anal. Calcd. for $C_{30}H_{52}O_2$: C, 81.01; H, 11.75. Found: C, 81.05, 80.86; H, 11.63, 11.77.

Cerinol Diacetate.—Cerinol is smoothly converted by acetic anhydride alone into a diacetate. This product crystallizes from ethyl acetate–ethyl alcohol in narrow almost needle-like laths which melt at 267–269°.

Anal. Calcd. for $C_{34}H_{56}O_4$: C, 77.22; H, 10.67. Found: C, 77.04, 77.05; H, 10.35, 10.40.

The Purification of Cerin.—Several recrystallizations of crude material from chloroform are necessary to obtain pure cerin. A properly purified sample should melt at 250–256°; at least six recrystallizations are necessary starting with crude extract. A sample so prepared yielded the following analytical results. Calcd. for $C_{30}H_{50}O_2$: C, 81.38; H, 11.39. Found: C, 81.37; H, 11.35. Less extended recrystallizations result in products with a broader melting range and a considerably lower carbon content. Cerin is not at all affected by refluxing with alcoholic potassium hydroxide, but is very sensitive to mineral acids.

Cerin Acetate.—The treatment of cerin with boiling acetic anhydride alone or with boiling acetic anhydride containing a trace of sulfuric acid results in the formation of a mixture of products from which it is not possible to obtain a pure substance. The reaction products, even after many recrystallizations, possess carbon and hydrogen contents which do not correspond to any of those demanded by cerin monoacetate, cerin diacetate or the acetate of a dehydration product, $C_{30}H_{48}(OCOCH_3)$. Under much milder conditions, however, by the use of pyridine and acetic anhydride at room temperature, it is possible to obtain a monoacetate of cerin; 1 g. of cerin was dissolved in 80 ml. of dry pyridine and 10 ml. of acetic anhydride was added over a period of about five minutes. The mixture was allowed to stand at room temperature overnight (*ca.* 25°). The product was isolated by dilution of the pyridine with water, and recrystallized in succession from benzene–ethyl acetate, ethyl acetate, benzene, ethyl acetate, glacial acetic acid and ethyl acetate. The substance melted at 256–259° with decomposition.

Anal. Calcd. for $C_{30}H_{52}O_3$: C, 79.28; H, 10.82. Found: C, 79.05, 79.19; H, 10.82, 10.88.

This product was further crystallized from glacial acetic acid, and finally from ethyl acetate, from which it separated in narrow almost needle-like laths which melted at 259–261°.

Summary

1. Friedelin oxime, 2,4-dinitrophenylhydrazone and *p*-nitrophenylhydrazone have been prepared.
2. Friedelin oxime undergoes the Beckmann rearrangement and yields a product which so far has defied all attempts to cleave it by hydrolysis.
3. Cerin methyl ether, its oxime and 2,4-dinitrophenylhydrazone have been prepared.
4. Cerin has been reduced to a dihydroxy compound which was characterized by the formation of a diacetate.
5. Cerin has been characterized by the formation of an oxime and a 2,4-dinitrophenylhydrazone.
6. The monoacetate of cerin has been prepared by acetylation in pyridine at room temperature.

College Park, Md. Received July 24, 1935

[Contribution from the Department of Physiological Chemistry, Teachers College, Columbia University]

Studies of Crystalline Vitamin B_1. XI. Presence of Quaternary Nitrogen[1]

By Robert R. Williams and A. E. Ruehle

The necessity for reconciling the chemical characteristics of the basic cleavage product[2] of vitamin B_1 with the undoubted binuclear character of the vitamin led our associate, Dr. E. R. Buchman, to suggest the presence of quaternary nitrogen in the latter. If present, the tetrasubstituted nitrogen should be recognizable by its strong basicity. On titrating the vitamin hydrochloride with sodium hydroxide the presence of a moderately strong basic nitrogen was revealed, too strong for a tertiary base though not strong enough for a true quaternary base. The basic cleavage product behaved as a typical tertiary base but its methiodide[2b] closely resembled the vitamin not only in basic strength but also in exhibiting an unusual pseudo basic behavior. Both the vitamin and the methiodide of its basic cleavage product required an additional molecular equivalent of alkali for com-

---

[1] Presented before the Division of Organic Chemistry at the New York Meeting of the American Chemical Society, April 22, 1935.

[2] (a) R. R. Williams, R. E. Waterman, J. C. Keresztesy and E. R. Buchman, This Journal, **57**, 536 (1935); (b) Paper X of this series, E. R. Buchman, R. R. Williams and J. C. Keresztesy, *ibid.*, **57**, 1849 (1935).

plete liberation of the base. This parallelism of behavior constituted strong evidence of a close structural resemblance between these compounds, associated with a quaternary nitrogen in each. In view of Dr. H. T. Clarke's suggestion[3] of the presence of a thiazole nucleus in the vitamin, it was of interest to secure similar data regarding synthetic thiazolium compounds. 4-Methylthiazole ethiodide behaved similarly to the methiodide of the basic cleavage product while 2,4-dimethylthiazole ethiodide exhibited the characteristics of a salt of a true quaternary base. These observations furnish strong confirmation of this feature of the structural formula of the vitamin recently announced by Williams.[3]

Birch and Harris[4] and Moggridge and Ogston[5] have recently described titrations of vitamin B_1 similar to our own. These authors, however, are neither in complete agreement with each other nor with us as to the interpretation to be placed on such curves. For that reason we feel the necessity of discussing our results somewhat in detail.

Experimental

Apparatus

The indicator electrode used was the MacInnes and Dole membrane type of glass elctrode,[6] made from Corning 015 glass and supported by lime glass tubing. The reference electrode was a normal calomel half-cell. The potential measurements were made with a Leeds and Northrup type K potentiometer and 2500-e galvanometer used in conjunction with a vacuum tube electrometer.[7] The titrations were carried out in a small cell through which a slow stream of nitrogen was passed to exclude carbon dioxide and to stir the solution. All measurements were made in an air thermostat kept at 25.0°.

No attempt was made to maintain a constant salt concentration because of the difficulty which would thereby be introduced in recovering the vitamin from the solution for other uses. Neither was any attempt made to evaluate liquid junction potentials except in so far as correcting for the "asymmetry potential" of the glass electrode, using calibrated buffers would eliminate this error. It is also recognized that the change in volume during titration introduces a small error in the values of the dissociation constants obtained.

Materials

NaOH and HCl.—0.1 *N* solutions were used in all titrations.

Vitamin B_1 was obtained by the method of Williams, Waterman and Keresztesy;[8] 50 mg. of the crystalline vitamin dissolved in 10 cc. of water served as the sample for titration.

The basic cleavage product (**hydrochloride**) was prepared by cleaving the vitamin with sodium sulfite.[2a]

Methiodide of Basic Cleavage Product.—Prepared by addition of methyl iodide to the cleavage product.[2b]

4-Methylthiazole Ethiodide.—Prepared as described elsewhere.[9]

2,4-Dimethylthiazole Ethiodide.—Prepared as described elsewhere.[9]

Experimental Results

The results obtained are shown graphically in Figs. 1–4. The pK_B values given in Table I represent the half neutralization points on the curves and are calculated from the relation $p\text{H} + p\text{OH} = 14$ for aqueous solution at 25° and the approximation[10] $p\text{OH} = pK_B$ at half the neutralization point of a weak base.

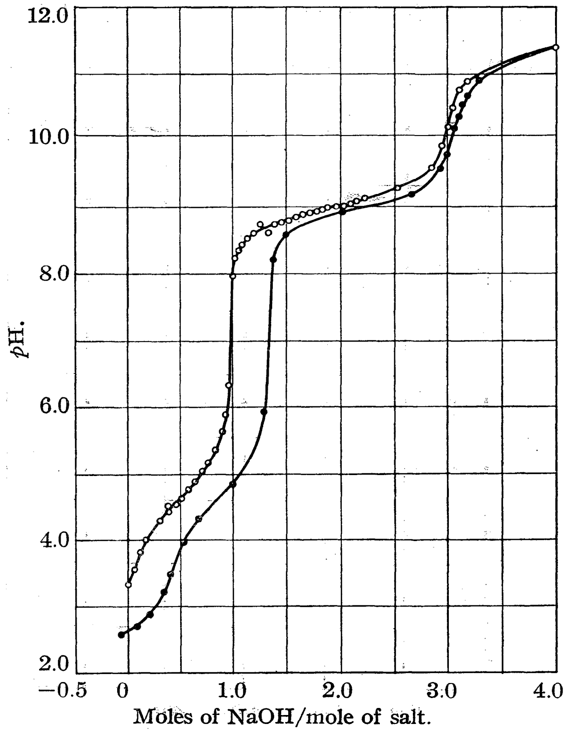

Fig. 1.—Titration of vitamin B_1: ○—○, titration with NaOH, ●—●, back titration with HCl.

The titrations demonstrate seven important points, six of which are illustrated directly by the figures.

[10] This approximation holds strictly only for weak bases. Hence the absolute values given in Table I for stronger bases are somewhat in error.

TABLE I

Base	pK_B
Vitamin B_1 (stronger base)	5.0
Vitamin B_1 (weaker base)	9.5
Basic cleavage product (quaternary)	4.1
Basic cleavage product (tertiary)	10.6
4 Methylthiazole (quaternary)	4.5
4 Methylthiazole (tertiary) (curve not shown)	10.4
2,4-Dimethylthiazole (quaternary)	2.8

1. Two bases are liberated, in titrating the vitamin with sodium hydroxide, one of which is considerably stronger than the other. The stronger base is somewhat weaker than would be expected for a quaternary base, but the strength of the base liberated from the methiodide of the basic cleavage product is of the same order of strength as the stronger base in the vitamin.

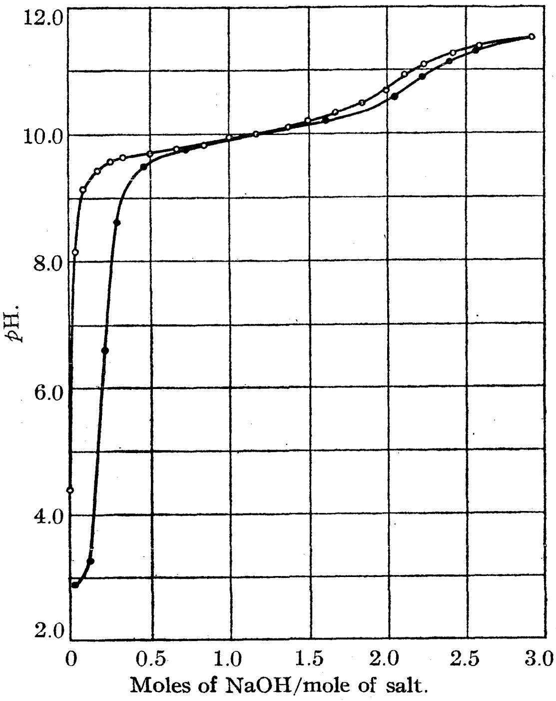

Fig. 2.—Titration of methiodide of basic cleavage product: ○—○, titration with NaOH; ●—●, back titration with HCl.

2. Both the vitamin and the methiodide of its basic cleavage product require an additional equivalent of alkali to liberate completely the strong base present in each.

3. During the portion of the titration referred to in (2) there is a marked slowness in coming to equilibrium. With each addition of reagent a large change in potential occurs, but after ten to fifteen minutes there is only a small net change. The behavior suggests the liberation of a very strong base with a slow rearrangement to a much weaker one. The additional equivalent of alkali required in this portion of the titration suggests that this "weaker base" gives rise to an acid which is neutralized as it is formed.

4. The back titrations of both the stronger base of the vitamin ($pK_B = 5.0$) and the methiodide of the basic cleavage product show a loss of material amounting to 10–20% of the original amount present. The slowness in attainment of equilibrium is equally evident in the back titration. The weaker base in the vitamin ($pK_B = 9.5$) is reneutralized by exactly one equivalent of acid, showing no alteration of the portion of the molecule associated with it.

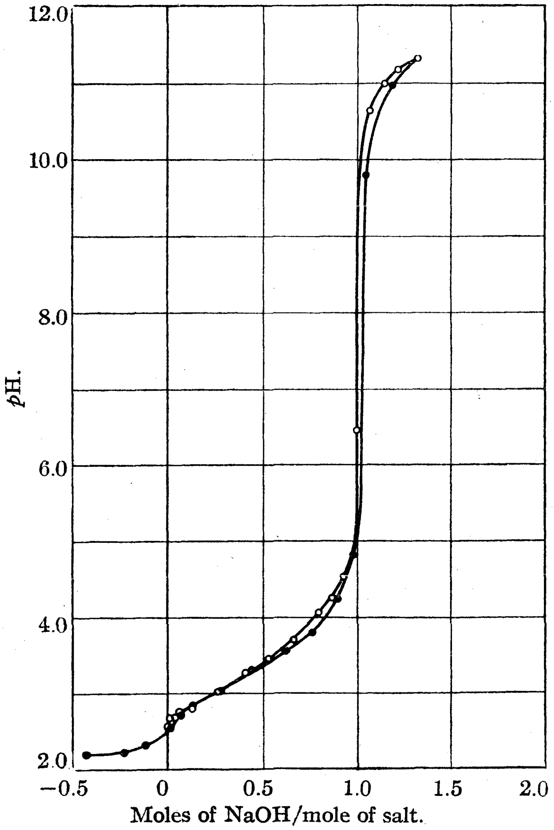

Fig. 3.—Titration of hydrochloride of basic cleavage product: ○—○, titration with NaOH; ●—●, back titration with HCl.

5. The hydrochloride of the basic cleavage product is demonstrated to be the salt of a very weak base which requires only one equivalent of reagent to liberate it. Equilibrium is attained almost instantaneously after each addition of sodium hydroxide. There is no loss of material on back titration.

6. The curve of 4-methylthiazole ethiodide is entirely analogous in form to that of the methiodide of the basic cleavage product. The same phenomenon of slowness in coming to equilibrium is manifest in both the forward and back titrations. Two equivalents of alkali are required to liberate the base and less than two of acid to reneutralize it.

7. The curve of 2,4-dimethylthiazole ethiodide, on the other hand, is the curve of a typical quaternary base, as is evident by comparison with the water curve. Evidently the methyl group in position 2 modifies the behavior of thiazolium salts in a marked way. A mauve color developed in this case on addition of the first drops of alkali (thiazolo-cyanine dye formation).[11] The back titration of this substance showed no significant points of inflection, apparently due to the relative stability of the colored substance, but afforded additional assurance of an entirely different behavior when position 2 is occupied by a methyl group.

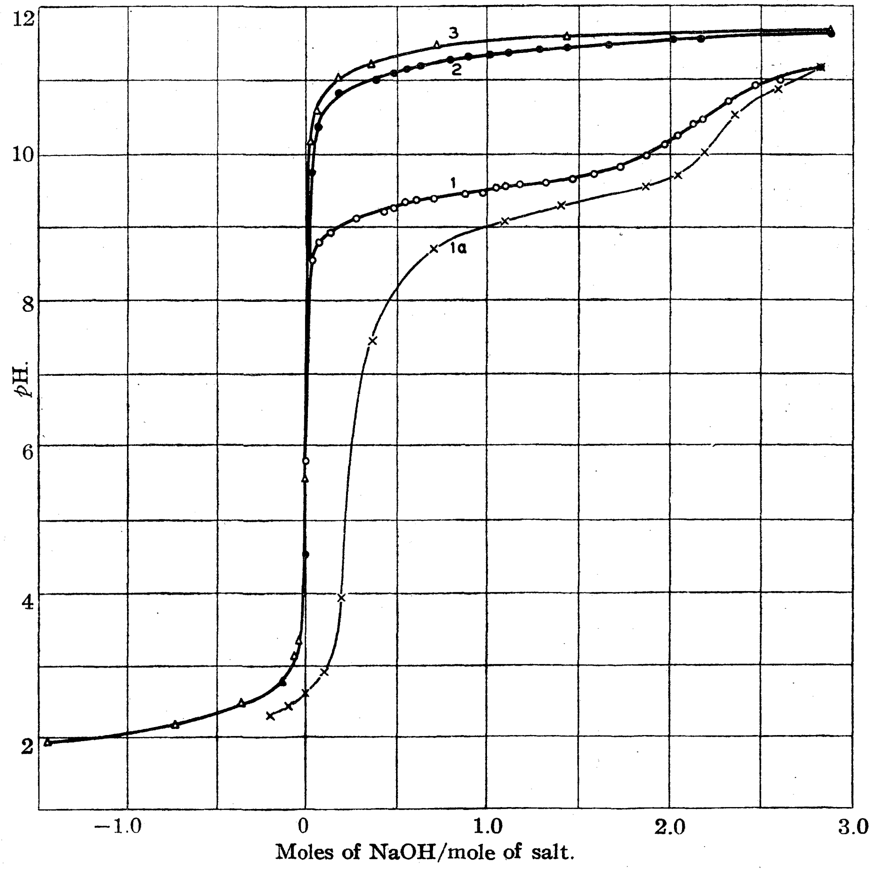

Fig. 4.—(1), Titration of 4-methylthiazole ethiodide with NaOH; (1a), back titration with HCl; (2), titration of 2,4-dimethylthiazole ethiodide with NaOH; (3), water curve.

Discussion of Results

There can be no doubt that the vitamin reacts exactly like the quaternary salt of its basic cleavage product toward sodium hydroxide, whereas its behavior is markedly different from that of the salt of the tertiary base. Furthermore, this behavior is not associated with the amino group contained in the vitamin, contrary to the suggestion of Moggridge and Ogston, since this group is not present in this cleavage product.[2b] Moggridge and Ogston have partially avoided the effect of the slow drift mentioned above by performing a rapid titration, which gives an indication of the actual strength of the stronger base. The curve is similar to that of the salt of a very strong base, although they conclude that there is no quaternary base present. It is unfortunate that their titration curve with equilibrium values is not shown above *p*H 7, as this should also reveal the presence of the quaternary base.

A study of the mechanism associated with the formation and neutralization of the pseudo base is in progress and will appear shortly in a paper by Dr. H. T. Clarke and associates. For the present it is sufficient to point out that the anomalous behavior of the vitamin closely resembles that of the quaternary salt of the basic cleavage product but not that of the salt of the basic cleavage product itself.

We are indebted to Dr. H. T. Clarke for advice and for furnishing us with samples of the synthetic thiazolium salts used in this study. We also wish to acknowledge financial aid by the Carnegie Corporation of New York through the Carnegie Institution of Washington.

Summary

1. Vitamin B_1 contains two basic groups, one of which is of the same order of strength as the nitrogen in the quaternary salt of its basic cleavage product and in 4-methylthiazole ethiodide.

2. The vitamin and the methiodide of its basic cleavage product, like 4-methylthiazole ethiodide, form pseudo bases in alkaline solutions, but this phenomenon is not exhibited by a 2-methyl substituted thiazolium base or by simple thiazoles.

The Dehydrogenation of Nicotine in Toluene as a Solvent

BY AVERY A. MORTON AND DAVID HORVITZ[1]

The experiments reported in this paper show that nicotine can be dehydrogenated by sulfur in boiling toluene as a solvent. This temperature is the lowest at which a dehydrogenation by sulfur or selenium has been carried out and is one of the few instances of the application of such a reaction to an alkaloid.[2] The object of this work was to perfect the exceedingly important method of dehydrogenation by lowering the temperature, controlling the concentrations, and changing the solvent so that the correctness of conclusions relative to the carbon framework of organic compounds might be subject to less doubt.[3] It was also desired to extend the application of dehydrogenation to nitrogen-containing compounds. Nicotine was chosen as suitable for study because the product of the proposed reaction is already known, having been prepared from nicotine by oxidation with potassium ferricyanide[4] or silver oxide[5] or by dehydrogenation over platinized asbestos at 320°.[6] Fusion of nicotine with sulfur has also been carried out by Cahours and Étard.[4]

Under the mild conditions attending the use of toluene as a solvent the amount of hydrogen sulfide evolved corresponds to 69% of the theoretical as given in equation 1 for the formation of nicotyrine, $C_{10}H_{10}N_2$. Actually nicotyrine was

$$C_{10}H_{14}N_2 + 2S = C_{10}H_{10}N_2 + 2H_2S \qquad (1)$$

obtained in only about 2.5% yield, the larger amount of material being thiodinicotyrine[7] $C_{20}H_{18}N_4S$ (equation 2), from which nicotyrine can be obtained by distillation over copper.[4] The yield of this substance when purified was about 18%.

$$2C_{10}H_{14}N_2 + 6S = C_{20}H_{18}N_4S + 5H_2S \qquad (2)$$

No appreciable quantities of tar were formed. The remainder of the material appeared to be unchanged nicotine and possibly products not completely dehydrogenated. Cahours and Étard[4] obtained this sulfur compound by the action of sulfur on nicotine in the absence of a solvent but failed to observe any nicotyrine.

Under a wide variety of conditions such as were possible by changing the concentrations and quantities of reagents the amount of hydrogen sulfide liberated could not be increased. Addition of acid at the end of the experiment failed to reveal any combined hydrogen sulfide. Iron, which has been claimed by Cheung[8] to break up sulfur addition compounds at higher temperatures, had no effect on the velocity or extent of hydrogen sulfide evolution. The addition of a small quantity of diphenylguanidine in the hope that it would act catalytically was found to inhibit greatly the rate and the completion of the reaction. Other solvents, boiling within the range of 99–121°, which were tried were epichlorohydrin, tetrachloroethylene, glacial acetic acid, and a gasoline fraction (99–102° b. p.). These solvents were far inferior to toluene both in the quantity of hydrogen sulfide formed and in the freedom from tarry products. Even the addition of acetic acid to toluene retarded greatly the rate of gas evolution although the total amount finally ap-

proached the same value obtained for toluene alone.

The success of this study has given encouragement to extend the use of solvents to the cases of cholesterol and abietic acid, which have heretofore given compounds of disputed structure[9] or yielded small amounts[10] of substances. Strychnine is also being investigated by this method. Solvents which boil higher than toluene are preferred in these cases. The results will be published shortly. The work on nicotine is being reported at this time because the recent paper of Blount,[2] in which the dehydrogenation of an alkaloid by selenium is mentioned, indicates a growing interest in this field.

Experiments

Choice of Solvent and Conditions.—Preliminary tests showed that no hydrogen sulfide was evolved when 0.5 g. of sulfur was refluxed for fifteen hours with 15 ml. each of epichlorohydrin, tetrachloroethylene, gasoline (99–102° fraction), glacial acetic acid, and toluene. Under the same conditions isopropyl propionate reacted with sulfur. Of the five suitable solvents toluene proved the best with respect to freedom from tarry products and quantity of hydrogen sulfide evolved when tested by refluxing 20 ml. of each with 0.5 g. (0.016 mole) of sulfur and 0.97 g. (0.006 mole) of nicotine (freshly distilled) for fifty hours. The hydrogen sulfide evolved was absorbed in ammoniacal zinc sulfate and titrated with standard iodine solution. Systematic variation of the quantities of sulfur, nicotine, and solvent showed that the largest quantity of sulfide gas, amounting to 69% calcd. according to equation 1, was obtained with 0.01 mole (1.6 g.) of nicotine, 0.225 mole (0.80 g.) of sulfur, and 20 ml. of toluene. Higher concentrations of nicotine produced some tar. Addition of 1.1 g. of alcoholized iron powder caused a somewhat decreased rate and quantity of gas. Diphenylguanidine, 0.2 g., reduced the total evolution of gas by 30%. Glacial acetic acid, 2.4 g., cut down the velocity to a fifth at the start but affected the amount finally obtained by only 11%. A huge excess of sulfur, amounting to over 100 times the theoretical, had no appreciable influence. No odor of methyl mercaptan was detected in any experiment.

Isolation of Nicotyrine and Thiotetrapyridine.—The quantities given above as being best were increased 25 times. The reaction was carried out by refluxing in a 2-liter flask heated in an oil-bath. At the end of ninety-one hours the evolution of gas had practically ceased. The resulting dark green solution was heated on a steam-bath under the vacuum created by a water pump until the distillation of toluene had ceased. The dark green viscous residue stood for two days without crystallization, a procedure which had been effective in causing solidification in other experiments. After placing the flask over solid carbon dioxide for two hours and then allowing to stand overnight, a large deposit of green crystals resulted. The supernatant liquid was poured off and the crystals washed with ether. They were then recrystallized twice from warm alcohol, yielding 7.6 g. of bright yellow crystals. The melting point after a third recrystallization remained at 151.5–153.5°. Cahours and Étard give 155° for this compound, thiodinicotyrine. Since no previous determination of its molecular weight had been made, the boiling point elevation in benzene was observed with the differential thermometer apparatus of Menzies: found with 0.0939 g. in 35.4 ml. of solvent, 303; with 0.1640 g., 314; calculated for $C_{20}H_{18}N_4S$, 346.

Upon distilling the solution, which had been poured off from the crude product, under 17 mm. vacuum a considerable additional amount of hydrogen sulfide was evolved. The fraction boiling from 143 to 153°, amounting to 1 ml., was collected. When redistilled at atmospheric pressure the main portion boiled at 268–274°. It is not as pure as the nicotyrine prepared by Wibaut and Overhoff[6] who found a boiling point of 280°. It was recognized as consisting chiefly of nicotyrine by its insolubility[11] in water, and by the melting point of its picrate derivative, which after six recrystallizations from alcohol melted at 160–161°. Blau gives 163–164; Wibaut 168–169°.

The above method of separation of the products proved much superior to extraction of the toluene solution with 5% alkali followed by distillation at atmospheric pressure of the toluene solution. Some nicotyrine was obtained together with tar and decomposition products. An attempt to precipitate the thiodinicotyrine by adding alcohol to the toluene concentrate before the crystals had formed was made. In spite of the fact that thiodinicotyrine is insoluble in alcohol, no crystals separated even on seeding and standing for several days at low temperatures.

Conclusions

Toluene has been found to be preferred over several other solvents of similar boiling point as a medium for the dehydrogenation of nicotine by sulfur. The temperature is lower than any hitherto employed for this purpose. The products are thiodinicotyrine and a small quantity of nicotyrine with practically no tarry materials.

Some β-Alkoxyethyl Esters of *p*-Aminobenzoic Acid

BY H. V. ASHBURN, A. R. COLLETT AND C. L. LAZZELL

In view of the fact that an ether linkage usually increases the solubility of organic substances in lipoids, it was thought worth while to prepare and study the physiological properties of a series of compounds of the anesthesine type but containing an ether linkage in the alcohol portion of the molecule.

The starting materials for this work were the mono-ethers of glycol. The methyl, ethyl and butyl ethers were obtained from the Carbide and Carbon Chemicals Corporation. The propyl, isopropyl, isobutyl and secondary butyl ethers were prepared by heating the corresponding alcohols with ethylene oxide in the presence of a small amount of sulfuric acid as a catalyst.[1] The tertiary butyl ether was prepared in the same manner except that acid aluminum fluosilicate was used as the catalyst.[2]

The ethers were purified by fractional distillation, using a distillation column packed with jack chain. Only samples having a boiling range of 0.5° or less were used.

p-Nitrobenzoates

The *p*-nitrobenzoates of these monoglycol ethers were prepared according to the method of Conn, Collett and Lazzell.[3] These esters are viscous, practically odorless liquids having a pale yellow color. They are insoluble in water but soluble in all the common organic solvents.

TABLE I

p-NITROBENZOATES

R in β-R-ethyl	Yield, %	B. p., °C.	$d^{25}_{\text{abs.}}$	n^{25}_{D}	γ^{25}	Formula	Nitrogen analyses, % Calcd.	Found	
Propoxy	84	181.6–182.6	1.1763	1.5165	37.8	$C_{12}H_{15}O_5N$	5.53	5.70	5.67
Isopropoxy	86	172.0–172.8	1.1741	1.5148	36.5	$C_{12}H_{15}O_5N$	5.53	5.50	5.55

s-Butoxy	80	183.5–184.5	1.1560	1.5124	36.1	$C_{13}H_{17}O_5N$	5.24	5.18	5.31
t-Butoxy	97	174.8–175.8	1.1579	1.5123	35.1	$C_{13}H_{17}O_5N$	5.24	5.29	5.30

Table I lists the analyses, physical constants and yields of all the new *p*-nitrobenzoates prepared. The analyses were made by titration with titanous chloride solution. All boiling points were taken under a pressure of 4.0 mm. with a thermometer completely immersed in the vapor. Refractive indices were determined by means of an Abbé refractometer at 25°. Surface tensions were obtained by means of a Du Noüy tensiometer at 25° and Harkins' correction for the ring method was applied. The yields are based upon the amount of glycol ether used.

p-Aminobenzoates

The *p*-aminobenzoates were obtained from the nitro compounds by reduction with hydrogen using Adams platinum–platinum oxide catalyst.[4]

One-tenth mole of the nitro compound was dissolved in 150 cc. of alcohol, 0.2 g. of Adams platinum–platinum oxide catalyst added and the solution shaken with hydrogen under an initial pressure of 45 lb./sq. in. until the theoretical amount of hydrogen was absorbed. The shaking with hydrogen was allowed to continue for an additional half-hour to ensure complete reduction. The catalyst was then filtered off and the alcohol removed by evaporation on the steam-bath. The red colored viscous oil remaining was dissolved in ether. The solution was then dried over anhydrous sodium sulfate, filtered, and dry hydrogen chloride passed in with cooling until precipitation was complete. The hydrochloride was filtered off, washed with dry ether until perfectly white and finally dried. To obtain the free base, the hydrochloride was dissolved in water, the solution cooled to 0–10° and dilute sodium carbonate solution added until the solution was alkaline. The free base was then filtered off and washed with cold water. The isobutyl, secondary butyl and tertiary butyl compounds were distilled under reduced pressure immediately after removing the alcohol.

Table II lists the analyses, physical constants and yields of these compounds. The analyses for nitrogen were made by the Kjeldahl method.

The picramides were prepared by the method given by Mulliken.[5]

The melting points of the hydrochlorides are not given since they apparently decompose before melting. The bases were all crystallized from ligroin with the exception of the tertiary butoxy compound which was crystallized from a water–alcohol mixture and the isobutoxy and secondary butoxy compounds which solidified after distillation when placed in a cool place for a few days, but these did not give definite melting points and could not be recrystallized. They apparently melt near room temperature. The yields are based upon the amount of glycol ether used.

Physiological data on these compounds will be reported in a later paper.

Summary

Five new β-alkoxy ethyl *p*-nitrobenzoates and a series of eight *p*-aminobenzoates have been prepared and some of their physical constants determined.

A Gaseous Discharge Tube Especially Designed as an Intense Source of Continuous Ultraviolet Radiation

BY R. H. MUNCH

In the study of certain gaseous absorption lines, during the course of some research work under the direction of Dr. F. T. Gucker, Jr., the author required an intense source of continuous ultraviolet radiation which was simpler and more efficient than any that could be found described in the literature. This article deals with the development of such a source. Beyond about 3500 Å. there are only three sources of continuous radiation: the so-called Lyman continuum[1] (to 300 Å.), the hydrogen continuum[2] (3657–1216 Å.) and the helium continuum[3] (1125–500 Å.). The hydrogen continuum, which is the most useful, may be excited with considerable intensity if about 1500 v. is applied to an ordinary discharge tube made with a long capillary viewed from the end. Such a tube, dissipating as much as 18 kw., must be made of quartz and water cooled. It is, therefore, expensive and is comparatively inefficient. A more convenient method of exciting the hydrogen continuum without using high voltage and water cooling is by means of thermoelectrons from a hot cathode as in the low voltage arc of Duffendack and Manley.[4] This arc passed between a heated tungsten filament and a disk anode, in a tube containing a palladium tube to admit hydrogen and a quartz window sealed on with wax. We built a tube differing from this only in having an oxide coated

cathode and a thin Pyrex window[5] equivalent to 1 mm. of quartz, but it was too weak a source even with ten times the current Duffendack and Manley used. Starting from this tube we finally evolved a source which combined the intensity of the high voltage tube with the simplicity of the low voltage arc.

Construction and Operation of the Tube.—Figure 1 shows the construction of this tube. The oxide coated cathode, C, is a 0.48 × 15.25 cm. piece of nickel gauze woven of 0.25 mm. wires 19 per inch, bent into a corrugated form having a 0.48 cm. cross section. One end is spot welded to the top of the cathode shield, S, and the other to a 0.10 cm. nickel wire. It is then painted with a water suspension of equal parts of barium and strontium carbonates and dried in an oven. Successive layers are applied until a heavy coating is obtained, since the life of the cathode in a hydrogen tube is proportional to the amount of oxide it has on it.

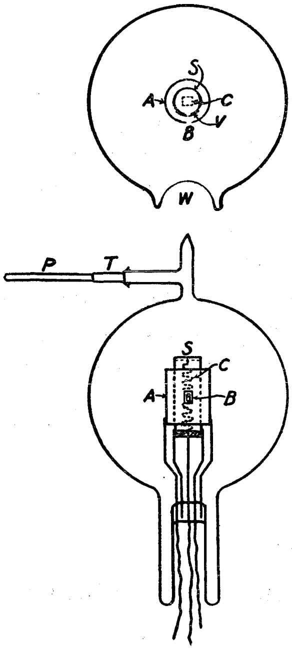

Fig. 1.

The cathode is surrounded by a cylindrical shield, S, of 0.125 mm. nickel, 4.06 cm. long and 1.25 cm. in diameter, which forms one lead to the cathode and is closed at the bottom by means of a porcelain disk (cross hatched) through which the second cathode lead passes. The only opening in the shield is a 0.66 × 3 mm. slit cut in a piece of 0.25 mm. sheet tungsten[6] welded in the side.

The anode, A, is a 2.2 × 2.86 cm. nickel cylinder made from 0.25 mm. sheet with a 0.32 cm. × 0.64 cm. hole, B, to correspond with the slit in the cathode shield. These parts are mounted as shown on a five wire stem which is then sealed into a 10 cm. Pyrex bulb. When the tube is in operation, the whole discharge between the cathode and the anode must pass through the small slit in the shield, and is viewed through the opening in the anode. This arrangement of parts gives a rectangular light source most suitable for a spectrograph or any instrument having a collimating slit. The extremely efficient source of electrons furnished by the oxide coated cathode, together with the short distance between anode and cathode, enable this tube to pass a given current at about 5% of the voltage required for an ordinary capillary tube. It requires no water cooling and could operate continuously at a current of 1.5 amp., or run for a short time at a higher current. Since the slit area was 2 sq. mm., the current density through the slit was 75 amp. per square centimeter for continuous operation and could be increased considerably for short periods. The use of a smaller slit was not practical, since it made the discharge hard to start.

The thin window, W, is made opposite the slits by first blowing a bubble about 3.2 cm. in diameter, then melting it back to about half its height and sucking it in carefully. The palladium tube, P, is now silver soldered to a copper tube, T, the end of which is flared and sealed on the *outside* of a piece of Nonex which is fused to the Pyrex from which the bulb is made. The external copper seal withstands sudden heating without developing cracks. The tube must now be evacuated and freed of all traces of moisture or carbon monoxide which might deactivate the cathode and would certainly produce line or band spectra. It is connected through a liquid air trap and large stopcock to a vacuum pump. The glass and metal parts are outgassed thoroughly by passing a discharge through the tube and sweeping it out with a stream of hydrogen at 2–4 mm. pressure. This is admitted by holding a Bunsen burner flame under the palladium tube, and its removal is regulated by the stopcock. When the spectrum becomes continuous, below 3657 Å., the tube is sealed off.

The electrical connections are similar to those of a "tungar" or a hot cathode mercury arc rectifier. The cathode, which requires 9 amp. at about 3 v., is supplied by a step-down transformer and connected in series with a rheostat and ammeter. The anode circuit, also containing a rheostat and ammeter, may be connected to any 110 volt circuit. The use of a. c. to heat the cathode and d. c. for the anode circuit gives the maximum cathode life. In operation, the fall of potential between anode and cathode is 30–35 v. If the discharge fails to start (before the tube has been outgassed or when the cathode is nearly spent) it may be started by touching the palladium tube with the type of Tesla coil used in testing for leaks in a vacuum system.

Performance of the Tube.—The improved hydrogen arc was found to be about thirty times as intense (for the same current) as the original type of Duffendack and Manley. Since the latter only used 50 m. a. as against 1.5 amp. as a moderate rating for the improved type, the total increase is about nine hundred fold since the intensity is proportional to the current density.[7]

We did not have the equipment necessary to compare the improved lamp with the high voltage arc, but if the intensity here also is proportional to the current, the increased efficiency of the new tube can be judged by the fact that it passes 1.5 amps. for about 75 watts total energy, instead of over 2 kw.

The determination of the absolute intensity of the continuum emitted by the lamp was outside

the scope of our work. However, a comparison was made with the mercury arc lines emitted by a G. E. "Labarc" when both sources were run at 1 amp. The continuum was 25% as intense as the 2483 and 2652 Å. lines, 7% as intense as the 2894 and 3022 Å. lines and 12% as intense as the 3350 Å. line. These figures should give anyone familiar with this field a satisfactory idea of the performance of the lamp.

The Tube as a Line Spectral Source.—This type of lamp operates when filled with helium, argon, or a mixture of argon and mercury; and presumably when filled with the other rare gases. The argon mercury mixture gave a spectrum from which the far ultraviolet lines, particularly the resonance line, were nearly absent due to the quenching effect of argon while the visible and near ultraviolet lines were very strong.

Acknowledgments.—The author wishes to express his appreciation to Dr. F. T. Gucker, Jr., for his encouragement and assistance in the course of this work and for his assistance in the preparation of the manuscript for publication. It is also a pleasure to acknowledge the helpful advice given by Dr. R. A. Fisher and Dr. W. S. Huxford of the Physics Department of Northwestern University.

Summary

A simple, low voltage hydrogen discharge tube especially designed as an intense source of continuous ultraviolet has been developed. It requires no water cooling, since it produces the same light intensity with only about 5% of the electrical power required by a high voltage hydrogen discharge tube. Details of construction and operation are given.

In addition to being useful as a source of continuous radiation it has been used as a source of the line spectra of mercury and the rare gases.

Some Thermodynamic Properties of Uni-univalent Halide Mixtures in Aqueous Solution

BY HERBERT S. HARNED

It has been shown experimentally by Güntelberg and by Harned that the logarithm of the activity coefficient of hydrochloric acid in chloride mixtures of constant total ionic strength varies linearly with the molality of the acid. Since these earlier studies, other investigations have confirmed this result.[1]

Recently, from a number of sources, sufficient evidence has been acquired to permit more extended observations of this relation, particularly with respect to concentration and temperature. The results obtained will have a special interest in connection with some recent generalizations made by Åkerlöf[2] regarding the behavior of these mixtures. Of still greater interest will be the limitations which the newer knowledge imposes upon Brönsted's theory of the specific interaction of ions.[3]

For our purposes, the law of the linear variation of the logarithm of the activity coefficient at constant ionic strength may be expressed for the systems of uni-univalent halide acid–halide salt mixtures in the following manner. Thus

$$\begin{aligned}\log \gamma_1 &= \alpha_1 m_1 + \log \gamma_1^0 = \log \gamma_{1(0)} - \alpha_1 m_1 \\ \log \gamma_2 &= \alpha_2 m_2 + \log \gamma_2^0 = \log \gamma_{2(0)} - \alpha_2 m_2\end{aligned} \quad (1)$$

where the ionic strength, $\mu = m_1 + m_2 =$ constant. The first of these equations refers to the acid (subscript 1) in the mixture, and second to the salt (subscript 2) in the same mixture. γ_1^0 and γ_2^0 are the activity coefficients of the acid at zero concentration in the salt solution and that of the salt at zero concentration in the acid solution, respectively. $\gamma_{1(0)}$ and $\gamma_{2(0)}$ are the activity coefficients of the acid and salt in pure aqueous solution of the acid and salt, respectively. Equation (1) is taken to be valid at any total ionic strength, μ.

The present communication contains measurements of the cells

H_2 (1 atm.) | HCl (0.01), NaCl(m) | AgCl | Ag Type I

which will serve to supplement the available accurate data on this subject. Results have been

obtained from 0 to 60° at 5° intervals and at salt concentrations which vary from 0 to 3 *M*. These in combination with the results of Harned and Ehlers, and Harned and Nims[4] make it possible to compute α_1 and α_2 in these mixtures from 0 to 40° and throughout wide ranges of total concentrations. Further data are now available for computing α_1 and α_2 of a number of uni-univalent halide acid–salt mixtures at 25°. The information derivable from these results, namely, the behaviors of α_1 and α_2 as functions of temperature and concentration, is an important addition to the knowledge of such mixtures.

Experimental Results[5]

The measurements of the cells (Type I) were carried out by a technique similar to that employed by Harned and Hamer,[6] and the results were obtained at round concentrations by the method described by them. Measurements at each concentration were made from 0 to 60° at 5° intervals. These were expressed to within ±0.05 mg. by the quadratic equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

The values of E_{25} and the constants *a* and *b* are given in Table I.

TABLE I

CONSTANTS OF EQUATION (2)

$m_1 = 0.01 \quad \mu = m_1 + m_2$

	E_{25}	$a \times 10^6$	$b \times 10^6$
0.01	0.46416	175	−3.0
.02	.44815	124	−3.0
.03	.43891	94	−2.95
.06	.42330	50	−2.9
.11	.40996	12	−2.8
.21	.39550	− 35	−2.8
.51	.37422	− 97	−2.65
1.01	.35502	−149	−2.5
2.01	.32949	−210	−2.0
3.01	.30906	−247	−1.5

Method of Computation of α_1 and α_2.—The values of α_1 may be computed directly at a given concentration if the activity coefficient of the acid in pure water and the activity coefficient of the acid in the salt solution are known. The first of these has been derived from measurements of the cells

$$H_2 \mid HX(m) \mid AgX \mid Ag;\ X = Cl:Br \qquad \text{Type II}$$

and the second from cells of Type I, or

$$H_2 \mid HX(m_1),\ MX(m_2) \mid AgX \mid Ag;\ \begin{cases} X = Cl:Br \\ M = Li, Na, K, Cs \end{cases} \qquad \text{Type I}$$

Thus

$$\alpha_1 = (\log \gamma_{1(0)} - \log \gamma_1)/(m - m_1) \qquad (3)$$

where the subscript 1(0) refers to the acid in pure water at a concentration μ.

The computation of α_2 from the values of α_1 and other known data may be made by the use of the Gibbs–Duhem equation in the form.

$$m_H \, d \ln a_H a_X + m_M \, d \ln a_M a_X = -55.5 \, d \ln a_W \qquad (4)$$

where a_H, a_M, a_X represent the activities of the ionic species denoted by subscripts and a_W is the activity of water. Since the anion is common in all the mixtures under consideration, $m = m_X = m_H + m_M$ = constant, this equation becomes

$$2m_1 \, d \log \gamma_1 + 2m_2 \, d \log \gamma_2 = -55.5 \, d \log a_w \qquad (5)$$

γ_1 and γ_2 equal the activity coefficients $(\gamma_H\gamma_X)^{1/2}$ and $(\gamma_M\gamma_X)^{1/2}$, respectively. According to equation (1), $d \log \gamma_1 = \alpha_1 \, d\, m_1$ and $d \log \gamma_2 = \alpha_2 \, d\, m_2$, whence equation (5) becomes

$$2\alpha_1 m_1 \, d\, m_1 + 2\alpha_2 m_2 d\, m_2 = -55.5 \, d \log a_w \qquad (6)$$

Let $m_1 = mx$; then $m_2 = (1 - x)m$, where x can have any value from 0 to 1. Employing these values in equation (6) and performing the integration, we obtain

$$x^2(\alpha_1 + \alpha_2) - 2\alpha_2 x = -55.5/m^2 \int_0^x d \log a_w \qquad (7)$$

an equation which is fundamental to all subsequent discussion.

Upon integration from x equals 0 to 1 or from the pure salt to pure acid solution, we readily obtain

$$\alpha_2 = \alpha_1 + (55.5/m^2) \log (a_1/a_2) \qquad (8)$$

where a_1 and a_2 are the activities of water of the pure acid and pure salt solutions, respectively. Equation (8) gives us a means of computing α_2 from α_1. Since the thermodynamic data of the halide electrolytes in water have been expressed in terms of activity coefficients, we have evaluated the activity ratio in equation (8) by means of the equation

$$\ln \frac{a_0}{a} = \frac{m}{55.5}\left[\nu + \frac{\nu}{m}\int_1^\gamma d \ln \gamma\right] \qquad (9)^7$$

a_0 is the activity of the pure solvent, and ν for the uni-univalent salts in question equals 2. The logarithm of the ratio of the activities of water of

solutions of two uni-univalent electrolytes at a given concentration, m, is readily found from two of these equations to be

$$\log \frac{a_1}{a_2} = \frac{2}{55.5}\left[\int_1^{\gamma_{2(0)}} m \, d \log \gamma_2 - \int_1^{\gamma_{1(0)}} m \, d \log \gamma_1\right. \tag{10}$$

whence from equation (8)

$$\alpha_2 = \alpha_1 + \frac{2}{m^2}\left[\int_1^{\gamma_{2(0)}} m \, d \log \gamma_2 - \int_1^{\gamma_{1(0)}} m \, d \log \gamma_1\right] \tag{11}$$

The subscript (0) refers to activity coefficients of pure aqueous solutions of the acid or the salt. When this subscript is omitted, the activity coefficient of the substance in question in the mixture is under consideration. Since α_1 is known by experiment and since the integrals on the right may be computed, α_2 may be calculated. This equation has been derived upon the assumption that equations (1) are valid. From experimental evidence we know that the first of these relations is true for the variation of log γ_1 with m_1 in the cases of hydrochloric and hydrobromic acids in their corresponding alkali salt solutions. Indeed judging from electromotive force and solubility measurements the law is valid within narrow limits in dilute solutions and also in solutions of potassium chloride or sodium chloride at 5 M and 6 M, respectively. No direct experimental data confirm the linear law for the logarithm of the activity coefficient of the salt in the acid solution, that is to say, the constancy of α_2. Since so much evidence confirms the validity of the first of the relations given by equation (1), we shall proceed by assuming the second of these relations to be valid.

The Halide Acid–Alkali Salt Mixtures at 25°. —The values of α_1 for hydrochloric acid in lithium, sodium, potassium and cesium chloride solutions and for hydrobromic acid in lithium, sodium, and potassium bromide solutions computed by equation (3) are compiled in Table II. The activity coefficient of hydrochloric acid in pure aqueous solution was obtained from the data of Harned and Ehlers and Randall and Young[8] and is given in the eighth row of the table. The ninth row of the table contains the activity coefficient of hydrobromic acid taken from the data compiled by Harned.[9] The preceding rows contain α_1 of the acids in the halide solutions designated. The sources of the data are given in the references below the table. The accuracy of this determination is difficult to estimate since it depends on the concentration. If we assume errors of ±0.05, ±0.1, ±0.2, and ±0.2 mv., at 0.1, 0.5, 1, and 3 M, respectively, then the maximum error in α_1 is ±0.004, ±0.0034, ±0.0034, and ±0.0011 at these concentrations. At 0.1 M Güntelberg's results are consistent to within

---

[8] Harned and Ehlers, THIS JOURNAL, **55**, 2179 (1933); Randall and Young, *ibid.*, **50**, 989 (1928).

[9] Ref. 7, Chap. XII, p. 772.

±0.02 mv. and are in agreement with Harned's values. The consistency of the present results as judged from graphs is of the order of ±0.001 at 0.1 *M*, ±0.0006 at 0.5 *M* and 1 *M*, and ±0.0004 at the higher concentrations.

The values of $(-\alpha_2)$ given in the second part of the table were obtained from α_1 and the activity coefficient data by means of equation (11). The values of $\log \gamma$ employed in the graphical integration for the sodium and potassium chloride and bromide solutions were taken from the data of Harned and Robinson and Sinclair, and for the case of cesium chloride from the combined data of Robinson and Sinclair and Schupp.[10] The values of $\log \gamma$ for the lithium chloride solutions were those of Robinson and Sinclair. In some cases, the earlier results were changed slightly to conform with the values of $\log \gamma_{0.1}$ given in Table II. Since we have employed data from so many sources, it is difficult to estimate the accuracy of the computation of $(-\alpha_2)$. From 0.5 to 3 *M* the consistency of the data as judged from graphs is of the order of ±0.002 and it appears that on the whole the results may be relied on to this extent.

Hydrochloric Acid–Sodium Chloride Mixtures from 0 to 40°.—For mixtures of hydrochloric acid and sodium chloride, accurate data are available which make possible the computation of α_1 and α_2 from 0 to 40° and from 0.3 to 3 *M*. The integral on the right of equation (11) was computed from activity coefficients of Harned and Ehlers (hydrochloric acid) and Harned and Nims (sodium chloride).[11] The values of α_1 were obtained from the electromotive forces given in Table I of the present communication and the electromotive force data of Harned and Ehlers.[12] The values at 0.1 *M* were obtained from the very careful measurements of Güntelberg (20°) and also those of Harned (25°). From 0.5 *M* to 3 *M*, the results are consistent to within the limit of ±0.0006 in the case of α_1 and ±0.001 in the case of α_2. Table III contains the values of these quantities at 25° and at 10° intervals from 0 to 40°.

[a] Güntelberg, *loc. cit.* [b] Harned, *loc. cit.* [c] The results at 25° differ slightly from those in Table II. This is due to the fact that the values in this table were smoothed against *T*.

Limitations of Empirical Rules of Åkerlöf and Thomas.—We shall first consider two empirical relations which Åkerlöf and Thomas have employed[2] for computing solubility data in concentrated solutions.

The first of these rules is expressed by

$$\log (\gamma_{1(0)}/\gamma_{2(0)}) = Bm \qquad (12)$$

where B is a constant. If this relation be employed in conjunction with equation (11), it is found that at constant temperature

$$(\alpha_1 - \alpha_2) = B \neq f(m) \qquad (13)$$

Further, if both this and equations (1) are valid, in other words if all these relations are linear, then

$$\left.\begin{aligned} (\alpha_1 - \alpha_2)\, m &= \log (\gamma_{1(0)}/\gamma_{2(0)}) \\ \log \gamma_1^0 &= \log \gamma_2^0 \end{aligned}\right\} \qquad (14)$$

and according to equation (11)

$$\log \frac{\gamma_{1(0)}}{\gamma_{2(0)}} = -\frac{2}{m}\left[\int_1^{\gamma_{2(0)}} m \,\mathrm{d} \log \gamma_2 - \int_1^{\gamma_{1(0)}} m \,\mathrm{d} \log \gamma_1\right] \qquad (15)$$

We may readily test these relations by means of the above data. From the activity coefficients of the acids and the pure salts at various concentrations, the left side of equation (12) was computed, and the value of B at each concentration was determined. For example in the case of the chlorides $\gamma_{1(0)}$ is the activity coefficient of hydrochloric acid and $\gamma_{2(0)}$ that of the designated chloride at a concentration, m. The results are given in Table IV.

It is to be noticed that when B is small, the variation of B with concentration is small, but that in general B decreases with increasing concentration. Where B is larger, the actual and

KBr	.168	.155	.149	

percentage deviation of B with concentration is greater. In Fig. 1, B is plotted against m and the variation of B with m is represented by the crosses and dashed lines. The solid lines in the figure represent the values of $(\alpha_1 - \alpha_2)$ obtained from Table II. In the cases of the lithium chloride–hydrochloric acid and lithium bromide–hydrobromic acid mixtures B does not vary appreciably with m and therefore $(\alpha_1 - \alpha_2) = B$ according to equation (13). This equality may not be exact but it is within the experimental error. In the case of the sodium salt mixtures B is slightly different from $(\alpha_1 - \alpha_2)$ and a similar but greater difference occurs with the potassium salt mixtures and finally a still greater difference with the cesium salt mixture. This is in accord with the character of equation (11) and the nature of the variation of B with m as well as the linear variations represented by equations (1).

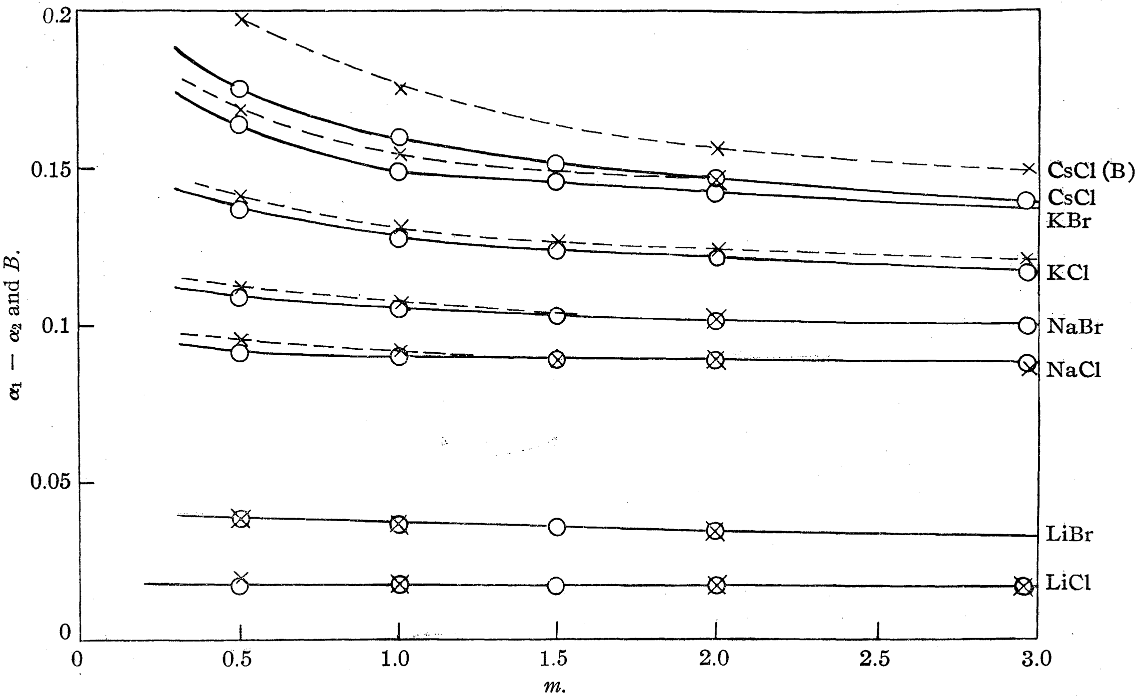

Fig. 1.—Plots of B and $\alpha_1 - \alpha_2$ vs. m for uni-univalent halide solutions: ×, B; ○, $\alpha_1 - \alpha_2$.

The variation of B with m conforms with the contentions of Robinson, and Scatchard and Prentiss,[13] who concluded from heat of dilution data and freezing point data, respectively, that B is not constant and is $f(m)$ in dilute solutions. Even in concentrated solutions care must be employed in the use of these relations while in dilute solutions it is obvious that it is not valid.

The second rule postulated by Åkerlöf and Thomas states that α_1 and α_2 are constants which do not vary with m. In dilute solutions, reference to Tables II and III and Figs. 2 and 3 shows that this is not the case. Since their observations refer particularly to concentrated solutions, we note that there is a general tendency for α_1 and α_2 to vary less as the concentration increases. But even in very concentrated solutions, these quantities still appear to be a function of m. For example, in the case of sodium chloride–hydrochloric acid mixtures α_1 tends to decrease somewhat up to 6 M while for the potassium chloride mixtures it passes through a minimum at about 1.5 M and then increases. We must conclude therefore that at constant temperature α_1 and α_2 are not characteristic constants of a given pair of electrolytes.

---

[13] Robinson, THIS JOURNAL, **56**, 2312 (1934); Scatchard and Prentiss, *ibid.*, **56**, 2320 (1934).

Further Discussion of the Derived Parameters, α_1 and α_2.—The curves in Fig. 2 which represent the values of α_1 and $-\alpha_2$ for hydrochloric acid–chloride mixtures are typical of all the results in Table II. In fact, the bromide mixtures exhibit behaviors which parallel those of the chloride mixtures. At higher concentrations, α_1 does not equal $(-\alpha_2)$. As the concentration decreases, there seems to be a tendency in some cases (*e. g.*, CsCl, NaCl, NaBr) for the values to approach each other somewhat. Potassium chloride and bromide mixtures exhibit a more complex behavior since the curves representing the variation of these constants with concentration cross. In some cases, $(-\alpha_2) > \alpha_1$ (*e. g.*, NaCl, LiCl) while in others (*e. g.*, CsCl) $\alpha_1 > (-\alpha_2)$.

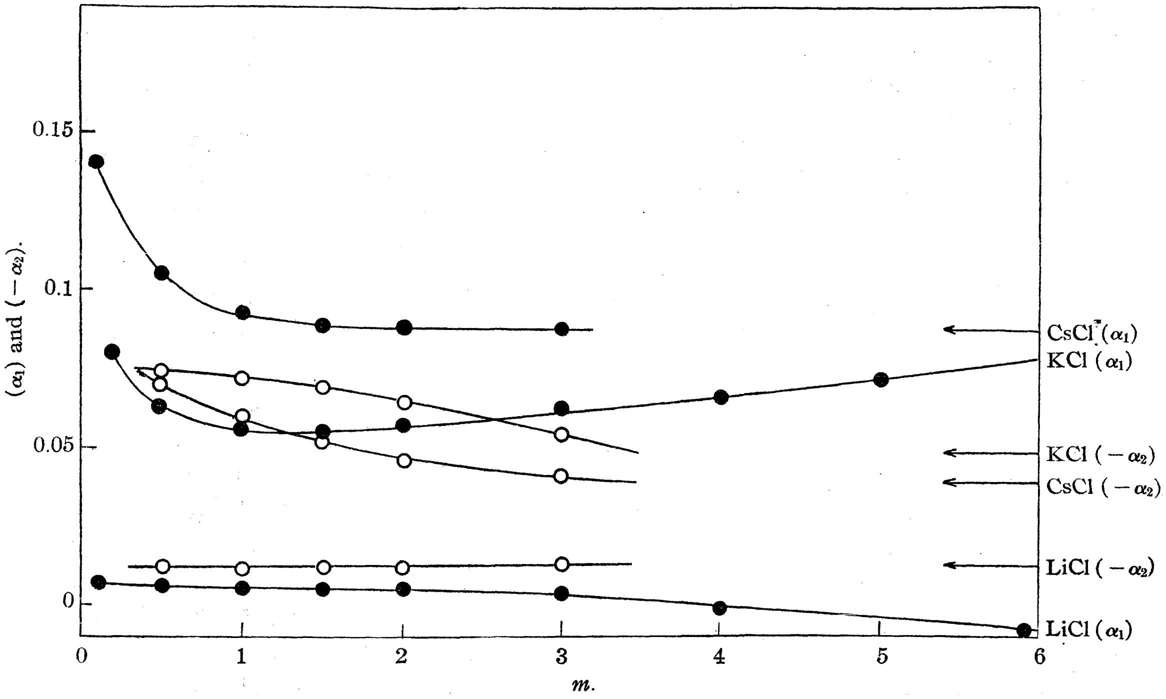

Fig. 2.—Plots of α_1 and $-\alpha_2$ *vs.* m for uni-univalent chloride–hydrochloric acid mixtures.

The best illustration of these behaviors is given by the sodium chloride mixtures and is shown by Fig. 3 in which the parameters, α_1 and $(-\alpha_2)$ are plotted against m at 0, 25 and 40°. As the concentration decreases, there is a tendency for the corresponding curves of α_1 and $-\alpha_2$ to approach each other somewhat but the evidence indicates that they do not meet even in the dilute solutions.

It is important to note that the values reported for α_1 and $-\alpha_2$ have been derived from electromotive force measurements which have been checked by measurements from various sources. The mixture data have been tested in a number of ways. For example, from mixture data by purely formal methods,[14] Harned was able to compute the activity coefficients of some single electrolytes. Another test of these data consists in computing dissociation constants and total heats of ionization of water in the salt solutions. Agreement was obtained with the best calorimetric data by Harned and Hamer for potassium chloride solutions. The values of α_1 for the chloride solutions at 0.1 *M* were obtained from the closely agreeing values of Güntelberg and Harned.[14] All the data of the activity coefficients of single electrolytes have been checked in a number of ways. The activity coefficients of hydrochloric acid agree with colorimetric data as shown by Harned and Ehlers. Those of the salt solutions at 25° have been found to be in agreement with the vapor pressure data of Robinson and Sinclair and Robinson.[15] At 0.5 *M* sodium chloride $(-\alpha_2)$ was found to be 0.0820 from the electromotive force data of Harned and Nims and 0.0814 from the freezing point data of Scatchard and Prentiss.[16] Further the reference value of γ in 0.1 *M* sodium chloride employed, namely, 0.778, agrees very

closely with 0.7784 recently obtained by Brown and MacInnes.[17] In view of these facts, we believe the results are within the limits of accuracy previously discussed.

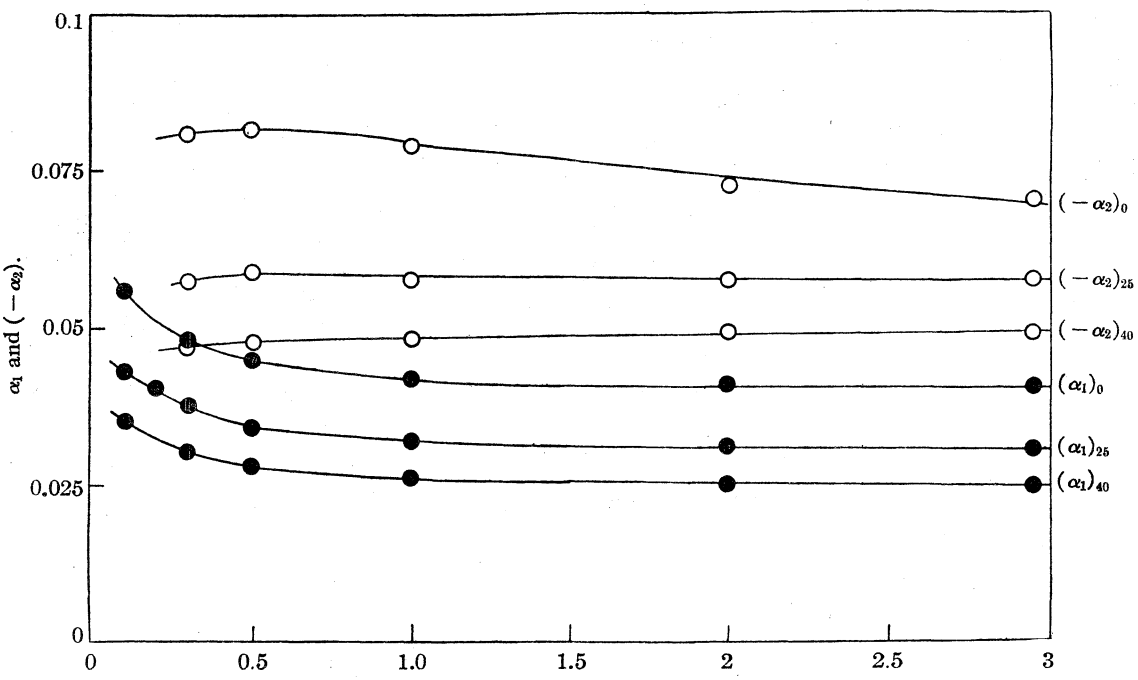

Fig. 3.—Plots of α_1 and $-\alpha_2$ *vs. m* for sodium chloride–hydrochloric acid mixtures at 0, 25 and 40°.

Theory of Specific Ionic Interaction

Since these results are of interest in relation to Brönsted's theory of specific ionic interaction, we shall introduce a few of the consequences of this theory.[18] The osmotic coefficient, ϕ, may be introduced into equation (7) by means of the relation

$$-\partial \log a_v = (\nu m/55.5 \times 2.303)\, \partial\phi \qquad (16)$$

and the equation for the variation of the osmotic coefficient in mixtures at constant total molality, *m*, may be obtained. Thus

$$x^2(\alpha_1 + \alpha_2) - 2\alpha_2 x = \frac{1}{m^2}\int_0^x \frac{\nu m}{2.303}\, \partial\phi \qquad (17)$$

As pointed by Güntelberg, the left side of this equation is quadratic. Brönsted's theory of specific ionic interaction applied to these mixtures leads to the conclusion that both the osmotic coefficient and the logarithm of the activity coefficient vary linearly with the composition. Thus

$$2.303B'm\partial x = \partial\phi \qquad (18)$$

where B' is a constant. Combining this equation with equation (17) and integrating, we find that

$$x(\alpha_1 + \alpha_2) - 2\alpha_2 = \nu B' \qquad (19)$$

for all values of *x* between 0 and 1. Consequently

$$\begin{aligned} \alpha_1 &= -\alpha_2 \\ \alpha_2 &= -(\nu/2)B' = -B' \text{ (1-1 Electrolytes)} \end{aligned} \qquad (20)$$

The theory of specific ionic interaction as originally formulated requires: (1) the linear variation of log γ at constant total molality (Eq. 1); (2) the linear variation of ϕ (Eq. 18); (3) that $\alpha_1 = -\alpha_2$. These results follow from the assumption that ions of like sign uniformly influence each other in a dilute salt solution. According to this formulation of the theory the factor $(\alpha_1 + \alpha_2)$ is a measure of the deviation from the theory, caused by specific interaction between ions of like sign. Upon the basis of the validity of (1) (Eq. 1), we have computed the factor $(\alpha_1 + \alpha_2)$ and found that at high concentrations it is finite. In this connection, we note that the thermodynamic result given by equation (17) does not require the equality, $\alpha_1 = -\alpha_2$, at any concentration including $m = 0$. Since this depends on the hypothesis of ionic interaction, we have not extended the curves in the figures to lower concentrations where the uncertainty becomes large. This consideration raises the interesting question as to whether $(\alpha_1 + \alpha_2)$ vanishes at any concentration. In Fig. 4, we have plotted the values of this factor against *m*. The dots and

(18) Brönsted, *ibid.*, **44**, 877 (1922); **45**, 2898 (1923).

the solid lines represent the results of this investigation. It is apparent that at higher concentrations, 0.3 *M* and above, $(\alpha_1 + \alpha_2)$ is finite and there is no definite indication that this quantity approaches zero as the concentration decreases. Since Brönsted's theory was never intended to apply to concentrations greater than 0.1 *M*, these results do not seriously contradict the theory although they definitely show that it is not valid at the higher concentrations.

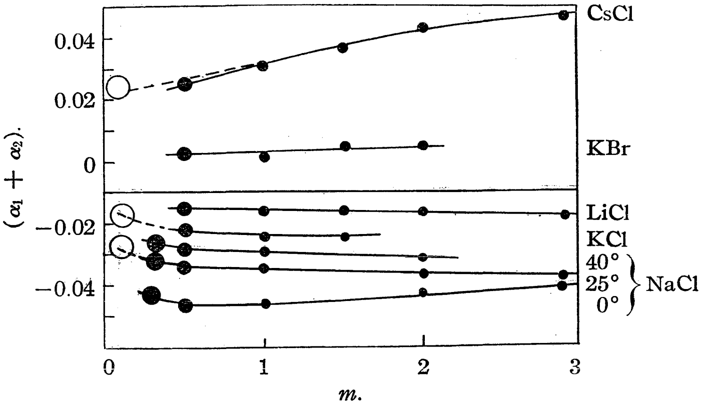

Fig. 4.—Plots of $(\alpha_1 + \alpha_2)$ *vs.* *m*.

It is apparent (Fig. 4) that the values of $(\alpha_1 + \alpha_2)$ of cesium chloride and sodium chloride mixtures differ considerably. The most recent results for activity coefficients at 0.1 *M* determined since these calculations were made conform to this distribution. According to our earlier discussion $\log \gamma_{1(0)} - \log \gamma_{2(0)} = \alpha_1 - \alpha_2$ if we neglect the small difference between $(\alpha_1 - \alpha_2)$ and *B*. Harned and Ehlers obtained −0.0989, and Randall and Young[19] obtained −0.0993 for $\log \gamma_{0.1}$ for hydrochloric acid at 25°. If we employ the mean of these results, and Brown and MacInnes' value of −0.1088 for $\log \gamma_{0.1}$ of sodium chloride, then $(\alpha_1 - \alpha_2) = 0.0097$. From Güntelberg's value of α_1 at 20°, we obtain 0.040 at 25°. Hence, $-\alpha_2 = 0.057$ and $(\alpha_1 + \alpha_2) = -0.017$. For cesium chloride, we use Robinson and Sinclair's value of 0.1238 for $-\log \gamma_{0.1}$. Güntelberg obtained 0.146 for α_1 at 20°. From the temperature coefficient of this quantity, we find that $\alpha_1 = 0.143$ at 25°. Therefore $-\alpha_2 = 0.1040$, and $(\alpha_1 + \alpha_2) = 0.0039$. If we introduce a correction due to the fact that $B > (\alpha_1 - \alpha_2)$, then the value of $(\alpha_1 + \alpha_2)$ is even higher. In the same manner by employing the values of $\log \gamma$ and α_1 given in Table II, we obtain 0.013 and −0.007 for $(\alpha_1 + \alpha_2)$ of the lithium and potassium chloride mixtures, respectively, which appear to lie between the values obtained for the other two salts. The circles in Fig. 4 represent these values with the exception of that of the lithium chloride mixtures, and the dashed lines a prolongation of the plots obtained from our data. Since a computation at this concentration is very sensitive, care must be exercised in drawing conclusions from the results. However, we believe that the spread and distribution of the results are significant. In the case of sodium chloride $(\alpha_1 + \alpha_2)$ seems to tend toward zero but it is too early to draw any conclusion regarding this matter.

These observations lead to some interesting alternative propositions. (1) If $\log \gamma$ varies exactly linearly with *m* at constant total molality (Eq. 1), then ϕ does not and specific effects between ions of like sign may occur. If this is the case, $(\alpha_1 + \alpha_2)$ may be finite when $m = 0$. (2) If $\log \gamma$ does not vary linearly with *m* at constant total molality, then the present results require that ϕ does not. Since $\log \gamma_1$ has been shown to obey the linear relationship within very narrow limits, we conclude that in the case of these mixtures any departure from a linear variation is greater for ϕ than for $\log \gamma$.

All our results depend upon the assumption that α_2 is constant, or that the second of the relations in equation (1) is valid. If this is not true, then the above indications of specific effects between ions of like sign may be subject to another interpretation. For instance, Scatchard and Prentiss have extended the theory of specific ionic interaction to terms including higher powers of the concentration. Without abandoning the fundamental postulate of the theory, they arrive at the conclusion that "neither $\log \gamma$ or ϕ need vary linearly except in very dilute solutions, and that α_1 need equal $-\alpha_2$ only at zero concentration."[20,21] It is possible that such an extended theory will account for the deviation from the original theory and exclude specific interaction between ions of like sign.

Summary

1. Measurements of the cells $H_2 \mid HCl(0.01), NaCl(m) \mid AgCl \mid Ag$ from 0 to 60° have been reported.

---

(20) Quoted from a private communication from Prof. George Scatchard.

(21) Scatchard and Prentiss, THIS JOURNAL, **56**, 2320 (1934).

2. From these and other suitable data, the values of α_1 and α_2 defined by equation (1) have been computed for a number of halide acid-halide mixtures.

3. It has been shown that the empirical rules of Åkerlöf and Thomas that (1) B is a constant and does not vary with the concentration, (2) α_1 and α_2 are not functions of m, are not valid. Neither B, α_1 or α_2 can be regarded as constants characteristic of a given pair of electrolytes.

4. The results have been discussed in relation to the original and extended theory of specific ionic interaction.

The Thermodynamics of Ionized Water in Sodium Chloride Solutions

BY HERBERT S. HARNED AND GEORGE E. MANNWEILER[1]

From measurements of the cells

$$H_2 \mid MOH(m_0), MX(m) \mid AgX \mid Ag, \text{ and} \qquad (A)$$

$$H_2 \mid HX(m_0), MX(m) \mid AgX \mid Ag \qquad (B)$$

$$M = Li, Na, K\ X = Cl^-, Br^-$$

the thermodynamic properties of the ions of water in potassium and lithium chloride solutions, and potassium and sodium bromide solutions, have been studied over wide temperature and concentration ranges.[2] The only determination of the activity coefficient and dissociation of water in sodium chloride solutions is contained in the contribution by Harned where the method of determining these quantities from cells without liquid junction was first developed.[3] Since these results were obtained from scattered data at 25° only, they have been redetermined from measurements of the above cells by employing a consistent and more accurate technique. Further, the results have been extended to cover a temperature range from 0 to 60°. From these results we have computed: (1) the ionization constant of water; (2) the ionic activity coefficient product of water in sodium chloride solutions; (3) the ionization of water in sodium chloride solutions; and (4) the heat of ionization of water and the partial molal heat of ionization of water in sodium chloride solutions.

Experimental Results

The electromotive forces of cells of types (A) and (B) may be expressed as functions of the temperature by means of the quadratic equations

$$E_A = E_{A(25)} + c\,(t - 25) + d\,(t - 25)^2 \qquad (1)$$

$$E_B = E_{B(25)} + a\,(t - 25) + b\,(t - 25)^2 \qquad (2)$$

The values of $E_{B(25)}$, a, and b are given in Table I of an earlier investigation[4] and the values of $E_{A(25)}$, c, and d are contained in Table I of this communication. Measurements were made by a technique similar to that employed by Harned and Hamer[2] and Harned and Copson.[2] The experimental results were the mean of three cells which were measured at the concentrations specified from 0 to 60° at 5° intervals. The deviations from the mean were ±0.04 mv. and the experimental results smoothed to round concentrations agree with those computed by equation (2) to within approximately this limit.

TABLE I

The Ionization Constant of Water, the Ionic Activity Coefficient and Dissociation of Water in Sodium Chloride Solutions.—The ionization constant of water was determined from these results by the two methods developed by Harned and Hamer. The equation for the cells of type A may be written in the form

$$E_A - E_0 + \frac{RT}{NF}\ln\frac{m}{m_0} = \frac{RT}{NF}\ln\frac{\gamma_H\gamma_{OH}}{a_{H_2O}} - \frac{RT}{NF}\ln\gamma_H\gamma_{Cl} - \frac{RT}{NF}\ln K \qquad (3)$$

which corresponds to equation (4) of Harned and Hamer. By employing the values of molal po-

tential of the silver chloride electrode, E_0, determined by Harned and Ehlers,[5] the left side of this equation was evaluated. This quantity was plotted against μ and extrapolated to zero μ, at which point it is equal to $(-RT/NF \ln K)$. From these values K was computed at 5° temperature intervals from 0 to 60°. This extrapolation is unusually favorable for the evaluation of K since the plots are straight lines with small slopes.

As a check of this determination, we have also evaluated K from our measurements of both cells of types A and B. This procedure does not require the values of E_0 determined by others and consequently serves as a good test of the general accuracy of the data. From the equations of the cells and the limiting equation of the theory of Debye and Hückel to which a term linear with μ is added, the equation

$$E_A - E_B - \frac{RT}{NF}\ln\frac{m_0^2\,(m + m_0)}{m} + \frac{RT}{NF}\,\frac{5.908 \times 10^6}{D^{3/2}\,T^{3/2}}\sqrt{2\mu} = \beta\mu - \frac{RT}{NF}\ln K \qquad (4)$$

may be derived. This equation corresponds to equation (16) given by Harned and Hamer. The left-hand member of this equation was evaluated, plotted against μ, and from its value at $\mu = 0$, K was computed. This method is not as favorable for the determination of K as the one previously described since the plots possess a greater slope. However, a good extrapolation was possible and the results checked those obtained by the first method within the experimental error. The values of the ionization constant thus obtained are in close agreement with the results of Harned and Hamer with the exception of the value at 0° where the difference was 1%. At the temperatures of 20 to 50° inclusive, the agreement is 0.1% or better, at 5, 10, 15, 55 and 60°, the agreement is 0.3 to 0.4%. The results at the designated temperatures are given in Table II.

TABLE II

THE IONIC ACTIVITY COEFFICIENT PRODUCT OF WATER IN SODIUM CHLORIDE SOLUTIONS, $\gamma_H\gamma_{OH}/a_{H_2O}$

μ	0	10	20	25	30	40	50	60
0.02	0.761	0.763	0.760	0.759	0.759	0.752	0.751	0.751
.03	.723	.732	.726	.725	.725	.717	.715	710
.06	.680	.666	.664	.664	.663	.653	.649	.643

.21	.560	.559	.557	.556	.553	.544	.538	.532
.51	.517	.520	.516	.514	.513	.502	.497	.488
1.01	.540	.542	.537	.535	.531	.517	.507	.495
2.01	.691	.699	.691	686	.681	.654	.629	.600
3.01	.971	.985	.972	.962	.948	.898	.855	.791
$K \times 10^{14}$	.1134	.2919	.681	1.007	1.470	2.914	5.482	9.651

By substitution of these values of K and the values of $\gamma_H\gamma_{Cl}$ in sodium chloride solutions computed from the electromotive forces of cells of type B in equation (3), the ionic activity coefficient product of water, $\gamma_H\gamma_{OH}/a_{H_2O}$, may be computed since the left side of this equation is known. The values of this quantity are given at convenient temperatures in Table II. Values at intermediate temperatures may be interpolated.

Because of the importance of this quantity for the study of ionic equilibria in aqueous solutions, we have given at convenient salt concentrations in Table III the values recently determined at 25° for cases of a number of uni-univalent salt solutions. Although on the whole the agreement with the results of Harned, Harned and Swindells, and Harned and James[6] is good when allowance is made for the differences in reference values, the recent results are the more accurate since a simpler method is used which permits better extrapolations.

There is one result characteristic of this quantity which is of interest. In Fig. 1, we have plotted [log $(\gamma_H\gamma_{OH}/a_{H_2O}) + 1$] against the quantity $\Sigma(1/a)$, or $(1/a_+ + 1/a_-)$ at concentrations of $\mu^{1/2}$ equal to 0.5 and 1. The ionic radii employed were taken from the values derived by Pauling[7] from crystallographic data for all ions except hydrogen ion. In the latter case, Bragg's[8]

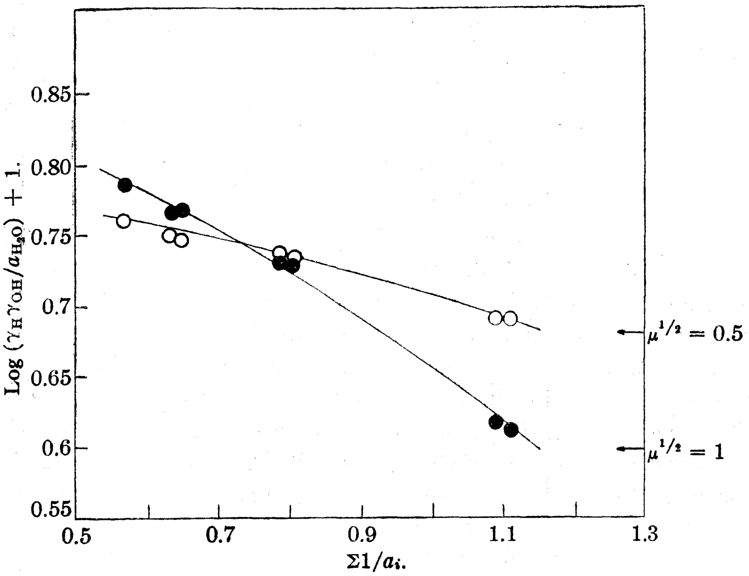

Fig. 1.—Plots of [log $(\gamma_H\gamma_{OH}/a_{H_2O}) + 1$] against $\Sigma 1/a_i$ at constant molality.

value was employed. $\Sigma 1/a$ was found to be 1.09, 1.11, 0.78, 0.80, 0.63, 0.65 and 0.57 for lithium bromide and chloride, sodium bromide and chloride, potassium bromide and chloride, and cesium chloride, respectively. The values are in the order $\Sigma 1/a$. Since the curves drawn through the points show only a slight curvature and since this result must be regarded as a rough approximation, we may represent it by a linear equation. Thus

$$\log \frac{\gamma_H\gamma_{OH}}{a_{H_2O}} = \log \frac{K}{m_H m_{OH}} = A - B\Sigma \frac{1}{a}; \quad [\mu = \text{constant}] \quad (5)$$

where K is the thermodynamic ionization constant, m_H and m_{OH} the molalities of the ions, and A and B are positive constants. Consequently

$$\log m_H m_{OH} = C + B\Sigma 1/a \quad (6)$$

where C is a constant. Thus, the smaller the value of $\Sigma 1/a$ for the ions of the salt, the greater the ionization of the solvent. This result is in the expected direction. The value of $B/\mu^{1/2}$ is a function of μ.

The Total Heat of Ionization of Water in Sodium Chloride Solutions

As shown by Harned and Hamer,[2b] the total heat of ionization of water may be computed from these results by the equation

$$\Delta H = -F(E_B - E_A)_{25} + FT(A) + F[(A) - 2T(B)]\ (t - 25) + F(B)\ (t - 25)^2 \quad (7)$$

where $(E_B - E_A)_{25}$ are the differences in electromotive forces of the cells at 25° and at a given concentration, t is °C., (A) equals $(c-a)$, and (B) equals $(d-b)$. a, b, c, and d are the constants of equations (1) and (2). The results may be expressed within the experimental error, estimated to be of the order of ±50 cal. or ±0.4%, by the equation

$$\Delta H = \Delta H_i + \omega\mu^{1/2} \quad (8)$$

The values of ΔH_i obtained by extrapolation agreed with those of Harned and Hamer to within this limit from 25 to 60°. At the lower temperatures the values obtained were about 80 cal. greater than those given by Harned and Hamer. The average value of ΔH_i is well represented by the equation

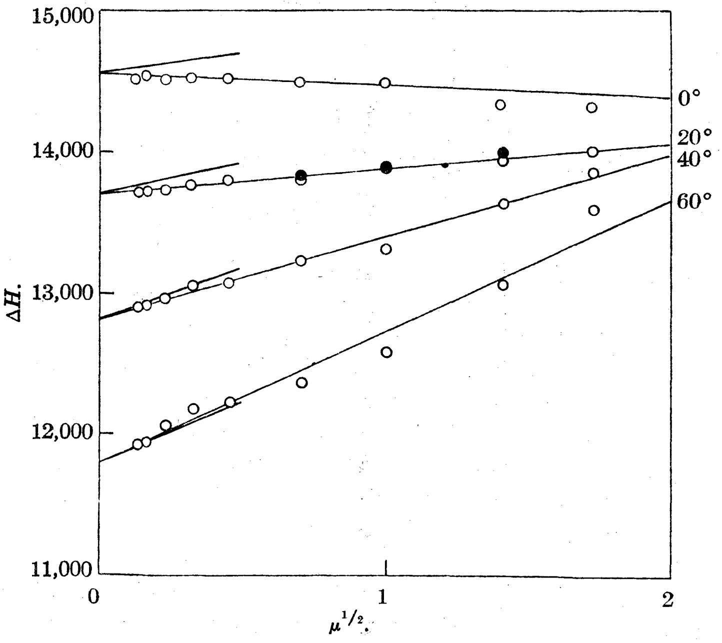

Fig. 2.—Plots of the total heat of ionization of water in sodium chloride solutions against $\mu^{1/2}$.

$$\Delta H_i = 20{,}182 + 0.026117T - 0.078067T^2 + 0.0000079127T^3 \quad (9)$$

In Table IV, the values of ω obtained from plots of ΔH *versus* $\mu^{1/2}$ are given at the temperatures designated.

Table IV

Values of the Constant of Equation (8)

t	ω	t	ω	t	ω
0	−40	25	290	50	700
5	0	30	370	55	780
10	50	35	460	60	860
15	130	40	550		
20	210	45	640		

In Fig. 2, we have plotted ΔH against $\mu^{1/2}$ at 0, 20, 40 and 60°. We have also indicated the limiting slope of the Debye and Hückel theory for the relative partial molal heat content of the ions of water. Our results should approach these slopes in very dilute solution ($m = 0.001$ or less). Since they cannot be extended to low dilutions with a high accuracy, no attempt has been made to employ the limiting laws for the purpose of extrapolation. As a confirmation of the correct character of the results at higher concentrations, we may compare our data with values of the same quantity determined from calorimetric measurements of the heat of neutralization of hydrochloric acid and sodium hydroxide by Richards and Rowe[9] at 20°. Their results are represented by the dots in Fig. 2. The agreement is within the limit of 40 cal.

Summary

1. Measurements of the cells

H_2 | NaOH (0.01), NaCl (m) | AgCl | Ag

H_2 | HCl (0.01), NaCl (m) | AgCl | Ag

in aqueous solution from 0 to 60° have been made.

2. From these the value of the ionic activity coefficient product of water in sodium chloride solutions has been computed.

3. It is shown that the logarithm of the ionization in alkaline halide solutious, $\log m_{\mathrm{H}}m_{\mathrm{OH}}$, at a given concentration varies nearly linearly with the sum of the reciprocal of the ionic radii. This is only a rough approximation but serves to show that ions of smaller radii cause the greater dissociation of the solvent.

4. The total heat content of the ionization of water and the relative partial molal heat content of the hydrogen and hydroxyl ions in sodium chloride solutions has been determined from 0 to 60°. Good agreement with the calorimetric heat of neutralization is found at 20°.

Studies of Crystalline Vitamin B_1. XII. The Sulfur-Containing Moiety

By H. T. Clarke and S. Gurin

The chemical investigation of vitamin B_1 was undertaken in this Laboratory on the invitation of Mr. R. R. Williams, who acquainted us with the sulfite cleavage reaction[1] and kindly furnished a supply of the crystalline vitamin and its basic cleavage product. Early in the course of our work we were able to suggest the presence of a thiazole nucleus in vitamin B_1, and this suggestion was incorporated by Williams in his tentative formula.[2]

In view of the presence of sulfur in the vitamin molecule,[3] our attention was primarily directed toward elucidation of the manner in which this element is combined, by the use of methods recently developed[4] for the study of sulfur in proteins. In the preliminary stages of this investigation, the recognition of the vitamin and its basic cleavage product as derivatives of thiazole was greatly aided by a study of their behavior toward alkaline plumbite and toward bromine water. Striking contrasts were observed between the two compounds with both reagents. When heated with the lead reagent, the vitamin yields lead sulfide relatively rapidly, while the thiazole base gives a visible precipitate only after several hours. Conversely, on treatment with bromine the base is largely oxidized to sulfuric acid under conditions in which the vitamin remains almost entirely unchanged and suffers little or no loss of physiological activity. On the basis of considerations discussed elsewhere,[4] the conclusion was almost inescapable that the sulfur atom in the base is linked to two carbon atoms in a structure of which the carbon groupings are more susceptible to oxidative attack than is the sulfur.

While this study was in progress, it was re-

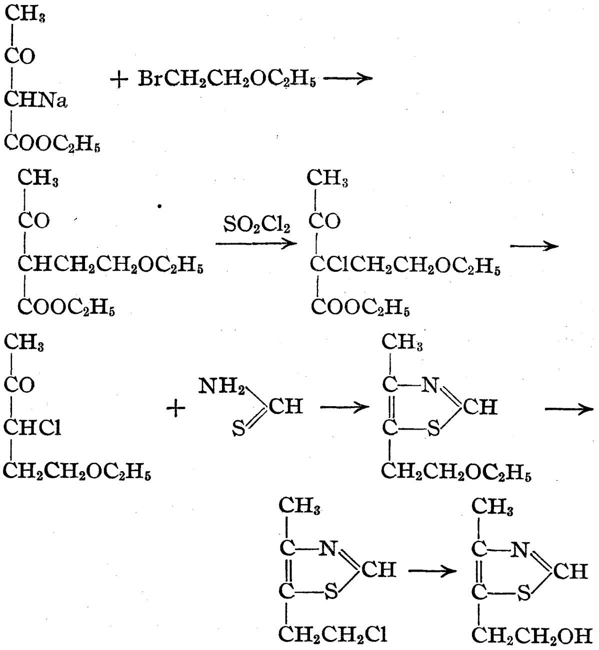
ported by Windaus, Tschesche and Grewe[5] that the vitamin could be split by the action of nitric acid into two fragments of which one contained the atom of sulfur originally present in the vitamin. Buchman, Williams and Keresztesy[6] then established the close relationship of the basic cleavage product to the acid $C_5H_5O_2NS$ of Windaus by demonstrating the formation of the acid from the base by oxidation with nitric acid.

A striking feature of this acid is its property of yielding lead sulfide on treatment with alkaline plumbite,[5] a clear indication of the bivalent condition of the sulfur. This resistance of sulfur to oxidation by nitric acid is characteristic of the thiazole nucleus; Roubleff[7] found dimethylthiazole-carboxylic acid to be stable toward boiling nitric acid, though other oxidizing agents broke down the ring with formation of sulfuric acid. Among the descriptions of the known methylthiazole-carboxylic acids, that of the 4,5 isomer[8] seemed to agree most closely with the observed properties of the acid prepared from the vitamin. Synthesis of this compound by an application of the simplified procedure of Willstätter and Wirth,[9] followed by a comparison of the methyl esters, established the identity of the two. The absorption spectra of the acids, determined in this Laboratory by Mr. A. E. Ruehle, showed almost exact coincidence.[10]

On oxidation with nitric acid, the basic cleavage product of the vitamin loses one carbon atom,[6] the resulting carboxyl group being derived from a hydroxyethyl group. The base may therefore be assigned the constitution  $\mathrm{CH}\left\langle\begin{matrix}\mathrm{N{-}CCH_2CH_2OH}\\ \| \\ \mathrm{S{-}CCH_3}\end{matrix}\right.$. The position of the hydroxyl group was inferred by Buchman, Williams and Keresztesy[6] from the optical inactivity and failure of the iodoform test; it can be rigorously established only by synthesis.[11] This has been accomplished by the accompanying scheme.



The last two products were found to be identical with the corresponding compounds derived from vitamin B. Attempts to employ ethylene chlorohydrin or β-chloroethyl acetate in the first step were unsuccessful. In the second step, reliance was placed on the specific action of sulfuryl chloride, which causes the introduction of chlorine exclusively at the α position in acetoacetic esters.

Reference has been made above to the contrasting behavior of the vitamin and the thiazole cleavage product toward plumbite and bromine. Precisely similar differences obtain with synthetic thiazoles and their quaternary salts; the former yield lead sulfide with difficulty and sulfate readily, the latter yield lead sulfide relatively rapidly[12] and sulfate slowly or not at all. This parallelism supports the idea[1] that in vitamin B_1 the thiazole moiety exists in the form of a quaternary salt.

This view is strengthened by the results obtained by Birch and Harris,[13] Moggridge and Ogston[14] and Williams and Ruehle[15] in electrometric titrations of the vitamin hydrochloride. These indicate reversible reaction with three instead of the anticipated two equivalents of alkali, the extra equivalent reacting at around *p*H 9, as if a pseudo acid were formed. 4-Methyl-

(12) The methylthiazole-carboxylic acid forms an exception to this generalization, in that its response to plumbite is nearly as rapid as that of the quaternary thiazolium salts. This effect is undoubtedly a reflection of the influence of the carboxylic group, which largely determines the instability to alkali in the case of cysteine and its derivatives.

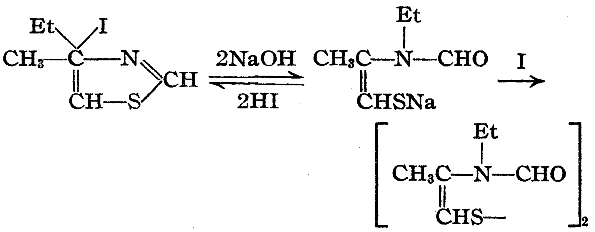
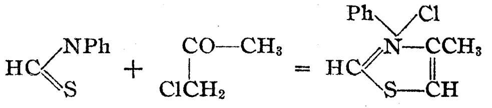
thiazole ethiodide behaves in a strictly analogous fashion.[15] We find that when this substance is treated with two equivalents of alkali in dilute solution, it acquires the ability to reduce one equivalent of iodine. The resulting product, which contains no iodine and is devoid of basic properties, is also formed by the action of air upon an alkaline solution of 4-methylthiazole ethiodide. Mills, Clark and Aeschlimann[16] have shown that alkali reversibly opens the thiazole ring in benzothiazole methiodide, with the formation of a sulfhydryl compound. It seems possible that a similar reaction occurs with the simple quaternary thiazolium base



Alkaline solutions of the vitamin also reduce iodine, but (possibly owing to side reactions attributable to the pyrimidine moiety) in considerably larger proportions. These questions are under investigation.

The reaction between vitamin B_1 and sulfite appears to be a function of the pyrimidine portion of the molecule, for attempts to regenerate thiazole bases from their ethiodides by the action of sulfite were uniformly unsuccessful; nor was cleavage under the same conditions observed with N-phenylthiazolium salts. The readiness with which this type of salt is synthesized



by the action of chloroacetone upon thioacylanilides is worthy of attention. These compounds, like vitamin B_1 and the thiazole ethiodides, respond readily to the alkaline plumbite test but not to that with bromine.

It seems probable that the opening of the ring by the action of alkali upon thiazolium salts is responsible for the readiness with which vitamin B_1 and other quaternary thiazole derivatives yield lead sulfide upon treatment with plumbite. The free thiazole bases presumably exist in the ammonium form to only a minute extent in the presence of alkali, and it is therefore not surprising that they break down extremely slowly under the experimental conditions.

Experimental

Action of Bromine on Vitamin B_1.—The extent to which sulfate is formed from the vitamin hydrochloride by bromine depends largely upon the concentration, as well as upon the temperature.

No sulfate is formed from relatively concentrated solutions. To a solution of 5.685 mg. of vitamin hydrochloride in 0.2 cc. of water bromine vapor was added by aspiration. A yellow, oily precipitate formed; the mixture was heated in boiling water, when the oil dissolved and the bromine escaped. This process was repeated twice. The resulting solution gave no precipitate with barium chloride. On heating with alkaline plumbite a black precipitate formed.

A solution of 3.07 mg. of vitamin hydrochloride in 1 cc. of water containing a visible excess of bromine was allowed to stand at room temperature for two hours, then warmed on the water-bath. On addition of barium chloride, 0.29 mg. of barium sulfate precipitated. This corresponds to 13.4% of the sulfur. In a similar experiment in which the warming was omitted, only 4.9% of the sulfur was converted into sulfate. When, on the other hand, a solution of 6.66 mg. of vitamin hydrochloride in 2.5 cc. of water was heated with excess of bromine for six hours at about 95°, the yield of sulfate was 71%.

Action of Iodine upon Vitamin B_1.—Addition of iodine in potassium iodide to solutions of the vitamin hydrochloride caused, even in very high dilutions, the precipitation of a resinous addition product which is almost insoluble in water or dilute mineral acid, readily soluble in alcohol, but not in chloroform. It dissociates on shaking with water and ether, the iodine passing into the ether; the vitamin was found, with unimpaired physiological activity, in the aqueous phase. No sulfate was produced.

Action of Alkaline Plumbite upon Vitamin B_1.—To 5.62 mg. of the vitamin hydrochloride were added 0.1 cc. of 10% lead acetate solution and 1 cc. of 10% sodium hydroxide. The clear, yellow solution was heated in a sealed tube under nitrogen at 90–95°. Precipitation of lead sulfide became apparent almost immediately, and appeared complete at the end of forty hours. After seventy-two hours the precipitate was collected and oxidized; it yielded 3.28 mg. of barium sulfate (80% of the theoretical amount). In a similar experiment, a 61% yield of sulfate was obtained after three hours' heating.

Action of Bromine upon $C_6H_9ONS \cdot HCl$.—A solution of 5.87 mg. of the hydrochloride of the basic cleavage product of the vitamin in 1 cc. of water was treated with bromine vapor as above. After being allowed to stand for twenty hours at room temperature, barium chloride was added: the resulting barium sulfate weighed 5.60 mg., corresponding to 73.3% of the sulfur. The supernatant solution was again treated with bromine; after twenty-four hours a further 0.23 mg. of barium sulfate had formed, bringing the total yield of sulfate to 76.4% of the theoretical amount. More sulfate was readily obtained from the supernatant by warming with bromine after neutralization with barium hydroxide.

---

(16) Mills, Clark and Aeschlimann, *J. Chem. Soc.*, **123**, 2353 (1923).

Action of Alkaline Plumbite on C_6H_9ONS.—To 6.00 mg. of the hydrochloride was added 1 cc. of a solution prepared by adding to 10% lead acetate solution twice the volume of 2 *N* sodium hydroxide necessary to form a clear solution. The mixture was heated in a sealed tube at 95°. After sixteen hours a small amount of lead sulfide had precipitated. After one hundred and twelve hours, the contents were acidified with hydrochloric acid and the liberated hydrogen sulfide distilled into a solution of bromine in dilute alkali. The resulting sulfate yielded 2.01 mg. of barium sulfate, corresponding to 25.7% of the sulfur. The volatile base in the residual solution required 1.15 cc. of 0.01 *N* acid, corresponding to 34.5% of the nitrogen; on treatment with mercuric oxide according to the process of Weber and Wilson,[17] the base removed corresponded to 0.65 cc. of 0.01 *N* acid, whence the yield of ammonia was 19.5% of the theoretical. This figure is undoubtedly too low owing to incomplete reaction with the mercuric oxide.

In the ensuing account, the temperatures indicated are uncorrected.

4-Methylthiazole.—This substance, previously prepared by reduction of 4-methyl-2-oxythiazole[18] and by diazotization of 4-methyl-2-aminothiazole,[19] was more conveniently obtained by an adaptation of the method of Willstätter and Wirth.[9] A solution of 5 g. of crude thioformamide[20] in 20 cc. of absolute alcohol was boiled with 8 g. of chloroacetone for one hour under reflux. Some ammonium chloride was filtered off; the filtrate was made distinctly acid with hydrochloric acid and evaporated to dryness. The residue was made alkaline and distilled; the distillate was freed from moisture and ammonia by warming with solid potassium hydroxide. The product, amounting to 3–4 g., distilled at 130°.

On treatment with bromine, a dilute solution of the hydrochloride yielded a yellow oily precipitate, soluble in acetic acid or alcohol; sulfate is rapidly formed in the cold. When heated with alkaline plumbite in a sealed tube at 95°, lead sulfide is formed, but so slowly as to be perceptible only after about four hours.

The ethiodide, prepared by heating the base with twice its volume of ethyl iodide in a sealed tube for forty hours at 95°, crystallizes from absolute alcohol in colorless bars, m. p. 144.5°.

Anal. Calcd. for $C_6H_{10}NSI$: I, 49.77. Found: I, 49.94.

On treatment in aqueous solution with bromine it yields an oily precipitate, but no sulfate is formed in the cold. With plumbite at 95°, lead sulfide forms rapidly, and precipitation appears to be complete after three hours.

On adding platinic chloride to a solution of the base in 0.2 *N* hydrochloric acid, a precipitate separated slowly. This was recrystallized from 0.1 *N* hydrochloric acid in 50% alcohol. The composition of the product, which melted without decomposition at 198°, indicated that the platinichloride had lost the elements of hydrochloric acid.[21]

Anal. Calcd. for $C_8H_{12}N_2S_2Cl_4Pt$: Pt, 36.35; S, 11.95. Found: Pt, 35.90; S, 11.41; after a second recrystallization, Pt, 37.08; S, 12.16.

2,4-Dimethylthiazole.—The base, b. p. 140°, was prepared from thioacetamide and chloroacetone in the same manner as the 4-methylthiazole; the yield was twice as large. The ethiodide[22] melted with decomposition at 212°.

Anal. Calcd. for $C_7H_{12}NSI$: I, 47.18. Found: I, 47.76.

4-Methylthiazole-5-carboxylic Acid.—To a solution of 5 g. of thioformamide in 100 cc. of ether was added 14 g. of ethyl α-chloroacetoacetate.[23] The mixture was allowed to stand for ninety-six hours at 0–5°, during which time 8.5 g. of thiazole carboxylic ester hydrochloride separated in colorless needles. After washing with ether, this was dissolved in water; the solution was made alkaline to thymolphthalein and shaken with five 20-cc. portions of ether. The ethereal solution was dried with sodium sulfate and evaporated. The residue, which crystallized on chilling, was distilled under reduced pressure; b. p. 140° (12 mm.); yield, 5.0 g. of ethyl 4-methylthiazole-5-carboxylate,[24] m. p. 28°.

The ethyl ester was hydrolyzed by boiling a solution of 1.2 g. of it in 25 cc. of alcohol containing 1.4 g. of sodium hydroxide for fifteen minutes under reflux. The alcohol was evaporated under reduced pressure, and the residue, dissolved in 10 cc. of water, was acidified to *p*H 3–4 with concentrated hydrochloric acid. The resulting precipitate was twice recrystallized from 150-cc. portions of boiling water; yield, 0.8 g. of colorless bars which sublimed at 255°.

Anal. Calcd. for $C_5H_5O_2NS$: C, 41.93; H, 3.52; N, 9.78; S, 22.4. Found: C, 42.03; H, 3.59; N, 9.51; S, 22.55.

The methyl ester, prepared by adding ethereal diazomethane to a suspension of the acid in dry ether, and evaporating to dryness, formed needles which melted sharply at 75° without recrystallization.

Anal. Calcd. for $C_6H_7O_2NS$: C, 45.82; H, 4.49; N, 8.92; S, 20.4. Found: C, 45.90; H, 4.52; N, 8.61; S, 20.34.

The melting point was unchanged by admixture of the methyl ester of the acid[6] prepared from vitamin B_1.

As observed by Windaus, Tschesche and Grewe,[5] the acid readily yields lead sulfide and ammonia on heating with alkaline plumbite. At 95°, the precipitation of sulfide was noticeable after less than an hour; after forty-four hours the yield of ammonia was 95% of the theoretical amount. On treating a solution in 0.05 *N* hydrochloric acid with bromine, sulfate is formed very slowly in the cold but rapidly on warming.

Ethyl α-2-Ethoxyethylacetoacetate.—To a solution of 11.5 g. of sodium in 350 cc. of absolute alcohol 65 g. of ethyl acetoacetate was added; to the gently boiling solution there was added 84 g. of ethyl β-bromoethyl ether during one and one-half hours. Heating was continued for ten hours under reflux with stirring. A small amount

of unreacted alkali was neutralized with alcoholic hydrogen chloride, the salts were precipitated with ether, and the filtrate evaporated under reduced pressure at room temperature. The residue, weighing 80 g., was fractionally distilled and the principal fraction collected at 85–90° (10 mm.). The yield was 56 g. (55% of the theoretical amount) of a colorless liquid.

Anal. Calcd. for $C_{10}H_{18}O_4$: C, 59.40; H, 8.91. Found: C, 59.20; H, 8.82.

Ethyl α-Chloro-α-2-ethoxyethylacetoacetate.—To 20.2 g. of ethyl α-2-ethoxyethylacetoacetate 15.2 g. of sulfuryl chloride was added, with stirring and ice-cooling, during thirty to forty minutes. Stirring was continued for an hour, while the temperature rose to 20–25°; 50 cc. of the ether was then added, and the mixture gently boiled for an hour to complete the evolution of sulfur dioxide and hydrogen chloride. The ether was distilled off and the residue fractionally distilled *in vacuo*. The first fraction (85–90° (12 mm.)), amounting to 6.7 g., consisted mainly of unchanged starting material; the principal fraction (115–118° (12 mm.)), weighing 15 g., was found by analysis to be not quite pure, but was not improved on further fractionation. It formed a colorless liquid with a pungent odor.

Anal. Calcd. for $C_{10}H_{17}O_4Cl$: Cl, 15.0. Found: Cl, 16.8.

Methyl α-Chloro-γ-ethoxypropyl Ketone.—A solution of 10 g. of the above chlorinated ester in a mixture of 20 cc. of acetic acid and 20 cc. of 15% aqueous sulfuric acid was boiled for four hours under reflux. Ethyl acetate and alcohol were then distilled off under slightly reduced pressure at 30–40°. A mixture of 20 cc. each of acetic acid and 15% sulfuric acid was added, and the whole again boiled for four hours. It was then diluted with an equal volume of water and shaken repeatedly with ether. After removal of moisture with sodium sulfate and evaporation of ether, the residue from the ethereal solution was distilled under reduced pressure; yield, 3.5 g. (50% of the theoretical amount), b. p. 72–73° (12 mm.).

Anal. Calcd. for $C_7H_{13}O_2Cl$: Cl, 21.6. Found: Cl, 22.7.

4-Methyl-5-β-ethoxyethylthiazole.—A mixture of 3.0 g. of the above chloroketone and 2.0 g. of thioformamide was allowed to stand for two days at 0–5° and was then warmed at 100° for one hour; 1.0 g. more of thioformamide was added and the mixture again heated for one hour. It was then dissolved in 10 cc. of water, acidified to Congo Red with concentrated hydrochloric acid, shaken repeatedly with ether, boiled to expel hydrogen sulfide, and made alkaline to thymolphthalein. After expelling the bulk of the ammonia by boiling under reflux, the volatile organic base was distilled out with steam. There was thus obtained 1.5 g. of a pale yellow oil, slightly soluble in water, miscible with alcohol and ether; b. p. 235° (with decomp.) by the capillary tube method of Emich.

No attempt was made to purify the base. It formed with platinic chloride a crystalline, sparingly soluble precipitate, consisting of orange needles, melting with decomposition at 154–155°.

Anal. Calcd. for $C_{16}H_{28}O_2N_2S_2Cl_6Pt$: S, 8.51; Pt, 25.95. Found: S, 8.69; Pt, 25.98.

On recrystallization from hot 50% acetone this changed, by loss of the elements of hydrogen chloride, into a nearly colorless, crystalline substance which melted without decomposition at 144–145°.

Anal. Calcd. for $C_{16}H_{26}O_2N_2S_2Cl_4Pt$: S, 9.42; Pt, 28.74. Found: S, 9.22; Pt, 27.8.

The base, on treatment with ethereal picric acid, yielded a sparingly soluble picrate, which after recrystallization from alcohol melted at 112°.

Anal. Calcd. for $C_{14}H_{16}O_8N_4S$: S, 8.00. Found: S, 8.02.

4-Methyl-5-β-chloroethylthiazole.—A solution of 0.627 g. of the ethoxy base in 5 cc. of concentrated hydrochloric acid was heated in a sealed tube for three hours at 150°. Ethyl chloride and excess hydrochloric acid were evaporated, and the residue was twice recrystallized from a mixture of absolute alcohol and ether; yield, 0.206 g.

Anal. Calcd. for $C_6H_8NSCl{\cdot}HCl$: N, 7.07; S, 16.16; Cl, 35.85; Cl^-, 17.93. Found: N, 7.32; S, 16.13; Cl, 35.55; Cl^-, 18.07.

The melting point, 127–128°, was unchanged on admixture of a sample (m. p. 130°) of the product originating[6] from vitamin B_1.

On treatment with picric acid in 50% alcohol, the hydrochloride yielded a sparingly soluble picrate, crystallizing in needles from absolute alcohol.

Anal. Calcd. for $C_{12}H_{11}O_7N_4SCl$: S, 8.19; Cl, 9.09. Found: S, 8.33; Cl, 9.04.

Its melting point, 138°, was unchanged on addition of the picrate (m. p. 139°) of the compound secured from the vitamin.

4-Methyl-5-β-hydroxyethylthiazole.—The mother liquor from the above hydrochloride was evaporated to dryness, dissolved in 5 cc. of water, heated in a sealed tube for four hours at 150°, and again evaporated to dryness. The hygroscopic, crystalline residue was recrystallized from a mixture of absolute alcohol with ether or dioxane; yield, 0.223 g.

Anal. Calcd. for $C_6H_9ONS{\cdot}HCl$: N, 7.80; S, 17.85; Cl, 19.74. Found: N, 7.89; S, 17.70; Cl, 19.90.

In crystalline form it was indistinguishable from the hydrochloride of the basic product from the vitamin.

A picrate separated on the addition of ethereal picric acid to the hydrochloride in alcohol. On recrystallization from absolute alcohol it melted at 162°.

Anal. Calcd. for $C_{12}H_{12}O_8N_4S$: N, 15.00; S, 8.60. Found: N, 15.05; S, 8.74.

The corresponding picrate originating from the vitamin melted at 162–163°; mixed m. p. 162–163°.

Action of Alkali and Iodine upon 4-Methylthiazole Ethiodide.—To a solution of 0.1244 g. of 4-methylthiazole ethiodide (4.88 millimole) in 10 cc. of water was added 13.1 cc. of 0.076 *N* sodium hydroxide. The colorless solution was titrated with 0.10 *N* iodine. On the addition of each drop, a red-brown precipitate formed which rapidly dissolved; 5.00 cc. was required (102% of the theoretical amount).

The solution, on being allowed to stand, deposited needles which after washing with water and recrystallizing from aqueous alcohol melted at 101–102°. Further crops were obtained by concentrating the mother liquors and recrystallizing; yield, 0.0578 g. The product is sparingly soluble in cold water and dilute hydrochloric acid, readily soluble in alcohol and in ether.

Anal. Calcd. for $C_{12}H_{20}O_2N_2S_2$: N, 9.72; S, 22.22. Found: N, 9.53; S, 22.36.

The same product was obtained by aeration: to a solution of 0.2 g. of the ethiodide in 10 cc. of water, 2 *N* sodium hydroxide was added until the *p*H was 10. A trace of ferrous sulfate was added and air was bubbled through the solution for forty hours. A yield of 0.072 g. of colorless needles, m. p. 101–102°, separated during the aeration; further quantities were obtained by extraction with ether.

2,4-Dimethyl-3-phenylthiazolium Salts.—A mixture of 7.0 g. of thioacetanilide, 5.7 g. of chloroacetone, and 5 cc. of absolute alcohol was boiled gently under reflux for one and one-half hours and then evaporated at 100°. The sirupy residue was repeatedly stirred with ether; the insoluble portion was dissolved in water and decolorized with charcoal. The chloride could not be crystallized; addition of picric acid caused the precipitation of an oil. Platinic chloride yielded a crystalline platinichloride, insoluble in water and in alcohol, which melted with decomposition at 245° after darkening at 240°.

Anal. Calcd. for $C_{22}H_{24}N_2S_2Cl_6Pt$: C, 33.49; H, 3.05; S, 8.13; Pt, 24.77. Found: C, 33.50; H, 2.80; S, 8.35; Pt, 24.86.

On adding potassium iodide in excess to an aqueous solution of the chloride, the iodide crystallized in the form of colorless needles, soluble in water, ethyl alcohol, chloroform, and ethylene chloride, sparingly soluble in butyl alcohol, insoluble in acetone, m. p. 210°.

Anal. Calcd. for $C_{11}H_{12}NSI$: C, 41.77; H, 3.79; N, 4.42; S, 10.09; I, 40.1. Found: C, 41.73; H, 3.49; N, 4.47; S, 10.19; I, 39.76.

No sulfate is formed by the action of bromine upon this substance, either in the cold or on warming for a short time. With alkaline plumbite, lead sulfide is rapidly produced at 95°.

4-Methyl-3-phenylthiazolium Iodide.—A mixture of 2.0 g. of thioformanilide and 5 cc. of chloroacetone was warmed to 50° for a few minutes; the resulting solution was allowed to cool to room temperature during two hours. On addition of ether, the product precipitated as a liquid. This was dissolved in 50 cc. of water, decolorized with charcoal, and treated with 3 g. of potassium iodide. The crystals which formed were recrystallized from water: colorless, rectangular plates, m. p. 241°.

Anal. Calcd. for $C_{10}H_{10}NSI$: S, 10.56; I, 41.9. Found: S, 10.67; I, 41.9.

The properties of this iodide closely resemble those of the 2,4-dimethyl compound.

Summary

1. The acid $C_5H_5O_2NS$ obtained by Windaus and collaborators by the action of nitric acid upon vitamin B_1 is shown to be 4-methylthiazole-5-carboxylic acid.

2. The basic product, obtained by Williams and his colleagues by treating vitamin B_1 with sulfite, is shown to be 4-methyl-5-β-hydroxyethylthiazole. This substance has been synthesized.

3. Experimental evidence is given in support of the view that the thiazole exists in the vitamin in the form of a quaternary salt.

The Action of Hydrogen Bromide on the Nitrogen Afterglow

BY W. H. RODEBUSH AND M. L. SPEALMAN

Rodebush and Ewart[1] reported that the addition of hydrogen bromide to the nitrogen afterglow, produced in moist nitrogen by means of the electrodeless discharge, caused quenching of the nitrogen afterglow with the simultaneous production of a brilliant orange glow at the point where the gases mixed. When this orange light was viewed with a small spectroscope, it appeared to consist of the prominent red and yellow first positive bands of nitrogen, and an orange band which they also attributed to nitrogen. With hydrogen iodide they observed that the nitrogen afterglow was quenched, and that a blue afterglow was produced which extended from the point where the gases mixed to the liquid–air cooled trap of the mercury vapor diffusion pump. This blue afterglow was attributed to iodine. With both hydrogen bromide and hydrogen iodide, considerable quantities of the corresponding ammonium halide were produced in the reaction tube.

It has been suggested, however, that the orange bands might be bromine bands. If this were true, the reactions of hydrogen bromide and hydrogen iodide with active nitrogen would be entirely similar since there was no doubt that the spectrum obtained when hydrogen iodide is added to active nitrogen is due to the iodine molecule. The behavior in the two cases, however, is so different as to cast doubt upon this point of view. The

---

[1] Ewart and Rodebush, THIS JOURNAL, **56**, 97 (1934).

luminescence of the hydrogen bromide is emitted in the immediate vicinity of the point of mixing, no matter how rapid the flow of gases. The primary reaction is presumably

$$N + HBr = NH + Br$$

Bromine molecules would therefore have to be formed by a following reaction which must be slow, and the concentration of bromine molecules must therefore be very low at the point of admission of the hydrogen bromide. It is possible for a bromine molecule to be formed by direct combination of an excited and unexcited bromine atom, but the probability of this process is extremely small.[2] A spectrographic investigation was the obvious solution to this question. The only difficulty is that, on account of the low intensities, it is not possible to use a very high dispersion.

Experimental

The electrical apparatus used with the electrodeless discharge was identical with that used in the work mentioned previously. A flowing system was used in which nitrogen was pumped through a Pyrex glass tube having a length of a meter or more, and an internal diameter of about 2.5 cm. The exciting coil was wrapped around this tube at the inlet end. The light from the discharge was prevented from reaching the slit of the spectrograph by surrounding the discharge region with a box, and by means of two right angle bends in the glass tube. The photographs were taken end-on of a 25-cm. section of the tube through either quartz or Pyrex glass windows. The connection to the vacuum pumps was about 3 cm. from the window. At the other end of this 25-cm. section of the tube the gas to be added to the nitrogen afterglow was introduced. A right angle bend in the reaction tube at this point served to prevent quite completely the superposition of the nitrogen afterglow spectrum on the photographic plate when something else was being photographed.

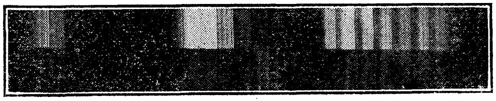

Fig. 1.

The upper photograph in Fig. 1 is a four-hour exposure of the nitrogen afterglow; the lower photograph is a two-hour exposure of the light produced on adding hydrogen bromide to the nitrogen afterglow. These pictures were taken consecutively on the same plate by using adjacent openings in the slide covering the slit of the spectrograph. Great care was taken not to jar the spectrograph or move the plate-holder during these exposures. A Hilger E-1 spectrograph having a glass optical system was used for these photographs. The slit width was about 0.05 mm.; the plate was a Type I-F Eastman spectroscopic plate.

Since the two exposures are of unequal length, no comparison of intensities may be made between them. The important point is that no bands appear in one exposure which are not present in the other. Under a low dispersion the first positive (afterglow) bands of nitrogen appear to have four or five heads. The effect of the presence of the hydrogen bromide is greatly to intensify two of these heads in certain bands while certain other bands as a whole are greatly weakened. The following tabulation of results may be made.

TABLE I

Transition (V′ − V″)	Effect	Transition (V′ − V″)	Effect
11–6	Greatly diminished intensity	13–9	Marked increase in intensity of two heads
10–5		9–5	
9–4		8–4	
12–8		7–3	
11–7		6–2	
10–6		12–9	
		11–8	
		10–7	
		9–6	

In connection with this action of hydrogen bromide it is of interest that bromine produced the same effects as hydrogen bromide on the distribution of intensities, so far as one could tell from spectrograms taken with a Bausch and Lomb quartz spectrograph. The Bausch and Lomb instrument, however, has a much lower dispersion than the Hilger spectrograph used. However, the similarity was so marked as to leave little doubt, and it therefore seems that it is the bromine atom rather than the hydrogen bromide molecule which is responsible for the effects observed.[3]

The blue afterglow produced by adding hydrogen iodide to the nitrogen afterglow was photographed with a Bausch and Lomb quartz spectrograph, and was found to consist of a continuum extending from 4800 to 2200 Å. interspersed with a great many broad, diffuse bands. Presumably this is a fluorescence spectrum of iodine.

Summary

The relative intensity of certain transitions in the nitrogen afterglow is greatly altered by the presence of hydrogen bromide or bromine, but the band spectrum of bromine was not observed.

The Critical Increment of Ionic Reactions. Influence of Dielectric Constant and Ionic Strength

BY W. J. SVIRBELY AND J. C. WARNER

Due to the pronounced influence of the properties of the medium upon the rate of reactions involving ions[1] and the fact that in all solvents these properties are usually functions of the temperature, it seems certain that these factors should be considered in discussions of the critical increment or energy of activation[2] of reactions in solution.

Influence of Dielectric Constant.—Salt effects may be eliminated by considering the velocity constant at zero ionic strength (k^0). In ionic reactions, the factor having the most pronounced influence upon k^0 at constant temperature is very likely the dielectric constant of the solvent. With this assumption, we may write

$$\log k^0 = f\,(D,T)$$

and

$$\frac{\mathrm{d}\log k^0}{\mathrm{d}T} = \left(\frac{\partial \log k^0}{\partial T}\right)_D + \left(\frac{\partial \log k^0}{\partial D}\right)_T \frac{\mathrm{d}D}{\mathrm{d}T} \qquad (1)$$

Multiplying Eq. (1) by $2.3RT^2$, one obtains a relation between the critical increment in a solvent of fixed composition and a medium of constant dielectric constant.

$$(E^0)_{\text{fixed comp.}} = (E^{0*})_D + 2.3RT^2\left(\frac{\partial \log k^0}{\partial D}\right)_T \frac{\mathrm{d}D}{\mathrm{d}T} \qquad (2)$$

For all common solvents and solvent mixtures, the dielectric constant decreases with increasing temperature and Eq. (2) predicts that if an increase in D causes a decrease in k^0, E^0 will be greater than E^{0*}. In attempting to decide which value should be considered the true energy of activation, one encounters the fundamental difficulty of splitting the rate equation into the customary kinetic and energy of activation terms. The success of the Brönsted–Christiansen–Scatchard theory would lead one to believe that changes in k^0 due to change of D with T should be included in the kinetic term. One should, therefore, consider E^* the true energy of activation since it arises from $(\partial \log k^0/\partial T)_D$. To the best of our knowledge, all investigators in the field of solution kinetics have called E, which is obtained from $\mathrm{d}\log k^0/\mathrm{d}T$ or $\mathrm{d}\log k/\mathrm{d}T$, the energy of activation. However, Eq. (2) is independent of any theory and gives the relation between the two critical increments when rate constants depend only on D and T.

The dielectric constants of most solvents and solvent mixtures may be expressed[3] in the form

$$D = ae^{-bT} \qquad (3)$$

where a and b are empirical constants. Hence, at any given temperature

$$\mathrm{d}D/\mathrm{d}T = -bD \qquad (4)$$

From experiments to determine the variation of k^0 with D at constant temperature, one may evaluate $(\partial \log k^0/\partial D)_T$ and then calculate E^* from E using Eqs. (2) and (4). For reactions between two ions, the Scatchard theory[1a] yields the relations

$$\log k^0 = -\frac{\epsilon^2 Z_A Z_B}{2.3rkDT} + C \qquad (5)$$

and

$$\left(\frac{\partial \log k^0}{\partial D}\right)_T = \frac{\epsilon^2 Z_A Z_B}{2.3rkD^2T} \qquad (6)$$

This predicts for reactions between ions of unlike sign $E > E^*$ and for reactions between ions of like sign $E < E^*$.

The whole treatment may be made more general, but more difficult to apply, by obtaining E^* from $(\partial \log k^0/\partial T)_{x_1, x_2 \ldots x_n}$ where $x_1, x_2 \ldots x_n$ represent all properties of the solvent which influence the rate and vary with the temperature.

Influence of Ionic Strength.—Knowing the velocity constants, at fixed temperature and dielectric constant as a function of the ionic strength (μ), one may find a relation between the critical increments at zero ionic strength (E^0) and at some fixed ionic strength by methods similar to those used in the previous section. For reactions between ions and uncharged molecules, the primary salt effect is generally small, and E should not change much with ionic strength. For reactions between ions, the usually valid Brönsted–Christiansen relation may be used.

$$\log k = \log k^0 + \log \frac{f_A f_B}{f_X} \qquad (7)$$

Assuming that the ion activity coefficients may

be expressed by the Debye theory, taking into account ion diameters, Eq. (7) becomes[1a,c]

$$\log k = \log k^0 + \frac{\epsilon^2 Z_A Z_B \kappa}{DkT(1 + \kappa b)} \qquad (8)$$

By differentiating Eq. (8) and multiplying by RT^2, one obtains a relation between E^0 and E at a fixed ionic strength. This treatment permits the interesting observation that for reactions between ions of unlike sign in solvents such as water, alcohols and water–alcohol mixtures, an increase in ionic strength should increase the critical increment in media of fixed dielectric constant but decrease it in solvents of fixed composition.

In the following sections these predictions concerning the influence of dielectric constant and ionic strength upon the critical increment will be compared with observed effects in the conversion of ammonium cyanate into urea.

Experimental

In this part, experiments are reported on the rate of reaction between ammonium ion and cyanate ion over the temperature range 30 to 70° in water (dielectric constant varying with temperature) and in mixtures of water with methyl alcohol at constant dielectric constants for the mixtures of 63.5 and 55.0. All materials were prepared or purified as described in previous papers,[4,1c] which also describe the procedure used in this investigation. All temperatures were checked against a thermometer recently calibrated by the Bureau of Standards. Thermostat temperatures were maintained constant within ±0.03°. Dielectric constants for water and for water–methyl alcohol mixtures were taken from the work of Åkerlöf.[3]

The limiting velocity constants (k^0) were calculated by Scatchard's[5] method which yields the integrated velocity equation[1c]

$$k^0 t = \left\{\frac{1 + 4A\sqrt{C}}{C}\right\} - \left\{\frac{1 + 4A\sqrt{C^0}}{C^0}\right\} \qquad (9)$$

A is the Debye–Hückel constant in $\ln f_i = -AZ_i^2 \sqrt{\mu}$. Average values of the limiting velocity constant (k^0_s) obtained by this method are listed in Table I. Deviations (δ) of the experimental value of $C/(1+4A\sqrt{C})$ from the value calculated from the average k^0_s are plotted against the experimental value of this function in Fig. 1.[1c] The filled circles represent values of $C^0/(1+4A\sqrt{C^0})$. Limiting velocity constants were also calculated from bimolecular constants determined by the method of slopes[1c,4] by Eq. (8) which applied to our reaction becomes

$$\log k^0 = \log k + \frac{3.63 \times 10^6 \sqrt{\mu}}{(TD)^{3/2} + 100.6\, DT \sqrt{\mu}} \qquad (10)$$

Average values of these limiting rate constants (k^0_G) are also given in Table I. In Table II, we give velocity constants at $\sqrt{\mu} = 0.194$ obtained by three methods: k_1 is obtained from k^0_s by the relation[1c]

$$k_1 = k^0_s/(1 + 2A\sqrt{\mu}) \qquad (11)$$

k_2 from k^0_G by Eq. (10), and k_3 is obtained directly from the slope[1c] of t (minutes) against $1/C$ at $\sqrt{\mu} = 0.194$. All data at 50° are taken from the work of Warner and Warrick[1c] and velocity constants at 70° were recalculated from the data of Warner and Stitt.[4] In Fig. 2, log k^0_s and log k_1

---

(4) Warner and Stitt, THIS JOURNAL, **55**, 4807 (1933).

(5) Scatchard, *ibid.*, **52**, 52 (1930).

are plotted against $1/T$ for water and the methyl alcohol–water mixtures of $D = 63.5$ and 55.0. (Lines obtained by plotting $\log k_G^0$ against $1/T$ are parallel to those obtained using $\log k_s^0$.) In each case, the deviations of experimental points from the best straight line are almost within the possible experimental error. There is, however, some indication of a trend toward decreased slopes in the lower temperature range. The linear relations shown in Fig. 2 may be expressed by the equations

H_2O, variable D

$$\log k_s^0 = 14.77 - 23{,}580/4.58T$$
$$\log k_1 = 14.36 - 23{,}240/4.58T \qquad (12)$$

CH_3OH–H_2O, $D = 63.5$

$$\log k_s^0 = 11.79 - 18{,}840/4.58T$$
$$\log k_1 = 11.92 - 19{,}380/4.58T \qquad (13)$$

CH_3OH–H_2O, $D = 55.0$

$$\log k_s^0 = 11.79 - 18{,}500/4.58T$$
$$\log k_1 = 11.80 - 18{,}850/4.58T \qquad (14)$$

The difference between the zero ionic strength critical increments at the fixed dielectric constants of (Table III) 63.5 and 55.0 is within the possible experimental error of ±150 cal. Due to salting out there is some uncertainty as to the actual dielectric constants of these mixed solvents which may contribute to the difference in critical increments. However, these experiments do lend some support to the hypothesis that the critical increment of reactions between ions should be fairly independent of the dielectric constant when the dielectric constant does not change with temperature. There is a large and significant difference between the critical increment in water and in the media of fixed dielectric constant. These differences are compared with the difference calculated by Eq. (2) in Table III. Eq. (2) applied to the conversion of ammonium cyanate into urea becomes

$$(E^0)_{H_2O} - E^{0*} = \frac{1050\,T}{D} \qquad (15)$$

In obtaining Eq. (15), $(\partial \log k_s^0/\partial D)_T$ is the experimental limiting slope of $\log k_s^0$ against D in CH_3OH–H_2O mixtures. dD/dT for water is taken from the work of Åkerlöf.[3] Since D decreases with increase in T, Eqs. (2) and (15) imply that if E^{0*} is constant $(E^0)_{H_2O}$ will increase with T. Unfortunately our experiments are not sufficiently precise to test this implication. Eq. (2) also predicts that E^0 will change from one solvent of fixed composition to another through changes in $(\partial \log k^0/\partial D)_T$ and dD/dT. By interpolation of our

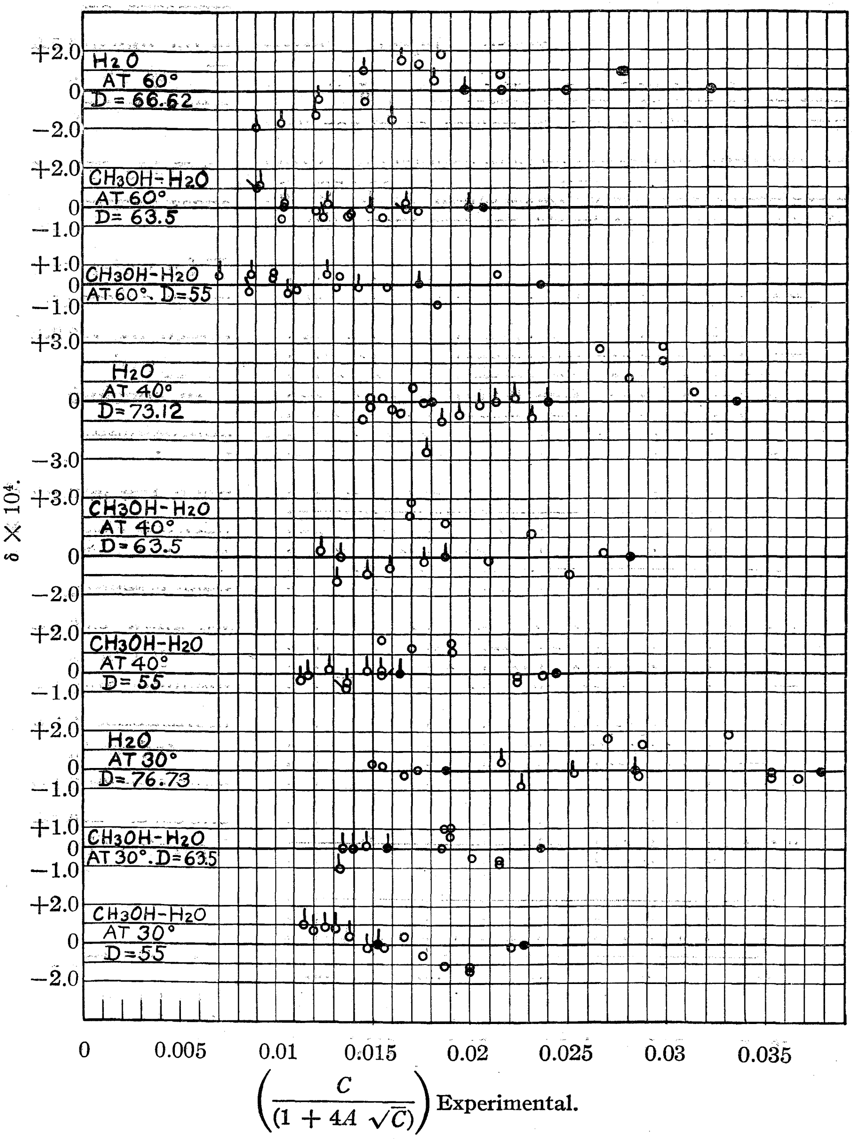

Fig. 1.

TABLE III

SUMMARY OF CRITICAL INCREMENT DATA

	H_2O	CH_3OH-H_2O $D = 63.5$	$D = 55.0$
E^0 (Exptl. at $\sqrt{\mu} = 0$)	23,580	18,840	18,500
$(E^0)_{H_2O} - E^{0*}$(Exptl.)		4,740	5,080
$(E^0)_{H_2O} -$ E^{0*}(Calcd. by Eq. 2 at 50°)		4,860	4,860
E(Exptl. at $\sqrt{\mu} = 0.194$)	23,240	19,380	18,850
E(Calcd. from E^0's Eq. 17 at 50°)	23,360	19,280	18,950
E(Calcd. from E^0's using Eq. (11) at 50°)	23,380	19,270	19,000

data at 40 and 50° and a slight extrapolation at 60° we are able to obtain values of k_s^0 for 28.3 wt. per cent. of methyl alcohol as solvent. From these data we obtain $(E^0)_{28.3\%\ CH_3OH} = 23{,}050$ cal., which is approximately 500 cal. less than $(E^0)_{H_2O}$.

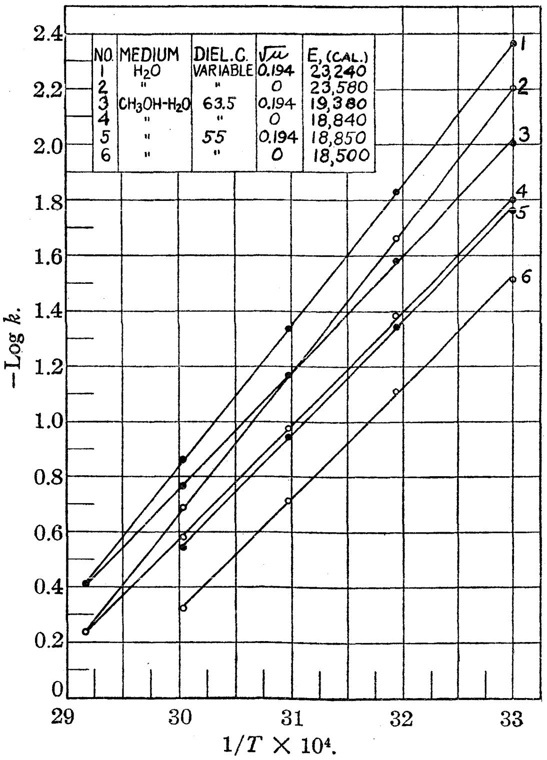

Fig. 2.—Influence of temperature on the rate of conversion of ammonium cyanate to urea in different media.

If $(\partial \log k_s^0/\partial D)_T$ is obtained from the experimental slope of log k_s^0 against D at 28.3% of methyl alcohol and dD/dT is obtained by interpolation of Åkerlöf's[3] data, Eq. (2) becomes

$$(E^0)_{28.3\%\ CH_3OH} - E^{0*} = 735\ T/D \qquad (16)$$

Assuming $E^{0*} = (E^0)_{D = 63.5}$, one calculates by Eq. (16), $(E^0)_{28.3\%\ CH_3OH} = 22{,}970$ cal.

By differentiating Eq. (10) and multiplying by RT^2, one obtains the following relation between the critical increments at $\sqrt{\mu} = 0$ (E^0) and at some fixed ionic strength

$$E = E^0 + 8.35 \times 10^6\ RT^2 \sqrt{\mu} \left\{ \frac{{}^3/{}_2T^{1/2}D^{3/2} + 100.6\ D \sqrt{\mu}}{(T^{3/2}D^{3/2} + 100.6\ DT \sqrt{\mu})^2} \right\} \left\{ 1 + \frac{\mathrm{d} \ln D}{\mathrm{d} \ln T} \right\} \qquad (17)$$

Using Eq. (17), we have calculated $(E)_{\sqrt{\mu} = 0.194}$ from E^0 for water and the two media of fixed dielectric constant. These calculated critical increments are compared to experimental values in the fourth and fifth rows of Table III. E and E^0 may also be related by taking logarithms and differentiating Eq. (11). Values of E calculated from E^0 by this method are given in the last row of Table III. There are no significant differences between these values and those calculated by Eq. (17). If E at $\mu = 0.1$ is calculated from E^0 for water, one obtains $(E)_{\mu = 0.1} = 23{,}280$ cal., which differs by about 0.5% from the values obtained by Walker and Hambly[6] and by Doyle[2a] at approximately the above ionic strength.

In conclusion, we must call attention to the approximate character of the relationships which have been derived and used. They are based upon the assumption that the rate of reactions between ions depends only upon the temperature, the dielectric constant of the medium and the ionic strength. From previous investigations,[1c,4] we know that this assumption is only approximately true for the rate of reaction between ammonium and cyanate ions. Considering these limitations, we believe we have satisfactorily accounted for the influence of dielectric constant and ionic strength upon the critical increments in this one case. The ideas presented in this paper are being tested with data on the rates of other ionic reactions which can be followed with greater precision.

Summary

1. On the assumption that the rates of ionic reactions are functions only of the temperature, dielectric constant and ionic strength, equations are derived which predict the influence of dielectric constant and ionic strength upon critical increments.

2. These predictions are in satisfactory agreement with observed effects in the reaction between ammonium and cyanate ions which was studied over the temperature range 30 to 70° in water, dielectric constant varying with temperature, and in mixtures of water with methyl alcohol at fixed dielectric constants for the mixtures of 63.5 and 55.0.

Studies of Crystalline Vitamin B_1. XIII. Ultraviolet Absorption of Some Derivatives of the Basic Cleavage Product and their Synthetic Analogs[1]

BY A. E. RUEHLE

Similarity in absorption of an unknown and a known compound is often insufficient to establish an identification. When, however, such a similarity is found to extend to a series of derivatives of each, a high degree of certainty of identification may be achieved. These principles are well illustrated by the case of the basic cleavage product[2] of vitamin B_1 and certain of its derivatives. Smakula[3] pointed out a similarity which now appears fortuitous between the absorption spectrum of a cleavage product of the vitamin and the spectra of certain pyrrole derivatives. In the present study a similarity in absorption is shown between the basic cleavage product and its derivatives and a corresponding series of synthetic thiazole derivatives amounting to virtual identification of the nucleus present. This result is in accord with the structural formula for vitamin B_1 recently announced by Williams[4] and the further chemical evidence adduced by Clarke and Gurin.[5]

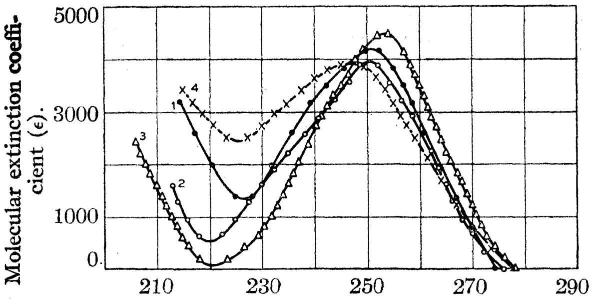

Fig. 1.—1, ●——● Basic cleavage product hydrochloride; 2, ○——○ 4-methylthiazole hydrochloride; 3, △——△ 2,4-dimethylthiazole hydrochloride; 4, ×——× 2-oxy-4-methylthiazole hydrochloride.

Experimental

The method of determining extinction coefficients was that used in obtaining the absorption curve of the vitamin,[6] namely, the use of the Hilger rotating sector photometer and E316 quartz spectrograph. The only innovation was the use of a hydrogen discharge tube as the source in rechecking most of the curves. Eastman I-O ultraviolet sensitized plates were used in exploratory work due to their greater range and latitude, while a more contrasting plate (Eastman DC Ortho) was used for final determination of the absorption spectrum.

I am indebted to my colleagues for samples of the basic cleavage product and its derivatives as well as for samples of synthetic thiazoles.[2,5,7] All samples were dissolved in distilled water and made slightly acid with sufficient hydrochloric acid to ensure the absence of excess free base.

Results and Discussion

The absorption curve of the basic cleavage product is seen in Fig. 1 to be similar to the curves of 4-methylthiazole 2,4-dimethylthiazole, and 2-oxy-4-methylthiazole. In Fig. 2 are shown the curves of the methiodide of the basic cleavage product and of 4-methylthiazole ethiodide. Again there is close correspondence, although the maximum appears at a shorter wave length when the nitrogen is quaternary. The oxidation product of the basic cleavage substance (identical with Windaus' oxidation product from the vitamin) is shown in Fig. 3. This curve agrees moderately well with that shown by Smakula.[3] In the same figure is shown the curve of synthetic 4-methylthiazole-5-carboxylic acid. The correspondence in absorption amounts to identity and the two

compounds have in fact been shown by chemical methods to be identical.[5] Absorption curves obtained subsequently on synthetic 4-methyl-5-β-hydroxyethylthiazole and its methiodide show equally close correspondence to the curves of the basic cleavage product and its methiodide, respectively, but are omitted from Figs. 1 and 2 for purposes of clarity. A case in which substitution produced little change in absorption is shown in Fig. 4, where the curves of the basic cleavage product and its chloro derivative (V)[7] are compared. The replacement of the β-hydroxyl group by chlorine apparently does not involve the portion of the molecule associated with the observed absorption.

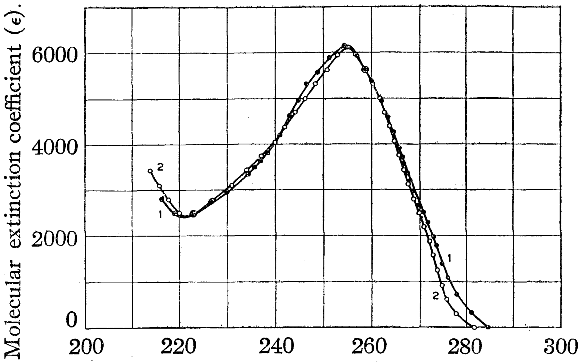

Fig. 3.—1, ●——● Oxidation product of basic cleavage product; 2, ○——○ 4-methylthiazole, 5-carboxylic acid.

I wish to thank Dr. R. R. Williams for suggesting this problem to me and for helpful criticism and advice. I am indebted to Drs. H. T. Clarke, E. R. Buchman and S. Gurin for generously supplying me with the samples used, and especially to Dr. Clarke for the use of the spectrographic facilities in his laboratory. I am further indebted to the Carnegie Corporation of New York through the Carnegie Institution of Washington for financial support in the purchase of materials necessary in the work.

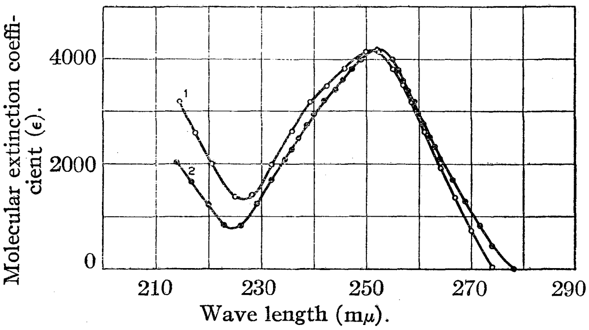

Fig. 4.—1, ○——○ Basic cleavage product hydrochloride; 2, ●——● chloro derivative of basic cleavage product hydrochloride.

Summary

The ultraviolet absorption of the basic cleavage product of vitamin B_1 is not only similar to that of the thiazoles but its derivatives exhibit absorption similar to that of corresponding thiazole derivatives.

Nitroso Compounds. IV. Reaction of Ethyl Nitrite with Certain Isopropyl and Cyclohexyl Ketones

BY JOHN G. ASTON AND M. GLENN MAYBERRY

In the present paper further[1] experiments with a variety of ketones and catalysts are described. It was found that when ethyl nitrite reacts with certain isopropyl or cyclohexyl ketones in the presence of concentrated aqueous hydrogen chloride as catalyst, substitution usually occurs both on the branched alpha carbon atom to yield the true nitroso compound and on the primary alkyl group to yield the α isonitroso compound.

$$2(CH_3)_2CHCOCH_2R + 2HNO_2 \longrightarrow 2H_2O + (CH_3)_2C(NO)COCH_2R$$

$$(CH_3)_2CHCOCH_2R + HNO_2 \longrightarrow H_2O + (CH_3)_2CHCOC(NOH)R$$

However, better yields of both products are obtained if acetyl chloride or dry hydrogen chloride is used as catalyst.[2]

The numerical results appear in Tables I, II and III.

The results using dry hydrogen chloride and acetyl chloride should be considered together as in the absence of any information concerning the mechanism[3] there is, *a priori*, nothing to distinguish between them. The somewhat surprising fact already discussed[1] is that with ethyl isopropyl ketone substitution occurs to an approximately equal extent on either alkyl group.

Another significant fact is that in the case of propyl isopropyl and *n*-butyl isopropyl ketones, no substitution occurred on the isopropyl group. However, only about 40% of the ketone yielded the isonitroso compound with the fate of the rest still in doubt. As it does not seem likely that there would be any difficulty in isolating the true nitroso compound, if formed, either due to increased solubility or rapid decomposition, we are tempted to believe that in these cases substitution only involved the primary alkyl group. The fact that the isonitroso compound was liquid necessitated conversion into its oxime with consequent loss, so that our inability to account for the rest of the ketone may be due to this cause.

With isobutyl isopropyl ketone the results are practically the same as with ethyl isopropyl ketone if one considers that the lower yield of isonitroso ketone is due to the fact that the isonitroso compound was isolated by converting it into its oxime. It is difficult to reconcile this fact with the immediately previous one. Speculating one might attribute the non-activity of the alpha hydrogen on the isopropyl group of *n*-propyl and *n*-butyl isopropyl ketones to (a) steric hindrance by the far end of the other alkyl group through incipient ring formation, or (b) to a higher relative activity (rate) of the alpha carbon on the *n*-propyl and *n*-butyl groups, inasmuch as Ponzio found that branching reduced the tendency for (rate of) substitution on the alpha carbon atom of a ketone by nitrous acid.[4]

Experimental

The Results with Aqueous Hydrogen Chloride.—These have been given in Table I. The procedure followed was in general the same as already given[1] with the following exceptions. The isopropyl α-isonitrosoisobutyl ketone is a liquid[5] and was isolated as the dioxime. The unreacted ketone and low boiling material was distilled off under reduced pressure, and the remaining liquid converted into diisopropyl glyoxime as described later. The isonitrosoethyl cyclohexyl ketone, which did not crystallize by simple evaporation of the reaction mixture, was isolated by

the method described below for isolating isonitrosoethyl isopropyl ketone from the reaction using acetyl chloride as catalyst.

The Results Using Acetyl Chloride.—The procedure followed is given below for ethyl isopropyl ketone. The yields, given in Table II, are based on the amount of ethyl nitrite absorbed except in cases where the amount of ketone reacted (unrecovered) was less than the amount of ethyl nitrite absorbed. Then the yield is based on the unrecovered ketone. The isonitroso compounds of propyl isopropyl and butyl isopropyl ketones, being liquids, were converted into the corresponding dioximes which were then isolated and identified as described under "Diisopropyl Glyoxime."

Products from Ethyl Isopropyl Ketone Using Acetyl Chloride as Catalyst.—To 45 g. (0.45 mole) of ethyl isopropyl ketone was added 5 g. of acetyl chloride. The theoretical amount of dry gaseous ethyl nitrite was passed in over a period of two and one-half hours, keeping the temperature between 45–55°. During the process, the reaction mixture turned green; 18 g. (0.24 mole) of ethyl nitrite was absorbed during the reaction. The reaction mixture deposited 15.2 g. (0.117 mole) of almost pure bimolecular ethyl α-nitrosoisopropyl ketone on standing overnight in the icebox.

The α-isonitrosoethyl isopropyl ketone was isolated from the mother liquor; 31.7 g. of the liquid was cooled in ice, shaken with 40 cc. of 10% solution of sodium hydroxide and 9 g. of a non-aqueous upper layer removed. The aqueous layer, after extraction with ether, was cooled in ice and acidified with dilute sulfuric acid. Precipitation of the isonitroso ketone was complete when the solution was neutral; 5.7 g. (0.0044 mole) was thus obtained nearly pure after washing with water.

The ether extract of the basic solution was then evaporated. The liquid remaining was combined with the liquid insoluble in sodium hydroxide solution and distilled; 7.3 g. (0.073 mole) of ketone, identified by refractive index and by isolation of its semicarbazone, was recovered.

The Results, Using Dry Hydrogen Chloride.—The yields in Table III were calculated on the same basis as in Table II. The isonitroso compounds were isolated as described above.

Products from Isopropyl Isobutyl Ketone Using Dry Hydrogen Chloride as Catalyst.—The theoretical quantity of dry gaseous ethyl nitrite was passed through a solution of 0.6 g. of dry hydrogen chloride in 32.5 g. of ketone over a period of one hour, starting at a temperature of 18°. After about ten minutes the liquid which had turned blue was heated to 45° and thus maintained for the remainder of the reaction; 9.6 g. (0.128 mole) of ethyl nitrite was absorbed. The reaction mixture after standing for two days in the icebox deposited 8.7 g. (0.055 mole) of white crystals of bimolecular α-nitrosoisopropyl isobutyl ketone which was almost pure after washing with ether.

Diisopropyl Glyoxime.—After filtering off the above solid, 15.7 g. of mother liquor was cooled in ice and shaken with 40 cc. of a 10% aqueous solution of sodium hydroxide; 9.5 g. of liquid did not dissolve. The aqueous layer, after separation and extraction with ether, was cooled in ice and made slightly acid with dilute sulfuric acid. The acid solution was extracted with ether, and the ether solution evaporated; 3.5 g. of liquid remained.

This liquid, containing the isonitrosoisobutyl isopropyl ketone was cooled in ice and shaken with a solution containing 4.7 g. of sodium hydroxide in 27.8 cc. of water. To this solution, with continued cooling, was added 2.7 g. of hydroxylamine hydrochloride dissolved in 11.7 cc. of water. The solution was then warmed to 40–50° for ten minutes and kept at room temperature for two days. After cooling in ice 1.8 g. (0.01 mole) of dioxime was precipitated by acidification with sulfuric acid. After recrystallization from chloroform it melted at 162–163°.[6]

The ether extract of the basic solution was evaporated and the remaining liquid combined with the material insoluble in the sodium hydroxide solution. When this was distilled, 6.7 g. of ketone identified by refractive index and by isolation of its semicarbazone was obtained.

Analyses and Molecular Weights.—The results of the necessary analyses on new compounds are given in Table IV and those of the molecular weight determinations in Table V.

TABLE IV

ANALYSES

Compound	Source	Calcd.		Found	
		C, %	H, %	C, %	H, %
Methyl nitrosocyclohexyl ketone	A	61.89	8.44	61.67	8.43
Ethyl nitrosocyclohexyl ketone	A	63.9	8.87	63.75	8.9
α-Isonitrosoethyl cyclohexyl ketone	A	63.9	8.87	63.75	8.88
α - Nitrosoisopropyl isobutyl ketone	A	61.1	9.62	61.22	9.72
Ethyl isopropyl glyoxime	B	53.12	8.92	53.41	9.11
Propyl isopropyl glyoxime	C	55.77	9.37	55.76	9.37

TABLE V

MOLECULAR WEIGHT DETERMINATIONS

Compound	Source	Calcd.	Found
(a) Cryoscopic in Benzene			
Bimolecular methyl nitrosocyclohexyl ketone	A	310	291
Bimolecular α-nitrosoisopropyl isobutyl ketone	B	314	316
(b) Rast Camphor Method			
Isonitrosoethyl cyclohexyl ketone	B	169.1	167.2
Ethyl isopropyl glyoxime	B	158.1	159.2
Propyl isopropyl glyoxime	C	172.1	175.7

In Tables IV and V the materials marked "A" were obtained by the action of ethyl nitrite on the ketones in the presence of aqueous hydrogen chloride, "B," of acetyl chloride and "C," of dry hydrogen chloride.

Known compounds were identified by melting point and with the exception of diisopropyl glyoxime by mixed melting point.

Structure of Nitroso Derivatives.—That a compound was a true nitroso derivative was shown by a double molecular weight and that the colorless crystals yielded a

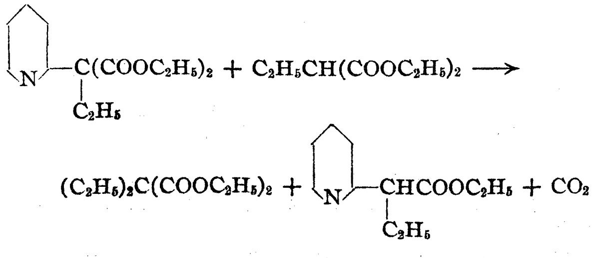
Ethyl-2-pyridylmalonic Ester

BY L. A. WALTER AND S. M. MCELVAIN

The observation that the presence of a pyridine nucleus in certain types of therapeutic agents definitely lowers the intravenous toxicities of these substances[1] suggested the preparation and pharmacological evaluation of some pyridyl substituted barbituric acids. The first work along this line was directed toward the preparation of 5-ethyl-5-(2-pyridyl)-barbituric acid. Although it has not been possible to obtain this barbituric acid by the condensation of urea with the corresponding malonic ester, the preparation and properties of the ethyl-2-pyridylmalonic ester seem to be of sufficient interest to report.

This ester was prepared by the reaction of 2-bromopyridine with sodio-ethylmalonic ester in the absence of alcohol. When the reaction was carried out in alcoholic solution practically all of the bromopyridine which reacted was converted into 2-ethoxypyridine. Even in the absence of alcohol the yield of the pyridyl substituted malonic ester was not high (19%). Considerable amounts of ethyl α-(2-pyridyl)-butyrate and diethylmalonic ester were obtained as by-products of the reaction. These products apparently were the result of the alkylation of ethylmalonic ester by the ethyl-2-pyridylmalonic ester, thus



All attempts to condense ethyl-2-pyridylmalonic ester with urea either by means of dry or alcoholic sodium ethoxide were unsuccessful. The reaction product was in each case α-(2-pyridyl)-butyramide. Thus the behavior of this pyridyl substituted malonic ester parallels that which has been observed[2] for diphenylmalonic ester. It appears, therefore, that the 2-pyridyl group when substituted in a malonic ester approaches the effectiveness of two phenyl groups in promoting the cleavage of the ester. When compared to a single phenyl group the 2-pyridyl group is certainly very much more effective in increasing the sensitivity of the malonic ester to cleavage. For example, it was found that after refluxing for one hour with alcoholic sodium ethoxide, ethyl phenylmalonic ester suffered alcoholysis to ethyl carbonate and the corresponding acetic ester to the extent of 31% while under the same conditions ethyl-2-pyridylmalonic ester underwent alcoholysis to the extent of 93%.

The unusual labilizing effect of the 2-pyridyl group on the carbethoxy group of this pyridylmalonic ester is probably associated with the 2-linkage. It is well known that certain pyridine substituents, such as methyl, halogen, etc., are most reactive when they are in the 2-position. In the 4-position they are somewhat less reactive, while in the 3-position they are least reactive and resemble more closely the corresponding benzene derivatives in their behavior. It would be reasonable to expect, therefore, that a 3-pyridylmalonic ester, when it is made, will be found to have a resistance to alcoholysis comparable to that of a monophenyl substituted malonic ester and consequently be the most promising intermediate for the preparation of a 5-pyridylbarbituric acid.

Experimental

Ethyl-2-pyridylmalonic Ester.—To a suspension of 13.6 g. (1 mol) of sodium ethoxide in 100 cc. of absolute ether was added 38 g. (1 mol) of diethyl ethylmalonate. The mixture was warmed until the solid material had dissolved and then the ether and alcohol were removed under diminished pressure. To the remaining sodio-ethylmalonic ester 50 g. of 2-bromopyridine[3] was added and the mixture heated, with stirring, in an oil-bath at 140–150° for thirty hours. The reaction mixture then was treated with 150 cc. of ether and the ethereal solution washed with water and dried. Distillation of this solution gave the following products: 2 g. of 2-ethoxypyridine, b. p. 66° (25 mm.); 30 g. of 2-bromopyridine, b. p. 92–93° (25 mm.); 15 g. of a mixture of ethyl and diethyl malonic esters, b. p. 108–114° (25 mm.); 9 g. of ethyl α-(2-pyridyl)-butyrate, b. p. 97–98° (2 mm.), d_4^{25} 1.0330, n_D^{25} 1.4873; 9 g. of ethyl-2-pyridylmalonic ester, b. p. 136–137° (2 mm.), d_4^{25} 1.0950, n_D^{25} 1.4849.

Anal. Ethyl α-(2-pyridyl)-butyrate. Calcd. for $C_{11}H_{15}O_2N$: C, 68.35; H, 7.83. Found: C, 68.20; H, 7.94. Diethyl ethyl-2-pyridylmalonate. Calcd. for $C_{14}H_{19}O_4N$: C, 63.35; H, 7.37. Found: C, 63.10; H, 7.39.

An attempt was made to prepare ethyl-2-pyridylmalonic ester by reaction of 2-bromopyridine with an alcoholic solution of sodio-ethylmalonic ester. From a run using 53 g. of 2-bromopyridine the only reaction product isolated was 20 g. (49%) of 2-ethoxypyridine. This compound was found to boil at 66° (25 mm.) and 160–161° (740 mm.); mercuric chloride derivative,[4] m. p. 152–153; hydrochloride, m. p. 90–91°.

Anal. Hydrochloride. Calcd. for $C_7H_{10}ONCl$: Cl, 22.21. Found: Cl, 22.17.

Reaction of Ethyl-2-pyridylmalonic Ester with Urea and Sodium Ethoxide.—To a solution of 7.9 g. of sodium ethoxide in 50 cc. of absolute alcohol was added 3.3 g. of urea and 7.5 g. of ethyl-2-pyridylmalonic ester. This solution was heated in a sealed tube at 100° for seven hours. After this time the alcoholic solution was diluted with 50 cc. of water and treated with the exact quantity of acetic acid necessary to react with the sodium ethoxide used. The alcohol then was removed under diminished pressure and the remaining aqueous solution extracted with ether. This ether extract was evaporated and the residue washed with petroleum ether to remove any unreacted ester. The tar-like material remaining was recrystallized from 25 cc. of water and gave 0.1 g. of crystals which after several recrystallizations from hexone melted at 188°. This material was shown not to be a barbituric acid by its elementary analysis.

The aqueous mother liquor from this crystallization together with the original aqueous solution was concentrated and from them was obtained 3.8 g. (80%) of α-(2-pyridyl)-butyramide, m. p. 125–126°. This same amide resulted from the ammonolysis of ethyl α-(2-pyridyl)-butyrate.

Anal. Calcd. for $C_9H_{12}ON_2$: C, 65.81; H, 5.85. Found: C, 65.79; H, 5.73.

When the ethyl-2-pyridylmalonic ester was heated with urea and dry sodium ethoxide the principal product of reaction was likewise the α-(2-pyridyl)-butyramide.

Alcoholysis of Ethyl-2-pyridylmalonic Ester and of Ethylphenylmalonic Ester.—A 3.0736-g. sample of each of these substituted malonic esters was refluxed for one hour with 50 cc. of absolute alcohol containing 1.2 g. of sodium ethoxide. The alcohol and any diethyl carbonate then was distilled off under diminished pressure and condensed by passing through a spiral surrounded by an ice-salt mixture. The residue remaining in the reaction flask was washed with ether to remove any unreacted malonic ester. The alcohol and ethyl carbonate, which previously had been distilled off, together with a small amount of water, were added to the residue and the resulting alkaline solution refluxed for thirty minutes. The solution was then acidified with sulfuric acid and the carbon dioxide evolved absorbed in ascarite and weighed. The carbon dioxide obtained from ethyl 2-pyridylmalonic ester weighed 0.4730 g. (92.7%) while that obtained from ethyl phenylmalonic ester amounted to 0.1548 g. (30.8%).

Summary

The preparation and properties of ethyl-2-pyridylmalonic ester are described.

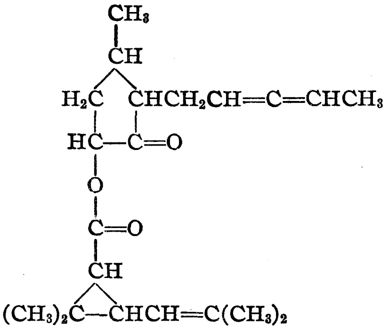
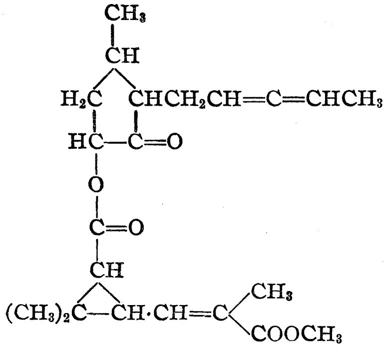
Constituents of Pyrethrum Flowers.[1] II. Isolation of Pyrethrin II

BY F. B. LAFORGE AND H. L. HALLER

The researches of Staudinger and Ruzicka[2] on the insecticidal principles of pyrethrum flowers are too well known to require detailed comment. In brief, the two active constituents, pyrethrin I and pyrethrin II, were shown to be esters of the cyclic ketonic alcohol pyrethrolone with chrysanthemum monocarboxylic acid and chrysanthemum dicarboxylic acid methyl ester, respectively, as represented by the formulas



Pyrethrin I



Pyrethrin II

Pyrethrin I was isolated from a partly purified extract of the flowers as the crystalline semicarbazone, which was hydrolyzed to the free ester, a liquid that could be distilled in a high vacuum. It was also prepared by esterification of pyrethrolone with chrysanthemum monocarboxylic acid.

The semicarbazone of pyrethrum II was not obtained pure, and the free ester was prepared only by esterification of pyrethrolone with chrysanthemum dicarboxylic acid methyl ester. The alcoholic and acidic components used in these partial syntheses of the two pyrethrins were obtained from mixtures of the semicarbazones of both.

Although the formulas of the pyrethrins proposed by Staudinger and Ruzicka have remained unquestioned, the authors themselves refer to the unsatisfactory properties of the semicarbazones, especially of the resynthesized pyrethrins, and point to the possibility of a change in the arrangement of the double bonds in the side chain of the alcoholic component and to possible steric changes during the reaction processes.[3]

To reduce the risk of changes that may occur in connection with the employment of semicarbazones, the pyrethrins should be prepared directly and under as mild conditions as possible.

Pyrethrum flowers are now purchased on the basis of their total pyrethrin content which is usually up to 1% or slightly more. Various analytical methods have been developed for their evaluation, some of which indicate only the total pyrethrin content, others the separate amounts of the two pyrethrins.

Because a wide difference of opinion exists as to the insecticidal value of each of the two compounds, it is of practical as well as of scientific importance to establish their relative toxicities. This can be best accomplished by isolating both pyrethrin I and pyrethrin II in pure condition and testing each one separately on insects.[4]

Extracts of the flowers made with organic solvents contain, in addition to the pyrethrins, comparatively large quantities of fats, waxes, fatty acids and other known and unknown substances which are regarded as inert from an insecticidal standpoint. The separation of the pyrethrins from these substances, which must constitute the first step in their isolation, has offered such unusual difficulties as to discourage attempts for its accomplishment.

(2) H. Staudinger and L. Ruzicka, *Helv. Chim. Acta*, **7**, 177 (1924).

(3) Staudinger and Ruzicka, *ibid.*, **7**, 448 (1924).

(4) With this object in view Gnadinger and Corl, THIS JOURNAL, **51**, 3054 (1929), have repeated the isolation of the mixed semicarbazones by the method of Staudinger and Ruzicka, and have separated that of pyrethrin II to the extent of obtaining a product melting at 56–59°. The analytical figures given by them for the free ester obtained from their semicarbazone indicate, however, that it was still a mixture of about 70% pyrethrin II and 30% pyrethrin I.

Staudinger and Ruzicka and all subsequent investigators have employed petroleum ether extractives as starting material. Dissolving this material in methyl alcohol containing a little water and refrigerating, effects a partial separation of fats and waxes. The material remaining in solution is transferred to petroleum ether, and the fatty acids are removed by extraction with aqueous alkali carbonate, an operation that is exceedingly unsatisfactory owing to the formation of emulsions. By this method preparations of 50 to 60% total pyrethrin content are obtained. These are employed for the isolation of the pyrethrins as semicarbazones.

The initial difficulties in the isolation of the pyrethrins, involving the removal of the fats, waxes and acids from the original extractive, are eliminated in the following process, which is described in detail in the experimental part of this article.

The petroleum ether extractive used contained about 30% of total pyrethrins, pyrethrin I and pyrethrin II being present in about equal amounts. Addition of a small quantity of water to an acetic acid solution of this material precipitated the fats and waxes in a semi-solid form, which, after hardening by cooling, were readily removed by filtration.

By addition of water to the filtrate and extraction with petroleum ether, a product was obtained with a total pyrethrin content of 60 to 65% but still containing fatty acids and other impurities.

For the extraction of the acids, the only suitable solvent that did not involve the formation of emulsions was aniline. By agitation of the pyrethrin concentrate in this solvent with aqueous potassium carbonate the fatty acids were removed. The product separated from the aniline by acid was a concentrate containing 65 to 70% of total pyrethrins.

When this mixture was dissolved in a mixture of acetic acid and petroleum ether and sufficient water was added to cause separation of the two liquids, the pyrethrin II tended to concentrate in the acid layer, and the pyrethrin I, together with most of the impurities, concentrated in the petroleum ether layer. By isolation of the material in the acid layer and several repetitions of the process, a concentrate was obtained containing 80 to 83% pyrethrin II and 3 to 8% of pyrethrin I.

For the final purification the concentrates were fractionated in a molecular still at a comparatively low temperature, yielding pyrethrin II of practically 100% purity.

Although it is possible to obtain fairly large quantities of the concentrate containing about 80% pyrethrin II, the losses in distillation are considerable. Pyrethrin II so obtained is a colorless, very viscous liquid. Instead of being dextrorotatory, as recorded by Staudinger and Ruzicka for the synthetic compound, it showed a slight levo rotation.

It is to be regarded as probable that the pyrethrin II which is isolated by the process described in this article is different from the pyrethrin II obtained by partial synthesis. It is also quite possible that one or more other compounds having the same empirical formula and general nature as pyrethrin II are present in pyrethrum extracts.

Work is now in progress on this phase of the problem and on the direct isolation of pyrethrin I.

Experimental

Preliminary Purification of Oleoresin.—The starting material, a commercial concentrated petroleum ether extract, consisted of a thick brown liquid with a total pyrethrin content of about 30%, in which the pyrethrins were present in about equal amounts. After removal of the remaining solvent by warming under reduced pressure (an essential step), 450 g. of the material was divided into nine 50-g. portions.

To each portion 75 cc. of glacial acetic acid was added, and the mixture was stirred until practically all had dissolved. The same quantity of acetic acid to which 15 cc. of water had been added was mixed with the solution, causing the separation of a semi-solid mass of material. The containers were then cooled in an ice-bath for about half an hour, after which the contents were filtered separately on cold Büchner funnels. The solid material consisted of fats and waxes with comparatively little occluded pyrethrins. The green filtrates were combined and after addition of decolorizing carbon were again filtered. The acetic acid solution was then divided into two or three portions and strongly diluted with water, and the separated oil was extracted with petroleum ether. A small quantity of insoluble dark sirup was discarded. The petroleum ether solution was washed with water, a little sodium chloride being added to break slight emulsions. After the solution had been dried with sodium sulfate, most of the solvent was recovered by distillation on the steam-bath; the remainder was removed under reduced pressure. The same method was used in isolating all pyrethrum concentrates referred to below from their acetic acid solutions.

The quantity of concentrate obtained from 450 g. of the original material was 140 g. It contained, besides other impurities, fatty acids, which were removed by dissolving the material in 400 cc. of freshly distilled aniline and agitating the solution for about ten hours at −10° with a solution of 140 g. of potassium carbonate in 600 cc. of water. The aniline solution readily separated from the slimy soap solution, which was drawn off and on acidification yielded the extracted fatty acids. The aniline solution was washed three times with saturated bicarbonate solution and then, with constant stirring, was slowly run into 400 cc. of concentrated hydrochloric acid and 400 g. of cracked ice. These procedures were usually carried out in two operations with half the quantities stated. The separated oil was taken up in a suitable quantity of petroleum ether. A small quantity of insoluble material was discarded. The residue obtained from the washed and dried petroleum ether solution consisted of 90 g. of yellow oil containing 38.9% of pyrethrin II and 29.2% of pyrethrin I. Only slight variations from these values were observed in similar runs.

The analytical results for pyrethrin II were obtained by the methoxyl method of Haller and Acree,[5] those for pyrethrin I by the method of Seil.[6] In some instances pyrethrin II was also determined by the method of Seil as a check on the methoxyl method. It was observed that concentrates with a content of pyrethrin II of the order of 80% as determined by the methoxyl method showed a value about 5 or 6% higher by the Seil method. Practically 100% pyrethrin II usually showed an apparent pyrethrin I content of 2 to 3% by the Seil method. This is not surprising, because abnormally large samples had to be employed to obtain a significant volume in the titration, and the values observed evidently were very close to the limits of error of the method.

Separation of Pyrethrin II from Pyrethrin I by Differential Solubility.—The 90 g. of partly purified material obtained by the process just described was dissolved in 200 cc. of glacial acetic acid and 400 cc. of petroleum ether in a separatory funnel, and 20 cc. of water was added in small portions with vigorous shaking.

The addition of water caused the solution to separate into two layers, a petroleum ether fraction (P) and an acetic acid fraction (A). The latter was washed with six 40-cc. portions of petroleum ether, yielding an acid fraction (A-1).

The combined petroleum ether washings were added to the petroleum ether fraction (P), and the resulting solution was washed with six 40-cc. portions of acetic acid containing 10 to 12% of water. These acid washings were combined (A-2).

The acid-washed petroleum ether solution (P-1) yielded about 35 g. of a product containing 43% pyrethrin I and 14.4% pyrethrin II. This was set aside for the isolation of pyrethrin I.

The acid solution A-2 was extracted once with 240 cc. of petroleum ether and then with two 60-cc. portions of the same solvent. The combined petroleum ether washings were designated P-2, and the washed acid solution was designated A-3.

The two acetic acid solutions A-1 and A-3 were combined, and the dissolved material was isolated by the addition of water and extraction with petroleum ether. The quantity of concentrate so obtained was 30 g. It contained 72.2% of pyrethrin II and 14.2% of pyrethrin I. The material will be referred to as of stage I.

This product was dissolved in 100 cc. of acetic acid and 200 cc. of petroleum ether, and 14 cc. of water was added in small portions, with vigorous shaking after each addition. The separated acid solution was washed with four 20-cc. portions of petroleum ether. The washings and the separated petroleum ether layer were added to solution P-2.

The dissolved material in the acid solution (A-4) was isolated by dilution with water and extraction with petroleum ether and 20 g. of material containing 76.5% of pyrethrin II and 7.4% of pyrethrin I was obtained (stage II).

At stage III, which is reached by repeating the solution in acetic acid–petroleum ether, addition of water and subsequent washing of the acid layer with petroleum ether, using corresponding quantities of solvents, the yield was about 14 g. of material containing 82.7% of pyrethrin II and 6% of pyrethrin I. It is necessary to repeat the process whenever at stage III the pyrethrin II content falls below 80%, but it is not possible by further repetition to raise it much above 83% when the proportions originally present were of the order given.

All petroleum ether extracts except P-1 were combined with P-2. The quantity of material obtained from these combined extracts was 25 g. When treated in a second series of operations according to the procedure described, it yielded 8 g. of concentrate containing at stage III about the same percentages of the two pyrethrins as the corresponding final product from the first series.

As the separation and concentration of pyrethrin II proceeds, the concentrates become progressively more viscous and lighter in color and more difficultly soluble in petroleum ether. A concentrate of more than 70% of pyrethrin II separates in part even from a moderately dilute petroleum ether solution on cooling, but this is of no advantage in purification, as the separated product carries the impurities with it.

The process described could probably be replaced by a continuous one involving the same principle, if the object were to prepare large quantities of concentrates of high pyrethrin II content.

Preparation of Pure Pyrethrin II from the Concentrate by Distillation in a Molecular Still.—From 8 to 10 g. of solvent-free concentrate containing about 80% of pyrethrin II and 3 to 8% of pyrethrin I was distilled in a Hickman-type molecular still of suitable size.[7] The still was heated in a small oil-bath kept at the constant temperature of boiling chlorobenzene (131°), the pressure as recorded by the mercury gage being about 10^{-6} mm. The distillation usually required eight to ten hours.

In the earlier trial runs a number of fractions were collected and analyzed to determine at which points the distillation should be interrupted. In later distillations three fractions were usually collected. The first fractions contained most of the pyrethrin I and the more volatile impurities. The second fractions generally consisted of 80 to 90% of pyrethrin II and were combined for redistillation. The third fractions were practically 100%

(7) K. Hickman, *J. Franklin Inst.*, **213**, 119 (1932).

pyrethrin II. There was always more than 50% loss due to polymerization in the still, and the still residue consisted of a glassy mass almost insoluble in all solvents. The yield of pure pyrethrin II was in no case more than 20% of the quantity of material distilled, but an additional quantity was obtained on redistillation of the second fractions.

The analytical results and physical constants for several samples are given below.

Preparation A.—*Anal.* Calcd. for $C_{22}H_{30}O_5$: C, 70.54; H, 8.08; $1CH_3O$, 8.28. Found: C, 70.63, 70.84; H, 7.69, 7.69; CH_3O, 8.10. Calcd. to pyrethrin II (mol. wt. 374), 97.72; n^{30}_{D} 1.5247; n^{20}_{D} 1.5285. *Rotation:* 0.135 g. in 2.28 cc. ether at 20° rotated $-0.34°$; $l = 0.96$ dm.; $[\alpha]^{20}_{\mathrm{D}}$ -6.0. 0.235 g. in 2.28 cc. benzene at 20° rotated $-0.42°$; $l = 0.96$ dm.; $[\alpha]^{20}_{\mathrm{D}}$ -4.2.

Preparation B.—*Anal.* Found: CH_3O, 8.24, 8.33. calcd. to pyrethrin II (mol. wt. 374), 99.66, 100.38; n^{29}_{D} 1.5258.

Preparation C.—*Anal.* Found: CH_3O, 8.07, 8.04; n^{20}_{D} 1.5259.

Preparation D.—*Anal.* Found: CH_3O, 8.00; n^{20}_{D} 1.5247.

It will be noted that none of the samples shows a pyrethrin II content of appreciably more than 100% as determined by the methoxyl method, indicating that none of them contained methyl pyrethrolone, alkyl esters of the chrysanthemum acids or other methoxyl containing impurities. These may have been present in the concentrates before distillation, but, being of much lower molecular weight, they would be removed in the more volatile fractions.

Summary

A procedure for the preparation of pyrethrin II is described.

Petroleum ether extractives of pyrethrum flowers are separated from fats and waxes by the employment of acetic acid.

The acids are removed from the concentrate by extraction in aniline solution with potassium carbonate.

Partial separation of pyrethrin II from pyrethrin I is accomplished by taking advantage of their different solubilities in a system consisting of diluted acetic acid and petroleum ether. Pyrethrin II tends to concentrate in the acid solution, pyrethrin I in the petroleum ether.

Concentrates so obtained containing about 80% of pyrethrin II and about 6% of pyrethrin I are distilled in a molecular still and yield pure pyrethrin II.

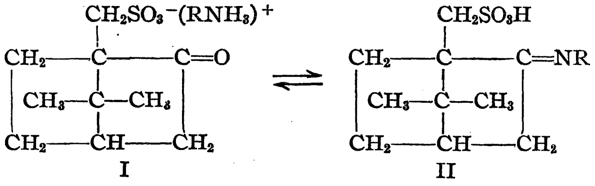
Anomalous Mutarotation of Salts of Reychler's Acid. III. Reduction of Ketimines of *d*-Camphor-10-sulfonic Acid. Formation of Sultams

BY R. S. SCHREIBER AND R. L. SHRINER

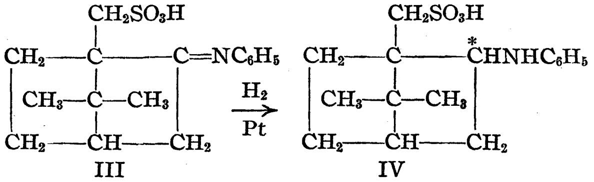
The mutarotation of salts of primary amines and Reychler's acid was ascribed[1] to the establishment of an equilibrium between the *d*-salt (I) and the *l*-ketimine (II).



I II

In order to establish the ketimine structure beyond question, the product of this reaction was subjected to catalytic reduction, since it is known that ketimines may be hydrogenated to secondary amines.[2]

The ketimine (III) obtained by the dehydration of the aniline salt of Reychler's acid readily absorbed one mole of hydrogen in the presence of platinum black and the hydrogenated product, 2-(N-phenylamino)-10-camphane-sulfonic acid (IV) was found to consist of the two diastereoisomers which would be expected because of the creation of a new asymmetric carbon atom at position 2. These isomers were separated by fractional crystallization. The α-form melted at 300–302° and had a specific rotation[3] of $-88.5°$ whereas the β-form melted at 350–351° and was dextrorotatory, $+8.5°$.



III IV

---

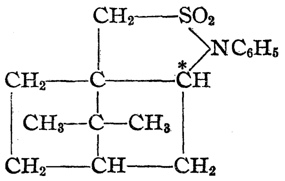
(2) Mignonac, *Compt. rend.*, **171**, 114 (1920); Rupe and Vogler, *Helv. Chim. Acta*, **8**, 832 (1925); Rupe and Metzger, *ibid.*, **8**, 838 (1925); **13**, 457 (1930).

(3) All specific rotations reported in this paper were determined at 25° with sodium D light.

Further evidence supporting the above structures was obtained by causing each of the isomers of IV to undergo ring closure leading to the formation of two isomeric sultams of the structure shown in V.

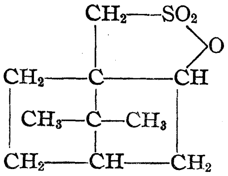


V

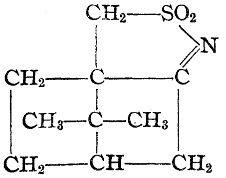
Treatment of the α-form of IV with either benzene-sulfonyl chloride or acetic anhydride produced the α-sultam (V) which melted at 172–173° and had a specific rotation of $-110°$ in chloroform. The β-form of IV could be converted to the β-sultam (V) by slightly more drastic conditions. The β-sultam melted at 137–138° and had a rotation of $+140.5°$ in chloroform.

These sultams were neutral compounds and their structure was proved not only by their analyses but by the fact that each isomer could be hydrolyzed by means of concentrated hydrochloric acid to the original α- and β-forms of 2-(N-phenylamino)-camphane-10-sulfonic acids (IV) in exactly the same fashion as other substituted sulfonanilides.[4]

The cyclization of the two forms of IV into the sultams shows that no rearrangements, which often occur in the camphor series, took place during the dehydration of the aniline salt. Examination of the literature revealed two similar cases of ring formation in the camphane series. Lipp and Holl[5] prepared a sultone VI by dehydrating 2-hydroxycamphane-10-sulfonic acid and Reychler prepared *d*-camphor-10-sulfonanhydramide[6] (VII).



VI



VII

Other sultams recorded are 1,8-naphthsultam prepared by Dannerth[7] and the sultam of 8-(2-aminophenyl)-naphthalene-1-sulfonic acid.[8]

Construction of the molecular models of the two isomeric forms of IV showed that in one model the sulfonic acid group and the amino group may approach closer to each other than in the isomeric model. Also, one model of the two isomeric sultams (V) possessed much more strain than the other. This difference is reflected in the properties of the two sultams. The β-sultam was formed with greater difficulty and hydrolyzed more easily than the α-sultam.

Experimental

Reduction of the Anil of *d*-Camphor-10-sulfonic Acid.—Thirteen grams of the anil, prepared by dehydration[1] of the aniline salt of Reychler's acid, was dissolved in 50 cc. of methyl alcohol and hydrogenated catalytically with 0.1 g. of platinum oxide-platinum black.[9] One mole of hydrogen was absorbed in four hours after which time the absorption of hydrogen stopped. The mixture was heated and the catalyst removed by filtration. When cool, the filtrate deposited 4.6 g. of crystals which melted at 288–295° (Maquenne block) and had a specific rotation[2] of $-78.0°$ in a mixture of equal volumes of chloroform and methyl alcohol. Several recrystallizations from methyl alcohol of this first crop gave 1.1 g. of the α-form in a pure state, with a constant melting point of 300–302° (Maquenne block) and a constant specific rotation of $-88.5°$. The mother liquor was evaporated to dryness, and then dissolved in 35 cc. of concentrated hydrochloric acid, which was heated to boiling and diluted with 150 cc. of water. This solution was allowed to stand overnight, during which time 4.6 g. of crystals separated. Recrystallization from dilute hydrochloric acid yielded 1.3 g. of the pure β-form. This form had a melting point of 350–351°, and a constant specific rotation of $+8.5°$ in a mixture of chloroform and methyl alcohol.

α-Form of 2-(N-Phenylamino)-camphane-10-sulfonic Acid (IV).—*Anal.* Calcd. for $C_{16}H_{23}O_3NS$: N, 4.53; S, 10.35; neut. eq. by titration, 309. Found: N, 4.49; S, 10.30; neut. eq., 308.3.

β-Form of 2-(N-Phenylamino)-camphane-10-sulfonic Acid (IV).—*Anal.* Calcd. for $C_{16}H_{23}O_3NS$: N, 4.53; S, 10.35; neut. eq. by titration, 309. Found: N, 4.34; S, 10.21; neut. eq., 309.2.

Sultam of α-Form of 2-(N-Phenylamino)-camphane-10-sulfonic Acid (V).—Five grams of the α-form of IV was heated with 15 g. of benzenesulfonyl chloride on a steam-bath until solution was complete (one to two hours). The mixture was then poured into excess of 5% sodium hydroxide to destroy the unreacted sulfonyl chloride, and the solution then acidified with hydrochloric acid. The insoluble product was recrystallized from methyl alcohol. The yield was 3.1 g. or 65% of the theoretical, m. p. 172–173°.

Anal. Calcd. for $C_{16}H_{21}O_2NS$: N, 4.71; S, 10.99. Found: N, 4.81; S, 10.92.

This compound was neutral, and did not give a neutral equivalent. The same compound was prepared by heating the α-form of IV with acetic anhydride for an hour on a

steam-bath. On dilution with water the sultam was precipitated. Recrystallized from methyl alcohol, it gave a melting point of 172–173°. No depression in melting point occurred when mixed with the product obtained above. Its specific rotation[2] in chloroform was −110°; in acetone −117.5°.

Sultam of β-Form of 2-(N-Phenylamino)-camphane-10-sulfonic Acid (V).—The β-form of IV could not be converted into a sultam by either of the two procedures used for the preparation of the α-form. In each case the original acid was recovered unchanged. It was prepared, however, by a slightly modified procedure. Two grams of the above β-form of IV was dissolved in 3 g. of pyridine to which was added 1.2 g. of benzenesulfonyl chloride. The mixture was warmed on a steam-bath for two hours, diluted with 10–15 cc. of water and filtered and recrystallized from ethyl alcohol. The yield was 1.2 g. or 64%. It melted at 137–138° and had a specific rotation in chloroform of +140.5°.

Anal. Calcd. for $C_{16}H_{21}O_2NS$: N, 4.81; S, 10.99. Found: N, 4.73; S, 10.99.

Hydrolysis of the α-Sultam of 2-(N-Phenylamino)-camphane-10-sulfonic Acid.—One gram of the sultam was refluxed with 35 cc. of concentrated hydrochloric acid for thirty-six hours, at the end of which time the insoluble material had disappeared. The solution was then evaporated to about 10 cc. and cooled. Filtration yielded 0.6 g. of crystals. The product melted at 300–302° and had the same specific rotation as the α-form of 2-(N-phenylamino)-camphane-10-sulfonic acid.

Hydrolysis of the β-Sultam of 2-(N-Phenylamino)-camphane-10-sulfonic Acid.—Four-tenths of a gram of the β-sultam was refluxed for eight hours with 20 cc. of concentrated hydrochloric acid. The solution was diluted with 25 cc. of water and evaporated nearly to dryness. On cooling, the β-form of 2-(N-phenylamino)-camphane-10-sulfonic acid crystallized. The yield was 0.25 g. or 60%. The melting point was 350–351° on the Maquenne block and the specific rotation checked that of the original β-isomer of IV.

Summary

The catalytic hydrogenation of the anil of *d*-camphor-10-sulfonic acid yielded two diastereoisomeric forms of 2-(N-phenylamino)-camphane-10-sulfonic acid. Loss of water converted each of these isomers into its corresponding sultam, and each of the latter could be hydrolyzed to their respective original isomers. These reactions constitute further evidence that the *levo*-rotatory products obtained by the dehydration of primary amine salts of Reychler's acid are ketimines.

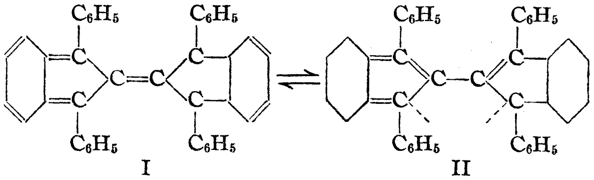
The Synthesis of Bis-2,2'-(1,3-diphenylindenol-3). A Contribution to the Rubrene Problem

BY J. C. ECK AND C. S. MARVEL

The question of the structure of rubrene has become of considerable interest to us because of its relationship to the problems involved in the rearrangement of certain types of polyynes. Recently Dufraisse and Willemart[1] have reported that Moureu's hydrocarbon $C_{42}H_{30}$, which is formed by the spontaneous rearrangement of tetraphenyldiphenylethynylethane,[2] can be oxidized with lead dioxide to give a 34% yield of rubrene. This observation is somewhat surprising since previous work has shown that chromic acid converts rubrene to *o*-dibenzoylbenzene,[3] whereas the same reagent oxidizes Moureu's hydrocarbon to *o*-benzoylbenzoic acid.[4]

The discoverers of rubrene[5] have considered it to be a difulvene of structure I which may be in equilibrium with a diindenyl form containing two trivalent carbon atoms, II. This diradical structure has also been advocated by Schönberg.[6]



I II

The structural formulas which have been assigned to rubrene and its many known derivatives are based on the reactions of the compounds and no confirmatory synthesis has been given for any compound in the series. The present work was undertaken with the hope of accomplishing the synthesis of rubrene or its closely related derivative, dihydroxydihydrorubrene, which has been assigned structure III.

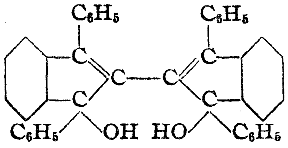
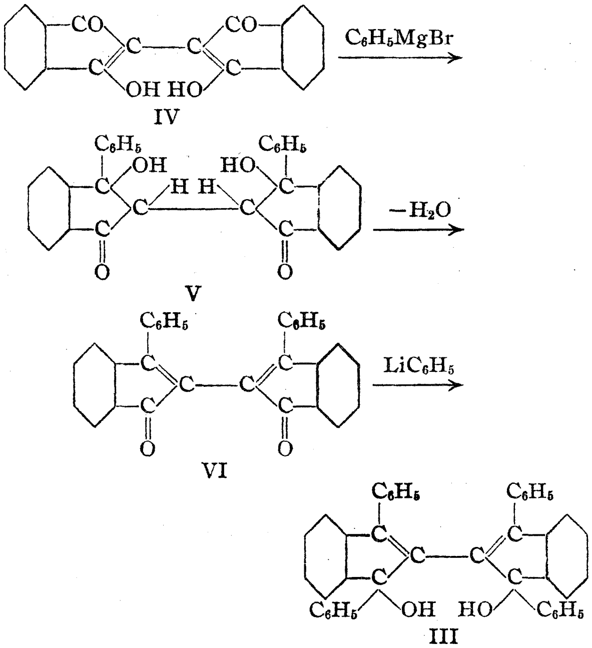
(5) The literature on rubrene has been summarized by Dufraisse, *Bull. soc. chim.*, [4] **53**, 789 (1933).

(6) Schönberg, *Ber.*, **67**, 633 (1934).



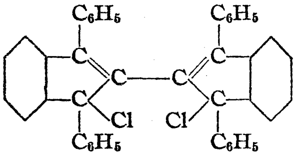
III

The starting point in our synthesis was bis-2,2′-(1,3-indandione) (IV) which was prepared by the method of Gabriel and Leupold.[7] This was converted to bis-2,2′-(1-phenylindanone-3-ol-1) (V) by the action of excess phenylmagnesium bromide. Since only two phenyl groups can be introduced into the molecule by this treatment, the bis-indandione (IV) must exist largely in the di-enolic form. Dehydration of compound V gave a good yield of bis-2,2′-(1-phenylindenone-3) (VI) which, with lithium phenyl, gave bis-2,2′-(1,3-diphenylindenol-3) (III). Lithium phenyl was used in this step to lessen the chance of 1,4 addition to the conjugated systems involved.[8] That the final product of these reactions had the formula (III) expected from the synthesis was established by its oxidation to *o*-dibenzoylbenzene in yields of 88% of the theoretical amount, and by the fact that the two hydroxyl groups could be replaced by chlorine atoms.



According to Dufraisse and Badoche[9] dihydroxydihydrorubrene, to which they assign structure III, melts at 307–308°; moderate heat converts it to rubrene monoxide by loss of water; dehydrating agents convert it to a white compound whose solutions have an intense violet fluorescence; and reduction converts it to rubrene. Our synthetic bis-2,2′-(1,3-diphenylindenol-3) (III) melts at 293°; sublimes unchanged at 280° at 3 mm. pressure; heating it with potassium acid sulfate at 250° or with phosphorus pentoxide at 100° affects it only very slightly, giving a trace of a substance which, in solution, shows a greenish fluorescence; reduction with iron in hydrochloric or acetic acid does not affect it.

The chloride VII which was prepared from the dihydro compound was treated with silver in the hope that the diradical II could be prepared. This reaction has not been studied extensively but sufficient work has been done to show that rubrene is not produced.



VII

Inspection of the formula of bis-2,2′-(1,3-diphenylindenol-3) (III) shows that it may exist in meso and racemic forms. It is possible that we have obtained one of these forms by our synthesis, whereas the other results from the oxidation of rubrene. However, the difference in chemical properties between our synthetic product and that obtained from rubrene seems to us to be too marked for these products to be meso and racemic forms.[10]

Experimental

Bis-2,2′-(1-phenylindanone-3-ol-1).—To a solution of phenylmagnesium bromide prepared from 15.7 g. of bromobenzene and 2.4 g. of magnesium in 200 cc. of anhydrous ether was added 10 g. of bis-2,2′-(1,3-indandione) suspended in 200 cc. of dry benzene. The reaction mixture was stirred for about twelve hours, and then the solvent was decanted from the black unreacted material into an aqueous solution of ammonium chloride. The reaction product precipitated in the ether–benzene mixture as soon as hydrolysis of the magnesium complex occurred. The straw-colored precipitate was collected on a filter, washed with water and dried in the air. The yield was 10 g. (65%).

This product was recrystallized by suspending it in about 300 cc. of dioxane, heating the solvent to boiling

[10] Koelsch and Richter have synthesized bis-2,2′-(1,3-diphenylindenol-3) and the corresponding dichloride by another series of reactions. Their products are identical in physical properties with the compounds which we have obtained. See Koelsch and Richter, THIS JOURNAL, **57**, 2010 (1935).

and filtering hot. On cooling the first extract, a yellow crystalline compound, melting at 345° (bloc Maquenne), was obtained.

Anal. Calcd. for $C_{30}H_{22}O_4$: C, 80.71; H, 4.93. Found: C, 80.78; H, 4.92.

The filtrate from this first fraction was used to re-extract the material which did not dissolve in the first treatment with hot dioxane. On cooling the second extract, a mixed product was obtained. However, when the filtrate from this portion was again used to extract the undissolved portion of the original material, a second isomer of the hydroxy ketone, melting at 358° (bloc Maquenne), was obtained.

Anal. Calcd. for $C_{30}H_{22}O_4$: C, 80.71; H, 4.93. Found: C, 80.91; H, 5.00.

Either of these products or the mixture of the two gave satisfactory results in the following experiment.

Bis-2,2′-(1-phenylindenone-3).—An intimate mixture of 10 g. of bis-2,2′-(1-phenylindanone-3-ol-1) and 10 g. of powdered, freshly-fused, potassium acid sulfate was placed in a large Pyrex test-tube and slowly immersed in a Wood's metal bath previously heated to 250°. This temperature was then maintained for twenty-five minutes. The reaction mass was occasionally stirred with a glass rod. The reaction mixture was cooled and extracted with water. The water-insoluble material was dissolved in 200 cc. of benzene and boiled with 2 g. of decolorizing carbon for about a half hour. This solution was filtered and concentrated to 25 cc. Slow addition of an excess of low-boiling petroleum ether precipitated the product as beautiful, red crystals. The yield was 7.8 g. (80%) of a product melting at 213–214°.

Anal. Calcd. for $C_{30}H_{18}O_2$: C, 87.8; H, 4.39. Found: C, 87.52; H, 4.44.

Bis-2,2′-(1,3-diphenylindenol-3).—A solution of lithium phenyl was prepared from 0.5 g. of lithium and 5.7 g. of bromobenzene in 150 cc. of anhydrous ether.[11] Unreacted lithium was removed and then 5 g. of bis-2,2′-(1-phenylindenone-3) dissolved in 200 cc. of dry benzene was added dropwise. The reaction mixture was stirred during this addition, and for about an hour afterward. This solution was hydrolyzed with aqueous ammonium chloride solution, the ether–benzene solution was washed thoroughly with water and dried over anhydrous sodium sulfate. The solution was then concentrated and, on cooling, the product separated. The yield was 4.9 g. (70%) of a product which melted at 293° (bloc Maquenne).

Anal. Calcd. for $C_{42}H_{30}O_2$: C, 89.04; H, 5.30. Found: C, 88.76; H, 5.28.

This reaction product was separated into two isomers by careful recrystallization from benzene. The less soluble form was yellow, and melted at 273° (bloc Maquenne). The more soluble form melted at 293° (bloc Maquenne). Heating the lower-melting product or allowing it to stand converted it to the higher-melting product.

Anal. Calcd. for $C_{42}H_{30}O_2$: C, 89.04; H, 5.30. Found: (low-melting isomer) C, 89.28; H, 5.57; (high-melting isomer) C, 89.20; H, 5.48.

Oxidation of Bis-2,2′-(1,3-diphenylindenol-3).—A mixture of 0.5 g. of the dihydroxy compound and 2.5 g. of potassium dichromate in 50 cc. of glacial acetic acid was heated under a reflux condenser for ten hours. The reaction mixture was poured into water and filtered. The precipitate was taken up in ether and the ether solution was extracted with aqueous sodium carbonate. The ether was removed in a current of air, and the residue taken up in alcohol, decolorized by boiling with norite, filtered and concentrated to a small volume. On cooling, 0.44 g. (88%) of *o*-dibenzoylbenzene, m. p. 145–146°, separated. The product showed no depression in melting point when mixed with a known specimen of *o*-dibenzoylbenzene.

Bis-2,2′-(1,3-diphenyl-3-chloroindenyl).—A solution of 0.1 g. of bis-2,2′-(1,3-diphenylindenol-3) in 25 cc. of anhydrous ether was saturated with hydrogen chloride and allowed to stand overnight. The solvent was evaporated and the residue recrystallized three times from acetone. The yield was 0.07 g. of a light yellow product which melted at 245–247° (bloc Maquenne).

Anal. Calcd. for $C_{42}H_{28}Cl_2$: Cl, 11.77. Found: Cl, 11.86.

A solution of this chloride in benzene was shaken with molecular silver for several days. The solution became greenish-yellow, and there was no indication of the red color of rubrene in solution.

Attempted Dehydration of Bis-2,2′-(1,3-diphenylindenol-3).—A small sample of the dihydroxy compound was heated for ten minutes at 250° with potassium acid sulfate. When the dehydrating reagent was removed, the organic material was dissolved in benzene. This solution showed a slight green fluorescence which was not shown by the original dihydroxy compound in benzene solution. However, no product except the starting material could be isolated from the reaction mixture. Treatment of the dihydroxy compound with phosphorus pentoxide at 100° for ten minutes gave the same results. The dihydroxy compound itself was heated to 280° at 3 mm. Under these conditions it sublimed undecomposed.

Attempted Reduction of Bis-2,2′-(1,3-diphenylindenol-3).—A suspension of the dihydroxy compound in hydrochloric acid was treated with iron filings but, after the iron had dissolved, the unchanged starting material was recovered. Likewise, treating the dihydroxy compound with iron and glacial acetic acid did not affect it.

Summary

Bis-2,2′-(1,3-diphenylindenol-3) has been synthesized and shown not to be identical with the product known as dihydroxydihydrorubrene.

The Reactions between Mercury Diaryls and Diarylselenium Dihalides

BY HENRY M. LEICESTER

In previous work on the synthesis of aromatic selenonium salts[1] it was shown that triarylselenonium chlorides could be prepared by fusing together diarylselenium dichlorides and mercury diaryls. Since at that time the chief interest lay in the study of the selenonium salts, the mechanism of their synthesis was not worked out. The course of this reaction has now been studied.

Since mercury diaryls were found to react with diarylselenium dihalides in solution, the mechanism of this reaction was first investigated. Both diarylselenium dibromides and dichlorides were used, and the procedure was the same in all cases. The equimolecular amounts of the reagents shown in Table I were mixed in the dry state and treated with about 25 cc. of carbon disulfide. The mixture was shaken for five minutes at room temperature. The mercury diaryls dissolved at once; the dihalides somewhat more slowly. When the dibromides were used, a white precipitate began to appear almost immediately, and the red color of the dibromide faded. After shaking, the mixture was allowed to stand for five to ten minutes. Precipitation was then complete. In the case of the dichlorides, the precipitation required from one to three days before it was complete. The precipitate was filtered off and crystallized from benzene if necessary, though usually it was very pure. The carbon disulfide was distilled from the filtrate and the residue dissolved in ether. A little aryl mercuric halide which remained undissolved was added to the main precipitate. The ether was then distilled off and the residue fractionated.

[a] Tol. = *p*-tolyl; Ph. = phenyl. [b] X = Br. [c] The amounts of selenide and bromotoluene were determined in separate experiments. [d] X = Cl.

The reactions which were studied quantitatively are summarized in Table I. The three reactions which correspond for the dichlorides to reactions 2 to 4 for the dibromides were studied only qualitatively, but the analogous reaction products were identified in each case.

Di-*p*-tolyl selenide, phenyl and *p*-tolyl mercuric bromides and chlorides were identified by mixed melting points with the known compounds; diphenyl selenide was converted to the dibromide for identification; *p*-bromotoluene was oxidized to *p*-bromobenzoic acid which was proved by mixed melting point; and bromobenzene was identified by conversion to *p*-nitrobromobenzene, and by mixed melting point of the latter with an authentic specimen.

It is therefore evident that the course of the reaction can be represented by the following general equation

$$R_2Hg + R_2SeX_2 = RHgX + RX + R'_2Se$$

where X is a halogen. The ease with which the selenium dihalides, especially the dibromides, halogenate the mercury compounds is noteworthy.

The reaction was next tried in acetone. When diaryl selenium dibromides were dissolved alone in this solvent, the powerful effect of bromoacetone on the eyes soon became apparent, and the red color faded from the solution. Evaporation of the solvent left diaryl selenides, which were identified as described above. The reaction occurred more rapidly in the case of di-*p*-tolylselenium dibromide than when diphenylselenium dibromide was used. This bromination of the solvent rendered study of the reaction with mercury diaryls unsatisfactory.

However, no corresponding chlorination occurred with diarylselenium dichlorides. In the cold, these reacted with mercury diaryls just as they did in carbon disulfide solution. When,

---

[1] Leicester and Bergstrom, THIS JOURNAL, **53**, 4428 (1931).

however, the reaction mixture was refluxed, a second reaction was observed. Thus, when diphenylselenium dichloride and mercury diphenyl were heated in acetone, a compound precipitated which was insoluble in boiling benzene, and could thus be separated from the phenyl mercuric chloride which was also formed. The amount of this new compound produced increased as the time of refluxing was lengthened. The substance was not very soluble in alcohol, but could be crystallized from this solvent in short needles, m. p. 259–260° (uncorrected). When it was treated with sodium hydroxide solution, mercuric oxide was precipitated. Triphenylselenonium chloride was isolated from the filtrate by the method previously described.[1] The compound was thus the double salt, triphenylselenonium chloride–mercuric chloride, a fact which was proved by comparing it with a sample of the double salt prepared directly from mercuric chloride and triphenylselenonium chloride. The behavior of the two substances was identical.

The reactions described above, with the exception of the second step in hot acetone, obviously differ from that which was previously observed in the fusion of the mercury and selenium compounds, since no selenonium salt was formed. Therefore, a more detailed study of the fusion of di-*p*-tolylselenium dichloride and mercury di-*p*-tolyl was made. This reaction has been earlier described[1] (p. 4434) but the proportions of the reagents there used were determined empirically. When an equimolecular mixture of the two compounds was heated to 140–150°, it fused to a brown liquid which cooled to a thick tar. When this was treated with ether, it was converted to a yellow powder. A hot benzene extract of the latter gave crystals of *p*-tolyl mercuric chloride when it cooled. The material which did not dissolve in benzene crystallized from alcohol in granular crystals, m. p. 216–217°. These gave mercuric oxide and tri-*p*-tolylselenonium chloride when they were treated with sodium hydroxide.

When a mixture of 0.76 g. of mercury di-*p*-tolyl and 1.30 g. of di-*p*-tolylselenium dichloride, a ratio of 1:2, was fused and treated as above, no *p*-tolymercuric chloride was isolated. However, from the ether extract was obtained di-*p*-tolyl selenide, and the odor of *p*-chlorotoluene was noticed. A yield of 1.29 g. or 98% of the mercuric chloride double salt, m. p. 216–217°, was obtained. When this was worked up in the usual way, it gave 86% of the tri-*p*-tolylselenonium salt which was identified by conversion to the iodide.

These facts show that the reaction which took place in carbon disulfide and cold acetone also occurred in the fusion, but that a further reaction then occurred between the aryl mercuric chloride, which now was not removed from the sphere of the reaction, and a second molecule of diarylselenium dichloride. The two steps in the reaction are

$$(CH_3C_6H_4)_2SeCl_2 + (CH_3C_6H_4)_2Hg = (CH_3C_6H_4)_2Se + CH_3C_6H_4Cl + CH_3C_6H_4HgCl$$

$$CH_3C_6H_4HgCl + (CH_3C_6H_4)_2SeCl_2 = (CH_3C_6H_4)_3SeCl{\cdot}HgCl_2$$

The occurrence of the second step in hot acetone is no doubt due to the solubility of the aryl mercuric chlorides in this solvent.

For further proof of the occurrence of the second reaction, equimolecular mixtures of di-*p*-tolylselenium dichloride and *p*-tolyl mercuric chloride were fused at 150–160° for one minute. The liquid bubbled at first, and became dark red-brown. It cooled to a hard solid. This was converted to an orange powder by stirring under ether. The ether extract contained a very small amount of an oily product which was not identified. A yield of 73% of tri-*p*-tolylselenonium chloride–mercuric chloride, m. p. 215–216°, was obtained.

Entirely analogous results were obtained by fusing together equimolecular amounts of diphenylselenium dichloride with *p*-tolyl mercuric chloride, and of di-*p*-tolylselenium dichloride with phenyl mercuric chloride. In the latter case, the selenonium iodide and picrate prepared from the reaction product had low melting points, as had been found for the corresponding products from the fusion of di-*p*-tolylselenium dichloride with mercury diphenyl.

Summary

1. In carbon disulfide solution, mercury diaryls react with diarylselenium dihalides to form aryl mercuric halides, aryl halides and diaryl selenides.

2. In the fusion of mercury diaryls and diarylselenium dichlorides, aryl mercuric chlorides are produced, and these react with more diarylselenium dichloride to form the mercuric chloride double salt of a triarylselenonium chloride.

3. In acetone solutions, diarylselenium dibromides brominate the solvent, and diarylselenium dichlorides in the cold react as in carbon disulfide and when heated, as in the fusion reactions.

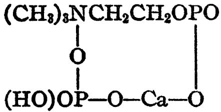
The Mono and Tricholine Esters of Orthophosphoric Acid[1,2]

BY ERNEST L. JACKSON

Of the three possible simple choline esters of orthophosphoric acid, the triester hitherto has not been reported and only the diester seems to have been obtained pure. Abderhalden, Paffrath and Sickel[3] described crystalline, apparently pure di-(choline bromide) phosphate which they prepared by the reaction of ethyl metaphosphate with choline bromide. The mixed ester, dimethyl mono-(choline chloride) phosphate, was prepared crystalline by Renshaw and Hopkins[4] while Langheld[5] reported the amorphous, impure chloroplatinate of ethyl mono-(choline chloride) phosphate and Abderhalden, Paffrath and Sickel[3] the sirupy, likewise impure ethyl mono-(choline bromide) phosphate. The present paper pertains to the mono and tricholine esters, particularly the preparation of the esters or a suitable derivative in high purity.

By heating choline chloride with a mixture of orthophosphoric acid and phosphorus pentoxide Schmidt[6] obtained a sirup which, by analogy with the reaction of choline chloride with sulfuric acid, he inferred to contain a phosphoric acid ester of choline. The further investigation of this reaction has now led to the preparation of the amorphous calcium salt of the monocholine ester (1)

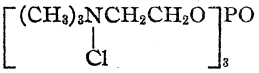


$$\begin{array}{l}(CH_3)_3NCH_2CH_2OPO(OH)\\ \qquad\quad | \qquad\qquad\qquad\quad |\\ \qquad\quad O \qquad\qquad\qquad\quad |\\ \qquad\quad | \qquad\qquad\qquad\quad |\\ (HO)OP{-}O{-}Ca{-}O\end{array}$$

I

, which, though free from choline, was contaminated with 3–4% of dicholine phosphate as shown by the isolation of its crystalline chloroaurate. Monocholine phosphate chloroaurate prepared from the calcium salt was crystalline, but contained a little impurity which could not be eliminated. The chloroplatinate, however, could be prepared pure and crystalline from the chloroaurate by removing the gold with finely divided silver[7] and forming the chloroplatinate from the resulting monoester. The pure chloroplatinate is suitable as a source of the monoester for pharmacological study as the platinum is eliminated readily by metallic silver and the monoester is stable in aqueous solution.

Trimethylamine condenses slowly with tri-β-chloroethyl phosphate either in toluene solution or without a solvent, but the products are sirups, probably mixtures consisting mostly of insoluble intermediate condensation products. Pure, crystalline tri(choline chloride) phosphate (II)



$$\left[\begin{array}{l}(CH_3)_3NCH_2CH_2O\\ \qquad\ \ |\\ \qquad\ Cl\end{array}\right]_3 PO$$

was prepared, however, by carrying out the reaction in anhydrous ethanol solution under selected conditions of temperature and concentration. When heated at 90° for two hours the pure triester, though showing no change in appearance and elementary analysis, acquires a considerably increased physiological activity,[2] evidently due to a partial conversion to a more active compound, perhaps through an intramolecular reaction with neurine chloride as a possible product. The triester yields readily a crystalline chloroaurate.

Experimental

Calcium Phosphato-ethyltrimethylammonium Phosphate (I).—A mixture of 12 g. of pure dry choline chloride, 8.4 g. of 100% orthophosphoric acid and 12 g. of phosphorus pentoxide was heated at 100° under reduced pressure for thirty minutes, the sirup stirred, the stirrer left in the mixture and the heating continued for thirteen hours. The glassy mass was dissolved in 150 cc. of cold water, the solution shaken with excess of calcium carbonate, some activated carbon added, and the solids filtered off and washed with water. The filtrate was neutralized to phenol red with calcium hydroxide solution, the calcium phosphate filtered off after adding some carbon, and the filtrate concentrated immediately under reduced pressure (bath, 60°) to about 100 cc., again neutralized to phenol red with calcium hydroxide solution, some carbon added and filtered off. The concentration was continued to a thin, colorless sirup which was poured slowly into 350 cc. of absolute ethanol, and the precipitated sirup stirred until completely solid and powdered. It was filtered off and washed with absolute ethanol; yield, 16–19 g. The amorphous, hygroscopic calcium salt was precipitated

[2] The preparation of the esters was undertaken at the suggestion of Dr. Maurice I. Smith in connection with his studies on the pharmacology of the phosphoric acid esters. The physiological action of the compounds, including triethyl and tri-β-chloroethyl phosphates, will be published by him in *Bull. Nat. Inst. of Health*, No. 165 (1935). The investigation was greatly facilitated by the analytical coöperation of Dr. E. Elvove and Mr. C. G. Remsburg of this Institute, to whom we express our thanks.

thrice from its solution in 20 cc. of water by ethanol. It was then free from choline,[2] but contained less than 5% of dicholine phosphate. The substance showed no hydrolysis[2] by *N* hydrochloric acid at 100° during fifty minutes.

Anal. Calcd. for $C_5H_{15}O_8NP_2Ca$: C, 18.79; H, 4.74; N, 4.39; P (ionizable), 9.72; P (total), 19.43; Ca, 12.55. Found (dried at 75° *in vacuo*): C, 18.85; H, 4.59; N, 4.17; P (ionizable), 11.65; P (total), 20.40; Ca, 12.73; Cl, 0.00.

Monocholine Phosphate Chloroaurate.—To 10.5 g. of thrice precipitated calcium salt dissolved in 50 cc. of cold 2 *N* hydrochloric acid was added an equimolecular amount of auric chloride in 50 cc. of the same solvent. The precipitate (0.9 g.) was filtered off, washed with cold 2 *N* hydrochloric acid and recrystallized twice from about forty parts of hot *N* hydrochloric acid (clusters of light yellow, short prismatic needles difficultly soluble in water); m. p. 271.5–272° (corr., decomp.). Its composition agreed with that of dicholine phosphate chloroaurate.

Anal. Calcd. for $C_{10}H_{27}O_4N_2PAu_2Cl_8$: C, 12.65; H, 2.87; N, 2.95; P, 3.27; Au, 41.59. Found (dried at 25° *in vacuo* over phosphorus pentoxide): C, 12.78; H, 2.80; N, 3.03; P, 3.27; Au, 41.40.

The principal product was the chloroaurate of monocholine phosphate which was obtained in fractions as homogeneous, long, yellow needles by repeated concentration of the filtrate under reduced pressure (bath, 50°); yield, 14.3 g. or 83%. The crude substance was recrystallized five times from 2 *N* hydrochloric acid, washed with cold water and dried at 80° *in vacuo;* m. p. 174–176° (corr.). The compound, though showing substantially the same analysis after another recrystallization, was somewhat impure. It is hygroscopic and easily soluble in water.

Anal. Calcd. for $C_5H_{15}O_4NPAuCl_4$: C, 11.47; H, 2.89; N, 2.68; P, 5.93; Au, 37.69; Cl, 27.11. Found: C, 12.56; H, 3.10; N, 2.91; P, 6.32; Au, 36.18; Cl, 26.03; Ca, 0.14.

Chloroplatinate.—An aqueous solution (30 cc.) of 2.5 g. of thrice recrystallized monocholine phosphate chloroaurate was shaken for a few minutes with 5 g. of finely divided silver,[7] the solids filtered off and the colorless filtrate concentrated under reduced pressure to a sirup, which was dissolved in 5 cc. of *N* hydrochloric acid and mixed with 33% excess of the theoretical chloroplatinic acid in 5 cc. of water. After adding ethanol to turbidity it was kept at 5° for several hours, the crystals filtered off, washed first with ice-cold 50% ethanol and then with absolute ethanol. A second crop was obtained by concentrating the filtrate under reduced pressure (bath, 50°) to about 5 cc. and adding ethanol to turbidity; yield, 1.7 g. or 92%. One recrystallization by dissolving it in 5 cc. of 0.5 *N* hydrochloric acid at 35–40° and adding 4 cc. of ethanol gave the pure chloroplatinate (1.3 g.) as clusters of orange-colored prismatic needles. For analysis the hygroscopic crystals were dried to constant weight at 25° *in vacuo* over phosphorus pentoxide; m. p. 207–208° (corr., decomp.).

Anal. Calcd. for $C_{10}H_{30}O_8N_2P_2PtCl_6 + 2H_2O$: H_2O, 4.44. Found:[8] H_2O, 4.28. Calcd. for $C_{10}H_{30}O_8N_2P_2PtCl_6$: C, 15.46; H, 3.90; N, 3.61; P, 7.99; Pt, 25.15; Cl, 27.41. Found:[9] C, 15.55, 15.59; H, 4.06, 4.07; N, 3.57, 3.65; P, 8.02, 8.13; Pt, 25.41, 25.67; Cl, 28.03.

Tri-β-chloroethyl Phosphate.—Sixty-four grams of phosphoryl chloride was added during twenty minutes to a mechanically stirred mixture of 106 g. of pure ethylene chlorohydrin and 125 cc. of dry carbon tetrachloride[4] at room temperature. After stirring for thirty minutes it was refluxed gently for sixteen hours, kept at 25° for two days, the carbon tetrachloride and a little ethylene chlorohydrin distilled off through a seven-bulb column (15 mm. at end) and the residue fractionated at 2–3 mm.; yield, 75 g. (60% on the chlorohydrin); b. p. 180–182° (2–3 mm.); $d^{20}{}_{20}$ 1.428. About 20 g. of product boiling above 215° (2–3 mm.) showed considerable decomposition on attempted distillation. Plimmer and Burch[10] reported about 12% yield, b. p. 140° (40 mm.) and *d* 1.39. The cause of the disagreement in boiling points is not apparent.

Anal. Calcd. for $C_6H_{12}O_4Cl_3P$: C, 25.22; H, 4.24; Cl, 37.26; P, 10.87. Found: C, 25.26; H, 4.39; Cl, 37.27; P, 10.69.

Tri-(choline chloride) Phosphate (Phosphato-tri-(ethyltrimethylammonium chloride)) (II).—A solution of 6.5 g. (0.11 mole) of trimethylamine and 10 g. (0.035 mole) of pure tri-β-chloroethyl phosphate in 12 cc. of anhydrous ethanol[11] was sealed at 0° and then kept at 30–33° for seven days, well-built prisms starting to separate after two to three days. After cooling to 0° the crystals were filtered off, washed with 8 cc. of cold isopropanol and dried at 25° *in vacuo* over calcium chloride; yield, 7.7 g. (48%). The filtrate, diluted with 25 cc. of isopropanol, gave on long standing at 5° about 0.3 g. of crystals. When dissolved in about six parts of absolute ethanol at 60° and decolorized with activated carbon, the triester crystallizes as colorless prismatic needles or elongated prisms in 80–85% yield with little, if any, alcoholysis. It is somewhat hygroscopic, is practically insoluble in benzene, chloroform and ether, difficultly soluble in warm isopropanol, soluble in warm ethanol and readily soluble in cold water to yield a neutral solution from which the chlorine is removed quantitatively by silver nitrate. Its decomposition point (incomplete) of about 245° (uncorr.) is not a suitable criterion of purity. Analyses of thrice recrystallized samples were essentially the same when dried to constant weight at 25° *in vacuo* over phosphorus pentoxide or at 90° *in vacuo*, but the physiological activity[2] was considerably increased by the two hours of heating at 90°.

Anal. Calcd. for $C_{15}H_{39}O_4N_3Cl_3P$: C, 38.90; H, 8.50; N, 9.08; Cl, 22.99; P, 6.70. Found: (dried at 25°) C, 38.68; H, 8.84; N, 8.97; Cl, 22.90; P, 6.85; (dried at 90°) C, 38.85; H, 8.68; N, 8.97; Cl, 22.76; P, 6.71.

Toluene was found unsuitable as a solvent in the prepa-

---

(8) Sample previously dried overnight at 25° *in vacuo* over calcium chloride.

(9) Prior to the determination of nitrogen (Kjeldahl) and phosphorus, the sample was digested for two hours with hot concentrated sulfuric acid and the platinum filtered off.

(10) Plimmer and Burch, *J. Chem. Soc.*, 284 (1929).

(11) It is important to use the specified proportions of tri-β-chloroethyl phosphate and ethanol. When 8 cc. of ethanol was used, the separation of a sirup with the crystals of the triester necessitated the interruption of the reaction after three days, removal of the crystals and dilution with ethanol. With 18 cc. the reaction time was considerably greater (twelve days) and the yield of triester was smaller (30%).

ration of the triester. Trimethylamine (6.5 g.) and tri-β-chloroethyl phosphate (10 g.) in 100 cc. of dry toluene, kept sealed at 25–30° for several days or at 78–80° for two days, gave a sirup. A solution of the sirup, prepared at 78–80°, in a mixture of isopropanol and ether yielded at 5° crystals (0.6 g.) which could be recrystallized from isopropanol (needles), but was not investigated further.

Chloroaurate.—The compound was precipitated by adding an aqueous solution (7 cc.) of 1 g. of pure triester to 10% excess of the calculated auric chloride in 10 cc. of water; yield, 2.7 g. It crystallizes from water (difficultly soluble) as clusters of short, yellow prismatic needles melting incompletely at 216° (uncorr.) and to a clear red liquid at 230°.

Anal. Calcd. for $C_{15}H_{39}O_4N_3PAu_3Cl_{12}$: C, 13.11; H, 2.86; N, 3.06; P, 2.26; Au, 43.07. Found (dried at 25° *in vacuo* over phosphorus pentoxide): C, 13.17; H, 2.88; N, 3.07; P, 2.28; Au, 43.20.

Summary

From the products of the phosphorylation of choline chloride with orthophosphoric acid and phosphorus pentoxide the amorphous calcium salt of the monocholine ester of phosphoric acid has been prepared free from choline but containing 3–4% of dicholine phosphate, a new chloroaurate of which is described. Monocholine phosphate chloroaurate prepared from the calcium salt was somewhat impure, but from it could be obtained the pure, crystalline chloroplatinate.

Trimethylamine condenses with tri-β-chloroethyl phosphate under appropriate conditions to give crystalline tri-(choline chloride) phosphate which yields a crystalline chloroaurate. An effect of heat on the pure triester is pointed out.

Improvements have been made in Plimmer and Burch's procedure for the preparation of tri-β-chloroethyl phosphate.

The Predominant Role of Association in the Dissociation of Simple Straight-Chain Sulfonic Acids in Water. I. Conductivity[1]

BY J. W. MCBAIN AND MARGARET D. BETZ

Among the simplest uni-univalent organic electrolytes are the straight-chain saturated alkyl sulfonic acids, RSO_3H, the higher members of which have been made for the first time and generously placed at our disposal by Prof. C. R. Noller and J. J. Gordon.[2] In a series of communications it will be shown that their behavior at great dilution is that of simple partially dissociated acids, but that in more concentrated solutions, such as from $N/20$ upward, a radical change takes place in their physical chemical properties, such as conductivity, freezing point and electromotive force.

This change is the opposite of that which the interionic attraction theory was set up to explain. It would appear to be due to association in the sense in which this term has so long been used in chemical science, as for example in describing the occurrence of double molecules in the vapor of acetic acid or in solutions of acetic and other acids in benzene. This association is not caused by Coulomb attraction of opposite charges, but it is due to van der Waals cohesive forces. It occurs even in spite of electrostatic repulsion, for it is very marked in the association of ions of like charge.

Since in all the more concentrated solutions the effect of association is so dominant as to submerge the ordinary behavior of interionic attraction, it must surely be a force of universal occurrence and a factor which is seldom negligible. This association must affect not merely ions but also the molecules from which they are derived. Since one of the authors introduced the conceptions of colloidal electrolytes and of neutral and ionic micelles more than twenty years ago,[3] it has been known that the group of colloidal electrolytes embraces more substances than the acids and bases put together.[4] However, it is not sufficiently recognized that colloidal electrolytes appear to be the rule rather than the exception in non-aqueous solutions and that even fairly simple substances in aqueous solution, such as

butyric acid[5] or potassium iodate,[6] partake of this behavior in measurable degree.

These sulfonic acids offer exceptionally favorable material for study on account of their ready solubility and complete freedom from hydrolysis. These hydrogen soaps are more colloidal than the ordinary alkali soaps of similar length of carbon chain.

Experimental

Macroscopic Observations on the Hydrogen Soaps.—The hydrogen soaps undecyl (C_{11}), lauryl (C_{12}) and myristyl (C_{14}), sulfonic acids, were in the form of very hygroscopic powders containing one molecule of water of crystallization. When added to water, the soaps form concentrated liquid crystal solutions which, when preparing the higher concentrations of isotropic solution, require several hours of heating at temperatures above 25° to redissolve completely in additional water. The highest concentrations of the sulfonic acids prepared in this manner were 1.13 N_w undecyl, 0.85 N_w lauryl, and 0.53 N_w myristyl. The more concentrated solutions of the undecyl and lauryl sulfonic acids were still stable at 0°. Myristyl sulfonic acid is less soluble and therefore above the freezing point of water has separated as an opaque white gel. As the temperature is raised, the myristyl sulfonic acid progressively dissolves, the curd becoming clearer and "melting" to a transparent solution at 15–16°. The sodium and potassium salts are so much less soluble that they require heating to 25 or 30°. All of the isotropic soap solutions froth freely, and undecyl and lauryl sulfonic acids yield a generous lather even at 0°.

Purest available potassium chloride and water (0.5×10^{-6} mhos) were used. Solutions were made up by weight and concentrations were determined by titration after being checked by refractive index with the Zeiss dipping refractometer with prism No. 1 and auxiliary prism. The readings in scale divisions were as follows.

Sulfonic acid		
Undecyl	$C_{11}H_{23}SO_3H$	$15 + 80\,m$ at 19.0°
Lauryl	$C_{12}H_{25}SO_3H$	$15 + 80\,m$ at 19.4°
Myristyl	$C_{14}H_{29}SO_3H$	$15 + 99\,m$ at 19.0°

As is well known, association does not much affect the value of molar refraction in solution.

The solubilities in grams per 100 g. of water of the calcium sulfonates were very approximately determined as follows.[7]

	Undecyl	Lauryl	Myristyl
Calcium	0.2	0.02	0.02

The densities at 25.00/4° were measured by Dr. M. E. L. McBain as follows, where molality, $m = N_w$ or weight normality.

Undecyl		Lauryl		Myristyl	
Concn., N_w	Density	Concn., N_w	Density	Concn., N_w	Density

Conductivity measurements were made with the Grinnell Jones–Dykes type of bridge, supplied by Leeds and Northrup, with an oil thermostat at 25 ± 0.01° and the H-shaped cell of McBain and Titley with cell constant 13.239. The conductivity of lauryl sulfonic acid solutions at 25° was unaltered by lapse of time or by previous heating and quick cooling.

The conductivity data are recorded in Tables I, II and III. In column 4 is given the Arrhenius ratio μ_v/μ_∞ where however μ_∞ is taken as 378 for the most dilute solutions below and including

0.01 N_w. For all the more concentrated solutions, as will be explained later, μ_∞ was taken as 426; probably (see later) this should have been increased to 546 in the most concentrated solutions, which would have decreased the final values of the ratio by about one-fourth.

During the past few years, it has become customary to calculate the degree of dissociation of uni-univalent electrolytes, $\alpha = \mu_v/\mu_\epsilon$, following the method of Sherrill and Noyes and MacInnes as developed by Shedlovsky, Davies, and others, upon the basis of the Debye–Hückel–Onsager and other equations. Incidentally, several authors have thus found that certain electrolytes, such as potassium nitrate or the potassium iodate already referred to, are not as fully dissociated as potassium chloride.

From the meager data available for large organic ions, we have taken the value for μ_∞ as $350 + 28 = 378$, where hydrogen ion accounts for 96.2% of the total. The initial Onsager slope for complete dissociation is therefore $\mu_\epsilon = 378 - 145.7\sqrt{N_v}$.

These conductivity data are plotted in Fig. 1. The curves are of the same form as those which have become familiar for ordinary soaps such as potassium laurate. The initial parts of the curves show that dissociation is definitely not complete and that the observed values for $\alpha = \mu_v/\mu_\epsilon$ correspond to approximate dissociation constants of the order of K = 0.01, 0.05 and 0.07. This compares with the value 0.3 for potassium laurate at 18°, that of hydrochloric acid and potassium chloride being taken as infinity. The values are only approximate on account of the associative factors which are beginning to assert themselves with increase in concentration. Figure 1 also includes for comparison the conductivity curves which are exhibited by fully dissociated uni-univalent and uni-decivalent electrolytes for 100% dissociation. In the latter case, according to Mukherjee,[8] the numerical factor in the final term of the Onsager equation is increased to 2925 (instead of our 145.7), and for a uni-centivalent electrolyte to 40,572. (That is, there would be no observable μ_v in all solutions accessible to measurement.) It is quite obvious that although the actual data lie below the limit for uni-univalent electrolytes, they all very greatly exceed the values possible for an ionic micelle regarded as a polyvalent ion in the ordinary sense. They show that the treatment of the ionic micelle as an ordinary polyvalent ion is wholly insufficient.[9]

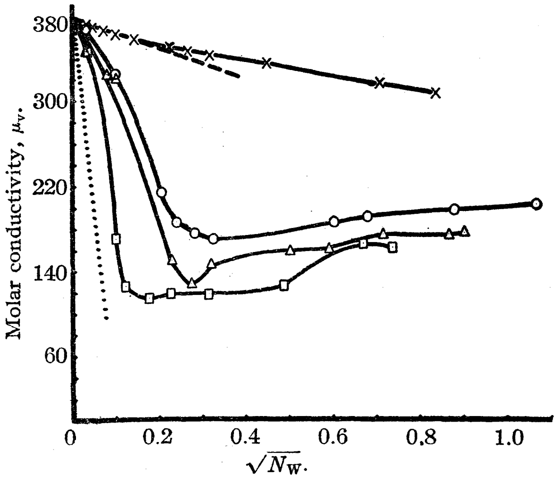

Fig. 1.—Molar conductivity: ×, hydrochloric acid "International Critical Tables"; ○, undecyl sulfonic acid; △, lauryl sulfonic acid; □, myristyl sulfonic acid. Dashed line indicates the slope for 100% for a uni-univalent electrolyte; dotted line indicates the slope for a uni-decivalent electrolyte.

The Behavior of these Acids at Ordinary Concentrations.—The most striking and remarkable feature exhibited by the conductivity of our sulfonic acids is the minimum at 0.1, 0.075, and 0.031 N_w solutions of undecyl lauryl, and myristyl, respectively. After passing through a minimum in these moderately dilute solutions, the conductivity rises markedly with increase of concentration. Such behavior in aqueous solution is unparalleled except by the higher sodium

(9) Thus, this suggestion thrown out by Van Rysselberghe and others is inappropriate since it is not in accordance with experiment [P. J. Van Rysselberghe, *J. Phys. Chem.*, **38**, 645 (1934)]. Similarly, the discussion of J. L. Moilliet, B. Collie, C. Robinson and G. S. Hartley [*Trans. Faraday Soc.*, **31**, 120 (1935)] is crippled by the same invalid assumption and also by the failure to recognize the existence of undissociated molecules and of their association products, the neutral micelles. Again, the conductivity, freezing point and electromotive force curves for soaps and for these sulfonic acids are not in accord with the simple mass action equation [compare R. C. Murray and G. S. Hartley, *ibid.*, p. 186].

and potassium soaps studied by McBain and collaborators[10] and the alkyl sulfates (salts and free acid) recently studied by Lottermoser and Püschel which closely parallel our findings.[11]

Figure 1 emphasizes by comparison with the initial Onsager slope the increasingly excellent conductivity of these acids in concentrated solution. It is enormously greater than that consonant with the behavior of a weak electrolyte as exhibited in the very dilute solutions, and still more so with the increasing weakness indicated in the slightly less dilute solutions before the minimum in conductivity is attained.

The conductivity rises above the minimum by 18, 36, and for myristyl no less than 45%. The old hypothesis of McBain and Salmon, which appears still valid, is that simple anions of low mobility associate to form ionic micelles of high mobility in accordance with Stokes' law, since they have retained their electrical charges. However, it is here necessary to assume an extraordinarily high mobility for the ionic micelle, rising to that of the hydroxyl ion for each charge on the ionic micelle. If the equivalent conductivity of the charges of the ionic micelle had been raised only to that of the chlorine ion, the maximum increase of conductivity would be the inadequate value 424/378 = 1.125 fold. That found by McBain and Williams[2] for acetyl sulfonic acid at 90° was likewise larger, namely, 1.25 fold. The existence of this remarkable enhancement of conductivity is therefore beyond dispute.

The alternative hypothesis adopted by Franklin and Kraus for solutions in liquid ammonia, to the effect that a large portion of the current may be borne by free electrons and be semi-metallic in nature, seems unnecessarily bold for these aqueous solutions. Also, the recent hypothesis of Fuoss and Kraus[12] applies only to minima in solvents of low dielectric constant and of very low dissociating power.

The Debye–Hückel theory was set up to explain why ions show less conductivity than that which corresponds to their intrinsic mobility. We have here the opposite phenomenon, a great and increasing conductivity in spite of inter-ionic attraction.

The intrinsic mobilities of ions in strong aqueous solutions are, however, really high. For example, in the diffusion of potassium chloride where the effects of interionic attraction almost completely eliminate themselves, the potassium and chloride ions actually move much faster than at infinite dilution.[13] The differential or "instantaneous" diffusion coefficients are far larger in concentrated solutions of potassium chloride than they are in pure water.

Equally relevant is the demonstration by McBain and Van Rysselberghe[14] by means of migration data that in all concentrated solutions containing even one ion that is more than univalent, complex anions are formed in large amount. Similarly, by means of ultra-filtration, McBain, Kistler and McClatchie[6] have shown that moderate concentrations of such salts as cadmium iodide or potassium or sodium iodates contain appreciable proportions of constituents so large that they are held back by an ultrafilter that is permeable to all simple ions and molecules.

A high conductivity per electrical charge must always occur where the linear velocity in cm./sec./volt/cm. is exceptionally high, as is the case with air bubbles and suspended hydrocarbons.[15] When further, the number of charges is equal to the number of chemical equivalents in the particle, we observe a very high total conductivity as in the present case.

Freezing point experiments to be described do not allow of any alternative hypothesis of increased relative concentration of hydrogen ion in stronger solutions, nor do they admit of measurable amounts of simple free molecules; nor is it apparent how a Grotthuss mechanism can be invoked in explanation of our data.

The enhanced mobility of the ionic micelle is not due merely to close packing as compared with the original ions, it is also due to the stripping off of the water of hydration from those ions in order that they may come into contact and be close packed and anhydrous in the interior of the particle.

Finally, the association here irresistibly dem-

---

[10] However, in 0.0025 *N* potassium, sodium, lithium and calcium (but not strontium nor strychnine) salts of gum arabic, D. R. Briggs observed a minimum [*J. Phys. Chem.*, **38**, 872 (1934)].

onstrated is real association, not the electrostatic clustering of ions in Bjerrum's well-known modification of the interionic theory that currently passes under the name. It is association of like parts of the uncharged portions of the molecules and ions under the influence of van der Waals forces.

Since neutral molecules are admittedly present in large proportion in dilute solutions, it would be very strange if these too did not associate with each other to form neutral micelles. Indeed, if it occurs with the ions in spite of electrostatic repulsion, it must be far more complete with the similar neutral molecules. For ordinary soaps, McBain and collaborators have deduced the presence of practically uncharged neutral micelles, using several distinct lines of evidence, none of which can otherwise be even semiquantitatively explained—ultrafiltration, ultracentrifuge and electrolytic migration.

Surely, if association can play so predominant a role in these simple cases, it must be of practically universal occurrence and only seldom completely negligible.

Summary

In dilute solutions, the straight chain sulfonic acids are simple partially dissociated electrolytes.

A remarkable transformation sets in at about $N/20$ where the conductivity is at a minimum, increasing with concentration by 18, 36 and 45% for the three sulfonic acids here studied.

The only explanation so far found is association of *like* ions to form ionic micelle, whose *equivalent* conductivity in concentrated solutions attains to that of the hydroxyl ion.

Association is so dominant that it completely submerges the ordinary features of interionic attraction.

Association in the Dissociation of Simple Straight-Chain Sulfonic Acids in Water. II. Freezing Point[1]

BY J. W. MCBAIN AND MARGARET D. BETZ

Conductivity has shown that in dilute solution the sulfonic acids are simple and moderately weak, but that with increasing concentration a transformation takes place, due to formation of ionic micelles whose equivalent conductivity rivals that of the hydroxyl ion itself. Here we present freezing point data which likewise show this great influence of association. The molal freezing point lowerings fall rapidly in very dilute solution, pass through a minimum, and steadily increase with rising concentration—again the opposite effect from such factors as usually determine dissociation constant and interionic attraction. Association of like ions, overcoming Coulomb repulsion, produces ionic micelles. Neutral molecules associate even more readily to form neutral micelles.

Freezing point measurements of free sulfonic acids are untroubled by the hydrolysis whose effects are often disturbing with ordinary soaps.[2] Myristyl sulfonic acid, like most of the soaps, is too insoluble for study at 0°. The lowering observed with sulfonic acids, like that with octoates, decoate, laurate and oleates, is readily measurable, but except in concentrated solution, much less than that for an acetate or hydrochloric acid.

Experimental Data

More concentrated solutions were investigated by the Beckmann method, which of necessity gives too low a freezing point, since a solution cannot continue to freeze except below its freezing point; however, undercooling was confined to 0.10°. More dilute solutions were measured by the Richards method, in some cases using a 0° room and a Beckmann thermometer, in others using a platinum resistance thermometer with a Leeds and Northrup Mueller bridge and high sensitivity type H galvanometer of 17 ohms resistance, reading more closely than 1/10,000

[a] Experiments by M. E. L. McBain.

The Osmotic Coefficient, g.—Activity coefficients have been so commonly employed, especially in this country, that there appears to be a tendency to forget that the osmotic coefficient of Bjerrum, g, and the i value of van't Hoff have exactly equal thermodynamic validity and significance. Bjerrum's g is identical with van't Hoff's i/v where v is the total number of ions producible at infinite dilution from one formula weight. g is $\Theta/v\lambda m$ and is also equal to the $1-j$ of Lewis and Randall. Following Guggenheim's notation[4]

$$\ln 1/N_0 f_0 \equiv g \ln 1/N_0 = L_F^\circ \Theta/RT^{\circ 2} = gm$$

and for freezing points of aqueous solutions within the experimental error even of the best determinations, $g = \Theta/\lambda m$. $N_0 \text{ d} \log f_0 = -N_S \text{ d} \log F_S$.

For ideal solutions, g, like the activity coefficient of the solvent, f_0, and that of the solute, f_S, becomes unity. However, as we have just seen, g varies directly with the actual lowering of freezing point just as directly as m, while the change in the activity coefficients is far more indirect.

The relation between osmotic coefficient g and activity coefficient f is very similar to that between concentration of the hydrogen ion and pH in that the first varies directly when the second is changing as the inverse logarithm.

So intent have workers in this field been during the last dozen years upon discussing the interionic attraction explanation of the deviation of electrolytes from the behavior of ideal solutions, that it seems to have been commonly forgotten that the actual freezing point lowering of hydrochloric acid never deviates from that of a truly ideal solution by more than 6% over the whole range of concentration from infinite dilution to 1 molar. Indeed, according to the "International Critical Tables," the greatest deficit is that for 0.1 *N* solution, amounting to only 5.2%. Thereafter, it approaches more closely to the lowering of an ideal solution, equaling it below 0.6 *M* and surpassing it by 6% in 1 *M* solution. Similarly, in 1 *M* solution, the lowering for sucrose is 10.9% above that of an ideal solution and that of potassium chloride only 12.5% below the ideal value.

Nevertheless, the numerical scale in which activity coefficients are expressed exaggerates these deviations, making the activity coefficients for these three solutes in 1 *M* solution 0.8404,[5] 1.221 and 0.601,[6] respectively. It is interesting that the activity coefficient of hydrochloric acid should be so much less than unity when its actual freezing point lowering exceeds that of an ideal solution. Activity is a partial quantity and possesses no more *direct* significance than does any other partial quantity such as partial specific

volume. For example, as shown by Lewis and Randall, the partial specific volume of magnesium sulfate is negative, which has very indirect connection with its real positive volume.

The Graphs of $j/\sqrt{m}$ Against $\sqrt{m}$.—The $j/\sqrt{m}$ graphs of Lewis and Randall here assume a characteristic form, decidedly different from that either of weak or of strong electrolytes (see Fig. 1). All crystalloidal electrolytes, from the strongest, like potassium chloride, through progressively weaker ones, like acetic acid, to the weakest, such as sucrose, must lie between the graph marked KCl and $K = 0$, as Randall and Allen[7] also have shown. For $K = 1$, the graph is a straight line. For weaker electrolytes, the height of the "hump" is a measure of the weakness and it rises to a value of 46 for acetic acid at $m = 10^{-5}$, all curves approaching the same limit as KCl for infinite dilution.

In very dilute solutions, the sulfonic acids exhibit this normal behavior of weak electrolytes and they are drawn with the slopes corresponding with the conductivity results. However, the heights of the maxima, 2.6 and 2.8 for the sulfonic acids, are those of a still weaker electrolyte for which $K = 0.005$; but this maximum does not lie at the position for such a weak electrolyte, namely, $m = 0.01$, but in the much stronger solution $m = 0.05$. Most striking and significant however is the disregard shown for the theoretical limiting curve $K = 0$. The graphs before reaching their maximum cut sharply across this boundary into the region forbidden for crystalloids whether electrolytes or not. Hence colloid is present in large quantity.

It is not enough to assume that the undissociated acid associates to form a colloid because of the very high conductivity which forces us to recognize the anions also as colloid. On the other hand, as will be shown in the next paper of this series dealing with electromotive force, it is not enough to assume that only the anions are colloid. Both molecules and anions must be colloidal for the total freezing point lowering is far less than that corresponding to the hydrogen ion indicated by the usual method of calculating e. m. f.

Cetyl sulfonic acid exhibits at 90° a similar high value of $j/\sqrt{m}$, apparently rising to a maximum of 2.5 at $m = 0.01$,[8] although this is in a dilution where the vapor pressure method becomes inaccurate. On the other hand, not even the highest soaps of sodium or potassium yield at 90° a value exceeding 1.2. For the laurates, it is only 0.64 and 0.67 at 90°, but at 0° the curve rises to a maximum of 1.65 for potassium laurate at $m = 0.1$ with the sudden nearly vertical dip in more dilute solutions which we have here found for the sulfonic acids.

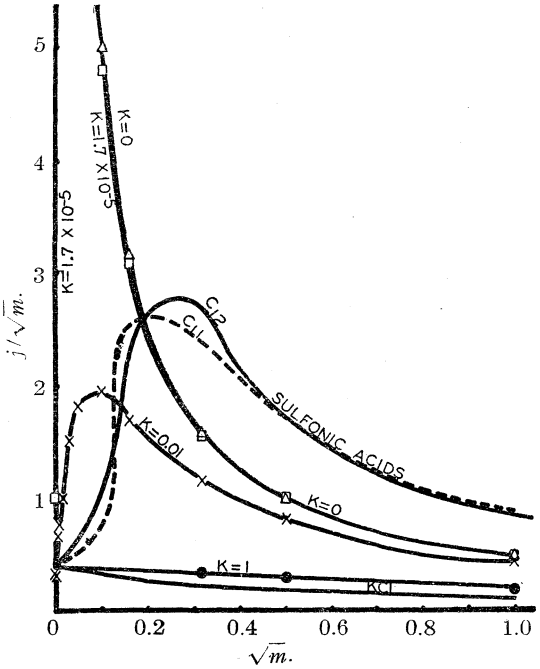

Fig. 1.—$j/\sqrt{m}$ graphs for sulfonic acids, showing their very different dehavior from that characteristic of either strong or weak electrolytes except in very dilute solution.

Discussion

Figure 2 exhibits the value of g of the sulfonic acids in comparison with hydrochloric acid. It will be noted that they too pass through a minimum and rise again with increase of concentration to the extent of 25 and 26%, respectively.

Figure 3 compares the activity coefficients[9] of lauryl, which is very similar to that of undecyl, with those of hydrochloric acid and of potassium laurate. The latter would appear to refute the suggestion of Linderstrøm-Lang[10] that soaps might be regarded as simple electrolytes 100% dissociated provided that the cations become lost as far as osmotic effects are concerned, upon

---

[7] M. Randall and C. Allen, This Journal, **52**, 1818 (1930). Dissociation constants deduced by their rule from freezing point data would not be legitimate or free from ambiguity for these substances.

[8] J. W. McBain and R. C. Williams, *ibid.*, **55**, 2254 (1933).

[9] Compare the discussion of J. W. McBain and M. M. Barker, *Trans. Faraday Soc.*, **31**, 149 (1935).

[10] K. Linderstrøm-Lang, *Compt. rend. trav. lab. Carlsberg*, **16**, No. 6, 1-47 (1926); for other incompatible evidence see J. W. McBain, This Journal, **50**, 1636 (1928).

finding themselves among the comparatively long anions (at most only 17 Å. long, but probably far less[11] or even spherical). It would further be necessary to assume that the anions are lost among each other and that ordinary ions added are not lost since, as is well known, they exert in soap solutions the full osmotic effects that they do in water. Since this is true for added potassium, sodium or hydrogen ions, it must be equally true of the same ions already present in the soap itself. In Fig. 3 for $m = 0.048$, $m = 0.22$, the activity coefficient of potassium laurate is almost that of the highly dissociated hydrochloric acid, whereas that of lauryl sulfonic acid with identical length of hydrocarbon chain is much less than half as great. According to his suggestion, the results should have been identical if only simple ions are present in both cases instead of differing by 2.5-fold.

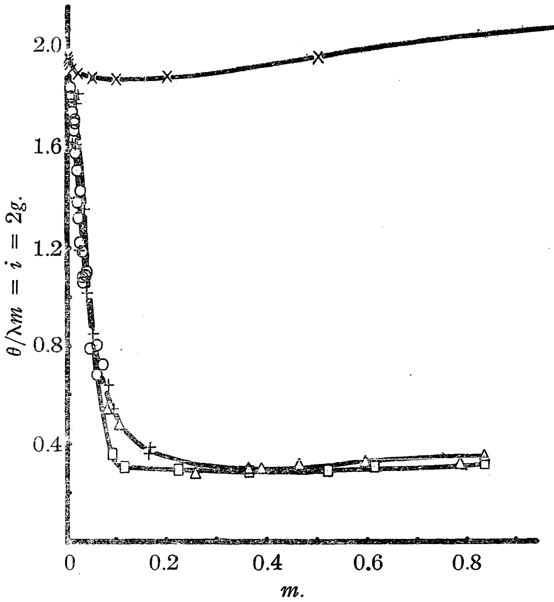

Fig. 2.—Osmotic coefficients of hydrochloric acid (×) and of undecyl (△) and lauryl (□) sulfonic acids.

It is obvious from the figures that the ionic micelle does not behave like a polyvalent ion whose charges are coincident. McBain,[12] in accordance with the suggestion of Bjerrum in 1923 and later corroborated by Scatchard and Kirkwood, explained this as being due to the distance apart of like charges on a single ionic micellar particle being greater than the average distance between ordinary ions in ordinary solutions such as potassium chloride. Simms,[13] whose work has not been accorded the attention it deserves for its fundamental importance in colloid phenomena and in the application of interionic attraction theory as the basis of electro-kinetics, has discussed the theory of widely spaced charges. He, in agreement with *ad hoc* calculations of Debye, formulated the influence of ionic strength for the two extreme cases; first where polyvalent charges coincide as in the Debye–Hückel theory of ordinary ions, and second where molecules or particles are polyvalent but with widely separated charges of like sign and behave effectively as univalent ions.

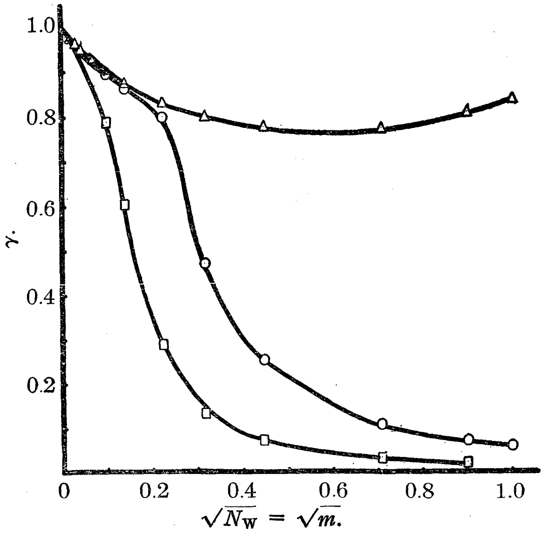

Fig. 3.—Activity coefficients of lauryl sulfonic acid (□), potassium laurate (○) and hydrochloric acid (△).

Summary

The osmotic coefficients of undecyl and lauryl sulfonic acids pass through a minimum in dilute solution, rising again with concentration by about 25%.

The graphs of $j/\sqrt{m}$ against $\sqrt{m}$ exhibit a highly characteristic form which departs strikingly from that of strong electrolytes or that for any simple weak electrolyte or non-electrolyte.

The only consistent interpretation of all the data is that whereas in dilute solutions they are simple moderately weak electrolytes, with increased concentration molecules and ions associate into neutral and ionic micelle, respectively, but that ionic micelles, owing to the wide spacing of their charges, have the ionic strength similar to uni-univalent electrolytes.

Straight-Chain Sulfonic Acids in Water. III. Electromotive Force[1]

BY J. W. MCBAIN AND MARGARET D. BETZ

Before attempting to determine concentration of hydrogen ion using a hydrogen electrode separated from a 0.1 N calomel electrode by a 3.5 N potassium chloride bridge, it is advisable to refer to the standard data on hydrochloric acid[2] and to compare them with the predicted values from $E = E_0 + E_D + 0.05915 \log 1/N_w f_H$ at 25°.

E_0 has been shown by Guggenheim and Schindler[3] to be equal to 0.3337 volt. E_D is calculable from the two extreme formulas, that of Henderson for a diffuse boundary

$$E_D = \frac{-RT}{F} \frac{C_1(U_1 - V_1) - C_2(U_2 - V_2)}{C_1(U_1 + V_1) - C_2(U_2 + V_2)} \log \frac{C_1(U_1 + V_1)}{C_2(U_2 + V_2)}$$

where $-RT/F = -0.05915$; $C_1 = C_{KCl} = 3.5$; $U_1 = 73.50$; $V_1 = 76.32 = V_2$; $C_2 = C_{HCl}$; $U_2 = 349.72$; and the transcendental equation of Planck for a sharp boundary $E_D = 0.05915 \log \xi$ where ξ is defined by the equation

$$\frac{\xi C_1 V_1 - C_2 V_2}{C_1 V_1 - \xi C_2 V_2} = \frac{\log (C_1/C_2) - \log \xi}{\log (C_1/C_2) + \log \xi} \times \frac{\xi C_1 - C_2}{C_1 - \xi C_2}$$

which may be solved by a short series of approximations. Both formulas neglect the actual laws of diffusion as revealed experimentally and in particular the acceleration, retardation and collision[4] effects exerted by different diffusion columns upon each other, which may even reverse the direction of diffusion.

It is interesting to note the large values of computed diffusion potentials and the minima and changes of sign in Table I. The familiar Bjerrum correction, subtracting values for saturated and half saturated salt bridges from each other, is not well supported by the data of the table, for the two formulas differ from each other and the last two columns of the table likewise differ. For dilute solutions, the Henderson formula agrees with the Bjerrum value within one millivolt if the Scatchard value for KCl/KCl be adopted, but then the Planck equation deviates from Bjerrum by +1 to −1.5 millivolts. The deviation for normal acid is very large in all cases.

.0001	5.0	4.6	− .4	3.6	2.9	− .7
.0000001		7.4			5.7	

In the opposite direction come the diffusion potentials of 3.5 KCl/0.1 KCl, 1.72 millivolts from the Henderson formula, 2.7 from the Cummings modification; 2.4 to 2.7 Scatchard,[3] 1.85 Guggenheim and Schindler,[3] and for 1.75 KCl/0.1 KCl, 1.38 by the Henderson formula. $n_{KCl} = 0.510$ from $m = 0$ to 0.5.

Our e. m. f. values for hydrochloric acid as compared with the best data for the nearest round concentrations are 0.991 N_v 0.3400 (0.3427, 0.3423); 0.0981 N_v 0.4010 (0.4020, 0.4012, 0.4010, 0.4004, 0.4000, 0.3998, 0.3995); 0.00972 N_v 0.4584 (0.4582, 0.4579); 0.000962 N_v 0.5165; 0.0000952 N_v 0.5739 volt.

f_{HCl} is taken from the calculations of Randall and Young.[5] If the assumption is made that $f_{H^+} = f_{HCl} = f_{Cl^-}$, we are able to compare the computed values with the best observed values for e. m. f. of hydrochloric acid in Table II, which shows a discrepancy of no less than 10 millivolts for N hydrochloric acid. Either the activity of the hydrogen ion in hydrochloric acid solution has been very greatly overestimated or the diffus-

sion potential is very different from that calculated from either the Planck or Henderson formula. The e. m. f. data for more dilute solutions agree with the computed values only within 2 millivolts.

E. m. f. Data for Sulfonic Acids and their Mixtures with Hydrochloric Acid.—Before presenting the e. m. f. data for the sulfonic acids themselves, we give Table III to show that as a first approximation the addition of hydrochloric acid to water and to a solution of sulfonic acid produces the same effect upon e. m. f. In other words, the activity of hydrochloric acid is not profoundly affected by the presence of the ionic micelle of the sulfonic acid. This is a result of general significance confirming similar previous findings with soaps and cetyl sulfonic acid, for it would indicate that in all mixtures containing polyvalent organic compounds or any other ions or particles where the charges are not concentrated in a point the effect of multivalence almost wholly disappears. Ordinarily the Debye–Hückel theory would postulate an ionic strength sufficient almost completely to obliterate the lowering of freezing point or the production of e. m. f. by any univalent ions present. Hence the principle of ionic strength as regards valency definitely does not apply; even the data for *p*H for the sulfonic acid solutions alone would serve to substantiate this important truth.

Since it is difficult exactly to predict what the hydrogen-ion concentration of a mixture of colloidal electrolytes with hydrochloric acid should be, we have inserted as a guide the last two columns as a comparison with the observations. One gives the mean of the two concentrations before mixing and the other assumes that the weight normality of the hydrogen ion referred to the solvent water in each of the separate solutions is maintained constant apart from the actual increase in the amount of water present; that is, that the degree of dissociation of neither sulfonic acid nor hydrochloric acid nor their activities is affected by mixing. Upon referring to the table, it will be seen that the concentration of hydrogen ion observed, with two exceptions, actually ex-

ceeds both of these values. The acidity of the mixture and the activity of the hydrogen ion is greater than that predicted, even though we have completely ignored in the computation any driving back of the dissociation of the incompletely dissociated colloidal electrolyte and also any effect of valency. Apparently, both of these items are insignificant in comparison even with the relatively minor effect of hydration.

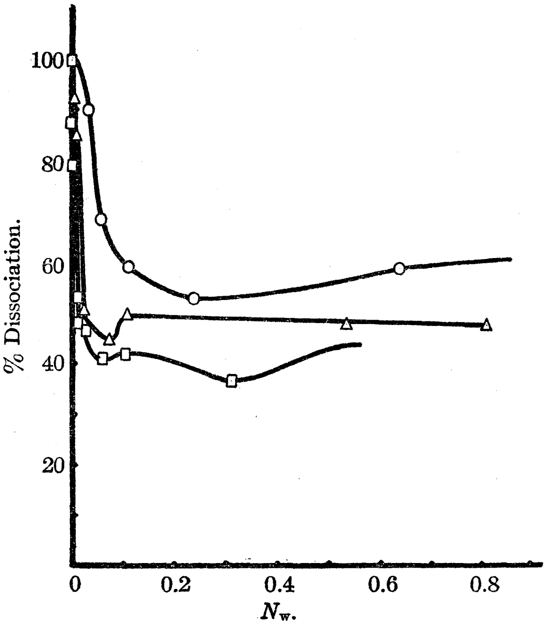

Fig. 1.—Degree of dissociation of undecyl (○), lauryl (△), and myristyl (□), sulfonic acids at 25°.

The method of calculation of hydrogen-ion concentration used in Table II is justified by its results, especially in view of the foregoing discussion of diffusion potentials. What we have done is to assume that the activity of the hydrogen ion is the same in solutions of hydrochloric acid as in solutions of sulfonic acids or their mixtures with hydrochloric acid that give the same e. m. f. This assumes equality of diffusion potential in both cases and also 100% dissociation of hydrochloric acid. We therefore plotted the best values for e. m. f. of hydrochloric acid against the logarithm of the concentration N_w and read off the concentration of hydrochloric acid and therefore of hydrogen ion responsible for each value of e. m. f. observed in all further experiments. The data are given in Table IV and the degrees of dissociation shown in Fig. 1. Less accurate data for 0° are given in Fig. 2, where if anything the hydrogen-ion concentrations appear greater.

Summary

Existing e. m. f. data for hydrochloric acid with a 3.5 N potassium chloride bridge have been compared with values computed from diffusion potentials and the activity coefficients of hydrochloric acid on the assumption that $f_H = f_{Cl} = f_{HCl}$. Discrepancies are noted which become very large, rising to 10 millivolts for 1 N hydrochloric acid.

Hydrochloric acid added to these colloidal electrolyte solutions of sulfonic acids produces slightly more effect upon e. m. f. even than it does in water, showing that the ionic micelles cannot be regarded as equivalent to polyvalent ions in which the charges are concentrated in one point.

In very dilute solution, the sulfonic acids behave like weak electrolytes and the degree of dissociation rapidly falls, but in more concentrated solution remains almost constant or tends to rise again.[6]

---

(6) Still larger readings in the most concentrated solutions are robbed of significance because precipitate forms between the sulfonic acid and the salt bridge and they change rapidly with time.

Straight-Chain Sulfonic Acids in Water. IV. Comparison of Results, and So-called "Hammarsten Effects"

BY JAMES W. MCBAIN

Colloidal electrolytes were discovered through comparison of conductivity with osmotic coefficient. Preceding parts of this series have shown that undecyl, lauryl and myristyl sulfonic acids, although conforming in dilute solution to the behavior of a simple half weak electrolyte, form the ionic micelle and neutral micelle characteristic of colloidal electrolytes in all stronger solutions. Further significant results follow from the comparison of these three kinds of data for the solutions between 0.1 and 1.0 N where the graphs tend to rise with concentration. The data are collected in Figs. 1, 2 and 3.

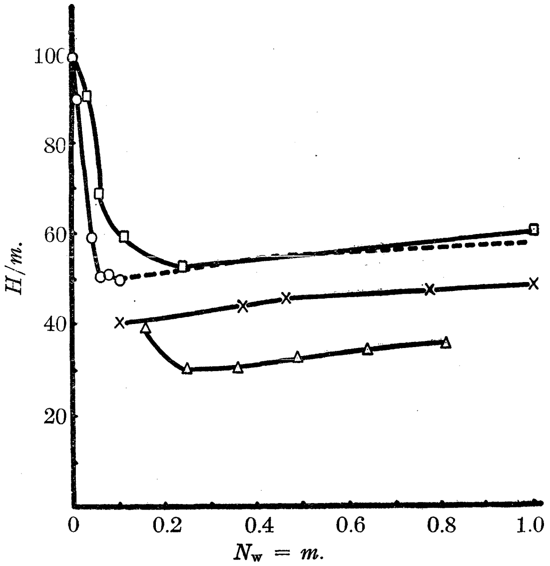

Fig. 1.—Hydrogen-ion concentration of undecyl sulfonic acid: □ is e. m. f.; ○ is conductivity, $100\mu\nu/\mu_\epsilon$; × is Arrhenius ratio, $100\mu/\mu_\infty$; △ is freezing point.

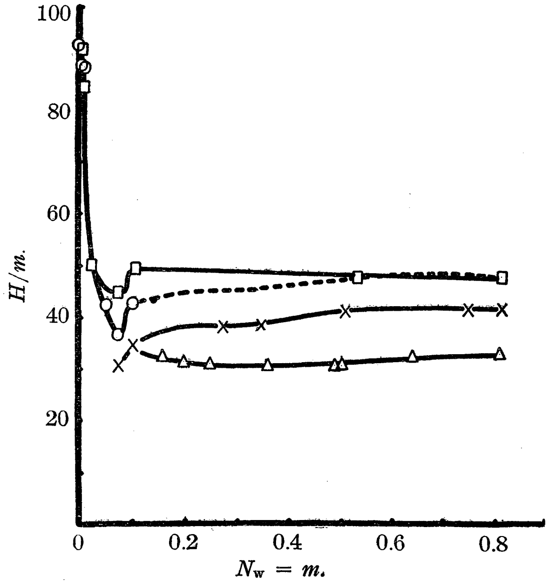

Fig. 2.—Hydrogen-ion concentration of lauryl sulfonic acid: □ is e. m. f.; ⊙ is conductivity, $100\mu\nu/\mu_\epsilon$; × is Arrhenius ratio, $100\mu_T/\mu_\infty$; △ is freezing point.

Before comparing the graphs on each figure, it is necessary to recall how they arise. Those for e. m. f. call for no comment, except that we have omitted the most concentrated solution for myristyl sulfonic acid on account of precipitation at the salt bridge. Those for undecyl sulfonic acid, judging from the dilute solutions, appear somewhat too high.

The first part of the conductivity curve, with points marked by circles, is the degree of dissociation according to the modern ionic attraction theory; but it passes through a minimum and leaves thereafter no basis for the calculation, since the results are already affected by the transition from simple electrolyte to colloidal electrolyte. Below and parallel to the last two circles lie the crosses representing Arrhenius conductivity ratios, $\mu v/\mu_\infty$ (where $\mu_\infty = \mu_{\mathrm{Cl}}$) showing how much is the dual effect of interionic attraction and of the assumption that hydrochloric acid is fully dissociated. The graph of circles is continued by us as a dashed line parallel to the crosses. This gives us an approximate value for the hydrogen-ion concentration, on the assumption that the steadily increasing correction upward for interionic attraction is balanced by the steadily increasing correction downward due to the steady increase in mobility of the ionic micelle from that of chloride ion to that of hydroxyl ion.

It is to be noted that these two curves for concentration of hydrogen ion or degree of dissociation practically coincide. Within the experimental error, conductivity and electromotive force have given the same result. The concentration of hydrogen ion increases faster than the total concentration. The degree of dissociation —doubtless into a changing product—increases with concentration, contrary in appearance to Le Chatelier's principle.

As regards freezing point lowering, there are only two curves because of the insolubility of myristyl sulfonic acid below 15°. In dilute solution they have no direct significance on this diagram because freezing point counts all molecules and ions, not merely hydrogen ion. Only after the transition to colloidal electrolyte is complete does freezing point measure hydrogen ion alone, because no simple molecules and no simple ions other than hydrogen ion are present.

We may therefore for these more concentrated solutions calculate the degree of dissociation of the total sulfonic acid into hydrogen ion and corresponding equivalents of ionic micelle by making use of exactly the same assumptions that we have employed in calculating e. m. f. If we assume that $f_{\mathrm{H}^+} = f_{\mathrm{Cl}^-} = f_\pm$ for hydrochloric acid, and if we assume that the activity coefficient of the hydrogen ion from the sulfonic acid is identical with that of hydrogen ion in hydrochloric acid solution containing exactly the same concentration of hydrogen ion, we need only compare the actual lowering of freezing point, Θ, of the sulfonic acid with one-half the lowering observed for solutions of hydrochloric acid itself, as recorded in "I. C. T.," in order to identify the concentration of hydrogen ion causing the whole of the freezing point lowering of the sulfonic acid and causing exactly one-half the lowering in the hydrochloric acid solution. In other words, we have assumed that the effect of interionic attraction upon hydrogen ion in the sulfonic acid solution is exactly the same as in hydrochloric acid solution of the same actual concentration of the hydrogen ion. We find per cent. dissociation at once by dividing this concentration so obtained by the molality of the sulfonic acid solution. In dilute solutions, where the colloidal electrolyte is breaking down into a simple electrolyte, this relation can no longer hold and the results are not included in the figures.

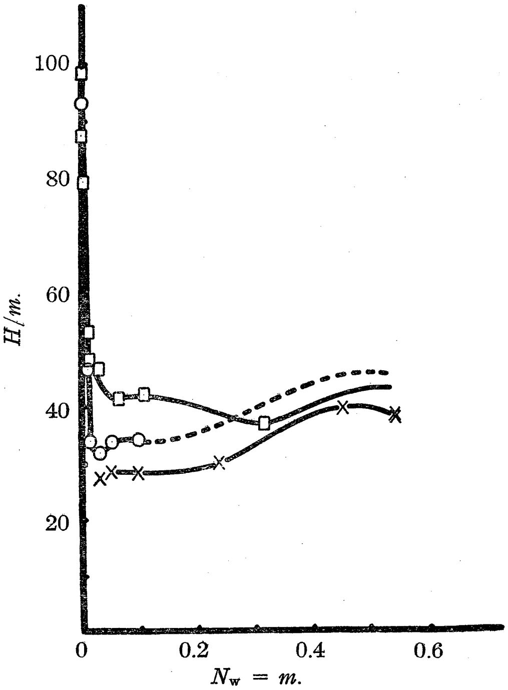

Fig. 3.—Hydrogen-ion concentration of myristyl sulfonic acid: □ is e. m. f.; ○ is conductivity, $100\mu v/\mu_\epsilon$; × is Arrhenius ratio, $100\ \mu v/\mu_\infty$.

It will be noted in the foregoing that precisely the same basis of assumption is made in calculating e. m. f. and freezing points. Incidentally, we take advantage of the direct proportionality between Θ and g, derived as follows, using the nomenclature of Guggenheim $g \ln 1/N_0 = L^0_F\Theta/RT^{\circ 2}$ with good approximation for aqueous solutions.

$$g \ln \frac{1}{N_0} \equiv \ln \frac{1}{N_0 f_0} \equiv g\left(N_S + \frac{N_S^2}{2} + \frac{N_S^2}{3} + \text{etc.}\right) = g\,N_S = gm$$

since $N_0 = 1 - N_S$. Whence $g = \Theta/\lambda m$.

The freezing point lowering is only about three-fifths that required for the concentration of hydrogen ion shown to be present by conductivity and electromotive force. This contradiction has to be accepted as a fact because it is far beyond any possible error of experiment, and we see no way of explaining it away as unreal without introducing some fantastic and unjustified assumption, such as that the actual conductivity observed is partly metallic or that some new class of impurity is present which does not lower freezing point but yet has a high conductivity. It cannot be due to any non-electrolyte or electrolyte present as impurity because the effect would be in the opposite direction of that here observed. It must be recalled that all three measurements were made on identical solutions.

Similarly, with 0.5 *N* cetyl sulfonic acid[1] at 90° the hydrogen-ion concentration, according to e. m. f., appeared nearly double that deduced from vapor pressure lowering. The only other authenticated instance is that of thymonucleic acid as studied by the Hammarstens, to which we shall return.

No such discrepancy has ever been observed between the many methods used to measure ordinary soaps.

So-Called "Hammarsten Effects."—Confusion has arisen through calling different things, some of them long since known,[2] "Hammarsten effect." Unquestionably, it is wholly legitimate to follow the usage of Linderstrøm-Lang[3] in defining as genuine "Hammarsten effect" the fact that the osmotic coefficient of thymonucleates depends upon the size of the cation. Thus the Bjerrum osmotic coefficient, g, $= i/v = \Theta/v\lambda m$, which is approximately equal to the osmotic pressure observed divided by the osmotic pressure of an ideal non-electrolyte of the same concentration, was observed by E. and H. Hammarsten[4] to be as follows

Cation	H^+	Na^+	NH_4^+	$(CH_3)_3NH^+$	$(CH_3)_4N^+$	$(C_2H_3)N^+$	$(C_3H_7)_3NH^+$
	0.70	0.80	1.20	1.35	1.45	1.50	1.74

Linderstrøm-Lang, however, did not agree with Hammarsten's explanation which assumed that "the small ions, I_1, are able to penetrate into the I_n ions and thus become osmotically inactive, whereas large ions I_2, are not capable of this." He concluded "that there must be far different and more profound causes and that Hammarsten's explanation, though perhaps necessary, is not sufficient." Jorpes and Hillgrew[5] also observed this kind of Hammarsten effect with various salts of Congo red.

For this genuine Hammarsten effect we may advance here a new explanation. The formation of neutral micelles is a process of association of molecules through orderly array of like parts. It is the organic radical which possesses this property. This close packing of parallel molecules can only occur if the cationic radicals, such as hydrogen, are so small as not to interfere. When these "heads" of the molecules, as they are commonly referred to in the literature on insoluble monomolecular films, become too large, their bulk interferes with the association of molecules to form neutral micelle. Meanwhile, the formation of ionic micelle, stripped of these cations, proceeds as usual. Thus the effect of large heads is to leave in the solution more ions and more simple molecules even if formation of ionic micelle is somewhat favored. Hence the lowering of freezing point or any other expression of g is measurably increased, the original genuine Hammarsten effect. This would explain the series of thymonucleates and the series of Congo reds.

The same principle or genuine Hammarsten effect also serves for the first time to explain many phenomena known to soap boilers who blend their raw materials to yield soaps of definite physical properties.[6] It also explains why hydrogen soaps

(2) Van Rysselberghe's use of the term which he defines as observing a value of van't Hoff's *i* of the order of 1 or less, was in fact the basis of the older work on dyes and soaps and the reason for recognizing the existence of colloidal electrolytes and their most characteristic feature, the ionic micelle. His suggestion [*J. Phys. Chem.*, **38**, 645 (1934)] that the ionic micelle may be treated as an ordinary polyvalent ion was based upon lack of data for other measurements and appears to be invalidated by the data referred to in the previous parts of this series. Similarly, F. G. Donnan's new definition "that the value of *g* may be affected by the action of the Coulomb field of the G^+ ions on the Cl^- ions, or by a variety of actions (Hammarsten effect)" likewise appears to be invalidated by its postulation of significant interionic attraction at great distances apart of ions.

are more colloidal than those of sodium and potassium.

Following Pauli and his collaborators,[7] McBain and Williams,[1] and Adair and Adair[8] conferred the name "Hammarsten effect" upon the divergence observed where the total freezing point lowering or osmotic coefficient g, is far less than that necessary to account for the hydrogen ion alone as measured by e. m. f. The only example was that of thymonucleic acid itself, not its salts, studied by E. Hammarsten in 1924.[4] Now, with four sulfonic acids, we have five examples altogether.[9] Linderstrøm-Lang's explanation[3] has been shown to be untenable. We shall now suggest a general explanation.

The Activity Coefficients of Individual Ions.—Guggenheim convincingly emphasized that activity coefficients of single ions had no meaning, since in measurements of activity hitherto the results had been a function of both ions, not separated from each other. However, this is not to say that the ions do not exist and do not each contribute a partial molal free energy, but merely that the individual activity coefficients had not been experimentally isolated.

Guggenheim himself, however, has defined an activity coefficient of hydrogen ion f_{H^+} which is arbitrarily set equal to $f_{\pm}$ or f_{HCl} the mean activity coefficient of the salt, and in which the definition is used only for dilute solutions. This is a different convention from that of MacInnes and Scatchard, who set f_{K^+} equal to f_{Cl^-} and equal to $f_{\pm}$ or f_{KCl}.

We will now show that if the experimental data here presented are valid they lead to a more definite evaluation of f_{H^+} which is not a mere arbitrary convention but which is fixed by the data themselves.

This is a direct result and explanation of McBain and Pauli's "Hammarsten effect," which otherwise has recently been referred to as "an affront to the second law of thermodynamics." This so-called Hammarsten effect is that hydrogen-ion concentration measured by e. m. f. with a liquid junction salt bridge appears far greater than as measured by freezing point or osmotic pressure.

The reason is, as was shown in deriving Figs. 1 and 2, that the conventional assumption was made that f_{H^+} equals f_{HCl} in these more concentrated solutions. Since added hydrochloric acid affects e. m. f. and freezing point of these solutions by approximately the same amount as it does in water, it was, and is, approximately correct to identify the concentration of hydrogen ion of a sulfonic acid solution with that of a solution of hydrochloric acid giving the same e. m. f. However, as regards freezing point lowering, although f_{H^+} may be taken as approximately the same for both cases, the freezing point lowering was quite arbitrarily ascribed equally to hydrogen and chlorine ions. That is, it was assumed that f_{H^+} equals f_{Cl^-} and this resulted in finding that the concentration of hydrogen ion so arrived at was only 60% of that corresponding to the e. m. f. data.

To reconcile freezing point with e. m. f. and explain away such "Hammarsten effect," it is only necessary to assume that f_{H^+} is only about one-half f_{Cl^-} and that the freezing point lowering of these more concentrated solutions is therefore more largely due to the chlorine ion than to the hydrogen ion. This brings up the values for hydrogen-ion concentration derived from freezing point to approximate equality to those from e. m. f. for the latter remain unchanged.

It is evident that this new approach toward measuring the activity coefficient of a single ion lends itself to further experimental test, since all data with single electrodes must conform if they are real. It is also evident that no information is obtainable from cells without liquid junctions because they measure, like freezing point in ordinary solutions, the geometric mean of both ions or the stoichiometric activity coefficient of the salt itself.

It is not without interest that in the preceding section devoted to e. m. f. it was shown that the existing data for e. m. f. of 1 N hydrochloric acid differ by no less than 10 millivolts from the value predicted on the assumption that $f_{H^+} = f_{HCl}$. This would corroborate the conclusion thus reached that $f_{H^+} < f_{HCl} < f_{Cl^-}$.

Constitution Diagram.—The constitution diagrams of these solutions resemble those of the soaps such as published by Miss Norris[10] for cetyl sulfonic acid, or more closely that of potas-

sium oleate at 18,[11] except that in previous diagrams boundaries should be raised by a few per cent. to allow for interionic attraction and 100% dissociation of hydrochloric acid. The middle line of the diagram is given from e. m. f. and conductivity data of Figs. 1, 2 and 3. Most of the transition between simple crystalloidal and colloidal electrolytes takes place between 0.05 and 0.15 *N* for undecyl and lauryl sulfonic acids and in still more dilute solution in myristyl sulfonic acid. Above 0.1 or 0.2 *N* there can be but little else than colloid and hydrogen ions. The concentration of ionic micelles will be equal to that of the hydrogen ion, the remaining sulfonic acid forming neutral micelles.

Summary

Hydrogen-ion concentration deduced from conductivity, freezing point lowering, and electromotive force for solutions of simple sulfonic acids above 0.1 *N* are compared.

Conductivity and e. m. f. (single electrode) agree in showing that the dissociation of the colloidal electrolyte is about 50%.

If the data for thymonucleic acid and for undecyl, lauryl, myristyl, and cetyl sulfonic acids are valid, it is shown that the activity coefficients of single ions may be measured. For example, in more concentrated solutions of hydrochloric acid, the activity coefficient of the hydrogen ion appears to be about half that of the chlorine ion and $f_{H^+} < f_{HCl} < f_{Cl^-}$ where $f_{H^+} f_{Cl^-} = f_{HCl}$.

A new explanation of the genuine Hammarsten effect is given, based upon steric hindrance to close packing.

Nitroso Compounds. III. Reactions of Organo-metallic Compounds with Alpha Halo Nitroso Compounds[1]

BY JOHN G. ASTON AND DAVID F. MENARD

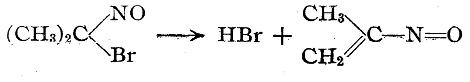
Introduction

This investigation originated in an attempt to obtain true nitroso hydrocarbons by the action of zinc alkyl on compounds of the type CR_1R_2-$Br(NO)$ in a way similar to that by which Bewad had obtained nitro compounds from their alpha bromo derivatives.[2]

Although this attempt failed, certain reactions involving the nitroso group were observed which were interesting from the standpoint of possible analogies between true nitroso compounds and aldehydes or ketones.

Splitting Out of the Hydrogen Halide

When 2,2-bromonitrosopropane was treated with anhydrous ammonia, only ammonium bromide resulted along with acetoxime. To explain this splitting out of hydrobromic acid the first step in the reaction may be tentatively written

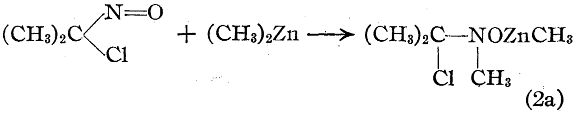


$$(CH_3)_2C\begin{matrix}NO\\Br\end{matrix} \longrightarrow HBr + \begin{matrix}CH_3\\CH_2\end{matrix}{>}C{-}N{=}O \qquad (1)$$

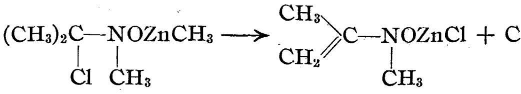
inasmuch as the unsaturated nitroso compound might well react to give acetoxime. It is not surprising therefore that the alpha halo nitroso compounds with dimethylzinc yield methane almost quantitatively by inducing the splitting out of hydrogen bromide and then reacting with it.

Reaction with Zinc Alkyls

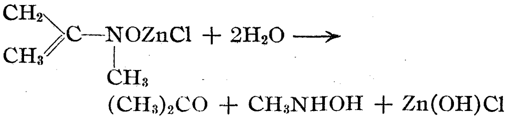
In the reaction of one mole of dimethylzinc and one mole of 2-chloro-2-nitrosopropane, one mole of methane is evolved per mole of chloronitroso compound. In the products of hydrolysis of the solid addition product methylhydroxylamine, acetone and acetoxime were observed. The first two arise from addition. The net reaction may be written



$$(CH_3)_2C\begin{matrix}N{=}O\\Cl\end{matrix} + (CH_3)_2Zn \longrightarrow (CH_3)_2\underset{Cl}{C}{-}\underset{CH_3}{N}OZnCH_3 \qquad (2a)$$



$$(CH_3)_2\underset{Cl}{C}{-}\underset{CH_3}{N}OZnCH_3 \longrightarrow \begin{matrix}CH_3\\CH_2\end{matrix}{>}C{-}\underset{CH_3}{N}OZnCl + CH_4 \qquad (2b)$$



$$\begin{matrix}CH_2\\CH_3\end{matrix}{>}C{-}\underset{CH_3}{N}OZnCl + 2H_2O \longrightarrow (CH_3)_2CO + CH_3NHOH + Zn(OH)Cl \qquad (2c)$$

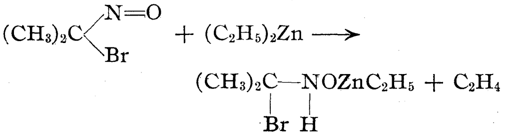
---

[1] From a thesis presented by David F. Menard in partial fulfilment of the requirements for the Ph.D. degree, June, 1934.

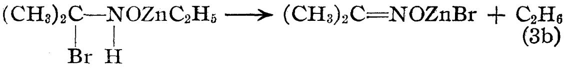
[2] Bewad, *J. prakt. Chem.*, [2] **48**, 368 (1893).

In this reaction and following ones, HX is represented as splitting out after addition and then reacting with the remaining zinc methyl linkage in the addition product. The reaction might as well have been represented as occurring by first splitting out HX and then adding of zinc methyl to the unsaturated nitroso compound. Indeed the presence of acetoxime indicates that some splitting out of HX from the chloronitroso compound does occur directly, followed by decomposition of the unsaturated nitroso compound. The yields of the various products show that no other reaction of importance occurs.

Diethyl zinc reacted with 2-bromo-2-nitrosopropane in the same way that dimethylzinc reacted on the chloro compound, yielding ethane with acetone and ethylhydroxylamine as the hydrolysis products. However, only about 70% reacted in this way while the remaining 30% was reduced as shown by the presence of ethylene in the gaseous mixture. It was assumed that one mole of ethane was formed for each mole of ethylene and the secondary reaction written



$$(CH_3)_2C\begin{matrix}\diagup N{=}O\\ \diagdown Br\end{matrix} + (C_2H_5)_2Zn \longrightarrow \underset{\substack{|\\Br}}{(CH_3)_2C}{-}\underset{\substack{|\\H}}{N}OZnC_2H_5 + C_2H_4 \quad (3a)$$



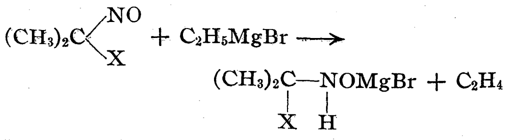
$$\underset{\substack{|\\Br}}{(CH_3)_2C}{-}\underset{\substack{|\\H}}{N}OZnC_2H_5 \longrightarrow (CH_3)_2C{=}NOZnBr + C_2H_6 \quad (3b)$$

$$(CH_3)_2CNOZnBr + H_2O \longrightarrow (CH_3)_2C{=}NOH + Zn(OH)Br \quad (3c)$$

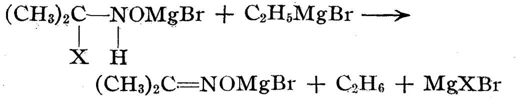
In keeping with this, acetoxime was also found in the products of hydrolysis of the mixed insoluble addition product.

Reaction with Grignard Reagents

When 2-chloro or 2-bromo-2-nitrosopropane was treated with ethylmagnesium bromide (2 moles of Grignard per mole of compound), no addition was observed; the principal reaction was a reduction similar to the secondary reaction observed with diethylzinc



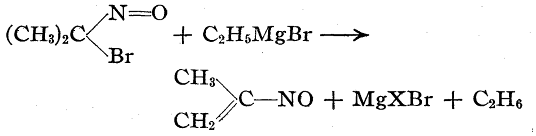
$$(CH_3)_2C\begin{matrix}\diagup NO\\ \diagdown X\end{matrix} + C_2H_5MgBr \longrightarrow \underset{\substack{|\\X}}{(CH_3)_2C}{-}\underset{\substack{|\\H}}{N}OMgBr + C_2H_4 \quad (4a)$$



$$\underset{\substack{|\\X}}{(CH_3)_2C}{-}\underset{\substack{|\\H}}{N}OMgBr + C_2H_5MgBr \longrightarrow (CH_3)_2C{=}NOMgBr + C_2H_6 + MgXBr \quad (4b)$$

$$(CH_3)_2C{=}NOMgBr + H_2O \longrightarrow (CH_3)_2C{=}NOH + Mg(OH)Br \quad (4c)$$

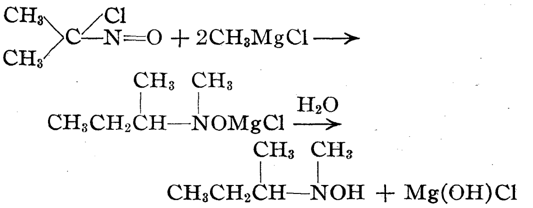
The products were ethane and ethylene and after hydrolysis of the insoluble addition compound, acetoxime and its hydrolysis products (acetone and hydroxylamine). Whereas reactions (4a and 4b) require equal molal quantities of ethane and ethylene, the ethane produced in both cases considerably exceeded the ethylene. This indicated a reaction



$$(CH_3)_2C\begin{matrix}\diagup N{=}O\\ \diagdown Br\end{matrix} + C_2H_5MgBr \longrightarrow \begin{matrix}CH_3\diagdown\\ CH_2\diagup\!\!\diagup\end{matrix}C{-}NO + MgXBr + C_2H_6 \quad (5)$$

involving the splitting out of hydrogen bromide, which reacted with the Grignard to yield ethane while the hypothetical unsaturated nitroso compound after hydrolysis yielded hydroxylamine as in the reaction with ammonia (1).

The reaction of one mole of methylmagnesium chloride on one mole of 2-chloro-2-nitrosopropane resulted in addition to the N=O group as the main reaction. Hydrolysis yielded methylhydroxylamine. The reaction of two moles of methylmagnesium chloride resulted in addition to the N=O group and simultaneous replacement of the halogen by the methyl group with rearrangement, yielding 68% of β-s-butyl-β-methylhydroxylamine



$$\begin{matrix}CH_3\diagdown\\ CH_3\diagup\end{matrix}C\overset{\diagup Cl}{-}N{=}O + 2CH_3MgCl \longrightarrow CH_3CH_2\overset{\substack{CH_3\\|}}{C}H{-}\overset{\substack{CH_3\\|}}{N}OMgCl \xrightarrow{H_2O} CH_3CH_2\overset{\substack{CH_3\\|}}{C}H{-}\overset{\substack{CH_3\\|}}{N}OH + Mg(OH)Cl \quad (6)$$

Methylmagnesium chloride acted similarly with 2-bromo-2-nitrosopropane. In this case a small amount of β-methyl-β-*t*-butylhydroxylamine was identified as well.

With phenylmagnesium bromide there was no addition or replacement of bromine by the phenyl radical. However, a 20% yield of benzene indicated splitting out of hydrogen bromide by a reaction similar to (5).

Kohler and Tishler[3] have discussed the analogous α-halo-ketone problem and have shown that Grignard reagents often react with ketones of the type $R_2C(X)COR$ to replace halogen by magnesium with the simultaneous production of the alkyl halide

$$R_2C(X)COR + R^1MgX^1 \longrightarrow R^1X + R_2C(MgX^1)COR \quad (7)$$

---

[3] Kohler and Tishler, THIS JOURNAL, **54**, 1595 (1932); **57**, 217 (1935).

In none of our experiments was there ever a detectable amount of alkyl halide which might have been produced by an analogous reaction.

Experimental

Preparation of 2-Bromo-2-nitrosopropane.[4]—Four hundred and twenty-seven grams (3.15 moles) of $NaAc\cdot 3H_2O$ dissolved in 500 cc. of water was added to a solution of 110 g. (1.5 moles) of acetoxime dissolved in 200 cc. of water. Five hundred grams of ice was added. With constant stirring and cooling, 239 g. (1.5 moles) of bromine was dropped in at such a rate that the solution was kept below 0°.

The dark blue oil was separated after standing for twenty minutes, washed with ice water and dried over 10 g. of anhydrous sodium sulfate in the cold. The last traces of water were removed by cooling in ether–carbon dioxide snow and filtering off the ice; yield, 46–54 g. (20–30%). The product was over 90% pure (bromine analysis).

Preparation of 2-Chloro-2-nitrosopropane.[5]—The procedure was as described for the bromo compound, the chlorine being introduced as a rapid stream; yield, 62%.

Reaction of 2-Bromo-2-nitrosopropane with Ammonia.—Dry ammonia was bubbled through a solution of 32 g. of 2-bromo-2-nitrosopropane in 50 cc. of anhydrous ether at 20–25° for four hours, when no further precipitation of ammonium bromide took place. The 2-bromo-2-nitrosopropane, carried over into a condenser cooled in ice–salt, was returned to the reaction flask from time to time. Fourteen grams of solid ammonium bromide (identified by analysis) was filtered off. The ether solution was fractionated, yielding 4.2 g. of bromo acetone, 2.8 g. of acetoxime and 2.4 g. of tar.

Reaction of Dimethylzinc with 2-Chloro-2-nitrosopropane.—The apparatus and procedure already described[6] were used. To a solution of 21.8 g. (0.204 mole) 2-chloro-2-nitrosopropane in 150 cc. of anhydrous ether at 0° was added 19.4 g. (0.204 mole) of dimethylzinc. The resulting mixture stood at room temperature for twenty-five hours. Analyses of the gas showed that 2.64 g. (0.165 mole) of methane was formed, or 81% based on reaction (2b).

No products were found in the ether solution. An insoluble solid addition product was hydrolyzed with dilute sulfuric acid. Analysis of the gas corresponded to a yield of 0.67 g. (0.042 mole) of methane, or 10.3% based on the zinc methyl used.

Continuous ether extraction of the aqueous solution yielded 5.67 g. (0.079 mole) of acetoxime and 0.60 g. of tar. In the aqueous portion 0.204 mole of zinc and 0.204 mole of chloride were identified. This was distilled and 5.58 g. (0.96 mole) of acetone was identified in the distillate. The residue, which reduced ammoniacal silver nitrate and iodine solutions, was reduced with 20 g. of zinc dust and 50 cc. of 6 *N* hydrochloric acid. It was then made alkaline and distilled into standard hydrochloric acid (free methylhydroxylamine is decomposed in hot aqueous alkali),[7] yielding 0.109 mole of methylamine hydrochloride, identified by analysis and by conversion to N-methyl-*p*-toluene-sulfonamide, m. p. 78–78.5°,[8] (confirmed by mixed melting point).

Reaction of Diethylzinc with 2-Bromo-2-nitrosopropane.—Thirty-five grams (0.289 mole) of diethylzinc was added to a solution of 44 g. (0.289 mole) of 2-bromo-2-nitrosopropane in 125 cc. of anhydrous ether as above; 2.09 g. (0.075 mole) of ethylene and 6.28 g. (0.209 mole) of ethane were found in the gases.

In the ether solution, 2.0 g. of bromoacetone and 1.7 g. of tar were identified.

On hydrolysis of the addition product 0.17 g. (0.006 mole) of ethylene, 2.61 g. (0.087 mole) of ethane, 9.4 g. (0.127 mole) of acetoxime, 2.89 mole of zinc, 0.265 mole of bromide, 8.0 g. (0.138 mole) of acetone and 0.118 mole of ethylhydroxylamine were found. The ethylhydroxylamine was reduced and converted to N-ethyl-*p*-toluenesulfonamide, m. p. 63°,[8] and identified by a mixed melting point.

Reaction of Two Moles of Ethylmagnesium Bromide with 2-Chloro-2-nitrosopropane.—An ether solution containing 0.748 mole of ethylmagnesium bromide was added to a solution of 40 g. (0.374 mole) of 2-chloro-2-nitrosopropane in 150 cc. of anhydrous ether as above except that nitrogen replaced the carbon dioxide; 4.15 g. (0.148 mole) of ethylene and 6.05 g. (0.201 mole) of ethane were found in the gas.

From the ether 3.9 g. of unreacted 2-chloro-2-nitrosopropane was obtained. No gas was evolved on hydrolysis of the insoluble addition product. From the ether extract 6.8 g. of liquid (b. p. 60–120°), 6.6 g. (0.90 mole) of acetoxime and 4.1 g. of tar were obtained. In the aqueous portion, 1.03 moles of halide, 11.0 g. (0.189 mole) of acetone and 0.123 mole of hydroxylamine[9] were identified. No other products were found.

Reaction of Two Moles of Ethylmagnesium Bromide with 2-Bromo-2-nitrosopropane.—An ether solution containing 0.0528 mole of ethylmagnesium bromide was added to a solution of 40 g. (0.264 mole) of 2-bromo-2-nitrosopropane in 170 cc. of anhydrous ether; 2.60 g. (0.294 mole) of ethane was found in the gas.

No products were found in the ether and no gas was evolved on hydrolysis of the insoluble addition product. From the ether extract 5.6 g. of unidentified liquids (b. p. 60–120°), 3.2 g. (0.044 mole) of acetoxime and 4.2 g. of tar were obtained. In the aqueous portion, 0.796 mole of bromide, 0.68 g. (0.012 mole) of acetone and 0.042 mole of hydroxylamine were identified.

Reaction of Two Moles of Methylmagnesium Chloride with 2-Chloro-2-nitrosopropane.—An ether solution containing 0.546 mole of methylmagnesium chloride was added to a solution of 29 g. (0.268 mole) of 2-chloro-2-nitrosopropane in 50 cc. of anhydrous ether. No gas was evolved.

The entire reaction mixture was hydrolyzed and continuously extracted with ether as previously. In the ether portion, after hydrolysis and continuous extraction of the entire reaction mixture, only 0.4 g. of chloroacetone

---

(4) Following the method of Piloty [*Ber.*, **31**, 454 (1898)], the yields were erratic and the material very impure.

(5) This method is superior to that of Ponzio, *Chem. Zentr.*, **77**, I, 1692 (1906).

(6) Menard and Aston, THIS JOURNAL, **56**, 1601 (1934).

(7) Kjellin, *Ber.*, **26**, 2382 (1893).

(8) Remsen and Palmer, *Am. Chem. J.*, **8**, 241 (1886).

(9) Acree and Johnson, *ibid.*, **38**, 316 (1907).

and 4.0 g. of tarry residue were identified. In the aqueous portion, 0.751 mole of chloride and 3.0 g. of acetone (0.054 mole) were identified.

The free base was steam distilled from the aqueous portion into hydrochloric acid solution after making alkaline without reduction. Evaporation of the distillate yielded a very hygroscopic hydrochloride which was entirely soluble in absolute alcohol. It reduced ammoniacal silver nitrate. Nineteen grams (0.14 mole) of this hydrochloride was reduced with 40.0 g. of stannous chloride (0.21 mole) and 40 cc. of concd. hydrochloric acid in the cold. After making alkaline, distilling the base into hydrochloric acid and evaporating to dryness, a solid hydrochloride was obtained; recrystallized twice from absolute alcohol, m. p. 242–244° in a sealed tube. *Anal.* Calcd. for $C_5H_{14}NCl$: Cl, 28.63. Found: (Volhard) Cl, 28.68.

The hydrochloride was converted into the oxalate (twice recryst. from absolute alcohol) m. p. 109–110°. *Anal.* Calcd. for $C_7H_{15}O_4N$: C, 46.90; H, 8.57. Found: C, 46.84, 46.75; H, 8.76, 8.60.

This was identified as N-methyl-*s*-butylamine oxalate by a mixed melting point with a known sample of oxalate. The known sample was prepared by the methylation of *s*-butylamine obtained by the reduction of methyl ethyl ketoxime.[10] The base[11] thus obtained was purified through the *p*-toluenesulfonamide, and converted into the oxalate, m. p. 110–111° (from absolute alcohol). (The oxalate of N-methyl-*t*-butylamine melts with decomposition at 166°.[12])

β-*s*-Butyl-β-methylhydroxylamine.—The reaction of methylmagnesium chloride with 2-chloro-2-nitrosopropane was repeated and the free β-*s*-butyl-β-methylhydroxylamine was extracted with ether after making alkaline, without previous reduction or distillation. A solid product, m. p. 59–60°, b. p. 86° at 101 mm., was obtained, but was difficult to keep pure. *Equivalent weight.* Calcd. for $C_5H_{12}ON$: 103.1. Found: 102.5–103.0.

In handling, this compound apparently absorbed water of recrystallization. *Anal.* Calcd. for $C_5H_{12}ON{\cdot}H_2O$: C, 49.54; H, 12.48. Found: C, 48.80, 48.81; H, 12.29, 12.49.

Reaction of Two Moles of Methylmagnesium Chloride with 2-Bromo-2-nitrosopropane.—An ether solution containing 0.474 mole of methylmagnesium chloride was added to 36 g. (0.237 mole) of 2-bromo-2-nitrosopropane dissolved in 100 cc. of dry ether.

After hydrolysis and extraction, in the ether layer were identified 0.3 g. of bromoacetone, 1.8 g. of acetoxime and 4.3 g. of tar. In the aqueous portion, 0.413 mole of halide and 1.3 g. of acetone were identified, and 4 g. of impure β-*s*-butyl-β-methylhydroxylamine, b. p. 85–93° at 115 mm. (a yield of 17%), and 3.4 g. of tar were extracted from it after making alkaline.

The entire portion (b. p. 85–93°) was reduced as in the previous experiment. The hydrochloride of the resulting amine, melting at 190–200°, was converted into the oxalate. Fractional recrystallization of the product from alcohol (2.0 g.) yielded (in order of increasing solubility) 0.1 g. of oxalic acid, m. p. 187°, 0.1 g. of oxalate, decomp. 166–167° (probably N-methyl-*t*-butylamine oxalate) and 1.4 g. of N-methyl-*s*-butylamine oxalate, m. p. 110–111°.

Reaction of One Mole of Methylmagnesium Chloride with One Mole of 2-Chloro-2-nitrosopropane.—An ether solution containing 0.400 mole of methylmagnesium chloride was added to a solution of 43 g. (0.400 mole) of the chloronitrosopropane. After standing overnight the blue ether solution was decanted from the solid addition product. Fractional distillation yielded only 4.0 g. of chloronitrosopropane. The solid addition product was hydrolyzed in the cold with dilute sulfuric acid. By continuous extraction with ether 0.78 g. of acetone, 3.40 g. of unreacted chloronitrosopropane, 0.07 g. of acetoxime (m. p. 60°), 3.0 g. of tar were obtained and separated by distillation. The aqueous portion after extraction was distilled to half its volume to remove 0.041 mole of acetone as ascertained by analysis of the distillate. The residue was reduced with zinc dust and hydrochloric acid, made alkaline, and the volatile bases (0.115 mole) distilled into standard hydrochloric acid. Evaporation of the distillate yielded a hygroscopic reducing salt. This was further reduced with stannous chloride and concentrated hydrochloric acid. The hydrochloride obtained after the usual procedure was crystallized from absolute alcohol (m. p. 137–159°). *Anal.* Calcd. for CH_6NCl: Cl, 52.50. Found: Cl, 47.1. This salt was undoubtedly methylamine hydrochloride while the impurity was probably N-methyl-*s*-butylamine.

Reaction of Phenylmagnesium Bromide with 2-Bromo-2-nitrosopropane.—This reaction was carried out in the same manner as the methyl Grignard experiments. To a solution of 54 g. (0.363 mole) of 2-bromo-2-nitrosopropane was added an ether solution containing 0.495 mole of phenylmagnesium bromide. The resulting mixture contained no excess phenylmagnesium bromide. It was worked up as before. Upon distillation the following products were identified in the ether layer, 13.1 g. of bromoacetone, a little diphenyl (corresponding only to that found originally present in the phenylmagnesium bromide solution) and 5.0 g. of tar.

The addition product was hydrolyzed and continuously extracted for sixty-eight hours to dissolve all tar and colored material. The following products were identified from the ether extract of the aqueous portion: 5.6 g. (0.096 mole) of acetone, 0.096 mole of hydroxylamine, 4.16 g. (0.057 mole) of acetoxime, 5.8 g. (0.074 mole) of benzene and 14.1 g. of tar.

Summary

1. The reactions of dimethyl- and diethylzinc on 2-bromo and 2-chloro-2-nitrosopropane have been studied and found to involve the nitroso group.

2. The reactions of methyl and ethyl Grignard reagents have also been studied with these same compounds and found to involve the nitroso group.

3. The β-*s*-butyl-β-methylhydroxylamine obtained by the reaction of two moles of methyl

The Conductance of Non-aqueous Solutions. I. Sodium Triphenylboron and Disodium Tri-α-naphthylboron in Diethyl Ether

BY HENRY E. BENT AND MAURICE DORFMAN

Considerable work has been published recently from this Laboratory dealing with the alkali metal derivatives of various organic compounds. These compounds are salt-like in their character and conduct an electric current in non-aqueous solutions. The dissociation constants of these salts are not known but the assumption has been made that they are all of the same order of magnitude.[1,2] The data of this paper will be used later to test this assumption and are of immediate interest in establishing the structure of disodium tri-α-naphthylboron. A preliminary report of the experimental method[3] is given.

Sodium triphenylboron is a peculiar compound.[4] Triphenylboron is saturated as far as primary valence forces are concerned. It is true that it may readily add other molecules such as ammonia by means of a coördinate covalence but this can hardly be the case for sodium. The sodium addition compound conducts an electric current in diethyl ether solution and therefore presumably the sodium ion is held to the triphenylboron ion by electrostatic force.[5] The stability of sodium triphenylboron is therefore apparently due to a large electron affinity of triphenylboron. This in turn is probably due to the fact that the negative ion may be represented by a large number of structures, which result in a stabilization as a result of the phenomenon of resonance.[6]

The compound disodium tri-α-naphthylboron is still more curious. The second sodium is held rather loosely.[7] It was not possible, however, to measure ΔF for the addition of the second sodium due to the fact that an amalgam which might be in equilibrium with the compound would be solid at ordinary temperatures.

It seemed quite possible that a study of the conductance of solutions of these compounds, especially when compared with sodium triphenylmethyl, might shed some light on their structure and properties.

The method used experimentally was the ordinary a. c. procedure for resistances up to about 10^6 ohms. For higher resistance a d. c. method was adopted. The two methods were found to check in the region in which they overlapped.

Experimental Part

The cell "A," buret "B," and the tube in which the sodium addition compound was prepared are shown in Fig. 1. Two sheets of platinum, 1 cm. wide by 2 cm. long, were held rigidly about 1 mm. apart as indicated at the right in Fig. 1. Six holes were drilled in the sheets and soft glass rods pulled down to the size of the holes. A small bead was placed at the middle of each rod, the platinum sheets slipped over the ends and then by means of a small flame the end heated until sufficiently soft to allow it to be mashed down with a graphite rod. Heavy platinum wires were welded to the sheets of bright platinum and these in turn welded to No. 40 platinum ribbon, the latter being sealed into Pyrex as described by Bent and Gilfillan.[8] The cell constant was 0.00898.

The sodium addition compound was prepared in "C" by shaking a known weight of the boron compound with 40% sodium amalgam. The product was poured into the buret quantitatively by distilling ether back into "C"

[3] This work was in progress before the first paper of Fuoss and Kraus [*ibid.*, **55**, 476 (1933)] appeared. In order to minimize the importance of polarization potentials they found it convenient to work with potentials as high as 150 v. In order to avoid the same difficulty we used potentials as small as possible, in most cases not more than 20 mv. A high sensitivity galvanometer made possible the use of these small potentials. Under these conditions polarization potentials gave no trouble.

[4] The stability of this compound has been reported in an earlier communication, Bent and Dorfman, *ibid.*, **57**, 1259 (1935).

[5] Krause and Polack [*Ber.*, **59**, 777 (1926)] state that sodium triphenylboron has a small conductivity in ether solution but give no quantitative data.

thereby washing the amalgam. Tube "C" was sealed off at the constriction. Solution was then poured into "A." Dilutions were accomplished by pouring a given quantity into "B" and distilling ether back into the cell. This procedure made it possible to work with extremely dilute solutions without introducing uncertainty due to water given off by the glass. The small amount of water liberated during the early part of a run would not affect appreciably the concentration of the original concentrated solution. Experiments on the most dilute solutions were then made in glass which had been in contact with the solution so long as to introduce no further appreciable error from this source.[9] The procedure of pouring all of the material into the cell and repeating the run with the same sample of material served as a check on the unimportance of decomposition due to water given off by the glass.

In making d. c. measurements a Wolf potentiometer, direct reading to 0.01 mv., was used to apply a variable potential to the cell. In series with the cell was a Leeds and Northrup type HS galvanometer, mounted on a Julius suspension. This instrument has a sensitivity of 1 mm. for 10^{-11} amp. The procedure consisted in determining the potential necessary to produce 10 cm. deflection of the galvanometer when applied through a standard resistance. The cell was then added to the circuit and the potential determined which would give the same deflection of the galvanometer. The accuracy of the measurement, therefore, is essentially that of the Wolf potentiometer. With the technique described above it was quite easy to obtain an accuracy of from 1–5% in the measurement of the resistance of the cells over the range from 2×10^4 to 5×10^8 ohms. When the specific conductance became as small as 5×10^{-10} further dilution had no effect. This was probably due to adsorbed material as the specific conductance of ether is less than 4×10^{-18}. This final value of 5×10^{-10} was taken as the specific conductance of the solvent and subtracted from the observed reading for the most dilute solutions where it would begin to be important.

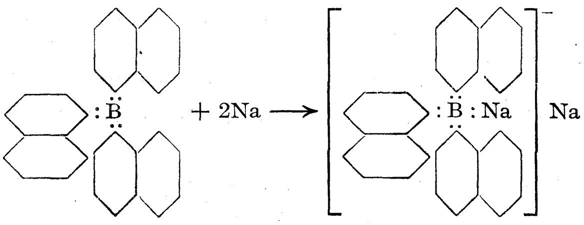
Discussion of Results

The fact that tri-α-naphthylboron can add two electrons suggested that the reaction with two atoms of sodium might be represented by the structural formulas



The two electrons from the sodium atoms are here assumed to complete a group of eight about a boron atom. One of the sodium ions is drawn to the boron atom by the strong electrostatic

---

(9) Bent and Lesnick, THIS JOURNAL, **57**, **1246** (1935).

force but the other is unable to approach so closely on account of the three phenyl groups attached to the boron. If this picture is correct, one would expect one of the sodium ions to dissociate very readily, giving rise to a relatively strong electrolyte.

A second possibility is that a quinonoid structure results in the localization of the negative charge at the para position of one of the benzene rings. If such a structure represents the molecule the absence of steric hindrance would permit both sodium ions to come close to the carbon atom, one on either side of the ring. A further argument in favor of the quinonoid structure is to be found in the fact that triphenylboron is not able to add a second atom of sodium. The oxidation potential of 1,4-naphthoquinone is 0.495 and of 1,4-benzoquinone is 0.711 v.[10] The larger oxidation potential is exhibited by that compound for which the quinonoid structure is relatively less stable. If this second hypothesis is correct then we would expect triphenylboron to add a second atom of sodium less readily than tri-α-naphthylboron. We attempted to prepare trianthracylboron (9, 10-anthraquinone has a potential of 0.157 v.) in order to test the influence of the oxidation–reduction potential. However, the methods used in preparing triphenylboron and tri-α-naphthylboron were not successful.

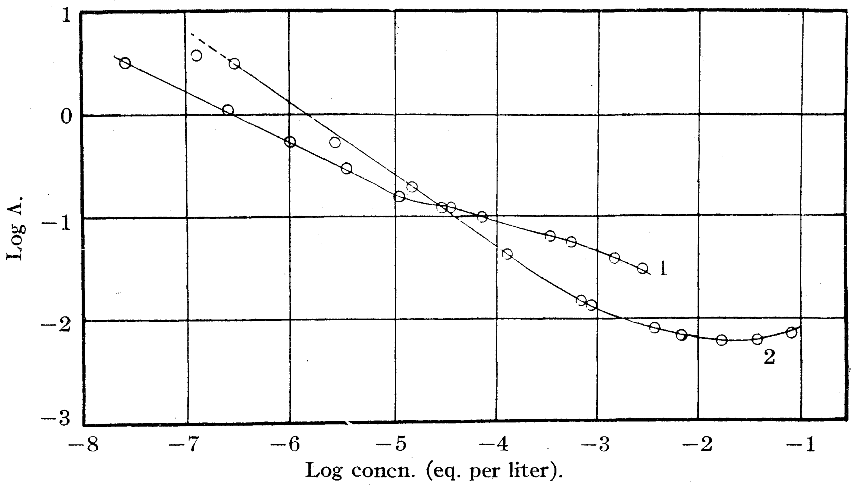


Fig. 2.—Curve 1, sodium triphenylboron; curve 2, disodium tri-α-naphthylboron.

It was in order to test these hypotheses with regard to the nature of the union of the two sodium atoms that the conductance experiments were initiated. To our great surprise we obtained the curves reported in Fig. 2. The curve for sodium triphenylboron (curve No. 1) which was run for comparison seems quite normal. There is a little kink in the curve at a rather smaller concentration than one might expect. The slope of the curve is −0.5, as one would expect for a uni-univalent electrolyte.[11]

It follows from Oswald's dilution law that if we are working at concentrations such that only a small fraction of the material is ionized we may write

$$K = \frac{(\mathrm{Na}^+)(\mathrm{R}^-)}{(\mathrm{NaR})} = \frac{\alpha^2 C}{(1-\alpha)} = \alpha^2 C = \frac{\Lambda^2}{\Lambda^2_\infty}\,C$$

$$\text{or } \log \Lambda = \log \Lambda_\infty K^{1/2} - {}^1/_2 \log C$$

Plotting log Λ against log C the slope should be −0.5. As is evident from the figure, however, disodium tri-α-naphthylboron is neither a much stronger electrolyte than sodium triphenylboron nor is the slope of the curve −0.5. On the contrary, the slope of the curve plotting log Λ against log C is −0.69 ± 0.02. This slope of approximately $^2/_3$ can be accounted for in the following way. If we assume that both sodium atoms ionize simultaneously, then we obtain the following equations.

$$K = \frac{(\mathrm{Na}^+)^2(\mathrm{R}^=)}{\mathrm{Na_2R}} = \frac{(\alpha C)^2(\alpha C)}{(1-\alpha)C} = \alpha^3 C^2 = \frac{\Lambda^3}{\Lambda^3_\infty}\,C^2$$

$$\text{or } \log \Lambda = \log \Lambda_\infty K^{1/3} - {}^2/_3 \log C$$

This gives an explanation for the slope of the conductance curve of $-{}^2/_3$ but leads to the very surprising conclusion that here we are dealing with a weak electrolyte presumably capable of ionizing in steps and yet both sodium atoms come off simultaneously. This cannot be accounted for by assuming simply that the two atoms are distantly located in the molecule, for, as has been shown by Adams,[12] such an assumption leads to the conclusion that the statistical factor would only double the apparent ionization constant. Evidently there must be possible some rearrangement of the molecule which can take place only when both sodium ions have been removed, or which, taking place when one ion is gone, suffi-

---

[10] "I. C. T.," Vol. 6, p. 334. These values are for 0.5 N HCl, 95% ethyl alcohol.

[11] Kraus and Fuoss, THIS JOURNAL, **55**, 21 (1933).

[12] Adams, *ibid.*, **38**, 1503 (1916).

ciently weakens the force of attraction for the second ion that it ionizes readily. The energy change for this rearrangement must be sufficiently large to more than offset the coulomb energy which would normally make the second sodium ion ionize with much less ease.

On the basis of these facts the following hypothesis is suggested. The two electrons furnished by the two sodium atoms are localized in the ion, on a carbon atom in a quinonoid ring. The two sodium ions are held closely to the negative charge, one on either side of the atom on which the electrons are localized. When one of the sodium ions leaves, the coulomb force of the single sodium ion then becomes too small to cause this localization of the electrons to continue. The pair of electrons then resonates among all of the various quinonoid structures which can be written for the molecule with the result that the effective size of the ion is greatly increased, the coulomb force weakened and the second sodium ionizes as though the salt were a strong electrolyte.

Referring now to the equilibrium data[13] we find what at first glance would appear to be a contradiction. One of the sodium atoms can be removed easily by shaking disodium tri-α-naphthylboron with an amalgam while the other sodium atom is removed only by shaking with a more dilute amalgam. This turns out not to be a contradiction, however, but is quite capable of being explained without modifying the above theory. If we are right in assuming that both electrons are located on the same atom and that they resonate together, then we would expect a large coulomb repulsion term on account of the proximity of the two negative charges. This would account for the difficulty of adding a second sodium atom to monosodium tri-α-naphthylboron. When we consider the process of ionization, however, we are not removing electrons and hence this coulomb term does not enter into the dissociation constants of the ions.

The theory which has just been outlined is in harmony with all of the observations which we have made on these compounds. It is of course desirable to have more data in order to test further the theory.

In a later communication the significance of the temperature coefficient of conductance will be considered. It is not unusual for weak electrolytes in non-aqueous solution to exhibit a negative coefficient.[14]

Summary

A simple method is described for measuring the specific resistance of non-aqueous solutions. This method has been used for specific resistances up to 5×10^{10} ohms.

The equivalent conductance for sodium triphenylboron and disodium tri-α-naphthylboron in ether solution has been determined at 0 and 25° and from 10^{-1} to 10^{-7} mole per liter.

The bearing of these results on the structure of disodium tri-α-naphthylboron is discussed.

Synthesis of Certain Pyridine Derivatives of Barbituric Acid

BY CARL SELLNER KUHN AND G. HOLMES RICHTER

The discovery of the substituted barbituric acids as hypnotics was followed by their administration in conjunction with various other drugs which enhanced their effectiveness. The analgesics and antipyretics are the most commonly used for this purpose. Since many of these drugs are basic, such as the alkaloids and other heterocyclic nitrogen compounds, they will form very definite "molecular compounds" with the acidic barbituric acid derivatives.

The effectiveness of drugs of this type suggests that the heterocyclic substituted barbituric acids would be interesting compounds. In contrast to the easy preparation of the molecular compounds or salts mentioned above, the introduction of a heterocyclic residue in the 5-position of barbituric acids presents a much more difficult problem, since the active halides and the aldehydes of this class of compounds are limited in number or are difficult to synthesize. A review of the literature on barbituric acids of this type shows that pyrazole,[1,2,3] imidazole,[4] piperidine,[5] indole,[6] thiazole,[7] furan[8] and tetrahydrofuran[9] rings have been introduced into the molecule.

Our laboratory has succeeded in preparing four new barbituric acids all containing the pyridine nucleus. Pure β-picoline was brominated to give β-picolyl bromide; this was then condensed with a substituted malonic ester to give an alkyl-β-picolylmalonic ester. The malonic ester was then condensed with urea in the usual fashion to give the 5,5-disubstituted barbituric acids.

Several attempts were made to join the pyridine ring directly to malonic ester and barbituric acid. Notwithstanding reported easy reactions of α-bromopyridine with many reagents, we were unable to condense α-bromopyridine with malonic ester. An effort was made to obtain the pyridine malonic ester through a Ladenburg rearrangement by treating pyridine with brominated malonic esters in the presence of catalysts but the easy decomposition of the malonic esters prevented the success of the experiment.

Experimental Part

(1) **β-Picoline.**—The β-picoline required for the preparation of the β-picolyl bromide was made by the method of P. Schwarz,[10] and gives a product free from the α and γ isomers.

Melting Points and Analyses of the Products

Name	M. p., °C.	Formula	% C Calcd.	% H Calcd.	% C Found	% H Found
5-(β-Picolyl)-5-ethylbarbituric acid	213–214	$C_{12}H_{13}O_3N_3$	58.28	5.30	58.80	5.71
5-(β-Picolyl)-5-*n*-propyl barbituric acid	250 dec.	$C_{13}H_{15}O_3N_3$	59.74	5.79	59.61	5.77
5-(β-Picolyl)-5-*n*-butyl barbituric acid	218–219	$C_{14}H_{17}O_3N_3$	61.06	6.23	61.73	6.81
5-(β-Picolyl)-5-*i*-amyl barbituric acid	229–230	$C_{15}H_{19}O_3N_3$	62.25	6.62	62.70	6.62

(2) **β-Picolyl Bromide.**—The preparation of this product by dissolving β-picoline in concentrated hydrochloric acid and brominating with two molecules of bromine at 150° is described by Dehnel.[11] The isolation of the bromide by treating the solution with sulfur dioxide, neutralizing with sodium carbonate, and extracting with ether must be carried out as rapidly as possible since the bromide may react with itself to give high molecular weight tars. β-Picolyl bromide is a lachrymator and a marked irritant for the skin, hence care must be taken in opening the sealed tubes and in handling the product.

(3) **Ethyl β-Picolylalkylmalonates.**—β-Picolyl bromide was condensed with ethyl ethylmalonate, ethyl *n*-propylmalonate, ethyl *n*-butylmalonate and ethyl *n*-amylmalonate. Since the method of condensation and purification was the same in all cases it will be described only for ethyl ethylmalonate.

One and six-tenths grams of sodium was dissolved in 22 cc. of absolute alcohol placed in a two-necked 200-cc. flask fitted with a condenser and stirrer. The resulting solution of sodium ethylate was cooled to 50° and 13.2 g. of ethyl ethylmalonate added. The β-picolyl bromide, which must be prepared shortly before each reaction due to its unstable nature, was thoroughly dried over anhydrous magnesium sulfate in ether solution. The ether solution of the bromide was added as rapidly as possible, the ether being distilled off during the addition by heating on the steam-bath. The mixture was heated for an hour on the steam-bath to complete the reaction. At the end of the reaction the remainder of the ether and the alcohol were distilled off.

The oily liquid and sodium bromide were washed with water to remove the salt and the oily layer removed with ether and extracted with 15% hydrochloric acid to remove the picolylmalonic ester. This acid solution was subsequently made alkaline and extracted with ether. The ether solution was dried over anhydrous magnesium sulfate and distilled, about 2 g. of a viscous red oil remained which apparently started to boil when the temperature of the bath reached 145–150° but due to the small amount of material and the obvious decomposition, no further attempts were made to distil the product.

(4) **5-(β-Picolyl)-5-ethyl Barbituric Acid.**—One and one-half grams of ethyl β-picolylethylmalonate, 0.62 g. of sodium, and 0.775 g. of urea were dissolved in 15 cc. of absolute alcohol in a Pyrex tube. The tube was sealed and heated with steam for twelve hours. At the end of this time the tube was opened and the contents washed in an evaporating dish, and the alcohol was removed on the hot-plate. The aqueous solution was carefully treated, dropwise addition, with 5% hydrochloric acid. At the turning point of congo red no precipitation took place, but when the solution was made slightly more acid an amorphous solid separated out of solution. This was recrystallized from 95% alcohol several times, yield 0.65 g.

The compound is soluble in dilute alkali and concentrated hydrochloric acid and warm alcohol; it is slightly soluble in hot water.

(5) **5-(β-Picolyl)-5-*n*-propylbarbituric Acid.**—The synthesis of this material was carried out in the same manner as described for the picolylethylbarbituric acid. Four grams of the β-picolyl-*n*-propyl ethylmalonate gave 0.52 g. of the barbituric acid. It was recrystallized four times from 95% alcohol.

(11) Dehnel, *ibid.*, **33**, 3496 (1900).

(6) **5-(β-Picolyl)-5-*n*-butylbarbituric Acid.**—The synthesis was essentially the same as for the lower homologs. Two and one-half grams of the substituted malonic ester gave 0.71 g. of the product when recrystallized three times from 95% alcohol.

(7) **5-(β-Picolyl)-5-isoamylbarbituric Acid.**—The method of preparation was the same as above. Four grams of the substituted malonic ester gave 1.4 g. of the product when recrystallized three times from alcohol.

Summary

1. The synthesis of four new heterocyclic derivatives of barbituric acid which contain the β-picolyl group in the 5-position is described.

Titration Curves and Dissociation Constants of *l*-Ascorbic Acid (Vitamin C) and Diethyl Dihydroxymaleate

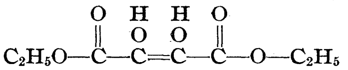
BY W. D. KUMLER AND T. C. DANIELS

Birch and Harris[1] using a micro method found the pK_a values of *l*-ascorbic acid at 16–18° to be $pK_{a_1} = 4.17$ and $pK_{a_2} = 11.57$. We have redetermined these constants at 22–23° using a macrohydrogen electrode and find values in agreement with theirs, namely, $pK_{a_1} = 4.12$ and $pK_{a_2} = 11.51$.

Although *l*-ascorbic acid is about four times as strong as acetic acid the generally accepted formula[2]  contains no carboxyl group, the acidity being attributed to the  $-\overset{|}{\underset{|}{C}}-\overset{\overset{H}{O}}{C}=\overset{\overset{H}{O}}{C}-\overset{\overset{O}{\|}}{C}-O-$ grouping.[2] As evidence that a structure of this type may give rise to relatively strong acid properties the case of reductone (glucose-reductone, gluco-reductone)  $H\overset{\overset{H}{O}}{C}=\overset{\overset{H}{O}}{C}-\overset{\overset{O}{\|}}{C}-H$ has been cited[2] which has a $pK_a = 5.0$.[3]

Reductone is the enol form of a 1,3-dialdehyde and these compounds like the enol forms of 1,3-diketones are undoubtedly much stronger acids than the enol form of the β-ketonic esters to which type of compound the structure assigned to *l*-ascorbic acid belongs. The enol form of acetylacetone has a $K_{a_{enol.}} = 1.3 \times 10^{-5}$ and the enol form of ethyl acetoacetate has a $K_{a_{enol.}} = 5 \times 10^{-9}$.[4] Thus for comparing acid strength reductone is not a correct analog of *l*-ascorbic acid.

We have measured the pK_a values of a β ketonic ester, diethyldihydroxymaleate



$$C_2H_5O-\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{O}}{C}=\overset{\overset{H}{O}}{C}-\overset{\overset{O}{\|}}{C}-O-C_2H_5$$

which contains the grouping to which the acidity of *l*-ascorbic acid has been attributed[2]  $-\overset{|}{\underset{|}{C}}-\overset{\overset{H}{O}}{C}=\overset{\overset{H}{O}}{C}-\overset{\overset{O}{\|}}{C}-O-$. Since the negativity of the  $C_2H_5O-\overset{\overset{O}{\|}}{C}-$ group is considerably greater than that of the  $HO-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{O}{C}}-$ group and the ester has two equivalent hydrogens it should actually be a stronger acid than *l*-ascorbic. However, from the pK_a values in Table I it is seen that *l*-ascorbic is much the stronger acid, its first dissociation constant being 1000 times as great as that of the other compound.

TABLE I

ALCOHOL–WATER SOLUTION

	pK_{a_1}	pK_{a_2}
l-Ascorbic acid	4.85	12.0
Diethyl dihydroxymaleate	7.88	12.3
Dimethyl dihydroxymaleate	7.85	12.3
WATER		
l-Ascorbic acid	4.12	11.51

The second dissociation constants have very nearly the same value, and in both cases are un-

---

[1] Birch and Harris, *Biochem. J.*, **27**, 595 (1933).

[2] Herbert, Hirst, Percival, Reynolds, Smith, *J. Chem. Soc.*, 1270 (1933).

[3] Von Euler and Martins, *Ann.*, **505**, 73 (1933).

[4] Acetylacetone $K_a = 1.5 \times 10^{-6}$, ethyl acetoacetate $K_a = 2 \times 10^{-11}$ (Landolt–Börnstein), acetylacetone $K_{enolization} = 0.132$, ethylacetoacetate $K_{enolization} = 0.004$ (Rice, "Mechanism of Homogeneous Organic Reactions," Chemical Catalog Co., p. 92). The $K_{a_{enol.}}$ constants were calculated from the above K_a's by use of the equation

$$K_{a_{enol.}} = K_a \frac{(K_{enolization} + 1)}{K_{enolization}}$$

doubtedly due to an enolic type of structure. The first constant of *l*-ascorbic acid is too strong to be attributed to an enolized α-hydroxy-β-ketonic ester but might be due to some other grouping such as the enol form of a hydroxy, 1,3-diketone, a free carboxyl group, or the opening of the lactone ring. We are aware of the various arguments which have been advanced against these types of structures[2] but in view of inability of the enolized α-hydroxy-β-ketonic ester structure to account for the first dissociation constant these arguments should be checked.

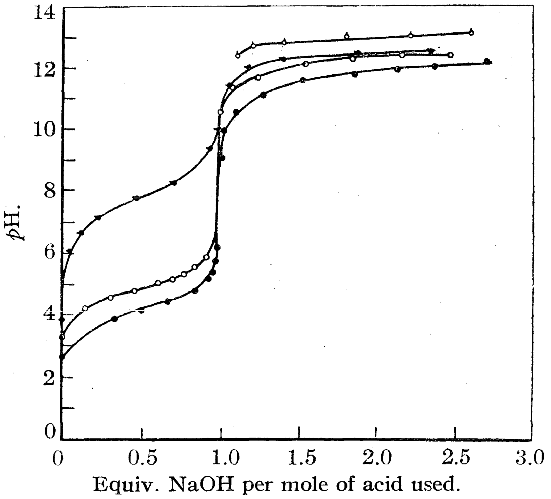


Fig. 1.—*l*-Ascorbic acid, ○: 0.0574 g. of acid, 4 ml. of alcohol, 4 ml. of water at beginning. Diethyldihydroxymaleate, -●: 0.0436 g. of compound, 4 ml. of alcohol, 4 ml. of water at beginning. No evidence of hydrolysis after thirty minutes at end of titration. Blank salt solution, ȯ: 0.109 g. of $NaC_2H_3O_2 \cdot 3H_2O$, 4 ml. of alcohol, 4 ml. of water. *l*-Ascorbic acid, ●: 0.0647 g. of acid, 5 ml. of water at beginning.

Experimental

A Hildebrand type hydrogen electrode and saturated calomel cell were used. These were checked against a standard phosphate buffer. A potentiometer–galvanometer circuit was used in obtaining the electromotive forces.

Due to the insolubility of the diethyl dihydroxymaleate in water the titrations were made in ethyl alcohol–water solutions which were 50% by volume at the start of the titration. Although the pK_a values are higher[5] in the alcohol solutions than in pure water they are strictly comparable with each other. The pK_{a_1} of *l*-ascorbic acid is 0.73 higher in the alcohol solution than in pure water.

As a check on the pK_a values of diethyl dihydroxymaleate the dimethyl ester was measured. Theoretically one would expect very little difference in the acidity of these two compounds and very little was observed as is shown by the pK_a values in Table I. However, since in the case of the dimethyl compound it was necessary to start with a 60% alcohol solution the values are not strictly comparable with the other two compounds but the errors thus introduced are less than 0.06 of a pK_a unit.

To demonstrate that the second pK_a is real and not an apparent effect due to the dilution of the 0.1 N sodium hydroxide, the curve for a sodium acetate blank is shown which falls definitely above the other curves.

Materials

Synthetic *l*-ascorbic acid was obtained from Hoffmann–LaRoche, Inc., and was used without further purification, m. p. 190°; literature m. p. 189, 190, 192°; molecular weight by titration 175.7, theoretical 176.1.

Dimethyl dihydroxymaleate was prepared by dissolving anhydrous dihydroxymaleic acid in the least quantity of anhydrous methyl alcohol and passing dry hydrogen chloride into the solution;[6] m. p. 150–151°, literature m. p. 151°.

Diethyl dihydroxymaleate was prepared by dissolving anhydrous dihydroxymaleic acid in anhydrous ethyl alcohol and passing dry hydrogen chloride into the solution;[7] m. p. 71–73°, literature 72–73°.

Dihydroxymaleic acid was prepared by oxidizing tartaric acid with hydrogen peroxide in the presence of ferrous iron[6] (p. 899).

Summary

The titration curves of *l*-ascorbic acid in water and of *l*-ascorbic acid and diethyl dihydroxymaleate in alcohol–water solution have been determined. The pK_a values of these compounds and of dimethyl dihydroxymaleate were measured. *l*-Ascorbic acid is 1000 times as strong as diethyl dihydroxymaleate. The apparent inability of the enolized α-hydroxy-β-ketonic ester type of compound to account for the acid properties of *l*-ascorbic acid suggests that some other grouping is responsible for its large first dissociation constant.

The Use of the Ortho–Para Hydrogen Conversion in the Detection of Free Radicals Produced in Photo-dissociation[1]

BY W. WEST

In considering the properties to be anticipated of the lighter free radicals which might be utilized to demonstrate their presence or absence in photochemical experiments, the paramagnetic properties which they should exhibit as the result of their possession of an odd electrom seem worthy of investigation. As, however, the low concentration of radicals to be expected in these experiments would make a direct determination of any change of susceptibility extremely difficult by ordinary magnetic methods, it was proposed to investigate the possibility of using the discovery of Farkas and Sachsse[2] that paramagnetic substances are capable of catalyzing the interconversion of ortho and para hydrogen for their detection. The method has already been used by Farkas and Sachsse in an investigation of the magnetic properties of B_2H_6,[3] and the possibility of its application to the problem considered here has also been stated by A. Farkas in his monograph.[4] If, for instance, methyl iodide vapor is dissociated by light to methyl radicals and iodine atoms in the presence of a mixture of ortho and para hydrogen which is not in equilibrium at the temperature of the experiment, the paramagnetic radicals should, during their period of free existence, be capable of changing the ortho–para ratio toward the equilibrium value, and the experimental finding of such a change could be taken as evidence of the production of paramagnetic substances, which, in this case, could scarcely be other than the methyl group or iodine atom. The result of absorption of radiation might also be the production of a molecule, without dissociation, in a paramagnetic excited state, which on collision with a hydrogen molecule might bring about conversion; but unless the excited state were metastable, its short life would cause such conversion to be negligibly rare in comparison with those brought about by the comparatively long lived free radicals.

Since the thermal conductivity method of Bonhoeffer and Harteck[5] will give false results for the ortho-para composition of a hydrogen mixture, if more than traces of gas other than hydrogen are admitted to the conductivity gage, it was necessary in these experiments, in which only liquid air was available as a refrigerant, to choose reactions in which the products contain little or no methane; carbon monoxide also is not removed by liquid air, but these experiments show that it can be fairly adequately removed by the usual cuprous-ammonium reagent. The production of molecular hydrogen is of course to be avoided, and also, as the conversion efficiency of hydrogen atoms is of the order of 10^6 times as great as that of substances effective in virtue of paramagnetic properties, the conversion in a reaction in which these are produced will mask that produced by other radicals. Methyl iodide, acetone, propionyl aldehyde and benzene were the substances examined.

Procedure

The platinum wire of the conductivity cell, spot welded to platinum leads, was 15 cm. long, 10 μ thick, with a resistance of some 50 Ω when carrying a heating current of 50 m. a. in hydrogen at 58 mm., the cell being immersed in liquid air maintained at constant level. In series with the wire was an accurate resistance of 50 Ω. From a measurement of the potential fall across this resistance by means of a Leeds and Northrup Student Type Potentiometer the current passing through the gage wire was calculated, and a measurement of the potential drop across the gage enabled its resistance to be determined. The heating current through the gage wire was made accurately the same for the different hydrogen samples required in a determination of the amount of conversion by adjusting a rheostat until a given potential difference existed across the standard 50 Ω resistance. Reproducibility of the gage resistance was usually within 0.01 Ω.

Dry hydrogen, freed from oxygen, from a 2-liter reservoir could be passed either directly to the gage ("ordinary" hydrogen, $o/p = 3/1$) or to the "converter" containing charcoal at liquid air temperature, where it was changed to approximately a 1:1 mixture ("converted" hydrogen). The converted hydrogen could be passed directly to the gage or bubbled through methyl iodide, etc., into the reaction vessel, a quartz tube 30 cm. long and 2.6 cm. in diameter, cemented to glass by silver chloride cement, and into a similar "blank" vessel (of glass, but with a silver chloride joint exactly like that in the reaction vessel) in

parallel with the reaction vessel. These vessels were filled to a total pressure of 1 atmosphere, the organic compounds being at a partial pressure equal to their vapor pressure at 20°. From these the contents could be passed through any necessary chemical absorbent and through a liquid air trap to the gage, which was filled by means of a capillary control to 58 mm. of mercury. The conversion was measured from gage resistance measurements in the presence of "ordinary," "converted," "illuminated" and "blank" hydrogen made immediately after one another. High vacuum technique was used throughout. Illumination was effected by two "cold" quartz mercury arcs 38 cm. long, placed as close as possible to the reaction tube, one consuming 300 watts at 3000 v., the other 500 watts at 5000 v. A large proportion of their luminous energy is at wave length 2537 Å. A fan directed on the arcs and reaction vessel kept the temperature practically that of the room. Radiation of wave length 1849 Å. was excluded by wrapping the reaction vessel in two layers of cellophane, 0.025 mm. thick.

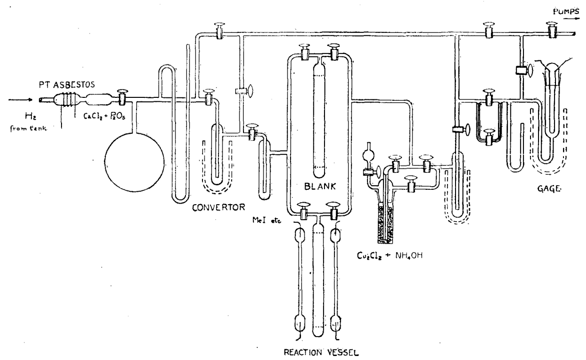

Fig. 1.—Reaction vessel.

Results

Preliminary experiments showed (a) a difference of about 1.8 Ω in the resistance of the gage wire in the presence of "ordinary" and completely "converted" hydrogen (b) a linear para-hydrogen concentration—resistance curve, (c) no change in the *o-p* ratio when a sample of converted hydrogen was left in the reaction vessel, without illumination, or in the blank overnight, whether in the presence or absence of methyl iodide vapor. Table I gives some representative results.

ΔR_1 is the difference in the gage resistance immersed in "illuminated" and "blank" hydrogen, respectively, and ΔR_0 the corresponding difference for "ordinary" and "converted."[6]

Table I

Substance	Exposure, min.	ΔR_1 ohms	ΔR_0	Corrected ΔR	% Conversion
Methyl	90	0.17	1.42	0.14	10
iodide	80	.21	1.79	.18	10[a]
	225	.68	1.79	.60	34[a]
	180	−.01	1.78		0[b]
Acetone	210	.60	.71	.31	44
	453	.90	1.03	.34	33

Benzene	110	.20	1.21		?
	128	.12	1.80		?

[a] The bracketed data refer to the same run. [b] Illumination through glass.

Corrections.—Since the presence of only a few per cent. of methane or carbon monoxide in the gas which reaches the gage will give completely fallacious results, special experiments were carried out on methyl iodide and acetone to find how much carbonaceous material escaped the traps. Methyl iodide was chosen in the first place because, although it has a strong continuous absorption at 2537 Å., the actual decomposition effected by illumination is very small. The iodine recovered after two hours of exposure of methyl iodide and hydrogen under the same conditions as in the conversion experiments required only 2.49 cc. of 5×10^{-3} *N* thiosulfate for its titration, equivalent, if one atom of iodine is produced for every molecule of iodide decomposed, to the decomposition of rather less than 0.5% of the iodide initially present. To determine directly the amount of methane produced under the conditions of these experiments, the gas resulting from two hours' exposure of methyl iodide and hydrogen under the conditions of the conversion experiments was passed by means of a Töpler pump through a liquid air trap into a gas buret. This was analyzed by slow combustion in excess oxygen over a heated platinum spiral by Dennis' method, and the products passed into an absorption pipet containing an accurately known volume (some 5 cc.) of 0.02 *N* baryta. A turbidity was produced, showing the presence of carbon dioxide; the excess baryta was titrated by 0.01 *N* hydrochloric acid (microburet) and an apparent methane percentage of 0.46 was found in the hydrogen. Mercury was used throughout the gas analysis, as confining liquid. A blank experiment on the hydrogen, unmixed with methyl iodide, but otherwise treated in the same way as in the former experiment, also gave a turbidity with baryta, apparently arising from carbon compounds in the short pieces of connecting rubber tubing and stopcock grease in the gas analysis apparatus, equivalent to 0.34% methane, so that a methane con-

---

[6] Values of ΔR_0 less than 1.8 Ω are due to a loss of efficiency of the charcoal in bringing about conversion to the low temperature equilibrium. After the introduction of air to the converter thorough baking out was found to be necessary to obtain a subsequent complete conversion to the 1:1 mixture.

tent of 0.12% is indicated in the hydrogen after two hours of illumination with methyl iodide.

The effect of this on the resistance of the gage wire can be estimated approximately in this way. From the calculated values of the rotational specific heats of ortho and para hydrogen at 93°K.,[7] one can calculate from the equation $\kappa = k\eta C_v$ the ratio of the thermal conductivities of 1/1 and 3/1 mixtures on the assumption that the viscosities are the same and that k is given by the somewhat uncertain equation[8]

$$k = {}^1/_4\,(9C_p/C_v - 5)$$

This ratio thus calculated is 0.963 for $\kappa(3/1):\kappa(1/1)$.

The thermal conductivity of hydrogen at 81°K. is given as 13.24×10^{-5},[9] and assuming this was for normal (3/1) hydrogen, the thermal conductivity for the 1/1 mixture is 13.77×10^{-5} and $\Delta\kappa = 0.53 \times 10^{-5}$. This corresponds to a difference in resistance in the gage wire of 1.79 Ω. In the experiment on methyl iodide in which an apparent change in resistance of 0.68 Ω was produced as the result of 225 minutes of illumination, 0.23% of methane might have been present in the hydrogen measured in the gage. The thermal conductivity of methane at 91.4°K. is given as 2.248×10^{-5},[10] and the conductivity of a mixture of 99.77% hydrogen (1/1) and 0.23% of methane would be 13.745×10^{-5}. The change in resistance in the gage wire produced by the presence of this amount of methane in the 1/1 mixture would be 0.085 Ω, compared with an observed change of 0.68 Ω, many times larger than could be accounted for by the production of methane. The change in gage resistance brought about in these experiments as the result of illumination seems attributable only to an actual change in the ortho–para ratio.

The acetone experiments were carried out with pure dry material in order to avoid the condensation reactions which take place in the presence of moisture.[11] The quantum yield in the photodecomposition of the vapor at wave length 26504 Å. is 0.33; half of the gaseous products consists of carbon monoxide and most of the rest of ethane; Damon and Daniels[11] report 10% of hydrogen in the product from the vapor, while Berthelot and Gaudechon[12] apparently from the photodecomposition of liquid acetone at the boiling point, find no hydrogen, but 5% methane in the products.

Removal of carbon monoxide by the cuprous ammonium complex ordinarily used for that purpose seemed the only method which would not disturb the ortho–para ratio, and the gas from the reaction vessel was slowly bubbled through a sludge of concentrated cuprous ammonium reagent and broken glass filling a trap between the reaction vessel and the liquid air trap. Special experiments showed that no conversion was brought about in this process. A direct determination of carbonaceous matter which escaped the traps, by the method previously described, showed the presence of 1.35% of such material estimated as methane or carbon monoxide as the result of three hours of exposure. The corrections have been made as before on the assumption that the interfering gas is methane; they would not be essentially changed if carbon monoxide were the disturbing substance. Although the corrections are considerable, there still remains a large resistance change in the gage as the result of illumination which cannot be accounted for by any methane or carbon monoxide possibly present.

Special significance is to be attached to the difference in the resistance changes produced by illuminating acetone and propionyl aldehyde, respectively. The quantum yield for the aldehyde decomposition of wave length 2537 Å. is about 1;[13] the principal products of decomposition are carbon monoxide and ethane, and an amount of hydrogen equal to 4% that of the carbon monoxide is reported. The products are of the same nature as and more in quantity than those from acetone; nevertheless, the observed change in resistance after illumination is only about one-sixth that produced by acetone. If the resistance change in the acetone experiments had been spurious, there would have been as large a change in the aldehyde experiments. The change of resistance observed in the aldehyde experiments is smaller than the corrections for the acetone experiments estimated as described above, and it seems very probable that it is entirely the effect of interfering material escaping the traps and that no appreciable ortho–para conversion is brought about by illuminated propionyl aldehyde. The

magnitude of the correction to be subtracted from the observed change of resistance in the acetone experiments seems therefore overestimated rather than underestimated.

There is a small decomposition of benzene vapor on illumination by the mercury arc,[14] and if the products are the same as in the mercury-sensitized photo-decomposition, hydrogen and methane will be present. In any case, the observed change of resistance was relatively small, and probably is almost entirely to be attributed to uncondensable products.[15]

Discussion

The net result of these experiments is that the illumination of 1/1 ortho-para hydrogen mixture in the presence of methyl iodide and of acetone vapor at room temperature by light of wave lengths in the continuous absorption region of the organic compounds leads to a greater change in the thermal conductivity of the hydrogen than can be accounted for by the spurious presence of uncondensable gas; and the only reasonable interpretation is that appreciable conversion of the hydrogen mixture toward the room temperature equilibrium has been brought about. As, apart from solid catalysts and atomic hydrogen, the only substances known to bring about this conversion at an appreciable rate at room temperature are paramagnetic substances, the only conclusion to be drawn is that the organic substances under the action of the light gave paramagnetic entities capable of bringing about the conversion. That these were free radicals, or possibly, also, from methyl iodide, iodine atoms, allows of no reasonable doubt. The primary dissociation of methyl iodide in the region of continuous absorption into methyl radicals and iodine atoms can therefore be taken as certain.

The difference in the behavior of acetone and of propionyl aldehyde with respect to ortho–para conversion is completely in accord with the conclusions of Norrish[16] that photodecomposition of the aliphatic ketones occurs with the production of free radicals and of the aldehydes with a primary separation of carbon monoxide and formation of a saturated hydrocarbon. It seems certain from the experiments reported here that any free radical production on illumination of propionyl aldehyde is either much smaller or involves a much shorter life than in acetone under the same conditions. Although the experiments of Leermakers[17] point conclusively to the existence of a chain reaction in the photo-decomposition of acetaldehyde at high temperature and hence presumably to the presence of radicals, the "chain yield" at 25° is only 0.03 and, to quote this author, "It is possible that there are two modes of decompositions of aldehydes, one resulting in radicals, the other in carbon monoxide and hydrocarbon directly." Also, the experiments on the ortho–para conversion are in satisfactory agreement with those of Pearson,[18] who, employing the mirror methods of Paneth for the detection of free radicals, showed that mirrors could be removed by the products of illuminated acetone, and to a much less degree by those of propionyl aldehyde, and concluded that acetone exposed to light produces radicals and propionyl aldehyde does not.

Summary

An attempt has been made to detect the presence of free radicals in photo-dissociations by making use of the effect discovered by Farkas and Sachsse of the paramagnetic interconversion of ortho and para hydrogen.

Conversion in excess of any possible spurious effect was found to be produced by methyl iodide and acetone vapors illuminated to radiation of frequency in their continuous absorption regions, and not by propionyl aldehyde nor benzene.

The results are interpreted as indicating the production of paramagnetic free radicals on illumination of methyl iodide and acetone. The occurrence of conversion from acetone and not from propionyl iodide is strong evidence in support of Norrish's hypothesis of a difference in mechanism in the photo dissociation of aliphatic aldehydes and ketones.

(15) The effect of benzene and of other hydrogen containing compounds reported by Farkas and Sachsse (*loc. cit.*) in bringing about ortho–para conversion is much too small to be detected in these experiments; that, for instance, methyl iodide itself does not bring about a conversion comparable to those noted here is shown conclusively by the blank experiments on methyl iodide, without illumination, and by the experiment on illumination through glass.

The Photolysis of Azomethane

BY GEORGE S. FORBES, LAWRENCE J. HEIDT AND DARRELL V. SICKMAN

Measurements of quantum yields provide a valuable check upon hypotheses regarding energy chains in the corresponding thermal reactions. Carried out in monochromatic light, and at temperatures where a wholly negligible fraction of molecules present can be activated in unit time by collisions, the energy available after reaction can be calculated, and then apportioned among various combinations of molecules presumably involved in subsequent collisions. The temperature coefficients, also, of such photolyses have an obvious bearing upon the interpretation of the data for the thermal reactions.

Ramsperger[1] reported a quantum yield somewhat over two for the photolysis of azomethane, using the treacherous method of light-filters. Under his experimental conditions the nonactinic light was from one-third to five times the light absorbed, and he apparently overestimated the necessary corrections. The initial reaction he wrote $CH_3—N{=}N—CH_3 + h\nu \longrightarrow C_2H_6 + N_2$. The energy of the photon at 366 mμ, 83,000 cal./mole and the heat of reaction, 20,000 cal./mole add up to 103,000 cal./mole of which the ethane would be expected to retain the greater part. Ramsperger has argued that each newly formed ethane molecule might provide energy of activation (51,000 cal./mole) for one new azomethane molecule, and thus bring the total decomposition up to the value observed.

We found it hard to understand why the quantum yield, if two, should be independent of both temperature and pressure as stated by Ramsperger. We were convinced that measurements at additional wave lengths (Ramsperger made use of λ 366 mμ only) would afford additional information.

We carried out four series of measurements, at initial pressures of 664, 377, 184 and 181 mm., respectively. Six wave lengths of monochromatic light were employed. We found that the quantum yield, ϕ, approaches unity as its upper limit for initial decomposition at low pressures. The photochemical temperature coefficient if $t \ngtr 226°$ was found to be zero, in agreement with Ramsperger, as became reasonable in the light of the revised quantum yield. But at 260° this coefficient was no longer negligible.

Experimental

The monochromator, spark source, uranyl oxalate actinometer and trapezoidal gas reaction cell, as well as details of operation and the necessary corrections, were essentially the same as in recent work on ozone in this Laboratory.[2,3] At λλ 366 and 313 mμ a constricted mercury arc[4] replaced the spark; its oscillations were controlled by thin annular films of mercury within ground joints.[5] The monochromatic intensities back of the exit slit ranged from 3.8×10^{16} to 7.4×10^{17} quanta per minute.

The actinometer cell used at λλ 366 and 335 mμ was trapezoidal in form, 3 cm. deep, and held 11 cc. of a solution containing 0.003 mole of washed uranyl oxalate and 0.003 mole of oxalic acid per liter. At λ 313 mμ the same solution was used in a rectangular cell 5 mm. thick, and holding 5 cc. The quantum yields have been shown by Forbes and Heidt[6] to be identical with those previously established by W. G. Leighton and Forbes.[7] At λλ 254 and 208 mμ the rectangular cell was used with a solution 0.001 *M* in uranyl sulfate and 0.005 molal in oxalic acid, standardized in this wave length range by Brackett and Forbes.[8] Since the gas cell and the actinometer cell were exposed alternately as described below, the fluctuations in intensity of the light source were not followed radiometrically.

The reaction cell was fused into the wall of a quartz beaker which served as a thermostat. A ring of felt surrounding the space between the front window and the exit slit tended to hold the temperature of the former at the temperature inside the cell. Two immersion heaters regulated automatically, or by hand, held temperatures constant within 0.05°. A layer of thermostating liquid over the meniscus of the mercury in the regulator in each case was found to increase greatly the sensitivity of the make-and-break to temperature changes. Water was used in the thermostat from 0 to 70°, diethylene glycol 70 to 125°, *n*-butyl phthalate 125 to 200° and castor oil 200 to 300°. Temperatures were recorded with a set of Anschütz thermometers. The monochromator was pivoted under the light source[9] so that its exit slit could swing into line with reaction cell or actinometer cell as desired.

Previous experience with the photolysis of ozone[2,3] had convinced us of the fundamental importance of rigorous purification of reactants and the elimination of stopcocks. The purifying train as well as the reaction cell was thoroughly flamed, and degassed by means of a diffu-

and then stored in a liter bulb. In view of these precautions it appeared proper to assume that initial pressures in the reaction cell represented azomethane exclusively. After introduction of gas, this cell, together with the spiral quartz manometer, was sealed off from the rest of the apparatus. The mercury manometer to which the zero readings of the quartz manometer were referred reproduced pressure changes within 0.05 mm.

Tables I to IV include all our photolytic measurements where Q and B are respectively quanta incident upon, and absorbed by, the gas per minute, with omission of the factor 10^{16}. A is the percentage of incident light absorbed by the gas. The average total pressure during a photolysis is $\overline{P}$ and the average partial pressure of azomethane calculated from Ramsperger's mechanism is $\overline{p}$. The temperature of the cell, t, follows. Time of a given photolysis is in minutes. The manometer and barometer readings in millimeters of mercury have been corrected to 0°, and the gas pressures reduced to 0° by means of the simple gas law. Following Ramsperger, our quantum yields, ϕ, represent the increase in the number of molecules, in the reacting system, per quantum absorbed, and were calculated by use of Ramsperger's absorption coefficients, k, except at 208 mμ, beyond the spectral range covered by him, where the absorption, in our cell, was evidently complete. As he obtained these data by using a spectrograph and calibrated screens, after the method of Ramsperger and Porter,[10] the uncertainties inherent in the filter method could not have vitiated the results. We were, however, obliged to make the undesirable assumption that the variation of extinction coefficients with temperature is unimportant over a range of 240°. Except at 260°, the highest temperature employed by us, the velocity of decomposition in the absence of light was negligible.

Discussion of Results

In order to make the corrections for transmitted light as small as possible the wave lengths 208 and 335 mμ (the latter corresponding to an absorption maximum of azomethane) were first employed. The *initial* value of ϕ is seen to be close to unity at 181 mm., a pressure intermediate between Ramsperger's greatest pressure and his next smaller one. But at 377 and 665 mm. $\phi = 0.77$, indicating clearly the increase in deactivation with pressure. The decrease in ϕ at all pressures, as decomposition increased at room temperature, is very striking. Ramsperger gives four averaged quantum yields only, one for each of four initial pressures, but we calculated relative values of ϕ for each of his twenty separate experiments, and found that his values also decreased with increasing decomposition at room temperature. The decrease of ϕ with increase of initial pressure was less noticeable in Ramsperger's results, because three out of four of his pressures were much smaller than any of ours. He observed that "a very slight deposit was formed on the front window of the reaction chamber" upon raising temperature from 20 to 100°. Such a deposit was evident to us almost immediately after beginning of illumination by λ 208 mμ in the pressure range in which we operated. No deposit was formed at λ 366 mμ. The photolysis of even one millimeter of gas was attended by a decrease in ϕ far greater than experimental error whenever a deposit was formed. As our material was insufficient in amount to permit of refilling the cell after each twenty-minute run, we had to resort to graphical treatment of results to eliminate this complication. In Fig. 1, plots of ϕ against pressure change yield a straight line within the limits of experimental error, which might be expected if the falling off in the light entering the cell, for *small* changes in extinction by the deposit on the window, were roughly proportional to the thickness of this de-

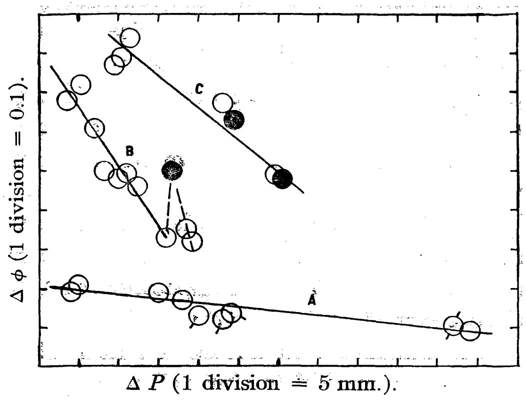

Fig. 1.—Δ ϕ/Δ P shown as independent of t (if $t \ngtr 226°$), and dependent on wave length only. Curve A at λ 366 mμ; circles at 25°, single-flag circles at 100°, double-flag circles at 226°. Curve B at λ 208 mμ; all experiments at 21°. The solid circle resulted just after heating the front window to 100° for twelve hours. Curve C at λ 335 mμ; all experiments at 21°. No break resulted (solid circles) upon heating the front window to 100° for twelve hours.

[10] Ramsperger and Porter, THIS JOURNAL, **48**, 1267 (1926).

posit. The opacity of the deposit is greatest at λ 208 mμ due in part to increased scattering. Interference rings were plainly seen after the deposit had become well developed, an observation in harmony with the fact that the light intensity was greatest at the center of the window, and fell off toward the edges. The deposit could be partially dispelled by gentle heating of the front windows over twelve hours, as is evident from Fig. 1 upon comparing experiment 1–6 with 1–7a at 208 mμ. On the other hand, no increase in transmission at λ 335 mμ was observable—compare 1–4 with 1–5, also 1–8 with 1–9. The falling off in ϕ with increase in decomposition was likewise much less rapid at λ 335 mμ than at λ 208 mμ—compare series 1–2, 1–4, 1–5, 1–8, 1–9 all at 335 mμ with 1–1, 1–3, 1–6 and 1–7 all at 208 mμ.

Unfortunately we had material insufficient to trace the relation between ϕ and λ over the entire wave length range. Still, series 2a where $\phi = 0.25$ at λ 254 mμ may properly be compared with the average of series 2–1 and experiment 2–3 at λ 208 mμ, $\phi = 0.54$. This increase in ϕ with size of the quantum indicates that the probability of dissociation before deactivation increases in the same sense. At λ 254 mμ the light energy, 110,000 cal./mole, is more than twice the activation energy, 51,000 cal./mole while at 208 mμ the ratio is nearly three. But even with this great excess of energy there is no evidence that a second azomethane molecule is activated and subsequently decomposed.

In view of the fact that ϕ is halved in going from λ 208 mμ back to λ 254 mμ, the approximate equality in ϕ for initial decomposition at λλ 366, 335 and 208 mμ is at first sight unexpected. However, the maximum in absorption at λ 335 mμ appears to correspond to absorption in the N=N bond, for the N–C bond does not absorb in this region as is evident upon examining for instance the absorption curve of acetamide.[11] Owing to the stability of the N=N bond and the fact that the two N–C linkages are *both* adjacent to it, a smaller quantum might well produce dissociation than in the case where a larger quantum is absorbed beyond the first absorption maximum, presumably by a single N–C bond.

The temperatures represented by the various points in Fig. 1, plot a, are distributed in random fashion along the (approximately) straight line, the slope of which, as pointed out above, is to be referred to the increase in the deposit upon the front window. It therefore seems permissible to draw the conclusion that the effect upon ϕ of an increase in temperature of 206° is incapable of detection. If the photolysis were a chain reaction at 226° the large percentage of molecules in high vibrational states at this temperature might contribute noticeably to the quantum yields.[12,13] At 260°, however, the dark reaction has become equal to one-third of the photochemical reaction, and the contribution of such molecules to the photochemical reaction rate is no longer negligible.

We are indebted to Dr. O. K. Rice for the opportunity to discuss with him various aspects of this research.

A subsequent paper will deal with approximate physical analyses of the reaction products both thermal and photochemical. In the light of these data it would appear that the reaction mechanism is closely similar in both cases.

Summary

Quantum yields, ϕ, for photolysis of azomethane at 181, 184, 377 and 665 mm. were measured by reference to a uranyl oxalate actinometer. Purification and photolysis alike were carried out in a train without stopcocks, following the technique and precautions developed in previous researches. Six monochromatic radiations were employed. By graphical methods allowance was made for deposition of difficultly volatile decomposition products upon the front window.

The quantum yield ϕ approaches unity as its upper limit for initial decomposition at low pressures.

A temperature increase, 20 to 226°, had no effect on ϕ. Evidently reaction chains are absent in this temperature interval. But in the vicinity of 260° the photochemical temperature coefficient became measurable.

With increasing pressure ϕ falls off rapidly, apparently because of collisional deactivation.

In the region 366 to 335 mμ approximately, ϕ passes through a maximum apparently corresponding to a maximum of absorption by the N=N bond. With increasing quanta ϕ next decreases to a minimum, then increases again when the N–C bond begins to absorb.

The Chemiluminescence of 3-Aminophthalhydrazide

BY LOUIS HARRIS AND ALMON S. PARKER

The oxidation of 3-aminophthalhydrazide in alkaline solution is accompanied by considerable light emission.[1] A knowledge of the quantum efficiency under various conditions may assist in interpreting the mechanism of this light emission. Measurements of the quantum efficiency have been reported for certain chemiluminescent reactions,[2,3] and while conclusions have been drawn from measurements with dilute flames, data for condensed phases are meager. In this investigation, measurements were made to determine the maximum quantum efficiency of the chemiluminescence of 3-aminophthalhydrazide and the effect of various factors on this efficiency.

A thermopile offers a more direct measure of the chemiluminescent energy than photometric measurements, but is usually too insensitive. However, if the light reaction zone is made to approach a point source, a larger fraction of the emitted light energy may be focused on the thermopile surface. A number of preliminary measurements indicated that if a solution of sodium luminol[4] containing hydrogen peroxide was thoroughly mixed with a large excess of strong oxidizing agent (alkaline hypochlorite), the light reaction could be confined to a small volume. Accordingly, a suitable reaction chamber was designed and the energy measurements effected with a thermopile.

Materials.—**1. Sodium luminol** was prepared according to directions.[5]

2. Hydrogen peroxide (3% U. S. P.) was analyzed before its addition to the sodium luminol solutions.

3. Sodium hypochlorite was prepared by bubbling commercial (tank) chlorine slowly through a solution *N* in sodium hydroxide and 2 *N* in sodium carbonate, with continuous stirring until the solution contained about 5% (by weight) available chlorine (as Cl_2). This solution was diluted to a chlorine content of 0.5 or 1.0%, and sodium carbonate added to bring the alkali concentration to 0.350 *N* (carbonate).

Any other chemicals used were of C. P. quality and distilled water was employed throughout.

Apparatus.—A number of reaction chambers were tested; that illustrated in Fig. 1 proved the most satisfactory. This chamber could be so operated that a brilliant spherical spot of light (2 mm. in diameter; slightly larger for the concentrated solutions) appeared at the point where the reactants met, with no residual light in the effluent. The chamber was constructed of standard size glass tubing with quartz tubing around the reaction zone. The sodium luminol plus hydrogen peroxide feed nozzle was 0.483 mm. in diameter. Stopcocks in the connecting lines from two 18-liter aspirator bottles, containing the reactants, regulated the gravity flow. The spot of light was focused by a quartz lens, 3.8 cm. in diameter and 19.1 cm. away, on the sensitive surface of a Kipp (micro) thermopile. (The image of this spot, formed by the lens, was slightly smaller than the active surface of the pile which was 28.26 sq. mm.) The thermopile was connected to a Leeds and Northrup H. S. type galvanometer. The thermopile–galvanometer system was calibrated with two standard lamps (Bureau of Standards).

Experimental Procedure

It was necessary to determine what part of the galvanometer deflection was due to heat of mixing or to any other extraneous effects. Proper shielding of the system prevented stray light from entering the thermopile. Preliminary measurements showed that it was advisable to store the bottles containing the reactants for twenty-four hours, before making measurements, in a thermally insulated room (24 to 25°) with the thermopile–galvanometer system. When sodium luminol solution (in the absence of hydrogen peroxide) was mixed in the chamber with the hypochlorite, the galvanometer deflection obtained was less than 1% of the maximum deflection when hydrogen peroxide was present. Likewise, when hydrogen peroxide solution alone was mixed with the hypochlorite, the deflection obtained was a negligible fraction of that obtained under normal conditions of operation.

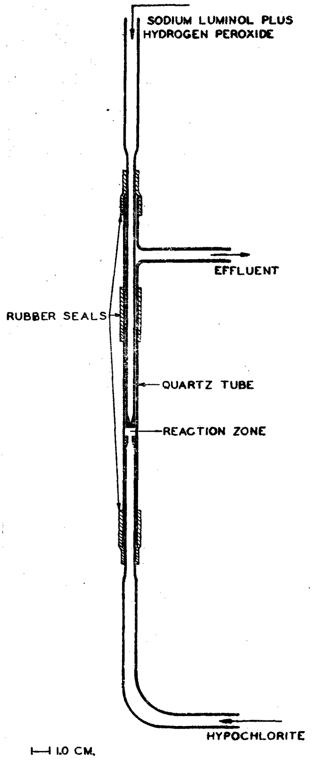

Fig. 1.—Reaction chamber.

The maximum flow of sodium luminol plus hydrogen peroxide was limited by the liquid head (about 1.5 m.) and the capillary feed nozzle (Fig. 1). After the rate of sodium luminol plus peroxide had been fixed, the flow of

hypochlorite was adjusted to give a small spot of light on the lens-side of the reaction zone. Under these conditions, moderate variations (as high as 15%) in the rate of flow of hypochlorite had no influence on the galvanometer deflection. When potassium ferricyanide plus sodium hydroxide was tried as the oxidizing agent, in place of hypochlorite, the light was no longer confined to a spot but filled the reaction zone and appeared dimmer than before.

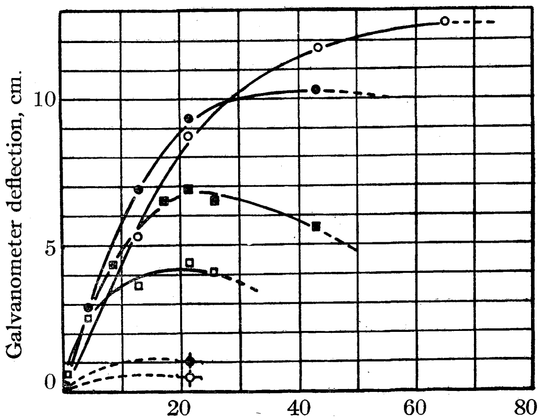
Data.—The data are presented in Figs. 2 and 3. Each of the galvanometer deflections plotted is the average of ten observations. The average deviation was 3%. Different batches of the reactant solutions gave the same deflections within 5%. The change in galvanometer deflection with varying rate of flow of sodium luminol plus hydrogen peroxide is shown in Fig. 2. By interpolation of these data, it was found possible to express all data for other rates of flow. The data, interpolated in this way, are presented in Fig. 3, which also shows how variations in the hydrogen peroxide concentration affect the galvanometer deflections.

Quantum Efficiency

It was assumed that the chemiluminescent intensity was equal in all directions and that the source might be considered as a point. The latter assumption was validated by measurements with a larger lens. Therefore, the galvanometer deflections were an easily calculated fraction of the total energy emitted.



Concentration of hydrogen peroxide, g. mole × 10^3/liter.

A spectroscope showed that the chemiluminescence extended from the violet, deep into the red. A quartz cell filled with distilled water, placed between the reaction zone and the thermopile, reduced the galvanometer deflections by about 10%. Jena filter OG2b, which transmits nearly 100% from 5780 to 20,000 Å., reduced the galvanometer deflection by about 98%, showing that only 2% of the chemiluminescent energy was of wave lengths longer than 5780 Å.

Photographs of the chemiluminescence and of the emission from a standardized lamp, taken with a Hilger E315 spectrograph and III-L Eastman Kodak plates, assisted in evaluating the energy distribution of the chemiluminescence. Most of the chemiluminescent radiation was in the wave length region 3800 to 5000 Å. with a flat maximum from 4100 to 4400 Å.

Inasmuch as the sodium luminol, hypochlorite and the product of the chemiluminescence each absorbs light of wave lengths shorter than 3700 Å., the energy observed may be only a fraction of the total produced.

The following constants and variables were used in the calculation of the quantum efficiency (Eff).

Eff = quanta emitted per molecule of sodium luminol introduced.
d = galvanometer deflection (cm.).
v = rate of flow of sodium luminol plus hydrogen peroxide (ml. per sec.).
a = concentration of sodium luminol (g. mole per ml.).
f = galvanometer calibration factor (8.556 ergs per sec. per cm. deflection).
λ = wave length of the maximum chemiluminescent intensity (4250×10^{-8} cm.).
l = fraction of the total emitted light focused on the thermopile (0.00246) (calculated from the geometry of the system).
t = fraction of light transmitted by lens and chamber wall (0.9).
h = Planck's constant (6.554×10^{-27} erg. sec. per quantum).
c = velocity of light (3.00×10^{10} cm. per sec.).
N = Avogadro's number (6.063×10^{23}).

$$\text{Eff} = \frac{d}{v \times a} \times \frac{f \times \lambda}{l \times t \times c \times h \times N}$$

Figure 4 shows how the quantum efficiency varies with the concentration of sodium luminol and with the rate of flow of sodium luminol plus hydrogen peroxide. The numerical value for the quantum efficiency, from the maximum of the lowest curve of Fig. 4, was calculated to be 2.8×10^{-3} quanta per molecule of sodium luminol introduced. At lower rates of flow of sodium luminol plus hydrogen peroxide the efficiency increased but never more than doubled.

Fluorescence Experiments

Even though the chemiluminescence extended over a rather broad band in the spectrum, it seemed of interest to study the emission of light from aqueous solutions of sodium luminol when they were illuminated by an external source. Most of the experiments were performed under daylight illumination with window glass interposed between the light and the solutions ($\lambda >$ 3400 Å.). The fluorescence was found to be much stronger when hydrogen peroxide was added to the sodium luminol. The fluorescence intensity was a maximum for concentrations of sodium luminol between 0.00025 and 0.00005 molal. Although the maximum quantum efficiency is also in this concentration range, no correlation between the two is implied. It is more likely that the dependence of the fluorescence on concentration is determined by the molal absorption coefficient (ϵ = 8000 approx. for wave lengths shorter than 3700 Å.).

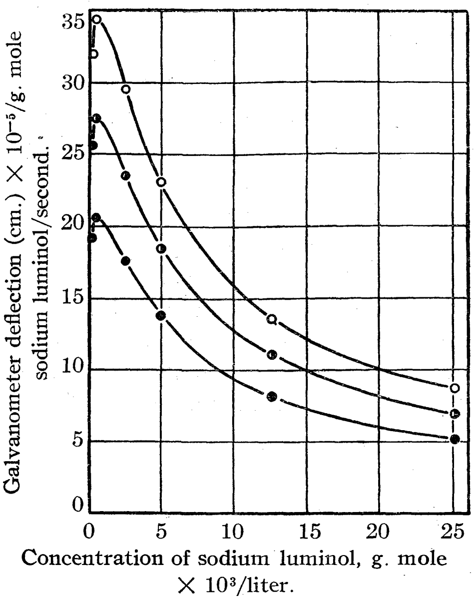

Fig. 4.—Variation of energy emitted per mole of sodium luminol, with its concentration. Concentration of hydrogen peroxide: maxima of Fig. 3. Concentration of hypochlorite, 1% Cl_2: concentration of alkali, 0.350 N.

○	0.1 ml./sec.
◑	0.5 ml./sec.
●	1.0 ml./sec.

Absorption Spectra Measurements

Quantitative measurements of the absorption spectra were made, in order to obtain further information concerning the reactants and products. The absorption of aqueous solutions of sodium luminol, and of mixtures of sodium luminol with hydrogen peroxide, extended from 3970 to 2400 Å. Each solution showed absorption maxima at 3500 and 2900 Å., and evidence of another maximum at shorter wave lengths than 2500 Å. Below 3600 Å. the absorption by sodium luminol is slightly but definitely different from that of solutions containing hydrogen peroxide, the necessary corrections having been made for absorption by hydrogen peroxide alone. Absorption by aqueous solutions of the product from the chemiluminescence extends from 5000 to below 2300 Å. The amount and character of the absorption depended upon the manner in which the reactants were brought together. The results indicate that the internal absorption, by the final products, and possibly by the intermediate products, reduces the light emission, especially for concentrated solutions. In evaluating the quantum efficiencies, however, the internal absorption has been neglected.

Discussion of Results

The change in energy emission with changing hydrogen peroxide concentration (Fig. 3) indicates that hydrogen peroxide plays a major role in the chemiluminescence. The fluorescence and the absorption spectra point to the same conclusion. Figure 3 indicates that each molecule of sodium luminol is associated with about four molecules of hydrogen peroxide. This, in conjunction with the other results, suggests a compound between sodium luminol and hydrogen peroxide. The binding between the two types of molecule is probably a loose one and the molecular ratio in the compound itself is not necessarily four to one.

The quantum efficiency, though low, is about 10,000 times higher than any thus far reported for condensed systems.[3] The comparatively high efficiency is, no doubt, assisted by the successful mixing. The prolonged chemiluminescence customarily observed seems to indicate that in those instances, the rate of reaction is limited by the rate of diffusion. The fact that the rate observed with potassium ferricyanide is less than with hypochlorite, indicates that a smaller concentration of the active oxidizing agent is produced in the former case. Recently,[6] there was reported an intense chemiluminescence in the oxidation of alkaline solutions of dimethyldiacridylium nitrate by hydrogen peroxide. The luminescent interval was shortened from hours to seconds and the light intensity increased considerably by the addition of a catalyst, osmium tetroxide, which decomposed the hydrogen peroxide. A similar result is obtained in the oxidation of sodium luminol by physical rather than chemical means.

Mechanism of Chemiluminescence

It seems fairly definitely established that sodium luminol plus hydrogen peroxide is the light-emitting molecule or its parent substance. The light-emitting molecule is brought to its energized state by reactions of the parent with some oxidizing substance. The relatively low quantum efficiency would then be explained by one or more of the following non-light producing processes: (a) simultaneous reactions of the reactants to form other substances; (b) reactions of the excited molecule with the oxidizing substance; (c) collisions "of the second kind" involving the excited molecules or the oxidizing substance. In addition, if transitions corresponding to the ultraviolet occur, the quantum efficiency is reduced, due to internal absorption.

Since the light-emitting process may consist of several steps, where the excited molecules do not fall directly to the ground level, it is difficult to draw conclusions concerning the energetics of the over-all reaction.

Summary

The oxidation of the sodium salt of 3-aminophthalhydrazide has been carried out under conditions to give a maximum light intensity. The quantum efficiency was found to be about 0.3%. Evidence for compound formation between hydrogen peroxide and the sodium salt has been presented. The mechanism of the chemiluminescence has been discussed.

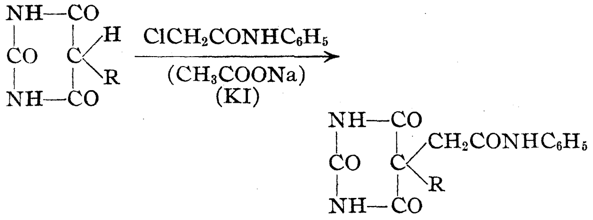
Alkyl-acetanilido-barbituric Acids

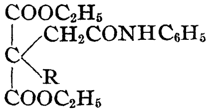
BY JOHN A. TIMM

Of the many derivatives of barbituric acid, which have been prepared and tested for their value as sedatives and hypnotics, the molecules of none, as far as the author is aware, contain the acetanilido group attached to the 5 carbon atom. The well-known use of acetanilide as an antipyretic suggested its use as a substituent in the barbituric acid ring. Accordingly various 5-alkylbarbituric acids have been condensed with chloroacetanilide using a modification of the method of Dox and Houston[1] who used sodium acetate to condense chloroacetone and barbituric acid in alcohol–water solution. In our experiments it was found that sodium acetate alone would not effect condensation but that if potassium iodide were added also condensation proceeded with satisfactory yields as follows.



The following barbituric acids were prepared by this method: 5-ethyl-5-acetanilido-; 5-*n*-butyl-5-acetanilido-; 5-isobutyl-5-acetanilido-; 5-isoamyl-5-acetanilido-; and 5-allyl-5-acetanilido-. Their possible pharmacological activity will be tested and published elsewhere.

Attempts were made to condense chloroacetanilide with the sodium salts of various ethyl monoalkylmalonates in absolute alcohol solution to obtain malonic esters of the type



which might then have been condensed with urea to form the desired barbituric acids. These attempts failed as did the similar ones of Dox and Houston[1] in which they attempted to condense chloroacetone with alkylmalonic esters.

Experimental Part

Barbituric Acids Containing the Acetanilido Group.—One molecular proportion of the appropriate alkyl-barbituric acid was dissolved in 35% alcohol by gentle heating on a water-bath in a flask provided with a stirrer and a reflux condenser. An equimolecular proportion of chloroacetanilide,[2] a one and one-half molecular proportion of sodium acetate, and a quarter molecular proportion of potassium iodide were dissolved in warm 80% alcohol. The second solution was added slowly to the first and the mixture refluxed with stirring for seven hours. The desired product crystallized partially during the process of the reaction. The mixture was cooled in an ice-bath and the product filtered off. Partial evaporation of the filtrate yielded a second crop of crystals. The product in each case was recrystallized from 80% alcohol. All are colorless, crystalline solids which melt with decomposition. Physical and analytical data of these new compounds are summarized in Table I.

TABLE I

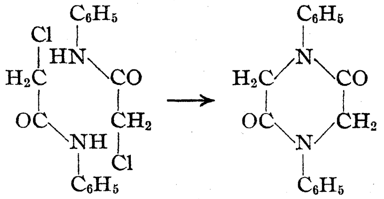
Attempt to Prepare Ethyl Acetanilidoethylmalonate.—When an equimolecular proportion of chloroacetanilide was warmed on a water-bath with the sodium salt of ethyl ethylmalonate until the absolute alcohol solution became neutral, condensation did not take place in the desired manner to form ethyl acetanilidoethylmalonate. A white solid separated which proved to be diphenyl-diketo-piperazine (m. p. 263°)[3] formed from the condensation of two molecules of chloroacetanilide:



The oily layer was extracted with ether; dried over sodium sulfate; the ether removed and the remaining oil distilled *in vacuo*. A colorless oil was obtained, b. p. 164° (9 mm.), which contained 7.24% of nitrogen. This could not have been ethyl acetanilidoethylmalonate whose nitrogen content is 4.36%. It might have been ethoxyacetanilide (N, 7.8%).

The author wishes to express his appreciation to Dr. Arthur J. Hill for his helpful suggestions during the progress of this work and to Mr. John B. Howard for his help in the analysis of these new compounds.

Studies in the Ketone Sugar Series. V. The Validity of Hudson's Rules of Isorotation in the Ketose Group. Preparation of the True α-Pentaacetylfructose<2,6>

BY EUGENE PACSU AND FRANCIS B. CRAMER

Twenty years ago Hudson and Brauns[1] prepared a positively rotating pentaacetylfructose by acetylation of β-tetraacetylfructose<2,6> in the presence of zinc chloride. Since this pentaacetate was different from the β-pentaacetylfructose<2,6> obtained[2] from the same tetraacetate by using sulfuric acid with acetic anhydride for the acetylation, it was allocated to the α-series. Five years later Brauns[3] prepared from β-tetraacetylfructose<2,6> two chloroacetylfructoses, designating the one having specific rotation[4] -161 in chloroform as the α-, and the one having 45.3 in chloroform as the β-form. Subsequently, Brauns' allocations were reversed at the suggestion of Hudson,[5] the dextrorotatory compound becoming the α-, and the levorotatory the β-chloroacetylfructose. On the assumption that these two isomers constituted an α,β-pair with the same ring which is present in the parent β-tetraacetylfructose, Hudson[5] calculated the rotation of carbon 2 to be $a_{\text{Cl}} = 37{,}800$, and that of the acetylated basal chain common to them, comprising asymmetric carbon atoms 3,4 and 5, to be $b_{\text{fruct. ac.}} = -21{,}200$. The fact that the constant a_{Cl} was found to be the same both in sign and magnitude as $A_{\text{Cl}} = 37{,}900$[6] for the aldoses was regarded as evidence that the substitution of —CH_2OAc for —H does not change the rotation of carbon atom 2. This conclusion seemed to be confirmed by the additional fact that the values of a_{F} and a_{Br} in the ketose group also have been found to be practically equal to the corresponding values of A_{F} and A_{Br} for the aldose group. It appeared therefore, safe to assume that $a_{\text{Ac}} = A_{\text{Ac}} = 19{,}100$, which is the average value for the aldoses. However, combining $a_{\text{Ac}} = 19{,}100$ with the constant $b_{\text{fruct. ac.}} = -21{,}200$, the specific rotations for α-, and β-pentaacetylfructoses become -5 and $-103°$, respectively, in chloroform, whereas the two known pentaacetates of fructose show 34.7 and $-121.0°$, respectively. In view of this disagreement, Hudson concluded that "it seems very unlikely that the dextrorotatory pentaacetate can be the expected α-form." As to the other known pentaacetate, of specific rotation $-121.0°$, Hudson stated that "it may be the expected β-form, though the difference of 18° in specific rotation makes such a conclusion uncertain." However, it was recently proved[7] that neither "α-chloroacetylfructose" nor "α-pentaacetylfructose" possesses a ring structure in its molecule, but both of these "α"-isomers are derivatives of the open-chain fructose, the former being 1,3,4,5-tetraacetyl 6-chloro*keto*fructose, and the latter 1,3,4,5,6-pentaacetyl*keto*fructose. Consequently, all calculations and conclusions based on the assumption that either the two chloro acetates or the two pentaacetates of fructose constitute α,β-stereoisomeric pairs, are invalid. This discovery *ipso facto* invalidated the above inference that the values of the different A_{x} constants for the aldoses are equal to those of the corresponding a_{x} constants in the ketose group. It also reopened the problem of the validity of the principle of optical superposition in the ketose series for further investigation. In order to test this principle it is necessary to know the optical rotations of a true α,β-stereoisomeric pair of any ketose or ketose derivative. It is remarkable that in the ketose series, contrasting with the aldose, no such true, α,β-pair has hitherto been known with cer-

(6) The revised mean value of this constant is $A_{\text{Cl}} = 39{,}450$. It is obtained by using $A_{\text{Cl}} = 38{,}100$ found by Hudson and Kunz [THIS JOURNAL, **47**, 2052 (1925)] for chloroacetyllactose instead of the old value of $A_{\text{Cl}} = 30{,}300$ [Hudson, *ibid.*, **46**, 462 (1924)].

(7) Pacsu and Rich, *ibid.*, **54**, 1697 (1932); **55**, 3018 (1933).

tainty. To be sure, Schlubach and Schröter[8] prepared a crystalline methylfructoside tetraacetate, which they regarded as representing the α-isomeride of the known β-methylfructoside tetraacetate<2,6>. However, the allocation of their substance to the α-series was made on a premise that was shown in Part IV[9] of this series to be incorrect. It seemed, therefore, advisable to search for another α-derivative of fructose that might be used as a key substance to test the validity of the principle of optical superposition in the ketose group. Such a substance has now been provided by the discovery of the true α-pentaacetylfructose<2,6>. On replacement of the chlorine atom in β-acetochlorofructose<2,6> by an acetoxyl radical, no Walden inversion occurs on carbon atom 2, if the reaction be carried out in acetic anhydride solution with silver acetate.[10] The reaction product represents the pure β-pentaacetylfructose<2,6>. However, a partial Walden inversion does take place on carbon atom 2, if the same exchange reaction be carried out in boiling acetic anhydride solution with anhydrous sodium acetate. The mixture so obtained was found to consist of about 71% of the β-pentaacetate and 29% of the α-isomeride. After separation from the β-compound, the α-pentaacetylfructose<2,6> was isolated in pure, crystalline form; m. p. 122–123°; specific rotation 47.4° in chloroform. Using the molecular rotation of the β-pentaacetate ([M] −47,200) and the new acetate ([M] 18,500), the constants $a_{\text{Ac}} = 32{,}850$ and $b_{\text{fruct. ac.}} = -14{,}350$ were obtained from the two equations: $-47{,}200 = -a_{\text{Ac}} + b_{\text{fruct. ac.}}$ and $18{,}500 = +a_{\text{Ac}} + b_{\text{fruct. ac.}}$. It is seen that $a_{\text{Ac}} = 32{,}850$ for the ketoses is very much larger than $A_{\text{Ac}} = 19{,}100$ for the aldoses. Knowing the value of $b_{\text{fruct. ac.}}$, it is now possible to calculate the different a_{x} values for the ketoses, and the specific rotations of the α-isomerides from the corresponding β-derivatives. For instance, the value of a_{OMe} is calculated from the molecular rotation of the known β-methylfructoside tetraacetate<2,6> ([M] −45,200) to be $a_{\text{OMe}} = 45{,}200\text{–}14{,}350 = 30{,}850$. Hence, the specific rotation of α-methylfructoside tetraacetate<2,6> will be $(30{,}850 - 14{,}350)/362 = 45.5°$. Schlubach's crystalline tetraacetylmethylfructoside is recorded as having specific rotation 45.0° in chloroform. The excellent agreement between these two values indicates that Schlubach's compound is really the α-isomeride of the tetraacetyl-β-methylfructoside<2,6>. Fifteen years ago Brauns[11] prepared a crystalline β-ethylfructoside tetraacetate<2,6> from tetraacetyl-β-fructose-<2,6> by ethylation and reported for the pure substance m. p. 83° and specific rotation −127.6° in chloroform. From the molecular rotation ([M] −48,000) of this compound, and using the above constant of $b_{\text{fruct. ac.}} = -14{,}350$, the value of $a_{\text{OEt}} = 48{,}000 - 14{,}350 = 33{,}650$ is obtained. Hence, the specific rotation of the α-isomeride is calculated to be $(33{,}650 - 14{,}350)/376.2 = 51.3°$ in chloroform. In Part IV[9] of this series, there has been described a new crystalline ethylfructoside tetraacetate with m. p. 103–104°, and specific rotation 51.6° in chloroform. Here again, the agreement between the calculated and the observed value is excellent, and it supports the conclusion that the new fructoside represents the α-form of Brauns' β-ethylfructoside tetraacetate <2,6>.

In Table I there are shown the values of the different a_{x} constants for the ketoses calculated from the known β-derivatives of fructose, and the corresponding A_{x} values for the aldoses. It is seen that these constants, with the exception of a_{OH}, are throughout larger in the ketose than in the aldose series. Table I also shows the calculated specific rotations of the α-isomerides. The very satisfactory agreement between calculated and observed rotations in the case of methyl- and ethylfructoside tetraacetate leads to the conclusion that Hudson's rules of isorotation hold closely in the ketose series. It will be attempted to prepare some of the unknown α-derivatives from the new fructose pentaacetate.

Experimental Part

Preparation of α-Pentaacetylfructose <2,6>.—To a gently boiling mixture of 7 g. of anhydrous sodium acetate and 70 g. of freshly distilled acetic anhydride there was added 13.7 g. of β-acetochlorofructose<2,6> in one portion. A rapid reaction took place and sodium chloride precipitated. After thirty minutes of boiling, the solution was filtered from the sodium salts and the filtrate was concentrated *in vacuo* to a sirup which was mixed with 300 cc. of ice-cold water. The oily precipitate obtained soon turned into a crystalline solid (10.8 g.) which showed specific rotation −71.6° in chloroform solution. The filtrate was neutralized with solid sodium bicarbonate, extracted with chloroform, the chloroform layer dried with calcium chloride and evaporated *in vacuo* to a thick sirup. The ether solution of the latter soon deposited crystals at 0°;

[a] From α- and β-ethylglucoside tetraacetate [J. H. Ferguson, THIS JOURNAL, **54**, 4086 (1932)]. [b] See Footnote 6. [c] This revised mean value is obtained by using A_{Br} = 59,300 [Hudson and Kunz, *ibid.*, **47**, 2052 (1925)] for bromoacetyllactose instead of A_{Br} = 56,500 [Hudson, *ibid.*, **46**, 462 (1924) .

yield, 1.1 g.; specific rotation −110.0° in chloroform. Since pure β-pentaacetylfructose<2,6> has the value of −120.9° in chloroform, and the pure α-pentaacetate has later been found to show specific rotation 47.4° in chloroform, the first crop (10.8 g.) of the reaction product obtained consisted of about 28.8% (3.1 g.) of the α- and 71.2% (7.7 g.) of the β-pentaacetate. The isolation of the isomerides was accomplished by a rough mechanical separation followed by one recrystallization from alcohol. The mixture (10.8 g.) was dissolved at room temperature in 250 cc. of absolute ether, and the solution was kept undisturbed in the icebox for several days. During this time 4 g. of crystalline material separated consisting of large crystals of the β-pentaacetate and small crystals of different appearance of the α-isomeride. The large crystals were sorted out (2.6 g.) and showed specific rotation −111.3° in chloroform; the small prismatic crystals of the α-isomeride (1.4 g.) showed the value of 26.5° in the same solvent. After one recrystallization from 10 cc. of absolute alcohol, the latter substance had m. p. 122–123°, $[\alpha]^{20}{}_D$ 47.4°; $[\alpha]^{20}_{6563}$ 38.0°; $[\alpha]^{20}_{5463}$ 56.0°; $[\alpha]^{20}_{4861}$ 73.0° and $[\alpha]^{20}_{4358}$ 94.3° in chloroform (0.2774 g. of substance, 10 cc. of solution; 2-dm. semi-micro tube; rotations, 2.63, 2.11, 3.11, 4.05 and 5.23° to the right, respectively); yield, 1.1 g. Another recrystallization from alcohol and a final one from chloroform by addition of ether at 0° did not change the rotation or melting point. The new acetate is soluble in most organic solvents except petroleum ether and cold alcohol. It is fairly soluble in hot water. In an acetyl estimation 0.2228 g. of the substance required 28.5 cc. of 0.1 *N* sodium hydroxide solution. The value calculated for the hydrolysis of five acetyl groups is 28.5 cc. The titrated solution (56.5 cc.) which contained 0.1028 g. of *d*-fructose, rotated sodium light 0.67° to the left in a 4-dm. tube at 20°, corresponding to specific rotation −92.0°, which is the constant rotation of *d*-fructose in water solution.

Summary

1. The true α-pentaacetylfructose<2,6> with m. p. 122–123° and specific rotation 47.4° in chloroform has been prepared. By the aid of this key substance it has been possible to calculate the correct a_x values for the ketone sugar derivatives.

2. The different a_x values for the ketoses are, with the exception of a_{OH}, throughout larger than the corresponding A_x values for the aldoses.

3. From the a_x values, the specific rotations of several α-fructose derivatives have been calculated. The excellent agreement between calculated and observed values of the methylfructoside tetraacetate of Schlubach as well as the ethylfructoside tetraacetate of Pacsu leads to the conclusion that (a) both compounds belong to the α-series (b) Hudson's rules of isorotation hold closely in the ketose group.

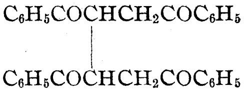
The Structures of the Dimolecular Reduction Products of Dibenzoylethylene

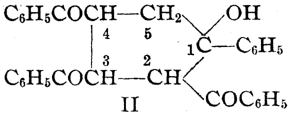
BY ROBERT E. LUTZ AND FRED S. PALMER

A dimolecular product has been obtained from the reduction of dibenzoylethylene (III) with the heterogeneous combination zinc and glacial acetic acid,[1] and further studies described in this and the two following papers have led to the isolation from the various reductions of a total of five isomers which are closely related structurally as is evident from the intertransformations described under Diagram 1. The results of our studies show that these five compounds are of two types. Two of them are *dl* and *meso* isomers of I and are designated for convenience as bis-dibenzoylethanes-A and -B. The other three appear to be cyclic internal ketols of these (II) and are named *cyclo*-bis-dibenzoylethanes-A, -B and -C.



$$\begin{array}{c} C_6H_5COCHCH_2COC_6H_5 \\ | \\ C_6H_5COCHCH_2COC_6H_5 \end{array}$$

I



II

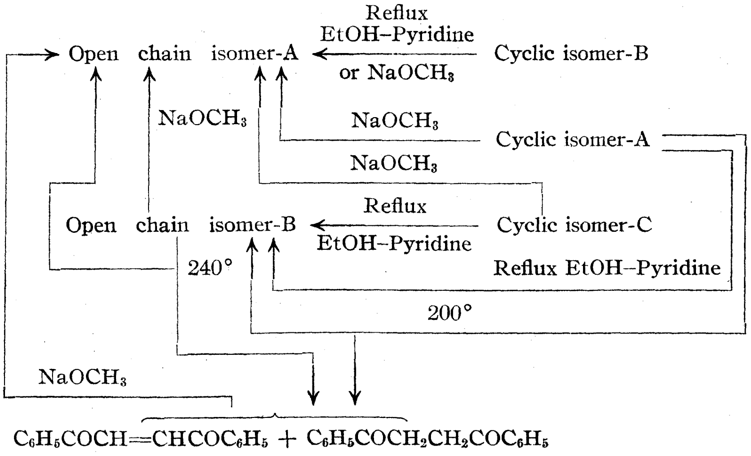


DIAGRAM 1.

All of these isomers are rearranged by sodium methylate into the open chain bis-dibenzoylethane-A which presumably separates from an equilibrium mixture through its exceeding insolubility in alcohol. In three of these transformations ring fission has taken place, presumably through reversal of an internal ketol condensation, and in at least two instances the configurations with respect to carbons 3 and 4 (formula II) have been reversed. The rearrangement of the cyclic isomers-A and -C into the open chain isomer-B may be accomplished also by refluxing in 85% ethanol containing pyridine; and the cyclic isomer-B under these conditions goes to the open chain isomer-A. The ring fissions in the latter cases, in contrast with those brought about with sodium alcoholate, take place without change in configuration, as is evident from the fact that both open chain stereoisomers are obtainable and are stable in boiling alcoholic pyridine. The open chain isomer-B is partly rearranged into the open chain isomer-A at 240° with some decomposition into dibenzoylethylene, dibenzoylethane and resinous materials; the open chain isomer-A slowly distils unchanged in the vacuum oven at this temperature. The cyclic isomers are unstable at temperatures above 200°; *cyclo*-bis-dibenzoylethane-A under these conditions is rearranged in excellent yield into the open chain isomer-B, accompanied by some decomposition giving small amounts of dibenzoylethylene and dibenzoylethane, III and IV.

It is very evident that the open chain isomers are the stable types and are formed easily by fission of the ring. The closure of the ring, however, has not been effected in any instance except during the actual formation of the dimolecular compounds in the reduction of dibenzoylethylene.

From the above facts it is clear that the configurations of the cyclic isomers-A and -C with respect to carbons 3 and 4 correspond to that of the open chain isomer-B, and the configuration of *cyclo*-B to that of the open chain isomer-A. The fact that, of the open chain isomers, A is the stable one (at 250°) and is the higher melting and the less soluble, suggests that possibly this is the *meso* form and that the isomer-B is *dl*,[2] and consequently that the cyclic isomer-B has the *cis* arrangement of

---

[1] Lutz, THIS JOURNAL, **51**, 3008 (1929).

[2] *Cf.* the *dl*- and *meso*-dibenzoyldihalogenoethanes [Lutz, *ibid.*, **48**, 2905, 2916 (1926); **49**, 1106 (1927)] and the dihalogenosuccinic acids.

benzoyl groups on carbons 3 and 4, and -A and -C the *trans*.

All of the reactions and relationships described in Diagram 1 are consistent with the formulation of the dimolecular compounds either as open chain polyketones (I) or as cyclic internal ketols of these (II).

Dehydration either with acetic anhydride and sulfuric acid or with acetyl chloride was found to confirm the structures assigned above to the two types of dimolecular products. The open chain compounds, as diastereoisomeric bis-saturated 1,4-diketones, lose two molecules of water under these conditions and give one and the same bisfuran V whereas the cyclic isomers behave like β-hydroxy ketones and lose only one molecule of water, as would be expected from the formula II, to give the cyclic α,β-unsaturated ketone IX.

The dehydration of the open chain bis-dibenzoylethanes-A and -B is illustrated in Diagram 2. The structure of the product, bis-2,5-diphenylfuran V, is clear from the fact that upon oxidation with the nitric and glacial acetic acid reagent, a yellow compound is obtained which corresponds in analysis and properties with bis-dibenzoylethylene VI, and which is easily reduced by means of sodium hydrosulfite to bis-dibenzoylethane-A. The reactions involved are characteristic,[3] and constitute adequate evidence for the open chain formulation of the dimolecular compounds in question, particularly in view of the fact that the cyclic isomers behave consistently in a different sense.

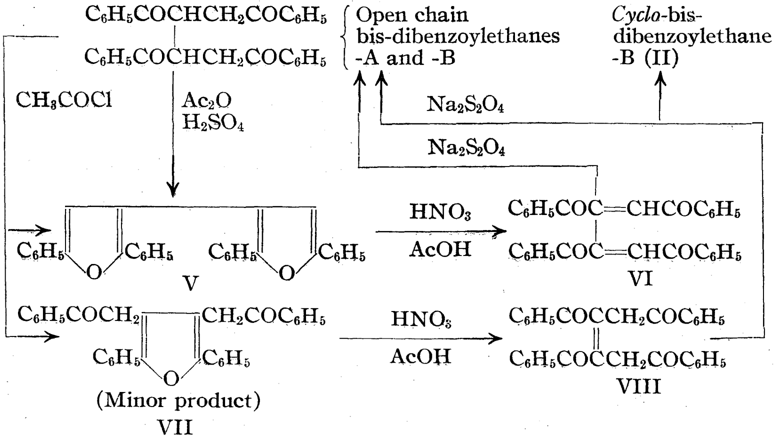

DIAGRAM 2.

A mono-dehydro compound, diphenacyldiphenylfuran (VII) theoretically could be formed also upon dehydration, since the open chain dimolecular compounds should be able to act also in the sense of the diphenacyl saturated 1,4-diketone. A search based on this consideration revealed such a product which was present in small amounts in the crude residues from the purification of the products of the dehydrations using acetyl chloride. This compound is oxidized by the nitric–glacial acetic acid reagent to a diphenacyldibenzoylethylene VIII (presumably the *cis* form), which in turn is reduced to a mixture of the dimolecular products by means of sodium hydrosulfite. These results are in complete accord with the various structures assigned in Diagram 2.

Bis-dibenzoylethane-A was synthesized by the direct condensation of dibenzoylethylene and dibenzoylethane by means of sodium methylate. This reaction (illustrated in Diagram 1) is analogous to the Michael condensation with α,β-unsaturated ketones and may be regarded as confirming the nature of the carbon chain in the dimolecular products. However, since all of the dimolecular compounds including the cyclic isomers are rearranged by means of sodium methylate into this same bis-dibenzoylethane-A, the reaction does not add further information concerning the isomerism. In connection with this reaction it is noteworthy that, whereas the condensation product is very stable and distils in high vacuum at 250°, the stereoisomeric bis-dibenzoylethane-B breaks down at this temperature, giving partly the more stable isomer-A (I) and also approximately equivalent amounts of dibenzoylethylene and dibenzoylethane, the products of a reversal of the Michael condensation.

The cyclic bis-dibenzoylethanes-A, -B and -C, in contrast with the open chain isomers, give on dehydration with acetic anhydride and sulfuric acid or with acetyl chloride only one product which is formed through the loss of one molecule of water and which is different from the diphenacylfuran obtained as described above. This characteristic reaction supports our formulation of the cyclic dimolecular compounds as substituted β-hydroxy ketones, and the dehydro compound as the cyclic

---

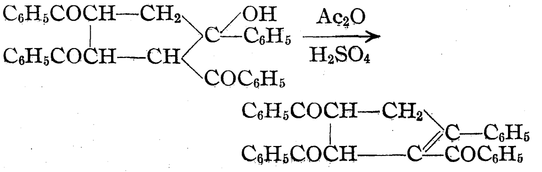
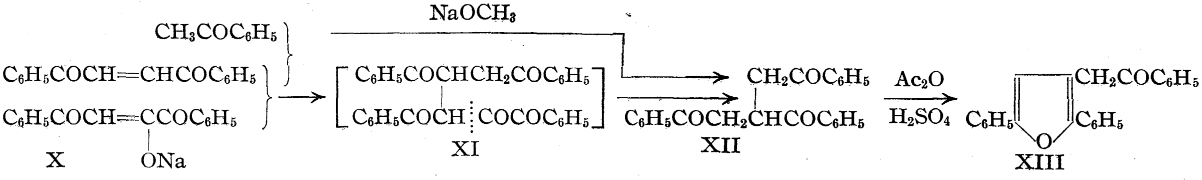
α,β-unsaturated ketone, 1-phenyl-2,3,4-tribenzoylcyclopentene, IX.[4] This hypothesis appears to be the only reasonable one available and is in complete accord with all of the facts.[5]



IX

Theoretically this dehydration product IX should exist in two diastereoisomeric forms, but only one has been obtained. Obviously in at least one instance reversal of configuration with respect to the groups about carbons 3 and 4 has occurred. The dehydro compound, unlike the true furans derived from I, does not react readily with the nitric–glacial acetic acid reagent under the usual conditions.

We had hoped through ozonization of this dehydro compound IX to accomplish fission of the ring and to obtain the pentaketone XI. We attempted to synthesize this pentaketone by the condensation of the sodium derivative of dibenzoylethenol and dibenzoylethylene. The reaction gave, however, tribenzoylpropane XII, a product clearly formed by hydrolytic cleavage of the desired and probably intermediate pentaketone. This hydrolytic product XII was synthesized also by the condensation of acetophenone and dibenzoylethylene, and its structure was confirmed by dehydration with acetic anhydride and sulfuric acid to the known phenacyldiphenylfuran XIII.[6]



X XI XII XIII

The ozonization of the cyclopentene IX did not proceed as expected, but nevertheless gave an ultimate result which was understandable and consistent with our formulation of the various compounds and reactions involved. The colorless compound obtained on hydrolysis of the noncrystalline product of ozonization proved to be a peroxide (XIV) from which the cyclopentene IX could be regenerated by gentle heating or by the action of potassium iodide, oxygen and iodine, respectively, being liberated. These reactions, particularly the latter, are typical of the peroxides of this type which are known.[7] Under the influence of sodium methylate the peroxide XIV is converted directly into tribenzoylpropane in small but significant yield; the reaction probably either involves rearrangement to the hypothetical pentaketone XI followed by hydrolytic fission, or proceeds through XV. The peroxide XIV when refluxed with 70% ethanol for twelve hours gave a new substance which according to analysis and molecular weight could be formed only through the loss of an atom of oxygen; this product must be the oxido compound of formula XV. The rearrangement with loss of oxygen of an α,β-peroxide to a β-diketone has been reported[8] but in the case in hand, since such a rearrangement is impossible without fission of the ring, it is not unreasonable to suppose that an oxide is formed. This compound under the influence of sodium methylate gives tribenzoylpropane XII in good yield. The reaction is accounted for in a reasonable way through a series of steps such as is illustrated in Diagram 3, namely, hydrolysis of the oxide system, ring fission involving a typical reversal of a ketol condensation (as in the change II $\xrightarrow{NaOCH_3}$ I), and hydrolytic splitting of the resulting product into tribenzoylpropane and phenylglyoxal (the latter would hardly be expected to be stable under the circumstances, and was not isolated).

While some of the steps in this degradation of the *cyclic* bis-dibenzoylethanes to tribenzoylpropane are not established with certainty, we believe nevertheless that the results constitute confirmatory evidence in support of the various structures assigned.

---

(4) *Cf.* the internal condensation of the dimolecular reduction products of α,β-unsaturated ketones such as mesityl oxide, phorone, benzalacetone, and benzalacetophenone [Harries and Hübner, *Ann.*, **296**, 295 (1897); Harries and Eschenbach, *Ber.*, **29**, 2121 (1896); Conant and Cutter, THIS JOURNAL, **48**, 1016 (1926)].

(5) A hydroxydihydro-1,4-pyran formula for the cyclic dimolecular compounds is a possible but very improbable alternative to the cyclic ketol formulation because, while it might account for the stereoisomerism and some of the reactions, it involves a cyclic hemiacetal linkage between an enol hydroxyl and a carbonyl group, for which there is no analogy.

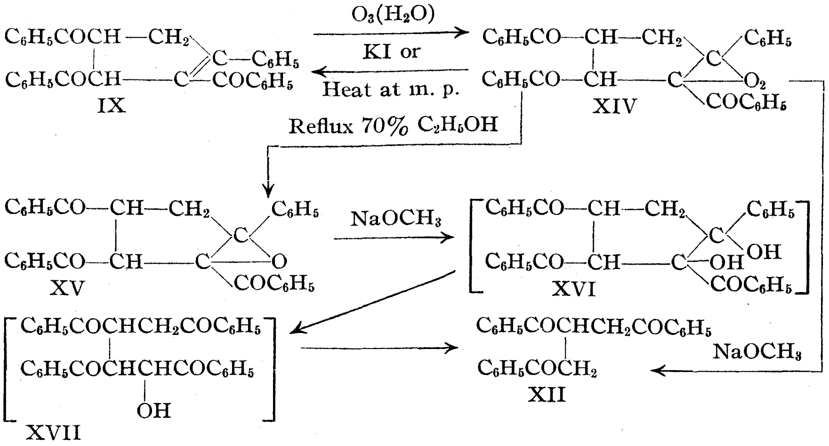

DIAGRAM 3.

Experimental Part

Bis-dibenzoylethane-A (1,6-diphenyl-3,4-dibenzoylhexanedione-1,6), I, is best prepared by the condensation of dibenzoylethane and dibenzoylethylene. A suspension of 2 g. of dibenzoylethane in 125 cc. of absolute ethanol was treated with a solution of 0.25 g. of sodium in 30 cc. of absolute ethanol, and the resulting mixture added with stirring over a period of three hours to a suspension of 2 g. of dibenzoylethylene in 100 cc. of absolute ethanol. The solids dissolved and a fine crystalline precipitate appeared. On standing for two hours, 2.5 g. of nearly pure product was obtained (yield 62%). It crystallized as short prisms from chloroform (adding a little petroleum ether) and from chlorobenzene; m. p. 202° (corr.). The method works equally well on a larger scale, and with methanol as the solvent. The compound is very difficultly soluble in hot ethanol (about 0.15 g. per 100 cc. at the boiling point), and acetone.

Anal. Calcd. for $C_{32}H_{26}O_4$: C, 81.01; H, 5.48. Found: C, 80.79; 80.66; H, 5.47; 5.69.

This isomer may also be prepared as follows: (a) 1 g. of *cyclo*-bis-dibenzoylethane-A was shaken with 100 cc. of absolute ethanol containing 0.4 g. of dissolved sodium. On standing for fifteen hours the crystalline precipitate was filtered from the red solution (0.2 g.), was recrystallized from chlorobenzene, and identified as bis-dibenzoylethane-A by mixed m. p. (b) A mixture of *cyclo*-bis-dibenzoylethane-B (0.01 g.) in 2 cc. of ethanol with 1 drop of pyridine was refluxed for twenty-four hours and deposited a cake of the characteristic granular crystals of the open chain bis-dibenzoylethane-A (identified by mixed m. p.).

This isomer is unaffected by fusion at 240–250° in the vacuum oven and distils slowly onto the cold finger condenser with a slight amount of decomposition. It is unaffected by prolonged refluxing in chlorobenzene or ethanol.

Bis-dibenzoylethane-B (1,6-diphenyl-3,4-dibenzoylbutanedione-1,6), I, is formed in small amounts in some of the reductions described in the following two papers, but it is difficult to isolate since it is the most soluble of the five dimolecular compounds. It is best prepared by rearrangement of *cyclo*-bis-dibenzoylethane-A in either of the following two ways: (a) a mixture of 5 g. of *cyclo*-bis-dibenzoylethane-A, 280 cc. of 85% ethanol, and 3.4 g. of pyridine was refluxed for twenty-four hours. On cooling and filtering 2.4 g. of nearly pure open chain isomer-B was obtained. A second crop was obtained from the filtrate (total yield 65–75%). (b) *Cyclo*-bis-dibenzoylethane-A was fused at 200° in the vacuum oven for one hour, giving a small amount of distillate which collected on the cold finger condenser (this was shown to be a mixture of approximately equal amounts of dibenzoylethane and dibenzoylethylene which were isolated and identified by mixed melting points). The fused mass, on crystallization from alcohol, proved to be nearly pure bis-dibenzoylethane-B. This isomer was obtained also as follows: 0.05 g. of *cyclo*-bis-dibenzoylethane-C was refluxed in 5 cc. of 95% ethanol with 4 drops of pyridine for twenty-one hours. On dilution with water 0.04 g. of nearly pure bis-dibenzoylethane-B was obtained and identified.

The compound crystallizes as characteristic thin square plates from ethanol; m. p. 168° (corr.).

Anal. Calcd. for $C_{32}H_{26}O_4$: C, 81.01; H, 5.48. Found: C, 80.84, 80.75; H, 5.49, 5.47.

The compound is not affected by long refluxing in ethanol.

Pyrolysis and distillation of 1 g. in the vacuum oven at 230–240° gave a distillate containing some bis-dibenzoylethane-A and considerable amounts of dibenzoylethane and dibenzoylethylene (identified by mixed melting points).

Rearrangement.—A solution of 0.07 g. in 5 cc. of methanol containing 0.05 g. of dissolved sodium, on standing for twenty-four hours, gave a crystalline deposit of the open chain isomer-A (0.05 g., identified by mixed m. p.).

3,3′-Bis-2,5-diphenylfuran, V.—Ten grams of bis-dibenzoylethane-A (or -B) was suspended in 50 cc. of acetic anhydride and 10–15 drops of concd. sulfuric acid. The resulting solution on standing for fifteen minutes was decomposed in ice water, giving 7.1 g. of nearly pure product which was crystallized from acetone; m. p. 195–196° (corr.).

Anal. Calcd. for $C_{32}H_{22}O_2$: C, 87.67; H, 5.02. Found: C, 87.57, 87.67; H, 5.08, 5.08.

One-gram samples of both isomers, I-A and I-B, on standing for eighteen hours in 50 cc. of acetyl chloride, with subsequent hydrolysis, gave mixtures consisting largely of the bis-diphenylfuran. The crude product was washed with hot alcohol, leaving the bis-furan as the residue; the washings contained the diphenacylfuran which is described below.

Bis-1,2-dibenzoylethylene (1,6-Diphenyl-3,4-dibenzoyl-2,4-hexadiene-1,6-dione), VI.—Ten grams of V was suspended in 75 cc. of glacial acetic acid and a solution of 5 cc. of concd. nitric acid in 25 cc. of glacial acetic acid was added slowly, the temperature maintained at 30–35°. The crystals went into solution and a yellow solid then separated. After ten minutes this was filtered; yield 6.3 g. of m. p. 205–210°. It was recrystallized from chloroform–acetone mixtures and from butanone; m. p. 214–218° (corr.).

Anal. Calcd. for $C_{32}H_{22}O_4$: C, 81.67; H, 4.72. Found: C, 81.61; H, 4.79.

Reduction of 0.5 g. with 3 g. of sodium hydrosulfite in 100 cc. of 70% ethanol (refluxing two hours) gave 0.24 g. of bis-dibenzoylethane-A (identified by mixed melting point). Catalytic reduction (platinum) in ethyl acetate was stopped when the reaction rate slowed down with the absorption of approximately one molecule of hydrogen, but gave largely non-crystalline products and a small yield of bis-dibenzoylethane-A. Zinc and glacial acetic acid reduction appeared to give two new products (*cf.* m. p. 160–165° and 199–200°) which have not yet been investigated.

2,5-Diphenyl-3,4-diphenacylfuran, VII.—The residue from evaporation of the alcohol washings from the main fractions in the above-described dehydration of the open chain bis-dibenzoylethanes with acetyl chloride, was fractionally crystallized from ethanol and gave a very small amount of the second product which melted at 164–165° (corr.).

Anal. Calcd. for $C_{32}H_{24}O_3$: C, 84.17; H, 5.31. Found: C, 84.10; H, 5.51.

(*Cis*)-1,2-diphenacyl-1,2-dibenzoylethylene (1,6-Diphenyl-3,4-dibenzoyl-3-hexene-1,6-dione) VIII.—A suspension of 0.1 g. of VII in 0.7 cc. of glacial acetic acid was treated with 0.05 cc. of concd. nitric acid in 0.25 cc. of glacial acetic acid. Immediate reaction at room temperature took place, a new crystalline product appearing. After standing ten minutes, cooling, and filtering, 0.085 g. of nearly pure product was obtained which, after several crystallizations from ethanol, melted at 183–184° (corr.).

Anal. Calcd. for $C_{32}H_{24}O_4$: C, 81.31; H, 5.12. Found: C, 81.19; H, 5.17.

Reduction of 0.016 g. with 2 g. of sodium hydrosulfite in 2 cc. of 70% ethanol (refluxing fifteen minutes) gave 0.015 g. of a mixture of bis-dibenzoylethanes melting at 182–183° which showed a mixed melting point depression with *cyclo*-bis-dibenzoylethane-C, but none with the cyclic isomer-B and the open chain isomer-A. The microscopic examination of the crystals indicated that the product is really the mixture of the latter two isomers as shown by the mixed melting points.

1-Phenyl-2,3,4-tribenzoylcyclopentene-1, IX.—Ten grams of *cyclo*-bis-dibenzoylethane-A was dissolved in 75 cc. of acetic anhydride at 90° and 8 drops of concd. sulfuric acid added, the mixture then being heated for twenty minutes at 90° and decomposed in ice water. On completion of hydrolysis the solid was precipitated nearly pure and was filtered and washed with water; yield 8.1 g. It crystallized from ethanol as large thin rhombic needles; m. p. 182° (corr.).

Anal. Calcd. for $C_{32}H_{24}O_3$: C, 84.17; H, 5.31. Found: C, 84.10, 84.09; H, 5.34, 5.31.

The 1-Phenyl-2,3,4-tribenzoylcyclopentene-1 Peroxide, XIV.—Ozonized oxygen was passed for four hours through a solution of 5 g. of IX in 30 cc. of dry chloroform. The solvent was then evaporated in a current of moist air and the residue allowed to stand in contact with water. The product was extracted with ether, and on concentrating a total of 3.5 g. of crystals was isolated; m. p. 115–118° (with effervescence). Recrystallization from chloroform–ether or ethyl acetate–ligroin mixtures gave the m. p. 132–133° (corr.) (with effervescence). Alcohol was not used for recrystallization since decomposition occurs in this solvent. Attempts to induce the oily ozonide to crystallize were unsuccessful, and digestion with water appeared necessary to obtain a crystalline product. Ozonization carried out in 80% glacial acetic acid gave directly the peroxide.

Anal. Calcd. for $C_{32}H_{24}O_5$: C, 78.66; H, 4.95. Found: C, 78.38; H, 4.88.

Pyrolysis of the peroxide by heating slowly to 140° gave a fused mass from which on crystallization from ethanol only IX was obtained (identified by mixed melting point). When pyrolysis was effected by sudden heating of the sample in an oil-bath at 140–150°, violent evolution of gas occurred with deposition of benzoic acid on the walls of the vessel. Crystallization of the residue from acetone gave a new substance of m. p. 217–219° (corr.) which gave the analysis, C, 82.52; H, 5.28; and molecular weight (Rast) 308, 291.

The action of potassium iodide in ethanol on the peroxide liberated free iodine and regenerated IX which was identified by mixed melting point.

Hydrolysis of 0.5 g. with 10 cc. of methanol containing 0.05 g. of dissolved sodium (standing twenty-four hours) gave a red solution from which 0.1 g. of tribenzoylpropane crystallized and was identified by mixed melting point.

1-Phenyl-2,3,4-tribenzoyl-1,2-epoxycyclopentane, XV.—Two grams of the peroxide XIV, on refluxing in 75 cc. of 70% ethanol for twelve hours, gave 1.35 g. of a new product which on repeated crystallization from butanone and from methanol (containing a little acetone) was obtained as thin rectangular scales of m. p. 117–119° (corr.) (a mixed melting point with the peroxide gave a sharp depression).

Anal. Calcd. for $C_{32}H_{24}O_4$: C, 81.31; H, 5.12; mol. wt. 472. Found: C, 81.48, 81.50; H, 5.35, 5.35; mol. wt. (freezing point in benzene), 450.

Hydrolysis of 0.5 g. in 10 cc. of methanol containing 0.05 g. of dissolved sodium (standing one week) gave a red solution from which 0.24 g. of solid crystallized. The product was washed with ethanol and identified by melting point (120–121°) and mixed melting point as tribenzoylpropane. From the filtrates 0.03 g. of benzoic acid was isolated.

Acetic anhydride containing concd. sulfuric acid reacts with the oxide to give a deep indigo-blue solution from which, even after refluxing, the oxide is recovered on hydrolysis.

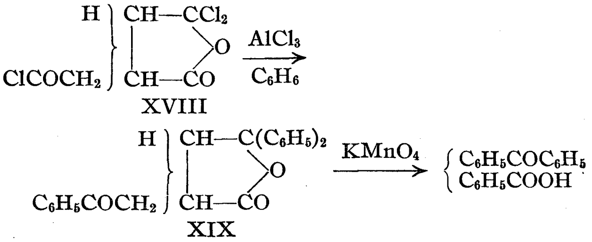
Tribenzoylpropane (1,4-Diphenyl-2-phenacyl-1,4-butanedione), XII.—The structure of the true tribenzoylpropane is evident from the mode of formation and dehydration to the furan as described in the foregoing discussion.

The product obtained by the Friedel and Crafts reaction on tricarballylic acid chloride[9] (XVIII) and supposed without evidence to be tribenzoylpropane, is different from our compound the structure of which is certain

---

[9] Emery, *Ber.*, **24**, 601 (1891).

from the above data. Since it is an isomer, this product must be either α- or β-phenacyl-γ,γ-diphenylbutyro-γ-lactone (XIX), a structure which finds strong support from the following facts; with phenylhydrazine only a monophenylhydrazone is formed[6] and on oxidation with alkaline permanganate approximately equivalent amounts of benzophenone and benzoic acid are produced.



Tribenzoylpropane (1,4-Diphenyl-2-phenacyl-1,4-butanedione) XII.—Three grams each of dibenzoylethanol and dibenzoylethylene were added to a solution of 0.3 g. of sodium in 30 cc. of methanol. On standing for twenty-four hours the substances dissolved and new crystals deposited. On cooling 1.3 g. of product was obtained which after repeated crystallization from ethanol melted at 122° (corr.). When the equivalent amount of the sodium salt of dibenzoylethanol was substituted in the reaction for the free enol and sodium methylate, the yield was raised to 50–60%. A third procedure is as follows: 2 g. of dibenzoylethylene in 25 cc. of methanol and 1.8 g. of acetophenone was treated with 0.2 g. of sodium dissolved in methanol. After several hours 0.5 g. of tribenzoylpropane crystallized.

Anal. Calcd. for $C_{24}H_{20}O_3$: C, 80.86; H, 5.66. Found: C, 80.51, 80.84; H, 5.61, 5.66.

Conversion into the known 2,5-diphenyl-3-phenacylfuran XIII was accomplished as follows: 0.2 g. of XII was dissolved in hot acetic anhydride containing one drop of concd. sulfuric acid. On decomposition with water 0.15 g. of diphenylphenacylfuran crystallized (m. p. 115–116° after repeated crystallization from ethanol [Paal and Schulze[6] reported 113°]). This product when treated with 40% hydrazine hydrate gave the characteristic ketazine melting at 214–215° (*cf.* Ref. 5).

α- or β-Phenacyl-γ,γ-diphenylbutyro-γ-lactone, XIX, (the so-called tribenzoylpropane of Emery[9]) was prepared from tricarballylic acid chloride exactly as described by Emery[9] in a yield of 48% (the rest of the material was an intractable resin). It gave a sharp mixed melting point depression with the true tribenzoylpropane XII described above. Tricarballylic acid chloride is hydrolyzed by water on standing for several hours, the acid being regenerated. A sample of the lactone XIX was suspended in alkaline permanganate (excess) and the mixture distilled. Pure benzophenone was obtained in the steam distillate in a yield of 50%. A similar yield of benzoic acid was recovered from the residual mixture.

Summary

The intertransformations and relationships of the five isomeric dimolecular reduction products of dibenzoylethylene are described. Two are open chain compounds and three are cyclic internal ketols.

Evidence for the open chain structures involves dehydration to mono- and bis-furans, oxidation to the unsaturated 1,4-diketone types, and reduction again to the original compounds. One of the open chain isomers was synthesized by condensation of dibenzoylethylene and dibenzoylethane.

The dehydration of the cyclic isomers gives a cyclic α,β-unsaturated ketone which is degraded by ozonization, through a peroxide and an oxide to tribenzoylpropane which was synthesized by condensation of acetophenone and dibenzoylethylene. The interpretation of these reactions and the bearing on the problem of structure is considered.

The product of the Friedel–Crafts reaction on tricarballylic acid chloride is shown to be a phenacyl-γ,γ-diphenylbutyro-γ-lactone.

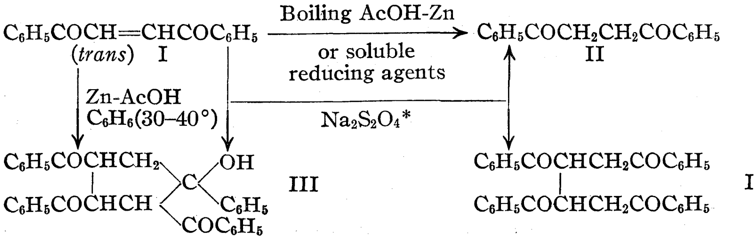
The Reductions of Unsaturated 1,4-Diketones with Zinc Combinations. The Formation of the Cyclic Dimolecular Products

By Robert E. Lutz, Lowry Love, Jr., and Fred S. Palmer

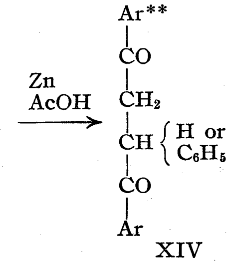
The reduction of unsaturated 1,4-diketones in homogeneous solution with soluble reducing agents leads exclusively to monomolecular products, the saturated 1,4-diketones or the corresponding furans. The mechanism undoubtedly involves initially the 1,6-addition of hydrogens or their equivalent at the oxygen atoms at the ends of the conjugated system, with oxidation–reduction potential a measure of the driving force in the reaction. The reduction with metal combinations, however, presents a more complex picture. *Trans*-dibenzoylethylene, which is reduced chiefly to dibenzoylethane (II) by zinc dust in hot glacial acetic acid, gives on slower reduction in the cold smaller amounts of II and very considerable yields of the dimolecular product, *cyclo*-bis-dibenzoylethane-A (III), the structure of which has been elucidated in the preceding paper. With zinc and benzene–glacial acetic acid mixtures at 30–35° (conditions most favorable to dimolecular reduction), there is produced largely the dimolecular product III and very little dibenzoylethane. In this type of reduction, therefore, dibenzoylethylene behaves to some extent like a simple α,β-unsaturated ketone.



* Special conditions (see experimental part).

Of the various unsaturated 1,4-diketones, *trans*-dibenzoylethylene is the one most prone to give dimolecular reduction products. Using zinc and glacial acetic acid at room temperature (typical conditions under which *trans*-dibenzoylethylene gives largely the dimolecular product) only monomolecular products are obtained from the following

V *Cis*-$C_6H_5COCH=CHCOC_6H_5$
VI *Cis*- and *trans*-$ClC_6H_4COCH=CHCOC_6H_4Cl$
VII *Trans*-$CH_3C_6H_4COCH=CHCOC_6H_4CH_3$
VIII *Trans*-$(CH_3)_3C_6H_2COCH=CHCOC_6H_2(CH_3)_3$
IX *Cis*-$C_6H_5COCBr=CBrCOC_6H_5$
X *Cis*-$C_6H_5COCH=C(C_6H_5)COC_6H_5$***
XI *Cis*-$C_6H_5COCBr=C(C_6H_5)COC_6H_5$
XII $C_6H_5COCH_2CHX$*COC_6H_5
XIII *dl*- or *meso*-C_6H_5COCHX*$CHXCOC_6H_5$



$$\mathrm{Ar^{**}\!-\!CO\!-\!CH_2\!-\!CH\{H\ or\ C_6H_5\}\!-\!CO\!-\!Ar}$$

XIV

*X = Cl or Br. **Ar = Corresponding aromatic group. *** Gave mainly the corresponding furan.

Other examples have been described in earlier papers.[1]

It is a striking fact that in reductions with zinc and glacial acetic acid at room temperature *trans*-dibenzoylethylene gives largely *cyclo*-bis-dibenzoylethane-A (III) whereas the *cis* isomer gives a nearly quantitative yield of the monomolecular product II (although other conditions were found under which the *cis* isomer also gave III in considerable amounts).

The Mechanism of Dimolecular Reduction.—The fact that *cyclo*-bis-dibenzoylethane-A is obtained under reducing conditions under which the open chain isomers are stable, definitely excludes the possibility that the ethylene linkage alone is involved, and indicates that a conjugate reaction occurs with cyclization taking place through the intermediate enolic groups. The results therefore furnish positive evidence for the generally accepted hypothesis that the reduction of α,β-unsaturated ketones by metal combinations involves a conjugate mechanism with the reaction beginning on oxygen.

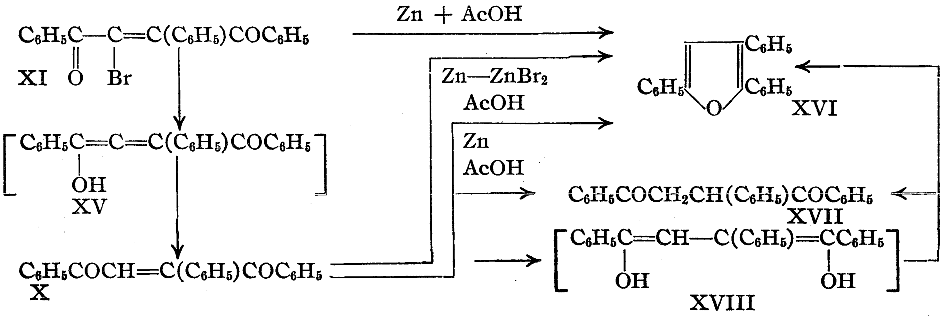
The usual 1,4-dimolecular reduction mechanism might seem to find support from the fact that under comparable conditions the *trans* isomer in

---

[1] (a) Lutz, This Journal, **51**, 3008 (1929); (b) Lutz and Taylor, *ibid.*, **55**, 1593 (1933); (c) Lutz and Wilder, *ibid.*, **56**, 2065 (1934).

contrast with the *cis* gives chiefly the dimolecular product, although both stereoisomers are reduced with comparable ease.[2] The stereochemical factor, however, may be without significance in view of the fact that *trans*-dibenzoylethylene with respect to tendency to undergo dimolecular reduction is unique among the unsaturated 1,4-diketones including *cis*-dibenzoylethylene. In consideration of this fact and in view of the known reactivity of enolic intermediates, an alternative and equally plausible mechanism is 1,6-reduction followed by condensation between the resulting enol or enolate and the reactive conjugated system of another molecule of unreacted dibenzoylethylene.

The zinc–glacial acetic acid reduction of dibenzoylphenylbromoethylene XI is of interest in connection with the catalytic effect of zinc bromide which is generated during the reduction.[3] The furan XVI is the chief product of this reaction. It is produced in much smaller yield in the reduction of dibenzoylphenylethylene X, but becomes the major product when zinc bromide is added to the reagents. The fact that dibenzoylphenylethane XVII and triphenylbromofuran are stable under the reaction conditions shows that the loss of bromine and the dehydrations to the furan XVI occur at some intermediate stage, and indicates that in both reductions there is formed in the final step the same intermediate dienol or dienolate (XVIII). The elimination of bromine from XI undoubtedly takes place through 1,4-reduction of the α-bromo ketone to the allenic enol or enolate XV.[4]



The zinc–acetone reductions of *dl*- and *meso*-dibenzoyldibromoethanes XIX are of interest because, in contrast with the dibenzoyldichloro- and monohalogeno-ethanes (XIII and XII), considerable yields of *cyclo*-bis-dibenzoylethane-A are obtained. *Trans*-dibenzoylethylene does not react under these conditions but does so when zinc bromide is added to the reagent, the products being the same as those obtained in the reduction of the dibromides where the zinc bromide is generated during the reaction.[5] Dibenzoylbromoethylene is not reducible by the Zn–ZnBr$_2$–acetone reagent. These facts suggest that the reduction of the dibromides under these conditions proceeds partly at least through elimination of bromine with the intermediate formation of dibenzoylethylene, followed by competing mono- and dimolecular reduction.

$$\underset{\text{XIX}\quad dl \text{ or } meso}{C_6H_5COCHBrCHBrCOC_6H_5} \longrightarrow \left[\underset{trans}{C_6H_5COCH{=}CHCOC_6H_5}\right] \longrightarrow \text{I} + \text{II}$$

This mechanism is consistent with the following facts: (a) the yield of *cyclo*-bis-dibenzoylethane-A is much higher in the reduction of dibenzoylethylene than in the case of the dibromides, as would be expected in view of the necessarily higher concentration of dibenzoylethylene during the reaction; (b) the monomolecular product predominates when *trans*-dibenzoylethylene is added slowly to the Zn–ZnBr$_2$–acetone mixture over a period of several hours so that the concentration during reaction is very low, thus simulating conditions involved in the reduction of the dibromides; and (c) dibenzoylbromoethane (XII) which could not

---

(2) Conant and Lutz, THIS JOURNAL, **45**, 1047 (1923). In homogeneous solution where the configuration is without appreciable effect, both carbonyl groups of either *cis* or *trans* isomers are surrounded by reductant ions and may be supposed to react practically simultaneously. In the reduction of the *cis* compound by metal combinations, the spatially proximate carbonyl groups also should be able to react in quick succession or simultaneously at the metal surface, whereas the reaction with the *trans* compound, initiated at one carbonyl oxygen with the other spatially removed from the immediate source of hydrogen, could hardly be completed as easily and would afford the maximum opportunity for the dimolecular coupling to become a competing or even the dominant reaction.

(3) Lutz, Tyson, Sanders and Fink, THIS JOURNAL, **56**, 2679 (1934).

(4) Such a hypothesis has been suggested in an earlier paper (Refs. 1c, 3). *Cf.* the formation of the allenic halogenomagnesium enolate by the action of the Grignard reagent on α-bromo-β-phenylbenzalacetophenone [Kohler and Tishler, THIS JOURNAL, **57**, 217 (1935)], and also the reactions between the Grignard reagent or magnesium [Fisher, *ibid.*, **57**, 381 (1935)] and α-halogeno ketones.

(5) Probably the effective reducing agent is a Zn–ZnBr$_2$ combination analogous to the Mg–MgI$_2$ reagent of Gomberg and Bachmann [THIS JOURNAL, **49**, 237 (1927)].

form dibenzoylethylene or its equivalent in an intermediate step, does not undergo dimolecular reduction.

Cis-dibenzoylethylene in contrast with the *trans* isomer is reduced by the Zn–$ZnBr_2$–acetone reagent to a mixture in which the monomolecular product predominates. From this fact, if the mechanism of reduction of the *dl* and *meso* dibromides suggested above is correct, it would follow that the *trans* isomer and not the *cis* is involved as intermediate, and that the elimination of halogen from the *dl* and *meso* dibromides does not take place in a consistent stereochemical sense.[6]

Experimental Part

Separation of the mixtures obtained in reductions where the dimolecular products are formed is exceedingly difficult and involves laborious fractional crystallizations. Mixtures of dibenzoylethane and *cyclo*-bis-dibenzoylethane-A were usually partly separated by taking advantage of the higher solubility and higher rate of solution, and also the more rapid rate of crystallization (despite its greater solubility) of the monomolecular product. Such mixtures were usually digested for a very short time with boiling ethanol and filtered quickly; the residue consisted chiefly of the dimolecular compound, and the first fraction crystallizing quickly from solution was largely dibenzoylethane. The last fractions of crystals thrown out from the alcohol solution by dilution with water, on similar digestion with hot alcohol, at times yielded the cyclic dimolecular isomers -B and -C when these were present in small amounts. The following method was used in the separation of some of the mixtures resulting from the sodium hydrosulfite reductions. The crude product was precipitated by diluting the reaction mixture with water, the aqueous solution containing the bisulfite addition compound XIX being worked up as described separately below. This crude residue was digested for a short time with boiling ethanol. The insoluble residue was filtered off quickly, and digested with hot benzene, again leaving an insoluble residue consisting largely of *cyclo*-bis-dibenzoylethane-C (which was purified by recrystallization from chlorobenzene). The benzene filtrate gave a crystalline product which on fractionally crystallizing from benzene or chloroform gave a pure sample of *cyclo*-bis-dibenzoylethane-B. From the alcohol filtrate from the first digestion, a small crop of *cyclo*-bis-dibenzoylethanes-B and -C was obtained, and then a mixture of *cyclo*-bis-dibenzoylethane-A and dibenzoylethane. The latter mixture was separated by fractional crystallization from ethanol; or when small samples were involved, by the following procedure: the mixture was dissolved in boiling ethanol and allowed to crystallize quietly, long needles of dibenzoylethane forming first; when these appeared to be fully developed, the mixture was filtered suddenly, and immediately a granular crystalline precipitate formed in the filtrate (with a little luck and care, this separation may be semi-quantitative, and was so used in several instances).

Cyclo - bis - dibenzoylethane-A (1 - phenyl - 2,3,4 - tribenzoylcyclopentanol-1) III, is best obtained by the action of zinc dust on *trans*-dibenzoylethylene in 6–1 benzene–glacial acetic acid solution at 30–40°. It is best purified by repeated recrystallization from benzene, and is obtained as short prisms of m. p. 161° (corr.).

Anal. Calcd. for $C_{32}H_{26}O_4$: C, 80.95; H, 5.53; mol. wt., 474. Found: C, 80.60, 81.08, 80.95, 80.92; H, 5.76, 5.77, 5.59, 5.53; mol. wt., 483, 499, 460.

Both dibenzoylethane and the above dimolecular product III have been found to be stable under the various reducing conditions. The very considerable amounts of resinous by-products found in various of the reductions are therefore not due to secondary reactions.

Cyclo-bis-dibenzoylethane-B (1-phenyl-2,3,4-tribenzoylcyclopentanol-1) III, was obtained from the sodium hydrosulfite reductions described above. It crystallized as tufts of needles from benzene, chlorobenzene, or ethanol; m. p. 202–203° (corr.).

Anal. Calcd. for $C_{32}H_{26}O_4$: C, 81.01; H, 5.48. Found: (dried *in vacuo* at 120°) C, 80.36, 80.44; H, 5.51, 5.76.

A solution of 0.05 g. in 2.5 cc. of methanol containing 0.03 g. of dissolved sodium was allowed to stand for three hours and deposited 0.05 g. of bis-dibenzoylethane-A which was identified by mixed melting point.

A solution of 1 g. in 30 cc. of warm acetic anhydride containing one drop of concd. sulfuric acid was decomposed in water and gave considerable brown resin from which 0.4 g. of the dehydro compound (1-phenyl-2,3,4-tribenzoylcyclopentene-1) was isolated and identified by mixed melting point.

Cyclo - bis - dibenzoylethane-C (1 - phenyl - 2,3,4 - tribenzoylcyclopentanol-1) III, was obtained in only small amounts from the fractional crystallization of the products of reduction of dibenzoylethylene with sodium hydrosulfite or with the Zn–$ZnBr_2$–acetone combination. It crystallized from benzene, chlorobenzene, or large volumes of ethanol as square plates; m. p. 204–205° (corr.).

Anal. Calcd. for $C_{32}H_{26}O_4$: C, 81.01; H, 5.48. Found: C, 80.68; H, 5.64.

A solution of 0.1 g. in 5 cc. of ethanol containing 0.06 g. of dissolved sodium was allowed to stand for three hours and 0.06 g. of nearly pure bis-dibenzoylethane-A crystallized and was identified by mixed melting point.

Dehydration of 1 g. with 30 cc. of acetic anhydride and one drop of concd. sulfuric acid (warmed to solution) gave 0.92 g. of nearly pure dehydro compound of m. p. 179° (identified by mixed m. p.).

Sodium hydrosulfite reduction of dibenzoylethylene, carried out in 60–65% ethanol, produces almost exclusively monomolecular reduction. However, it was found that certain sam-

---

[6] The elimination of bromine might perhaps be pictured as taking place stepwise, involving 1,4-reaction of the effective reducing agent with the α-bromo ketone system (*cf.* Ref. 4) rather than with the system Br–C–C–Br, since this would account for the failure of configuration to influence the reduction. The actual dimolecular coupling may take place according to the mechanisms described above or possibly through condensation of the intermediate dibenzoylethylene with unchanged dibromide or an enolate such as $C_6H_5COCHBrCH{=}C(OZnBr)C_6H_5$ (a 1,4-Reformatsky reaction).

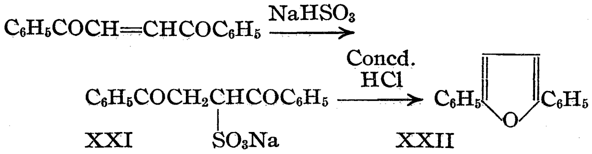
[a] The corresponding saturated 1,4-diketone. [b] *Cyclo*-bis-dibenzoylethane-A. [c] The various products are indicated by symbol. The open chain bis-dibenzoylethanes = IV-A and -B and the cyclic isomers III-A, -B and -C; dibenzoylethane sulfonate = XXI. [d] N. q. = nearly quantitative. This was the case, however, only when good sodium hydrosulfite was used. [e] Using samples of sodium hydrosulfite which had been standing in the laboratory for several years and which had very evidently deteriorated and contained considerable amounts of $NaHSO_3$. [f] Due to the difficulty of separating the mixtures many of the yields were determined only roughly, and indicated by the symbols: L = large amounts, vl = very large, S and vs = small and very small, tr = trace. [g] Technical $Na_2S_2O_4$ used. [h] A considerable amount of unchanged material was recovered. [i] There was isolated also a 5% yield of II-C. [j] A considerable yield of a new compound of m. p. 248.5° (long thin rectangular scales from butanone) was isolated but has not yet been identified. It is probably not a simple dimolecular isomer since it is unaffected by boiling Ac_2O and H_2SO_4. [k] The product was nearly pure and the rest of the material resinous. [l] Traces of by-products were isolated from larger scale runs but not enough material was obtained for study.

ples of the reagent which had deteriorated gave considerable quantities of dimolecular products and of sodium bisulfite addition compound XXI. These results could be partially duplicated with the best grades of sodium hydrosulfite only under special conditions, namely, adding the solid reagent slowly to a 90% ethanol solution of dibenzoylethylene. Under these conditions there were produced large amounts of *cyclo*-bis-dibenzoylethane-A and smaller amounts of the cyclic isomers-B and -C, dibenzoylethane, and the sodium bisulfite addition compound. In one experiment when a concentrated aqueous solution of technical sodium hydrosulfite was added to a hot alcohol solution of dibenzoylethylene, the *open chain* bis-dibenzoylethane-B (IV) was obtained as the chief product; this is the only case aside from catalytic reduction where an open chain dimolecular product was formed in considerable amounts and isolated.

The sodium bisulfite addition compound XIX is a typical product of a 1,4-addition, and is formed nearly quantitatively when dibenzoylethylene is treated in 90% ethanol with sodium bisulfite. It is not easily hydrolyzed and is converted into diphenylfuran XXII by the action of boiling concd. hydrochloric acid.



The sulfonate was best prepared by allowing a mixture of 5 g. of *trans*-dibenzoylethylene, 4 g. of sodium bisulfite, and 110 cc. of 85% ethanol to stand for two hours. The solution was evaporated and the residue crystallized from ethanol: yield 84%; m. p. 255–262° (corr.). The analyses for S, C and H were unsatisfactory but approximated the values calculated for the formula XXI.

When refluxed for one hour with concd. hydrochloric acid, the sulfonate was converted into 2,5-diphenylfuran which was identified by mixed melting point with an authentic sample prepared by the action of acetic anhydride and a trace of concd. sulfuric acid on dibenzoylethane.[7]

Summary

The reduction of *trans*-dibenzoylethylene with zinc and acetic acid under varying conditions leads to the formation of dibenzoylethane and the cyclic dimolecular reduction product, *cyclo*-bis-dibenzoylethane-A, but *cis*-dibenzoylethylene gives largely, and other unsaturated 1,4-diketones exclusively, monomolecular products.

The formation of the cyclic dimolecular product is regarded as evidence for the conjugate mechanism.

The catalytic effect of zinc bromide in the reductions of dibenzoylphenylethylene and dibenzoylphenylbromoethylene is discussed, together with the probable mechanism.

The zinc–acetone reductions of the halogeno derivatives of dibenzoylethane are considered and a mechanism for the dimolecular reduction of the dibenzoyldibromoethanes is proposed.

Circumstances are described under which sodium hydrosulfite reduction of dibenzoylethylene gives large amounts of dimolecular products and sodium bisulfite addition compound.

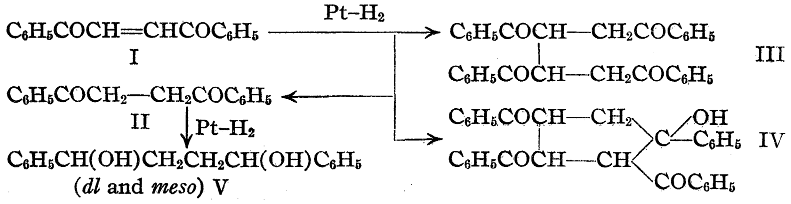
The Catalytic Hydrogenation of Unsaturated 1,4-Diketones

BY ROBERT E. LUTZ AND FRED S. PALMER

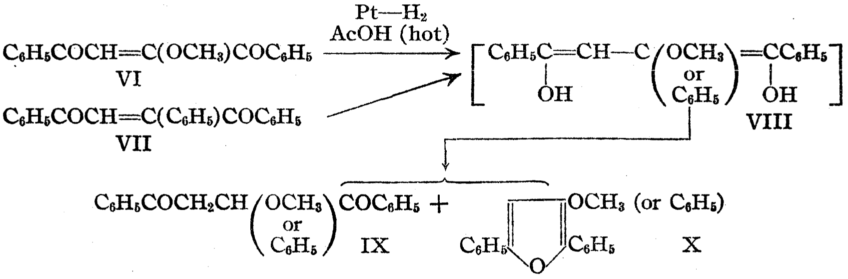
These studies were made in order to compare the catalytic hydrogenation of the unsaturated 1,4-diketones with reductions utilizing ordinary homogeneous and heterogeneous combinations. In the case of *trans*-dibenzoylethylene (Table I) chiefly the platinum catalyst was used with the following as solvents: methanol, 95% ethanol, dilute ethanol, acidified ethanol, glacial acetic acid, dioxane, ethyl acetate and decalin. With few exceptions there resulted mixtures of dibenzoylethane II and open chain and cyclic bis-dibenzoylethanes-A, III and IV, the relative yields varying considerably. Small yields of bis-dibenzoylethane-B also were obtained in many cases, but neither *cyclo*-bis-dibenzoylethane-B nor -C was isolated.



The yields of the difficultly soluble bis-dibenzoylethane-A, which crystallizes out during reaction, are probably fairly accurate as listed in the tables. However, the yields of the other products could be determined only approximately in many cases because of the difficulty of separating the mixtures and because there was undoubtedly some loss through further reduction. The primary stage of the reaction goes very rapidly, but the products are all reducible further slowly, as was shown in separate experiments, with the absorption of sufficient hydrogen to account for reduction of all of the carbonyl groups. The reductions listed in Table I were all stopped after the first and rapid phase of the reactions appeared to be complete, and involved usually the absorption of approximately 0.7–0.8 molecule of hydrogen. The dimolecular products upon further hydrogenation gave only non-crystalline products, but dibenzoylethane gave the two known stereoisomeric diphenylbutane-1,4-glycols V which were isolated in one experiment and identified. The material not accounted for in the tables was non-crystalline and was not identified.

When the rate of reduction is diminished through the use of smaller amounts of catalyst or lowered temperature, the *cyclic* dimolecular isomer-A (IV) predominates and very little of the open chain isomer III is formed. On the other hand, when the reaction proceeds very rapidly through the use of an excess of catalyst, the open chain isomer-A predominates and the yields of the monomolecular product and of the *cyclo*-bis-dibenzoylethane-A drop to a minimum. The total yield of dimolecular products, however, remains approximately constant.

In view of the effectiveness of small amounts of acid in promoting normal saturation of the alicyclic double bond in pseudocodeine,[1] two runs were made on dibenzoylethylene in alcohol with added hydrochloric or sulfuric acid. A striking increase in the yield of dibenzoylethane was observed (from 5–20 to 40%) and the yields of dimolecular products dropped almost to zero. Unfortunately the larger part of the product was non-crystalline and not identified, but the marked effect of the added acid on the course of the reduction was nevertheless unmistakable.



In glacial acetic acid the yield of the dimolecular product, *cyclo*-bis-dibenzoylethane-A, is consistently high (40–60%) regardless of the addition of ammonium chloride (to simulate conditions in the reduction of pseudocodeine hydrochloride) or of sodium acetate or hydrochloric acid. Only traces of the open chain bis-dibenzoylethane-A were found, together with bis-dibenzoylethane-B in yields varying from 5–20%. Considering all of the catalytic reductions undertaken, the yield of the normal reduction product, dibenzoylethane, reaches a minimum of 0–5% when glacial acetic acid–0.5% hydrochloric acid is the solvent. In all of the reductions in glacial acetic acid the main product is the same cyclic dimolecular isomer-A which is obtained in the zinc dust reductions under approximately similar solvent conditions.

It is noteworthy that reduction with platinum catalyst in dioxane as the solvent gives largely, and in ethyl acetate almost exclusively, monomolecular reduction. The use of Raney nickel catalyst in ethanol and in decalin also decidedly favors monomolecular reduction. In the inert solvents, then, the normal saturation of the ethylene double bond reaches a maximum.

It is a striking fact that *cis*-dibenzoylethylene, upon reduction under conditions wherein the *trans* isomer is converted chiefly into dimolecular products, gives largely the monomolecular product, dibenzoylethane, in 45–50% yields, together with about a 20% yield of a mixture of dimolecular products. This result finds a close parallel in the zinc–glacial acetic acid reduction where the *cis* isomer also shows a far greater reluctance to undergo dimolecular reduction than does the *trans* isomer.

In Table II is listed a series of experiments on various other unsaturated 1,4-diketones and related compounds. In every case the only crystalline products isolated were monomolecular, and no crystalline dimolecular products were found. Some dimolecular reduction may have occurred since in many cases considerable amounts of non-crystalline and unidentified by-products were formed. In any case the yields of monomolecular product were usually much greater than in the case of reduction of *trans*-dibenzoylethylene under comparable conditions. These results show dibenzoylethylene to be unique and the only compound of the series to undergo di-

---

[1] Lutz and Small, THIS JOURNAL, **54**, 4715 (1932).

molecular reduction easily, a phenomenon already noted in the zinc–glacial acetic acid reductions.

The reduction of dibenzoylmethoxyethylene VI and of dibenzoylphenylethylene VII is of particular interest because furans are formed to a considerable extent, the conditions chosen being similar to those which lead to furan formation in zinc dust reductions.[2]

The mono and dibromo derivatives of both dibenzoylethylene and dibenzoylethane are reduced catalytically (using platinum) to dibenzoylethane without the formation in any case of appreciable amounts of the dimolecular products.

$$\left.\begin{array}{ll} \mathrm{C_6H_5COCH{=}CBrCOC_6H_5} & \mathrm{XI} \\ \mathrm{C_6H_5COCBr{=}CBrCOC_6H_5} & \mathrm{XII} \\ \mathrm{C_6H_5COCH_2CHBrCOC_6H_5} & \mathrm{XIII} \\ \mathrm{C_6H_5COCHBrCHBrCOC_6H_5} & \mathrm{XIV} \end{array}\right\} \xrightarrow[\mathrm{EtOH}]{\substack{\mathrm{Pt} \\ \mathrm{H_2}}} \begin{array}{l} \mathrm{COC_6H_5} \\ | \\ \mathrm{CH_2} \\ | \\ \mathrm{CH_2} \\ | \\ \mathrm{COC_6H_5} \end{array}$$

Discussion of Results.—The formation of dimolecular products in catalytic hydrogenation was unexpected because, despite the many compounds that have been studied, this phenomenon has been observed in very few cases, namely, citral, dibenzalacetone, and certain α,β-unsaturated nitro compounds.[3]

A striking and significant parallelism exists between catalytic and zinc–acetic acid reductions of the unsaturated 1,4-diketones. The following facts are established in both types of reduction: (a) dimolecular reduction occurs to a very considerable extent with *trans*-dibenzoylethylene, (b) the same *cyclo*-bis-dibenzoylethane-A is obtained as the chief dimolecular product when glacial acetic acid is the solvent, (c) *cis*-dibenzoylethylene shows a far greater tendency to undergo normal saturation of the ethylene linkage than the *trans* isomer, (d) *trans*-dibenzoylethylene is the only unsaturated 1,4-diketone to give large yields of the dimolecular products under ordinary conditions, and (e) roughly the same degree of furan formation occurs during the reductions of VI and VII. It is quite likely therefore that the mechanism of the main course of catalytic and metal combination reductions of *these unsaturated 1,4-diketones* under conditions involved in the experiments covered by the above five points is similar.

The formation of the stable cyclic dimolecular compounds and furans during catalytic reduction in alcohol or in glacial acetic acid may be regarded as proof that in respect to the main course of these reactions a direct addition of hydrogen to the ethylene linkage does not occur but rather conjugate reactions involving one or both carbonyl groups, in the case of dibenzoylethylene giving enolic intermediates such as $\mathrm{C_6H_5}\underset{\substack{|\\ \mathrm{OH}}}{\mathrm{C}}{=}\mathrm{CHCH}{=}\underset{\substack{|\\ \mathrm{OH}}}{\mathrm{C}}\mathrm{C_6H_5}$ and $\mathrm{C_6H_5COCHCH{=}C(OH)C_6H_5}$, and in the cases of

$$\begin{array}{l} \mathrm{C_6H_5CO\underset{|}{C}HCH{=}C(OH)C_6H_5} \\ \mathrm{C_6H_5COCHCH{=}C(OH)C_6H_5} \end{array}$$

VI and VII leading to the results summarized in the diagram (*cf.* discussion of mechanism in the preceding paper). The conjugate mechanism for catalytic hydrogenations of α,β-unsaturated ketones, which has been assumed without proof,[4] is open to some question.[5] Our results constitute positive evidence for the existence of such a mechanism in some cases, but it is obviously far from certain that the phenomenon is general.

In this connection it is noteworthy that sorbic and muconic acids[6] to some extent undergo conjugate hydrogenation but it is uncertain as to whether or not the carbonyl oxygens are involved.

Pertinent to this discussion is the work of Conant and co-workers[7] on irreversible reductions. Soluble reducing reagents are regarded as acting through electron transfer, and catalytic hydrogen by addition of a hydrogen molecule, the latter occurring in cases where the hydrogen electrode potential is considerably above the "apparent reduction potential" (*i. e.*, the highest potential of reducing agents which will cause appreciable reduction in a reasonable time).[8] Catalytic reduction of dibenzoylethylene which has an "apparent reduction potential" above that of the hydrogen electrode, involves, as might have been predicted, a mechanism in which hydrogen or more likely electrons add to oxygen; however, dibenzoylphenylethylene, which on catalytic hydrogenation also undergoes conjugate addition involving the oxygens, has an "apparent reduction potential" which is very considerably below that of the hydrogen electrode.[8]

Catalytic hydrogen, while it may add at the ends of conjugated systems which include ter-

minal oxygen atoms and does so to a considerable extent in the case of *trans*-dibenzoylethylene, probably does not involve the conjugate mechanism exclusively. Under some conditions, notably in the solvents ethyl acetate, dioxan, decalin or acidified ethanol, *trans*-dibenzoylethylene gives largely dibenzoylethane. Possibly the ethylene linkage in these cases reacts to a large degree directly with hydrogen. Pertinent to this point is the problem of the stereochemistry of addition which can be followed when completely substituted ethylenes are used as in the case of salts of dimethylmaleic and fumaric acids and the dimethylstilbenes.[9] Addition of hydrogen to the oxygens in the case of unsaturated 1,4-dicarbonyl compounds would undoubtedly destroy the stereoisomerism and no oriented addition would be possible; this appears to be the case for example in the zinc–acetic acid reduction of *cis* and *trans* di-(2,4,6-trimethylbenzoyl)-dimethylethylenes where identical products are obtained regardless of the configuration of the starting material.[2b] When consistent *cis* addition does occur it seems reasonable to suppose that only the ethylene linkage is involved, as is undoubtedly the case in the catalytic hydrogenation of the dimethylstilbenes.[3] In the reduction of the salts of dimethyl maleic and fumaric acids both 1,6 and 1,2 reductions are possible; slow catalytic hydrogenation favors stereochemical orientation, and probably therefore involves exclusively 1,2 addition to the ethylene linkage; but in the case of metal combinations leading to unoriented addition, the conjugate type of reduction undoubtedly predominates.[10] We had hoped to obtain evidence along this line by catalytic hydrogenation of the diaroyldimethylethylenes, $\mathrm{ArCOC(CH_3){=}C(CH_3)COAr}$; while zinc and acetic acid reductions have been successful,[2b] catalytic hydrogenations proceed very slowly and fail to give the expected and known crystalline primary reduction products.

Experimental Part

The various hydrogenations described in Tables I and II were carried out in the usual way. In the case of dibenzoylethylene in alcohol as solvent the material was partly in suspension at the beginning. Reduction with platinum catalyst proceeds very rapidly with absorption of from 10–50 cc. per minute in small runs of from 2–10 g. When the dibenzoylethylene is used up (evident from disappearance of the yellow color), the rate of absorption drops to 0.5–1.0 cc. per minute, at which point the absorption usually reached from 0.7–0.8 mole. The reaction ordinarily was stopped at this point to minimize the secondary stages of the reduction. Probably the oils and resins which comprise the residue of material not accounted for in the yields listed in the tables are partly the result of the secondary reductions involving one or more of the carbonyl groups of the various primary reduction products. In separate experiments it was shown that each of the dimolecular products slowly absorbs approximately 3–4 molecules of hydrogen under the usual conditions (platinum in alcohol), accounting for reduction of all of the carbonyl groups.

TABLE I

SOME TYPICAL CATALYTIC REDUCTIONS OF *TRANS*-DIBENZOYLETHYLENE AT 25–27° AND ATMOSPHERE PRESSURE

The material not accounted for was non-crystalline.

Pt oxide catalyst per g. subs., g.	Solvent per g. subs., g.	Solvent	Dibenzoylethane %	% Dimolecular Cyclo A	% Dimolecular Open chain A	% Dimolecular Open chain B

Ni[c]	30	Decalin	75[a]	...	...	...

A few qualitative experiments which were not worked up adequately deserve mention. With platinum catalyst (1–100 g. of substance) in 95% ethanol at 0°, results were obtained similar to those found with smaller amounts of catalyst at ordinary temperature, largely *cyclo*-bis-dibenzoylethane-A being obtained with smaller amounts of the open chain isomer-A. When ethanolic sodium acetate was used as solvent at room temperature chiefly the open chain bis-dibenzoylethane-A was obtained and little else but resinous material. Substitution of the palladium on barium sulfate catalyst in a few instances was without significant effect on the course of reduction.

[a] In some runs considerable amounts of the dimolecular product was formed and correspondingly less of dibenzoylethane. [b] S = small amounts, possibly as high as 10–15%. [c] Raney catalyst.

---

(9) Ott, *Ber.*, **61**, 2124 (1928).

(10) The unoriented addition of hydrogen in the metal combination reduction of the dimethylstilbenes may possibly involve one or both of the phenyl groups through conjugate addition with consequent destruction of stereoisomerism in the intermediate step.

Hydrogenation of dibenzoylethane using platinum catalyst in ethanol proceeded with absorption of 2 moles of hydrogen, giving an oil which on fractional crystallization was separated into the *dl*- and *meso*-diphenylbutane-1,4-glycols which were identified by mixed melting points with authentic samples prepared by the catalytic reduction of the acetylenic glycols.[11]

TABLE II

CATALYTIC REDUCTION OF SOME TYPICAL UNSATURATED 1,4-DIKETONES AND RELATED COMPOUNDS

Except as otherwise indicated these reductions were carried out at 25–27° and atmospheric pressure, using the platinum oxide catalyst (0.01–0.02 g. per g. of substance) in 95% ethanol as solvent (35–70 cc. per gram of substance).

Compound	Yield of monomolecular product, %
Cis-dibenzoylethylene	45–50[a]
Trans-dibenzoylmethylethylene	75
Cis-dibenzoylphenylethylene	62 (25[b])
Trans-di(2,4,6-trimethylbenzoyl)ethylene	86
Trans-di(4-chlorobenzoyl)ethylene	44
Trans-di(4-methylbenzoyl)ethylene	19
Dibenzoylmethoxyethylene	[c]
Cis-dibenzoylbromoethylene[d]	40
Cis-dibenzoyldibromoethylene[d]	84
Dibenzoylbromoethane[d]	68
dl-Dibenzoyldibromoethane[d]	44

[a] The rest of the material was accounted for as oils and small amounts of dimolecular products totaling 10–20% in yield. [b] This yield was obtained from an experiment carried out in glacial acetic acid at 100°, and triphenylfuran was obtained also in yields of 45–50%. Dibenzoylphenylethane is unaffected by these conditions and catalyst, and was recovered nearly quantitatively unchanged in a typical experiment. [c] This experiment, carried out in glacial acetic acid at 75–80°, gave largely the oily dibenzoylmethoxyethane (not identified) and a yield of 35–40% of diphenylmethoxyfuran (identified by mixed melting point with an authentic sample). [d] Palladium on barium sulfate as catalyst (0.1–0.15 g. per g. of substance).

Summary

The catalytic hydrogenation of *trans*-dibenzoylethylene under different conditions results in both mono- and dimolecular products, while other unsaturated 1,4-diketones, including *cis*-dibenzoylethylene and the halogen derivatives, undergo largely monomolecular reduction.

The striking parallelism between catalytic and zinc combination reductions is shown and is regarded as indicative of a common reaction mechanism.

The formation of furans and of cyclic dimolecular products is adduced as evidence that in these cases catalytic hydrogenation involves conjugate addition.

Sulfur-Containing Barbiturate Hypnotics

BY D. L. TABERN AND E. H. VOLWILER

Early in the history of barbituric acid synthesis, two or three simple 5,5-disubstituted 2-thio derivatives were made, with the aim of preparing from them by removal of the sulfur atom, the therapeutically promising oxygen analogs. Einhorn[1] and others studied the sulfur elimination through reduction, then oxidation and by the action of strong acids under pressure. They noted the comparative instability of the thiobarbiturate ring, reduction of the diethyl derivative by sodium amalgam, for instance, yielding chiefly the malonic diamide.

No serious attempt at pharmacologic evaluation seems to have been reported, and no study of higher homologs has been made as in the case of the simple barbituric analogs. Fischer and Mering[2] gave a 7-kilogram dog orally a dose of one gram of diethylthiobarbituric acid with the result that "one hour later he slept, did not react to any stimulation, and died after eight hours."

Dox and Hjort[3] have included mention of the same compound in a series of simple and N-alkyl barbiturates. They state that fine and coarse tremors mask the anesthesia which is characterized by preanesthetic excitement and cyanosis.

In spite of these unfavorable pharmacologic indications, the desire to secure hypnotics more readily broken down in the body for the production of short hypnosis and even surgical anesthesia, led to the decision several years ago to make a

critical and systematic study of the higher alkyl substituted thiobarbiturates. The recent appearance of a note by Miller, Munch and Crossley[4] prompts the present publication of our earlier studies which have subsequently progressed to the stage of extensive clinical application.

Preliminary experiments demonstrated that not only could the desired compounds be synthesized by conventional methods in satisfactory yields, but that from the pharmacological and clinical side, certain members of the group were indeed powerful hypnotics of very brief action. In proper dosage, the results were frequently striking; following intravenous administration, sleep followed at once; surgical anesthesia ensued within five minutes; and not more than twenty minutes later the animal was again on its feet almost normal.

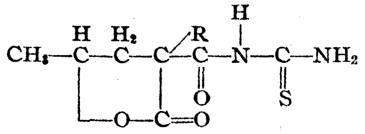
In general, the thio analogs of those disubstituted barbituric acids previously found most valuable as hypnotics, ranked highest in efficiency. Furthermore, certain thiobarbiturates were definitely more active as hypnotics than the oxygen analogs. Toxicities were not in general correspondingly higher, and it is possible to select several members of the series possessing very favorable ratios of effective to toxic doses.

The sulfur atom seemed to exert an additional influence in shortening the period of destruction within the body, and hence the duration of the hypnotic action.

Experimental

While the thiobarbituric acid derivatives may be prepared by several methods, we have found it convenient for experimental purposes to use the requisite malonic esters with somewhat more than the calculated amount of dry powdered thiourea in alcoholic sodium ethylate or its equivalent at 100–120°. Purification is best effected by dissolving in sodium hydroxide and reprecipitating by carbon dioxide followed by recrystallization from alcohol (75–90%). The pure acids are all somewhat yellowish solids that crystallize more readily than the oxygen analogs.

Johnson and Hill[5] have reported that under essentially these conditions, diallyl and benzyl allyl malonic esters yield open-chain compounds of the formula



We have repeated these experiments with much larger quantities of materials; our compounds melt somewhat higher, and both analyses and pharmacologic evaluations show that they *must be* only the normally expected thiobarbiturates.

The following example illustrates the method of preparation.

The Ethyl (1-Methylbutyl) Thiobarbituric Acid.—One hundred and thirty grams of ethyl (1-methylbutyl)-malonic ester is added to a concentrated solution of sodium ethylate prepared from 34 g. of sodium in absolute alcohol; with stirring, 60 g. of finely divided thiourea is added, and the mixture refluxed for ten hours. Most or all of the solvent is evaporated and the residual mass dissolved in cold water. The barbituric acid derivative so formed is precipitated by the addition of dilute hydrochloric acid. It may be purified by solution in dilute sodium hydroxide solution and precipitation by carbon dioxide.

Final purification is best carried out by solution in cold alcohol, heating to 50° and dilution with water to a 50% alcohol content. The ethyl (1-methylbutyl)-thiobarbituric acid so obtained is a white crystalline solid melting at 158–159° and readily forming salts with alkalies.

While the thiobarbiturates readily form stable salts, these are sometimes not easily obtained in the crystalline state. For instance, when ethyl isoamyl thiobarbituric acid in alcoholic solution is treated with one mole of alkali, the solution may be evaporated to dryness, leaving a glass which is rendered friable only by drying completely in a good vacuum.

In other instances, crystals were ultimately secured which permitted seeding of the concentrated alcoholic solutions and the separation of crystalline salts.

Such salts are hygroscopic and dissolve readily in water and alcohol to give strongly alkaline solutions. For instance, sodium ethyl (1-methylbutyl)-thiobarbiturate, in 2.5% solution, has a *p*H of approximately 10.4 to 10.6 (as determined by the glass electrode).

Another characteristic of the sodium salts is the avidity with which they hold solvents of crystallization (alcohols, chloroform, benzene, etc.) even on drying *in vacuo* at 80–100°.

Solutions of the sodium salts are rather unstable, being decomposed quite completely at the end of thirty-six hours at 60°. In the case of the ethyl *s*-butyl thiobarbituric acid, an alkali-insoluble compound, melting point about 100°, being probably the amide, was first secured; on the addition of acid, much carbon dioxide, but no hydrogen sulfide, was evolved and a compound, probably the acetyl urea, melting at 155–156°, was precipitated.

The calcium salts are best prepared by adding strong calcium chloride solution to a solution of the sodium salt in water. Mono and dialkylamine salts may be prepared

---

(5) Johnson and Hill, *Am. Chem. J.*, **46**, 356 (1911).

by dissolving the thiobarbituric acid in an excess of amine and removing the excess *in vacuo*. These salts are likewise readily soluble in water, but easily hydrolyzed.

The salts give intense green or brown solutions or precipitates with compounds of copper, iron, nickel, cobalt, etc. These appear to be analogous to the colored cobalt salts which Koppanyi[6] and others have employed for the colorimetric estimation of simple barbiturates. Here, however, the greater residual valence of the sulfur permits the use of aqueous rather than anhydrous media.

On attempting to prepare the N-(or S)-allyl derivatives by the method normally used for the synthesis of N-alkyl barbiturates, that is the reaction of allyl bromide with the sodium salts in aqueous or alcoholic solutions, unstable semi-solids gradually evolving allyl mercaptan were secured. Synthesis through the use of the N-alkyl thioureas is being studied.

The action of potassium permanganate on ethyl-(1-methylbutyl)-thiobarbituric acid in alkaline solution, yielded the oxygen analog (Nembutal); when an unsaturated group was present, however, extensive change of a still undetermined nature took place. Hydrogen peroxide in alkaline solution either left the acid unchanged or, if used in sufficient excess, led to poorly defined products. Freshly precipitated silver oxide formed a complex addition product soluble in sodium hydroxide, but insoluble in ammonium hydroxide, water, alcohol, and acids.

TABLE I

THIOBARBITURATES

	M. p., °C.	Nitrogen Calcd.	Found
Ethyl allyl	172–173	13.2	13.1
Ethyl isopropyl	192	13.1	12.76
Ethyl *n*-butyl	144–145	12.3	12.07
Ethyl *s*-butyl	163–165	12.3	12.4
Ethyl (2-methylallyl)	160–161	12.3	12.4
Ethyl isoamyl	167–169	11.6	11.52
Ethyl (1-methylbutyl)	158–159	11.6	11.7
Ethyl *n*-hexyl	136–137	10.9	11.1
Ethyl 2-ethylbutyl	137–138	10.9	10.8
Ethyl cyclohexyl	205–207	11.03	11.1
Ethyl phenyl	215–217	11.3	11.2
Methyl (2-methylallyl)	128–130	13.2	13.45
Diallyl	134	12.5	12.5
Allyl 2-methyl allyl	180–182	11.7	11.67
Allyl *s*-butyl	142–143	11.7	11.83
Allyl (1-methylbutyl)	127–129	11.0	11.04
Allyl benzyl	140–150	10.2	10.38
Ethyl (3-chloro-2-butenyl)	128–130	10.7	10.85

Pharmacologic

We are indebted to Mr. H. C. Spruth of the Pharmacologic Department, Abbott Laboratories, for the pharmacologic investigation of the thiobarbiturates, which will be reported in detail elsewhere. It is of interest, however, to record here preliminary data regarding certain of the most promising compounds. Intravenous injection into rabbits has been found to be the method of choice because it is thus possible to evaluate not only the effective and toxic doses, but also gain some information regarding relative depths of depression and sleeping times. The latter point is important since for compounds designed for the production of brief surgical anesthesia the sleeping time must be as brief as is consistent with proper depth of hypnosis and recovery must be rapid.

TABLE II

THIOBARBITURATES

	Minimum effective dose mg./kg.	Minimum lethal dose, mg./kg.	Sleeping time min. mg./kg.
Diethyl	75	>200	64 at 100
Ethyl isopropyl	30	80–100	97 at 40
Ethyl *n*-butyl	20	90–100	22 at 40
Ethyl *s*-butyl	15	>50	15 at 25
Ethyl (2-methylallyl)	30		
Ethyl isoamyl	30	55–60	78 at 40
Ethyl (1-methylbutyl)	10	35–40	14 at 20
Ethyl (2-ethylbutyl)	10	40	
Diallyl	30	>125	
Allyl (2-methylallyl)	20		
Allyl *s*-butyl	10	50	13 at 20
Ethyl (3-chloro-2-butenyl)	Convulsions 20 mg./kg.		

It will be seen that several of the compounds indicated fulfil to a considerable degree the properties desired. In clinical experience they have also proved of practical value.

Summary

A series of disubstituted thiobarbituric acids has been synthesized and characterized. Several of these compounds are powerful hypnotics. When injected intravenously into animals, they produce very prompt sleep, from which the animals recover rapidly. The sulfur in these compounds appears to accelerate their destruction in the body.

Studies in the Physical Chemistry of Betaines and Related Substances. I. Studies of Dielectric Constants and Apparent Molal Volume[1]

BY JOHN T. EDSALL AND JEFFRIES WYMAN, JR.

Introduction

The betaines and the amino acids occupy a distinctive place among organic substances. Both these classes of compounds are distinguished by their unusually high melting points, by their high solubility in water and insolubility in truly nonpolar solvents, and by the fact that in all cases their solutions have a dielectric constant greater than that of the solvent. All these properties find a natural explanation in terms of their structure as zwitterions.

In additon to these general resemblances, however, there are certain notable differences between the two classes of compounds. Instead of the $—^+NH_3$ group found in the amino acids, the betaines contain the group $—^+NR_1R_2R_3$, where the R's may be almost any organic radicals, but are generally methyl groups. This structure greatly increases both the volume and the basic strength of the nitrogenous radical, and results in important modifications in the properties of the molecules. Moreover, the betaines, unlike the amino acids, are soluble not only in water but in alcohol and in mixtures of alcohol with ether or benzene. Furthermore, their dissociation constants and other properties indicate that they remain as zwitterions, and do not pass over to the uncharged form, in all of these solvents. This has made possible the present study of their dielectric behavior in solvents both of very high and very low dielectric constant, which reveals certain new relationships between the dielectric effect of zwitterions and the properties of the solvent. One highly polar molecule closely related to the betaines, N-dimethylanthranilic acid, is very soluble in pure benzene, and its dipole moment in this solvent has been directly determined, as well as its dielectric increment in other solvents, and its dissociation constants.

Moreover, in the case of the betaines, in distinction from the amino acids, it is possible to obtain in pure form the uncharged molecule corresponding to a given zwitterion. Thus, to a betaine of the type $(CH_3)_3{}^+NRCOO^-$, there corresponds the uncharged ester $(CH_3)_2NRCOOCH_3$. We have made an experimental study of one such pair, namely, ortho benz betaine and its isomer, dimethylanthranilic acid methyl ester. The striking contrasts found between them throw considerable light on the relation of the electric charges to the properties of the molecule.

In one important class of these substances, namely, the benz betaines, the electric charges on the zwitterion are closely attached to the benzene ring. Owing to the rigid nature of this structure the moments of these compounds can then be calculated with greater reliability than has hitherto been possible in other cases, and considered in relation to their dielectric effects in polar solvents.

Zwitterions, like ions, produce electrostriction of the solvent, an effect which in theory should decrease as the radius of the charged group or ion increases. The increase in bulk of the charged nitrogenous group in the betaines as compared with amino acids should therefore lead to a decrease of electrostriction, and our density measurements confirm this conclusion. The electrostriction due to the betaines becomes much greater in media of low dielectric constant than in water. A fairly extensive study of this phenomenon has been carried out, and the results obtained are in general accord with theoretical expectations.

Preparation of Materials

Betaine [N-Trimethylglycine, $(CH_3)_3N^+CH_2COO^-$] was obtained from a pure sample of betaine hydrochloride (Eastman Kodak Co.) by the action of silver oxide, recrystallized four times from absolute alcohol by gradual addition of anhydrous ether, and dried forty-eight hours in a vacuum desiccator over phosphorus pentoxide; m. p. 293°.[2]

Other betaines described below were liberated from their halogen salts and purified by the same method.

Pyridine Betaine [$C_5H_5N^+CH_2COO^-$].—The hydrochloride was prepared by heating pyridine with chloroacetic acid.[3] Heating for five hours at about 60° gave a purer product than a shorter heating at a higher tempera-

---

[1] A preliminary account of part of this work was published in *J. Biol. Chem.*, **105**, Proc. XXIV (1934).

[2] Willstätter, *Ber.*, **35**, 584 (1902).

[3] E. von Gerichten, *ibid.*, **15**, 1251 (1882).

ture. The hydrochloride was dissolved in alcohol and crystallized by addition of ether. The free betaine was liberated and purified as described above. Its behavior on heating was exactly as described by von Gerichten.

Dimethylphenyl Betaine [$C_6H_5(CH_3)_2N^+CH_2COO^-$].—The hydrochloride was prepared by heating dimethylaniline with chloroacetic acid.[4] The reaction proceeded much more slowly than for pyridine betaine: twelve to eighteen hours heating on the water-bath was required, and the yield even then was less good than for pyridine betaine. A considerable amount of an impurity with a deep blue color was present, which went into solution with the free betaine when the latter was liberated from the hydrochloride. The impurity, like the betaine, was soluble in water and alcohol and insoluble in ether; but it proved to be soluble in acetone, or in a mixture of 90% acetone and 10% alcohol, in which the betaine is insoluble, and the two substances were separated by this means. The purified betaine melted at 124–126° (in agreement with Willstätter and Kahn).

Dimethylanthranilic Acid Methyl Ester [ortho $(CH_3)_2N$-$C_6H_4COOCH_3$].—To a solution of 340 g. of anthranilic acid (2.5 moles) in 500 cc. of water containing just enough potassium hydroxide to allow a faintly alkaline solution, 1600 g. (12.7 moles) of dimethyl sulfate is added, with stirring, during two and a half hours; 40% potassium hydroxide is added simultaneously at such a rate as to maintain a faintly alkaline reaction. The temperature is held at about 10° during the addition of the first half; it is then gradually raised to 65°. The resulting oily ester is taken up in ether, dried over calcium chloride, and distilled under reduced pressure. The yield was 150 g. (33% of the theoretical amount); b. p. 139° at 16 mm.

Dr. W. D. Peterson, who developed this method in Professor E. P. Kohler's laboratory, obtained in one preparation a yield as high as 75%, using smaller quantities of material than those above given.

Dimethylanthranilic acid [ortho$(CH_3)_2NC_6H_4COOH$] was obtained almost quantitatively by heating its methyl ester with excess of water for eight hours in a reflux condenser.[5] It was purified by recrystallization from ether and melted at 68°.

Ortho Benz Betaine [$(CH_3)_3N^+C_6H_4COO^-$].—Methyl iodide was added to dimethylanthranilic acid methyl ester (1.5 moles of iodide per mole of ester) and the solution left to stand. The iodide of the methyl ester of ortho benz betaine slowly crystallized out. The yield after one week in the cold was 15–20%, in agreement with Willstätter and Kahn. A large additional yield was obtained when the reacting mixture was allowed to stand for several weeks longer.

The iodide of the betaine ester, after crystallization from alcohol, was treated with silver oxide, whereby the free betaine is liberated. Subsequent purification as described above; m. p. 223–224°.

Meta Benz Betaine.—The iodide was prepared from meta aminobenzoic acid and three moles of methyl iodide, following the method of Griess[6] as modified by Cumming,[7] and the free betaine liberated and purified as described above (m. p. 236–238°).

The betaine was also prepared by the action of dimethyl sulfate (4 moles) on *m*-aminobenzoic acid. When the reaction was complete, most of the salt in the system was precipitated by addition of alcohol; the filtrate was concentrated *in vacuo* until nearly all alcohol was removed; the betaine was then precipitated as the triiodide by addition of iodine dissolved in hydriodic acid. The triiodide was converted to the iodide, as described by Willstätter and Kahn for the triiodide of *p*-benz betaine.

Para Benz Betaine.[4,8]—The iodide was prepared from para aminobenzoic acid and methyl iodide, by essentially the same procedure as the meta compound. The melting point of the free betaine was 252–255°.

Methods and Experimental Results

Dielectric Constant.—The dielectric constant of solutions of the betaines and related compounds in various solvents was determined by a resonance method previously developed.[9] Measurements were made at 25°, at a variety of wave lengths between 3 and 26 meters. In no case was there any indication of variation of dielectric constant with frequency in this range. The settings were least sharp, indicating relatively greatest absorption, for solutions in alcohol and solvents containing a large proportion of alcohol. In all cases, excepting a few involving solvents of relatively low dielectric constant, the dielectric constant was found to be strictly linear in the concentration of solute in moles per liter, and the experimental results can be expressed in terms of a first degree equation involving the dielectric constant of the solvent ϵ_0 and the slope of the dielectric constant concentration curve δ. In the small number of cases where this was not so the deviation from linearity was generally slight and the limiting value of δ for infinite dilution could be estimated from a graph with considerable accuracy. In Table I the data in regard to dielectric constant are given on this basis in terms of ϵ_0 and δ. Cases in which the curves were not linear are marked with an asterisk and the limiting value of δ is followed by the value, enclosed in brackets, reckoned from the difference between the dielectric constant of the most concentrated solution and that of the solvent. In the right-hand column of Table I is given in each case the range of concentration studied. The contents of this table are shown graphically in Fig. 1.

Several of these substances have also been studied by Devoto, although only in aqueous

solution, and his δ values, which differ somewhat from ours, may be given for comparison: betaine, +25[10]; N-dimethylanthranilic acid, +16.7[11]; *o*-benz betaine, +20;[11] *m*-benz betaine, +58;[11] *p*-benz betaine, +68.[11]

Optical Polarizations

In the case of N-dimethylanthranilic acid and its methyl ester, values of the optical polarization were determined from measurements of the refractive index for sodium light made with a Pulfrich Zeiss refractometer. The index of refraction of the pure ester at 25° was found to be 1.55743 and the density was 1.0950. This gives a polarization of 52.69 cc. The polarization of the ester was also calculated from the index of refraction at 25° of a 0.3867 molar solution in

---

[10] Devoto, *Gazz. chim. ital.*, **64**, 76 (1934).

[11] Devoto and Ardissone, *ibid.*, **64**, 371 (1934).

benzene and the value obtained was 52.3 cc.

The index of refraction of the pure acid, which melts at 68°, could not well be measured; the optical polarization was therefore calculated from measurements of the refractive index at 25° of aqueous solutions at three concentrations with the following results: 0.1631 molar, 45.9 cc.; 0.1295 molar, 46.4 cc.; 0.0925 molar, 45.6 cc. We may accept 45.9 cc. as a value correct to at least 1%.

Total Polarizations and Electric Moments

In the case of N-dimethylanthranilic acid and its ester it is possible on the basis of the foregoing data and that on the densities given in the following section to calculate the polarizations and electric moments in benzene. The results, extrapolated to infinite dilution, are as follows: for the acid, 879 cc. for the polarization and 6.31×10^{-18} e. s. u. for the moment; for the ester, 140 cc. for the polarization and 2.05×10^{-18} e. s. u. for the moment.

Densities and Apparent Molal Volumes

The density of N-dimethylanthranilic acid methyl ester, measured with a pycnometer at 25°, was found to be 1.0950. The densities of the solid *o*-, *m*-, and *p*-benz betaines were determined to an accuracy of about 0.2% by flotation in benzene–chloroform mixtures, in which they are insoluble, with the following results: *o*-benz betaine, 1.290; *m*-benz betaine, 1.299; *p*-benz betaine, 1.261.

The apparent molal volumes of the various substances studied were calculated in the usual way from the density of the solutions, together with the density of the solvents, measured with a pycnometer. Each substance was measured at two or three concentrations in each solvent studied (concentration of solute 1 to 4% by weight, generally from 2 to 3% by weight) and the apparent molal volumes listed in Table II are the averages of these individual determinations. There was no evidence of any significant change with concentration. The apparent molal volumes in water are probably reliable to within 1 cc. and the others to within 2 cc., except in the very volatile alcohol ether mixtures, where the error may be 4 or 5 cc.

Dissociation Constants of N-Dimethylanthranilic Acid and its Methyl Ester.—The dissociation constants were determined at 25° with the hydrogen electrode, using a bubbling electrode of the Simms type.[12] Before titration dimethylanthranilic acid methyl ester was converted into its hydrochloride (m. p. 145–146°, after recrystallization) which is readily soluble in water, and the hydrochloride was titrated with sodium hydroxide. The following values of the logarithmic dissociation constants (pK') were obtained (pK'_1 and pK'_2 refer to dimethylanthranilic acid, pK'_E to its methyl ester; concentration of substances titrated was 0.04 molar).

Water	1.4	8.42	5.55
90% Ethanol		8.15	2.4

so great that pK_1' could not be exactly determined. It probably lies between 1 and 2. From the earlier measurements of Cumming[13] (in aqueous solution at 25°) we calculate pK_1' as 1.36, pK_2' as 8.64, and pK_E' as 3.70. This last value diverges greatly from our own. We believe our value to be the more reliable of the two, as it is based on seven different sets of e. m. f. measurements, in which the ratio of ester to ester hydrochloride was varied from 7:1 to 1:7. The values of pK' calculated from these measurements all lay within 0.06 of the value given in Table III. On the other hand Cumming (who employed a catalytic method) obtained shifting values which he himself regarded as not altogether reliable.

Discussion

Dielectric Constant.—In the case of polar solutions the interpretation of the dielectric constant offers a very difficult problem, at the present time lacking a theoretical solution from general principles. Certainly the Clausius–Mosotti relation is inapplicable and indeed yields results probably many times too small for the polarizations. On the other hand consideration of a variety of experimental results in the light of our knowledge of molecular structure suggests that the dielectric constant itself is in a general way proportional to the volume polarization. An attempted rationalization of the situation has been given by one of us[14] which leads to the result that in the case of polar liquids the Clausius–Mosotti relation for the volume polarization p in terms of the dielectric constant ϵ is to be replaced by the expression

$$p = (\epsilon - 1)/3 \qquad (1)$$

This expression would afford a ready explanation of the additive character of the dielectric constant so apparent in the case of polar solutions and of the close correlation between δ, the dielectric increment per mole of solute, and the polarization of the solute in substances for which there is a basis for estimating the polarization, notably the aliphatic amino acids which exist as zwitterions. Hitherto, however, there has always been a considerable degree of uncertainty in such estimates of the polarizations arising principally from the possibility of free rotation of the carbon atoms in the aliphatic chains, involving a change in the distance between the oppositely charged groups of the zwitterionic molecule.

In the benz betaines the groups bearing the positive and negative charges are attached to the relatively rigid benzene ring, and the separation of the charges, and consequently the moments and polarizations, can be reckoned with considerably less uncertainty. We may in fact calculate the separation of the charged groups in *o*-, *m*- and *p*-benz betaine, assuming the molecules to be undistorted, quite simply from models based on data from recent x-ray and electron diffraction studies.[15] In each the positive charge of the zwitterion is assumed to be located at the center of the nitrogen atom, and the negative charge midway between the two oxygens of the carboxyl group, owing to the resonance involving these. The locus of the carboxyl carbon atom is taken to

---

be on the straight line passing through the corresponding carbon of the benzene ring and the center of the hexagon, the ring itself being regarded as plane; the same is assumed also for the nitrogen atom. The various interatomic distances (in Ångströms) are taken as follows: carbon to carbon in the ring, 1.39; carboxyl carbon to adjoining carbon in the ring, 1.54; nitrogen to adjoining carbon in the ring, 1.4; oxygen to carboxyl carbon, 1.29. The angle subtended by the two oxygens at the carboxyl carbon atom is taken as 125°. This gives 1.29 cos (125°/2) = 0.6 Å. for the distance from this carbon atom to the locus of the negative charge, and this distance, owing to symmetry, is in a direction radial to the ring. The dipole distances (*i. e.*, distances between the positive and negative charges of the zwitterions) calculated from these models are 3.23, 5.49, and 6.36 Å. for *o*-, *m*- and *p*-benz betaine, respectively.

In the case of *o*-benz betaine the distance calculated in this way would seem to be too small in view of the size of the carboxyl group and of the methyl groups attached to the nitrogen atom. If we take the carbon to hydrogen distance as 1.07, the radius of the hydrogen atom as half the hydrogen to hydrogen distance or 0.75/2, the distance from the nitrogen to the carbons of the methyl groups as 1.4,[16] and assume the tetrahedral arrangement for the four valences of the nitrogen atom, we may estimate the minimum dipole distance as in the neighborhood of 3.9 Å. This estimate[17] is based on the assumption that there is free rotation of both the carboxyl carbon and nitrogen atoms about the valences joining them with corresponding carbon atoms of the ring. It would seem, therefore, that the ortho compound must be somewhat deformed and exist in a state of strain involving a certain amount of potential energy.[18] This would be expected to give rise to an effect of "steric hindrance" to the introduction of the methyl groups into this molecule, and corresponds to the fact that it is indeed much more difficult to effect the complete methylation of the amino group in anthranilic acid than in *m*- and *p*-aminobenzoic acids.[19]

If we adopt for the dipole distances of the *o*-, *m*- and *p*-benz betaines the values 3.9, 5.49, and 6.36, respectively, the corresponding moments are 18.6, 26.2 and 30.4 $\times 10^{-18}$ e. s. u. The same moments calculated from the data on the dielectric constant in water by means of Eq. (1), taking the optical polarization in each case as 52.7 (*i. e.*, the value experimentally determined for the uncharged isomer N-dimethylanthranilic acid methyl ester) are 21.9, 31.0 and 36.4. The values are 18, 18, and 20% too high, respectively. It would seem therefore that the moments, or polarizations, calculated from Eq. 1, though probably somewhat too high, are closely proportional to the true values as far as we can estimate them.

The behavior of the benz betaines as we pass to solvents of lower dielectric constant consisting of alcohol–water mixtures, alcohol, and alcohol–benzene mixtures is apparent from Fig. 1. Unfortunately it is impossible to dissolve these substances in pure benzene itself. If we make use of Eq. (1) to calculate the polarizations from these data, we obtain the results shown graphically in Fig. 2. The polarizations of course follow the δ values quite closely and are fairly constant down to a dielectric constant of about 20. It is impossible to extend the measurements on the para compound below this point owing to its insolubility, but the polarizations of the ortho and meta compounds fall rapidly from here on with diminishing dielectric constant of the solvent. Indeed it is extraordinary that the δ values for both these compounds (and of glycine betaine) seem to be converging toward the value 5.1 actually observed in the case of dimethylanthranilic acid in benzene.

The results obtained for ortho and meta benz betaine in the solvents of lowest dielectric constant actually studied, are given in Table IV. Here we have tabulated, in addition to the dielectric constant of the solvent and the δ value, the molal polarizations (P) and the corresponding moments (μ), calculated first from the Clausius–Mosotti equation at infinite dilution and then from Equation 1. In these calculations the apparent molal volumes are taken to be the same as in alcohol, namely, 133 cc. and 124 cc. for the ortho and meta compounds, respectively (they contribute at most less than 10% to the calculated polarizations), and the optical polarizations are again taken as 52.7 cc. For comparison, the results of similar calculations for betaine are included, in which the volume is taken as 91.9 cc. and the optical polarization as 35 cc.

TABLE IV

Compound	ϵ (Solvent)	δ	P, cc., Clausius–Mosotti	P, cc., Eq. 1	$\mu \times 10^{18}$ Clausius–Mosotti	$\mu \times 10^{1}$ Eq. 1
Ortho B B	4.579	10.7	813	3725	6.05	13.2
Meta B B	3.191	10.1	1177	3457	7.36	12.8
Betaine	3.205	7.0	814	2401	6.11	10.7

It should be noted that in this range the values calculated on any basis are changing rapidly with the dielectric constant of the solvent. Nevertheless, however, we interpret the dielectric constant in this doubtful region, it appears clear that the moments of the betaines in these solvents of very low dielectric constant are decidedly lower than in water. It might be supposed that this effect is due to association of dipoles. Hooper and Kraus[20] have recently shown for certain highly polar molecules dissolved in benzene that the δ value and molal polarization decrease rapidly with increasing concentration at concentrations in the neighborhood of 0.001 molar. Hence the apparent moments deduced from studies at concentrations greater than this are much lower than the true moments determined at very great dilutions. Kraus interprets these phenomena as being due to association of dipoles, with decrease in apparent moment, at the higher concentrations. It seems improbable that our data on the betaines can be explained on this basis. In N-dimethylanthranilic acid in benzene there is actually a slight increase of δ from the value 5.1 observed at the lowest concentration 38×10^{-5} to the value 5.5 obtained at a concentration of 0.43; in the case of *p*-benz betaine in 19.9% benzene–ethanol δ is constant in the range 78×10^{-5} to 31×10^{-4} molar. Only in the case of betaine (N-trimethylglycine) in certain solvents is there anything resembling the effect described by Hooper and Kraus, and for this compound we have based our calculations on the limiting value of δ for the lowest concentrations.

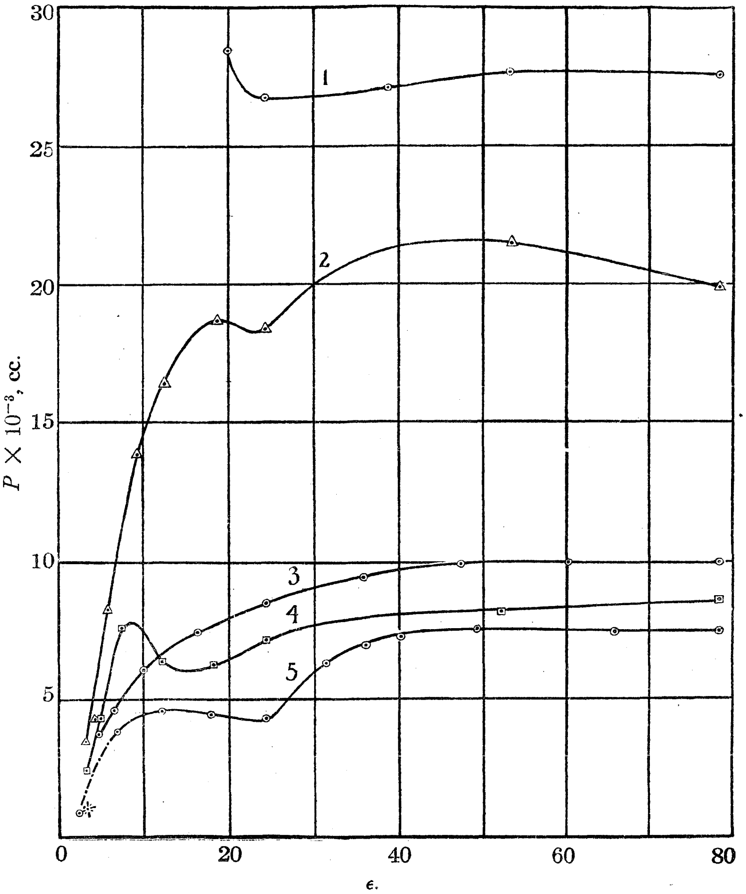

Fig. 2.—Polarizations calculated from Eq. 1, in relation to dielectric constant of solvent. The point marked by an asterisk, corresponding to pure benzene, is calculated by the Clausius–Mosotti relation: 1, *p*-benz betaine; 2, *m*-benz betaine; 3, *o*-benz betaine; 4, glycine betaine; 5, N-dimethylanthranilic acid.

If we accept the reality of the great reduction in moment indicated by the results in solvents of low dielectric constant and reject an explanation based on association, it remains to account for this in terms of a change in the individual molecules. The most natural explanation is probably in terms of a distortion of the valence bonds uniting the carboxyl carbon and the nitrogen atoms to the corresponding carbons of the ring. Such a distortion, involving a decrease in the dipole distance easily reckoned on the basis of simple geometrical considerations, would lead to a decrease of electrostatic energy inversely proportional to the dielectric constant of the solvent. If we regard this energy as that arising from two opposite elementary charges ($\pm e$) uniformly distributed over two equal spheres of radius b whose centers are separated by a distance R, we may apply the formula given by Scatchard[21] for the electrostatic energy E per mole.

$$E = \frac{Ne^2}{\epsilon}\left(\frac{1}{b} - \frac{1}{R}\right)$$

---

[20] Hooper and Kraus, THIS JOURNAL, **56**, 2265 (1934).

[21] See Cohn, McMeekin, Edsall and Weare, *ibid.*, **56**, 2270 (1934).

In this expression ϵ denotes the dielectric constant of the medium and N is Avogadro's number. On the basis of this formula and the geometry of the molecule we can calculate the energy change $E_0 - E$ associated with a given angular distortion ω of both the valences uniting the nitrogen and carboxyl carbon atoms to the ring. In the ortho and meta compounds the distortion is assumed to take place in the plane of the ring, which makes it most effective; in the case of the para compound it makes no difference in what plane the bending occurs. The results of the calculation, expressed in calories per mole, for a medium of dielectric constant unity, are given in Fig. 3. This figure shows how much greater must be the tendency for a distortion of the valence bonds in the ortho compound than in the two others and how relatively small is the tendency in para benz betaine. The question then arises how such a decrease of electrostatic energy compares with the corresponding energy increase due to valence distortion itself. Stuart[22] has estimated that the distortion of a valence bond by 10° involves an increase of potential energy of the order of 1000 to 2000 calories per mole. Although we do not know how this varies with the angle, nevertheless it is clear that in solvents of low dielectric constant there will probably be a considerable distortion and corresponding reduction of moment of the ortho and meta molecules. In water, calculation shows that such an effect would be relatively insignificant. It may well be that the greater dipole moment and the smaller tendency for this to reduce itself in less polar solvents accounts for the very much smaller solubility of p-benz betaine in solvents of low dielectric constant. It would appear, however, at least in the case of the ortho compound, that this deformation would demand an approach of the charged groups to a distance actually less than that consistent with the bulk of these groups, discussed above. In regard to this, it is conceivable that when the forces become very great the interfering methyl groups are actually forced aside or that the carboxyl carbon atom is prevented from rotating, or both, with the result that the locus of the negative charge is brought into close proximity to the positively charged nitrogen atom; to this effect might be added the result of an actual polarization of the molecule under the influence of the strong field arising from the zwitterionic charges of the molecule itself in a medium of low dielectric constant.

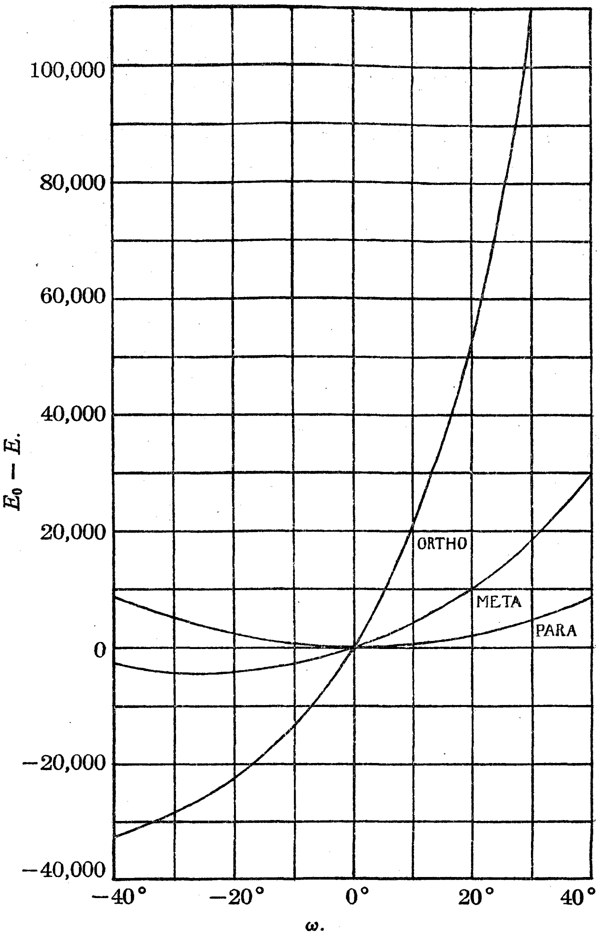

Fig. 3.—Energy change in relation to angular distortion, ω, of valence bonds for the benz betaines. Negative values of ω correspond to an increase of distance between the charges.

Of course the possibility remains of an intramolecular rearrangement of the betaines into their uncharged isomers, with a great resultant decrease in moment. At very high temperatures such a transformation does occur, as Willstätter[23] has shown. Under the conditions of our experiments, however, there has never been any sign of this. The uncharged isomers (*i. e.*, the methyl esters of the dimethylated aminobenzoic acids) are low melting substances, readily soluble in ether and benzene. When the betaines, dissolved in the solvents of lowest dielectric constant studied, were treated with ether, they were quantitatively precipitated, and no trace of ether-soluble material could be found. Furthermore,

---

[22] Stuart, *Phys. Rev.*, **38**, 1372 (1931).

the betaine so isolated showed no change of melting point from that of the substance as originally prepared.

For comparison with the betaines, we have studied the properties of one of these uncharged substances, namely, dimethylanthranilic acid methyl ester. This substance, dissolved in benzene, gives a δ value of $+0.570$ and has a moment of 2.05×10^{-18} e. s. u. In solvents of higher dielectric constant the δ value becomes negative. The results are included in Fig. 1 and show the striking contrast in behavior between this moderately polar molecule and the zwitterionic betaines.

The behavior of the ester is in marked contrast with that of N-dimethylanthranilic acid itself. This substance shows throughout a high δ value characteristic of zwitterionic structure, although in details it differs decidedly from glycine betaine, pyridine betaine, and ortho benz betaine in regard to δ. In pure benzene its moment is 6.31×10^{-18} e. s. u. or more than three times that of the ester. The detailed character of the variation both of δ and of the polarization (calculated from Eq. 1) with the dielectric constant of the solvent may be seen from Figs. 1 and 2. It would appear therefore that N-dimethylanthranilic acid remains largely in the zwitterion form even in pure benzene.

The study of its dissociation constants and that of its ester (Table III) further supports the view that this substance is a zwitterion, at least in water and in alcohol–water mixtures. According to the relations developed by Ebert[24] the ratio K_z of zwitterions to uncharged molecules in a solution of a simple ampholyte is given by the equation

$$K_z = (K_1/K_E) - 1$$

where K_1 is the first dissociation constant of the acid and K_E that of its ester, both being expressed as acid dissociation constants. On the basis of the data given in Table III this yields a value of approximately 12,000 for K_z in water and about 10 in 90% alcohol. There seems no doubt whatever therefore that in these solvents dimethylanthranilic acid exists predominantly in the zwitterion form. That a large proportion of zwitterions should remain in pure benzene is certainly surprising on the basis of our general knowledge of dissociation constants as a function of the dielectric constant of the solvent.[2]

It may be noted that N-dimethylanthranilic acid shows very unusual properties in other respects also.[26] Unlike most zwitterions it is very soluble not only in water but also in alcohol, acetone and benzene, and quite soluble even in ether and carbon tetrachloride. It melts at 70° to a clear liquid which solidifies on cooling and the solid so obtained shows all the properties of the original substance. In contrast with this, most zwitterionic acids melt between 200 and 300°, and decompose on melting. Likewise this compound shows markedly different properties from the other ortho, meta and para aminobenzoic acids, whether the nitrogen is unmethylated, monomethylated or dimethylated. These melt at temperatures from 140 to 180°; they are sparingly soluble in water, appreciably more soluble in alcohol or benzene; and their dissociation constants and those of their esters indicate values of K_z in water which are not far from unity.[27] Devoto[28] has indeed reported a δ value of about 40 for meta aminobenzoic acid in water, while that for dimethylanthranilic acid is only 12,[29] but there are no essential inconsistencies here since the charged zwitterions in the meta compound possess higher dipole moments than those in an ortho compound and hence even though they do not predominate so completely over the uncharged molecules they still have a much higher effect on the dielectric constant of the solvent.

It should be noted that the δ value and the polarization of dimethylanthranilic acid calculated from Eq. 1 are lower in all solvents studied than for ortho benz betaine (see Figs. 1 and 2). It seems not improbable that this is because of the substitution of a hydrogen atom for one of the methyl groups, which permits the positive and negative radicals to pack together more closely and results in a decrease of dipole moment. Indeed the moment in water calculated from Eq. 1 is 18.9×10^{-18} e. s. u., or about 14% less than that of ortho benz betaine. 3.23 Å., the dipole dis-

tance calculated from the model of the molecule in the undistorted condition is 17% less than 3.9, the dipole distance of the more bulky benz betaine. In any case the very remarkable properties of dimethylanthranilic acid clearly demand further study for they are unparalleled among all the ampholytes known to us.

Apparent Molal Volumes and Electrostriction of the Solvent

Betaines, possessing charged groups, produce electrostriction of the solvent, similar to that which has been shown to occur in solutions of amino acids.[30] The magnitude of the effect may be estimated by a comparison with similar uncharged substances, and with the aid of Traube's atomic volumes. In Table V are listed the apparent molal volumes in water calculated from Traube's theory for the substances studied, the observed volumes, and the estimated electrostriction, which is given by the difference between the observed and calculated volumes. Certain typical amino acids are also listed for comparison. In the last column is tabulated the value ΔE, which represents the difference in electrostriction between a given betaine and a corresponding amino acid (ortho, meta and para benz betaines are considered to correspond approximately to α, β and γ amino acids, respectively).

TABLE V

BETAINES IN WATER

Substance	Apparent molal vol., cc. Calcd.	Obs.	Electrostriction, cc./mole	ΔE
Betaine	105.9	97.7	8.2	5.1
Dimethyl phenyl betaine	151.4	146.8	4.6	8.7
Ortho benz betaine	151.4	146.5	4.9	8.4
Meta benz betaine	151.4	145.0	6.4	8.0
Para benz betaine	151.4	141.3	10.1	5.8
Pyridine betaine	108.8	99.6	9.2	4.1
Dimethylanthranilic acid	135.2	134.6	0.6	12.7
Glycine	57.0	43.5	13.5	..
α-Aminovaleric acid	105.9	92.7	13.2	..
β-Alanine	73.3	58.9	14.4	..
γ-Aminovaleric acid	105.9	90.0	15.9	..

It is apparent that when hydrogen atoms, surrounding a charged nitrogen, are replaced by the more bulky methyl or phenyl groups, the electrostriction diminishes. In betaine, with three methyl groups, the decrease is 5.1 cc. out of 13.3, an average value for an α-amino acid. Substitution of a phenyl for a methyl group, as in dimethylphenyl glycine, produces a further diminution of 3.6 cc. These results experimentally observed accord closely with what would be expected from the theory of electrostriction produced by ions in solution.[31] The smaller a given ion the more intense will be the electric field in its immediate neighborhood and the greater the orientation and compression effects producing electrostriction of the solvent.

These data suggest an approach to the solution of another problem. It has hitherto been impossible to decide whether most of the electrostriction produced by amino acids is due to the carboxyl or to the amino group since only the effect of the two groups in combination can be observed. In dimethyl phenyl betaine, however, the electrostriction produced is 8.7 cc. less than that characteristic of α amino acids. Almost all this diminution must be due to an effect on the charged nitrogen atom although the electrostriction produced by the carboxylic group may also be slightly diminished by the introduction of the large groups adjacent to it. It seems fair to assume, however, that at least 8.7 cc. of the total electrostriction (13.3 cc.) characteristic of α amino acids is due to the amino group and, therefore, not more than 4.6 cc. to the carboxyl group. Adopting tentatively the same ratio for the two groups when the charges are far apart and the total electrostriction is some 20 cc. per mole, we should assign approximately 13 cc. to the amino and 7 cc. to the carboxyl group. Utilizing the calculations of Vosburgh, Connell and Butler[32] for the relation between electrostriction and ionic radius, we may deduce an apparent radius of 2.25 Å. for the amino and 2.9 Å. for the carboxyl group.

In solvents of lower dielectric constant, the apparent molal volumes of the betaines are invariably smaller than in water. The same is true for salts, as was shown long ago by Carrara and Levi[33] and more recently by the careful and exact measurements of Vosburgh, Connell and Butler.[34] In the betaines the decrease in apparent molal volume is greater the greater the separation of the charged groups. Thus the value for

---

(30) Cohn, McMeekin, Edsall and Blanchard, *J. Biol. Chem.*, **100**, Proc. XXVII (1933); THIS JOURNAL, **56**, 784 (1934). Reference may be made to these papers for the details of the calculation of electrostriction values.

ortho benz betaine is 13 cc. per mole lower in absolute alcohol than in water; for para benz betaine, it is 22 cc. lower.

In solvents other than water, the electrostriction of the betaines cannot be calculated directly from Traube's atomic volumes, since the "Covolume" of Traube varies with the solvent employed in a manner depending largely on the particular substance studied.

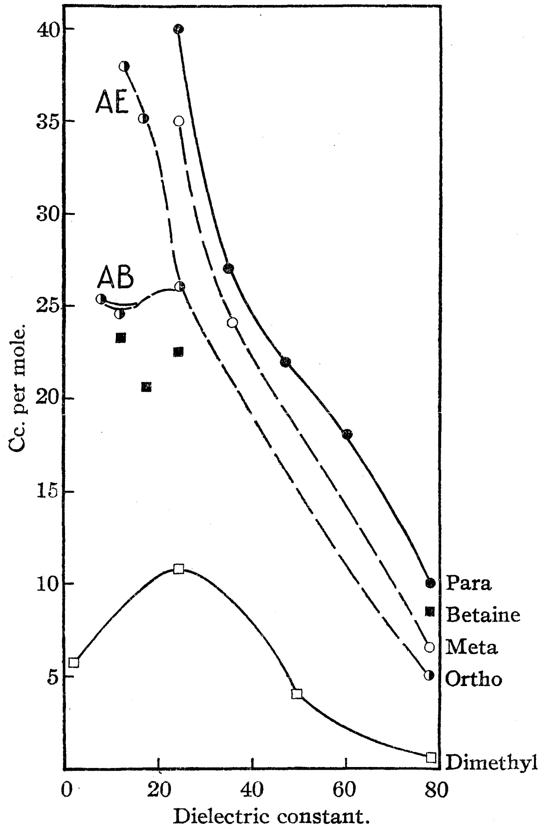

Fig. 4.—Electrostriction of betaines and dimethylanthranilic acid in various solvents: abscissa, dielectric constant of solvent; ordinate, electrostriction in cc. per mole; ◑, *o*-benz betaine; ○, *m*-benz betaine; ●, *p*-benz betaine; ■, betaine; □, dimethylanthranilic acid. The values for dimethylphenyl-betaine (not shown) are almost identical with these for *o*-benz betaine. The branch of the *o*-benz betaine curve marked AE refers to alcohol–ether mixtures; that marked AB, to alcohol–benzene mixtures.

We can, however, estimate the electrostriction directly by comparing a betaine in any given solvent with the isomeric uncharged ester *in the same solvent.* The difference between the two apparent molal volumes gives the contraction of the system due to the reaction $(CH_3)_2NRCOOCH_3 \longrightarrow (CH_3)_3N^+RCOO^-$; *i. e.*, by definition, the electrostriction.

We have taken dimethylanthranilic acid methyl ester as the uncharged isomer for comparison with all the benz betaines and with dimethylphenylglycine.[35] Its apparent molal volume in alcohol and in benzene is shown in Table II. It will be seen that the two volumes are almost identical, and that both are about 8 cc. higher than the value (151.4 cc.) calculated from Traube's theory for water.[36] (The ester is insoluble in water, so that this determination cannot be made directly.) For purposes of interpolation we have assumed the apparent molal volume of the ester in alcohol–water mixtures to vary linearly with the weight fraction of alcohol in the solvent, from 151.4 to 159.0 cc. In other organic solvents the value 159 cc. (identical with that in alcohol and benzene) has been taken.

In the case of betaine (trimethylglycine) we have no data on the uncharged isomer, dimethylglycine methyl ester. We have therefore calculated its volume in water from Traube's theory (see Table V) and have assumed the value in alcohol and other organic solvents to be 8 cc. greater than in water by analogy.

Dimethylanthranilic acid differs from its ester by one CH_2 group, whose contribution to the volume of the molecule is known to be nearly constant and equal to 16.3 cc. per mole in all solvents. To estimate the apparent molal volume of the acid in the uncharged form, therefore, we have subtracted 16.3 cc. from the volume of the ester in the same solvent. The difference between this value and the observed apparent molal volume of the acid yields the electrostriction. The electrostriction of the substances studied is plotted against the dielectric constant of the solvent in Fig. 4.

It may be seen from the figure that the electrostriction produced by the benz betaines is four or five times as great in ethyl alcohol (ϵ = 24.3) as in water (ϵ = 78.5) while that of trimethylglycine is nearly three times as great.

We may compare these experimental results with the effects to be expected theoretically from the calculations of Vosburgh, Connell and Butler for ions. Para benz betaine may be selected for comparison, since in this substance the charged groups are widely separated, and their mutual influence is small. The electrostriction in water is

---

[35] Traube [*Sammlung Chem. Vorträge*, **4**, 255 (1899) and references there given] has shown that the apparent molal volumes of uncharged ortho, meta and para isomers are identical within 1 or 2 cc.

[36] This is in harmony with the finding of Traube that apparent molal volumes of uncharged compounds are generally 8 to 13 cc. greater in organic solvents than in water.

10 cc. per mole, of which we may tentatively assign 6 cc. to the carboxyl and 4 cc. to the methylated amino group.[37] Groups producing this amount of electrostriction in water should from the tables of the above-named authors in ethanol produce 23 and 18 cc. of electrostriction respectively, or a total of 41 cc. The observed value in ethanol (Fig. 4) is 40 cc. The agreement is far better than we should have any right to expect, considering the approximations involved in the theory itself and in its application to such substances as the betaines.

The results in mixed solvents are more difficult to interpret. It should be noted, however, that the electrostriction produced by ortho benz betaine is markedly greater in alcohol–ether mixtures than in alcohol–benzene mixtures of the same dielectric constant. It seems probable that this difference is correlated with the fact that ether is much more compressible than benzene.

It will be noted from Fig. 4 that the electrostriction of dimethylanthranilic acid is almost zero in water, and in all solvents is much lower than that of any of the betaines. Qualitatively these low values appear to parallel the relatively low δ values of this substance, and suggest that its electrical constitution must differ in some significant respect from that of the betaines.

Summary

1. Dielectric constant increments and apparent molal volumes have been determined for various betaines, and for N-dimethylanthranilic acid and its methyl ester in a variety of solvents ranging from water to benzene.

2. For the relatively rigid benz betaines, approximate dipole moments have been calculated on the basis of known interatomic distances. These have been compared with the values calculated from the observed dielectric increments with the aid of theoretical considerations.

3. In solvents of low dielectric constant, the dielectric increments (and probably the moments) of all the betaines studied fall far below their values in water. This effect appears to be due to actual deformation of the molecules rather than to association.

4. N-Dimethylanthranilic acid appears to exist largely as a zwitterion, not only in water and alcohol, but also in pure benzene, in which its dipole moment is more than three times as great as that of its methyl ester.

5. The electrostriction of the solvent produced by betaines in water is less than that produced by similar amino acids, presumably due to the greater bulk of the positively charged group in the betaines.

6. The electrostriction due to the betaines is much greater in solvents of low dielectric constant than in water, and the magnitude of the effects observed is in good accord with theoretical predictions.

The "Salting-in" of Hydrogen Peroxide by Electrolytes

BY M. H. GORIN

Non-electrolytes are in general salted out of solution by the addition of electrolytes. The magnitude of this effect varies widely with the nature of the electrolyte and non-electrolyte, and in a few cases even changes in sign. However a search of the literature revealed that sodium chloride and sodium sulfate give relatively large salting-out effects with all non-electrolytes so far investigated, excepting hydrogen peroxide; Livingston[1] found the activity coefficient, $\gamma_{H_2O_2}$, of hydrogen peroxide to be less than unity in aqueous solutions of these salts. This is a "salting-in" effect of sodium chloride and sodium sulfate on hydrogen peroxide. On account of the exceptional nature of this result it was considered worth while to check Livingston's work with sodium chloride, and to study the behavior of hydrogen peroxide with several other electrolytes. The data are presented in Table I and plotted together with Livingston's in Fig. 1.

The experimental method used was the same as Livingston's; the distribution ratio of hydrogen peroxide between the salt solutions and iso-

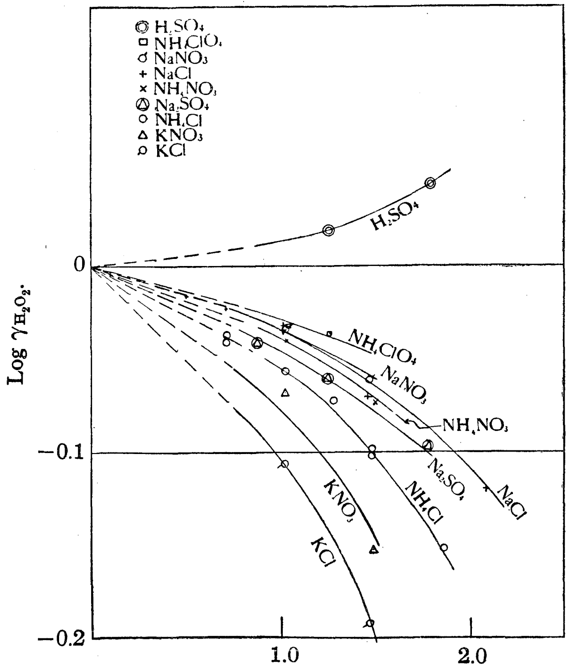
[a] Solvent is isoamyl alcohol. [b] Solvent is 3 parts acetophenone + 1 part carbon tetrachloride. [c] μ is given in moles per 1000 g. of water.

amyl alcohol was determined; $\gamma_{H_2O_2}$ is given by the expression $\gamma_{H_2O_2} = R_0/R$ where R_0 is the distribution ratio of hydrogen peroxide between pure water (*i. e.*, hydrogen peroxide in water/hydrogen peroxide in isoamyl alcohol), and isoamyl alcohol, and R the distribution ratio of hydrogen peroxide between the salt solutions and isoamyl alcohol. The value, 7.08 ± 0.01, was found for R_0, while Livingston[1] used 6.95, an average between his value, 6.87, and that of Calvert,[2] 7.03 ± 0.05. In the case of ammonium chloride a solvent made up by adding one part of carbon tetrachloride to three parts of acetophenone was also used for the partition experiments, in order to confirm the results. R_0 was found to be 18.37 ± 0.07 for this mixture. The partition coefficient for pure acetophenone was found to be 11.55 ± 0.08. This value is far greater than the one previously given in the literature,[3] and is probably very much more nearly correct since the permanganate method used by these investigators[3] was found to give high results in the presence of acetophenone.



Square root of ionic strength.

Fig. 1.

It is seen from Table I and Fig. 1 that $\gamma_{H_2O_2}$ is not only less than unity in sodium chloride and sodium sulfate solutions but also in solutions of all the salts studied; and that only in the case of sulfuric acid is $\gamma_{H_2O_2}$ greater than unity. Furthermore, the order of the "salting-in" of hydrogen peroxide by the ions under consideration as determined from Fig. 1, is as follows: $K^+ > NH_4^+ > Na^+ > H^+$ and for the negative ions, $SO_4^= > Cl^- > NO_3^- > ClO_4^-$. Randall and Failey[4] in an extensive survey of the subject, tentatively arranged these ions along with some others in the following order of decreasing "salting-out" power on non-electrolytes in general: $Na^+ > K^+ > NH_4^+ > H^+$ and $SO_4^= > Cl^- > NO_3^- > ClO_4^-$. A comparison of this classification with that found for hydrogen peroxide reveals that the order for the "salting-in" of hydrogen peroxide by negative ions is exactly the same as the order for the "salting-out" of non-electrolytes in general. The same could be said about the positive ions if sodium ion were excluded.

It should be noted that log $\gamma_{H_2O_2}$ has been plotted against $\mu^{1/2}$ instead of against μ, as would be required by the Debye–McAuley relation, log $\gamma = K\mu$. This was done because when plots of log $\gamma_{H_2O_2}$ against μ were tried, s-shaped curves resulted in the case of ammonium chloride; for this salt the measurements cover a wide range of ionic strength and the individual points were most closely determined. The other curves in Fig. 1

were drawn using the one for ammonium chloride as a model. It appears, therefore, that the Debye–McAuley law is not suitable for the case of hydrogen peroxide.

The evidence here presented proves that the behavior of hydrogen peroxide in solutions of electrolytes is different from that of other non-electrolytes; and requires that the hydrogen peroxide molecules tend to displace the water molecules surrounding all ions. However, in the case of the very small hydrogen ion there is a small "salting-out" effect instead of the relatively large "salting-in" effects shown by other ions. This is probably due to the preferential formation of hydronium ion, since it is reasonable to assume that the equilibrium

$$H_3O_2^+ + H_2O = H_3O^+ + H_2O_2$$

lies far to the right; and to the fact that hydronium ion carries relatively little hydrogen peroxide or water.

The displacement of water by hydrogen peroxide can be explained by the higher dipole moment of the peroxide molecule than that of the water molecule in the neighborhood of an ion. The following structure for hydrogen peroxide would yield a dipole moment of 3.01×10^{-18} as compared with 1.84×10^{-18} for water.

This structure differs from the one assigned to hydrogen peroxide in the gas phase by Penney and Sutherland[5] and can only exist in the strong potential fields surrounding an ion.

The dipole moment of gaseous hydrogen peroxide[6] is practically the same as that of water. Penney and Sutherland[5] have found that the most plausible structure of hydrogen peroxide is a highly skewed one, with an oxygen–oxygen single bond and a hydrogen atom on each oxygen, without free rotation around the O—O bond, the most stable configuration being the one in which the O—H bonds make an angle of 90° with each other. The $\mathrm{O{-}O}{\diagup}^{\mathrm{H}}$ bond angle is the same as in water, 110°, and the dipole moment for this model agrees very well with the observed one.[6] But the difference in potential between the model given in Fig. 2 and the stable configuration of the gaseous state was found by Penney and Sutherland[5] to be only of the order of magnitude of 25,000 calories. Therefore, it is probable that the hydrogen peroxide molecule assumes the structure shown in Fig. 2 as it approaches an ion, since the potential at the surface of even a large ion tending to rotate the O—H dipole is far greater in magnitude than 25,000 calories.

The order of the "salting-in" of hydrogen peroxide by the various positive and negative ions remains to be explained. The structure given in Fig. 2 for the hydrogen peroxide molecule is very similar to that of the water molecule as it orients itself around a negative ion; that is, the H—H distances are nearly the same in the two molecules and therefore it would be expected that hydrogen peroxide would tend to displace water around all negative ions since it has a higher dipole moment. Therefore, the order for the "salting-in" of hydrogen peroxide would be identical with the order for the "salting-out" of other non-electrolytes by negative ions, because the ions which hold the most water would be expected to hold the most hydrogen peroxide. This expectation agrees very well with the experimental findings for the four negative ions investigated. When oriented toward a positive ion, however, the water molecules can pack more closely around it than the peroxide molecules, since in this case the oxygen atoms rather than the hydrogen atoms are pointing toward the ion. Therefore, even though hydrogen peroxide has a higher dipole moment than water, it might be expected that in the case of the very smallest positive ions the equilibrium would favor water practically completely and as the ions increased in size hydrogen peroxide would begin to displace water. Only in the case of the larger positive ions, should hydrogen peroxide be "salted-in" in the same order as other non-electrolytes are "salted-out." The above discussion

explains the experimental result that hydrogen peroxide is "salted-in" more by potassium ion than by sodium ion, while other non-electrolytes are "salted-out" more by sodium ion than by potassium ion.

In conclusion I wish to express my gratitude to Professor W. C. Bray for suggesting the problem, and for his very helpful suggestions and criticism during the progress of the work.

Acetylene Polymers and their Derivatives. XXII. α-Dialkylaminomethyl-β-vinylacetylenes

BY DONALD D. COFFMAN

The reaction of primary acetylenic compounds with formaldehyde and secondary aliphatic amines in dioxane has recently been shown to give good yields of aminomethyl derivatives having the formula $RC{\equiv}CCH_2NR_2$.[1] This reaction has been applied to vinylacetylene, and it proceeds smoothly with low molecular weight secondary aliphatic amines according to the equation

$$CH_2{=}CHC{\equiv}CH + CH_2O + HNR_2 \longrightarrow$$
$$\text{(I)}\ CH_2{=}CHC{\equiv}CCH_2NR_2 + H_2O$$

Members of this new class of amines (I) have been prepared by allowing a dioxane solution of vinylacetylene and paraformaldehyde to react with dimethylamine, diethylamine, piperidine and dicyclohexylamine in an autoclave at 100°. The reaction furnishes the lower members of the series in good yields. The properties of the amines obtained in this way are indicated in Table I. The compounds are stable, colorless liquids with characteristic odors.

PROPERTIES OF α-DIALKYLAMINOMETHYL CHLOROPRENES

Nature of amine		B. p., °C.	d^{20}_{4}	n^{20}_{D}	MR Calcd.	MR Found	Exaltation
(VI)	$(CH_3)_2N$-	56–58 at 11 mm.	0.9615	1.4895	42.40	43.73	1.33
(VII)	$(C_2H_5)_2N$-	71–73 at 5 mm.	.9500	1.4895	51.63	52.78	1.15
(VIII)	$(CH_2)_5N$-	90–92 at 3.5 mm.	1.0137	1.5193	54.05	55.59	1.54

The reactions of several typical members of this new class of amines have been studied. Compounds (III) and (IV) are readily hydrogenated to the corresponding saturated tertiary amines whose properties and derivatives agree with those already recorded in the literature.

Compounds (II), (III) and (IV) add hydrogen chloride in the presence of cuprous chloride, but they react more slowly with aqueous hydrochloric acid than does the parent hydrocarbon[2] so that elevated temperatures are required. The products (VI), (VII) and (VIII) of the reaction correspond in composition to structure (IX). By analogy with the formation of chloroprene from vinylacetylene, structure (IX) seems most likely.

(IX) $CH_2{=}CHCCl{=}CHCH_2N(R)_2$

(X) $p\text{-}CH_3C_6H_4SCH_2CH_2C{\equiv}CCH_2N(CH_3)_2$

The physical properties of these substituted chloroprenes are indicated in Table II. They are colorless liquids which darken on standing. Like chloroprene, they react with α-naphthoquinone and with maleic anhydride but the products are black tars. Unlike chloroprene, they polymerize very slowly even at 100° or when exposed to light, and no rubber-like polymer has yet been obtained from them. It has already been shown that α-substitution in 1,3-dienes decreases con-

siderably the rate of polymerization.[3,4] Furthermore, these compounds have polymerization inhibiting groups cast directly in the molecule.

Thio-*p*-cresol readily adds to (II) in the presence of ultraviolet light. The product is a yellow oil corresponding in composition to formula (X). Since the mode of addition of thiophenols has been established thoroughly and since in the case of divinylacetylene only the ethylenic bonds are involved in the addition, the assigned structure seems likely.[5,6] Other addition reactions also take place. One molecule of methanol adds to (II) in the presence of sodium methoxide. The oily product is completely destroyed by permanganate. The theoretical amounts of bromine and iodine are absorbed by (II), but the products were black undistillable sirups. Exhaustive methylation of (II) with methyl iodide and silver oxide gives for the most part a tar, but an unsaturated hydrocarbon C_5H_4 is obtained in poor yield. The compound absorbs oxygen rapidly and when heated gelled and finally exploded violently.

Experimental Part

Preparation of α-Dialkylaminomethyl-β-vinylacetylenes.—The general method of preparation consisted in heating in an autoclave at 100–105° for fourteen to seventeen hours a dioxane solution of secondary aliphatic amine, vinylacetylene and paraformaldehyde. The only especial precaution observed in the preparation consisted in thoroughly cooling in an ice-bath the solution obtained by mixing the amine and paraformaldehyde. After the reaction had ceased for the most part, the vinylacetylene was added. During the heating period, care was taken that the thermal decomposition temperature of vinylacetylene (*ca.* 110°) was not reached. The products of the reaction were isolated in one of two ways. The reaction mixture from small runs was poured into dilute acid, and the aqueous solution was thoroughly ether extracted. The free amine was liberated from its salt by the addition of alkali, and after extraction was dried over potassium hydroxide and distilled under diminished pressure. In the case of large runs, the reaction mixture was separated into its components by fractional distillation under diminished pressure. Table III indicates the condition used and the yields of products obtained. Table IV contains the analytical data for the products.

TABLE III

Product	Amine	Moles of Vinylacetylene	$(CH_2O)_x$	Dioxane solvent, cc.	Time and temp., °C.	Yield of product, %

Hydrogenation of (III) and (IV) to Corresponding Saturated Tertiary Amines.—α-Diethylaminomethyl-β-vinylacetylene (0.25 mole) and 0.2 g. of platinum catalyst in 100 cc. of absolute ethanol absorbed 0.757 mole of hydrogen (107% of the amount required by theory) during thirty minutes. The catalyst was filtered from the solution and the filtrate was fractionally distilled through a good column. There was received 24 g. (yield 67% of the theoretical amount) of colorless oil identified as *n*-amyldiethylamine. Its constants are: b. p. 155–157° at 760 mm.; d^{20}_4 0.7663; n^{20}_D 1.4250; MR (calcd.), 47.70; MR (obsd.), 47.77.

Anal. Calcd. for $C_9H_{21}N$: N, 9.80. Found: N, 9.96.

The amine readily formed a picrate which melted at 52–53° after recrystallization from ethanol. The constants of the amine and the melting of its picrate are in good agreement with those recorded in the literature.[7] The amine is recorded as boiling at 155–158° at 735 mm. and the picrate as melting at 55°.

α-Pentamethyleneaminomethyl-β-vinylacetylene (0.2 mole) and 0.2 g. of platinum catalyst in 50 cc. absolute ethanol absorbed 0.51 mole of hydrogen (85% of the amount required by theory) during forty minutes. The catalyst was filtered from the ethanol solution and the filtrate was fractionally distilled. There was received 25 g. (yield 80% of the theoretical amount) of N-*n*-amylpiperidine. Its constants are: b. p. 192–195° at 760 mm.; d^{20}_4 0.8412; n^{20}_D 1.4602; MR (calcd.), 50.12; MR (obsd.), 50.55.

Anal. Calcd. for $C_{10}H_{21}N$: N, 9.03. Found: N, 9.15.

The amine readily formed a picrate which melted at 100–101° after recrystallization from ethanol. N-*n*-Amylpiperidine boils at 196° at 769 mm. and its picrate melts at 107°.[8]

Conversion of α-Dialkylaminomethyl-β-vinylacetylenes to α-Substituted Chloroprenes

Addition of Hydrogen Chloride to (II).—The amine (55 g.) was dissolved with cooling in 200 g. of 38% hydrochloric acid containing cuprous chloride (5 g.). The solution was heated at 60° during sixteen hours. It was then added dropwise with cooling to a solution of potas-

sium hydroxide (112 g.) in 200 cc. of water. The insoluble amine was separated, dried and distilled. There was received 42 g. of colorless product (VI). The yield was 58% of the theoretical amount. After standing a short time, the amine was badly discolored. The substituted chloroprene (VI) reacted very rapidly with maleic anhydride and with naphthoquinone, but the products were black tars. Unlike chloroprene, it polymerized very slowly when exposed to light. After two and one-half months under a 100-watt lamp, a sample contained 10% of insoluble gelatinous polymer.

In the absence of cuprous chloride (II) adds hydrogen chloride very slowly; the product of the reaction is chiefly a tar but a 10% yield of (VI) was received.

Anal. Calcd. for $C_7H_{12}NCl$: Cl, 24.40. Found: Cl, 24.24.

Addition of Hydrogen Chloride to (III).—The amine (68 g.) was dissolved with cooling in 200 g. of 38% hydrochloric acid containing cuprous chloride (5 g). After the solution had been heated sixteen hours at 60°, the amine was freed by the addition of excess alkali, separated, dried and distilled. There was received 40 g. of the monohydrochloride (VII) or 46% of the theoretical amount. The product gave tars when allowed to react with maleic anhydride or naphthoquinone, and it polymerized very slowly. Only a trace of polymer was formed by heating the monomer during forty-three hours at 100°. When exposed to the light of a 100-watt lamp during three months, the monomer formed a semi-granular polymer (less than 10%).

Anal. Calcd. for $C_9H_{16}NCl$: Cl, 20.46. Found: Cl, 20.84.

Addition of Hydrogen Chloride to (IV).—The amine (75 g.) was dissolved with cooling in 200 g. of 38% hydrogen chloride containing cuprous chloride (5 g.). The solution was allowed to stand for sixty-six hours at 35° and was finally heated at 60° for five hours. The product was isolated in the usual manner and there was received a 56% yield of (VIII). This substituted chloroprene contained only a trace of polymer after exposure to the light of a 100-watt lamp during three months.

Anal. Calcd. for $C_{10}H_{16}NCl$: Cl, 19.13. Found: Cl, 18.85.

The Addition of Thio-*p*-cresol to (II).—Thio-*p*-cresol (62 g.) was dissolved in 55 g. of amine (II), and the solution was exposed to the light of a Cooper–Hewitt lamp for twenty-four hours. The pale yellow liquid was washed with dilute alkali and water, and was then dried and distilled in vacuum. There was received 43 g. of dimethylamino-1-pentin-2-yl-5-*p*-thiocresyl ether (X). The yield was 30% of the theoretical amount. Its physical constants are: b. p. 156–158° at 0.5 mm.; d^{20}_4 1.0151; n^{20}_D 1.5620; MR (calcd.), 73.09; MR (obsd.), 74.44.

Anal. Calcd. for $C_{14}H_{19}NS$: N, 6.01. Found: N, 6.18.

The Addition of Methanol to (II).—The amine (2.25 moles) and absolute methanol (2.47 moles) in which sodium (0.22 mole) was dissolved were heated in an autoclave at 100° for twelve hours. The reaction product was poured into a large volume of water, and the water-insoluble material was separated, dried and vacuum distilled. There was received 125 g. of product corresponding in composition to the addition of one molecule of methanol to (II). The product (yield 40%) had a powerful fish-like odor. Its constants are: b. p. 69–71° at 1 mm.; d^{20}_4 0.8987; n^{20}_D 1.5400; MR (obsd.), 48.82.

Anal. Calcd. for $C_8H_{15}NO$: N, 9.93. Found: N, 10.52.

Attempts to establish the structure of this compound by permanganate oxidation were unsuccessful; the amine was completely destroyed. Attempts to add two molecules of methanol to (II) were unsuccessful; the products obtained were tar-like and were for the most part undistillable *in vacuo.*

Exhaustive Methylation of (II).—Exhaustive methylation of (II) with methyl iodide and potassium hydroxide or silver oxide gave for the most part a tar, but a hydrocarbon—presumably pentatetraene ($CH_2{=}C{=}C{=}C{=}CH_2$)—was obtained in poor yields. It absorbed oxygen rapidly and when heated it gelled and finally exploded violently.

The most convenient method for carrying out the methylation consists in treating the methyl iodide quaternary salt of (II) (m. p. 182–184°) with an excess of freshly precipitated silver oxide in aqueous suspension. The quaternary salt (97 g.) in 300 cc. of water was agitated with silver oxide (100 g.) at 45°. When the test for the presence of ionic iodide in the aqueous solution was negative, the silver iodide was filtered off and the filtrate was vacuum distilled. From the condensate there was received 4 g. of hydrocarbon. The residue consisted entirely of tar. The product appeared to boil from 80–90° when distilled immediately; n^{20}_D 1.4778.

Anal. Calcd. for C_5H_4: C, 93.75; H, 6.25. Found: C, 91.97; H, 6.74.

Summary

The reaction between vinylacetylene, paraformaldehyde and secondary aliphatic amines yields α-dialkylaminomethyl-β-vinylacetylenes. Several transformation products of typical members of this new class of amines are described.

Acetylene Polymers and their Derivatives. XXIII. Cyano-4-butadiene-1,3

BY DONALD D. COFFMAN

Compounds of the formula $CH_2{=}C{=}CHCH_2X$ in which X is Cl, Br, I, OH or OAc survive a series of metathetical reactions without undergoing rearrangement.[1] Of these compounds, the chloride and bromide are readily and irreversibly rearranged to $CH{=}CXCH{=}CH_2$, and the iodide rearranges spontaneously.

Because of the ease with which the chloride, bromide and iodide are rearranged, it appeared likely that the action of sodium cyanide on chloro-4-butadiene-1,2 (I) might yield cyanoprene (II), a compound which should be of especial interest as a precursor of synthetic rubber. As a matter of fact cyano-4-butadiene-1,3 (III), isomeric with (II), is obtained in poor yields when an alcoholic solution of sodium cyanide is allowed to react with (I). The reaction evidently proceeds in a normal metathetical manner and is followed by rearrangement of one of the double bonds. Certain by-products formed during the reaction are indicated in subsequent paragraphs.

(I)	$CH_2{=}C{=}CHCH_2Cl$
(II)	$CH_2{=}C(CN)CH{=}CH_2$
(III)	$CH_2{=}CHCH{=}CHCN$
(IV)	$ClCH_2CH{=}CHCH_2CO_2C_2H_5$
(V)	$CH_3OCH_2CH{=}CHCH_2CN$

The structure of cyano-4-butadiene-1,3 (III) is established by its analytical composition and by the following reactions.

It is converted to β-vinylacrylic acid by cold acid hydrolysis and it is readily hydrogenated to *n*-amylamine. Alkaline permanganate oxidizes it to oxalic acid. In ethanol solution, the nitrile adds hydrogen chloride. The reaction consists of 1,4-addition and esterification giving rise to ethyl chloro-5-pentenoate-Δ^3 (IV). The ester (IV) is readily oxidized by alkaline permanganate to chloroacetic acid. When cyano-4-butadiene-1,3 is heated with naphthoquinone or maleic anhydride the only evidence of reaction is the formation of a polymeric mass. However, as has already been pointed out,[2] negative results in the Diels–Alder reaction are of no value in the demonstration of structure, since many 1,3-dienes fail to react.

Results already presented[3] show that to obtain a high rate of polymerization, the terminal carbon atoms in a 1,3-diene must be free of any substituents, but the new nitrile nevertheless polymerizes about twenty times as fast as isoprene and gives a rubber-like product. It polymerizes spontaneously on standing, and the polymerization is greatly accelerated at 100°. After three weeks at ordinary temperature, a 5% yield of α-polymer was obtained. On the other hand, after thirteen hours at 100°, the α-polymer was obtained in 14% yield along with a 42% yield of dimer. Antioxidants act as powerful inhibitors for this transformation. The plastic polymer obtained under the influence of heat may be compounded and cured, and, although the plastic properties of the product were never entirely suppressed, the rubber-like material possessed considerable elasticity. Under the influence of light cyano-4-butadiene-1,3 polymerizes to a granular product identical in appearance with ω-polychloroprene.

Under the conditions of preparation cyano-4-butadiene-1,3 is very reactive. It readily adds methanol to form two chemical individuals obtained as by-products.

The first of these is an unsaturated oil corresponding in composition to the addition of one molecule of methanol to the 1,3-diene (III). Oxidation of the oil with permanganate yields methoxyacetic acid. These facts indicate that it has the structure methoxy-1-cyano-4-butene-2 (V). It evidently is formed by the 1,4-addition of methanol.

The second of these is an oil corresponding in composition to the addition of two molecules of methanol to (III) and apparently it is formed by the addition of one molecule of methanol to (V). It is obtained not only as a by-product in the preparation of (III) but also by allowing (III) to react in a methanol solution of sodium methoxide. When hydrolyzed it yields a dimethoxyvaleric acid. Hydrolysis, demethylation by hydrobromic acid, and elimination of two molecules of water produce an unsaturated lactone which on hydrogenation yields δ-valerolactone.

These facts furnish a basis for a discussion of

[2] Coffman and Carothers, *ibid.* **55**, 2040 (1933).

[3] Carothers, *Ind. Eng. Chem.*, **26**, 30 (1934).

its structure. Formulas (VI) and (VII) represent the only possibilities consistent with the facts for the structure of a compound formed by the addition of one molecule of methanol to (V).

(VI) $CH_3OCH_2CH_2CH(OCH_3)CH_2CN$
(VII) $CH_3OCH_2CH(OCH_3)CH_2CH_2CN$

No direct experimental method is available for a decision between these two structures since the hydroxy acids derived from each present the possibility of six-membered ring formation required to obtain δ-valerolactone.

Experimental Part

I. Preparation of Cyano-4-butadiene-1,3.—Sodium cyanide (250 g.) was dissolved in a solution of 250 cc. of water and 700 cc. of methanol in a 3-liter flask equipped with stirrer and reflux condenser. Chloro-4-butadiene-1,2 (354 g.) was introduced, and the mixture was heated gently with agitation until the reaction became exothermic. After the reaction had proceeded for an hour, the mixture was cooled and the sodium chloride was removed by filtration. The filtrate was poured into 1.5 liters of water, the water-insoluble layer was separated, and the aqueous solution was twice extracted with ether. The water insoluble layer and the ether extracts were combined and dried over calcium chloride. The ether was evaporated and by distillation of the residue 90 g. of crude product boiling from 36° (50 mm.) to 55° (3 mm.) was received. This material was washed once with cold dilute hydrochloric acid and was dried over magnesium sulfate. Distillation of the dried material gave 64 g. of cyano-4-butadiene-1,3 which boiled at 49–53° (30 mm.).

The physical properties of cyano-4-butadiene-1,3 are: b. p. 135–138° (760 mm.) with polymerization; 65–68° (58 mm.), 48–50° (28 mm.); d^{20}_4 0.8644; $n^{20}D$ 1.4880; *MR* (obsd.), 24.57; *MR* (calcd.), 24.10.

Anal. Calcd. for C_5H_5N: N, 17.72; mol. wt., 79. Found: N, 17.48; mol. wt., 80.

During the preparation of the nitrile considerable amounts of by-products were formed by the addition of methanol to the 1,3-diene. These products obtained along with some polymeric material account, in part, for the utilization of chloro-4-butadiene-1,2.

II. Proof of Structure of Cyano-4-butadiene-1,3

Hydrolysis to β-Vinylacrylic Acid.—Cyano-4-butadiene-1,3 (10 g.) was introduced into a solution of 60 cc. of concd. hydrochloric acid in 100 cc. of ether. After standing for six days at ordinary temperature the solution was diluted with water to 500 cc. total volume, and the solution was continuously ether extracted for twenty-one hours. Distillation of the dried ethereal extract gave a small amount of β-vinylacrylic acid[4] which melted at 71° after recrystallization from petroleum ether. The distillation residue was a polymeric mass.

Anal. Calcd. for $C_5H_6O_2$: C, 61.22; H, 6.12; neut. eq., 98. Found: C, 61.00; H, 6.16; neut. eq., 100.2.

Conversion to Ethyl β-Vinylacrylate.—To well-cooled ethanol (100 g., 95%) in a liter flask was added 100 g. of concd. sulfuric acid. Cyano-4-butadiene-1,3 (40 g.) was then introduced, and the solution was refluxed for seven hours. After three hours the solution was very viscous. The cooled reaction mixture was poured into ice water, and there separated a large amount of soft, plastic and rubber-like polymer. Ether extraction of the solution and distillation of the dried ethereal extract gave a small amount of ethyl β-vinylacrylate which boiled at 65–67° (30 mm.); d^{20}_4 0.9336; $n^{20}D$ 1.4723; *MR* (obsd.) 37.81; *MR* (calcd.), 35.13. The literature[5] records the physical constants of ethyl β-vinylacrylate as b. p. 70–71° (31 mm.); d^{20}_4 0.938.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.67; H, 7.94. Found: C, 66.69; H, 7.71.

Ethyl β-vinylacrylate failed to form an addition compound when heated with naphthoquinone, and polymerized to a rubber-like mass after ten hours at 100°.

Reduction to *n*-Amylamine.—With a platinum catalyst, cyano-4-butadiene-1,3 (10 g. or 0.126 mole) in 25 g. of acetic anhydride absorbed 94% (0.477 mole) of the theoretical amount of hydrogen during eight hours. The reaction mixture was filtered from the catalyst and distilled, the portion boiling from 200–250° being collected. Redistillation gave 10 g. of colorless liquid which boiled at 112–116° (4 mm.); d^{20}_4 0.9146; $n^{20}D$ 1.4472; *MR* (obsd.), 37.75; *MR* (calcd.), 37.96.

Anal. Calcd. for C_7H_5ON: N, 10.85. Found: N, 10.92.

Hydrolysis of N-*n*-amylacetamide gave *n*-amylamine which boiled at 102–106°; d^{20}_4 0.7584; $n^{20}D$ 1.4093. The literature records the constants for *n*-amylamine as b. p. 104°, d^{19} 0.766. The amine was positively identified by conversion to *p*-bromobenzenesulfon-*n*-amylamide which, after recrystallization from petroleum ether, melted sharply on the block at 54°. The literature[6] records the melting point of *p*-bromobenzene-sulfon-*n*-amylamide as 55°.

Permanganate Oxidation of Cyano-4-butadiene-1,3.—An analytically pure sample of cyano-4-butadiene-1,3 (40 g.) was introduced into an aqueous solution (300 cc.) containing 28 g. of potassium hydroxide. Potassium permanganate (330 g.) was added in small amounts during four hours with vigorous agitation at 30°. The mixture was decolorized with sulfur dioxide, and the manganese dioxide was filtered off and washed with water. The combined filtrates were cooled, strongly acidified and continuously ether extracted. Evaporation of the dried ethereal extract gave a crystalline residue which, after washing with ethyl acetate–petroleum ether mixture, was dissolved in a small amount of water, boiled with Norite, filtered and cooled. The white crystals which separated melted sharply on the block at 101–102° with resolidification either alone or when mixed with an authentic sample of oxalic acid dihydrate.

Neutral equivalent. Calcd. for $H_2C_2O_4 \cdot 2H_2O$: neut. eq., 63.0. Found: neut. eq., 64.0.

Addition of Hydrogen Chloride to Cyano-4-butadiene-1,3.—Cyano-4-butadiene-1,3 (41 g.) was dissolved in 50

g. of 95% ethanol containing 44 g. of dry hydrogen chloride. After the mixture had stood for sixteen hours at ordinary temperature, it was heated for two hours at 80°. The cooled mixture was poured into ice water, and the water-insoluble layer was separated, washed with water and dried over calcium chloride. Distillation of the crude product (55 g.) in an efficient still gave 21 g. of pure chloro ester and a high boiling residue which could not be distilled without decomposition. The yield of ethyl chloro-5-pentenoate-Δ^3 was 25% of the theoretical amount. It boiled at 67–69° (0.5 mm.), 72–74° (1 mm.), d^{20}_{4} 1.0862; n^{20}_{D} 1.4612, *MR* (obsd.), 41.08; *MR* (calcd.), 40.58.

Anal. Calcd. for $C_7H_{11}O_2Cl$: Cl, 21.85; mol. wt., 162.5. Found: Cl, 22.02; mol. wt., 159.

Ethyl chloro-5-pentenoate-Δ^3 was oxidized to chloroacetic acid by potassium permanganate. The chloro ester (32 g.) was introduced into water (250 cc.) and potassium permanganate (85 g.) was added in small amounts during three hours with vigorous agitation. The mixture was decolorized with sulfur dioxide, and the manganese dioxide was filtered off and thoroughly washed with water. The combined aqueous filtrates were strongly acidified, and the aqueous solution was continuously ether extracted. The dried ethereal solution on evaporation and distillation of the residue gave 8 g. of crude chloroacetic acid which, after recrystallization from petroleum ether and chloroform, melted sharply on the block at 60–61°. The literature records its melting point as 61–63°.

Neutral equivalent. Calcd. for $C_2H_3O_2Cl$: neut. eq., 94.6. Found: neut. eq., 93.4.

Chloroacetanilide was prepared as a solid derivative. It melted sharply on the block at 134–135°. The literature records the melting point as 134–135°.[7]

Polymerization of Cyano-4-butadiene-1,3

Light Polymerization.—A sample of cyano-4-butadiene-1,3 in glass exposed to a 200-watt Mazda lamp for 112 hours at 40–50° was completely converted into a colorless granular mass of rubber-like globules. This granular product is identical in appearance with ω-polychloroprene. In a parallel sample isolated from the light, the only change was a slight increase in viscosity and the appearance of a tarry speck of granular polymer.

Heat Polymerization.—(1) Cyano-4-butadiene-1,3 also polymerized spontaneously on standing; after three weeks a sample of the nitrile gave a 5% yield of alcohol insoluble polymer. This soft, plastic, rather rubber-like mass was compounded with 1% of phenyl-β-naphthylamine and 5% of zinc oxide and was heated at 125° for thirty minutes. Vulcanization was apparently far from complete but the product had good elasticity and fair strength. A sample stretched 1400% without breaking; on release it instantly returned to 250% of its initial length and after ten minutes to 200%.

(2) A sample of the 1,3-diene heated in a glass tube at 100° for thirteen hours was converted to a colorless, viscous sirup which contained 14% of alcohol-insoluble polymer, 42% of high-boiling oil, and 21% of unchanged monomer. The high-boiling material had a molecular weight corresponding to a dimer, but its analytical composition indicated that considerable oxygen had been absorbed. The physical properties of the high-boiling oil are: b. p. 150–165° (3 mm.); d^{20}_{4} 1.0358; n^{20}_{D} 1.5118.

Anal. Calcd. for $C_{10}H_{10}N_2$: N, 17.72; mol. wt., 158. Found: N, 14.68; mol. wt., 160.

The alcohol-insoluble material was a soft, plastic, rubber-like mass. It was compounded with 0.5% of tetramethylthiuram disulfide, 1% benzidine, 3% sulfur, 5% zinc oxide and 1% phenyl-β-naphthylamine and heated at 125° for one hour. The plastic properties were partly suppressed, but the vulcanization was very incomplete. The product could be stretched without breaking to 1800% of its initial length; on release it instantly returned to 400%, and after ten minutes to 200%, its initial length.

(3) Cyano-4-butadiene-1,3 (10 g.) was added to a sodium hydroxide solution (120 g., 17% NaOH), and the mixture was heated to refluxing. During fifteen minutes ammonia was evolved and a polymeric mass commenced to separate from the mixture. After sixteen hours of refluxing all of the nitrile had been converted to a brown, hard, brittle solid (8 g.). The solid was finely ground in a mortar and was repeatedly washed in boiling water. The product after being washed with alcohol and ether was thoroughly dried at 110°. The material was quite hard and very insoluble in common organic solvents.

Anal. Calcd. for $(C_5H_5N)_x$: N, 17.72; C, 75.95; H, 6.33. Found: N, 15.30; C, 76.34; H, 7.38.

IV. By-Products in the Preparation of Cyano-4-butadiene-1,3

In the preparation of cyano-4-butadiene-1,3 large amounts of by-products are formed. The aqueous alcoholic solutions from six preparations of the nitrile (as already described) were continuously ether extracted for twenty-four hours. Fractionation by careful distillation of the dried ethereal extract showed it to consist essentially of three constant-boiling fractions having the compositions of (V) C_6H_9ON, (VI) $C_7H_{13}O_2N$, and (VIII) $C_7H_{10}O_2N$. Considerable amounts of material were discarded as foreshots obtained during the distillation.

(1) Proof of Structure of Methoxy-1-cyano-4-butene-2. Oxidation to Methoxyacetic Acid.—The first fraction (C_6H_9ON) consisted of 63 g. of colorless oil which boiled at 65–67° (7 mm.); d^{20}_{4} 0.9318; n^{20}_{D} 1.4397; MR (obsd.), 31.40; MR (calcd.), 30.90.

Anal. Calcd. for C_6H_9ON: C, 64.86; H, 8.11; N, 12.61; mol. wt., 111. Found: C, 65.40; H, 8.01; N, 12.58; mol. wt., 112.

Methoxy-1-cyano-4-butene-2 (44 g.) was introduced into 200 cc. of water and potassium permanganate (127 g.) was added in small portions during four hours with vigorous agitation. The mixture was decolorized by sulfur dioxide, and the manganese dioxide was filtered off and macerated in a mortar with water. The combined aqueous filtrates, strongly acidified with sulfuric acid, were subjected to continuous ether extraction. The dried ethereal extract was evaporated, and by distillation of the residue there was received 5 g. of organic acid which boiled at 115–117° (29 mm.). The acid was positively identified as methoxyacetic acid by conversion to methoxyacetamide. The amide, after recrystallization from absolute ethanol,

---

[7] Meyer, *Ber.*, **8**, 1153 (1875).

melted sharply on the block at 95–96° either alone or when mixed with an authentic specimen of methoxyacetamide. Methoxyacetamide is reported in the literature[8] as melting at 96.5°.

(2) **Conversion of Dimethoxyvaleronitrile to Dimethoxyvaleric Acid and to δ-Valerolactone.**—The second fraction ($C_7H_{13}O_2N$) consisted of 288 g. of colorless oil which boiled at 70–73° (1 mm.); d^{20}_4 0.9788; n^{20}_{D} 1.4288; MR (obsd.) 37.68; MR (calcd.), 37.63.

Anal. Calcd. for $C_7H_{13}O_2N$: C, 58.74; H, 9.09; N, 9.79; mol. wt., 143. Found: C, 58.82; H, 8.81; N, 10.13; mol. wt., 143.

This same nitrile was obtained by the addition of methanol to cyano-4-butadiene-1,3 with sodium methoxide as catalyst. Cyano-4-butadiene-1,3 (79 g.), stabilized by hydroquinone, was added dropwise during half an hour to a vigorously agitated solution of 2 g. of sodium in 64 g. of anhydrous methanol at 60°. After an hour the reaction mixture was cooled, diluted with water and ether extracted. The ethereal solution was washed with dilute acid and dried. From the dried ethereal solution there was received by distillation in an efficient column 32 g. of dimethoxyvaleronitrile which boiled at 72–74° (1 mm.); d^{20}_4 0.9777; n^{20}_{D} 1.4289. The yield was 23% of the theoretical amount. In the absence of alkaline catalysts, the addition of methanol to cyano-4-butadiene-1,3 does not take place. The nitrile (40 g.) and absolute methanol (40 g.) were heated for four hours at 90° in a sealed tube. By distillation there was recovered 32 g. of methanol and 22 g. of nitrile. The residue was polymeric material.

Hydrolysis to Dimethoxyvaleric Acid.—Into a solution of 67 g. of concd. sulfuric acid in 100 cc. of water was introduced 53 g. of dimethoxyvaleronitrile. The solution was refluxed vigorously for four hours and was then repeatedly ether extracted. Evaporation of the dried ethereal solution and distillation of the residue through an efficient column gave 23 g. of recovered nitrile and 15 g. of dimethoxyvaleric acid which boiled at 119–122° (1 mm.); d^{20}_4 1.0800; n^{20}_{D} 1.4428; MR (obsd.), 39.75; MR (calcd.), 39.35.

Anal. Calcd. for $C_7H_{14}O_4$: C, 51.85; H, 8.64; neut. eq., 162. Found: C, 52.40; H, 8.79; neut. eq., 162.

Conversion to δ-Valerolactone.—Dimethoxyvaleronitrile (71 g. or 0.5 mole) was refluxed for eighteen hours with 300 g. of 48% hydrobromic acid. The mixture was diluted to 500 cc. and was continuously ether extracted for seventy hours. The dried ethereal solution was evaporated, and the residue (42 g.) on distillation gave 20 g. of lactone which boiled at 83–85° (3 mm.). The remainder of the material was high boiling, acid to litmus, and contained halogen. The properties of the lactone are: b. p. 226–228° (760 mm.), 83–85° (3 mm.); d^{20}_4 1.1439; n^{20}_{D} 1.4869; MR (obsd.), 24.64; MR (calcd.), 22.43.

Anal. Calcd. for $C_5H_6O_2$: C, 61.22; H, 6.12; mol. wt., 98. Found: C, 60.86; H, 6.33; mol. wt., 100.

The lactone was faintly acid to litmus, but could not be titrated directly with alkali. It absorbed bromine readily, forming a liquid bromide which was not characterized. No solid polymer separated from a sample of lactone heated at 140–150° during eight hours.

The unsaturated lactone (0.234 mole) and a platinum catalyst in 25 cc. of absolute ethanol absorbed 79% (0.184 mole) of the theoretical amount of hydrogen during twenty minutes. The reaction mixture was filtered from the catalyst and distilled. There was received 16 g. of colorless pleasant smelling liquid which had the properties of δ-valerolactone. It boiled at 86–89° (5 mm.), 219–222° (760 mm.); d^{20}_4 1.0794; n^{20}_{D} 1.4503. The lactone formed a solid polymer when heated during eight hours at 150°.

Anal. Calcd. for $C_5H_8O_2$: C, 60.00; H, 8.00. Found: C, 59.76; H, 8.19.

The physical constants for δ-valerolactone as recorded in the literature[9] are b. p. 215–220° (760 mm.), d^{20}_{20} 1.1130; n^{20}_{D} 1.4600. Those recorded for γ-valerolactone[10] are b. p. 207–208 (760 mm.), d^{25} 1.0465; n^{20}_{D} 1.4303. The lactone (1 cc.) when heated with 3 cc. of hydrazine hydrate at 120° for two hours gave a crystalline product. After recrystallization from ethanol–ethyl acetate mixture the product melted sharply on the block at 105° and it had a composition corresponding to the hydrazide of δ-hydroxyvaleric acid.

Anal. Calcd. for $C_5H_{12}O_2N$: N, 21.21. Found: N, 20.97.

(3) The third fraction ($C_5H_{12}ON_2$) was not identified. It consisted of 123 g. of oil which boiled at 131–134° (0.5 mm.); d^{20}_4 1.0293; n^{20}_{D} 1.4480.

Anal. Calcd. for $C_7H_{10}ON_2$: C, 60.89; H, 7.25; N, 20.29; mol. wt., 138. Found: C, 61.76; H, 7.42; N, 19.38; mol. wt., 147.

Summary

The action of alcoholic sodium cyanide on chloro-4-butadiene-1,2 yields cyano-4-butadiene-1,3. The compound polymerizes much faster than isoprene and yields a rubber-like product. It readily undergoes 1,4-addition with hydrogen chloride and with methanol. The transformation products are ethyl chloro-5-pentenoate-Δ^3 and methoxy-1-cyano-4-butene-2.

The Crystal Structures of Rubidium and Ammonium Fluoborates

BY J. L. HOARD AND VIRGINIA BLAIR

Introduction

Potassium and rubidium fluoborates have been reported[1] to be isomorphous with the corresponding perchlorates, which are known[2] to possess the barite structure. No crystallographic data have been reported for ammonium fluoborate, a compound of most interesting chemical properties.[3] Although an ammonium salt is expected usually to be isomorphous with the analogous potassium or rubidium salt, the formation in a number of fluorides of hydrogen bonds between nitrogen and fluorine has been observed[4] to result in fundamental changes in structural type. Inasmuch as no fluoborate had been previously studied by x-ray methods, and since, moreover, we considered it quite possible that hydrogen bonds might exist in the ammonium salt and cause it to assume a different structural type, we have carried through structure determinations for rubidium fluoborate and ammonium fluoborate. We have found that both compounds belong to the barium sulfate structural type; the structure of the ammonium salt seems, however, to be somewhat modified as a result of hydrogen bond formation.

Ammonium fluoborate was prepared by adding ammonia to a solution of boric acid in 45% hydrofluoric acid, and evaporating to dryness. The ammonium fluoborate was purified by sublimation and recrystallized from aqueous solution.

Rubidium fluoborate was crystallized from a solution prepared by dissolving equivalent quantities of rubidium chloride and boric acid in 45% hydrofluoric acid. Even after recrystallization under conditions of constant temperature at 0°, no specimen was obtained measuring as much as 1 mm. in its longest dimension.

Data for the x-ray study were obtained from Laue and oscillation photographs.

Determination of the Structure

Using the notation of Wyckoff,[2] which is also the assignment of axes customarily used by crystallographers for crystals with the barite structure, the smallest unit of structure of ammonium fluoborate is an orthorhombic one with $a_0 = 9.06$ Å., $b_0 = 5.64$ Å., $c_0 = 7.23$ Å., containing $4NH_4BF_4$. The similar unit of rubidium fluoborate has $a_0 = 9.07$ Å., $b_0 = 5.60$ Å., $c_0 = 7.23$ Å., also containing four molecules. Although lattice constants are known only to within about half a per cent., it seems sure that b_0 is definitely smaller in the rubidium salt. The units in both cases are confirmed by extensive Laue and oscillation data.

All lattices except the simple orthorhombic are eliminated by the appearance of "forbidden" reflections. The regular vanishings[5] are those required by the space groups C_{2v}^9 and V_h^{16}. The morphology of the crystals is apparently holohedral, and we are able to base a satisfactory structure on V_h^{16}-*Pnma.*

Upon investigation we find it possible to assign both ammonium and rubidium fluoborates to the barite structural type. The positions of the various kinds of atoms together with the parameter values which lead to reasonably good agreement between calculated and observed intensities are given below (the notation is that of Wyckoff, Reference 2, page 283). The positions used are

4(*c*): $u\frac{1}{4}v$; $u + \frac{1}{2}, \frac{1}{4}, \frac{1}{2} - v$, $\bar{u}\frac{3}{4}\bar{v}$; $\frac{1}{2} - u, \frac{3}{4}, v + \frac{1}{2}$, and 8(*d*): xyz; $x, \frac{1}{2} - y, z$; $x + \frac{1}{2}, y, \frac{1}{2} - z$; $x + \frac{1}{2}, \frac{1}{2} - y, \frac{1}{2} - z$; $\bar{x}\bar{y}\bar{z}$; $\bar{x}, y + \frac{1}{2}, \bar{z}$; $\frac{1}{2} - x, y, z + \frac{1}{2}$; $\frac{1}{2} - x, y + \frac{1}{2}, z + \frac{1}{2}$.

We find

$RbBF_4$

4 Rb in 4(*c*) with $u = 0.315$, $v = 0.335$; 4 B in 4(*c*) with $s = 0.932$, $t = 0.696$; 4 F_I in 4(*c*) with $o = 0.069$, $p = 0.597$; 4 F_{II} in 4(*c*) with $m = 0.813$, $n = 0.567$; 4F_{III} in 8(*d*) with $x = 0.923$, $y = 0.043$, $z = 0.810$.

NH_4BF_4

4 NH_4 in 4(*c*) with $u = 0.308$, $v = 0.328$; 4 B in 4(*c*) with $s = 0.947$, $t = 0.697$; 4 F_I in 4(*c*) with $o = 0.086$, $p = 0.603$; 4 F_{II} in 4(*c*) with $m = 0.830$, $n = 0.563$; 4 F_{III} in 8(*d*) with $x = 0.936$, $y = 0.043$, $z = 0.811$.

We next outline the procedure followed in determining the listed parameter values.

The relatively large atomic number of rubidium

causes it to assume a dominating role in the x-ray scattering by rubidium fluoborate. As a first approximation we neglect the scattering of the lighter atoms, and use the intensity data to fix rough values of the rubidium parameters; because of the near identity in size of NH_4^+ and Rb^+ we may assume that we also obtain by this process approximate values of the ammonium parameters. We then introduce other atoms in the general regions to be anticipated, and calculate intensities for various combinations of the parameter values until we obtain a fairly detailed agreement with the observed intensities. This procedure is greatly simplified by the reasonable assumption of a regular BF_4^- tetrahedron. The size of the tetrahedron thus assumed can be determined, although only roughly, from a consideration of the (0*k*0) reflections, which involve but one degree of freedom. Thermal vibrations of the atoms within the lattice are responsible for a large and unknown decrease in atomic scattering powers. We can say only that observed intensity data fix the parameter of fluorine along *b* so as to limit the B–F separation (assuming a regular tetrahedron) to the range between about 1.40 and 1.47 Å. A value[6] of 1.43 Å. for this interatomic distance, obtained from the theoretical work of Pauling on ionic and covalent radii, is employed in the parameter determinations reported in this paper.

In Table I we give comparisons between calculated and observed intensities of x-ray reflections for a variety of planes. The *f*-values of Pauling and Sherman[7] are employed throughout this paper. No temperature factor is included, so that with increasing sin Θ continually mounting discrepancies between calculated and observed intensities are to be anticipated. By comparison with a scale prepared for the purpose, we have visually estimated the listed intensities; large differences in intensities, irregular crystal shapes, and the collection of data from various photographs combine to make these estimates rather uncertain. We have, nevertheless, attached numerical values to them, for we regard this scheme as more illuminating and somewhat more precise than the appellations "strong," "weak," etc. To compare relative intensities of corresponding reflections between the two salts, the values given for rubidium fluoborate must be multiplied by five.

Table I

Comparison of Calculated with Observed Intensities of x-Ray Reflections

	$RbBF_4$			NH_4BF_4

220	41	36	220	52	16
230	7.0	3	230	1.7	1
240	5.1	2	240	2.9	0
410	68	48	410	38	16

In consideration of the many parameters which are involved and the uncertainties already mentioned the intensity data of Table I seem quite consistent. The true parameter values may well differ appreciably from those given; we believe, however, that the structures of these two compounds are actually somewhat different. This point is made clear in the next section.

Discussion of the Structure

A diagram of the structure of ammonium fluoborate is shown in Fig. 1. A list of the interatomic separations which have a direct bearing upon the question of the stability of these structures is given in Table II.

The coördination of fluoride about rubidium ions is such as to place 12 F^- about each Rb^+ at distances ranging from 2.90 to 3.46 Å., with an average value of 3.05 Å. Each NH_4^+ is surrounded by 12 F^- at distances ranging from 2.83 to 3.39 Å., also with an average value of 3.05 Å.

TABLE II

INTERATOMIC DISTANCES IN RUBIDIUM AND AMMONIUM FLUOBORATES

$RbBF_4$			NH_4BF_4		
Atom	Neighbor	Separations, Å.	Atom	Neighbor	Separations, Å.
B	F_I, F_{II}, $2F_{III}$	1.43	B	F_I, F_{II}, $2F_{III}$	1.43
Rb	F_I	2.91	N	F_I	2.83
Rb	F_{II}	2.92	N	F_{II}	2.83
Rb	$2F_{III}$	2.89	N	$2F_{III}$	2.86
Rb	$2F_{III}$	2.91	N	$2F_{III}$	2.94
Rb	$2F_{III}$	2.97	N	$2F_{III}$	3.08
Rb	$2F_I$	3.11	N	$2F_I$	3.18
Rb	$2F_{II}$	3.44	N	$2F_{II}$	3.39
F_{II}	$2F_{III}$	3.17	F_{III}	$2F_{III}$	3.01
F_{III}	$2F_{III}$	3.18	F_I	$2F_{II}$	3.16
F_I	$2F_I$	3.28	F_I	F_{II}	3.27

In $(NH_4)_2SiF_6$ each NH_4^+ is equidistant from 12 F^- with NH_4-F = 2.99 Å.

Leaving out of consideration the (seemingly unavoidably) large values of 3.13 and 3.46 Å., we see that the eight smaller Rb-F separations vary within the narrow range from 2.89 to 2.97 Å., with an average of 2.93 Å. This feature of the structure is certainly to be anticipated when dealing with the rubidium ion, which, when isolated, is spherically symmetrical. We find that a similar assignment of parameter values to the ammonium salt leads to intensity predictions which are in some cases rather definitely unsatisfactory; to be entirely rid of these discrepancies, it seems necessary to introduce the type of distortion next to be described.

Examination of an ammonium fluoborate structure with the parameters of the rubidium salt shows that there is just one reasonably satisfactory way in which each ammonium ion might form its maximum number of four hydrogen bonds with fluoride ions. Our assignment of parameter values in ammonium fluoborate surrounds each nitrogen by four fluoride ions at tetrahedron corners, F_I and F_{II} at a distance of 2.83 Å., and 2 F_{III} at 2.86 Å. We find two tetrahedral (bond) angles of 119.5°, a third of 134°, and the fourth of only 84.5°. The interatomic separations indicate that the hydrogen bonds are rather weak, since in NH_4HF_2 the average N-F separation is 2.76 ± 0.06 Å. We believe that the N-F separations in ammonium fluoborate may well be somewhat smaller than those given, for we have introduced what we regard as the minimum amount of distortion from the $RbBF_4$ parameters necessary to account for the intensity data. It seems possible, moreover, that the two hydrogen bonds involving F_I and F_{II} may be somewhat stronger than those involving F_{III}, since the unavoidably large M-F separations of Table II involve F_I and F_{II}. Such an assignment of parameter values, which leads to entirely satisfactory predictions, and to N-F_I = 2.80 Å., N-F_{II} = 2.80 Å., N-F_{III} = 2.87 Å., is as follows: u = 0.308, v = 0.332; s = 0.947, t = 0.693; m = 0.833, n = 0.555; o = 0.089, p = 0.605; x = 0.933, y = 0.043, z = 0.807. We regard it as quite possible that still smaller N-F separations exist within the structure, but we see no possibility of ascertaining the precise state of affairs.

In NH_4F and NH_4HF_2 the formation of hydrogen bonds between nitrogen and fluorine causes these compounds to assume structures belonging to crystal classes entirely different from the corresponding potassium or rubidium salts. That hydrogen bonds in ammonium fluoborate seems quite probable, but their presence results in but slight changes either in parameter values or in lattice constants.

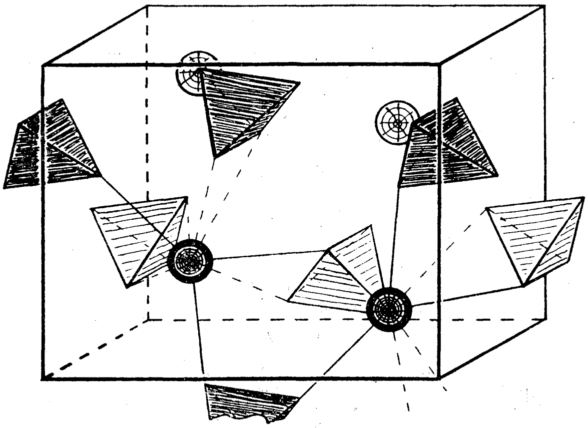

Fig. 1.—The structure of ammonium fluoborate. The positions of nitrogen atoms and of fluoborate ions are indicated respectively by the circles and the regular tetrahedra. Figures heavily shaded are centered in the plane $y = 1/4$, those lightly shaded in $y = 3/4$. The coördination of fluoride about ammonium ions is shown by the lines connecting vertices of the tetrahedra with the circles; the solid lines indicate hydrogen bonds.

Summary

x-Ray data show rubidium fluoborate and ammonium fluoborate to possess similar orthorhombic units of structure with a_0 = 9.07 Å., b_0 = 5.60 Å., c_0 = 7.23 Å. and a_0 = 9.06 Å., b_0 = 5.64 Å., c_0 = 7.23 Å., respectively. Both compounds crystallize with the barium sulfate type of structure, space group V_h^{16}-*Pnma*, being aggregates of

BF_4^- tetrahedra and Rb^+ or NH_4^+ ions. A regular BF_4^- tetrahedron with B-F = 1.43 Å., is assumed in order to determine the eleven parameters of the structure. The rubidium ions are first placed approximately by neglecting the scattering of the other much lighter atoms; these are then assigned parameter values which lead to a generally acceptable agreement between calculated and observed intensities of x-ray reflections. An identical assignment of parameter values in ammonium fluoborate leads to only fair agreement between calculated and observed intensities; these are much improved by the introduction of small distortions which may be interpreted as a tendency toward the formation of hydrogen bonds between nitrogen and fluorine.

Derivatives of Piperazine. VII. Procaine Analogs, Part I

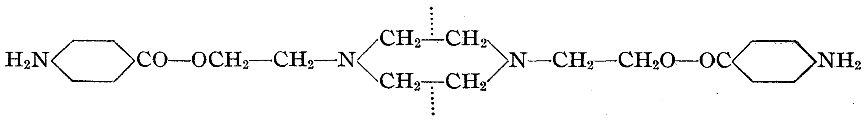
BY DAVID E. ADELSON, L. G. MACDOWELL AND C. B. POLLARD

Considerable work has been done in the field of alkyl *p*-aminobenzoates to ascertain the relationship between chemical constitution and physiological action. Such investigations have included the preparation of procaine analogs containing dissimilar alkylamino groups,[1] aliphatic and aryl aliphatic acids in the place of *p*-aminobenzoic acid[2] and unsaturated groups in the side chain of the acids.[2] Other studies have shown the effect of increase in the length of the carbon chain of the alkyl group and the effect of branched-chain alkyl derivatives in the procaine series.[3] Soderman and Johnson[4] and Roberts and Johnson[5] have studied procaine analogs containing different aromatic acids. Numerous other investigations, far too extensive to list here, have been carried out to determine the effect of increasing molecular weight on the anesthetic properties of compounds of the procaine type.

The purposes of the present investigation were (1) to study the effect of cyclic diamines, such as piperazine, and various types of aliphatic secondary amines on the therapeutic properties of the procaine molecule, (2) to determine the effects thus produced by the increased nitrogen content of the molecule and (3) to devise a simple method for obtaining piperazino-1,4-bis-(β-ethanol) in good yield.

Pyman[6] has prepared the latter compound in 41% yield from piperazine and 2-chloroethanol. The present workers have prepared piperazino-1,4-bis(β-ethanol) in quantitative yield by a method analogous to that used by Horne and Shriner[7] in the preparation of β-diethylaminoethanol.

It is apparent that the di-*p*-aminobenzoate of piperazino-1,4-bis-(β-ethanol) is in reality a "double" procaine molecule. If the molecule is split into symmetrical halves as indicated by the dotted lines, it is logical to consider the molecule as being composed of two similar parts, each of which has a smaller molecular weight than procaine. The percentage of nitrogen in procaine is 11.86, whereas the di-*p*-aminobenzoate of piperazino-1,4-bis-(β-ethanol) contains 13.59% N. Hence the new molecule contains more nitrogen per unit molecular weight than procaine and in addition possesses a cyclic diamino linkage. It will be interesting to learn the modifications which these two effects will produce in the therapeutic properties of procaine.



Experimental

Piperazino-1,4-bis-(β-ethanol).—Twenty-one grams of anhydrous piperazine[8] was dissolved in an equal weight of boiling methanol contained in a flask fitted with a condenser. A stream of ethylene oxide was passed into the solution until the theoretical quantity had been absorbed.

[8] Pollard, Bain and Adelson, *ibid.*, **57**, 199 (1935).

The heat of reaction was sufficient to keep the solution at reflux temperature. Upon cooling the addition compound crystallized out, yield 42 g. (98%). Piperazine-1,4-bis-(β-ethanol) crystallizes from amyl acetate in large prisms which melt at 135–135.5°.

Anal. Calcd. for $C_8H_{18}N_2O_2$: N, 16.09. Found: N, 16.07.

Di-*p*-nitrobenzoate of Piperazino-1,4-bis-(β-ethanol).—This compound is prepared in 50% yield from the above by treatment with *p*-nitrobenzoyl chloride in cold alkaline solution. Recrystallization from xylene gives small yellow granules which melt at 158–158.5°.

Anal. Calcd. for $C_{22}H_{24}N_4O_8$: N, 11.86. Found: N, 11.74.

Di-*p*-aminobenzoate of Piperazino-1,4-bis-(β-ethanol).—Reduction of the di-*p*-nitrobenzoate with a large excess of powdered iron[3] followed by extraction with hot xylene yields this compound. It is purified by solution in dilute hydrochloric acid followed by reprecipitation with dilute alkali and recrystallization from xylene as silky needles, m. p. 203–204°.

Anal. Calcd. for $C_{22}H_{28}N_4O_4$: N, 13.59. Found: N, 13.55.

The tetrahydrochloride of the di-*p*-aminobenzoate of piperazino-1,4-bis-(β-ethanol) is prepared by dissolving the free base in dilute acid and evaporating the solution *in vacuo* at room temperature. The crystals thus formed are very hygroscopic and must be oven-dried prior to analysis. The compound is stable in boiling water.

Anal. Calcd. for $C_{22}H_{32}N_4O_4Cl_4$: N, 10.04. Found: N, 9.83.

Summary

1. Piperazino-1,4-bis-(β-ethanol) has been prepared in good yield. From it have been synthesized the di-*p*-nitrobenzoate, the di-*p*-aminobenzoate and the tetrahydrochloride of the latter.

2. The therapeutic properties of the tetrahydrochloride of the di-*p*-aminobenzoate of piperazino-1,4-bis-(β-ethanol) will be investigated.

Normal Fatty Acid Amides of Ethylenediamine

BY N. BEVERLEY TUCKER[1]

The purpose of the work herein reported was to record the physical properties, chiefly the melting points, of the normal fatty acid diamides of ethylenediamine. The amides were all prepared alike, *i. e.*, the diamine was boiled for forty-eight hours with the calculated double molar quantity of the ethyl ester of the desired acid. The resulting solid product was recrystallized to constant melting point, the lower members to the butyric from a mixture of ethyl acetate and alcohol, others from absolute alcohol. The first six members of the series were examined under the polarizing microscope, and their solubilities in three solvents were measured. Results are summarized in the tables.

The diacetyl,[2] dipropionyl and dibutyryl[3] derivatives, as well as several related compounds, have been reported.[3,4]

TABLE I

MELTING POINTS AND SOLUBILITIES

(Melting points were measured with complete stem immersion to eliminate stem correction)

		Solubility at 25°C. in g./100 cc.			N, %	
Derivative	M. p.	Water	Abs. EtOH	Et. acetate	Calcd.	Found
C_2	173–173.5	68.3	13.1	0.25	19.4	...
C_3	189.0	40.8	13.8	.26	16.27	16.22
C_4	191–191.3	4.78	13.7	.28	14.00	13.69
C_5	183.0	0.35		.48	12.28	...
C_6	177–177.3	.02	6.48		10.94	11.18
C_7	171.5	Too small	2.49	.11	9.80	9.82

Melting points of higher members of the series: C_8, 169–169.5; C_{10}, 164.0; C_{11}, 160.5; C_{12}, 159.0; C_{13}, 156–156.4; C_{14}, 154.5; C_{15}, 153.0; C_{16}, 148.5; C_{17}, 149.5–150.

Results of Experiments

In the tables, derivatives of ethylenediamine of the general formula $C_2H_4(NHCOR)_2$, where R is straight chain, are designated as the C_n derivative, where n = the total number of carbon atoms in the acid.

Grateful acknowledgment is made of the assistance of Professor E. Emmet Reid. The writer also wishes to thank Professor Edward Steidtmann for assistance in measuring crystal properties.

Preparation of a Potent Vitamin A Concentrate[1]

BY HARRY N. HOLMES, HAROLD CASSIDY, RICHARD S. MANLY AND EVA R. HARTZLER

Since Vitamin A has not yet been isolated, it is highly desirable that improved methods for the preparation of potent concentrates be developed.

Other workers in this field have obtained Vitamin A concentrates of very high values. Karrer, Morf and Schöpp[2] in 1931 succeeded in preparing a pale yellow oil of approximately 105,000 "blue value." (Values based upon the Carr–Price[3] color test and upon Karrer's own calculation that his standard cod-liver oil had a Vitamin A potency of 10 blue value). Heilbron, Heslop, Morton, Webster, Rea and Drummond[4] have published data on a concentrate of 65,000 blue value, while Carr and Jewell[5] have more recently obtained a concentrate of 78,000 blue value. The English workers, like Karrer, based their valuation upon the Carr–Price color test. Their concentrates were prepared by vacuum distillation.

The "blue value" signifies the number of blue units read with a Lovibond tintometer for 0.04 g. of solid dissolved in anhydrous chloroform immediately after reaction with the antimony trichloride reagent. It is obvious that "blue units per gram" could also be calculated by multiplying "blue value" by 25.

Concentration by Freezing.—The liver oil of halibut (Hippoglossus) was saponified in the Parke–Davis laboratories, the non-saponifiable portion removed by a solvent and most of the cholesterol frozen out. In our laboratory the first step was to transfer the concentrate from methyl alcohol to pentane by washing out the alcohol with water.

The pentane solution was next subjected to drastic freezing for a week or ten days in a bath of ethyl alcohol and carbon dioxide snow. To filter out the noticeable precipitate we employed in our earlier work an ultra-filter bomb of heavy metal which could be entirely surrounded by a bath of ethyl alcohol and carbon dioxide snow. Through this strong filter (Fig. 1) the filtrate could be forced by a pressure of 50–100 pounds of nitrogen. This method was very satisfactory when working with small quantities as it prevented any warming up of the mixture with annoying dissolving of the precipitate during filtration and also permitted the exclusion of air. With larger quantities, however, the filtration of such

gummy material was found to be too slow. In our more recent work we have adopted a suggestion by Dr. Karl Link, using suction filtration through a layer of carbon dioxide snow packed in a coarsely sintered glass filter. Such filtration is rapid, requiring only a few minutes for completion. Moreover, the carbon dioxide snow prevents warming up of the solution and provides an inert atmosphere for protection of the vitamin. The filtrate was then allowed to warm up to room temperature and some of the solvent was removed under suction to remove the dissolved carbon dioxide.

The solution (under nitrogen) was stored in carbon dioxide snow until ready for use. By this process the concentrate usually was improved from the 30,000–40,000 blue value as received in our laboratory to a value of 45,000–50,000. In one instance a blue value of 60,000 was obtained.

Concentration by Tswett Columns.—The column method of filtration through adsorbent powders as originated by the botanist, Tswett,[6] for the separation of plant pigments is peculiarly suited to the concentration of such a heat-sensitive substance as Vitamin A. The more highly adsorbed materials appear in bands near the top of the column, while the less strongly adsorbed materials appear farther down the column.

Karrer and Morf[7] used this method quite extensively in research with vitamin A and with the carotenoid pigments. They used calcium oxide or hydroxide, while Karrer, Morf and Schöpp[2] used alumina, and Karrer and Schöpp employed calcium carbonate.[8]

Although Karrer and his associates cut the adsorbent column into three sections and extracted from the rich middle section, we have found it to be advantageous to obtain fractions of different degrees of potency by washing the entire column with a suitable solvent. The less strongly adsorbed and more soluble materials are washed through first with the more strongly adsorbed and less soluble material following at a slower rate. Frequent changes of the receiver (maintaining an atmosphere of nitrogen) then enable us to obtain filtrate fractions of varying composition.

Although such a well-known adsorbent as carbon must have been tried, its use has not been reported, probably because of serious loss of the vitamin due to oxidation. We have used Norit carbon very extensively with excellent results, but only after taking great precautions in its activation to remove air and replace it with nitrogen.

Since carbon is a non-polar adsorbent while magnesia is somewhat polar it would be expected that the two should show somewhat different preferential adsorption from a complex mixture such as the crude vitamin A concentrate. With this idea in mind we have adopted the procedure of running the solution of concentrate first through carbon and then through a magnesia prepared from the precipitated hydroxide with the idea that the carbon would remove certain impurities and the magnesia others with a resulting product of greater purity than that obtained from either adsorbent alone.

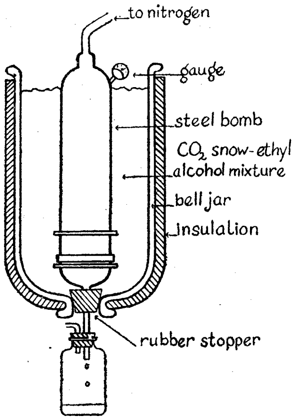

Fig. 1.—Low temperature filtration.

Results.—A large number of filtrate fractions have been obtained in this Laboratory with blue values of 100,000 or higher.

Using carbon alone we have obtained 41 fractions from several different oils with blue values of from 90,000 to 130,000.

TABLE I

No. of fractions	Blue value
23	90,000–100,000
12	100,000–110,000
5	110,000–120,000
2	120,000–130,000
1	130,000

Using magnesia alone two fractions were obtained with blue values between 90,000 and 100,000.

Using carbon followed by magnesia we have obtained 14 fractions with blue values between 90,000 and 140,000. They are distributed as shown in Table II.

Our first attempt using this procedure gave us the best results so far obtained. Circumstances, however, did not permit us to obtain a biological assay although we had about half a gram of the

richest material. We had removed the solvent from the oily residue under reduced pressure and had stored it under nitrogen in carbon dioxide snow for two days. At the end of that period the oily material had become crystalline, and its blue value had fallen to 1050. We learned too late that our valuable half gram should have been stored at once in cold methyl alcohol for protection.

It may be of interest to note that Karrer considered a standard cod liver as having a "blue value" of 10. Upon this basis our best concentrate was at least 14,000 times as potent in vitamin A as such standard cod-liver oil while Karrer's best concentrate was 10,500 times his standard.

Description of Color Test.—The values given in this paper were all measured by the Carr–Price reaction[3] using antimony trichloride in anhydrous chloroform according to the directions of the "Cod-liver Oil Colour Test Sub-Committee of the British Pharmacopoeia Commission" and reading blue values with a Lovibond tintometer.

Drummond and Morton[9] examined six oils biologically, colorimetrically and spectroscopically and found very good agreement between the three methods. More recently Lathbury[10] has stated that cod-liver oils and vitamin A concentrates show a constant ratio between the results of the biological, chemical and physical methods of measurement.

We read rather consistently, with our particular tintometer, several per cent. higher than Parke, Davis & Company, so all values in this paper have been corrected accordingly. Recently, we found our colorimetric assays of a group of four liver oils in close agreement with those by Parke, Davis & Company in Detroit, and in their English laboratory at Hounslow. Two of these oils had been cross checked with the spectro-absorption instrument in Morton's laboratory (England) and Brode's laboratory (Ohio State University) as well as in Detroit.

Bio-assay of a Potent Concentrate.—Parke, Davis & Company made a bio-assay on one of our earlier potent concentrates which was obtained by use of a carbon column and which gave for us a color assay of 94,000 blue value. The material was dissolved in a commercial cottonseed oil to which had been added 1% of soy bean lecithin as antioxidant. The bio-assay value obtained corresponded to 91,200 blue value, the feeding level required being 0.24 gamma per day, a feeding level remarkably low in comparison with the others recorded in the literature.

The same sample was also analyzed in the Parke–Davis laboratory for vitamin D and found to contain 18,620 Steenbock D units per gram.

Effect of Moist Air on Color Test.—We have recently demonstrated in this Laboratory that an increase in humidity has an inhibiting effect on the formation of the blue color with the antimony trichloride reagent. By enclosing our tintometer, and all apparatus, in a glass case in which we were able to control the humidity to some extent we obtained readings showing an average of over 10% decrease in the blue values with a rise in relative humidity from 35 to about 60%. The best vitamin A values we have so far obtained were read in July, 1934, under humid conditions in our basement, which averaged about 20°F. (11°C.) cooler than the official outdoor temperature. It seems probable, therefore, that our reported values of that month really deserved a higher rating.

Materials

Pentane.—The pentane used was a low boiling petroleum fraction (b. p. 30–45°) obtained from the Viking Distributing Co., Charleston, W. Va.

Chloroform.—U. S. P. grade from the Dow Chemical Co., Midland, Michigan.

Antimony Trichloride.—Baker C. P. anhydrous antimony trichloride. The reagent was made up with especially purified dry chloroform to a concentration of 21–23% of antimony trichloride in chloroform.

Carbon.—Grade "A," pharmaceutical Norit, obtained from L. A. Salamon Co., 216 Pearl St., New York City.

Magnesium Oxide.—In the earlier work we prepared our own magnesium oxide from Parke–Davis milk of magnesia by filtering and drying. This process was quite tedious, however, and we have recently been using a similar magnesia, "Micron Brand," 2641, obtained from the California Chemical Corp., Newark, California. This was used by Strain[11] in the purification of carotenes.

Alumina.—The alumina used was purchased from the J. T. Baker Company, Phillipsburg, N. J., under the trade name of "Hydralo."

(10) Lathbury, *ibid.*, **28**, 2254 (1934).

(11) Strain, *J. Biol. Chem.*, **105**, 523 (1934).

Silica.—The silica used was Holmes' chalky silica gel prepared in the Severance Laboratory.

"Hyflo Super Cel."—A siliceous earth with practically no adsorbent qualities, purchased from Johns-Manville, Cleveland.

Nitrogen.—Compressed gas, from the Ohio Chemical Co., Cleveland, containing less than 0.05% oxygen. This trace of oxygen was removed by passing the gas through alkaline pyrogallol.

Methods

Our columns were set up according to the diagram in Fig. 2. The tip of the column tube was tightly plugged with glass wool and the entire system was then filled with nitrogen. A thin mixture of activated carbon and pentane, well shaken, was then poured into the column and allowed to settle. While the level of the liquid fell to the upper level of the column of carbon the tube was tapped with a block of wood to dislodge gas bubbles. A pentane solution of the concentrate was then carefully added and allowed to filter down through the carbon with the aid of slight suction at B, while nitrogen entered the top of the column at A. After all the solution of concentrate had entered the carbon, pentane was carefully added through the separatory funnel and allowed to wash the concentrate down through the carbon. Fractions of the filtrate of from 50 to 150 cc. each were collected. Upon changing receivers, stopcocks B and C at the bottom were closed (cutting off suction), B was opened to admit nitrogen to the partially evacuated receiver before removal, and a clean nitrogen-filled bottle was connected.

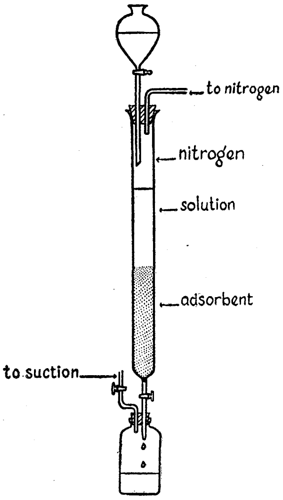

Fig. 2.—Column for selective adsorption.

Only slight suction can be used, otherwise the powdered adsorbent packs too tightly for effective filtration. To aid in hastening the filtration through magnesia columns we used a heat-treated siliceous earth, "Hyflo Super Cel," mixed in equal part by weight with the magnesia as suggested by Strain in his work on carotenes. This siliceous earth is a poor adsorbent but aids in more uniform packing of the magnesia and in more rapid filtration. Both powders were activated together (after thorough mixing) in order to remove any moisture or oxygen present.

Our usual practice was to filter about 6 g. of concentrate, contained in 50 cc. of pentane solution, through a column of carbon 2.5 cm. in diameter and 23 cm. high (about 40 g. of carbon). The filtrate from a column of this size contained from 1 to 40 mg. per cc.

Summary

1. Cholesterol and some other impurities were frozen out of a pentane solution of the nonsaponifiable portion of halibut-liver oil; the resulting solution was then fractionated by Tswett adsorption columns with an improved technique. Using a column of a specially prepared oxygen-free carbon followed by treatment with a column of a new type magnesia a concentrate of vitamin A at least 40% more potent than any previously recorded was obtained.

2. Lovibond tintometer readings were checked biologically and spectrographically in the Parke–Davis laboratories and elsewhere.

3. The most potent concentrate had a blue value of at least 140,000.

The Mercuration of Ethylenes and Reactions of the Methoxy Mercurials

BY GEORGE F. WRIGHT[1]

Introduction

When an unsaturated compound is treated with mercuric acetate in alcohol solution, the elements of methoxymercuric acetate combine with the ethylene. The nature of the product has been the subject of controversy for some years and the evidence has been well summarized by Adams, Roman and Sperry.[2] These authors as well as others[3,4] have rejected Manchot's hypothesis[5] that such mercurials are molecular compounds of the type $RCH{=}CHR'\cdot R''OHgX$ (I) and they have preferred the second of two mechanisms of formation which designate the reaction as ordinary addition to a double bond. More recent work has substantiated the structure for the mercurials as III rather than I. Marvel and co-workers,[6] by separating disastereomers with different rotations from the mercuration of optically active cinnamic esters, have shown that

asymmetric centers are actually produced in the synthesis. Likewise the instability of the mercurials finds a parallel in the analogous organomagnesium compounds,[7] which exhibit the same tendency to decompose into the unsaturated compound and the alkoxy metal salt.

This communication is concerned with further proof for the existence of structure III as well as a critical study of its mode of formation. To this end the methoxymercurials have been prepared from *cis* and *trans* methyl cinnamate, isostilbene, styrene, propenylbenzene, cyclohexene and 1-phenylbutadiene-1,3. In general their properties are identical with those of analogous mercurials already known. Specifically the rates of formation as well as the type differences intrinsic in the ethylenes used indicate that the first of the alternative mechanisms suggested by Adams, Roman and Sperry actually takes place. This disposes of an obnoxious feature of mechanism B, namely, the formation of the ether III from the ester II at a carbon atom which would not be expected to enhance the tendency toward this limited reaction. This tendency should be greater when such a carbon atom is surrounded with increased unsaturation; the greater ease of mercuration found with styrene and cyclohexene as compared with methyl cinnamate and isostilbene suggest that this etherification is at least not the controlling step in the reaction.

Furthermore, a kinetic study of *cis* methyl cinnamate mercuration at varied concentrations indicates that the reaction is second order. The results are complicated by the existence of a measurable equilibrium, demonstrated in the cases of methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate and α-acetoxymercuri-β-methoxy-β-phenylethane; nevertheless, the agreement among the second order constants leaves little doubt that the rate-controlling reaction is bimolecular. Such an order militates against mechanism B, where the etherification involved in the second step should be pseudo-unimolecular, especially in the higher dilutions.

The question arises whether the formation of II in the first step of mechanism B might not control the rate and thus explain the second order constants. It is undeniable that addition products of unhydrolyzed mercuric salts to ethylenes do exist,[8] either as type II or as the molecular compound $RCH{=}CHR'\cdot HgX_2$ (IV). However, Hugel and Hibou have observed that addition compounds of type II are formed in a few minutes. With the exception of the styrene reaction, none of the methoxy mercurials (Type III) is formed so rapidly. Furthermore, if formation of II were the rate-controlling step the choice of alcohol used as reactant should have relatively little effect upon the reaction velocity whereas, in point of fact, the mercuration proceeds slowly in water but is much more rapid in methanol, although progressively slower when higher alcohols are employed.[9] It is, then, unlikely that the second order constants are a result of the reactions involving mechanism B.

Mechanism A is supported by several innovations in the reaction. First, the addition of a small amount of nitrate ion markedly accelerates the process. This would be expected if hydrolysis of mercuric salt were a prerequisite to formation of III.[10] Second, the addition of sodium methylate (necessarily toward the end of the reaction to avoid precipitation of mercuric oxide) soon carries the reaction to completion. This latter modification, to be sure, does not differentiate between mechanisms A and B. Its action becomes more understandable when addition of an equivalent of acetic acid to a methanol solution of the acetoxymercurial is found not to shift the equilibrium. Likewise when cyclohexene is treated with methoxymercuric chloride, prepared by interaction of equivalent amounts of sodium methylate and mercuric chloride, the product, 1-chloromercuri-2-methoxycyclohexane,

[10] Mellor, "Inorganic and Theoretical Chemistry," Longmans, Green and Company, New York City, 1923, Vol. IV, p. 991.

is difficult to explain on any basis other than mechanism A. Unfortunately for a good case, the formation of intermediates like type II or IV can also be demonstrated. Thus, if styrene in an inert solvent is treated with mercuric acetate for some hours and the solvent and excess of styrene are removed, the residue when treated with methanol is converted to α-acetoxymercuri-β-methoxy-β-phenylethane. When this method is applied to cyclohexene the mercurial does not form. Although the reaction with styrene may be misleading because of difficulty in extracting the excess of reactant, the significant yield indicates that the intermediate does form. There is, however, no good reason to assume that the styrene intermediate reacts *per se* rather than in its dissociation fragments, styrene and mercuric acetate.

There is, of course, the possibility that in methanol solution methoxymercuric acetate exists as methoxy and acetomercury ions which add at random to the double bond. This should give rise to a mixture of diastereomers, whereas each mercurial actually produced is a chemical individual. Furthermore, when *cis* and *trans* methyl cinnamates are mercurated the isomeric racemic forms are obtained, respectively. On the basis of random addition the pure compounds obtained would not be expected. The fact that methyl *cis* cinnamate reacts about three times as fast as the *trans* isomer,[11] as shown by the relative half-lives (Fig. 1), likewise indicates that the addition proceeds by way of the undissociated methoxymercuric acetate, for the space configuration should offer but little hindrance to the ions. In the case of the geoisomeric stilbenes this is even more apparent since the *trans* stilbene does not react at all, although a good yield of mercurial is obtained from the *cis* isomer (isostilbene). It is in keeping with this concept that nitrate ion (assumed only to promote alcoholysis) does not cause *trans* stilbene to mercurate.

On the basis of this evidence it is believed that formation of the α-methoxy mercurials proceeds *via* mechanism A, as a result of the tendency of mercuric salts to hydrolyze or alcoholize in an appropriate medium.

Since the methoxy mercurials are stable toward aqueous alkali, it has been customary to consider the mercuration complete when this reagent no longer precipitates mercuric oxide. This test has been found to be unreliable and quite misleading. The disappearance of mercuric ion may coincide, as in the case of the rapid reaction with styrene, with completion of the formation of III, but in the greater number of cases the reaction is not finished when the mercuric ion disappears. This discrepancy between removal of mercuric ion and the end of the reaction is illustrated in Fig. 1, the notation Hg indicating the time at which no mercuric ion is detectable. Such a test is evidently not an absolute criterion of completion of reaction.

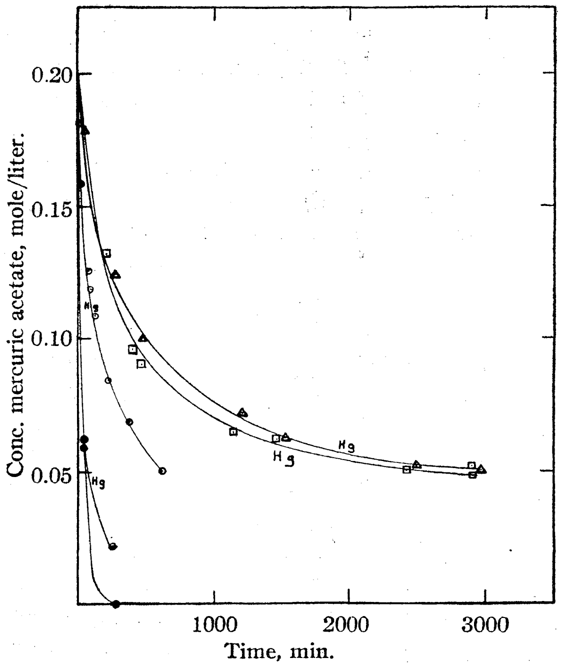

Fig. 1.—△, Isostilbene; □, *trans* methylcinnamate; ○, *cis* methylcinnamate; ◒, *trans* methylcinnamate + nitrate ion; ●, isostilbene + nitrate ion.

Reports concerning the instability of these mercurials have not been exaggerated. In addition to the ease of acid splitting, they decompose thermally to regenerate the unsaturated compounds. This has been shown in the case of *meso* and *dl* methyl α-chloromercuri-β-methoxy-β-phenylpropionate, the decomposition temperatures being 159 and 170°, respectively. In both cases *trans* methyl cinnamate is the sole product.

When methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate is treated with alcoholic ammonium sulfide, the acetoxymercuri group is replaced by hydrogen and methyl β-methoxy-β-phenylpropionate is produced.[12] It has been

---

[11] This is in agreement with selective mercuration of the cinnamic acids, Biilmann, *Ber.*, **35**, 2571 (1902).

[12] Schoeller, Schrauth and Struensee, *ibid.*, **44**, 1432 (1911).

found that hydrogen sulfide in alcoholic pyridine, also aqueous sodium thiosulfate, is equally efficient in this transformation. The reaction appears to be limited to acids and esters, since every other mercurial tried yielded only the parent ethylene. In the case of the styrene mercurial, using sodium thiosulfate there was evidence for the transient existence of either the thiosulfate mercurial[3] or the *bis*-mercurial but the intermediate could not be isolated and styrene was the only product.

The positions assumed by the elements of methoxy mercuric acetate upon addition to a double bond are known with certainty in *dl* methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate. The *meso* form derived from methyl *cis* cinnamate was shown to have a similar structure by conversion with sodium thiosulfate to β-methoxy-β-phenylpropionic acid. Since this method failed with every other mercurial, the structures of the styrene and propenylbenzene mercurials were ascertained by bromination and subsequent elimination of hydrogen bromide with sodium methylate. The resulting α,β-unsaturated ethers were hydrolyzed to acetophenone and propiophenone. As a reliable structure proof, such a method is obviously dependent on the mechanism of bromination of these dissociable mercurials.

Bromination of these acetoxymercurials was found to proceed stepwise. The first equivalent of bromine formed the bromomercuri compound (apparently with liberation of peracetyl bromide), while the second equivalent severed the C–Hg bond to form the bromo derivative. In like manner, bromocyanogen, although incapable of breaking the C–Hg link, does react to give the bromomercurial. As another case in point, the first equivalent of acetyl chloride reacts with methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate to form the chloromercuri compound; an excess of this reagent produces methyl *trans* cinnamate.

The mercuration of 1-phenylbutadiene-1,3 proceeds stepwise and, on the basis of insecure ozonization data, the first addend enters the 3,4-positions. All attempts to establish the positions of the methoxy and mercuri groups proved fruitless. Only one of these attempts is worthy of mention. When the 3,4-[methoxychloromercuri]-1-phenylbutene-1 was reduced with one equivalent of hydrogen, using the Adams catalyst, the products were 1-phenylbutadiene-1,3 and 1-phenylbutane; the reduction proceeded as if the addend were not present.

The 1-chloromercuri-2-methoxycyclohexane initially produced from cyclohexene has been designated as the labile form, inasmuch as long refluxing in ethanol converts it to a lower melting isomer, the stable form.

The author takes this opportunity to thank Professor E. P. Kohler for the suggestions offered during the course of this work. He is also indebted to Dr. P. D. Bartlett for aid in interpreting the kinetic data.

Experimental

Titration with Potassium Thiocyanate.—When 0.001 mole of *trans* methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate was dissolved in 5 cc. of methanol and this solution thrown into 100 cc. of water, titration with standard alkali, using phenolphthalein as the indicator, showed an equivalence of one. The addition of ferric nitrate dispersed the pink color; subsequent titration with standard potassium thiocyanate showed a mercury equivalence of 0.525. This indicated a dissociation[13] of 5% since the organomercurial consumes only half of the thiocyanate required for a mercuric salt. The percentage of dissociation was unaffected by addition of 0.0005 mole of acetic acid.

A similar titration with α-acetoxymercuri-β-methoxy-β-phenylethane consumed one equivalent of alkali and one mercury equivalent of thiocyanate. Since it was evident that the thiocyanate was decomposing this mercurial, the water solution, prior to titration, was extracted twice with 5-cc. portions of chloroform (per 0.001 mole of mercurial). The water solution now contained only inorganic mercury since salts of mercury are almost insoluble in chloroform, although the organomercurials are extremely soluble in this extractant. Titration of this solution with thiocyanate showed that 0.072 equivalent of mercuric salt remained after extraction; the styrene mercurial was 7.2% dissociated.

Trans methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate was again titrated using the chloroform extraction method and the compound was found to be 2.5% dissociated. This latter figure is probably more accurate than the 5% value because the endpoint is very ephemeral when much of the organomercurial is present.

Using this method of following the mercury concentration, solutions of 0.01 mole of mercuric acetate and 0.01 mole of the unsaturated compound in methanol were made up to the desired volume and the reaction was maintained at 25 ± 2°. Samples were withdrawn at intervals, diluted with 100 cc. of water, and titrated within three minutes. Since the mercuration in water is much slower than in methanol, this error is of no significance. The rate of reaction with styrene was much too fast to be measured but at its completion 8% of the mercuric acetate remained. This checks closely with the value (7.2%) obtained for the dissociation of the mercurial in pure methanol. The reac-

---

(13) Dissociation in this sense means reversion to methoxymercuric acetate and the unsaturated compound.

tion with cyclohexene was somewhat slower but the titration (even with the chloroform extracted solution) was very erratic and at best it indicated that the acceleration due to added sodium methylate was approximately that observed in the actual preparation of the mercurial.

A series of such determinations with *cis* methyl cinnamate at concentration of 0.4, 0.2 and 0.1 molar gave a second order constant varying from 0.041 to 0.032 within the first half-life of the reaction. The second order constant for the reaction with isostilbene varied from 0.011 to 0.006, while that for *trans* methyl cinnamate was about 0.012. When the mercuration of this latter compound (at 0.2 molar) was three-fourths completed (twenty-nine hundred minutes), upon addition of 0.05 mole of sodium methylate, further titration showed the equilibrium was attained in ten minutes. The effect of prior addition of 0.05 g. of concentrated nitric acid to the 0.2 molar mercuric acetate solutions used in the *trans* methyl cinnamate and isostilbene reactions is shown in Fig. 1.

Mercuration of *trans* Methyl Cinnamate.[9]—To a solution of 3.18 g. (0.01 mole) of mercuric acetate in 25 cc. of methanol was added 0.05 g. of concentrated nitric acid, followed by 1.94 g. (0.012 mole) of methyl cinnamate. After seventy-five minutes at 25° a test portion gave no precipitate with 10% sodium hydroxide and the product began to crystallize in the reaction mixture. In a similar run, but using no nitric acid, about thirty-six hours must elapse before these conditions prevail, although the reaction is complete in eight hours when carried out at 50°. The acetoxymercuri compound was immediately filtered off (wt. 1.11 g., m. p. 142°) and the filtrate treated with dilute sodium chloride solution to yield 2.70 g. of methyl α-chloromercuri-β-methoxy-β-phenylpropionate, m. p. 134°. The total yield is 88% as compared with 84% in the analogous run using no nitric acid.

When the acetoxymercuri compound is treated with one equivalent of acetyl chloride in chloroform or acetone, the chloromercuri compound results. An excess of acetyl chloride regenerates *trans* methyl cinnamate. The chloromercuri compound is recovered unchanged from twelve hours of refluxing in ethyl acetate.

Mercuration of *cis* Methyl Cinnamate.—A solution of 1.78 g. (0.011 mole) of *cis*-methyl cinnamate[14] (m. p. −3°) and 3.18 g. (0.01 mole) of mercuric acetate in 25 cc. of methanol was filtered after nine hours and the filtrate treated with 2% sodium chloride solution. The precipitated methyl α-chloromercuri-β-methoxy-β-phenylpropionate was crystallized from ethanol to melt at 141° and weighed 2.07 g. (50%). A mixed melting point with the diastereomer obtained from *trans* methyl cinnamate (m. p. 134°) was lowered 20°.

Anal. Calcd. for $C_{11}H_{13}O_3HgCl$: C, 30.77; H, 3.05. Found: C, 31.10; H, 3.13.

When either of the diastereomers was decomposed thermally under 25 mm. pressure the distillate (*ca.* 50% of theoretical) was entirely *trans* methyl cinnamate. Under these conditions the *cis* mercurial decomposed at 157°; the *trans* decomposed at 170°. When the *cis* mercurial is refluxed for eight hours in ethyl acetate there is no tendency toward isomerization; the mercurial is recovered unchanged.

β-Methoxy-β-phenylpropionic Acid.—To a 10% sodium thiosulfate solution was added 4.52 g. (0.01 mole) of *trans* methyl α-acetoxymercuri-β-methoxy-β-phenylpropionate. After ten minutes of agitation ether was added and the reaction set aside for twelve hours. The ether layer was separated. The aqueous layer was filtered to remove a black precipitate and the filtrate carefully acidified with 10% hydrochloric acid. The acid which slowly separated melted at 102°. It was combined with the acid of similar melting point obtained by saponification of the separated ether layer with 10% sodium hydroxide solution. Total yield was 1.09 g. or 60.5%. A similar treatment of the *cis* mercurial yields the identical acid, as does the reaction between sodium thiosulfate and anhydro α-hydroxymercuri-β-methoxy-β-phenylpropionic acid.

α - Chloromercuri - β - methoxy - α,β - diphenylethane.—After three days at room temperature a solution of 12.72 g. (0.04 mole) of mercuric acetate and 6.3 g. of isostilbene (b. p. 102° (2 mm.)) in 100 cc. of methanol was stirred while 2% aqueous sodium chloride was added slowly. The solid was filtered off and crystallized from ethanol to melt at 141°. It weighed 11.18 g. or 64% yield. Recrystallization from ethanol raised this melting point to 143°. When the reaction was refluxed the time was decreased to one-third. Addition of 0.05 g. of *concd.* nitric acid decreased the reaction time to four hours at room temperature. *Trans* stilbene could not be mercurated under any of these conditions.

Anal. Calcd. for $C_{15}H_{15}OHgCl$: C, 40.27; H, 3.38. Found: C, 40.35; H, 3.55.

Every attempt to regenerate pure isostilbene or to form α,β-diphenylethyl methyl ether failed. Treatment of the mercurial with hydrogen sulfide in alcoholic ammonia or alcoholic pyridine reaction with sodium thiosulfate, steam distillation from aqueous hydrochloric acid, oxalic acid or potassium iodide all yielded an equilibrium mixture of the isomeric stilbenes.

α-Acetoxymercuri-β-methoxy-β-phenylethane.—To a suspension of 159 g. (0.5 mole) of mercuric acetate in 1 liter of methanol was added 52 g. (0.5 mole) of styrene. The mercuric salt dissolved immediately; a test portion gave no mercuric oxide with 10% aqueous sodium hydroxide. A solution of 20 g. (0.5 mole) of sodium hydroxide in 25 cc. of water was added; following this treatment 800 cc. of methanol was distilled off. The residue was filtered and the filtrate evaporated *in vacuo.* The residue was extracted with 50 cc. of boiling benzene to remove sodium acetate and the resulting solution diluted with 1600 cc. of boiling petroleum ether (b. p. 60–70°). After a slow crystallization 117 g. (60%) of product melting at 64–65° was filtered off. The evaporated filtrate yielded 12 g. of impure product. Recrystallization from the mixed solvent raised the melting point to 70°.

Anal. Calcd. for $C_{11}H_{14}O_3Hg$: C, 33.42; H, 3.57. Found: C, 33.65; H, 3.78.

The mercurial was unchanged by twelve hours reflux with *t*-amyl alcohol. It reverted to styrene in boiling acetic anhydride but this reagent is without effect at 25°. Acetyl chloride (in acetone or chloroform), methylmagne-

---

[14] I am indebted to Professor G. B. Kistiakowsky for generously supplying the *cis* methyl cinnamate and the isostilbene used in this investigation.

sium bromide[15] or sodium thiosulfate solution (in part) only served to regenerate styrene.

α - Benzoxymercuri - β - methoxy - β - phenylethane.—A solution of 3.18 g. (0.01 mole) of mercuric acetate in 25 cc. of methanol was treated with 1.09 g. (0.011 mole) of styrene. Eight cc. of 10% aqueous sodium hydroxide (0.02 mole) was added, followed by 1.22 g. (0.01 mole) of benzoic acid. After filtration the solution was diluted with water. The crystalline precipitate weighed 3.73 g. (82%) and melted at 79°. It was crystallized from 110 cc. of petroleum ether (b. p. 60–70°) to melt at 80°. The compound was unchanged by eight hours of refluxing in toluene.

Anal. Calcd. for $C_{16}H_{16}O_3Hg$: C, 42.01; H, 3.53. Found: C, 41.73; H, 3.53.

α - Bromomercuri - β - methoxy - β - phenylethane was obtained almost quantitatively by treating the acetoxymercuri compound either with an excess of aqueous potassium bromide or with one equivalent of bromine in methanol solution at 0°. It was likewise obtained in 50% yield by treating a solution of the acetoxymercuri compound in either methanol or chloroform with two equivalents of bromocyanogen. It was crystallized from ethanol to melt at 63°.

Anal. Calcd. for $C_9H_{11}OHgBr$: C, 26.03; H, 2.67. Found: C, 26.10; H, 2.67.

Intermediate in Styrene Mercuration.—The existence of the intermediate in this reaction was demonstrated by adding 3.18 g. (0.01 mole) of mercuric acetate to a solution of 1.09 g. (0.011 mole) of styrene in 10 cc. of dioxane. After several days of intermittent shaking the reaction was filtered and the filtrate evaporated under 2 mm. pressure on a water-bath at 30°. The gummy residue was washed four times with 25-cc. portions of petroleum ether (b. p. 20–40°) and was then covered with 10 cc. of methanol. After twenty-four hours the methanol was removed *in vacuo* and the residue treated with dilute aqueous potassium bromide. The precipitate was crystallized from ethanol to give a 26% yield of the bromomercurial, melting point 63°, identified by mixed melting point.

β-Methoxy-β-phenylethyl Bromide.—Following the prescribed procedure,[4,16] a 70% yield of this compound, b. p. 84–86° (3 mm.), was obtained from the bromomercurial. The reaction is slower in chloroform solution; the mercuric bromide precipitates and the resulting solution must be washed with sodium sulfite to remove hypobromite, but the product is identical.

α-Methoxy-α-phenylethylene was obtained in 45% yield (b. p. 86–89° (18 mm.)) by refluxing this bromo compound with an excess of sodium methylate solution. It was identified by hydrolysis with 2.5% aqueous sulfuric acid to acetophenone, authenticated by mixed melting point.

β - Chloromercuri - α - methoxy - α - phenylpropane.—A solution of 15.9 g. (0.05 mole) of mercuric acetate in 125 cc. of methanol was treated with 6.89 g. (0.058 mole) of phenylpropene-2 (b. p. 57.5–58° (10 mm.)). Within four hours a test portion gave no mercuric oxide with 10% aqueous sodium hydroxide. At the end of eighteen hours 0.05 mole of sodium methylate solution was added. Twenty-four hours later the reaction was filtered and the solvent removed *in vacuo*. The residue was shaken with 2% aqueous sodium chloride. After an hour the aqueous layer was decanted and the gummy residue extracted with 100 cc. of boiling ethanol. Six days elapsed before crystal clusters formed which were filtered off and crystallized from ethanol to melt at 95–95.5°, weight 4 g. or 21%.

Anal. Calcd. for $C_{10}H_{13}OHgCl$: C, 31.17; H, 3.40. Found: C, 31.00; H, 3.40.

Since the mother liquors were not amenable to further crystallization the solvent was removed *in vacuo* and the residue was dissolved in 50 cc. of chloroform followed by 4.8 g. (0.03 mole) of bromine. After twenty-four hours the colorless solution was decanted from mercuric salt and washed with iced sodium sulfite solution, then with water and finally dried with anhydrous sodium sulfate. Following evaporation of the solvent the residue was distilled under 14 mm. pressure. The distillate, b. p. 107–125°, wt. 2.24 g., was refluxed for five hours with 0.05 mole of sodium methylate solution. The methanol was removed by evaporation, the residual oil being taken up in ether, washed to neutrality with water, dried with anhydrous sodium sulfate and distilled *in toto*. The distillate was hydrolyzed with alcoholic hydrochloric acid[17] and the semicarbazone prepared directly from this solution. This derivative contained an alkali insoluble impurity which was crystallized from methanol to melt at 183°. However, the great part of the product was precipitated by neutralizing the alkaline solution and was crystallized from ethanol to melt at 173–174°. A mixed melting point with propiophenone semicarbazone was not lowered.

β-Bromo-α-methoxy-α-phenylpropane was prepared from 0.01 mole of the pure β-chloromercuri-α-methoxy-α-phenylpropane and 0.02 mole of bromine in chloroform solution essentially as described above. The product boiling at 122–125° weighed 1.35 g. (92%), $n^{26}D$ 1.5412.

α-Methoxy-α-phenylpropene was prepared from this bromo compound, by the procedure already described, in 31% yield as an oil, b. p. 96–97° (19 mm.), $n^{26}D$ 1.5347. It was identified by hydrolysis with alcoholic hydrochloric acid; the semicarbazone prepared from this solution showed no depression in melting point when mixed with propiophenone semicarbazone.

Labile 1-Chloromercuri-2-methoxycyclohexane.—A solution of 9.84 g. (0.12 mole) of cyclohexene in 250 cc. of methanol was treated with 3.8 g. (0.1 mole) of mercuric acetate. A test portion removed immediately upon solution of the mercuric salt gave no mercuric oxide with 10% aqueous sodium hydroxide. After thirty-six hours the mercurous salt was filtered off and the filtrate evaporated *in vacuo*. Alternatively if, after a reaction period of ninety minutes, 0.1 mole of sodium methylate solution is added, the reaction can be worked up shortly afterward and the solvent can be removed at atmospheric pressure. The residue was suspended in water and 10% aqueous sodium chloride was added. When the precipitated oil solidified after occasional agitation, it was filtered off. This crude product, wt. 33 g., m. p. 109°, was crystallized from ethanol to weigh 26 g. (75%) and melted at 114–115°. Further purification from a solution of 150 cc. of benzene and 30 cc.

of petroleum ether (b. p. 30–60°) did not raise the melting point.

Anal. Calcd. for $C_7H_{13}OHgCl$: C, 24.07; H, 3.75. Found: C, 23.97; H, 3.92.

Stable 1 - Chloromercuri - 2 - methoxycyclohexane.—When the labile mercurial is refluxed for fifteen hours in ethanol, an isomer, m. p. 86°, crystallizes almost quantitatively from the filtered solution. The melting point is not raised by further crystallization from ethanol.

Anal. Calcd. for $C_{17}H_{13}OHgCl$: C, 24.07; H, 3.75. Found: C, 24.06; H, 3.79.

Intermediates in Cyclohexene Mercuration.—To a solution of 2.7 g. (0.01 mole) of mercuric chloride in methanol was added a solution of 0.23 g. of sodium in 10 cc. of methanol. To the suspension of white precipitate was added 0.98 g. (0.012 mole) of cyclohexene. After twenty-four hours the white precipitate was filtered off; it contained no cyclohexene mercurial and rapidly became yellow in presence of moisture. The filtrate was concentrated *in vacuo* and the residue treated with dilute aqueous sodium chloride. The precipitate was crystallized from ethanol to weigh 0.15 g. (4%). It was 1-chloromercuri-2-methoxycyclohexane, m. p. 114–115°, identified by mixed melting point.

When 0.02 mole of sodium methylate was used under otherwise identical conditions the yield of mercurial was 5%.

Demonstration of the type of intermediate encountered with styrene (*vide supra*) could not be reproduced when 0.01 mole of mercuric acetate was dissolved (with comparative ease) in 5 cc. of cyclohexene. After twenty-four hours the excess of cyclohexene was removed at 30° under 25 mm. pressure and the oily residue extracted five times with 25-cc. portions of petroleum ether (b. p. 20–40°) The washed residue was treated with dilute sodium chloride solution. No chloromercurial could be isolated from the precipitate.

1-Lactomercuri-2-methoxycyclohexene.—Mercuric lactate was prepared by treating a solution of 31.8 g. (0.3 mole) of 85% lactic acid in 200 cc. of water with 21.6 g. (0.1 mole) of red mercuric oxide. After two days with occasional shaking the solution was filtered and the solvent removed *in vacuo*. The residue was diluted with 100 cc. of ethanol. Next day the granular solid was filtered off and washed with alcohol; it weighed 17 g., after drying over sulfuric acid, and melted at 144° with decomposition. Evaporation of the alcoholic filtrate in a current of air yielded successive fractions of impure salt.

To a suspension of 3.78 g. (0.01 mole) of this salt in 25 cc. of methanol was added 0.98 g. (0.012 mole) of cyclohexene. After two days 4 cc. of 10% aqueous sodium hydroxide was added, the solution filtered and the solvent removed *in vacuo*. The residue was extracted with 80 cc. of boiling petroleum ether (b. p. 90–120°). The compound crystallizing therefrom weighed 1.74 g. (43%) and melted at 91–92°. It was recrystallized from the same solvent for analysis (m. p. 92°).

Anal. Calcd. for $C_{10}H_{18}O_4Hg$: C, 29.81; H, 4.51. Found: C, 29.44; H, 4.61.

Chloromercurimethoxyphenylbutene.—To a solution of 3.18 g. (0.01 mole) of mercuric acetate in 25 cc. of methanol was added 1.56 g. (0.012 mole) of freshly distilled phenyl butadiene. After five minutes a test portion gave no precipitate of mercuric oxide with 10% aqueous sodium hydroxide. After four hours the reaction was filtered to remove mercurous salt and 10% aqueous sodium chloride was added slowly to the filtrate. The oil which precipitated soon solidified and was filtered, washed twice with water and twice with petroleum ether. The yield of product melting at 89° was 3.35 g. (85%). It was crystallized from 25 cc. of ethanol to melt at 92°.

Anal. Calcd. for $C_{11}H_{13}OHgCl$: C, 33.25; H, 3.30. Found: C, 33.52; H, 3.37.

Following an identical procedure bromomercurimethoxyphenylbutene was obtained by substituting a solution of potassium bromide. The yield was 4 g. (91%) melting at 75–76°. This was crystallized from 35 cc. of ethanol to melt at 76°.

Anal. Calcd. for $C_{11}H_{13}OHgBr$: C, 29.90; H, 2.97 Found: C, 29.57; H, 2.97.

Ozonization of Chloromercurimethoxyphenylbutene.—A solution of 3.97 g. (0.01 mole) of the mercurial was dissolved in 12 cc. of dry chloroform. This solution was ozonized at 0° for five hours. The solvent was removed in a stream of dry, oxygen-free nitrogen. After adding 10 cc. of water the nitrogen stream was continued for two days; the outlet tube bubbled through a solution of phenylhydrazine hydrochloride. The benzaldehyde phenylhydrazone thus formed (70%) melted at 148–150° and after purification was identified by mixed melting point. A test portion taken from the aqueous suspension of decomposed ozonide at this time gave no mercuric oxide with 10% sodium hydroxide. The aqueous layer was decanted off and the residue washed thoroughly with ether. This residue was then covered with 10 cc. of 5:8 aqueous hydrochloric acid and the passage of nitrogen was resumed but no odor of acrolein could be detected, nor was phenylpyrazoline found in the absorption tube. After twenty-four hours the acid layer when treated with sodium hydroxide precipitated mercuric oxide. The remainder of the decomposed ozonide was found to be chiefly mercurous chloride.

Diacetoxymercuridimethoxyphenylbutane.—To a solution of 6.36 g. (0.02 mole) of mercuric acetate in 55 cc. of methanol was added 1.43 g. (0.011 mole) of phenylbutadiene (b. p. 86° (11 mm.)). After two hours a test portion gave no precipitate with 10% aqueous sodium hydroxide. Twelve hours later 40 cc. of methanol was distilled off and the residue filtered and chilled to 10°. The crystalline product weighed 7.62 g. (35%) and melted at 142–145°. Crystallization from a mixture of 25 cc. of benzene and 35 cc. of petroleum ether (b. p. 60–70°) raised the melting point to 149° with little loss of material.

Anal. Calcd. for $C_{16}H_{22}O_6Hg_2$: C, 27.00; H, 3.12; Hg, 56.40. Found: C, 26.53; H, 3.18; Hg, 56.43.

This procedure was varied by using a 33% excess of mercuric acetate and, subsequent to the twelve-hour reaction period, adding sodium methylate solution until appearance of the first permanent yellow coloration. The reaction after a day was worked up as before to give a 60% yield based on the phenylbutadiene.

Dichloromercuridimethoxyphenylbutane.—A solution of 0.4 g. (0.001 mole) of chloromercurimethoxyphenylbutene in 5 cc. of methanol was treated with 0.32 g. (0.001 mole) of mercuric acetate. The latter dissolved immediately but test portions gave a precipitate with 10% aqueous sodium hydroxide for twelve hours. After thirty-six hours a solution of 10% sodium chloride was added. The precipitated solid melted roughly at 100°. After washing with hot ethanol it melted at 180° and weighed 0.16 g. The compound can be obtained more easily by treating the diacetoxymercuridimethoxyphenylbutane in methanol with exactly two equivalents of dilute hydrochloric acid. The compound crystallizes slowly from acetone.

Anal. Calcd. for $C_{12}H_{16}O_2Hg_2Cl_2$: C, 21.68; H, 2.43. Found: C, 21.60; H, 2.52.

Summary

1. The rate of mercuration of ethylenes has been found to depend on a bimolecular reaction.

2. Some *cis* ethylenes mercurate more rapidly than the *trans* isomers.

3. An alternative mechanism is suggested to explain the mercuration.

CAMBRIDGE, MASS. RECEIVED APRIL 5, 1935

The Reaction between 2,3-Dimethyl-1,4-naphthoquinone and Phenylmagnesium Bromide.[1] I

BY H. MARJORIE CRAWFORD

Numerous studies have been made of the reactions between quinones and Grignard reagents. Only in the cases of anthraquinone[2] and phenanthraquinone[3] were the reactions clean-cut and the yields good. The mono- or di-addition product resulted, depending on the relative amounts of reactants.

If there was a possibility of a 1,4 addition to a conjugated system besides the addition to the carbonyl group, the reactions were complicated, many different products resulted and tars and oils formed the main products of the reaction. Bamberger[4] studied the reaction of methylmagnesium iodide on *p*-xyloquinone and identified six solid products which accounted for only one-fourth of the quinone used. Another fourth was reduced to the hydroquinone, and amorphous solids and oils remained. Franssen,[5] using α-naphthoquinone, isolated a di-addition product in 25% yields, but obtained colored amorphous products, reduction products and tars. Thinking that these complex results might have been due to hydrogen atoms attached to the quinone nucleus, Smith and Crawford[6] studied the reaction between a fully substituted quinone (duroquinone) and phenylmagnesium bromide and found that in this case also the reaction was very complex. The main product of the reaction was an oil (80%) and from the other 20% eight solids were separated and identified. 1,2- and 1,4-addition occurred as well as reduction and the formation of double compounds of the quinhydrone type.

Discussion of the Reaction and Products

In the present work, 2,3-dimethyl-1,4-naphthoquinone was chosen because it appeared to be intermediate in structure between duroquinone, which gave complex results, and anthraquinone which gave clean-cut results. However, it seems that as long as any 1,4-conjugated system is open the reaction is complicated, even though one side of the quinone is blocked by a benzene ring. The predicted mono- and di-addition products were obtained as well as double compounds, reduction products and dehydration products.

Three types of reaction products were formed and will be discussed separately, although all were formed at the same time. If one or one and a half moles of phenylmagnesium bromide was used per mole of the quinone, mono- and di-addition products were formed. If two moles of phenylmagnesium bromide were used per mole of quinone, di-addition products predominated.

A. Reduction Products.—The reduction of quinones by Grignard reagents is quite general and, regardless of procedure, reduction products

---

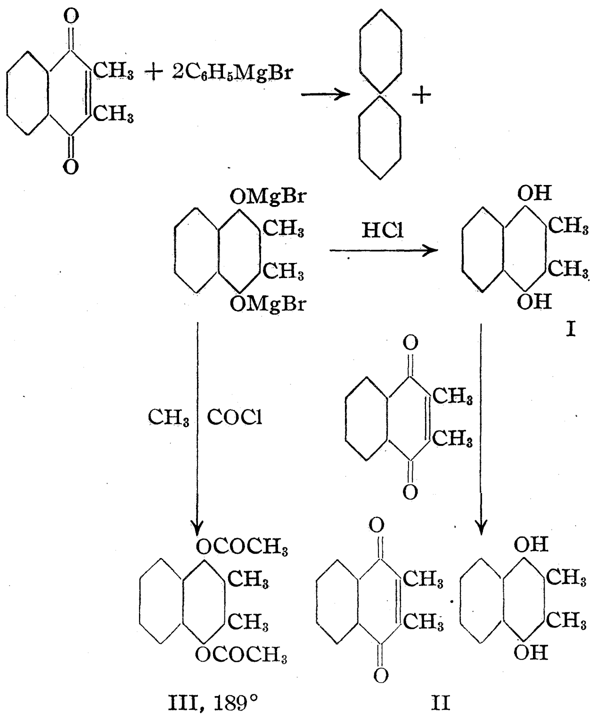
[6] Smith and Crawford, THIS JOURNAL, **50**, 869 (1928).

were obtained corresponding to about 10% of the quinone.

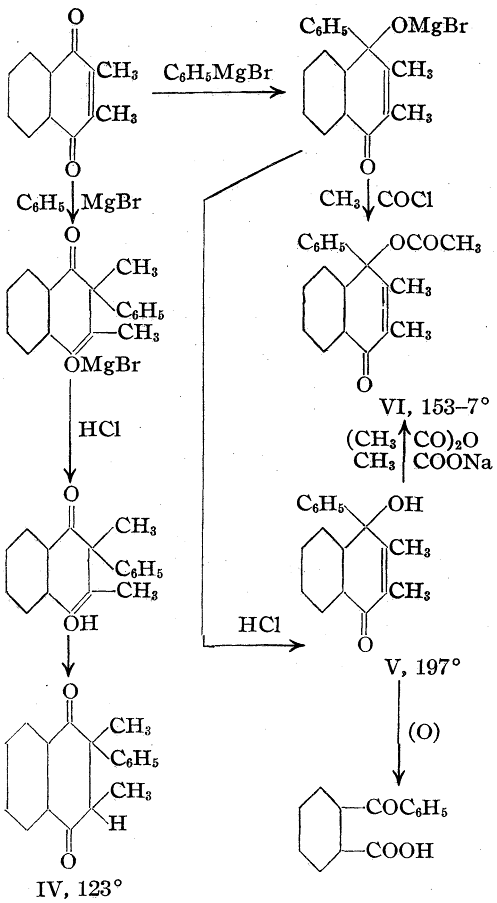


The diacetate of the hydroquinone (III) was obtained when the green reaction mixture was decomposed by acetyl chloride. The hydroquinone (I) was formed when the reaction mixture was decomposed by ice and hydrochloric acid. It was isolated as the quinhydrone (II), a black solid.

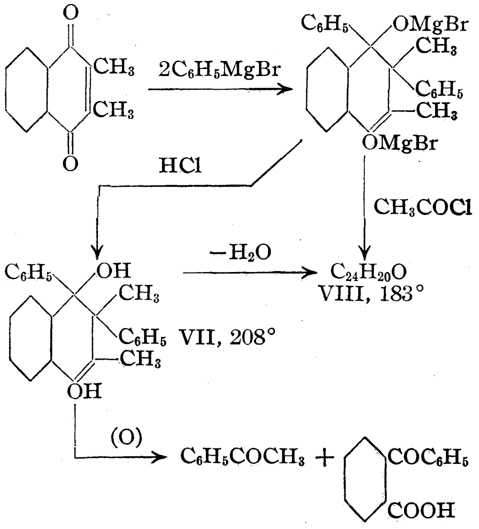
B. Mono-addition Products.—One molecule of phenylmagnesium bromide may react with one molecule of the quinone to give either a 1,2 or a 1,4 addition product (see next diagram).

The 123° compound (IV) was obtained in small amounts in two runs. Oxidation to give acetophenone indicates a 1,4 addition. The keto structure is more probable than the enol first formed, for the Grignard machine[7] shows no active hydrogen.

The 197° compound (V) had one active hydrogen and one carbonyl group (Grignard machine), and on oxidation gave *o*-benzoylbenzoic acid. The 197° compound was obtained in all reactions, and accounts for about one-fourth of the solid products isolated. The corresponding 153–157° acetate (VI) was obtained once when the reaction mixture was decomposed by acetyl chloride.



C. Di-addition Products.—The main solid product in most reactions was the 208° compound (VII)



Its structure was established by analyses, by the fact that the Grignard machine showed two active hydrogens and no carbonyl group, and by oxidation to acetophenone and *o*-benzoylbenzoic acid.

---

[7] Kohler and co-workers, THIS JOURNAL, **49**, 3181 (1927); **52**, 3736 (1930).

The nature of the 183° compound (VIII) is under investigation. It corresponds to a di-addition product minus one molecule of water, and is obtained by treating the metallic addition product with acetyl chloride, or from the 208° compound by reagents which suggest a pinacol rearrangement.

Another di-addition product (IX) melting at 203° was obtained in very small amounts (less than 0.5 g.). It was isolated from the reaction mixture in the form of a double compound (X) containing two molecules of quinone to one molecule of the 203° compound.

$$\underset{\text{IX, 203°}}{C_{24}H_{22}O_2} + 2C_{12}H_{10}O_2 \rightleftarrows \underset{\text{X, 137°}}{C_{24}H_{22}O_2 \cdot 2C_{12}H_{10}O_2}$$

There is also a dehydration product, $C_{24}H_{20}O$, (XI) related in some way to the 203° compound (IX). These products are being further investigated.

Total yields of solid products from 348 g. of quinone (1.87 mole) and 3.5 moles of phenylmagnesium bromide: quinone and quinhydrone, 65 g.; 208° compound, 40 g.; 197° compound, 20 g.; 123° compound, 2.4 g.; 137° compound, 14 g.

Total yields of solid products from 55.8 g. of quinone (0.3 mole) and 0.55 mole of phenylmagnesium bromide when the reaction mixture was decomposed by excess acetyl chloride: quinone, 7.6 g.; 153° acetate, 0.22 g.; 189° diacetate, 7.9 g.; 183° compound, 1.1 g.

Experimental Part

All combustions were carried out using the semi-micro method of Lauer and Dobrovolny.[8] Molecular weight determinations were made by the lowering of the freezing point of benzene, or by the Rast method using camphor as the solvent.

Preparation of the 2,3-Dimethyl-1,4-naphthoquinone.—The quinone was prepared from 2,3-dimethylnaphthalene according to the method of Kruber[9] in 41–48% yields, m. p. 125–127°. Variations in the procedure, including lower temperatures and the use of a stirrer, did not affect the yield. Glacial acetic acid was the best solvent for recrystallization.

The Reaction between 2,3-Dimethyl-1,4-naphthoquinone and Phenylmagnesium Bromide.—Reactions carried out as nearly alike as possible gave different results, and for this reason the quinone was divided into small amounts and the reaction products worked up separately. One, one and a half or two moles of phenylmagnesium bromide were used per mole of quinone.

A freshly prepared Grignard solution containing approximately 0.1 mole of phenylmagnesium bromide per 100 cc. was added slowly to a suspension of 18.6 g. (0.1 mole) of 2,3-dimethyl-1,4-naphthoquinone in ether. The solid addition product was bright green. The mixtures were allowed to stand overnight before decomposing with ice and hydrochloric acid. The water layer, colored bright purple by quinhydrone, was extracted with ether. The ether solutions, after evaporating to about 50 cc., were diluted to 100 cc. with diisopropyl ether. Crops of solid obtained on standing were filtered off and washed with diisopropyl ether. Similar crops were combined for crystallization. In every case a dark oil was the main product.

In three cases the first green magnesium addition products, after standing for four hours, were decomposed with excess acetyl chloride and allowed to stand overnight, then treated with ice and hydrochloric acid. The yields in these cases were small and the acetates hard to isolate. The main product was the diacetate of the hydroquinone. The 153–157° acetate (VI) and the 183° compound (VIII) were obtained in small amounts.

Diphenyl could always be obtained by steam distillation of the oils, or from the ether filtrate if the original green magnesium compound was removed by filtration.

In one case the quinone was added to the Grignard reagent and the green precipitate first formed dissolved to give a yellowish brown solution. The yield of solids was low.

The Hydroquinone, I.—The hydroquinone was isolated in practically every reaction as the black quinhydrone.

It was also prepared from the quinone by reduction with boiling 80% acetic acid and excess zinc dust. The solution turned dark red at first, but in twenty minutes was practically colorless. A white precipitate formed as soon as the filtered solution cooled, but all attempts to filter, wash and dry it, even in an atmosphere of nitrogen, resulted in color changes from white through pink, lavender and purple, to black. The melting point is around 135–140° but no very definite results could be obtained due to its extreme ease of oxidation.

The Quinhydrone, II, m. p. 136–140°.—This substance was obtained in most of the reactions. It could be recrystallized from alcohol or ether and separated from the dark red solution as glistening black leaflets. Considerable oxidation to quinone occurred unless the recrystallization was carried out rapidly.

Anal. Calcd. for $C_{24}H_{22}O_4$: C, 76.97; H, 5.93. Found: C, 76.21, 76.87; H, 5.93, 6.17.

The compound dissociates in solution and while the quinone is very soluble in benzene, the hydroquinone is not so soluble. This gave a high result for the molecular weight, 224 instead of 187.

Diacetate of the Hydroquinone, III, m. p. 189–189.5°.—This diacetate was formed when the solid magnesium addition product was treated with acetyl chloride. It was also made by boiling the quinone with acetic anhydride and zinc dust, and from the impure hydroquinone by treatment with phenylmagnesium bromide followed by acetyl chloride. It is white when pure, and is soluble in chloroform but only slightly soluble in alcohol and benzene.

Anal. Calcd. for $C_{16}H_{16}O_4$ (272.1): C, 70.55; H, 5.92.

1,4 - Dioxo - 2,3 - dimethyl - 2 - phenyltetrahydronaphthalene, IV, m. p. 123°.—This mono-addition product was obtained in very small yields in two runs: 2.4 g. from 348 g. of quinone. It is a white solid, quite soluble in alcohol, ether and benzene. Half a gram was boiled for five hours with 2 g. of potassium dichromate in 15 cc. of acetic acid. An ether extract of the neutralized oxidation mixture was treated with semicarbazide, and gave acetophenonesemicarbazone.

Anal. Calcd. for $C_{18}H_{16}O_2$ (264.1): C, 81.78; H, 6.11. Found: C, 81.19, 81.04; H, 6.07, 5.99; mol. wt. (benzene), 257.3, 256.4.

1-Oxy-4-oxo-2,3-dimethyl-1-phenyldihydronaphthalene, V, m. p. 197–197.5°.—This compound is formed in practically all reactions. It is a white solid soluble in pyridine, 1,4-dioxane, chloroform and ether, but only slightly soluble in alcohol and benzene, and practically insoluble in diisopropyl ether. A mixture of chloroform and alcohol was best for crystallization. Phosphorus tribromide in bromoform solution gave a red brown oil. A solution of 1 g. of the 197° compound and 0.7 g. of hydroxylamine hydrochloride in 50 cc. of pyridine heated on the steam-bath for twelve hours gave 0.95 g. of the starting material unchanged.

Anal. Calcd. for $C_{18}H_{16}O_2$ (264.1): C, 81.78; H, 6.11. Found: C, 81.57, 81.68, 81.65; H, 6.20, 6.17, 6.24; mol. wt. (camphor), 265.6, 280.3.

The Grignard machine showed 1.12 moles of methane liberated and 1.86 moles of methylmagnesium iodide reacting per mole of 197° compound.

Oxidation.—One gram of the 197° compound and 3 g. of potassium dichromate in 25 cc. of glacial acetic acid were boiled for six hours. The mixture was then diluted with 100 cc. of water, neutralized with sodium carbonate and extracted with ether. An ether extract of the acidified water layer gave *o*-benzoylbenzoic acid melting at 126–128°.

Treatment of the 197° compound with sodium followed by acetyl chloride, and heating with acetyl chloride alone failed to give the acetate.

Acetate of 1-Oxy-4-oxo-2,3-dimethyl-1-phenyldihydronaphthalene, VI, m. p. 153–157°.—A mixture of 1.6 g. of the 197° compound, 2 g. of fused sodium acetate and 30 cc. of freshly distilled acetic anhydride was boiled for four hours. After cooling, water was added to dissolve the sodium acetate, the layers were separated and the water layer discarded. After the addition of alcohol and the evaporation of the solvents, 0.73 g. of the very soluble acetate separated.

This acetate was also obtained once (0.22 g.) when the original green metallic addition product was decomposed by acetyl chloride. It is very soluble in alcohol, ether, ethyl acetate and diisopropyl ether, and crystallizes in needles.

Anal. Calcd. for $C_{20}H_{18}O_3$: C, 78.39; H, 5.92. Found: C, 78.53, 77.90, 78.15; H, 5.80, 5.98, 6.00.

1,4 - Dioxy - 2,3 - dimethyl - 1,2 - diphenyldihydronaphthalene, VII, m. p. 208–209°.—This compound was formed in larger amounts than any of the other addition products. It is a white solid, soluble in ethyl acetate, pyridine, 1,4-dioxane and chloroform, but only slightly soluble in alcohol, benzene and ethers (diethyl, diisopropyl and diisoamyl). The best solvents for recrystallization are ethyl acetate or a mixture of alcohol and chloroform. From the reaction mixture the 208° compound and the 197° compound (V) often separate together as an apparently homogeneous material melting at 175°. Separation could be effected by dissolving the 175° material in boiling chloroform, then adding diisopropyl ether. The first solid separating was mainly the 197° compound. The middle fractions melted at 175°, and the final fractions were mainly the 208° compound.

Anal. Calcd. for $C_{24}H_{22}O_2$ (342.2): C, 84.17; H, 6.48. Found: C, 83.93, 84.04, 83.86; H, 6.56, 6.55, 6.51; mol. wt. (camphor), 347.8.

The Grignard machine showed 1.6, 1.7, 1.8 moles of methane per mole of the 208° compound. The gas was shown to be methane by analysis. The slight solubility of the 208° compound in solvents inert to the methylmagnesium iodide prevented further reaction.

Oxidation.—Two grams of the 208° compound and 6 g. of potassium dichromate in 50 cc. of glacial acetic acid were heated under reflux for five hours, then cooled and diluted with 200 cc. of water. The solution was neutralized with potassium hydroxide and extracted with ether. The ether solution, on treatment with semicarbazide, gave acetophenonesemicarbazone. The water solution was acidified with sulfuric acid and extracted with ether. The white solid, melting 126–128° was shown to be *o*-benzoylbenzoic acid by conversion to anthraquinone and mixed melting point with a known sample of anthraquinone.

Potassium permanganate in acetone failed to oxidize the 208° compound. When 1 g. of the 208° compound was heated for twelve hours on the steam-bath with hydroxylamine hydrochloride in pyridine solution, 0.63 g. was recovered unchanged, and 0.5 g. of an oil remained.

In an attempt to make the acetate by adding acetyl chloride to the magnesium derivative resulting from the reaction of the 208° compound with Grignard reagent, a white solid was obtained which melted at 183° (VIII). Treatment of the 208° compound with phosphorus tribromide in bromoform solution gave the same 183° compound. Heating 1 g. of the 208° compound on the steam-bath for six hours with zinc chloride and hydrochloric acid in benzene, or heating 1 g. for an hour with 0.5 g. of iodine in 50 cc. of acetic acid gave practically quantitative conversion to the 183° compound. This latter method was the procedure followed by Bachmann and Chu[3c] in rearranging their 9,10-diaryldihydrophenanthrenediols to diarylphenanthrones. Heating the 208° compound with 20% sulfuric acid for one half hour caused no loss of water.

$C_{24}H_{20}O$, VIII, m. p. 183°.—This compound results when the 208° compound loses a molecule of water. It was also formed when the original green reaction mixture was treated with acetyl chloride. After separating the diacetate of the hydroquinone, the remaining oils were distilled under reduced pressure. The fraction boiling 250–270° (15 mm.) finally gave 1.1 g. of the 183° compound from 70.4 g. of oil.

This compound is very soluble in alcohol, ether and benzene and separates in shining white leaflets. Heating 0.5 g. of the 183° compound with 20 cc. of constant boiling hydrobromic acid for three hours gave 0.4 g. of unchanged material. The starting material was recovered unchanged after heating on the steam-bath for seven hours with hydroxylamine. After heating 1 g. for five hours with potassium dichromate at the boiling point of acetic acid, 0.75 g. of the 183° compound was recovered unchanged.

Anal. Calcd. for $C_{24}H_{20}O$ (324.2): C, 88.84; H, 6.22. Found: C, 88.81, 88.87; H, 6.42, 6.22; mol. wt. (benzene), 315.1, 329.1.

The Grignard machine showed no active hydrogen, but 1.05 mole of methylmagnesium iodide reacted per mole of the 183° compound.

$C_{24}H_{22}O_2$, **IX**, m. p. 203–204°.—This white di-addition product was very soluble in benzene and alcohol, and was obtained from the reaction mixture in the form of a double compound (X) with two molecules of quinone. The clear crystals first obtained soon became opaque and sticky even in a desiccator. Less than 0.5 g. was available for study and the oxidation of 0.2 g. of this was inconclusive, so no structure can be assigned at this time.

Anal. Calcd. for $C_{24}H_{22}O_2$ (342.2): C, 84.17; H, 6.48. Found: C, 84.86, 83.75, 83.70; H, 6.66, 6.44, 6.46; mol. wt. (benzene), 338.8.

$C_{24}H_{22}O_2 \cdot 2C_{12}H_{10}O_2$, **X**, m. p. 137–138°.—The thick prisms of this yellow compound separated from various reaction mixtures and could be recrystallized from diisopropyl ether. Recrystallization from alcohol gave first quinone, then 137° compound, and finally the very soluble white di-addition product (IX). When the white compound (IX) and quinone were recrystallized together from alcohol, the yellow 137° compound was formed. The quinone could also be separated from the white compound by steam distillation.

Anal. Calcd. for $C_{24}H_{22}O_2 \cdot 2C_{12}H_{10}O_2$ ([342 + 2(186)]/3 = 238): C, 80.63; H, 5.93. Found: C, 79.66, 79.56; H, 5.96, 5.80; mol. wt. (benzene), 226.2.

$C_{24}H_{20}O$, **XI**, m. p. 124°.—This dehydration product is related in some way to the 203° compound (IX), and was obtained only once (2.15 g.) out of fifteen runs. The structure is still under investigation. Oxidation with potassium dichromate gave acetophenone and *o*-benzoylbenzoic acid.

Anal. Calcd. for $C_{24}H_{20}O$ (324.2): C, 88.84; H, 6.22. Found: C, 88.98, 88.64; H, 6.22, 6.40; mol. wt. (benzene), 316.5, 314.9.

The Grignard machine showed no active hydrogen, but 0.7 mole of methylmagnesium iodide reacted per mole of the 124° compound.

The author wishes to thank Lillian G. Hoagland, formerly instructor at Vassar College, for much preliminary work on other methods of preparing the quinone, and for the preparation of the hydroquinone and its diacetate.

Summary

1. Whenever a 1,4-conjugated system in a quinone is open to attack by a Grignard reagent the reaction is complex and the yields of solids low.

2. A study of the reaction between 2,3-dimethyl-1,4-naphthoquinone and phenylmagnesium bromide shows that several reactions take place at the same time and the quinone acts more like duroquinone than like anthraquinone.

3. Eleven new compounds, products of this reaction and their derivatives, are described and structures are proposed for seven of them. About 70% of the reaction product is a dark oil.

4. The study of the dehydration products is being continued.

POUGHKEEPSIE, N. Y. RECEIVED JULY 12, 1935

NOTES

The Decomposition Voltage of Grignard Reagents in Ether Solution

By Elliot Q. Adams

Evans, Lee and Lee[1] have found decomposition voltages of Grignard reagents ranging from 0.86 volt for allylmagnesium bromide, to 2.17 volts for phenylmagnesium bromide. If the *differences* in the decomposition voltages of the saturated aliphatic derivatives produced by the introduction of one methyl group are taken, it is

$$\begin{array}{llllll}
\alpha_1 & -0.66 & \alpha_2 & -0.21 & \alpha_3 & -0.10 \\
 & & & -0.18 & & \\
\beta_1 & +0.14 & & & & \\
 & +0.17 & & & & \\
\gamma_1 & -0.10 \text{ (Evans, Lee and Lee)} & & & &
\end{array}$$

$$\begin{array}{lll}
\Delta pK_A/pK_{A(\text{subst.})}\alpha & = & -0.68 \\
\beta \quad \text{(Derick)} & = & -0.19 \\
\gamma & = & -0.06 \\
\delta & = & -0.02
\end{array}$$

α_1, α_2, α_3 represent the changes *in volts* in the decomposition potential of Grignard reagents in ether solution, produced by replacing, respectively, the first, second, and third α-hydrogen by methyl; β_1 and γ_1 represent similarly the changes *in volts* produced by the first methyl group in, respectively, the β and γ positions. α, β, γ and δ are the changes in Derick's function[3] produced by substituting chlorine for, respectively, the α-, β-, γ- or δ-hydrogens in butyric or valeric acid, or their chlorinated derivatives.

found that successive substitutions in the alpha position produce diminishing decreases in the decomposition potential, and that the effect of substitution in the beta position is opposite in sign to that of alpha or gamma substitution. Conant[2] has found that irreversible oxidation–reduction potentials are represented by equations similar in form to those for oxidation–reduction equilibrium potentials. Derick[3] has pointed out that the relative effects of substituents on the logarithms of the ionization constants of organic acids ($\Delta pK_A/pK_{A(\text{substituted})}$ in present-day notation) are reduced approximately 3-fold by each additional carbon atom between the carboxyl and the substituent, without change in sign. The results of Evans, Lee and Lee agree within the error of measurement with the series

$$-0.63{:}\mp 0.21{:}-0.07 = 9{:}\pm 3{:}1$$

that is, 3-fold reduction in the effect of successive alpha replacements, as well as with increasing distance from the MgBr radical. In the latter case, there is also an alternation in sign of the effect.

The results for phenyl- and allylmagnesium bromides indicate an effect of unsaturation alternating in sign, and less for the more distant double bond, in qualitative agreement with the rule for methyl groups.

[1] W. V. Evans, F. H. Lee and C. H. Lee, This Journal, **57**, 489–490 (1935).

[2] J. B. Conant and M. F. Pratt, *ibid.* **48**, 3178–3192 (1926).

[3] C. G. Derick, *ibid.* **33**, 1182 (1911). The approximate numerical agreement between Evans, Lee and Lee's results in volts, and Derick's is, of course, a coincidence. Since pK_A for unsubstituted aliphatic acids is of the order of 5 and with a single strongly negative α-substituent becomes about 3, the unit of Derick's function for singly substituted acids will range from 3 to 5 pK units. (1 volt $\simeq$ 17 pK units.) The form of Derick's function provides for a diminishing effect on pK_A with successive substitutions, but the decrease even in the case of α-substitution is not as great as that shown in the results of Evans, Lee and Lee. Since the acid hydrogen in substituted acetic acids is separated by a carbon and an oxygen atom from the α-carbon of the chain, while in the Grignard reagents the magnesium atom is directly attached, a factor of the order of 9 is to be expected. There is, to be sure, no reason to expect the effect of a methyl group on the irreversible breaking of the bonding of magnesium to carbon in ether solution to be identical with the effect of chlorine on the equilibrium of the bonding of hydrogen to oxygen in aqueous solution.

Some Acyl Derivatives of *o*-Anisidine

By Lawrence H. Amundsen and C. B. Pollard

We have prepared a number of acyl derivatives of *o*-anisidine, the majority of which have not been described in the literature. The monoacyl derivatives were prepared by the action of the corresponding acyl chlorides upon 2 molecular proportions of *o*-anisidine.[1]

The diacyl derivatives were prepared by boiling a toluene solution of *o*-anisidine with 2.5 molecular proportions of acyl chlorides under reflux for twelve to eighteen hours. The dibenzoyl derivative precipitated upon cooling the solution and the dipropionyl derivative was obtained by evaporation of the toluene.

The first six compounds are very soluble in most organic solvents but only moderately soluble in pentane, hexane, etc. The next four compounds are very soluble in chloroform, dioxane and acetone, fairly soluble in alcohol, slightly

Addition of Methyl Alcohol to Dialkylacetylenes

BY G. F. HENNION AND J. A. NIEUWLAND

The many well-known reactions of acetylene and its homologs with hydroxylated compounds (alcohols, carboxylic acids, etc.) are characterized by the fact that they proceed quite readily in an appropriate acid medium in the presence of a small amount of a suitable mercuric salt. The mechanism of this catalysis has engaged our attention for some time. There is little doubt but what the reaction of an acetylene with methyl alcohol, for example, produces first a vinyl ether which in turn immediately adds a second molecule of alcohol to form the ketal or acetal. There is evidence to indicate that the mercuric salts function only in the first of these reactions.

In attempting to determine whether the catalytic mercuric salt forms an intermediate with the acetylene by addition or substitution (or both) we have succeeded in adding methyl alcohol to two dialkylacetylenes in the usual way.[1] This indicates quite clearly that an intermediate of the mercury acetylide type is not essential to the mechanism of catalysis.

Preparation of 2-Octyne.—This compound was obtained by the action of methyl iodide on sodium amylacetylide in liquid ammonia: b. p. 132–136°; d^{32} 0.751; $n^{32}{}_D$ 1.4227.

Reaction of 2-Octyne with Methyl Alcohol.—The catalyst was prepared by heating together momentarily 3 g. of red mercuric oxide, 1 ml. of $(C_2H_5)_2O{\cdot}BF_3$, 0.5 g. of trichloroacetic acid, and 3 ml. of methyl alcohol. The reaction was carried out and the product purified as previously described.[1] From 55 g. of 2-octyne there was obtained 48 g. of 3,3-dimethoxyoctane: yield, 55%; b. p. 90–92° at 26 mm.; d^{25} 0.8552; $n^{25}{}_D$ 1.4171; MR calcd. 51.67, found 51.22.

Anal. Calcd. for $C_{10}H_{22}O_2$: C, 68.89; H, 12.73. Found: C, 69.00; H, 12.79.

Hydrolysis of a 1-ml. sample yielded a ketone which was in turn converted to the semicarbazone. The latter melted at 112–113° which agrees with the value of 112° given by Pickard and Kenyon[2] for the semicarbazone of 3-octanone.

Reaction of Methoxy-4-butyne-2 with Methyl Alcohol.—A sample of this acetylene[3] was obtained through the courtesy of Dr. Wallace H. Carothers of E. I. du Pont de Nemours & Company to whom our sincere thanks are extended.

The catalyst was prepared as described above and the reaction carried out in the usual way. Forty-two grams of the acetylene yielded 42 g. of 2,2,4-trimethoxybutane, b. p. 67–69° at 30 mm.; yield, 57%. This compound has been obtained previously from vinylacetylene.[4]

p-Bromophenacyl Formate, a Solid Derivative of Formic Acid

BY CHARLES D. HURD AND ROBERT E. CHRIST

It was found by Judefind and Reid[1] that many aliphatic acids could be identified easily as their *p*-bromophenacyl esters. These solid esters made excellent derivatives for the acids. According to these authors, however, formic acid gave negative results. In contrast to this statement, we have found that formic acid behaves regularly. The preparation of *p*-bromophenacyl formate is a simple matter and the compound makes an admirable derivative. It melts at 140°.

One gram of sodium formate (solid) was dissolved in 5 cc. of water and 10 cc. of 95% alcohol. Then 1 g. of *p*-bromophenacyl bromide was added. The solution was boiled until nearly all the solvent had disappeared. More alcohol was added and it was boiled another half hour until the solvent had nearly disappeared. Finally, the product was dissolved in dilute alcohol and then cooled. The crystalline product was filtered and recrystallized from dilute alcohol. A total of 0.38 g. of product was obtained which possessed a melting point of 140°.

Equally good results were obtained by refluxing instead of boiling away the solvents. Then, the first amount of alcohol is sufficient.

Optical Rotation Study of the New Orally Effective Principle of Ergot

BY E. C. KLEIDERER

Commercial production of the orally effective principle recently isolated from ergot has provided an adequate source for an intensive study of its properties.

The free base, called ergotocin by Kharasch and Legault, was crystallized from benzene and dried *in vacuo* for about eight hours. It melted at 157–158° (corr., bath at 150° when sample was introduced). The maleate salt was prepared from the crystalline base, and dried *in vacuo*.

The initial specific rotations of the free base in various solvents are given below. All rotations in this investigation were made in a one-decimeter tube at 28° unless otherwise stated. Due to the slight solubility of the base in cold chloroform and benzene, the rotations in these solvents were taken in a Landolt heating chamber.

TABLE I

Solvent	Wt. and vol. of solvent	α_D	$[\alpha]_D$
Distilled water	0.0276 g. in 10 cc.	+0.21°	+76.1°
Abs. methyl alcohol	.0485 g. in 15 cc. tube, 2 dm.	+ .26°	+40.2°
Cyclohexanol	.00659 g. in 1 cc. (micro)	+ .21°	+31.6°
Chloroform	.0179 g. in 10 cc.	− .08° at 50°	−44.7° at 50°
Benzene	.0164 g. in 10 cc.	− .10° at 75°	−61.0° at 75°

The rotation of the methyl alcoholic solution of the free base on standing at room temperature became more dextro as shown in Table II, while no change was observed on a water solution of the free base after standing at room temperature for one hundred hours.

TABLE II

Time, hr.	Initial	17	30	71.5	95.5
$[\alpha]^{28}_D$	+40.2°	+48.0°	+53.1°	+59.6°	+61.8°

The methyl alcohol was evaporated from the sample which had stood ninety-five and one-half hours, the residue recrystallized from benzene and the dried (*in vacuo*) product dissolved in water giving $[\alpha]^{28}\text{D}$ +95.4°. The melting point of the initial sample was 157–158° (dec.) and of the sample obtained from the 95.5-hour solution was 160–161° (dec.).

By the isolated rabbit uterus method,[1] the physiologic activity of the base obtained from the 95.5-hour sample was about 90% of that of the initial sample.

Initial rotations of the maleate salt of the new base were as follows.

TABLE III

Solvent	Wt. and vol. of solution	$\alpha^{28}\text{D}$	$[\alpha]^{28}\text{D}$
Distilled water	0.1042 g. in 10 cc.	+0.48°	+46.2°
Abs. methyl alcohol	.1017 g. in 25 cc.	+ .308°	+37.9°

Rotations were again made on these same solutions after standing at room temperature for forty-eight hours, and were found to be as follows: on the water solution $\alpha^{28}\text{D}$ +0.56°, $[\alpha]^{28}\text{D}$ +53.7°; on the methyl alcohol $\alpha^{28}\text{D}$ +0.20°, $[\alpha]^{28}\text{D}$ 24.6°. The forty-eight-hour methyl alcohol solution was evaporated *in vacuo* to dryness at room temperature, water was added to bring the solution up to the original methyl alcohol volume. The rotation was $\alpha^{28}\text{D}$ 0.214°, $[\alpha]^{28}\text{D}$ 52.9°. The physiologic activity of these forty-eight-hour samples as determined by the isolated rabbit uterus method was approximately the same as that of an initial sample.

The explanation of these results is not clear at present; evidently some change is occurring in the molecule which affects the optical rotation, but which does not greatly affect the physiologic activity. Changes of rotation have been noted in the cases of ergotinine and ergotamine which have been ascribed to a change into ergotoxine in the former case and into ergotaminine in the latter case. This explanation does not appear to be a logical one for the changes occurring here, since the physiologic activity seems to be practically unchanged and since the product obtained from a solution of the salt of the new base in methyl alcohol and the product obtained from a solution in water appear to be the same.

The author wishes to express his thanks to Dr. K. K. Chen and to Mr. E. E. Swanson of the Lilly Research Laboratories for their aid in determining the physiologic potency.

An Improved Method of Extraction

BY CHARLES A. MARLIES AND VICTOR K. LA MER

In an investigation on the acid and salt catalysis of nitramide,[1] NH_2NO_2, a novel method of extraction was employed in the final stage of the preparation of this interesting compound. In the customary method[2] the compound is extracted from its aqueous solution, some forty extractions with ether being necessary on account of the exceedingly unfavorable distribution ratio. The improvement consists of immersing the flask containing the nitramide solution and supernatant ether layer into a "dry ice" freezing mixture and swirling until the water layer solidifies completely. The nitramide passes into the ether layer which is decanted through a filter. Complete extraction was achieved by repeating the process three times. The yield obtained on evaporation of the four combined ether extracts was 80%, whereas the maximum yield by the previous method was but 25%, in agreement with the experience of Brönsted's laboratory.[3]

The low yields by the previous[2] method are probably due to decomposition during the prolonged evaporation of the large volume of ether. Nitramide is an extremely unstable substance and the catalytic action resulting from the concentration of the ever-present impurities (including water) during the evaporation probably causes considerable loss by decomposition.

This method of freezing the solvent during extraction should prove generally useful not only in cases where the distribution ratio is unfavorable but also to remove small amounts of material from large volumes of solution, provided, of course, that solid solution is not an important complication.

DIMENSIONS OF SOAP MOLECULES AS SUPPOSEDLY DEDUCED FROM SURFACE TENSION MEASUREMENTS

Sir:

The surface tension measurements of Du Noüy [*Phil. Mag.*, [6] **48**, 664 (1924)] as carried out with the ring method were recently reproduced by Washburn and Berry [This Journal, **57**, 975 (1935)] using the capillary rise method for sodium palmitate solutions. The equilibrium surface tension–concentration curve shows three minima and the same number of maxima.

According to the Gibbs theorem for these concentrations no adsorption at all takes place. Instead, the interpretation of Du Noüy as now repeated by Washburn and Berry introduces the hypothesis that the minima are due to condensed films on the water surface, but differing in orientation corresponding to the three dimensions of the adsorbed molecule. No other confirmation for the validity of this view has been available.

However, the assumptions on which the theory of Du Noüy is based—besides contradicting the thermodynamics of Gibbs—are also objectionable. First, the acceptance of the supposition that the adsorbed quantities are proportional to the concentrations is quite untenable. Second, in calculating the surface tensions the possible influence of the angle of contact was completely disregarded, because it was tacitly taken for granted that perfect wetting always occurred.

This point, alone, seems to lead to a very plausible explanation of the experiments, if they are compared with the wonderful results of Miss Blodgett [This Journal, **57**, 1007 (1935)], who proved the existence of polymolecular soap films of alternating orientation as adsorbed on glass and other solids, when in contact with the solutions. The same phenomenon, unfortunately, is to be expected at the platinum ring of Du Noüy as well as at the walls of the glass tubes.

As Miss Blodgett showed, the first layer of molecules is always fixed with the active groups toward the adsorbent, whereas the paraffin groups are directed toward the solution. Therefore, with increasing concentration the glass or platinum is covered at first with a film of paraffin character which, as is well known, repels water. But the second layer may be orientated in the opposite direction, causing a decrease of the angle of contact. Consequently the apparent surface tension rises, unless a new paraffin surface is deposited.

The author in collaboration with E. J. Better applied the bubble pressure method, as being independent of the angle of contact, for the measurement of oleate solutions. Only one minimum was found, and that at a higher concentration than any of the minima of Du Noüy.

THE RELATIONSHIP OF ERGOTOCIN TO ERGOMETRINE

Sir:

Dudley and Moir [*Brit. Med. J.*, i, 520 (1935)] recently described the isolation from ergot of an alkaloid, chemically and pharmacologically different from any of the then known alkaloids of ergot, which they named ergometrine.

Although there were strong grounds for believing that ergotocin [Kharasch and Legault, This Journal, **57**, 956 (1935)] was identical with ergometrine, Kharasch and Legault have not adopted this view, but have suggested that the two substances may be different [*e. g.*, *Lancet*, i, 1243 (1935)]. They have now published a formula, $C_{21}H_{27}O_3N_3$, for ergotocin [This Journal, **57**, 1140 (1935)], while analyses of ergometrine and its salts now very accessible [Dudley, *Pharm. J.*, iv, **80**, 709 (1935)] indicate the formula $C_{19}H_{23}O_2N_3$, which is still being critically examined. [Further work on this substance since this "Communication" was dispatched (July 11, 1935) affords convincing evidence that this formula is correct.]

Ergometrine: *Anal.* Calcd. for $C_{19}H_{23}O_2N_3$: C, 70.15; H, 7.08; N, 12.92. Found: C, 70.0; H, 6.96; N, 12.91.

Ergometrine Hydrobromide. *Anal.* Calcd. for $C_{19}H_{23}O_2N_3 \cdot HBr$: C, 56.15; H, 5.91; N, 10.35; Br, 19.71. Found: C, 56.24; H, 6.19; N, 10.71; Br, 19.76.

Ergometrine Hydrochloride. *Anal.* Calcd. for $C_{19}H_{23}O_2N_3 \cdot HCl$: C, 63.08; H, 6.64; N, 11.62; Cl, 9.82. Found: C, 63.1; H, 6.81; N, 11.29; Cl, 9.54.

Ergometrine Oxalate: *Anal.* Calcd. for $C_{19}H_{23}O_2N_3 \cdot$

$H_2C_2O_4$: C, 60.73; H, 6.02; N, 10.12. Found: C, 60.58; H, 5.98; N, 10.18.

Taken by themselves these formulas would seem to support Kharasch and Legault's contention, but all other available evidence points to the identity of the substances. It is therefore probable that the apparent difference in elementary composition is not real, and that further analyses of ergotocin and its salts may yet lead to the establishment of its complete identity with ergometrine.

THE SYNTHESIS OF BIS-2,2'-(1,3-DIPHENYLINDENOL-3)

Sir:

In connection with attempts to synthesize rubrene we have prepared bis-2,2'-(1,3-diphenylindenol-3) by the following series of reactions

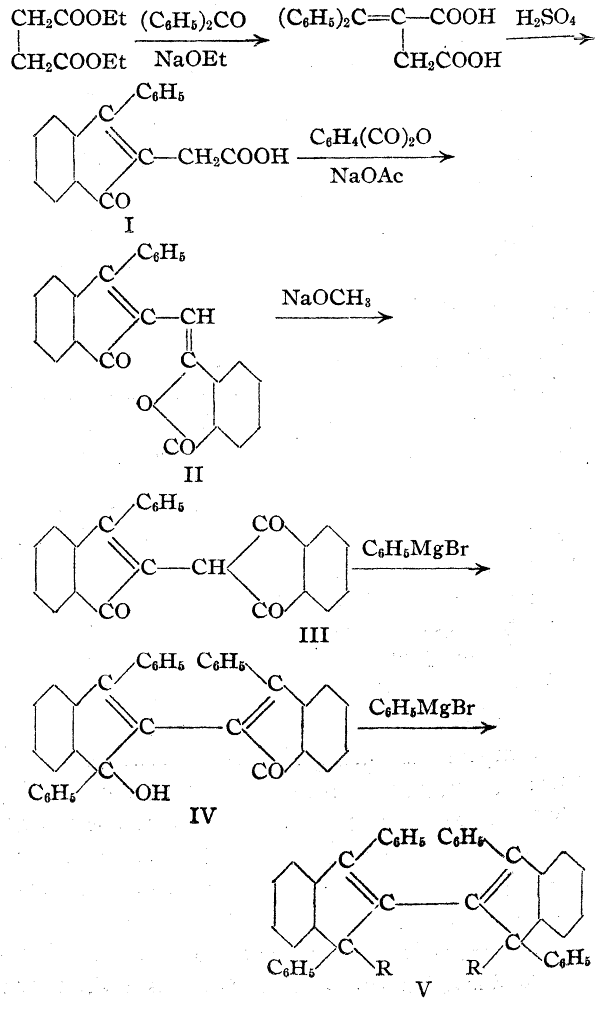

TABLE I

PROPERTIES OF COMPOUNDS INVOLVED

Compound	M. p., °C.	Formula	Analyses, % Calcd. C	Calcd. H	Found C	Found H
I	166–167	$C_{17}H_{12}O_3$	[a]			
II	173.5–174	$C_{24}H_{14}O_3$	82.2	4.0	81.9	4.3
III	190.5–191.5	$C_{24}H_{14}O_3$	82.2	4.0	82.0	3.9
IV	244–245	$C_{36}H_{24}O_2$	88.5	4.9	88.0	4.8
V, R = OH	292	$C_{42}H_{30}O_2$	89.0	5.3	89.0	5.5
V, R = Cl	237–242	$C_{42}H_{28}Cl_2$	83.6	4.6	83.6	4.6

[a] Stobbe and Vieweg, *Ber.*, **35**, 1728 (1902).

The product is identical with the one obtained by a different method by Eck and Marvel [THIS JOURNAL **57**, 1898 (1935)].

TABLE II

PROPERTIES OF BIS-2,2'-(1,3-DIPHENYLINDENE) DERIVATIVES

Compound	Source	M. p., °C.[c]	Mixed m. p., °C.[d]
V, R = OH	[a]	293	291
	[b]	292	
V, R = Cl	[a]	240–245	237–242
	[b]	237–242	

[a] Eck and Marvel. [b] Koelsch and Richter. [c] Melting involves decomposition, and the temperature at which it occurs depends to some extent on the stage of subdivision of the compound and on the rate of heating. [d] We are indebted to Professor Marvel for the melting points reported here.

Like these authors we have found the derived dichloride to be unreactive toward metals (zinc or mercury). The dichloride, however, appears to give an alkali derivative with 40% sodium amalgam and we hope to make use of this reaction in converting it into the di-radical.

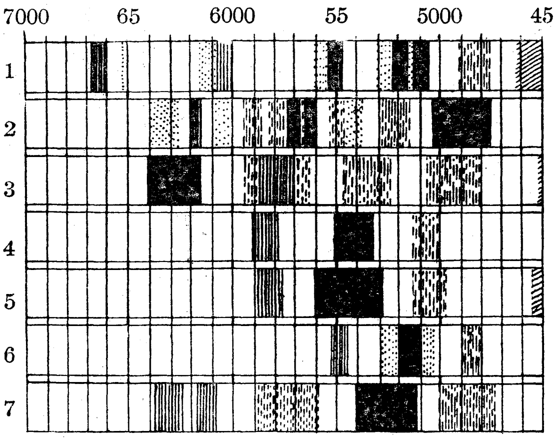
FORMATION OF PORPHYRINS FROM PYRROLE AND ALDEHYDES

Sir:

Porphyrin formation was observed under the following conditions: pyrrole, C. P., was dissolved in a solution of gaseous acetaldehyde (I) or formaldehyde (II) in methanol (saturated in the cold), and the reaction mixture was either (a) kept at room temperature for several weeks, or (b) heated under reflux for fifteen to twenty-five hours, or (c) heated in a sealed tube to 85–90° for ten to twenty hours in a water-bath.

The reaction mixture was then subjected to vacuum distillation to remove the methanol and the aldehyde; the oily residue was taken up in warm pyridine, transferred into ether and the ether solution was fractionated with hydrochloric acid. The results are indicated in a somewhat abbreviated form in the chart of the absorption spectra.



Absorption spectra.

(1) Porphyrin from reaction I (pyrrole + acetaldehyde) in ether. (2) Porphyrin from reaction II (pyrrole + formaldehyde) in ether. (3) Porphyrin from reaction I in 0.05% hydrochloric acid. (4) Porphyrin from reaction II in 3.0% hydrochloric acid. (5) Copper complex salt of porphyrin from reaction I in ether. (6) Copper complex salt of porphyrin from reaction II in ether. (7) 3% hydrochloric acid fraction from the reaction pyrrole + furfuraldehyde in ether.

The main fraction in case I enters 0.5% hydrochloric acid and has a hydrochloric acid number of 0.075. The main fraction in case II enters 3% hydrochloric acid, its hydrochloric acid number is 3.3. The porphyrin from I crystallized in rhomb-shaped crystals, the one from II in platelets. The corresponding copper complex salts and hemins were prepared.

The yield increased upon addition of pyridine to the original solution, or when suitable agents (*e. g.*, $CaCO_3$ + MgO, $PbCrO_4$) were added; the resulting porphyrins were different from the ones mentioned above when the reaction was performed in presence of PbO_2.

Further studies are in progress to secure information on the structure of the porphyrins formed, and to determine the applicability of the reaction to other aldehydes; a comprehensive report of the research will soon be published. From theoretical considerations and in the light of numerous porphyrin syntheses by H. Fischer [*Ann.* since 1926; H. Fischer and H. Orth, "Die Chemie des Pyrrols," Leipzig, 1934 and 1935], the main porphyrin formed from acetaldehyde and pyrrole seems to be α,β,γ,δ-tetramethylporphin. The reaction between formaldehyde and pyrrole apparently leads to porphin, the as yet hypothetical tetracyclic parent ring system of the porphyrins, and hence, also the fundamental structure in the physiologically important pigments, hemin and chlorophyll.

CONTRIBUTION TO THE KNOWLEDGE OF THE TESTICULAR HORMONE

Sir:

The communication of E. S. Wallis and E. Fernholz [THIS JOURNAL, **57,** 1511 (1935), received July 15] occasions the present note. In an article accepted on June 1 and published in the number of *Helv. Chim. Acta* [**18,** 986 (1935)] which appeared on July 1, we described the preparation of androstene-3,17-dione (I) and suggested the probability that the testicular hormone (not then isolated) is identical either with this diketone or with androstene-3-one-17-ol (II).

At our request, Dr. E. Tschopp in Basel began the investigation of this hypothesis by submitting (I) to the usual tests on capons and castrated rats. The details of his study, which were communicated to the League of Nations committee in London (July 15–17), will be published elsewhere; they are summarized in the table.

Substance investigated	Capon unit	Seminal vesicle wt. in mg. after 20 days[a] 50 γ daily	100 γ daily	200 γ daily
(I) Androstene-3,17-dione	100 γ	25	51	285
(III) Androstane-3,17-dione	100 γ	16	27	51
(IV) Androstane-3,17-diol	15 γ	14	25	40
(V) Androsterone	60 γ	11	14	17

[a] The control animals had a seminal vesicle weight of about 6 mg.

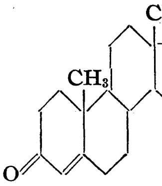
Compared in terms of capon units, (I) is five times as effective on seminal vesicle growth as (V), on the basis of the 50 γ daily dose; on the basis of the 200 γ daily dose, however, (I) is 25 times as effective as (V). The corresponding activity ratios for (IV) and (I) are 1:12 and 1:50, respectively.

This constituted the first description of the physiological activity of a substance of known constitution which exhibits the relationship between rat-tests and capon-test potency characteristic of testicular extracts. The natural expectation that this observation would prove significant in the elucidation of the constitution of the testicular hormone was fulfilled with surprising promptitude.

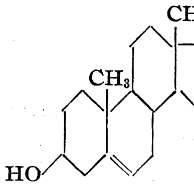
Laqueur, *et al.* [*Z. physiol. Chem.*, **233**, 281 (1935), appearing on June 7] described the isolation of a testicular hormone of unknown constitution (m. p. 154°), with a capon activity of about 10 γ, which was called testosterone (VI). Although (VI) showed the characteristic difference in capon-test and rat-test effectiveness, the published figures do not permit a rigorous comparison with (I).

At London, Laqueur expressed the opinion, based on chemical evidence, that (VI) is an isoandrosterone. The physiological activity of (I) suggested further investigation of (VI) and we have recently learned by private communication from Prof. Laqueur that (VI) yields (I) upon oxidation. Therefore it appears highly probable that formula (II) is that of testosterone (VI).

In pursuance of the program outlined in our paper (*loc. cit.*) we reduced androstene-3-ol-17-one (VII) with sodium and alcohol to androstene-3,17-diol (VIII), m. p. 175–178° corr. Utilizing the greater reactivity of the 3-substituent we partially oxidized the dibromide of (VIII) to produce (II) upon subsequent debromination. We also partially saponified the diacetate of (VIII) to produce the 17-monoacetate, which, upon oxidation of its dibromide and debromination, should yield the acetate of (II).



(I)



(VIII)

Further details will be published elsewhere, and we hope that the previous announcement of our research program (*loc. cit.*), together with the work initiated before the isolation of testosterone, may serve as a reservation of this project.

Footnote (*Sept. 7*).—At the time this note was written the author was unaware that testosterone (androstene-3-one-17-ol) had already been synthesized in his laboratory in Zürich by his assistants. The substance was made by partially saponifying the unsaturated diol diacetate and oxidation of the monoacetate dibromide.

EXPERIMENTS ON THE CONSTITUTION AND PREPARATION OF THE TESTICULAR HORMONE

Sir:

In the preceding Communication of L. Ruzicka it is evident from the dates given that the publication of his experiments on the preparation of androstendione-3,17 antedates the publication of our experiments on the preparation of this same compound. However, we would like to state that the particular issue of the *Helv. Chim. Acta* to which reference is made was not received in our library until August 8, three days after the publication of our experiments, and that a sample of dehydroandrosterone prepared by our method (received by THIS JOURNAL, June 4) was sent to Professor Butenandt on May 20. We were unaware, therefore, of Professor Ruzicka's experiments, and our suggestion as to the constitution of the testicular hormone and our experiments on its preparation were made independently. At the time of the appearance of his article in the *Helv. Chim. Acta* we were engaged in the preparation of 17-hydroxy-androsten-one-3, and we had succeeded in preparing androstendiol (m. p. 175°), and its diacetate (m. p. 159°) by the reduction of our synthetically prepared dehydroandrosterone when the above Communication reached us. In view of Professor Ruzicka's Communication, and of his request that this project be reserved we are discontinuing our work in this particular direction.

THE PREPARATION OF β-CHLOROVINYLARSINE SULFIDE

Sir:

β-Chlorovinylarsine sulfide was first described by Lewis and Stiegler [THIS JOURNAL, **47**, 2546 (1925)] as a clear, amber-colored plastic mass insoluble in the usual solvents other than carbon disulfide and possessing an extraordinarily irritating and noxious odor.

We have succeeded in obtaining this substance, β-chlorovinylarsine sulfide, in a crystalline condition by the following procedure. Hydrogen sulfide was conducted for two hours through a solution of 45 g. of β-chlorovinyldichloroarsine (b. p. 78° at 12 mm.) in 50 cc. of alcohol. The solution became noticeably warmer and a yellow viscous oil gradually separated out. After two hours separation ceased and this was taken as the end of the reaction. The resulting product was an amber-yellow viscous oil which adhered to the walls of the flask. The alcoholic solution was poured off, the oil washed repeatedly with alcohol and then dissolved with warming in carbon disulfide. After cooling and distilling off part of the solvent, the substance separated in crystalline form. In order to obtain a more complete separation an equal volume of benzene may be added to the solution; yield 20 g. or 51% of the theoretical. After recrystallization from benzene and drying in a vacuum desiccator, the melting point was 114°.

Anal. Calcd. for C_2H_2ClSAs: As, 44.49; Cl, 21.05; S, 19.03. Found: As, 44.55; Cl, 21.06; S, 19.27.

β-Chlorovinylarsine sulfide crystallizes in cubes, possesses a pale yellow color and a weak, not unpleasant, odor; is easily soluble in carbon disulfide, less so in benzene and ether and insoluble in water. Under the influence of sunlight the substance acquires an orange color.

THE ISOLATION OF CROTYL AND METHYLVINYLCARBINYL BROMIDES

Sir:

The composition of bromide mixtures arising from the action of hydrogen bromide and phosphorus tribromide on crotyl alcohol or methylvinylcarbinol has been the subject of much discussion. Some claim that pure products [Charon, *Ann. chim. phys.*, [7] **17,** 216 (1899); Prévost, *Ann. chim.*, **10,** 113 (1928); Claisen and Tietze, *Ber.*, **59B,** 2344 (1926); Juvala, *Ber.*, **63B,** 1989 (1930)] are obtained from alcohols of this type while others report the formation of mixtures of bromides but have not separated them [Baudrenghien, *Bull soc. chim. Belg.*, **31,** 160 (1922); Meisenheimer and Link, *Ann.*, **479,** 211 (1930); Young and Prater, This Journal, **54,** 404 (1932); Gredy and Piaux, *Bull. soc. chim.*, [5] **1,** 1481 (1934)]. The bromides obtained in this Laboratory have always been mixtures. We have recently separated these mixtures into the primary (crotyl bromide) and secondary (methylvinylcarbinyl bromide) isomers by fractional distillation at 0°. The properties are $n^{23}\text{D}$ 1.4805 and 1.4612; $d^{25}{}_4$ 1.3335 and 1.2998; b. p. 49° and 31.0° at 93 mm., >107° and 86.5° at 760 mm., and +2.0° at 5 mm. and −2.0° at 14 mm. for the primary and secondary isomers, respectively. Mixtures of these bromides may be analyzed from density or refractive index measurements since these properties are linear functions of the composition.

Both of the pure bromides rearranged to an equilibrium mixture of 14% secondary and 86% primary in a few days at room temperature, in less than one hour at 75° and in less than five minutes at 100°. If a mixture of the bromides is subjected to slow distillation at atmospheric pressure through a 100-cm. packed column, almost pure secondary bromide is obtained as a distillate. Equilibrium is so rapidly established in the boiler that the secondary bromide is replaced as fast as it is removed from the top of the column.

It is now evident that the bromides reported by Juvala, Baudrenghien and Gredy and Piaux having $n^{23}\text{D}$ 1.4750 to 1.4759 contained from 24–29% of secondary bromide. Their compositions were dependent on the method of distillation and had nothing to do with the method of preparation. The bromides used by Gredy and Piaux must have gone to equilibrium after the refractive index was taken and before the Raman spectra were measured, since their analysis of 90% primary and 10% secondary is qualitatively in agreement with the equilibrium composition and not with the composition calculated from the refractive index.

In the light of these developments, crotyl alcohol and methylvinylcarbinol are being converted into bromide mixtures by various reagents under conditions designed to avoid rearrangement of the product. The composition of these mixtures will be reported in the near future.

NEW BOOKS

Annual Review of Biochemistry. Vol. IV. Edited by JAMES MURRAY LUCK, Stanford University. Annual Review of Biochemistry, Ltd., Stanford University P. O., California, 1935. vii + 639 pp. Illustrated. 15.5 × 23 cm. Price, $5.00.

The fourth volume in this series of annual reviews introduces two new sections on choline and allied substances by J. H. Gaddum, and on growth substances in plants by K. V. Thimann. The biochemistry of malignant disease as reviewed by Barbara E. Holmes differs somewhat from the discussion of malignant tissue prepared by E. Boyland a year ago.

Several new reviewers contributed to this volume, including M. H. Jacobs, on permeability; R. Sonderhoff, on biological oxidations and reductions; J. B. Sumner, on enzymes; Sir J. C. Irvine and G. J. Robertson, on the chemistry of the carbohydrates and the glycosides; E. Chargaff, on the chemistry of the acyclic constituents of natural fats and oils; E. J. Cohn, on the chemistry of the proteins and amino acids; C. Artom, on fat metabolism; B. A. Houssay, V. Deulofeu, and A. D. Marenzi, on the hormones; P. Eggleton, on the chemistry of muscle; R. Kuhn, on plant pigments; and F. C. Steward, on the mineral nutrition of plants.

In addition to these reviews, the volume also includes the following: The chemistry and metabolism of the compounds of sulfur, by H. B. Lewis; the chemistry and metabolism of nucleic acids, purines and pyrimidines, by L. R. Cerecedo; carbohydrate metabolism, by C. F. and G. T. Cori; the metabolism of amino acids and proteins, by Y. Kotake; the metabolism of creatine and creatinine, by W. C. Rose; detoxication mechanisms, by B. Harrow and C. P. Sherwin; vitamins, by L. J. Harris; nutrition, by S. Brody; the metabolism of brain and nerve, by E. G. Holmes; chemical embryology, by J. Needham; the alkaloids, by R. Robinson; immunochemistry, by M. Heidelberger; the chemistry of bacteria, by M. Stephenson. About a dozen sections or subjects that were reviewed in Volume III are omitted from the current volume, these being subjects that apparently are being covered in this series every other year or thereabouts. In fact it appears to be the policy of the editors to alternate certain subjects and the current volume covers subjects that were included two years ago but were not included in Volume III.

Comments made by the reviewer a year ago respecting Vol. III apply equally well to the recent issue of Vol. IV. The surveys are concise, and critical, and must be very serviceable to the workers in this expansive field of biochemistry. Thimann's review of growth substances in plants, covering, as it does, contributions dating back ten years, constitutes a welcomed addition to the book. Not only has he discussed cell elongation and root formation in the higher plants, but he has included a consideration of growth substances for fungi, and yeast (bios) as well.

It appears to the reviewer that errors have been made in the diagrammatic formulas of tachysterol and the compound intermediate between it and calciferol on page 364. The two double bonds in the ring system are not represented here as conjugated, despite the fact that the text immediately above described them as such, and they were so represented by Rosenheim and King in their paper to which reference is made in the bibliography appended to this chapter.

C. H. BAILEY

The Principles of Quantum Mechanics. By P. A. M. DIRAC. Second edition. Oxford University Press, 114 Fifth Ave., New York, 1935. xi + 300 pp. 16 × 24 cm. Price, $6.00.

This is a book intended for those who are interested in deepening their understanding of the essential significance of quantum mechanics, rather than in the actual solution of problems. The list of topics treated contains few that will not be already familiar to the reader; the method of approach, however, is wholly different from those usually followed.

To the exposition of this method of approach, the first six of the thirteen chapters are devoted. The author's aim is to find statements of the laws of nature which shall be as far as possible free from quantities depending upon arbitrary frames of reference or particular states of mind of the observer. Where such quantities do enter, they must merely illustrate fundamental relations, the latter remaining invariant under all possible transformations of the special terms in which they are stated. This guiding principle is developed in terms of the theory of vectors according to which the mathematical relations of directed quantities can be formulated without the introduction of any particular coördinate system or set of reference vectors, although this is required for the solution of any particular problem. In the present application, the vectors are imagined as existing in a space of infinite number of dimensions. Any particular vector corresponds to a particular state of knowledge of the observer concerning the state of the system under discussion, such as that each particular "observable" (energy, angular momentum, etc.) has a certain probability of having each of its possible values. "Eigenstates" are those for which one or more observables certainly have particular "eigenvalues," and the corresponding vectors, forming a complete orthogonal set, may conveniently serve as coördinate axes in terms of which other vectors may be expressed numerically. Owing to the characteristic impossibility of assigning definite values to several observables simultaneously, the eigenstates and the reference frames corresponding to different observables do not in general coincide. The squares of the coefficients with which the eigenvectors of a given observable must be taken in order to produce by vectorial addition any given vector (as an eigenvector of another observable) are equal to the probabilities that a measurement of the given observable, performed upon the system in the given state, will yield as result the several corresponding eigenvalues.

In order to determine these coefficients, and to discuss other relations between the vectors, it is necessary to introduce tensors, which correspond to observable quantities. When expressed in terms of a given coördinate system, the tensors take the form of the familiar matrices of ordinary presentations of quantum mechanics. The customary processes of matrix multiplication thus appear as simply special methods of representing operations of combining tensors and vectors, whose real meaning (similar to the scalar product of two vectors) is quite independent of any particular system of axes, and which therefore are well suited for stating fundamental laws.

The picture so far is limited to a particular instant of time, and is therefore not properly relativistic. This is a defect which it has not been possible to remedy. The next few chapters are devoted to a study of the way in which the vectors change with the time, giving an account of the motions occurring in the system. An alternative presentation regards the vectors as stationary, but referred to moving axes; the tensors corresponding to observables then become functions of the time. On this basis is developed the theory of simple problems such as motion in a central field, perturbations, collision effects, etc., the final results being those already well-known.

The last three chapters, on Radiation, Relativistic Electron and Field Theory, are devoted to subjects in which the author himself has done much of the pioneer work, and will be valuable as a convenient unified presentation of the essential material.

The book is carefully worked out and well-written. Naturally, it is extremely arduous reading for anyone not accustomed to the formalism and abstractness of modern physical theory, but in the opinion of the reviewer the effort expended upon it will be richly rewarded.

ALBERT SPRAGUE COOLIDGE

Étude Thermodynamique de la Tension Superficielle. (A Thermodynamic Study of Surface Tension.) By RAYMOND DEFAY. Preface by Th. DeDonder. Gauthier-Villars et Cie., Éditeurs, 55 Quai des Grands-Augustins, Paris, France, 1934. xi + 372 pp. 16 × 24 cm. Price, fr. 30.

This volume coördinates the work of the author on surface tension published 1929 to 1934 and contains the material of his doctorate thesis. In the first part of the work he takes up from the beginning the thermodynamic problem of capillary and adsorption phenomena, using the approach of DeDonder, which postpones the assumption of equilibrium to a later point in the reasoning than in the treatment of Gibbs and thus enables the presentation of certain results more general than those of Gibbs. The equilibrium assumptions which the reviewer has noted as being thus postponed are those relating to phase equilibrium and to equilibrium with respect to chemical reactions.

In his logical development he rejects the hypothesis that the surface phase is autonomous, *i. e.*, that its thermodynamic properties can be expressed by functional relations containing only variables appropriate to the surface phase itself. This is of consequence only when there is not equilibrium; for when the hypothesis of "localization of equilibrium" is admitted—that any portion of a system in equilibrium constitutes itself a system in equilibrium—the usual results for equilibrium are obtained.

The reviewer does not agree with a remark (page 77) that this latter hypothesis is introduced by Gibbs when he writes his equation 476, but considers it explicitly introduced in the beginning when Gibbs states that in case of equilibrium the criteria must be satisfied in *all possible variations.*

Defay introduces the radius of curvature into his equations by means of the relation $p'' - p' = \sigma/(R_1 + R_2)$, which is assumed from mechanics. He places the dividing surface always within the region of discontinuity, insisting that the location of this dividing surface is not arbitrary (page 99). His treatment here is very clear. Yet his remarks on Gibbs and his followers seem not entirely adequate, and Gibbs' statements on page 234 seem ignored: (1) that the position of the quantity σ, considered as a tension, is in the surface of tension and, strictly speaking, nowhere else; (2) that the value of σ is independent of the position of the dividing surface, when this is plane; and (3) that the positions which he will consider will not vary from the surface of tension sufficiently to make this distinction of any practical importance. Defay has a right to his own development and this is in several respects simpler than that of Gibbs. The gain here is accompanied, however, by a loss—Defay is not able to derive the Gibbs equation for the so-called adsorption isotherm and does not discuss it.

Under the heading "Catalysis at a Distance," Defay shows the theoretical possibility (depending on the non-autonomy of the surface phase) that a surface may act as a catalyst without any exchange of mass and that surface catalysis can affect the affinity of a reaction.

The phase rule is extended to systems containing surface phases (in both parts of the book) and is often applied in the treatment. Various thermodynamic theorems are generalized to take account of the presence of surface phases and the possibility that equilibrium is not reached.

It is pointed out (page 17) that the surface tension is not necessarily equal (when there is adsorption) to the superficial free energy per unit area.

The second part of the work is so written as not to require preliminary study of the first part. It is entitled "The Extrema [maxima or minima] of Surface Tension and the Indifference of Capillary Systems" and deals mostly with the azeotropic properties of such systems. The conditions of equilibrium of systems containing surfaces which meet *along edges* are discussed, but without consideration of the effects of gravity. The rule of Antonoff 1907 is traced to Poisson 1831 and it is shown that (in a system uninfluenced by gravity) this rule is inconsistent with the presence of edges between coexistent surface phases. Theorems of Duhem, of Saurel, and of Gibbs and Konovalow are generalized.

The book is clearly written by an author obviously competent in mathematics and the theory of thermodynamics. The symbols chosen will give little or no difficulty to readers of Gibbs. There is no index, but the table of contents is unusually effective as it contains over 150 headings.

L. J. GILLESPIE

Physique Moléculaire. Matière et Énergie. (**Molecular Physics. Matter and Energy.**) By VICTOR HENRI, Professor at the University of Liége. Hermann et Cie., Éditeurs, 6 Rue de la Sorbonne, Paris, France, 1933. v + 436 pp. 16 × 24.5 cm. Price, fr. 110.

The ten chapters of the book are entitled: Discontinuity of matter, Determination of the number of molecules, The chemical elements, X-ray spectra, Atomic numbers, Periodic System, Radioactive elements, Isotopes, Disintegration and synthesis of elements, Space properties of the elements, Kinetic theory of gases, Atomic structure.

Inspired by an early attachment to the Leibnizian monadology, the gifted author has burst the walls of his own specialty and tried to write in one moderate-sized volume a compact yet penetrating account of nearly all those aspects of modern molecular and atomic physics which are of special significance for chemistry. Henri's own early studies (1908) of the Brownian movement in rubber latex gave him an interest in molecular theory and the determination of N which make the first chapter (on the discontinuous structure of matter) unusually excellent. In the chapter on the chemical elements (p. 61) he espouses a lost cause when he tries to limit the word "element" to a single atomic species.

The later chapters contain good discussions of ionization and resonance potentials and their significance for the periodic system. The Bohr theory is discussed in some detail, but modern quantum ideas are hardly mentioned. The spatial properties of atoms and ions receive some attention.

The book was surprisingly up to date when it was published two years ago, but has already fallen somewhat behind the rush of new developments in its field. It contains a large number of very useful literature references, but is marred by careless proof reading, particularly of English names. Some random examples are thalium, Lokyer, isote for isotope, Stockes, Bridgeman for Bridgman, John Tydall. On p. 355 and elsewhere Davisson and Germer's discovery is credited to Davisson and Kunsman.

NORRIS F. HALL

The Chemistry of Organic Compounds. A Year's Course in Organic Chemistry. By JAMES BRYANT CONANT, Professor of Chemistry, Harvard University. The Macmillan Company, 60 Fifth Avenue, New York, 1933. x + 623 pp. 14.5 × 22.5 cm. Price, $4.00.

The present text, designed for a full year course in organic chemistry, and an appropriate expansion of the author's excellent "Brief Introductory Course," has much to recommend it. It is concisely and logically written; it adapts itself admirably to classroom usage; and it gives a true appreciation of the scientific method.

The author has made use of the electron theory of valency with excellent discrimination, employing it in cases where it is generally regarded as of value to the organic chemist, and avoiding it when it would make for confusion in the minds of elementary students.

There is material beyond the scope of the usual course, but this is of particular advantage for the instruction of the honors type of student, to whom, in most institutions, special reading is given.

In short, then, this text is a very notable addition to the group of the few worthwhile texts of its degree of difficulty in organic chemistry.

ARTHUR J. HILL

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. Volume XIV. **Fe** (Part III), **Co.** By J. W. MELLOR, D.Sc., F.R.S. Longmans, Green and Co., 114 Fifth Avenue, New York City. viii + 892 pp. 277 figs. 15.5 × 25 cm. Price, $20.00.

The first part (416 pages) of this volume concludes the section on iron, recounting the physical and chemical properties of the salts of iron. The remainder of the volume (some 476 pages) is devoted to the element cobalt and its compounds.

The treatment throughout is analogous to, and maintains the same high quality as, that of previous volumes.

There remain but two volumes of this monumental handbook to appear: Volume XV, covering nickel and the elements of the platinum group other than platinum itself, and Volume XVI, covering platinum and containing the General Index for the whole Treatise. The publisher states that both of these volumes are in the press.

ARTHUR B. LAMB

Annual Tables of Constants A. T. C. and Numerical Data Chemical, Physical, Biological and Technological, published under the patronage of the International Union of Chemistry. Volume X (1930). McGraw-Hill Book Co., Inc., 330 West 42d St., New York, 1935. Two parts, about 1800 pages. Price (for subscribers) cloth, $20.00.

In the Introduction to this Volume X (1930) of the Annual Tables, Dr. Marie, Editor-in-Chief, states:

"When Volume IX was published in 1931, we hoped that the period of the difficulties which we had to overcome was at last over and that we should be able to take up again the publication of annual Volumes. This hope, however, was not fulfilled. The financial means which we thought we could rely upon have been reduced to such an extent that we were compelled to suspend the printing of the Annual Tables. The general economic crisis is responsible for this situation. Consequently, we had to postpone the publication of Volume X, which brings to a close our 2nd series and of the Index to this series.

"We hope that this work will be completed in the course of 1935. We further hope to be able, at the same time, to start with the publication of the data of the years 1931 to 1934 in Volume XI, which is to be the first of our 3d series."

This volume follows the same method and exhibits the same excellence that have characterized the earlier volumes. Dr. Marie and his collaborators deserve both our gratitude and our congratulations in having kept alive this important branch of scientific documentation during a prolonged and world-wide period of depression.

It also should not be forgotten by those who have difficulty with the French language that all texts in the Annual Tables of Constants are given in both French and English.

ARTHUR B. LAMB

An Introduction to Quantum Theory. By G. TEMPLE, F.R.S., Ph.D., D.Sc., Imperial College of Science and Technology, London. D. Van Nostrand Company, Inc., New York, 1934. 196 pp. 14 × 22 cm.

This book covers the topics usual to an elementary text on quantum mechanics, including a discussion of both the wave equation and matrix mechanics, with a few elementary applications; finally the relativistic theory of the electron is presented. The treatment is based squarely on classical mechanics and relativity, and the relation between these older branches of physics and the quantum mechanics is constantly brought out and emphasized. For this reason the book will be useful to those who are interested in the fundamental aspects of the subject. It may also be recommended to beginners in quantum mechanics who are thoroughly grounded in classical physics, though it seems likely that on account of its rather abstract and formal style it will not appeal to chemists as much as some of the other books on the subject now available.

O. K. RICE

Atomic Structure and Spectral Lines. By ARNOLD SOMMERFELD. Translated from the Fifth German Edition by HENRY L. BROSE, M.A., D.Phil., D.Sc., Lancashire-Spencer Professor of Physics, University College, Nottingham. Volume I. E. P. Dutton and Company, Inc., 286–302 Fourth Avenue, New York, 1934. xi + 675 pp. 151 fig. 14.5 × 22.5 cm. Price, $10.80.

In the development of quantum theory since the advent of the Bohr atom in 1913, there has probably been no one book which has been first and last of as great value and influence as the various editions of Sommerfeld's "Atomic Structure and Spectral Lines." In this connection we may well quote what the translator (Brose) says of Professor Sommerfeld: "He has earned the gratitude of physicists throughout the world for carrying out so successfully the monumental task of a comprehensive and lucid exposition of modern atomic physics." The volume in question is such a well-known one that a review of its contents seems scarcely necessary, except to remark on how it differs from the earlier editions. Like the earlier ones, it does not utilize the methods of quantum mechanics, except for occasional quotation of results. Instead the presentation of the new mechanics is deferred to a promised second volume, which will be an amplification of Sommerfeld's well-known and excellent "Wellenmechanische Erganzungsband" (translated under the title "Wave Mechanics"). Of course this plan keeps the procedure in the first volume from being too mathematical, and there is a great deal to be said in favor of the author's statement that "it is possible to understand the new theory only by building it up from the old." Still there are many cases where the situation is really more lucid and intelligible if the new analysis has first been developed.

As compared with earlier editions, sections have been added on the Pauli principle, hyperfine structure, complex spectra, and other subjects. In the discussion of helium, one misses the dramatic quotation from Faust "Hier stock'ich schon; wer hilft mir weiter fort?" found in earlier editions. The dilemma of the helium atom has been explained away by the new quantum mechanics, and the words of Faust are no longer necessary. However, the revision is not sufficiently drastic and recent that the volume can be classed as up-to-date, particularly as regards references to the literature. It is, for instance, somewhat startling to learn that the most recent experimental determinations of the hydrogen fine structure are those of G. Hansen in 1925. Actually a whole bibliography could be given of later papers. It is now, we believe, generally conceded that the old theory of Fues and Wentzel of "partially penetrating orbits" discussed in section 5 of Chap. VII is not the true explanation of the anomalous behavior of the principal series of mercury, but that rather the latter is due to a perturbation effect, as proposed by Shenstone and Russell in 1932, and so on.

A major reason why the volume is not more modern is that whereas the German edition was written in 1931, the English translation did not appear until 1934, without any attempt to collate with publications in the intervening period (except for a translator's addendum of five papers largely on nuclear structure).

J. H. VAN VLECK

Alkaloidhaltige Genussmittel, Gewürze, Kochsalz. (Alkaloid-Containing Luxuries, Condiments, Cookery Salt.) By E. BAMES, A. BEYTHIEN, C. GRIEBEL, H. HOLTHÖFER, P. KOENIG, R. STROHECKER, K. TÄUFEL, J. TILLMANS. Bömer–Juckenack–Tillmans, "Handbuch der Lebensmittelchemie," Vol. VI. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1934. ix + 604 pp. 344 figs. 17.5 × 25.5 cm. Price, RM. 76; bound, RM. 79.60.

This is volume six of a series of eight volumes of a Handbook of Food Chemistry which are not appearing in numerical order. Volume one—a general introduction to the series—was reviewed in THIS JOURNAL [**56,** 1429 (1934)] by C. A. Browne. This volume is divided into six principal sections and an appendix, each by a separate compiler: I, Coffee, coffee substitutes and adulterants (Täufel); II, tea, tea substitutes, maté and cola (Strohecker); III, cocoa and chocolate (Beythien); IV, tobacco (Koenig); V, condiments (Griebel); VI, cooking salt (Strohecker); and the supplement which gives a very brief digest of the laws and regulations under which the products are sold in various countries (Holthöfer–Bames). Under coffee (for example), the compiler (Dr. Täufel) describes the botanical and geographical sources of the product, its varieties and physical properties and gives methods for the determination of the principal chemical constituents such as ash, water-soluble extract, caffeine, nitrogenous substances, etc. The composition of unroasted and roasted coffee and the changes which take place in roasting are discussed at considerable length. Several brands of "caffeine-free" coffees are named and the methods for preparing them are described in a general way. The chapter on the microscopical characteristics of coffee and its substitutes is by Griebel, although most of the drawings are taken from Moeller rather than from the author's publications. The other sections of the work are treated in a similar manner. The references to German writings on all of the topics are very complete but the authors have made almost no use of the literature in English. It is difficult for the reviewer to understand how it was possible to compile a work of this character and omit nearly all references to American or English contributors. For example, the Power–Chesnut method for determining caffeine, which was published in 1919, and which has been adopted by the Association of Official Agricultural Chemists, is not mentioned. Instead, other less reliable methods are given. Again, the Self and Rankin method for the determination of theobromine and theophylline, which has been known for several years and is official now in the British Pharmacopoeia, is not considered.

Six methods for determining volatile oils in such materials as cinnamon and cloves are given but no editorial opinion is expressed as to which is considered best. The Clevenger method, which has attained such wide recognition in this country because of its relative simplicity and broad applications, is overlooked. Even where the original papers on other topics are in English, such as Schmitt's researches on the assay of theophylline, the compiler refers only to abstracts in German. The reviewer did not observe a single reference to any method adopted by the Association of Official Agricultural Chemists and noted but few references to papers published in its Journal. The volume includes a workable index. Throughout the work there is neglect to discuss critically the merits of the several methods for the determination of a given substance where more than one procedure is given. From the standpoint of the analyst this is the most conspicuous fault in the volume. Because of its lack of critical judgments and because of its general ignoration of the chemical literature of the world (except German) this volume of the work will not be as serviceable to American chemists as it would otherwise have been. It is hoped that these defects will be remedied in future editions.

Ricinus Lipase, its Nature and Specificity[1]

BY HERBERT E. LONGENECKER[2] AND D. E. HALEY

The lipolytic principle of the castor bean (*Ricinus communis*) has engaged the attention of many research workers since its presence was first proved in 1890 almost simultaneously by Green[3] and Sigmund.[4] However, a review of the available literature on the active substance, Ricinus lipase, has failed to reveal any general concordance of experimental results. Haley and Lyman's discovery[5] that with oils optimum conditions for activity were obtained only within narrow limits of hydrogen ion concentration, about *p*H 4.7–4.8, made it necessary to repeat most of the previous work.

The object of the present investigation was to prepare a highly active, dry and stable preparation of Ricinus lipase from resting castor seeds and to study the nature of its action and its relative specificity in the hydrolysis of various vegetable and animal oils. These studies were undertaken to elucidate the mode of action of Ricinus lipase and to contribute to the knowledge of enzyme action in general.

Experimental

A. Preparation of Lipase Material.—Ricinus lipase was prepared from large size castor beans[6] by hulling and macerating them, extracting the fat as completely as possible with low boiling petroleum ether (20–40°), and finally drying, pulverizing and sifting the finished product through a 60-mesh sieve. This is a modification of the method given by Haley and Lyman.[5] Other methods for the preparation of Ricinus lipase have been reviewed by Longenecker.[7] Most of them are less suitable.

B. Estimation of Activity.—In all experiments reported here, a standard procedure was adopted for the determination of lipolytic activity: 1.00 gram of oil was weighed into five-cc. hard-glass bottles and two drops of toluene added to prevent bacterial action. To this was added a weighed quantity of enzyme material and its activator, tenth normal acetic acid. The *p*H of the resulting mixture was 4.8. It was emulsified by vigorous shaking for three minutes. Digestion was carried on at a temperature of 37°. To prevent loss of any of the digestion materials, the bottles were stoppered with paraffined corks. The results reported represent averages of triplicate determinations. "Blanks" always accompanied the samples.

After a definite time of incubation, the reaction mixture was placed in 50 cc. of hot 95% alcohol and the free fatty acids in the digestion mixture were titrated with 0.1 *N* alkali using phenolphthalein as the indicator. The starting time for each experiment was that time when acetic acid was added to the digestion mixture; the final time, when the reaction mixture was placed in the alcohol. It was found by preliminary experiments that no hydrolysis took place until after addition of the acid and that hydrolysis was completely inhibited in the amount of alcohol used in the titration.

Titration results are of little value, *per se*, in studies of the relative specificity of lipolytic catalysis of oils although several workers have reported their findings in this way. A more significant expression is the percentage of oil hydrolyzed or the number of moles of triglyceride hy-

(7) Longenecker, M. S. Thesis, The Pennsylvania State College, 1934.

drolyzed. For the calculation of the percentage hydrolysis, the formulas suggested by Sudborough, Watson and Varma and Wilson and Merrill[8] have been used as a basis. The difference between the volume of alkali required for the sample and that required for the blank is a measure of the fatty acids resulting from the direct cleavage of glycerides due to the action of the lipase; the ester number is a measure of the total fatty acids in glyceride combination. To obtain the percentage hydrolysis, the following formula has been used

$$\frac{\text{cc. } 0.1\ N \text{ alkali (sample)} - \text{cc. } 0.1\ N \text{ alkali (blank)}}{\text{Saponification no.}^{a} - \text{Free fatty acid no.}^{a}} = \%\ \text{hydrolysis}$$

[a] Expressed in cc. of 0.1 N alkali.

C. Activity of Old and New Preparations.—The ability of Ricinus lipase to retain its activity over a long period was demonstrated in the following experiment in which the activity of a sample similarly prepared by one of us in 1924 was compared with that of a freshly prepared sample: 1.00 gram of olive oil and 0.6 cc. of 0.1 N acetic acid were used; the amount of enzyme material was varied; one set of samples (A) was shaken for three minutes at the start, then allowed to stand for twenty-four hours at 29–30°; another set of samples (B) was shaken continuously by machine for fourteen hours then allowed to stand for ten hours at 29–30°. The results are given in Table I.

TABLE I

COMPARISON OF ACTIVITIES OF TEN-YEAR OLD AND NEW PREPARATIONS

Treatment	Percentage ten-year old sample 0.050 g.	0.100 g.	Hydrolysis new sample 0.050 g.	0.100 g.
A	6.79	17.82	77.83	86.00
B	14.03	49.36	85.43	86.70

TABLE II

TYPICAL RATE OF REACTION AND THE EFFECT OF TEMPERATURE AND SHAKING

In each experiment, 1.00 g. of olive oil, 0.6 cc. of 0.1 N acetic acid, 0.100 g. of lipase material and two drops of toluene were shaken together and incubated at 37–38°. A, shaken for three minutes at the start. B, shaken for three minutes at the start, let stand for thirty minutes and shaken again for two minutes. C, same as A except that temperature was 27–28°.

Time of digestion	Percentage hydrolysis A	B	C
5 min.	11.02	...	...
10 min.	19.35	...	25.88
15 min.	31.91	...	...
20 min.	38.33	...	44.70
30 min.	39.22	...	...
40 min.	50.63	...	55.88
45 min.	...	57.93	...
50 min.	51.91	...	...
60 min.	59.60	66.39	59.66
2 hrs.	65.37	74.85	67.80
3 hrs.	71.14	79.34	71.90
5 hrs.	72.42	80.50	...
10 hrs.	74.21	...	...
24 hrs.	77.80	77.42	...

D. Rate of Hydrolysis of Olive Oil.—Olive oil was selected as a substrate to demonstrate, first, typical rates of reaction and second, some of the factors influencing it. In Table II, data are given which express (A) a normal rate of reaction, (B) the effect of shaking the digestion mixture after the reaction has proceeded for thirty minutes and (C) the effect of temperature.

E. Relative Specificity of Ricinus Lipase Action.—A study of the rates of hydrolysis of various members of a general group of substances should yield information as to the relative specificity or affinity of an enzyme for a particular substrate. A variety of oils of vegetable and animal origin were selected for specificity studies. Rates of hydrolysis of these oils are found in Table III.

Discussion

In analyzing and interpreting these results the nature of the active material must be considered. "Ricinus lipase" has been used here to represent the hulled, fat-free, resting castor seeds. Proteins, carbohydrates and salts originally present have not been removed from the final product.

It is significant that a ten-year old preparation retained a fairly high activity compared with a fresh sample. Enzymatic activity is known to decrease considerably in short periods, especially when the enzymic material is in solution. Dry preparations are usually more stable. So far as the authors can ascertain, however, there is no report in the literature showing the retention of activity of any enzyme preparation over a period of ten years.

One condition that appears to be a *sine qua non* factor for Ricinus lipase activity is the colloidal state. One may assume that an emulsion arises in a heterogeneous system such as the digestion mixture of oil, enzyme and dilute acid. Sudan III and conductivity tests indicated in this work that it is of the water-in-oil type under the experimental conditions. This type of emulsion was favorable for the action of Ricinus lipase. In fact, there is every reason to believe that the enzyme is not as active in an emulsion of the opposite type.

The production of a suitable emulsion was aided decidedly by shaking the digestion mixture. Shaking by hand for three minutes ensured that approximately the same degree of emulsification was obtained at the beginning of each experiment. Once formed, however, the emulsion was not stable. It tended to separate into layers of water and oil within one-half hour, when the rate of hydrolysis began to decrease. Shaking the digestion mixture at this point restored the emul-

Rape	39.52	48.36	54.95	62.02	71.49	69.89	77.44	81.14	83.45
Sperm	10.18	13.71	16.83	20.36	18.28	18.89	23.68	19.53	23.47
Soybean	17.66	35.05	53.13	61.30	77.64	73.99	84.35	84.94	89.17
Whale	16.77	25.33	26.26	28.98	32.82	35.14	37.67	41.81	41.71

sion and with it there was an increased rate and extent of reaction in a given time, as is seen in Table II.

A higher percentage of hydrolysis in cases where a lower temperature was used, as shown also in Table II, can be correlated with the stability of the emulsion. In each case it was observed that the tendency for the emulsion to break was much less at the lower temperature.

That Ricinus lipase exhibits a differential rate of attack for various oils appears obvious from Table III. Previous investigators have reported similar experiments and results.[9-13] In the majority of cases, it has been emphasized that the Ricinus lipase exhibited a relative specificity for those glycerides of high molecular weight. The results above seem to offer support for this argument, with a few exceptions. Thus, for the various oils used, listed in the order of decreasing percentage hydrolysis, the mean molecular weights are:

Oils	Mean mol. wt.	Oils	Mean mol. wt.
Peanut	870	Linseed	786
Castor	921	Neat's-foot	995
Corn	895	Peach kernel	785
Cottonseed	870	Coconut	589
Soybean	869	Whale	590
Rape	956	Fish	616
Olive	765		

However, if another line of reasoning be adopted, this apparent specificity disappears almost entirely. When the number of moles of glyceride hydrolyzed after a given time is considered, no relative specificity of Ricinus lipase is observed. The results are all of the same order of magnitude and the probability that any individual variations are due to an actual difference in specificity is very low indeed.

Summary and Conclusions

A dry, stable and highly active preparation of Ricinus lipase has been obtained from hulled castor beans by extracting the fat with low boiling petroleum ether, pulverizing and sifting the residue of the bean through a 60-mesh sieve. The activity of this fresh preparation was compared with that of one ten years old. Considerable activity was obtained with the latter.

A water-in-oil emulsion appears to be desirable for Ricinus lipase action. The formation of this emulsion was aided by shaking and by lower temperatures of incubation.

Rates of hydrolysis of a variety of oils of vegetable and animal origin were obtained for studies on the nature of action and specificity of Ricinus lipase. Under the experimental conditions, Ricinus lipase catalyzed the hydrolysis of the following oils, listed in order of decreasing percentage hydrolysis after a given time: peanut, castor, corn, cottonseed, soybean, rape, olive, linseed, neat's-foot, peach kernel, coconut, whale, fish and sperm. An analysis of the data on the basis of the number of moles hydrolyzed revealed that the lipase showed no specificity in its attack on glyceride molecules containing carbon chains of different length.

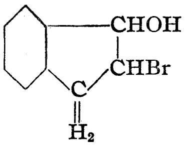
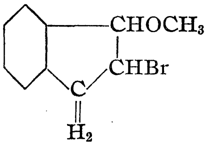
Some Bromine Derivatives of Indene and Indane[1]

BY H. D. PORTER AND C. M. SUTER

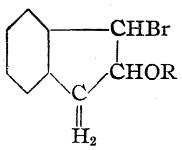
It was shown by Courtot[2] and co-workers that the well-known indene bromohydrin has structure I since on oxidation it gives 2-bromo-1-indanone. Von Braun and Weissbach[3] therefore logically assumed that the methoxybromoindane obtained from indene dibromide and methanol had structure II. On the other hand, Jacobi[4] has presented evidence indicating that the alkoxybromoindanes prepared in this manner correspond to III.



I



II



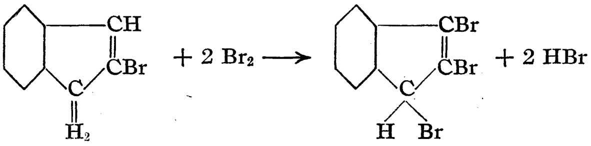
III

The present investigation was undertaken to explain this apparent contradiction and amplify the available information concerning other bromine derivatives of indene and indane.

Indene bromohydrin, either upon pyrolysis at 150–160° or by dehydration with phosphorus pentoxide, is converted into 2-bromoindene, m. p. 38–39°. The structure of this compound was confirmed by reaction with sodium ethoxide and hydrolysis of the resulting ethoxyindene to 2-indanone by the action of dilute acid. Thermal decomposition of indene dibromide likewise gives 2-bromoindene although the yield is somewhat lower. Jacobi[4] reported that the compound formed in this reaction was 1-bromoindene. Apparently unknown to Jacobi, 1-bromoindene had been prepared previously[5] by the action of cyanogen bromide upon indenylmagnesium bromide and has quite different properties from the 2-bromoindene obtained from indene dibromide. As evidence for the structure he proposed, Jacobi found that the Grignard reagent of the bromoindene gave indene-1-carboxylic acid. It would not be surprising to obtain this acid from 2-bromoindene because of the activity of the methylene hydrogens in indene toward Grignard reagents.[6] However, upon repeating Jacobi's experiment numerous times, the only product isolated was a low yield of indene-2-carboxylic acid.[7]

2-Bromoindene is inert toward boiling aqueous alkali or potassium formate in methanol. It adds hydrogen bromide in glacial acetic acid to give indene dibromide, identified by hydrolysis to the bromohydrin. Various attempts to alter the manner in which addition occurred by a change of solvent and the presence of hydroquinone or benzoyl peroxide[8] were unsuccessful.

Bromine reacts readily with 2-bromoindene in carbon tetrachloride at room temperature with evolution of hydrogen bromide. The product obtained is apparently 1,2,3-tribromoindene as it contains only one hydrolyzable bromine and upon oxidation gives phthalic acid.



IV V

The exact mechanism of the bromination is uncertain. The "tribromoindane" obtained by Jacobi[4] from his supposed 1-bromoindene is probably V. 1,2,3-Tribromoindane had been prepared considerably earlier[5] by addition of bromine to 1-bromoindene. It is a solid melting at 133–134° while Jacobi's product was described as an oil. Jacobi's 1,3-dibromo-2-hydroxyindane (m. p. 90°), VI, is unexplained as the VII obtained in this investigation did not crystallize. 1,2,3-Tribromoindane, obtained from indene dibromide and bromine,[9] was found to be unexpectedly inert toward hydrolysis and no hydroxydibromoindane could be isolated for comparison with Jacobi's product.

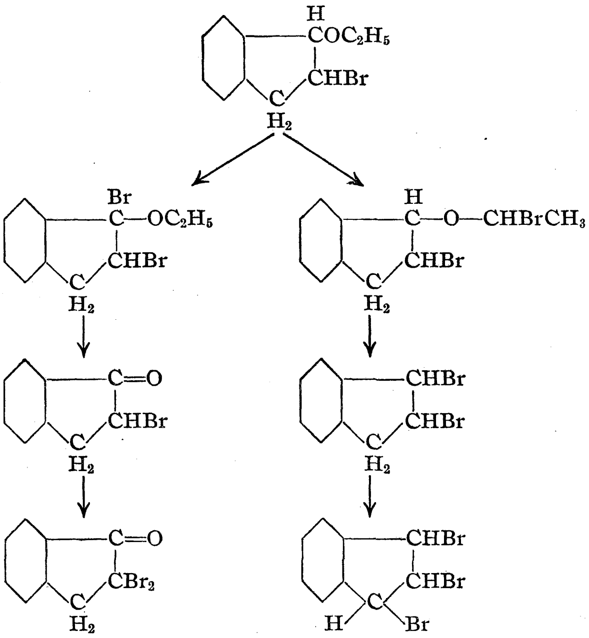
Refluxing indene dibromide with ethyl alcohol gives a mixture containing 1-ethoxy-2-bromoindane, 2-bromoindene and indene dibromide. The pure ethoxy compound is obtainable by adding pyridine to the mixture to carry the alcoholysis to completion or by removal of the unchanged indene dibromide by hydrolysis to the bromohydrin or glycol. Jacobi's 3-bromoindene[4] was apparently a mixture of indene dibromide and ethoxybromoindane. It was noted in one preparation of the ethoxy compound that calcium chloride which was accidentally introduced into the mixture greatly increased the amount of 2-bromoindene formed. Here sodium carbonate was added to hydrolyze the unchanged indene dibromide.

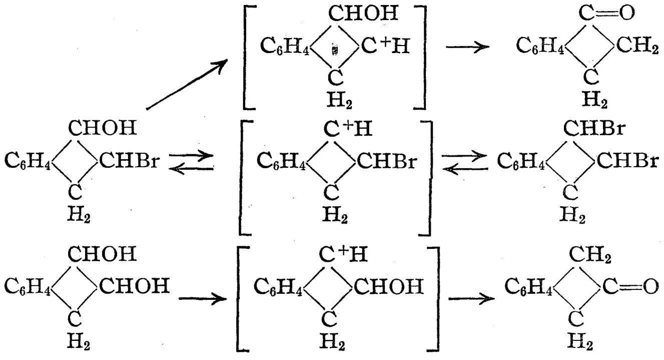


The structure of the ethoxybromoindane was established by converting it into 1-indanone through reaction with sodamide in liquid ammonia followed by acid hydrolysis of the enol ether.

The bromine in 1-ethoxy-2-bromoindane is quite unreactive, prolonged heating with aqueous sodium hydroxide or potassium acetate in glacial acetic acid having little effect. Bromination in boiling carbon tetrachloride gave a mixture of 2,2-dibromo-1-indanone and 1,2,3-tribromoindane. The formation of these products is explainable upon the basis of the behavior of α-chloro ethers toward heat.[10] The reaction probably proceeds by the steps indicated above.

Trans indene glycol was obtained in 60–70% yields by hydrolysis of indene bromohydrin with aqueous sodium carbonate. This yield is twice that obtained by the hydrolysis method of Weissgerber[11] and the procedure is much simpler than the one involving the preparation and hydrolysis of indene diacetate.[11,12] Conversion of the glycol and of indene oxide[12] to 2-indanone by boiling with dilute acid has been reported by several investigators.[11,12,13] In the present work it was found that both indene bromohydrin and 1-ethoxy-2-bromoindane under similar treatment yield 1-indanone. Since indene bromohydrin was found to be readily obtainable from a drip oil fraction containing less than 50% indene, both indanones are now readily accessible.

The formation of 1-indanone from indene bromohydrin has considerable bearing upon the validity of the mechanism advanced by Whitmore[14] to explain aldehyde and ketone formation from the hydrolysis of dibromides. According to this mechanism the hydrolysis of indene dibromide or treatment of indene bromohydrin with dilute acid should produce 2-indanone, whereas actually none of this results. As long as the bromine atom remains attached to carbon atom 2 the hydrogen joined to this carbon is apparently immobilized. This is not the case for the corresponding hydrogen in indene glycol. These reactions may be formulated thus



By analogy it seems likely that in the conversion of an aliphatic dibromide containing a tertiary bromine to an aldehyde or ketone the formation of the glycol precedes that of the carbonyl compound.

Practically all of the indene dibromide employed in this investigation was prepared from indene bromohydrin and hydrobromic acid. This dibromide was found to be identical with that obtained directly from indene. In view of the recent work of Bartlett[15] upon the *cis* and *trans* cyclohexene chlorohydrins, it is probably that indene bromohydrin is the *trans* isomer as it yields indene oxide with great ease. Correspondingly, the indene chlorohydrin obtained in larger amount by the hydrolysis of indene dichloride[2] would be the *trans* isomer. The fact that 1-indanone was obtained as the final product in the action of sodium methoxide upon the other (*cis*) indene chlorohydrin tends to confirm these structures.

Experimental

Indene Bromohydrin.—Bromine water was added in successive 2-liter quantities to 165 g. of a crude indene, b. p. 176–182°, obtained by the fractionation of drip oil or crude solvent naphtha[16] and the mixture stirred vigorously. The spent bromine water was siphoned off before addition of the next portion. When no more bromine reacted the pasty product was filtered and washed with benzene. The yield was 95 g. or 31%, assuming the starting material to be 100% indene. The product thus prepared melted at 126–128°. Similar preparations employing pure indene have been described previously.[17]

Preparation of 2-Bromoindene.—(1) A solution of 22 g. of indene bromohydrin in 150 cc. of carbon tetrachloride was refluxed with 7 g. of phosphorus pentoxide for two hours. The solution was decanted from the phosphoric acid and distilled. The fraction distilling at 123–124° (22 mm.) solidified on cooling and after recrystallizing from methanol melted at 38–39°. The yield was 11 g. or 55% of the theoretical amount.

(2) Heating 10.5 g. of indene bromohydrin in a small flask in an oil-bath at 155–160° for two hours gave 4 g. of crude 2-bromoindene, b. p. 123–128° (17 mm.). A better method was as follows. A mixture containing 25 g. of indene bromohydrin and 40 cc. of bromobenzene, b. p. 156°, was distilled very slowly, additional bromobenzene being added at the same rate through a dropping funnel. The end of the reaction was indicated by the absence of water in the distillate. Distillation of the residue gave 10.2 g. or 45% of the theoretical amount of product, boiling at 125–127° (23 mm.), which solidified upon standing. Recrystallization gave the pure 2-bromoindene, m. p. 38–39°.

Anal. Calcd. for C_9H_7Br: Br, 41.02. Found: Br, 40.9.

2-Indanone from 2-Bromoindene.—Two grams of 2-bromoindene was added to 10 cc. of 100% ethyl alcohol in which 0.5 g. of sodium had been dissolved. The mixture was refluxed for three hours, poured into excess 10% sulfuric acid and steam distilled. After removal of the alcohol a small amount of an oil came over. Upon crystallization from petroleum ether this melted at 57–58°. This was identified as 2-indanone[18] by conversion to the oxime, m. p. 152°.

Refluxing 2-bromoindene with 2 *N* sodium hydroxide for two hours gave negative results, as did refluxing with potassium formate in methanol for sixteen hours.

Indene-2-carboxylic Acid.—Four grams of 2-bromoindene was treated with 0.5 g. of magnesium in 25 cc. of dry ether. The reaction was started by using a few drops of an ethylmagnesium bromide solution. After refluxing for two hours the solution was cooled and carbon dioxide introduced. After working up the product in the usual manner there was obtained 0.5 g. of indene-2-carboxylic acid,[7] m. p. 228–229°. The only other product noted was indene. Various modifications of this procedure gave substantially the same results.

2-Bromoindene and Hydrogen Bromide.—A solution containing 0.5 g. of 2-bromoindene in 5 cc. of 37% hydrogen bromide in glacial acetic acid was allowed to stand for a day. The oil obtained, n^{25}_D 1.6285, gave upon refluxing in an acetone–water mixture for two hours and cooling, crystals of indene bromohydrin, m. p. 128°. This result was not affected by the addition of a small amount of either benzoyl peroxide or hydroquinone to the acetic acid solution.

The reaction between hydrogen bromide and 2-bromoindene in benzene in the presence of benzoyl peroxide was incomplete after two days. The only reaction product found was again indene dibromide. When the benzoyl peroxide was replaced by hydroquinone the 2-bromoindene remained practically unchanged after two days. Warming the reaction mixture on the steam-bath, however, again gave a trace of indene dibromide.

Bromination of 2-Bromoindene.—To 7.4 g. of 2-bromoindene dissolved in carbon tetrachloride was added bromine in the same solvent until the color persisted. During the course of the reaction hydrogen bromide was evolved copiously. The solution was washed with aqueous sodium bisulfite, dried, and the solvent allowed to evaporate. The product was an oil, n^{25}_D 1.6615, d^{25} 2.12. It could not be distilled but judging by its analysis and behavior it was a pure substance. The yield was 13 g. or 97% of the theoretical amount.

Anal. Calcd. for $C_9H_5Br_3$: Br, 68.05. Found: Br, 67.8.

Oxidation with aqueous potassium permanganate gave phthalic acid, m. p. 184–186°, which upon heating above its melting point gave the anhydride, m. p. 128°.

Hydrolysis of 1,2,3-Tribromoindene.—The tribromoindene decomposed to a tar when treated with aqueous alkali. Hydrolysis by boiling in acetone–water solution over calcium carbonate followed by steam distillation gave a few drops of an oil, n^{22}_D 1.6350, which analyzed for a dibromoindenol.

Anal. Calcd. for $C_9H_6OBr_2$: Br, 55.3. Found: Br, 54.9.

Indene Dibromide from Indene Bromohydrin.—A mixture of 38 g. of indene bromohydrin and 130 cc. of

[15] Bartlett, This Journal, **57**, 224 (1935).

[16] This material was supplied through the courtesy of Mr. R. B. Harper, Vice-President, and Mr. E. F. Pohlmann, Chief Testing Engineer, of the Peoples Gas Light and Coke Company of Chicago, to whom we wish to express our appreciation.

[17] Pope and Read, *J. Chem. Soc.*, **99**, 2071 (1911); **101**, 760 (1912).

[18] Schad, *Ber.*, **26**, 222 (1893), first prepared this compound.

47% hydrobromic acid was stirred on the steam-bath for three hours. The oily layer was separated, dried with calcium chloride and distilled at 1 mm. The main fraction, b. p. 100–105°, was indene dibromide, n^{25}_{D} 1.6290, d^{25}_{4} 1.747. The yield was 31 g. or 61% of the theoretical amount. The product distilling at 77–100° (1 mm.), which came over as a forerun, solidified upon cooling and proved to be 2-bromoindene, m. p. 38–39°. Some difficulty was encountered at first in inducing the indene dibromide to crystallize. Satisfactory results were finally obtained by cooling its petroleum ether solution to a low temperature. The product, m. p. 32°, was found to be identical with that obtained from indene. No other dibromide could be isolated.

Pyrolysis of Indene Dibromide.—(1) Upon heating 25.6 g. of indene dibromide in a flask in an oil-bath at 200–210° for one hour hydrogen bromide was evolved and the residue distilled at 113–115° (13 mm.). It solidified upon cooling and after recrystallization from alcohol melted at 38–39°. A mixed melting point with 2-bromoindene gave the same value. The yield was 3.3 g. or 16% of the theoretical amount.

(2) Refluxing 19 g. of indene dibromide in 30 cc. of dry tetralin (b. p. 205–210°) as long as hydrogen bromide was evolved (four hours) gave 4.8 g. or 36% of the theoretical amount of 2-bromoindene.

Preparation of 1-Ethoxy-2-bromoindane.—(1) A mixture of 40 cc. of 100% ethyl alcohol and 20 g. of indene dibromide was refluxed for four hours. During the third hour a total of 6.5 g. of pyridine was added slowly. Water was then added and the oily layer separated, washed, dried and distilled. There was obtained 6.7 g. of product, b. p. 144–148° (19 mm.), which is 38% of the theoretical amount. A portion, b. p. 147–148° (19 mm.), n^{25}_{D} 1.5515, d^{25}_{4} 1.344, was analyzed.

Anal. Calcd. for $C_{11}H_{13}OBr$: Br, 33.15. Found: Br, 33.2.

In similar experiments in which pyridine was not added the product always contained unchanged dibromide, besides a trace of 2-bromoindene.

(2) In another experiment, after refluxing 40 g. of indene dibromide with 105 cc. of alcohol containing about 5 g. of calcium chloride for five and one-half hours, 20 cc. of water and enough saturated sodium carbonate solution were added to make the mixture alkaline. This was then stirred on the steam-bath for four hours. More water was added and the product separated and dried. There was obtained 13.4 g. of material, b. p. 143.5–144.5° (17 mm.), which is 38% of the theoretical amount. A forerun of 9 g. of 2-bromoindene, b. p. 132–136°, was also recovered.

Proof of Structure of 1-Ethoxy-2-bromoindane.—A solution of sodamide in liquid ammonia was prepared by treating 0.24 g. of sodium with 50 cc. of the solvent in the presence of a trace of ferric oxide. To this solution was added 2.5 g. of the ethoxy compound. The residue remaining after the gradual evaporation of the ammonia was extracted with ether and the oil thus obtained was steam distilled from 10% sulfuric acid. From the oil in the distillate there was obtained through treatment with hydroxylamine hydrochloride and sodium acetate in methanol followed by dilution with water, crystals of 1-indanone oxime,[19] m. p. 143–144°. This was identified by a mixed m. p. with an authentic sample.

Bromination of 1-Ethoxy-2-bromoindane.—A boiling solution of 2.5 g. of the ethoxy compound in 25 cc. of carbon tetrachloride was treated with bromine as long as reaction occurred. The solvent was removed and the residue recrystallized from petroleum ether. This was a mixture, m. p. 100–106°, in which two types of crystals were evident. Those with a needle-like appearance were separated mechanically and after recrystallization from methanol melted at 133–134°. A mixed melting point indicated the substance to be 1,2,3-tribromoindane.[9] Fractional crystallization of the original mixture from ether or ether–benzene gave rhombic crystals likewise melting at 133–134°. These were found to be 2,2-dibromo-1-indanone[19] through comparison with a sample of this substance prepared from 1-indanone.

Preparation of Trans Indene Glycol.—The following procedure was found to be more convenient than those in the literature.[11,12] A mixture of 350 cc. of saturated aqueous sodium carbonate and 17 g. of indene bromohydrin was stirred on the steam-bath for three hours. After cooling, the mixture was filtered and the product treated with hot water to separate the glycol from an insoluble tarry material. Cooling the water solution gave 6.8 g. of *trans* indene glycol, m. p. 159°, which is 60% of the theoretical amount. The water-insoluble material (4.7 g.) upon treatment with methanol left a residue which melted above 285°. Treatment of 1-indanone with aqueous sodium carbonate gave a similar product while the glycol was unaffected by long heating with the carbonate. It seems probable that 1-indanone is the precursor of this by-product.

Preparation of 1-Indanone.—A mixture of 400 cc. of 7% (by volume) sulfuric acid and 20 g. of indene bromohydrin was refluxed for ten hours. Steam distillation gave an oil, b. p. 117–118° (15 mm.), which solidified upon cooling and melted at 42° after crystallizing from petroleum ether. The yield was 10 g. or 80.6% of the theoretical amount. The oxime melted at 145–146°.

Preparation of 2-Indanone.—Refluxing 4 g. of *trans* indene glycol with 7% (by volume) sulfuric acid for one hour gave 2.5 g. or 71% of 2-indanone, m. p. 58–59°.

1-Indanone from 1-Ethoxy-2-bromoindane.—A mixture of 20 cc. of 10% (by volume) sulfuric acid and 1.1 g. of the ethoxy compound was refluxed for eight hours. Steam distillation gave 0.32 g. or 53% of an oil, identified as 1-indanone by conversion to the oxime, m. p. 143–144°.

Summary

1. 2-Bromoindene has been obtained by pyrolysis or dehydration of indene bromohydrin, pyrolysis of indene dibromide and as a by-product in other reactions. Its structure is evident from its mode of preparation and its reactions.

2. Reaction of indene dibromide with ethyl alcohol gives 1-ethoxy-2-bromoindane. Various reactions of this compound have been investigated.

3. The action of dilute sulfuric acid upon in-

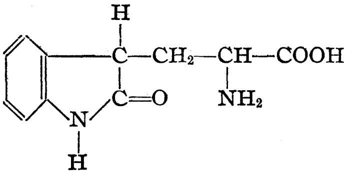
Studies in the Indole Series. VI. On the Synthesis of Oxytryptophan and Further Studies of 3-Alkylation of Oxindoles[1]

BY PERCY L. JULIAN, JOSEF PIKL AND FRANK E. WANTZ

The program of investigation into the chemistry of oxindoles, undertaken some time ago in this Laboratory, centered largely in its first phase around 1,3-dimethyloxindoles since these offered convenient starting material for the synthesis of physostigmine.[2] The ease with which these 1,3-dialkyloxindoles underwent alkylation in the 3-position, led us to attempt the synthesis of oxytryptophan (I) by way of condensation reactions similar to those recently communicated.

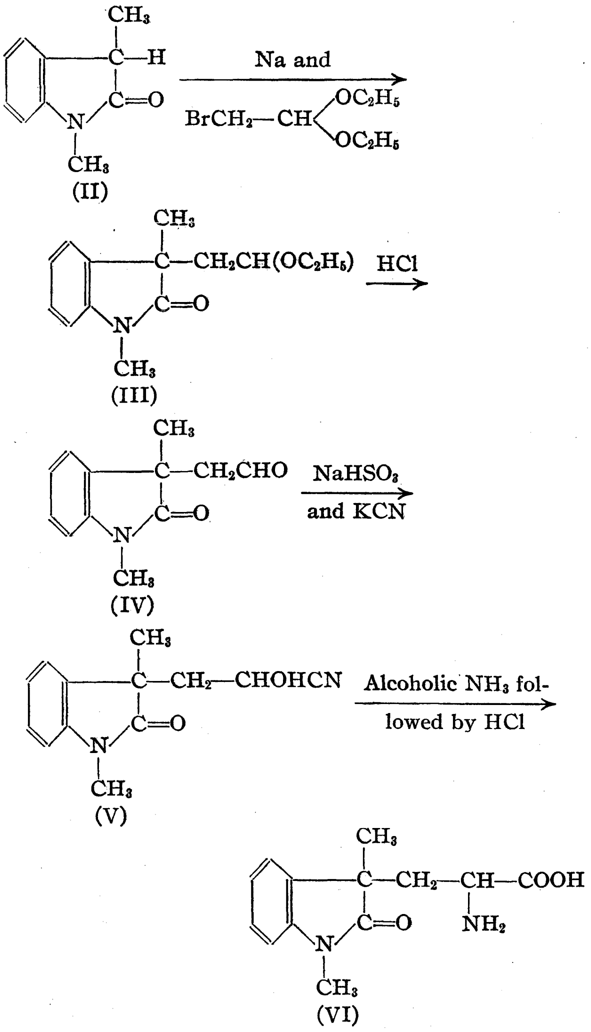


(I)

Much attention has been directed recently to this amino acid (I) since it has been indicated by Kotake[3] to be the first transformation product in the intermediary metabolism of tryptophan in the animal organism. Moreover, proof of the conversion of tryptophan into oxytryptophan, which might occur through certain oxidases, would probably explain the origin of many natural products containing the indole nucleus, among these physostigmine.[4]

In order to eliminate complications which might arise from possible enolizations of the hydrogen atoms in positions 1 and 3 of ordinary oxindole (VII), we decided to test out our proposed condensations, for introduction of the grouping —CH_2—$CH(NH_2)COOH$ into the 3-position of oxindoles, on 1,3-dimethyloxindole (II), with which we were quite familiar.

This paper reports the successful synthesis of the expected dimethyloxytryptophan (VI). 1,3-Dimethyloxindole was condensed with bromoacetal, the product (III) hydrolyzed and the aldehyde (IV) converted by way of the well-known Strecker synthesis into the amino acid (VI).



Attempts to carry out the same reactions with oxindole (VII) failed of their purpose, the initial condensation with bromoacetal presenting difficulties. That this is probably not due to enoli-

---

[1] Abstracted in large part from the senior research of Frank E. Wantz at DePauw University, 1934–1935.

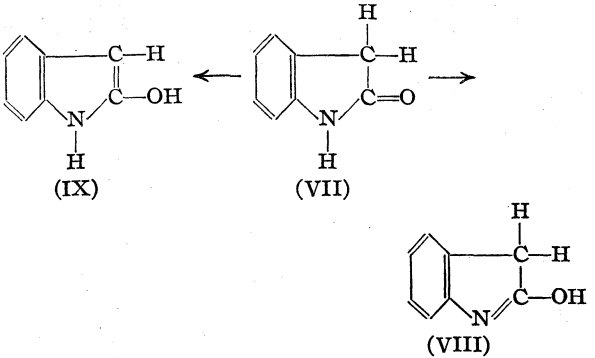
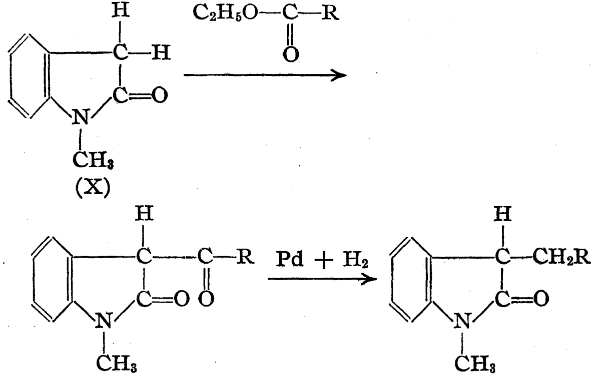
zation of (VII) in the sense represented by formula (VIII) rather than (IX) is indicated by the results obtained with (VII) in the Grignard machine. It gives two moles of gas and consumes two moles of reagent.



(IX) (VII) (VIII)



(X) (XI) (XII)

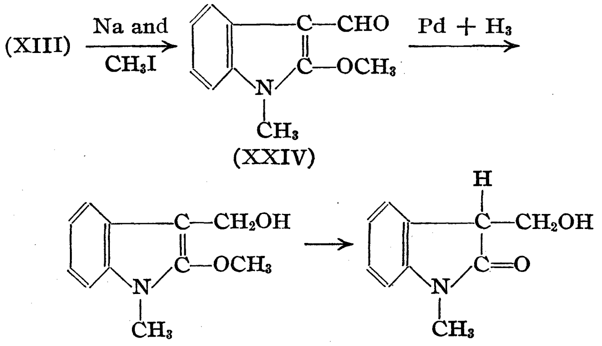
Condensation even of 1-methyloxindole (X) with bromoacetal could not be smoothly effected, despite numerous attempts.

We were therefore compelled to work out an entirely different procedure for smooth 3-alkylation of oxindoles not bearing an alkyl group in the 3-position, and the initial results with 1-methyloxindole (X) are communicated in this paper.

This new procedure makes use of 3-acyloxindoles (XI) which we have been able to obtain quite readily and in excellent yield through condensation of the oxindole (X) with esters. These 3-acyloxindoles, though readily cleaved by acids or bases, are cleanly hydrogenated catalytically to the corresponding 3-alkyl derivatives (XII). Table (I) shows the 3-acyloxindoles we have employed, together with the corresponding reduction products.

Compounds (XVIII) and (XIX), resulting, respectively, from condensation of the oxindole (X) with malonic ester and reduction of the product secured, are of particular interest to us in our attempts to synthesize oxytryptophan, for they point to possible successful outcome of this synthesis through condensation of oxindole with phthalimido-malonic ester, reduction of the resulting acyl derivative and hydrolytic cleavage to the amino acid (I). The results of this study will be reported in a later communication.

That the enolic hydrogen atom in position 3 of the acyloxindoles is responsible for the ease with which catalytic reduction takes place is suggested by the failure to reduce 1,3-dimethyl-3-acetyloxindole (XVII) by the same procedure. This latter substance was prepared by treating the sodium salt of (XV), suspended in acetone, with methyl iodide. It is interesting to note that 1-methyl-3-formyloxindole, methylated by this same procedure, gave an O-methyl derivative (XXIV),[5] which rapidly took up hydrogen when reduced catalytically to yield (XXV), a substance which is apparently readily hydrolyzed to the oxindole alcohol (XXVI). This compound is interesting in that it is the anhydride of *o*-methylamino-tropic acid.



(XXIV) (XXV) (XXVI)

The substances (XXI) and (XXIII) were included in this study because of their close resemblance to bufotenine (XXVII), one of the toad secretions.

It has been pointed out by Jensen and Chen[6] that bufotenine has remarkable effect upon the blood pressure. Dr. Jensen (Laboratory for Endocrine Research, Johns Hopkins Medical School) has kindly undertaken investigation of (XXI) and (XXIII) for action similar to that of bufotenine in raising the blood pressure.

The authors are grateful for a grant from the Rosenwald Fund, which is defraying some of the expenses of this and other investigations. They also wish to renew their expressions of appreciation to Dean W. M. Blanchard, Head of the Department, for his untiring labor in making this research program possible.

Experimental Part

A. Synthesis of β-1,3-Dimethyloxindolylalanine (VI)

1,3-Dimethyloxindolylacetal (III).—To a cooled solution of 6.9 g. of sodium in 90 cc. of absolute alcohol, a mixture of 49 g. of 1,3-dimethyloxindole and 55 g. of bromoacetal was added. After heating on the water-bath (gently at first) for one hour under reflux, the mixture was poured into water, taken up with ether, the ethereal extract washed with water and distilled. At 11 mm., 56 g. of material boiling at 170–185° was collected. For analysis the portion boiling at 182.5–183.5° (11 mm.) was collected.

Anal. Calcd. for $C_{16}H_{23}O_3N$: C, 69.26; H, 8.36. Found: C, 69.65; H, 8.33.

1,3-Dimethyloxindolylacetaldehyde (IV).—43.2 grams of the acetal (III) was covered with 300 cc. of 5% hydrochloric acid and shaken frequently. Solution occurs after about two hours. Allowed to stand overnight, it was then made alkaline with a generous excess of sodium carbonate and extracted with ether. The ethereal extract on distillation gave a quantitative yield of aldehyde (IV), b. p. 177–178° (12 mm.).

Anal. Calcd. for $C_{12}H_{13}O_2N$: C, 70.93; H, 6.40. Found: C, 70.66; H, 6.80.

The semicarbazone, prepared in the usual manner, melts at 206°, recrystallized from dilute alcohol.

Anal. Calcd. for $C_{13}H_{16}O_2N_4$: C, 59.98; H, 6.19. Found: C, 59.82; H, 6.42.

1,3-Dimethyloxindolylacetaldehydecyanhydrin (V).—To a well-stirred mixture of 64 g. of aldehyde (IV), 35 g. of sodium bisulfite, 50 cc. of water and 100 cc. of ether, a mixture of 25 g. of potassium cyanide and 30 cc. of water was added. The beautifully crystalline cyanhydrin which separated was filtered and washed generously with water and then a little ether; yield 50 g.; recrystallized from ether–petroleum ether, m. p. 142°.

Anal. Calcd. for $C_{13}H_{14}O_2N_2$: C, 67.82; H, 6.09. Found: C, 67.80; H, 6.33.

β-1,3-Dimethyloxindolylalanine (VI).—Twenty grams of cyanhydrin (V) was warmed for seven hours at about 60° with 16 cc. of 12% absolute alcoholic ammonia. The reaction product was poured into 50 cc. of 10% hydrochloric acid, whereby all went into solution. When sufficient water was added to bring the acid concentration down to about 3%, a precipitate was formed which was removed by shaking with ether. The aqueous solution was evaporated on the water-bath almost to dryness, and 10 cc. of concentrated hydrochloric acid added. This mixture was then heated on the water-bath for eight hours, after which the whole mass was taken up in 300 cc. of alcohol and alcoholic ammonia added until no more precipitate formed. The precipitate, consisting mainly of ammonium chloride, was filtered off, and ether added to the filtrate to precipitate the amino acid; 10.5 g. of product was obtained. After several recrystallizations from

---

[5] Julian, Pikl and Boggess, THIS JOURNAL, **56**, 1797 (1934).

[6] Jensen and Chen, *Ber.*, **65**, 1310 (1932).

80% alcohol it was fairly pure, m. p. 188° with decomposition, colorless, thin rhombic flakes. It still contained traces of ammonium chloride, very difficult to remove by this procedure.

Anal. Calcd. for $C_{13}H_{16}O_3N_2$: C, 62.88; H, 6.49. Found: C, 62.26; H, 6.60.

Heated above its melting point in a sublimation tube in vacuum, the acid loses carbon dioxide and pure 1,3-dimethyloxindolylethylamine[7] distils over, yielding a picrate, m. p. 186°, identical with that described in an earlier communication.

B. Preparation and Catalytic Reduction of 3-Acyloxindoles

Preparation of the 3-Acyloxindoles.—The general procedure was to add a mixture of 1 mole of oxindole (X) and 1.2 moles of ester to a 10% solution of sodium ethylate containing 1.3 moles of sodium. In most cases the sodium salt separated, was filtered off and decomposed with dilute hydrochloric acid.

In the case of the condensation of (X) with malonic ester the procedure above gave a difficultly soluble substance, m. p. 225°, doubtless the trimolecular condensation product. When from two to three moles of ester was employed and the oxindole dropped into the mixture of ethylate and ester, the product consisted almost entirely of the dimolecular condensation product, m. p. 67°, recrystallized from ether–petroleum ether.

The isolation of the condensation product between oxindole and dimethylaminoacetic ester called for further modification of the procedure since this product behaves like an amino acid. The sodium salt of the condensation product was decomposed with excess 10% hydrochloric acid in the cold, then sodium bicarbonate was added rapidly and the free amine extracted with chloroform. The chloroform extract was concentrated and upon addition of ether to the hot solution the acyl amines (XX) and (XXII) snowed out. Recrystallized from chloroform and ether.

For preparation of (XXII) two new oxindoles were prepared, which have not hitherto been described, namely, 1-methyl-5-hydroxyoxindole and 1-methyl-5-ethoxy-oxindole. These were prepared from chloroacetyl chloride and N-methylphenetidine in the same manner as described for the 3-methyl analog.[8] 1-Methyl-5-hydroxy-oxindole melts at 187° recrystallized from alcohol.

Anal. Calcd. for $C_9H_9O_2N$: C, 66.23; H, 5.56. Found: C, 66.20; H, 5.55.

1-Methyl-5-ethoxy-oxindole melts at 92°, recrystallized from ether–petroleum ether.

Anal. Calcd. for $C_{11}H_{13}O_2N$: C, 69.07; H, 6.86. Found: C, 68.76; H, 7.14.

Catalytic Reduction of the 3-Acyloxindoles.—For the first four and the last acyl oxindole listed in Table I, the procedure was to dissolve the oxindole in alcohol and reduce at about 1.5 atmospheres' pressure with from 0.05 to 0.1 its weight of Adams palladium oxide catalyst. The product after filtration was extracted with ether, the ether solution washed with sodium hydroxide to remove unchanged material and distilled. The yields were from 50 to 70% of the theoretical.

The acyloxindoles (XX) and (XXII) (Table I) were suspended in ten times their weight of absolute alcohol, about one-tenth this quantity of glacial acetic acid was added, and about 0.2 as much catalyst as oxindole employed. It was necessary to heat the mixture in the hydrogenation vessel to about 50° and maintain this temperature for reduction to proceed smoothly. The products were filtered, the alcohol removed in vacuum, the residue taken up in 3% hydrochloric acid and separated from an appreciable quantity of non-basic material by extraction with ether. The aqueous solution was made alkaline with sodium hydroxide, extracted with ether, and the ethereal extracts distilled under diminished pressure.

Summary

1. 1,3-Dimethyloxindole is smoothly condensed with bromoacetal, in presence of sodium ethylate, to yield 1,3-dimethyloxindolylacetal. The aldehyde resulting from hydrolysis yields by the Strecker synthesis the expected dimethyloxytryptophan.

2. Condensation of oxindole and 1-methyloxindole with bromoacetal by the same procedure could not be effected.

3. Several 3-acyloxindoles have been easily reduced catalytically to 3-alkyloxindoles, and it is hoped to employ the appropriate acyloxindole for the synthesis of oxytryptophan.

4. Substances related to bufotenine have been prepared by catalytic reduction of the appropriate acyloxindoles, particularly the ethyl ether of 1-methyl-2-oxybufotenine.

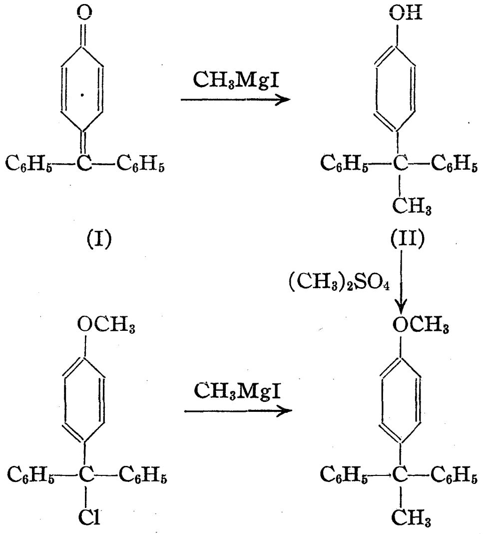
The Action of the Grignard Reagent on Certain Fuchsones[1]

BY PERCY L. JULIAN AND WILLIAM J. GIST

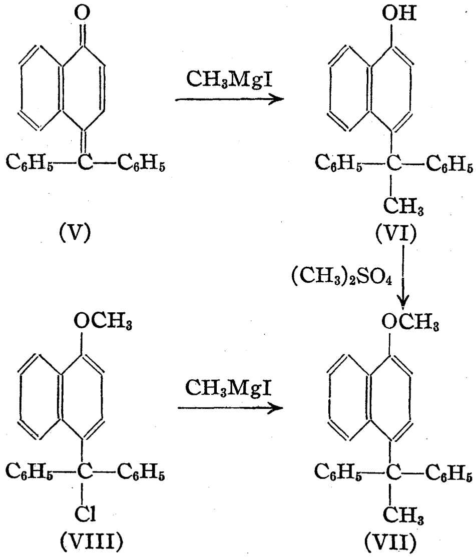
The only conclusively proven case of 1,6-addition of the Grignard reagent to a conjugated system of multiple linkages is the recently reported reaction between this reagent and methylene anthrone.[2] Of the three other cases found in the literature[3] only that one reported by Baeyer and Villiger deserves further attention, since the two cases recorded by Nakanishi have been reinvestigated and shown not to represent 1,6-addition.[2,4]

Baeyer and Villiger suggest without proof that the reaction product which they secure on treating fuchsone (I) with methylmagnesium iodide has the constitution (II). It is, if their assumption is correct, a product formed by 1,6-addition to a conjugated system similar to that found in methylene anthrone.



In connection with an investigation of the hindrance to 1,6-addition offered by various groupings, we have reëxamined the reaction studied by Baeyer and Villiger. To prove the constitution of the phenol (II) we methylated it in the usual manner with methyl sulfate. The product should have the constitution (III). The only other attractive possibility of synthesizing a compound like (III) arises out of Gomberg's observation[4a] that triphenylchloromethane reacts with methylmagnesium iodide, giving 1,1,1-triphenylethane in 70% yield. Accordingly, we treated the triaryl halide (IV) with methylmagnesium iodide, and secured a product identical with (III) obtained by methylating the addition product of Baeyer and Villiger. Their assumption was therefore a good one and the reaction is another case of 1,6-addition.

We have extended this study to include naphthofuchsone (V) and anthrafuchsone (IX). To the former methylmagnesium iodide adds 1,6 as in the case of fuchsone, but in much poorer yield. The constitution of the addition product has been proved in similar fashion, the triaryl halide (VIII) reacting smoothly with methylmagnesium iodide, yielding (VII).



With anthrafuchsone (IX) no trace of 1,6-addition could be detected, and the substance secured is the 1,2-addition product (X), the constitution of which has been proved by oxidation with chromic acid to anthraquinone and benzophenone.

Inasmuch as the completely arylated analogs of (II)—methyl group replaced by aryl residue—are among the easiest substances to prepare[5] it

seemed probable that phenylmagnesium bromide would likewise add 1,6 to fuchsone and to naphofuchsone. Despite numerous attempts, however, none of the readily crystallizing oxytetraarylmethanes could be isolated, only intractable gums resulting. Even on methylating these gums we could distil none of the pure methyl ethers from the products. The action of phenylmagnesium bromide on fuchsone and naphthofuchsone, therefore, is in marked contrast to that of methylmagnesium iodide on these substances, and if any amount of the 1,6-addition product is formed, it is present in such small quantities that the isolation of it is extremely difficult. One is reminded of the observation of Kohler[6] that "in most cases in which both 1,2- and 1,4-addition occur, the relative quantity of 1,4-addition product is always larger with alkyl than with arylmagnesium compounds." Our results indicate a similar conclusion with respect to 1,6-addition of aryl and alkyl magnesium derivatives.

Phenylmagnesium bromide reacts readily with anthrafuchsone (IX), the product being the 1,2-addition compound (XI).[7] This compound interested us because of the similarity in structure to another substance (XIII) on which we recently reported,[2a] and which we found to rearrange readily into the isomer (XIV). The new dihydroanthranol (XI), subjected to the same treatment, underwent no rearrangement and was recovered unchanged. In the earlier paper dealing with compound (XIII) we expressed the belief that certain steric influences might conceivably render the dihydroanthracene modification the more stable of the two, although generally the tendency to pass over into the modification containing the anthracene structure is so marked that least provocation effects this rearrangement. The additional phenyl group attached to the ω-carbon atom of (XI) seems to offer the necessary hindrance to rearrangement and it is the stable modification, while in the case of (XIII) and (XIV), the latter is certainly the more stable isomer, and no treatment could reconvert it into (XIII), although evidence for equilibrium between the two forms in solution could be adduced.

All attempts at replacement of the hydroxyl group in compound (XIII) led to derivatives having the structure corresponding to (XIV) and gave back (XIV) on hydrolysis. When the hydroxyl group in (XI) was replaced by halogen, and the resulting halide warmed for half an hour with moist calcium carbonate in acetone, the original carbinol was recovered. This is not satisfactory evidence that the halides have the structure (XII) since rearrangement might have occurred in the course of reconversion into carbinol. Moreover, solutions of both chloride and bromide (XII) are distinctly fluorescent, indicating that these might have the anthracene structure (XVI). To gain more light on this we prepared, according to Bergmann,[7] a substance to which he ascribes the formula (XV). From our experience with brominating phenylbenzylanthracene,[2a] we should secure (XVI) on brominating (XV). We did get a bromo compound, but one entirely different from our bromo derivative (XII). Hydrolysis of it

[7] Bergmann, *Ber.*, **63**, 1041 (1930).

with calcium carbonate yielded none of our carbinol (XI). Whether Bergmann's compound (XV) has actually the structure assigned we have not investigated, for when we found that it and its bromo derivative had no relationship to our substances, further work with it was discontinued.

The authors acknowledge gratefully a generous grant from the Rosenwald Fund and likewise the assistance and unstinted support of their first teacher of chemistry, Dean W. M. Blanchard, Head of the Department.

Experimental Part

1,1-Diphenyl-1-*p*-anisylethane (III)

(a) **From Fuchsone.**—Five grams of fuchsone, which we find is most conveniently prepared in large quantity according to the method of Bistrzycki,[8] was treated in the usual manner with 3 moles of methylmagnesium iodide. The crude product obtained on working up the Grignard was methylated in 10% sodium hydroxide solution with methyl sulfate. After destroying excess alkylating agent with alkali, the product was poured into water, extracted with ether, the ethereal solution washed and distilled. At 0.1 mm. and with air-bath temperature of 196°, 3.5 g. of a greenish-blue liquid distilled. Recrystallized from ether–petroleum ether it melted at 77°.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.50; H, 6.94. Found: C, 87.41; H, 7.23.

(b) **From Diphenyl-*p*-anisylchloromethane (IV).**—Five grams of the chloromethane (IV) was treated with 3 moles of methylmagnesium iodide, worked up on the usual way and distilled. The product, which came over at the same temperature as recorded above, melted at 77° and was identical in all respects with (III) secured from fuchsone.

Preparation of Naphthofuchsone (V).—The preparation described in the literature[9] we found to be troublesome and result in poor yields. The same type of procedure employed in the preparation of fuchsone, however, gave excellent results. The methyl ether of benzoyl α-naphthol was prepared according to the method employed by Scholl and Seer[10] for the ethyl ether, all heating avoided during the Friedel–Crafts reaction. We had little success with the method suggested by Fierz-David and Jaccard.[11] Our product, however, melted at 83° and was identical with that described by these authors.

Diphenyl-4-methoxynaphthylcarbinol, which resulted from the action of phenylmagnesium bromide on the methyl ether of benzoyl-α-naphthol, seems not to have been described heretofore. It melts at 162°, recrystallized from ether–petroleum ether.

Anal. Calcd. for $C_{24}H_{20}O_2$: C, 84.66; H, 5.93. Found: C, 84.59; H, 5.83.

The chloride (VIII), m. p. 151°, could not be isolated readily by passing hydrogen chloride into the ether solution of the carbinol. It was obtained on treating the carbinol with thionyl chloride. Conversion into the fuchsone (V) was effected by heating at 180–200° until evolution of methyl chloride was complete. Our fuchsone was identical with that described in the literature.[9]

1,1-Diphenyl-1,4-methoxynaphthylethane (VII), secured from naphthofuchsone (V) as well as from the chloride (VIII) described above, distilled at 220–230° (temperature of air-bath) and 0.1 mm., and melted at 144°, recrystallized from ether–petroleum ether.

Anal. Calcd. for $C_{25}H_{22}O$: C, 88.70; H, 6.56. Found: C, 88.68; H, 6.78.

9-Methyl-10-benzhydrylidene-9,10-dihydroanthranol-9 (X).—Obtained by the action of methylmagnesium iodide on anthrafuchsone, this substance melted at 223°, recrystallized from ether–petroleum ether.

Anal. Calcd. for $C_{28}H_{22}O$: C, 89.79; H, 5.93. Found: C, 89.68; H, 6.04.

On oxidation with chromic acid in glacial acetic acid solution it yielded anthraquinone and benzophenone. In the Grignard machine it gave one mole of gas and consumed one mole of reagent.

9-Phenyl-10-benzhydrylidene-9,10-dihydroanthranol-9 (XI) has already been described by Bergmann. On passing dry hydrogen chloride into an ethereal solution, the tertiary halide (XII) slowly crystallized out. Recrystallized from chloroform and ether, it melted at 220° with decomposition, beginning to turn dark at 185°.

Anal. Calcd. for $C_{33}H_{23}Cl$: C, 87.09; H, 5.10. Found: C, 86.78; H, 5.39.

When a benzene solution of the chloride is shaken with molecular silver it gives a deep reddish-brown solution, the color of which is almost completely discharged by passing in atmospheric oxygen. The peroxide, however, could not be induced to crystallize. Petroleum ether threw out an amorphous powder.

The bromide prepared as was the chloride melted at 165° with decomposition, while a bromo derivative of Bergmann's hydrocarbon (XV) melted at 143° and mixed melting point showed strong depression. When the 143° bromo derivative was hydrolyzed with moist calcium carbonate in acetone, only low melting material having no resemblance to the carbinol (XI) was secured.

Summary

1. The reaction between fuchsone and methylmagnesium iodide is another case of 1,6-addition. α-Naphthofuchsone behaves like fuchsone toward this reagent. None of the 1,6-addition products could be isolated from the reaction of these fuchsones with phenylmagnesium bromide.

2. 10-Benzhydrylidene-9-phenyl-9,10-dihydroanthranol-9 is stable and does not rearrange into its isomer with the anthracene structure. Its halogen derivatives likewise have apparently the dihydroanthracene structure.

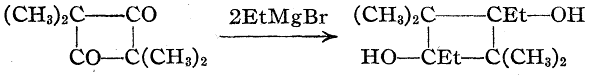
The Reaction of Ketenes with Grignard Reagents

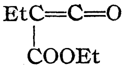
BY CHARLES D. HURD, RALPH N. JONES AND F. H. BLUNCK

Diphenylketene and phenylmagnesium bromide react[1] to produce a derivative of triphenylvinyl alcohol. With ketene[2] itself, the course of the Grignard reaction has not been established because of the vigor and complexity of the process. Toward the dimer of dimethylketene, ethylmagnesium bromide[3] adds to give the cyclic glycol in high yields



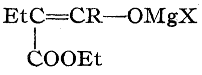
$$\begin{array}{l}(CH_3)_2C-CO \\ \quad\; | \qquad | \\ \quad\; CO-C(CH_3)_2\end{array} \xrightarrow{2EtMgBr} \begin{array}{l}(CH_3)_2C-CEt-OH \\ \qquad\quad | \qquad | \\ HO-CEt-C(CH_3)_2\end{array}$$

The present paper extends the Grignard reaction to ethyl ethylketenecarboxylate, (A), and its dimer (K).



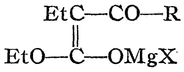
$$\begin{array}{l}EtC{=}C{=}O \\ | \\ COOEt\end{array}$$

(A)



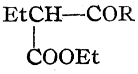
$$\begin{array}{l}EtC{=}CR-OMgX \\ | \\ COOEt\end{array}$$

(B)



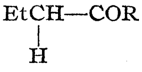
$$\begin{array}{r}EtC-CO-R \\ \| \\ EtO-C-OMgX\end{array}$$

(C)



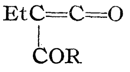
$$\begin{array}{l}EtCH-COR \\ | \\ COOEt\end{array}$$

(D)



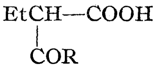
$$\begin{array}{l}EtCH-COR \\ | \\ H\end{array}$$

(E)



$$\begin{array}{l}EtC{=}C{=}O \\ | \\ COR\end{array}$$

(F)



$$\begin{array}{l}EtCH-COOH \\ | \\ COR\end{array}$$

(G)

Three types of addition should be considered, namely, at the ketene carbonyl, at the ester carbonyl, or 1,4-addition at the C=C—COOEt group. Since the ester group is known[4] to be more sluggish toward Grignards than the aldehyde group the first type should be favored instead of the second but no such basis of comparison is available for the third.

Addition of a Grignard reagent according to type 1 would produce (B), type 2 would produce (F), and type 3 would produce (C). On simple hydrolysis, both B and C would yield the β-keto ester (D), whereas F would yield the ketone E via G. If the reaction went via D, therefore, type 2 would be eliminated.

No satisfactory means of distinguishing between types 1 and 3 was found but the great reactivity of ketene, CH_2CO, toward Grignard reagents makes it appear reasonable that type 1 should be favored. Also, since $>C\begin{smallmatrix}OR \\ OMgX\end{smallmatrix}$ is an unstable configuration, (C) may decompose spontaneously to (F), in which case no (D) would arise.

That (C) may be a stable intermediate is apparent because some unsaturated esters (such as $PhCH{=}CPhCO_2CH_3$ and $PhCH{=}CHCO_2C_6H_5$) react with phenylmagnesium bromide to give saturated esters[5] ($Ph_2CHCHPhCOOCH_3$ and $Ph_2CHCH_2COOC_6H_5$, respectively), evidently by intermediates related to (C).

When phenyl- or ethylmagnesium bromides were added to (A), the esters (D) were formed: ethyl α-benzoylbutyrate and ethyl α-propionylbutyrate. Hydrolysis of these esters yielded the ketones (E), namely, phenyl *n*-propyl ketone and ethyl propyl ketone.

When (A) was added to the phenylmagnesium bromide (*i. e.*, the Grignard in excess) phenyl α-ethyl-β,β-diphenylvinyl ketone (J) was one of the reaction products. These steps account for its presence:

$$(A) \longrightarrow (B) \xrightarrow{PhMgBr}$$

$$\underset{(H)}{(PhCOCEt{=}CPhOMgX)} \xrightarrow[H_2O]{PhMgBr} \underset{(J)}{Ph_2C{=}CEt-COPh}$$

This normal type of addition of the Grignard reagent to (H) in producing (J) would probably not have occurred if 1,1-dibenzoylpropane, which would come from (H) by hydrolysis, were taken instead with the Grignard reagent. The analogous case is that of 1,1-dibenzoylethane, which gave[6] no phenyl α-methyl-β,β-diphenylvinyl ketone but yielded (with PhMgBr) propiophenone and triphenylcarbinol.

The structure of (J) is supported by its behavior on ozonization. The products were those predicted, namely, benzophenone, benzoic acid and propionic acid.

In one run with ethylmagnesium bromide the addition product (B) was pyrolyzed instead of hydrolyzed. No evidence for the allene ester, $CH_3CH{=}C{=}CEtCOOEt$, was found. This ester would be anticipated if HOMgBr were detached from (B). Instead, ethyl bromide was evolved in quantity, together with an unidentified, unsaturated liquid boiling at 100–110°. In view of the

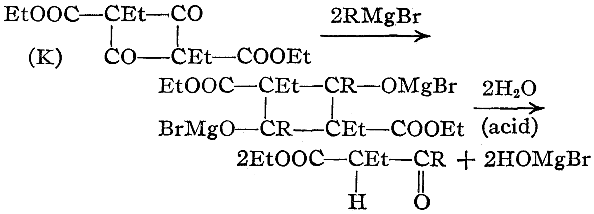
(6) Kohler and Erickson, THIS JOURNAL, **53**, 2306 (1931).

non-production of the desired allene ester, this reaction was not studied further.

Phenyl- and ethylmagnesium bromides were also treated with the dimer (K) of the ketene. As with the ketene, a vigorous reaction resulted and the reaction products were β-keto esters (D) which, on hydrolysis, yielded ketones (E). Here again, practically no reaction occurred at the ester carbonyl. These steps appear probable



$$\begin{array}{l}\mathrm{EtOOC{-}CEt{-}CO}\\ \mathrm{(K)\quad CO{-}CEt{-}COOEt}\end{array} \xrightarrow{\mathrm{2RMgBr}} \begin{array}{l}\mathrm{EtOOC{-}CEt{-}CR{-}OMgBr}\\ \mathrm{BrMgO{-}CR{-}CEt{-}COOEt}\end{array} \xrightarrow[\mathrm{(acid)}]{2H_2O} \mathrm{2EtOOC{-}\underset{H}{CEt}{-}\underset{O}{CR}} + \mathrm{2HOMgBr}$$

The facile, hydrolytic rupture of the C–C bonds in the cyclobutane nucleus is noteworthy, but the reaction of (K) with aniline at 100°, whereby ethyl ethylmalonanilate, $\mathrm{EtO_2CCHEtCONHPh}$, is formed,[7] is somewhat analogous. The findings differ in kind from those of Wedekind and Miller[8] who reported direct addition of RMgX to the cyclobutanedione, but resemble those of Kohler and Erickson[6] who reported a C–C split with certain β-diketones.

Direct dehydration of ethyl hydrogen ethylmalonate proved to be an effective means of synthesis: $\mathrm{EtOOCCHEtCOOH} + P_2O_5 \longrightarrow \mathrm{EtOOCCEt{=}C{=}O} + 2HPO_3$. This saves three steps in the older procedure[9] which also started with ethyl hydrogen ethylmalonate.

Ethyl hydrogen ethylmalonate was synthesized from ethyl ethylmalonate. A method of synthesizing the latter from ethyl sulfate was developed. The older procedure employed ethyl bromide.

Experimental Part

Ethyl Ethylmalonate, $\mathrm{EtCH(COOEt)_2}$

From Ethyl Bromide.[9]—A 62% yield was obtained by the ethyl bromide method in a 3-mole run. This method is economical because the sodium bromide which separates is so readily recoverable.

Careful fractional distillation was required in the purification. Unused ethyl malonate was collected at 88–91° (12 mm.), only 10° below that of the desired homolog. A 60-cm. Vigreux column was employed. The ethyl ethylmalonate taken possessed these constants: b. p. 96–99° (12 mm.), d^{20}_4 1.005, n^{20}_D 1.4171. The density is a convenient criterion of purity for the d^{20}_4 value for ethyl malonate is 1.054. In order to demonstrate the absence of ethylmalonate in the ethyl ethylmalonate used, some of the ester was hydrolyzed to ethylmalonic acid and the latter pyrolyzed to butyric acid. Duclaux values on this material were correct for pure butyric acid.

From Ethyl Sulfate.—In a 2-liter, three-necked, round-bottomed flask which is fitted with a mechanical stirrer, dropping funnel and reflux condenser, 29 g. (1.25 moles) of sodium was dissolved in 300 cc. of absolute alcohol. While still warm (60–75°), 200 g. (1.25 moles) of technical ethyl malonate was added slowly to it. To this solution, which was well stirred, was added 155 g. (1 mole) of ethyl sulfate without cooling. The addition should be fast enough to keep the alcohol boiling, but under control. The time for the addition was 25 minutes, after which the solution was refluxed for one hour on a hot plate. The alcohol was then distilled off and the residual solution heated for one hour at 160–165°, and for three hours at 145–150°. After cooling, water was added to the residue, the ester layer removed, washed with dilute alkali, then with water and dried with calcium chloride. On vacuum distillation, the ethyl ethylmalonate was collected at 100–103° (14 mm.); yield, 200 g. (1.07 moles). This is an 86% yield based on the ethyl malonate or a 54% yield based on the ethyl sulfate (assuming the reaction $\mathrm{Et_2SO_4} + \mathrm{2CH_2(COOEt)_2} + 2\mathrm{Na} \longrightarrow \mathrm{2EtCH(COOEt)_2} + \mathrm{Na_2SO_4}$). No better yield of ethyl ethylmalonate was obtained when 2 moles each of ethyl malonate and sodium were taken instead of 1.25 moles, even when the hot reaction period was extended to twenty hours.

When exactly molar quantities of the three reactants were taken and refluxed in alcohol for two to three hours (without subsequent heating at 145–165°) the yield was 0.80–0.88 mole. This is an 80–88% yield based on the ethyl malonate or a 40–44% yield based as above on the ethyl sulfate.

Synthesis of other Reagents.—Staudinger and Bereza's[9] directions were followed and confirmed for the syntheses of ethyl hydrogen ethylmalonate,[10] its acid chloride (α-carbethoxybutyryl chloride),[11] and α-bromo-α-carbethoxybutyryl chloride. The reported yields in the conversion of the last substance into ethyl diethylcyclobutanedicarboxylate (K) and its depolymerization into (A) were 61 and 80%, respectively, whereas our experience was 50 and 15–30%.

Ethyl Ethylketenecarboxylate from Ethyl Hydrogen Ethylmalonate.—One hundred grams of dried sand and 50 g. of phosphorus pentoxide were mixed in a liter flask which was placed in an oil-bath at 180–200°. The flask was connected to an upright condenser containing water at 75–85°, hot enough to force over the ketene, but cool enough to keep back impurities. Another cold water condenser and a receiver held at −78° were used to condense the ketene. The system was evacuated to 15 mm. and 30 g. of the acid was added rapidly through an attached dropping funnel. In this process the effort was made to cover the entire surface of the dehydrating mixture. Nine grams (34%) of distillate accumulated in thirty minutes. This, on redistillation, gave 6 g. (23%) of the

[10] The use of 95% alcohol for the alcoholic potassium hydroxide also gave satisfactory results.

[11] In this synthesis, it was found more convenient to add the acid to the phosphorus pentachloride than *vice versa*.

ketene. b. p. 45–55° at 11–12 mm. The ketene was kept at −78° to retard polymerization effects.

Distillation of the residue gave a small fraction at 89–91° (11 mm.), n^{23}D 1.4171 which was ethyl ethylmalonate. At a still higher temperature a small fraction of butyric acid was collected, evidently a decomposition product of ethylmalonic acid. The butyric acid was identified by its odor, solubility in water and Duclaux constants. Although most of the ethyl hydrogen ethylmalonate underwent dehydration, a small, concurrent disproportionation was also encountered.

The ketene (0.5 g.) reacted with pure aniline to produce ethyl ethylmalonanilate (yield, 0.8 g.) as stated by Staudinger and Bereza[9] but no reaction was found between the ketene and β-naphthylamine (in benzene).

Reactions with Grignard Reagents

Phenylmagnesium Bromide and (A). First Experiment.—Twenty-five cc. of absolute ether (distilled from a Grignard preparation) and 8.5 g. (0.06 mole) of the ketene were mixed. Then 0.06 mole of phenylmagnesium bromide was dropped into it. Following the vigorous reaction, the solution was refluxed for one-half hour, then stirred with dilute sulfuric acid. The ether layer was removed, washed with dilute sodium carbonate and dried over calcium chloride and distilled. Vacuum distillation (11 mm.) of the residue gave these fractions: (1) 70–120°, 3 g.; (2) 120–170°, 7 g. Redistillation of the 3 g. fraction revealed no constant-boiling material. It distilled between 90–120° (11 mm.). The 7-g. fraction was chiefly ethyl α-benzoylbutyrate.[12] Six grams of it was collected at 159–162° (11 mm.). Its identity was established as follows: (1) its saponification number was 215 (calcd. 210); (2) it was refluxed for 2.5 hours with a 5% solution of potassium hydroxide, then ether extracted, the extract dried and the ether removed. The 2 g. of residue contained some diphenyl but it was largely phenyl *n*-propyl ketone. It gave a semicarbazone, m. p. 184–185° after one crystallization. The recorded value[13] is 188°.

Second Experiment.—In this run, 0.077 mole (11 g.) of the ketene was dropped into a solution of 0.2 mole of phenylmagnesium bromide. By adding the ketene rather than the Grignard reagent, the latter was in great excess throughout.

The reaction product was hydrolyzed with cold, dilute acid. After separation and removal of ether the residue was distilled at 15 mm. There was 0.3 g. of diphenyl and 5.0 g. of liquid collected between 100–140°. The residue from the distillation was taken up in alcohol. On cooling, 2.5 g. of white crystals, m. p. 126–127°, separated. Five cc. of liquid, presumably ethyl α-benzoylbutyrate, was left on evaporation of the alcohol.

A small quantity of the same crystalline material was obtained by interaction of α-bromo-α-carbethoxybutyryl chloride (8 g.) and the Grignard reagent from 13 g. of bromobenzene. Only 0.1 g. was isolated when the former was added to the latter. The reverse type of addition, which should have given better yields, was not tried.

The crystalline material was phenyl α-ethyl-β,β-diphenylvinyl ketone (J). It was non-volatile in steam. It was unaffected by acetic anhydride and did not undergo hydrolysis by refluxing with dilute sulfuric acid or concd. sodium hydroxide solutions. A mixed melting point determination with triphenylcarbinol showed a depression to 109–115°, which showed the virtual absence of the latter.

Anal. Calcd. for $C_{23}H_{20}O$: C, 88.4; H, 6.45. Found: C, 87.7, 87.6; H, 6.28, 6.44.

Ozonolysis of (J).—The sample (1.85 g.) was dissolved in 80 cc. of carbon tetrachloride and 5.4 liters of ozonized oxygen was passed through. The ozonide was insoluble. Eighty cc. of water was added and the mixture distilled until all the carbon tetrachloride and much of the water had been removed. The residue contained about 0.5 g. of benzophenone, present as a yellow oil. When treated with hydroxylamine, 0.6 g. of benzophenone oxime, m. p. 143°, was formed.

The carbon tetrachloride layer was separated from the distillate and evaporated. The oily residue was taken up in hot water. On cooling, 0.7 g. of benzoic acid separated, m. p. 121°. No attempt was made to determine the propionic acid content of the carbon tetrachloride layer.

The water layer was neutralized with 49.10 cc. of 0.053 *N* sodium hydroxide, then evaporated to a volume of 5 cc. Ten cc. of alcohol and 0.5 g. of *p*-bromophenacyl bromide were added and the mixture refluxed for one hour. On cooling, the more insoluble *p*-bromophenacyl benzoate, m. p. and mixed m. p. 118° (yield, 0.3 g.), separated. By concentrating the filtrate, crystals were obtained which melted about 39°. After two recrystallizations, the melting point was raised to 59°, which is characteristic of *p*-bromophenacyl propionate.

Phenylmagnesium Bromide and the Dimer of (A).—When phenylmagnesium bromide solution was dropped into an ice-cold solution of 25 g. of (K) in 50 cc. of absolute ether, a vigorous reaction occurred until nearly the calculated quantity had been introduced. Then the mixture was refluxed for an hour and worked up as in the preceding "first experiment." On distillation at 30 mm., these fractions were obtained (°C., g.): 107–111, 7; 115–120, 8; 120–130, 3; 150–165, 5; 170–175, 15; some residue. The first two fractions appeared to be a mixture of the ketene and its dimer (A and K). Similar material was produced in the distillation of the dimer (K) to produce (A). Thus, distillation of 50 g. of (K) at 25 mm. gave: 50–100°, 20 g. of (A); 109–112°, 13 g.; 125–127°, 2 g.; 140–150°, 5 g.; some residue. The 107–120° portions from both experiments, on alkaline hydrolysis, yielded ethylmalonic acid of neutral equivalent 67 and m. p. 100–105°. (Values, if pure, would be 66 and 112°, respectively.) Carbon dioxide was detached (as shown by lime water test) from this acid by pyrolysis and the butyric acid residue yielded *p*-bromophenacyl butyrate of m. p. 59–60° (literature, 62°) with *p*-bromophenacyl bromide.

The 15-g. fraction (b. p. (30 mm.) 170–175°) was chiefly ethyl α-benzoylbutyrate. Six grams of it gave rise to 4 g. of phenyl *n*-propyl ketone, b. p. 200–210°; semicarbazone, m. p. 185–186°.

Ethylmagnesium Bromide and (A). First Experiment.—The calculated quantity of ethylmagnesium bromide in dry ether was added dropwise with stirring into 4 g. of the ketene (also in ether and cooled by ice). An-

---

[12] Hope and Perkin, *J. Chem. Soc.*, **95**, 2047 (1909).

[13] Sorge, *Ber.*, **35**, 1074 (1902).

other 4-g. portion of the ketene was added to the solution and the process repeated till 17.5 g. of the ketene had been used. Then the mixture was refluxed for a half hour, cooled and mixed with ice and dilute sulfuric acid. The ether layer was removed, washed with water, with 5% sodium carbonate solution and dried with calcium chloride. There was 15 g. of residue after removal of the ether. Most of it distilled at 97–100° (18 mm.) but there were higher (100–110°) and lower boiling fractions. The latter, which was collected at 65–70° (40 mm.) and which weighed about 1 g. possessed a mol. wt. of 147–156. The quantity at hand was insufficient for definite characterization.

The mol. wt. of the 97–100° (18 mm.) fraction was 162, 172 (calcd. for $C_9H_{16}O_3$, 172). This material was largely ethyl α-propionylbutyrate. In another similar run (from 5 g. of the ketene) the product was hydrolyzed by stirring with dilute alkali until dissolved and then acidified with 50% sulfuric acid. Ethyl propyl ketone was extracted from it with ether and characterized as the semicarbazone. The latter melted at 107–108° after two crystallizations from water. Michael[14] lists 111° as the m. p. for this semicarbazone.

Second Experiment.—Twenty-two grams (0.15 mole) of the redistilled ketene (b. p. 50–53° (11 mm.)) in 10- and 12-g. portions was treated as before with 0.16 mole of ethylmagnesium bromide. After the half-hour period of refluxing, the ether was distilled away and the temperature of the oil-bath progressively raised to 200°. A drop of paraffin lessened the tendency of the residue to foam. A distillate was obtained near 200°. The temperature was increased to 300° and finally a free flame was used. The 6 g. of liquid obtained was redistilled into two fractions: (1) 37–45°, 3 g.; (2) 45–110°, 2 g. The mol. wt. determination, high bromine content, and b. p. of fraction (1) confirmed its identity as ethyl bromide. Over half of fraction (2), on redistillation, boiled at 100–110°. The substance was unsaturated and 0.0034 mole of it (0.4265 g.) absorbed 0.0032 mole of bromine solution, indicative of one double bond. The mol. wt. values found were 113.7 and 117.4.

Ethylmagnesium Bromide and the Dimer of (A).—Fifteen grams of the dimer, diluted with 50 cc. of dry ether, was taken. Into it (ice cold) was dropped the calculated amount of ethylmagnesium bromide. The reaction mixture was worked up as with the ketene. These fractions were obtained at 12 mm.: 95–97°, 5 g.; 97–145°, 2 g.; 145–155°, 2 g.

The identity of the higher boiling fractions was not established but the 95–97° fraction was ethyl α-propionylbutyrate, the same as from the ketene itself. Hydrolysis yielded ethyl propyl ketone as before; semicarbazone, m. p. 108.5–109°.

Summary

Ethyl ethylketenecarboxylate was prepared by direct dehydration of ethyl hydrogen ethylmalonate with phosphorus pentoxide. The behavior was studied of this ketene and its dimer toward phenyl- and ethylmagnesium bromides. Addition was found to occur preferentially at the ketene carbonyl, giving β-keto esters. No allene type was produced when the addition product of the ketene and ethylmagnesium bromide was pyrolyzed. Instead, ethyl bromide and an unsaturated compound were formed.

Ethyl malonate was converted to ethyl ethylmalonate by the use of ethyl sulfate and sodium ethoxide.

The Reaction between Ethylene and Chlorine in the Presence of Chlorine Acceptors. The Photochlorination of Ethylene

BY T. D. STEWART AND BERNHARDT WEIDENBAUM

This work was instigated by the concept of the reaction between ethylene and chlorine being a chain reaction, similar to the photochemical formation of benzene hexachloride from benzene and chlorine, which has been shown to have a quantum efficiency of the order of 100. That these two reactions have a common intermediate was shown by Stewart and Hanson[1] when they found that ethylene passed into a solution of chlorine in benzene in the dark yielded benzene hexachloride, in the ratio of about ten moles of chlorine reacting with benzene for each one reacting with ethylene, or an induction factor of ten.[2]

These photochlorinations are now commonly considered to involve chlorine atoms or possibly the complex Cl_3, with no clear way as yet of distinguishing their relative importance.[3] The chlorinations of hydrogen and of saturated hydrocarbons involve the same variables.

The Photochlorination of Gaseous Ethylene.—To ascertain that this addition reaction, normally

---

[1] Stewart and Hanson, THIS JOURNAL, **53**, 1121 (1931).

[2] Two years ago, Mr. Harold Pitt, in this Laboratory, succeeded occasionally in obtaining an induction factor of 70–100. Rigid exclusion of oxygen and low partial pressures of ethylene permitted the longer benzene–chlorine chains.

[3] Dickinson and Carrico, THIS JOURNAL, **56**, 1478 (1934).

slow in the gas phase, proceeds without complication as a photochemical reaction, a mixture of chlorine and ethylene gases, each at a pressure of ten centimeters of sulfuric acid, was illuminated by light of approximately 4360 Å.

Preparation of Materials.—Chlorine was prepared by heating a tube of copper chloride which was sealed in the line. Ethylene was prepared from the dibromide with zinc, scrubbed with 95% alcohol, dried over calcium chloride and phosphorus pentoxide and condensed in liquid air. The first portion upon evaporation was discarded, the rest stored under pressure in a bulb sealed to the line. There was rigid exclusion of water and oxygen in the line. Electrolytic hydrogen passed over hot copper and through a liquid air trap was used.

The light source was a 500-watt tungsten lamp, about 46 cm. from the 130-cc. reaction flask. Two Zeiss monochromator filters were used; calibrated screens varied the light intensity. Evacuation was achieved with a mercury diffusion pump. The partial pressure of each gas was measured on a sulfuric acid manometer, which also served to follow the reaction rate.

In every experiment the reaction flask was first "cleaned up" by exploding a mixture of hydrogen and chlorine in it, and then evacuating to a pressure less than 10^{-5} mm. of mercury. The criterion of cleanliness was the absence of appreciable induction period upon explosion.

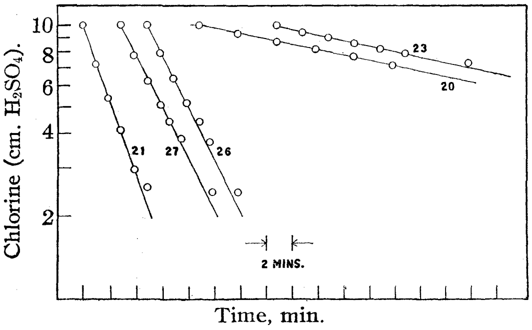

Fig. 1.—The photochemical addition of chlorine and ethylene gases.

If the pressure of chlorine is plotted against time on semi-logarithmic paper, a linear relationship is found to exist during the early part of the reaction. As the reaction proceeds, deviation from linearity is observed; this is caused probably by a concurrent reaction, such as the chlorination of the addition product. In Fig. 1 the results of a few experiments, in which the initial pressure of the reactants is kept constant and the light intensity varied, are plotted. Table I gives a summary of the initial rates as a function of the intensity of the incident light; the rates are given in arbitrary units and were obtained from the slopes of the curves.

TABLE I

EFFECT OF LIGHT INTENSITY UPON THE RATE OF ADDITION OF ETHYLENE AND CHLORINE

Experiment number	Light intensity	Rate
2-21	1	3.39
2-26	0.67	2.31
2-27	.67	2.31
2-28	.47	1.63
2-29	.47	1.62
2-18	.379	1.24
2-22	.372	1.23
2-19	.148	0.54
2-24	.148	.54
2-20	.059	.25
2-23	.059	.25

These data are plotted in Fig. 2, from which it is apparent that a linear relationship exists between the incident light intensity and the initial rate of the reaction. The rate law may then be expressed

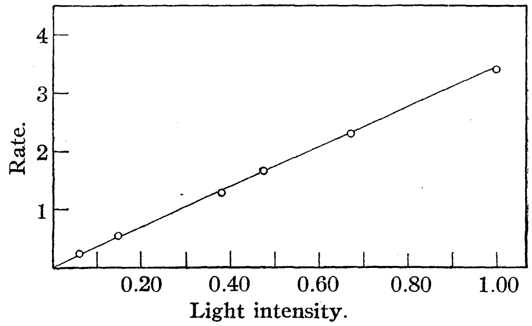

Fig. 2.—Effect of light intensity.

$$\frac{-d(Cl_2)}{dt} = kI_{\text{abs.}} = KI_0(Cl)_2$$

Although the quantum yield was not measured, there is little doubt that it is very large, since explosions of these gases are obtained when illuminated under the proper conditions.

It is possible to derive this rate law on the basis of several mechanisms, in each of which one chain-continuing intermediate (Cl or Cl_3) reacts much more rapidly with ethylene than in any other way, to form another intermediate which may either continue the chain or terminate the chain at the walls. For instance

$$Cl_2 + h\nu \longrightarrow Cl + Cl \qquad (1)$$

$$Cl + Cl_2 \longrightarrow Cl_3 \qquad (2)$$

$$Cl_3 + C_2H_4 \longrightarrow C_2H_4Cl_3 \qquad (3)$$

$$C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \qquad (4)$$
$$C_2H_4Cl_3 + W \longrightarrow C_2H_4Cl_2 + {}^1/_2Cl_2 \qquad (5)$$

or

$$Cl_2 + h\nu \longrightarrow Cl + Cl \qquad (1)$$
$$Cl + C_2H_4 \longrightarrow C_2H_4Cl \qquad (2)$$
$$C_2H_4Cl + Cl_2 \longrightarrow C_2H_4Cl_3 \qquad (3)$$
$$C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \qquad (4)$$
$$C_2H_4Cl_3 + W \longrightarrow C_2H_4Cl_2 + {}^1/_2Cl_2 \qquad (5)$$

The rate determining step in each case is equation (4), and either mechanism yields the experimental rate law. In any case it is evident that ethylene must have a very high collision efficiency with the intermediate, in order that within wide limits its concentration should not affect the rate.[4]

The Reaction of Chlorine in a Mixture of Ethylene and Hydrogen.—This reaction was measured in the apparatus just described. Before each experiment the walls were "cleaned up" as usual. The reaction with ethylene could be followed by the manometer at room temperature; that with the hydrogen was measured by taking a manometer reading with the vessel in a liquid air-bath whose temperature was measured with a gold resistance thermometer.

Table II gives some of the data obtained. Some experiments of identical results are omitted, as well as measurements taken at intermediate time intervals. The table headings are self-explanatory, except that the manometer reading is arbitrary and differences only are significant. The initial partial pressures are measured; final ones are calculated from the manometer readings on the assumption of a simple addition reaction to ethylene, and in experiments 2–9 and 2–11, from measured loss of hydrogen.

In the dark reaction no detectable reaction with hydrogen occurred during the ethylene–chlorine reaction. Even in the presence of light, a hydrogen–ethylene ratio of 9.64/1 permitted only 10.7% of the total chlorine reacting to react with the hydrogen, or a reactivity in favor of the ethylene of about 81-fold. If this be interpreted solely in terms of the difference in the heats of activation of the two reactions, since the heat of activation of the photochemical hydrogen-chlorine reaction is 6000 calories, that for the ethylene–chlorine photochemical reaction is less than 1400 calories.

TABLE II

THE REACTION IN MIXTURES OF ETHYLENE, CHLORINE AND HYDROGEN

	...	...	...	35.40	50	83.81

[a] To complete the reaction the 500-watt lamp was held close to the reaction vessel until perceptible change in the manometer ceased. The total pressure drop, 16.5 cm., was practically equal to the original ethylene pressure.

The Ethylene–Chlorine Reaction in Ethylene Chloride and in Pentane as Solvents.—Commercial ethylene chloride was refluxed over both calcium chloride and phosphorus pentoxide for several hours each, and distilled into dried bottles at 83.4–83.6°. The purifications of the *n*-pentane,[5] ethylene and chlorine have been described.[6] Carbon tetrachloride was refluxed for twelve hours with chlorine and iodine, washed with alkali, acid and water successively, dried with calcium chloride and refluxed over phosphorus pentoxide for six hours. It was distilled at 76.6° into carefully dried bottles.

Procedure.—Stock solutions of the olefin and chlorine in the solvents concerned were kept at 0° in an ice-bath. The reaction vessel, which usually was a 125-cc. glass-stoppered Erlenmeyer flask, was also immersed in an ice-bath. A known amount of each solution was pipetted into

---

(4) It is estimated that if chlorine and ethylene, each at a pressure of 0.001 of an atmosphere, were illuminated in a 130-cc. cylindrical reaction vessel, the rate of disappearance of chlorine atoms by reaction with ethylene should be nearly equal to the rate at which they combine at the wall.

(5) The refractive index of the carefully purified pentane was measured in a Pulfrich refractometer, referred to air at 20°.

$n^{20}{}_D$ 1.35750 $n^{20}{}_\alpha$ 1.35572
$n^{20}{}_\beta$ 1.36187 $n^{15}{}_\alpha$ 1.35854

(6) Stewart and Weidenbaum, THIS JOURNAL, **57**, 1702 (1935).

the reaction flask; as a rule the olefin was added first and then the chlorine. After the reaction had proceeded for the time interval desired, it was "quenched" by adding an aqueous solution of potassium iodide. The iodine liberated was determined by titration with sodium thiosulfate of suitable strength, using the method suggested by Liebhafsky.[7] The amount of hydrogen chloride produced, which was a measure of the induced substitution reaction, was obtained then by titrating the contents of the reaction flask with sodium hydroxide of suitable strength; brom cresol green was used as the indicator for this titration because of the distinctness of the end-point in spite of the two phases being present.

The stock solution of olefin was analyzed by adding a known amount of a solution of bromine in carbon tetrachloride, which was approximately twice the amount that would be required by the sample of olefin used. The mixture was kept in the dark for two hours at 0°. At the end of this time the uncombined bromine was determined by adding an aqueous solution of potassium iodide and titrating with sodium thiosulfate.

Experimental Results.—A large number of experiments using ethylene dichloride as the solvent for the reaction between chlorine and ethylene were performed with various changes in the experimental conditions. These included various ratios of the concentration of chlorine to that of ethylene over a range of 0.5 to 2, different treatment of the reaction vessel, such as burning it out in order to clean up the walls, variation of the temperature from 0 to 25°, and changes in the order of mixing the reactants.

When the concentration of each reactant was 0.05 *M* or larger, the reaction proceeded too rapidly to allow a study of its kinetics to be made. The induction factor was never greater than 0.1; here the induction factor is given by the ratio of the number of moles of hydrogen chloride produced to the number of moles of chlorine that are used by the olefin in the addition reaction.

Pentane was next used as the solvent. Here again the reaction was exceedingly rapid, being over 95% complete in fifteen seconds, but an induction factor as large as 2.8 was observed. Some typical results are given in Table III.

The members of the last two pairs of experiments differed only in the order in which the reagents were added.

TABLE III

THE CHLORINATION OF PENTANE INDUCED BY ETHYLENE

Time, seconds	Concentration × 10^3 Chlorine	Concentration × 10^3 Ethylene	Induction factor
30	8.6	25.0	2.8
30	16.0	6.7	0.85
30	3.8	13.0	2.3
30	3.5	18.7	2.6

60	3.64	0.93	0.7
60	3.64	0.93	0.6
60	0.57	1.85	1.9
60	0.57	1.85	1.9

It is seen that from 35.5 to 73.6% of the reacting chlorine produces hydrogen chloride. Moreover, if at a given initial chlorine concentration the initial ethylene concentration is increased, more substitution occurs (items 3, 4, 6 and 7); conversely a relative increase in the chlorine concentration decreases substitution (items 5 and 8). The substitution is probably upon the pentane, as the use of ethylene dichloride as a solvent for the same reactants produced but about 10% substitution at a maximum; pentane and chlorine alone do not react in the time allowed.

The question arises as to whether the intermediate in this induced substitution of pentane is the same molecule as the intermediate in its photochemical chlorination. Chlorine atom may be an intermediate in both the chain reaction of addition to ethylene and the chain reaction of substitution upon pentane, but as in the case of the hydrogen–chlorine reaction, ethylene should be an efficient inhibitor for the pentane–chlorine reaction. Increasing ethylene should decrease, not increase, the substitution if chlorine atoms were responsible. It would appear then, that some derivative of ethylene is the intermediate in the substitution reaction. If chlorine atom were competed for by both ethylene and chlorine, and if of the two products C_2H_4Cl promoted substitution and Cl_3 promoted addition, the facts could be qualitatively accounted for. We may then write

(1a) $Cl + Cl_2 \longrightarrow Cl_3$
(1b) $Cl + C_2H_4 \longrightarrow C_2H_4Cl$
(2) $C_2H_4 + Cl_3 \longrightarrow C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \ldots$
(3a) $C_2H_4Cl + Cl_2 \longrightarrow C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \ldots$
(3b) $C_2H_4Cl + C_5H_{12} \longrightarrow C_2H_4 + C_5H_{11} + HCl$
(4) $C_5H_{11} + Cl_2 \longrightarrow C_5H_{11}Cl + Cl \ldots$

with appropriate chain breaking steps. While the data do not permit a quantitative test of this mechanism, it may be interesting to derive an

---

(7) Liebhafsky, THIS JOURNAL, **53**, 165 (1931).

expression based upon it, for the instantaneous values of the induction factor as functions of the relative concentrations of reagents and of the various specific reaction rate constants. Assuming that the source of chlorine atoms is thermal decomposition and that any possible substitution due to the reaction

$$Cl + C_5H_{12} \longrightarrow C_5H_{11} + HCl$$

is slow compared to reaction (3b) above, and assuming as a chain terminating reaction

$$C_2H_4Cl_3 + W \longrightarrow C_2H_4Cl_2 + {}^1/_2Cl_2$$

we may write

$$\text{Induction factor} = \frac{d(HCl)}{dt} \Big/ \frac{d(C_2H_4Cl_2)}{dt} = K_{1b}K_{3b} \times \frac{(C_2H_4)}{(Cl_2)} \times \frac{(C_5H_{12})}{K_{1a}K_{3b}(C_5H_{12}) + K_{1a}K_{3a}(Cl_2) + K_{1b}K_{3a}(C_2H_4)}$$

The subscripts relate the specific reaction rate constants to the equations above. It is seen that should by accident the competitive reactions 1a, 1b and 3a, 3b, be equal in rate, so that $K_{1a} = K_{1b}$ and $K_{3a} = K_{3b}$, the expression reduces to

$$\text{I. F.} = (C_2H_4)/(Cl_2)$$

since here (C_5H_{12}) is large compared to (C_2H_4) or (Cl_2). Similarly, if ethylene be in large excess, or excessively reactive, causing only equations (3a) and (3b) to operate as competitive, it reduces to

$$\text{I. F.} = K_{3b}(C_5H_{12})/K_{3a}(Cl_2)$$

It should be stressed that the induction factors measured are integrated values over wide ranges of relative concentrations of reagents.

A very rapidly reacting ethylene should produce more substitution (reaction 1b being favored) than a slowly reacting one. The compound to be substituted must be very reactive, favoring reaction 3b over reaction 3a; ethylene chloride as solvent is perhaps for this reason less attacked than pentane. It is thus seen that ethylene does inhibit the normal chain of pentane chlorination; if it did not, conditions would be found where the induction factor approximated the quantum efficiency factor in the photochemical reaction. Experience with the induced benzene–chlorine addition lends credence to this expectation. But in addition to this inhibition, a new path is furnished for the substitution reaction, favored by excess of ethylene. Further evidence of this interpretation will be presented in a succeeding paper.[8]

Summary

1. The photochlorination of gaseous ethylene proceeds at a rate proportional to the chlorine concentration at constant light intensity, and independent of the ethylene concentration.

2. Practically no hydrogen reacts in a mixture of hydrogen, chlorine and ethylene, either in the dark or when illuminated, while the ethylene–chlorine reaction goes to completion.

3. The ethylene–chlorine reaction in ethylene dichloride solution is very rapid, and involves less than 10% of the chlorine in substitution; while in pentane solution from 37 to 73% of the chlorine substitutes, and the amount of the substitution is increased by an increase in the ethylene/chlorine ratio.

BERKELEY, CALIF. RECEIVED JULY 22, 1935

---

[8] Stewart and Smith, THIS JOURNAL, **52**, 2869 (1930), found that excess chlorine, when reacting with ethylene on surfaces coated with the reaction products, served to decrease the reaction rate and *increase* substitution. They obtained a maximum induction factor of unity, much higher than is found here in homogeneous solution. The difference in behavior is very real; one possible reconciliation is as follows. The series of reactions given above still holds, but the intermediate $C_2H_4Cl_3$ may react at the wall, not alone to produce Cl_2 as is often assumed for a chain breaking step, but also to give hydrogen chloride and products which no longer propagate a chain. Thus excess chlorine, winning in the competition for chlorine atom, might give an intermediate with ethylene which decomposed homogeneously one way, but at a surface differently. This could be true particularly on a surface which did not catalyze the chlorine–ethylene addition, since such a surface might also not catalyze recombination of chlorine atoms and thereby would give opportunity for the type of decomposition leading to substitution.

The Viscosity of Solutions of Salts in Methanol

BY GRINNELL JONES AND HOLMES J. FORNWALT

Introduction

Grüneisen[1] long ago showed experimentally that, although the viscosity–concentration curves for aqueous solutions of salts are approximately linear, nevertheless they exhibit systematic deviation from the simple linear relationship at low concentrations. The first plausible explanation of this "Grüneisen Effect" was offered by Jones and Dole,[2] who ascribed it to an increase in viscosity due to the electrical attraction between the ions. The increment of the viscosity due to this cause varies as the square root of the concentration and, therefore, becomes relatively more important at low concentrations in comparison with other effects which vary linearly with the concentration. Jones and Dole, Jones and Talley, and Wolfenden[3] and his associates have demonstrated that the equation $\eta = 1 + A\sqrt{c} \pm Bc$ is valid for aqueous solutions of many salts up to 0.2 N or above.

Falkenhagen and Dole, and Falkenhagen and Vernon[4] have deduced from the Debye theory of interionic attraction a complicated but explicit expression for the coefficient A of the square root term as a function of the mobilities and valences of the ions, the dielectric constant and viscosity of the solvent, the temperature and the usual universal constants which appear in the equations of the interionic attraction theory. Jones and Talley, and Wolfenden and his associates, have found a gratifying agreement between the values of A found experimentally for aqueous solutions of several salts and those computed by the equation of Falkenhagen and Vernon.

Finally Onsager and Fuoss[5] have proposed a generalized expression for the properties of solutions as a function of the concentration which in the case of viscosity would give the equation $\eta = 1 + A\sqrt{c} + Bc + Dc \log c + \ldots$ for the variation of the viscosity with the concentration, but without discussing the agreement of this equation with the available data.

The recent advances summarized above make it desirable to test the validity of these new relationships when applied to non-aqueous solutions. Methanol was chosen as the solvent to be studied because the dielectric constant is substantially lower than that of water and therefore the equation of Falkenhagen predicts a larger value of the coefficient A than for water solutions. This in turn means that the "Grüneisen Effect" should be more pronounced. Moreover, methanol has sufficient solvent power for many salts and gives solutions having a conductivity comparable with that of aqueous solutions and, therefore, the ionization must be substantial and the interionic attraction theory applicable.

Another object of this investigation was to obtain viscosity data to be used in the interpretation of conductance data on methanol solutions which were being determined simultaneously in this Laboratory.

Earlier investigations of the viscosity of solutions of salts in methanol have been made by Ewart and Raikes,[6] Tower,[7] and Harry C. Jones and E. C. Bingham.[8]

Experimental

Preliminary trials showed that the addition of water to methanol increases the viscosity at the rate of about 4% for each per cent. of water added. It was, therefore, evident that great care must be taken to purify the alcohol and to prevent the absorption of water from the air during the preparation and manipulation of the solutions.

The methanol used was a synthetic product made by the Commercial Solvents Company. A letter from the company stated that it contained no ethyl alcohol, less than 0.03% acetone and less than 0.2% water. It was purified by treatment with magnesium methylate in accordance with the method of Lund and Bjerrum,[9] followed by fractional distillation through a column 75 cm. long. The middle fraction consisting of about three liters of methanol boiling within about 0.04° of the true boiling point of

64.65°, as given by Timmermans and Hennaut-Roland,[10] was collected in storage reservoirs with suitable protection from the moisture in the air. These reservoirs were provided with standardized interchangeable ground glass connections with the flasks used to make the solutions. During the progress of the work it was discovered that the methanol contained a trace of ammonia. Therefore, in the later part of this work the methanol after purification as described above was distilled again from solid anhydrous copper sulfate, as recommended by Hartley and Raikes,[11] although the results were not influenced significantly by the change in procedure. The average density at 25° of the seventeen batches whose density was determined was 0.786545 g. per milliliter. The maximum difference between the density of any batch and the mean was only 0.00001.

The four salts used in this investigation were the chloride, bromide, and iodide of potassium, and ammonium chloride. All were carefully purified and dried and are believed to have contained no impurity in significant amounts. The salts were weighed out and solutions of the desired concentration prepared with suitable precautions to prevent absorption of moisture from the air during the preparation of the solutions and subsequent transfer to the pycnometers and viscometers. All concentrations are expressed in gram molecules per liter of solution at 25°. The viscometric technique was the same as that already described in earlier papers from this Laboratory.[12] Kinetic energy corrections have been applied to the data. Two different quartz viscometers having periods of 623 and 539 seconds with water at 25° were used. Duplicate runs on the same filling rarely differed by more than 0.02 second. The variations caused by removing the viscometer from the thermostat, cleaning and drying it and replacing the solution did not exceed 0.05 second, and were usually less than this. The viscosities given in the tables are relative to that of pure methanol at the same temperature. The viscosity of the solution, η, was always compared with that of the same sample of methanol which was used to prepare the solution. The comparative measurements on the solution and on pure methanol were always made on the same day in the same instrument and with every care to maintain all conditions which might affect the results (temperature, mounting, timing mechanism, etc.) as nearly constant as possible. The relative viscosities given are, therefore, believed to have been determined more precisely than the absolute viscosity of methanol is known.

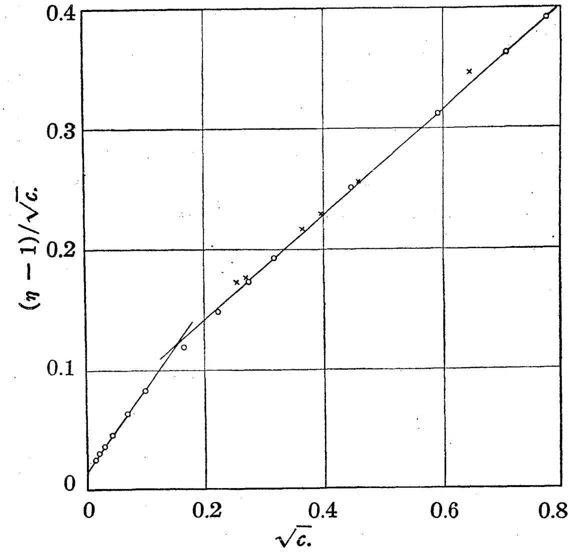

Fig. 1.—Test of the Jones and Dole equation: ○, Jones and Fornwalt; ×, Ewart and Raikes.

Potassium Iodide.—The results on potassium iodide solutions are shown in Table I and in Figs. 1 and 2. The density of potassium iodide solutions in methanol at 25° can be expressed by an equation of the form suggested by Root;[13] $d^{25}{}_4 = 0.786545 + 0.148096c - 0.007833c^{3/2}$; with an average deviation between our observed values and those computed by this equation of only 0.0021%.

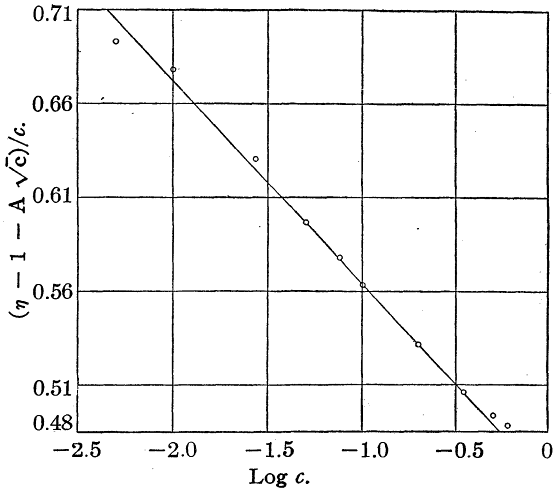

Fig. 2.—Test of the Onsager and Fuoss equation.

If the viscosity–concentration curves were linear the quantity $(\eta - 1)/c$ should be a constant, but column four shows that this quantity diminishes rapidly with increasing concentration at low concentrations but that, unlike most aqueous solutions, $(\eta - 1)/c$ does not pass through a minimum within the range of concentrations studied, which extends almost to saturation. The "Grüneisen Effect" is more pronounced in this case than for aqueous solutions. The Jones and Dole equation was then tested by plotting $(\eta - 1)/\sqrt{c}$ against $\sqrt{c}$ which gave a straight line up to and including $c = 0.01$. The coefficients A and B were then determined by the method of least squares using the data up to $c = 0.01$; giving η

$= 1 + 0.0159\sqrt{c} + 0.6747c$. As will be seen from Table I this equation agrees with the data up to $c = 0.01$ with an average deviation of only 0.002% but fails badly above this concentration. This same plot shows that the points from $c = 0.05$ to $c = 0.6$, inclusive, are also on a different straight line whose equation is $\eta = 1 + 0.05546\sqrt{c} + 0.43362c$ with an average deviation of 0.05%. The data were also used to test the Onsager and Fuoss equation: $\eta = 1 + A\sqrt{c} + Bc + Dc \log c$ by plotting $(\eta - 1 - A\sqrt{c})/c$ against $\log c$, which should give a straight line if the Onsager and Fuoss equation is valid and if the proper numerical value of A has already been chosen. Using the value $A = 0.0159$ already determined, an approximation to a straight line was found for the middle range of concentration (see Fig. 2). The two highest concentrations ($c = 0.5$ and $c = 0.6$) are clearly out of line. The deviations at the dilute end, although apparently large, are not significant because this method of plotting is extremely sensitive at the dilute end to experimental errors or to the value of A chosen. The method of least squares was then used to determine all of the coefficients in the Onsager and Fuoss equation using the data up to $c = 0.35$. The result was

$d^{25}_4 = 0.786545 + 0.067895c$.

Jones and Dole equation: $\eta = 1 + 0.0151\sqrt{c} + 0.7635c$.

Onsager and Fuoss equation: $\eta = 1 + 0.00367\sqrt{c} + 0.43974c - 0.21803c \log c$.

$\eta = 1 + 0.01575\sqrt{c} + 0.45174c - 0.10874c \log c$. The values computed from the equation are shown in the last two columns of Table I. As will be seen, this equation is better between $c = 0.027$ and $c = 0.35$ than any other equation known to us, but gives low results at $c = 0.5$ and $c = 0.6$ and is not as good as the Jones and Dole equation at $c = 0.01$ and below *if the constants are chosen to fit the data over the entire range up to* $c = 0.35$.

Ammonium Chloride.—Taking up the salts studied in order of decreasing solubility we find that ammonium chloride presents a picture very similar to potassium iodide. The density can be expressed by the Root equation with an average deviation of less than 0.001%; $d^{25}_4 = 0.786545 + 0.039225c - 0.008672c^{3/2}$. Again it was found that the Jones and Dole equation, $\eta = 1 + 0.0183\sqrt{c} + 0.6610c$ holds up to $c = 0.01$ but not above. The Onsager and Fuoss equation $\eta = 1 + 0.02129\sqrt{c} + 0.43823c - 0.09196c \log c$, is the best between $c = 0.01$ and $c = 0.35$, but not as good as the Jones and Dole equation for the more dilute solutions. The "Grüneisen Effect" is similar to potassium iodide solutions but slightly more pronounced.

Potassium Bromide and Potassium Chloride.—Owing to their limited solubility these salts do not give as severe and useful tests of the equations in which we are interested as the other salts studied. The densities of the solutions of both of these salts can be expressed as a linear function of the concentration (see Tables III and IV) with an average deviation of less than 0.002%. All four salts show the "Grüneisen Effect" in a similar degree. Again we find that the Jones and Dole equation is valid up to $c = 0.01$ but not above, and that the Onsager and Fuoss equation is better than the Jones and Dole equation for solutions more concentrated than $c = 0.01$.

General Discussion

Earlier investigations cited above have shown that the Jones and Dole equation is valid for aqueous solutions of salts which diminish the viscosity of water up to about 0.2 normal and to a considerably higher concentration for some salts which increase the viscosity. On the other hand, for these methanol solutions the Jones and Dole equation is valid only up to 0.01 normal.

All four of these salts give aqueous solutions which within certain ranges of concentration and of temperature, have a viscosity less than that of the pure solvent but none of them diminishes the viscosity of methanol at 25°. No salt has yet been found to have this effect in methanol solution. The B term in the Jones and Dole equation is positive for all methanol solutions that have yet been studied, but is negative for many salts in water solutions.

Falkenhagen and Vernon have used the Debye theory of interionic attraction to derive an expression for the coefficient of the square root term which for uni-univalent salts reduces to

$$A = \frac{1.45}{\eta_0\sqrt{2DT}}\left[\frac{l_1 + l_2}{4l_1l_2} - \frac{(l_1 - l_2)^2}{(3 + 2\sqrt{2})l_1l_2(l_1 + l_2)}\right]$$

where η_0 and D are the absolute viscosity and dielectric constant of the solvent, T is the absolute temperature, and l_1 and l_2 are the equivalent conductances of the ions present; and the factor 1.45 is computed from universal constants. The values of A for the four salts have been computed by this equation using: $\eta_0 = 0.00542$ (a preliminary value from our own measurements, details to be published later); $D = 31.5$ (after Åkerlöf[14]); and the following values for the equivalent conductances of the ions; K^+, 53.8; Cl^-, 51.3; Br^-, 55.5; I^-, 61.0; NH_4^+, 59.0 (after Hartley and Raikes, and Ulich[15]).

The results are shown in Table V and compared with the values of A obtained directly from our experimental data by the use of the Jones and Dole equation and the Onsager and Fuoss equation. The agreement is sufficiently close to show that Falkenhagen's theory is correct in its fundamentals even if it may require some modification or elaboration in detail. Of special significance is the comparison of these results in methanol solutions with the investigations on aqueous solutions referred to above. For aqueous solutions A has a value of 0.005 (more or less for various salts), whereas an inspection of the Falkenhagen and Vernon equation shows that the lower value of η_0 and D for methanol in comparison with water should make A about threefold larger. This is confirmed by our experimental data.

TABLE V

COMPARISON OF THE THEORETICAL AND EXPERIMENTAL VALUES OF THE COEFFICIENT OF THE SQUARE ROOT TERM A

Salt	Theoretical Falkenhagen	Experimental Jones and Dole	Experimental Onsager and Fuoss
KCl	0.0173	0.0151	0.0037
KBr	.0165	.0142	.0133
KI	.0158	.0159	.0158
NH_4Cl	.0165	.0183	.0213

Summary

1. The absolute density and relative viscosity at 25° of many solutions of potassium chloride, potassium bromide, potassium iodide and ammonium chloride in methanol have been measured covering a range of concentration from extreme dilution nearly to saturation.

2. The density of solutions of these salts in methanol may be expressed by an equation of the form suggested by Root for aqueous solutions.

3. Although all of these salts may cause a decrease in viscosity when dissolved in water, none of them shows this effect when dissolved in methanol.

4. All of these solutions show the "Grüneisen Effect" strongly.

5. The data are used to test the validity of several equations for the viscosity as a function of the concentration.

The Structure of Sodium Sulfuric Acid Ester of Galactan from Irideae Laminarioides (Rhodophyceae)

BY W. Z. HASSID

In a previous paper[1] the writer reported the isolation of a new carbohydrate from a red alga, *Irideae laminarioides*, which proved to be a sodium sulfuric acid ester of galactan. A tentative formula was proposed for this compound.

In the following work the compound has been subjected to a series of chemical processes, whereby the structure and the linkages involved between its groupings were studied.

Experimental

Acetylation of the Sodium Sulfuric Acid Ester of Galactan.—Haworth's method for acetylation of inulin[2] was followed with some modifications. Three grams of the finely powdered sodium sulfuric acid ester of galactan, prepared from *Irideae laminarioides* was stirred with 5 cc. of pyridine at 80° for half an hour. After cooling to room temperature, 30 cc. of acetic anhydride was slowly added with thorough mixing of the ingredients. After several hours 15 cc. of acetic acid was also added to the mixture. The substance did not, however, dissolve as in the case of acetylated inulin prepared by Haworth. This preparation was tested for its acetyl content at three or four day intervals, and it was observed that its acetyl value was gradually rising. After about two weeks, the acetyl value became constant and corresponded to two hydroxyl groups per one molecule of galactose.

For the acetyl determination the following method was used. About 20 cc. of 0.1 *N* sodium hydroxide was added to 0.1 g. of the acetylated substance in a flask and after standing for several hours was titrated with 0.1 *N* hydrochloric acid.

Duplicate determinations on 0.1 g. of material required 5.5 cc. of 0.1 *N* hydrochloric acid. The acetyl value was found to be 23.6%. Calculated acetyl content for two acetyl groups in $C_{10}H_{13}O_{10}SNa$ was 24.7%.

The hydrogen atoms of two hydroxyl groups in the compound were replaced by acetyl groups. The addition of 0.1 *N* sodium hydroxide regenerated the two hydroxyl groups using up an equivalent amount of alkali. The ethereal sulfate group was not saponified under these conditions.

Preparation of Galactan.—The ethereal sulfate group could be hydrolyzed off the compound either by acid or alkali.

(a) The acid hydrolysis was accomplished in the following manner. Thirty grams of the original material was hydrolyzed with 600 cc. of 0.5 *N* sulfuric acid under a reflux condenser for five hours at a temperature of 65–70°. The solution was then cooled and neutralized with barium hydroxide. The barium sulfate precipitate was filtered off and washed. The filtrate was concentrated under reduced pressure to a thick sirup and poured into an excess of 95% alcohol. The galactan precipitated as an amorphous white mass. It was dried at 50° in a vacuum oven. The yield was about 13 g. Its specific rotation (*c*, 0.4) in water, $[\alpha]_D$ was +82.2. Its reducing value, after hydrolysis of the substance with 2% sulfuric acid at 105–110° for seven hours and neutralization of the acid with barium hydroxide, was 95.8%.

(b) The alkali hydrolysis was accomplished as follows. Five grams of the original substance was placed in a flask containing 100 cc. of water and 5 g. of barium hydroxide. The mixture was heated under a reflux condenser at 70°. As the hydrolysis progressed, the sulfate ion precipitated by the barium as barium sulfate could be seen forming and settling at the bottom of the flask. The barium sulfate precipitate was then filtered off, a little hot saturated barium hydroxide added to the filtrate, and the mixture again heated under the reflux condenser at the same temperature. This operation was repeated a few times until no more barium sulfate precipitate could be seen forming. The solution was then cooled and the excess of hydroxide neutralized with dilute sulfuric acid. The precipitate was filtered off and washed, the filtrate concentrated and the galactan precipitated out from 95% alcohol. It was then dried in the vacuum oven at 50°. Its specific rotation (*c*, 0.4) in water, $[\alpha]_D$ was +78.0°.

The reducing value after hydrolysis with 2% sulfuric acid at 105–110° for seven hours and neutralization of the acid was 86.3%. This low reducing value is probably due to the incomplete removal of the sulfuric acid group or destruction of some of the carbohydrate by the alkali.

Methylation of the Sodium Sulfuric Acid Ester of Galactan.—Seventeen grams of the substance was methylated by the procedure described by Haworth and Learner[3] for methylation of inulin. A methylated sirup was obtained. After the addition of 30 cc. of absolute alcohol, and upon standing, a white amorphous mass was precipitated. The solid was filtered off, washed with absolute alcohol, and dried at 50°.

The methoxy content of the methylated substance was determined by Dore's method[4] with the following modification. The water in one of the two U-tubes of the apparatus was replaced by a 5% solution of cadmium sulfate. This was done in order to take care of the sulfur present in the compound which in the presence of hydrogen iodide is reduced to hydrogen sulfide and precipitated by the silver as silver sulfide. By introducing cadmium sulfate, the hydrogen sulfide was decomposed and trapped as cadmium sulfide.

A methoxy determination was made on the methylated substance. It was found to be 14.8%.

This partially methylated substance was subjected twice

to further methylation with Purdie's reagents. Its methoxy content was raised to 20.0%.

A third methylation with the Purdie reagents did not increase the methoxy content. The substance was, apparently, completely methylated. The results obtained agreed well with the calculated value for two methoxy groups in the compound $C_8H_{13}O_8SNa$, 21.23%.

The specific rotation (*c*, 0.8) in chloroform, $[\alpha]_D$ of this methylated compound was +17.2.

Hydrolysis of the Methylated Compound and Preparation of Dimethylmethylgalactoside.—Six grams of the methylated substance was hydrolyzed with 300 cc. of 2% sulfuric acid under a reflux condenser at a temperature of 105–110° for seven hours. The solution was cooled and nearly neutralized with barium hydroxide and completely neutralized with silver carbonate. The precipitate was filtered off and extracted four times with 100-cc. portions of chloroform. The chloroform extracts were dried with anhydrous sodium sulfate. The sodium sulfate was filtered off and after evaporating the chloroform under reduced pressure, a sirup was obtained, which did not crystallize after standing for several days. This sirup reduced Fehling's solution and did not precipitate barium sulfate on the addition of barium chloride after boiling a small amount with hydrochloric acid.

This showed that the methylated polysaccharide was hydrolyzed to a methylated monosaccharide, and that the sulfuric acid group was split off.

The methylated monosaccharide was then converted into its glycoside by boiling with 75 cc. of methyl alcohol containing 2 g. of hydrogen chloride under a reflux condenser for eight hours. The acid was then neutralized with silver carbonate and the filtered solution was evaporated to a sirup which was extracted with benzene and evaporated again. The sirup distilled at 90° and 0.1 mm. pressure. This sirup was taken up in a little petroleum ether and left standing in the cold with occasional stirring. In the course of a few days the sirup gave a crystalline substance, which did not reduce Fehling's solution, and apparently was dimethylmethylgalactoside.

Its methoxy content was 39.0%; calculated OCH_3 content for dimethylmethylgalactoside, $C_6H_{18}O_6$ was 41.8%; $[\alpha]_D$ (*c*, 0.8) in water was +97.2.

Preparation of Trimethylgalactan.—Twenty-five grams of galactan prepared by the acid hydrolysis, was methylated by the method of West and Holden.[5] A methylated sirup was obtained, which, upon the addition of a little petroleum ether and stirring, set to a mass of crystals. The crystals were filtered off and dried at 40°. The specific rotation of this substance (*c*, 0.8) in water $[\alpha]_D$ was +32.4. Its methoxy content was 44.5%. The calculated value for OCH_3 content in trimethylgalactan $C_9H_{16}O_5$ was 45.6%.

Preparation of Trimethylgalactose from the Methylated Galactan.—Eighteen grams of the methylated galactan was hydrolyzed with 400 cc. of 2 *N* hydrochloric acid in a distilling flask for an hour under a reflux condenser, using a boiling water-bath. The solution was cooled, saturated with sodium sulfate and extracted four times with 150-cc. portions of chloroform. The combined chloroform extracts were dried with sodium sulfate. Five grams of carboraffin was added and filtered on a dry talc filter, prepared on a small Büchner funnel. The solution was then transferred into a distilling flask, and the chloroform distilled off under reduced pressure. The remaining sirup was then distilled under 0.1 mm. pressure. About 12 g. of the sirup distilled over at 94°. An attempt to crystallize this sirup failed.

The sirup reduced Fehling's solution, and its specific rotation (*c*, 0.8) in water, $[\alpha]_D$ was +129.0. Its methoxy content was 40.9%. The calculated value for three OCH_3 groups, trimethylgalactose in $C_6H_{18}O_6$ was 41.8%.

An attempt to prepare an osazone from this trimethylgalactose failed. This fact shows that the hydroxyl on the second carbon atom must be occupied by one of the methoxy groups.

Oxidation and Esterification of the Trimethylgalactose.—The degradative oxidation of this compound was carried out in two stages, involving first the oxidation to the lactone by bromine water, and second, its conversion into a dibasic acid. This mode of procedure in stages possesses the advantage that the final product is homogeneous, whereas this is not the case when the methylated sugar is oxidized directly with nitric acid.

Ten grams of the sirup was placed in a glass-stoppered flask to which 8 cc. of bromine and 50 cc. of water were added. The contents of the flask were placed at a temperature of 30° for seven hours with frequent shaking. At the end of that time the oxidation was not complete, as it gave a positive test with Fehling's solution. After keeping the flask at the same temperature for about seventy-two hours with occasional shaking, the solution was devoid of action toward Fehling's solution. The excess of the bromine was removed by aëration and this was followed by treatment of the solution with litharge and finally with silver oxide until neutral to litmus. The filtrate was saturated with hydrogen sulfide, again filtered, and the solution evaporated to a sirup. This sirup was extracted several times with anhydrous ether; the ether was evaporated, and a sirup was obtained.

The sirup obtained from the oxidation with bromine weighing about 7 g. was treated with 56 cc. of concentrated nitric acid and warmed for half an hour at 50–60°, whereupon oxidation commenced. The temperature was gradually raised to 90°, and so maintained for five hours. At the end of that time the reaction ceased and the solution was transferred to a distilling flask and diluted with water. The nitric acid was removed by distillation under diminished pressure with frequent additions of water. The residue was dried at 80° in the vacuum oven overnight.

This sirup was esterified by boiling with 100 cc. of methyl alcohol containing 3 g. of hydrogen chloride under a reflux condenser for eight hours. The acid was neutralized with silver carbonate and the filtered solution was evaporated to a sirup. The small quantity of mineral matter was removed by extracting the sirup in benzene and then evaporating the solution. The sirup distilled at 0.1 mm. pressure and 95°. Its specific rotation (*c*, 0.8) in water, $[\alpha]_D$ was +41.1°. Its methoxy content OCH_3, was 51.1%; calculated for $C_9H_{16}O_7$, dimethylarabodimethoxyglutarate was 52.5%.

Isolation of a Dimethoxyhydroxyglutaric Acid from the Esterified Substance.—About 4 g. of the sirup, dimethyl-

---

[5] E. S. West and R. F. Holden, THIS JOURNAL, **56**, 930 (1934).

arabodimethoxyglutarate, was hydrolyzed with 50 cc. of 2% hydrochloric acid at 90° for two hours. The acid was neutralized with silver carbonate, the solution filtered and evaporated under diminished pressure, extracted with chloroform and the chloroform again distilled off.

The sirup was then distilled at 0.1 mm. pressure. The water-bath was replaced by an oil-bath as the sirup did not distil at 100°. A small amount (not enough to analyze) distilled over at 115°. The temperature was raised but no more of the sirup would distil over. The residue was then examined for its methoxy content and this was found to be 31.1%.

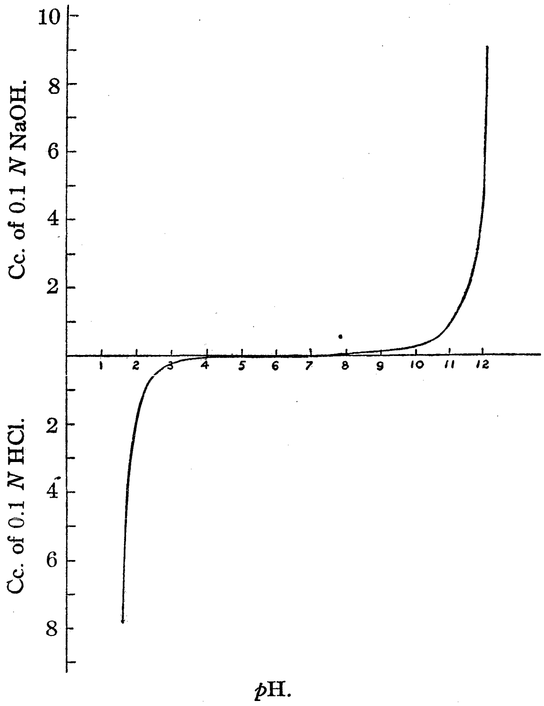

Fig. 1.—Titration curve of sodium sulfuric acid ester of galactan.

0.0921 gram of the sirup, on heating with 0.1 *N* sodium hydroxide and titrating with 0.1 *N* hydrochloric acid, required 9.3 cc. of 0.1 *N* sodium hydroxide for its neutralization. The undistilled residue was apparently dimethoxyhydroxyglutaric acid. The calculated value for the methoxy content of dimethoxyhydroxyglutaric acid, $C_7H_{12}O_7$, was 29.8% and its titration value for 0.0921 g. is 8.8 cc. of 0.1 *N* sodium hydroxide. This suggests that part of the acid is in the form of its lactone which would account for the high results obtained.

Evidence to Show that the Sodium Sulfuric Acid Ester of Galactan is a Salt of a Strong Acid.—The *p*H of a 1% solution of the acid previously obtained (1) was 3.6. On further continuation of the electrodialysis, the *p*H could be reduced to 2.86.

0.3 gram of this acid was titrated with 0.1 *N* sodium hydroxide. The amount required was 0.82 cc. The theoretical value for the titration of 0.3 g. was 1.24 cc. The titration, therefore, showed this acid to be of a greater equivalent weight than the theoretical one. The theoretical value of one equivalent weight of the acid $[(C_6H_9O_4)OSO_2OH]$ being 242, the calculated value from the titration was 366.

On further experimentation with this acid, it was found that part of the sulfur group was hydrolyzed off during the process of dialysis. It was noticed that by adding a solution of barium chloride to the anode compartment of the dialysis apparatus, a precipitate of barium sulfate was formed. This showed that some of the sulfate was hydrolyzed off the compound and moved through the membrane to the positive electrode. This accounts for the apparent high equivalent weight.

A 1% solution of the neutral salt itself (*p*H 6.8) was then taken and a titration curve was run by adding 0.1 *N* acid and 0.1 *N* alkali. A curve typical of that of a salt of a strong acid was obtained as shown in Fig. 1.

The specific conductance at 25° of various concentrations of the salt of the compound was then determined by using an electrical conductivity apparatus with the following results.

Solution, %	Specific conductance at 25°
2.0	2.53×10^{-3}
1.0	1.43×10^{-3}
0.5	6.88×10^{-4}
.25	3.68×10^{-4}
.125	1.84×10^{-4}

A 2% solution of sodium sulfuric acid ester of galactan, the specific conductance of which is 2.53×10^{-3} reciprocal ohms at 25°, is equivalent to 0.076 *N*. If we compare this with the specific conductance of 0.02 *N* potassium chloride, which is 2.77×10^{-3} reciprocal ohms at the same temperature, we find that the specific conductance of the salt is about 25% of that of the potassium chloride. The low specific conductance of the salt may be due to the fact that the solution of the compound in question is highly viscous and colloidal, and its large negative ion is probably highly hydrated and has a low mobility.

The neutrality of the compound, the shape of its titration curve and its specific conductance show that the sodium sulfuric acid ester of galactan is a salt of a strong acid.

Determination of Molecular Weight of the Sodium Sulfuric Acid Ester of Galactan.—The molecular weight of this compound was determined cryoscopically, the semimicrochemical method of Rieche[6] being used.

The rise in temperature when 30 mg. was dissolved in 5 cc. of water was 0.004°.

From the formula $M = 1000\ (C \times S)/S' \times \Delta$, where M is molecular weight, C is boiling point constant of water, S is weight of substance, S' is weight of solvent, Δ is rise in temperature, the value of the molecular weight of the substance was calculated as 780.

Considering that this substance is a sodium salt of a strong acid, the above value should be multiplied by two; thus, the approximate molecular weight becomes 1560. If we divide this value by the weight of one unit in the compound $[(C_6H_9O_4)OSO_2ONa]_n$ which is 264, the value n becomes 5.91. The data seem to indicate that there are approximately 6 units per one molecule of the compound. We can therefore, write the empirical formula for this compound as $[(C_6H_9O_4)OSO_2ONa]_n$, where n is approximately 6.

---

[6] A. Rieche, *Ber.*, **59**, 2186 (1926).

Discussion

The empirical formula for the sodium sulfuric acid ester of galactan was established from the analytical data as $[(C_6H_9O_4)OSO_2ONa]_n$.[1] The analytical data shown in the experimental work also indicate that this non-reducing polysaccharide consists entirely of galactose units and sodium ethereal sulfate groups and that there is one unit of galactose for each ethereal sulfate group.

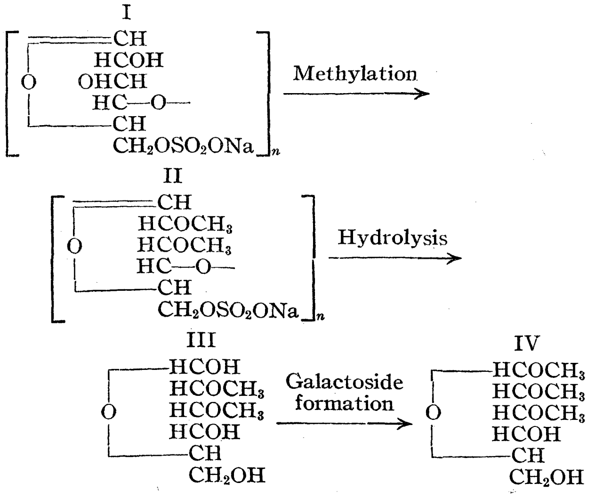
Two questions arise: (1) how are these galactose units linked together in the polysaccharide and (2) what position does the ethereal sulfate group occupy?

It is evident that the terminal carbon atom is tied up in a galactosidal linkage between the individual galactose units, from the fact that the substance is non-reducing. On complete methylation of the original compound two methoxy groups could be substituted for the same number of hydroxyls. That there are two free hydroxyl groups in one unit of galactose is confirmed by the fact that by acetylation of the compound two acetyl groups could be introduced into it.

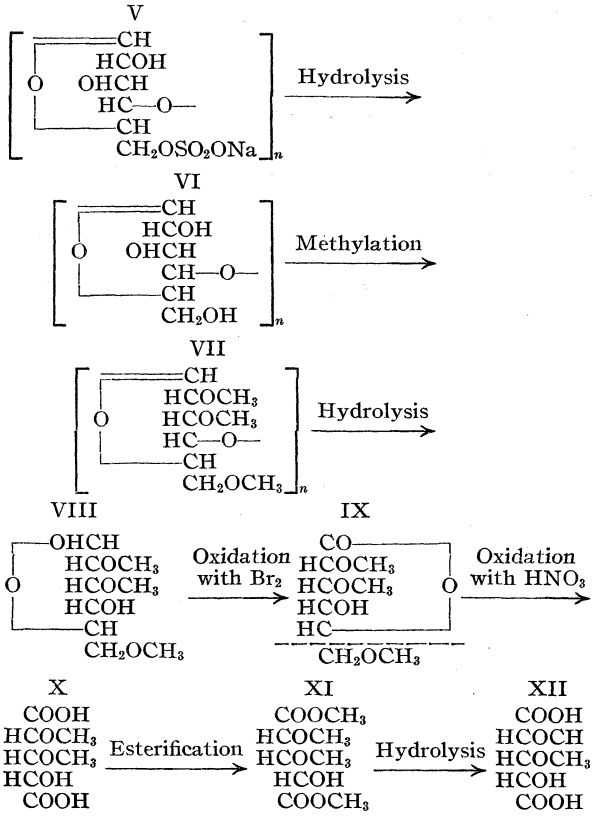
Acid hydrolysis of the methylated compound resulted in a reducing dimethylgalactose. The linkages holding together the galactose units, apparently, were broken with simultaneous splitting off of the ethereal sulfate group.

When the dimethylgalactose was boiled with methyl alcohol containing 3% hydrochloric acid, dimethylmethylgalactoside was obtained.

The above series of changes can be expressed by the equations



On hydrolyzing off the ethereal sulfate group of the original compound (V), galactan was obtained (VI). Upon methylation and subsequent hydrolysis of the trimethylgalactan (VII), trimethylgalactose was obtained (XIII). Oxidation with bromine, then with nitric acid and subsequent esterification, resulted in a dimethylarabodimethoxyglutarate. On hydrolysis of this dimethylarabodimethoxyglutarate, dimethoxyhydroxyglutaric acid was obtained.



It is evident that one of the methyl groups in the trimethylgalactose (VIII) is on the primary alcohol group, because, after splitting off the sixth carbon atom of the substance by oxidation with nitric acid, dimethoxyhydroxyglutaric acid was obtained, a substance with only two methyl groups.

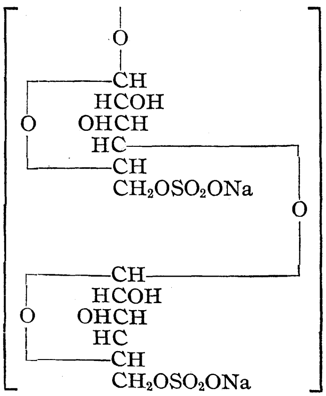
This shows that there could be no 1,6 linkage between the individual units in the original compound (V), because if we assume this to be true, the ethereal sulfate group could not have been attached to the sixth carbon atom, and should have occupied any other one of the five positions of carbon atom groups in the galactose unit. After hydrolyzing off the ethereal sulfate group and methylating the compound, a trimethylgalactan would have resulted, which had no methyl group on the sixth carbon atom. On hydrolysis of the compound and subsequent oxidation with nitric acid, a trimethoxyglutaric acid would have been obtained instead of a dimethoxyhydroxyglutaric acid (XII) as was the case. This, therefore, eliminates the possibility of 1,6 linkage.

The linkage between both of the first carbon atoms of the individual units is excluded, because a trimethylgalactan would have been obtained in (II) instead of a dimethylgalactan, and a tetramethylgalactan in (VII) instead of a trimethylgalactan.

The linkage between the first and second carbon atoms is eliminated on the basis that no osazone could be obtained from a trimethylgalactose (VIII). If there were a 1,2 linkage in the polysaccharide, a free hydroxyl should have resulted on the second carbon atom group on hydrolysis of the trimethylgalactan to the trimethylgalactose, and, consequently, the preparation of an osazone should have been possible.

The linkage of 1,5 between the units may also be eliminated, if we assume the usual amylene ring of the galactose itself. Since the four positions, 1,1, 1,2, 1,5 and 1,6 are eliminated, only the two possibilities, 1,3 and 1,4 remain. Since the 1,3 linkage has never been found, while the 1,4 is common in many disaccharides and polysaccharides, it is, therefore, reasonable to assume that the latter is more probable.

Presumably the ethereal sulfate group exists as a side chain formed by replacement of an hydroxyl group. The position of this ethereal sulfate group is uncertain. However, from consideration in a previous paper[1] this group is assigned to the sixth C atom as the most probable position. Further studies are being undertaken in attempt to establish this point.



In accordance with these considerations, the arrangement shown is tentatively proposed, indicating the linkage between two units.

The molecular weight determination indicates that the polysaccharide is made up of approximately six of these building units, perhaps similarly arranged.

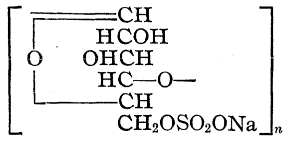
The writer wishes to express his indebtedness to Mr. W. H. Dore under whose general direction this work was carried out. The many valuable suggestions received materially aided the progress of the work.

Summary

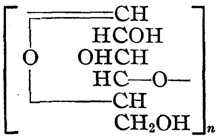
1. The sodium sulfuric acid ester of galactan isolated from *Irideae laminarioides* indicates that it is a salt of a strong acid. This is shown from the titration curve of the substance and also its conductivity data.

2. When the sodium sulfuric acid ester of galactan was subjected to electrodialysis, the sodium was removed and the substance initially neutral became acid, *p*H of about 3. This resulting substance, apparently, was sulfuric acid ester of galactan. It could not be obtained in pure form because the sodium could not be entirely dialyzed out and also because part of the sulfuric acid group was split off in the process of dialysis.

3. A tentative structural formula shown is proposed for the substance in which *n* seems to be approximately 6.



4. The sulfuric acid group in this compound was removed by hydrolysis and a polysaccharide was thus obtained which, in the chemical sense, is a pure galactan.



This is, apparently, the first time that a homogeneous galactan, consisting entirely of galactose units, was obtained from a plant.

The Viscosity of Liquid Phosphorus

BY ALAN NEWTON CAMPBELL AND SIDNEY KATZ

This work was undertaken, firstly as an application of Smits' theory of allotropy and, secondly, to evaluate a physical constant which had not been determined at the time this work was commenced (September, 1934). Smits[1] draws attention to the abnormally low viscosity of liquid phosphorus in the neighborhood of the melting point of the α-white (ordinary yellow) form. The viscosity is abnormally low in the sense that the molten form is supercooled by 550° with respect to the stable violet form, and Tammann[2] has shown that there is usually a sudden and large increase of viscosity with increasing supercooling. Smits, however, quotes no figures and presumably his statement is based on visual observation of the mobility of phosphorus.

The first part of our work consisted in raising molten phosphorus to a fairly high temperature in the viscometer, chilling as rapidly as possible to the solid state and determining the viscosity just above the melting point. Such treatment has been found slightly to alter the melting point of substances, even in the absence of intensive drying, and might be expected to show an effect on the viscosity, particularly if the internal equilibrium is one between simple and associated molecules. On the latter assumption the viscosity of a rapidly chilled liquid would be less than normal, since there would be a deficiency of polymerized particles.

Toward the conclusion of this work, an abstract was received of work on the viscosity of phosphorus carried out by Dobinski[3] in the previous year. His measurements give the viscosity of phosphorus over the temperature range, 17.5–79.9°. As the original paper[4] is somewhat inaccessible, we reproduce his figures here.

DATA OF DOBINSKI

Dobinski plotted his results in accordance with the formula of Andrade[5] and, as the graph changes slope at low temperatures, he concluded that association becomes appreciable below 49°. He observed visual indications of an internal equilibrium but he did not investigate the equilibrium shift by chilling experiments.

Experimental

An Ostwald viscometer of the ordinary type was used in this work. The plan of procedure in all cases consisted in maintaining the temperature of the phosphorus at some initial temperature until internal equilibrium was presumably established. The viscometer was then plunged in ice water to "freeze" the equilibrium, and then placed in a thermostat just above the normal melting point. Times of flow were then read in rapid succession until a steady value was reached, or until experimental difficulties, such as the appearance of particles of a solid form, made further readings impossible.

The phosphorus used in these experiments had been in stock for many years and it is not possible to state its origin. It had been kept in a subdued light, and was only superficially coated with a more stable form. It was purified by the method of Cohen and Olie[6] and then stored under water in a dark cupboard. A fresh preparation was made every ten days.

To displace the liquid phosphorus in manipulation and purification, either nitrogen or carbon dioxide was used. To remove the residual oxygen and moisture, the gases passed through hot copper turnings, pyrogallol solution, spiral water condensers, sulfuric acid bubblers, calcium chloride towers and phosphorus pentoxide towers.

The thermostat used in the viscosity determinations had a variation of ±0.02° over the range 20–40°. From 40 to 60° the temperature variation was greater, about ±0.05°. For heating bath in the experiments on shift of internal equilibrium a glycerol bath was used, and this had no temperature regulation, the temperature being kept approximately constant by adjusting the heating flame.

It is well known that white phosphorus is photosensitive; the rate of transformation to more stable forms is greatly enhanced when the phosphorus is illuminated. To minimize this effect direct light was excluded from the labora-

tory. Operations were carried out in a fume-cupboard whose walls were covered with black paper. The heating bulb of the thermostat was also covered with black paint. Observations were made by means of a ruby-colored photographic light.

The viscometers were of a 5-cc. lower bulb capacity and had a water run time of about eighty seconds or more at room temperature. The stems were calibrated for five different volumes as shown in Fig. 1. A complete series of run times was taken for each of the five volumes over the temperature range in which the phosphorus was to be investigated. As standardizing liquid water was used for the range 20 to 80°. The water used was laboratory distilled water, redistilled from potassium hydroxide and potassium permanganate through a block tin condenser; it was collected and stored in a silica flask. For standardization at the higher temperatures, monobromobenzene was used. It was purified by dehydration over calcium chloride and redistilling the fraction with the correct boiling point being collected. After the conclusion of a series of runs with phosphorus, the apparatus was dismembered, and the viscometer restandardized. No appreciable variation was ever observed.

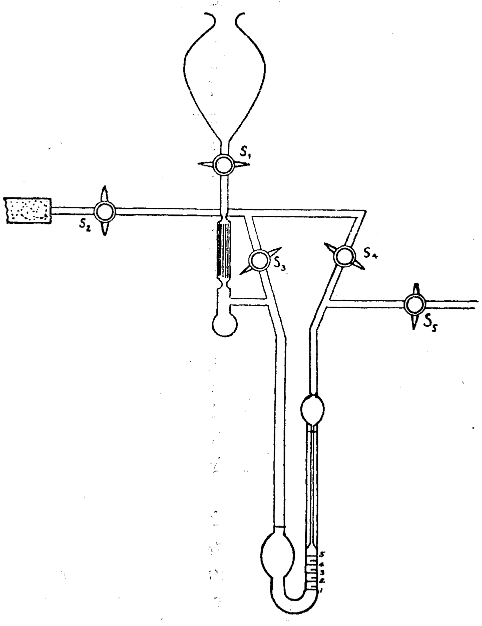

Fig. 1.

The very simple apparatus of Fig. 1 was used. The viscometer proper was wired to a wooden mount, to which were attached small spirit levels. The preliminary work had shown that molten phosphorus rapidly develops a thin yellowish scum,[7] and eventually particles of the stable violet form. As soon as particles commenced to deposit on the walls the apparatus had to be cleaned. Hence, after a day's running the apparatus was completely dismembered and the viscometer cleaned. After rebuilding, the apparatus was again cleaned. It was then thoroughly flushed for at least two hours with nitrogen or carbon dioxide.

The mode of operation was as follows. The reservoir of the apparatus was half filled with hot water and a few cc. of the purified liquid phosphorus then forced into it. The apparatus was full of inert gas and stopcocks, S_2, S_3, S_4 and S_5, being open, inert gas was streaming through the apparatus. Stopcock S_1 was then cautiously opened and phosphorus allowed to enter the capillary filled tube, drop by drop. The capillaries served to filter off any scum which might be formed at the phosphorus–water interface. The small round bulb below was intended to trap any impurities heavier than liquid phosphorus, but none were detected. The phosphorus was then allowed to run very slowly into the viscometer till the large lower bulb was approximately full. S_1 was closed and the phosphorus in the upper part of the system frozen by chilling the upper tube. From this point on work was performed as rapidly as possible to obtain the maximum number of runs before the accumulation of red phosphorus rendered the readings unreliable. By opening and closing suitable cocks, the phosphorus was brought to the level, O, in the bulb of the viscometer and the volume read from the level attained in the calibrated limb. Application of pressure then drove the phosphorus through the capillary of the viscometer, to the graduation mark above the bulb. With stopcocks S_1, S_2, and S_5 closed, and S_3 and S_4 open, the phosphorus was then under uniform gas pressure in both limbs.

Our first experiments dealt with the effect of rapid chilling from a high temperature on the viscosity at a fixed temperature. The viscometer and its contents were kept in the high temperature glycerol bath for from one-half to one hour. It was removed and plunged into ice water to "freeze" the equilibrium. It was then immersed in the thermostat which was set at a temperature slightly above the melting point of α-white phosphorus. Run times were taken in rapid succession as soon as the phosphorus was sufficiently liquid. At the same time, the time interval from the moment of placing the viscometer in the thermostat to the beginning of each run was noted. The results of a set of determinations are given below. In several cases, runs were begun before the phosphorus in the lower bulb had completely melted. The presence of unmelted phosphorus during a run is indicated by an (x). Data for runs so marked are, of course, meaningless. The thermostat temperature was 45.0°.

It is apparent that chilling from 80° has produced no effect on the viscosity. Considering the 100 and 120° figures, and discounting the asterisked figures, where unmelted phosphorus was present, there is some indication of a decrease in run-time with time. One would expect, however, if the pseudo-components of phosphorus stand in the relation of simple and associated molecules that chilling from a high temperature

would give rise to a solid, and eventually to a melt, abnormally high in simple molecules, and therefore having a viscosity lower, not higher, than normal. The only conclusion we feel justified in drawing is that the effect, if it be real, is very slight; in other words, the internal equilibrium in liquid phosphorus is very rapidly established.

The normal viscosities of phosphorus were determined in the same way, except, of course, that the prior heating and chilling were omitted. At 140°, in spite of the rapidity of working, the viscometer became badly clogged with red phosphorus in a very short time, but below this temperature no difficulty was experienced from this cause. In the supercooled region, little difficulty due to solidification was experienced above 25°. At 25° spontaneous crystallization occurred once, and at 20° three or four times. It is well known that the velocity of crystallization of phosphorus is very great[8] and once nuclei are developed, crystallization is almost instantaneous. By slowing the stirrer somewhat to minimize vibration, a satisfactory set of readings was obtained at 20°. The effect of shock on initiating spontaneous crystallization has been demonstrated.[9] Attempts at 17.5° invariably resulted in solidification half way through the runs, and it was found impossible to supercool to 15° without spontaneous crystallization occurring immediately.

Calculations and Results

In the determination of the viscosity of phosphorus about two hundred runs were made.

The density and viscosity of water were obtained from the "International Critical Tables." The figures of Meyer and Mylius[10] were used for the density and viscosity of bromobenzene. The data for the density of phosphorus were taken from a paper by Pisati and De Franchis and from Dobinski.[11] The former made dilatometric measurements over the range 20–280°. Dobinski developed an empirical formula

$$D = 1.76705 - 0.0009222(t - 20)$$

which shows good agreement with the figures of Pisati and De Franchis, especially up to about 60°. The density figures of both Pisati and De Franchis and of Dobinski were used in a series of preliminary calculations of viscosity. Determinations to four figures, of which only three are probably significant, gave the same results for both sets of densities.

The data for the standardizing fluid were determined at very nearly the same temperature as the corresponding phosphorus run. The greatest difference was at 48°, where the nearest water determination was at 50°. In order that the volume of standardizing fluid and of phosphorus might be the same, time of flow of standardizing fluid was determined for each volume graduation of the viscometer. Where the value of phosphorus did not exactly coincide with a calibrated volume, half-interval interpolation was employed. It was found that intervals of less than half a scale division gave rise to variations less than the working limits of the stopwatch.

Dobinski plotted the logarithm (Napierian) of viscosity against the reciprocal of the absolute temperature, in accordance with the method of Andrade (*loc. cit.*) and, as he obtained a change of slope toward lower temperatures, he deduced that association was setting in. We, therefore, repeated our determinations twice, over the range of 25 to 60°, where the highest accuracy is obtainable, using fresh preparations, fresh apparatus

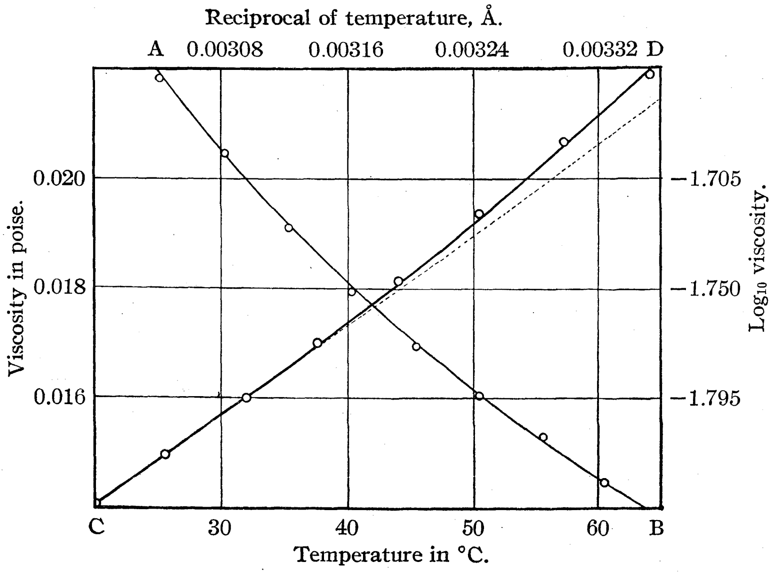

Fig. 2.—Curve AB, temperature–viscosity; Curve CD, reciprocal of temperature—log of viscosity.

and fresh calibrations. The two sets of observations were practically identical. They were therefore averaged and these results are appended to our previous results in Table III. Viscosities are given to three significant places. The common logarithms of the viscosities and the variation in temperature of the thermostat, as measured with a Beckmann thermometer, are also given. The repeat figures differ very slightly from our previous figures, with the exception of the figure for 60°, which the plot of our earlier figures showed to be discordant.

In Fig. 2, (a) viscosity is plotted against temperature for the range 25 to 60°; (b) the logarithm (common) of the viscosity is plotted against the reciprocal of absolute temperature, between the same temperature limits.

Discussion

There is no evidence of a change of viscosity when heated phosphorus is suddenly chilled, under our experimental conditions. There are logically four explanations of this, of unequal probability.

1. Smits' theory is incorrect.

2. The equilibrium displacement on cooling is so rapid that it is complete before solidification takes place. This is in agreement with Smits' own belief. He comments on the rapidity with which the inner equilibrium of liquid phosphorus is established just above the melting point of the α-white form.[12] We were not able to apply the anti-catalytic effect of intensive drying.

3. The temperature–composition curve of the inner equilibrium of liquid phosphorus is practically vertical, that is, the temperature change of internal equilibrium is too small to be detectable.

4. The shifting internal equilibrium does not reflect itself in viscosity change. In other words, the pseudo-components are isomers and not polymers.

Considering the viscosity figures as such, it is apparent that the agreement with Dobinski's figures is good, being well within 1%, below 60°. Above this temperature, the error probably increases with rising temperature, but it cannot be great, since, when all our figures,

[12] "Theory of Allotropy," p. 233.

including the figure for 140° and eliminating our first figure for 60°, which is obviously discrepant, are plotted against temperature, a smooth curve is obtained. Dobinski's figures do not extend above 80°. When our figures are plotted by the method of Andrade, the same change in slope is observed as with Dobinski's figures. If, therefore, Andrade's theory is sound, so is Dobinski's deduction, *viz.*, association of liquid phosphorus becomes appreciable below about 45°. If this is so, possibilities 3 and 4 (above) are ruled out. It is very probable that 2 contains the real explanation of our failure to observe positive results.

Summary

1. Experiments have been carried out on the effect of rapid chilling on the viscosity of phosphorus.

2. The viscosity of liquid phosphorus has been determined between the temperature limits 20–140°. The agreement with the prior figures of Dobinski (range 17.5–79.9°) is very good. As most of our work was carried out in ignorance of the very recent work of Dobinski, it appears that the viscosity of phosphorus is now known with a satisfactory degree of accuracy, at least over the temperature range common to both.

3. Association becomes appreciable in liquid phosphorus below 45°. The bearing of this and of the chilling experiments on Smits' theory is discussed.

The Potentials of Cells in Liquid Ammonia Solutions. The Thermodynamic Constants of the Ammino Cadmium Chlorides and of Cadmium Chloride

BY CLIFFORD S. GARNER, EMERSON W. GREEN AND DON M. YOST

Introduction

The present investigation was undertaken to determine the suitability of the cadmium amalgam–hexammino cadmium chloride half-cell as a reference electrode for electromotive force measurements in liquid ammonia, and to evaluate the thermodynamic constants of the ammino cadmium chlorides and cadmium chloride.

For the purpose of establishing an electromotive series in the ammonia system it is desirable to refer all half-cells to some half-cell whose potential is taken arbitrarily as zero. Such a half-cell in the aqueous system is the hydrogen electrode. The same half-cell is here adopted for the liquid ammonia system in which the ammonium ion corresponds to the hydrogen ion of the aqueous system.

In this paper are presented the results of measurements on cells of the type Zn(amalg., N_2), $ZnCl_2 \cdot 6NH_3(s)$, NH_4Cl(in $NH_3(l)$, f.), $CdCl_2 \cdot 6NH_3(s)$, Cd(amalg., N_1) together with the thermodynamic constants for the ammino cadmium chlorides and cadmium chloride. Provisional values of known potentials in terms of the standard hydrogen half-cell in liquid ammonia are also presented.

Preparation of Materials and Experimental Procedure

Ammonia.—The gas from a tank was passed over solid potassium hydroxide, condensed into a trap containing metallic sodium, and then fractionated over into an auxiliary vessel.

Mercury.—Mercury was repeatedly sprayed through nitric acid, and washed and dried. It was then redistilled five times in a current of air.

Zinc.—C. P. zinc sticks were scraped free from an oxide coating, placed in a sectioned Pyrex tube and distilled in four fractions in a current of pure dry hydrogen. It was then stored in weighing bottles filled with hydrogen.

Cadmium.—C. P. cadmium sticks were purified and stored in the same manner as for zinc.

Hydrogen.—The gas from a tank was passed through platinized asbestos at 350° to remove oxygen, and then through anhydrous phosphorus pentoxide to dry it.

Zinc Chloride.—Analytical reagent zinc chloride was fused, and immediately upon solidifying it was placed on the zinc amalgam in the cell. A stream of pure hydrogen was passed through the cell during this operation.

Cadmium Chloride.—A nearly saturated solution of recrystallized cadmium chloride (C. P.) was prepared containing a very small amount of hydrochloric acid to prevent hydrolysis. The solution was placed in a desiccator containing sulfuric acid, and the crystals resulting were filtered, pressed dry, and then placed in a flask. The flask was evacuated and at the same time heated to nearly the melting point of the cadmium chloride. Portions of the purified cadmium chloride were then placed on the cad-

[a] By formality is meant the number of formula weights per thousand grams of solvent.

mium amalgam in the cell. This last operation was carried out in an atmosphere of pure hydrogen.

Ammonium Chloride.—Analytical reagent ammonium chloride was recrystallized several times from water, and after subliming it was stored in a vacuum desiccator.

The Amalgams.—Purified mercury was distilled over into a receiver and a weighed piece of metal added in an atmosphere of hydrogen. The receiver was then partially evacuated, sealed off, and placed in a shaking device for about twenty hours. The receiver with contents was then weighed, the tip was broken off in a stream of hydrogen and the amalgam poured into a hydrogen-filled vessel provided with a number of side tubes. Equal portions were allowed to flow into the small side tubes which were then sealed off under hydrogen at atmospheric pressure. The empty receiver was weighed after these operations had been completed. It was found necessary to evacuate and bake thoroughly all apparatus coming in contact with the amalgams to prevent formation of oxides. The amalgams were always clean and bright.

The cell used was essentially the same as that described by Elliott and Yost.[6] A Leeds and Northrup Type K potentiometer was used in connection with a sensitive null galvanometer for making the electromotive force measurements. The standard cell was carefully calibrated against a new laboratory standard.

Results of the Experiments

Since no data were available on the solubility of cadmium chloride in liquid ammonia, a single rough determination was made using a modified method based on that of Hunt and Boncyk.[1] The value obtained was 0.0011 mole of $CdCl_2$, as such, per 1000 g. of liquid ammonia at 25.0°, but due to the inadequacy of the method for very slightly soluble salts, this is to be regarded as an upper limit. It is probable that the true solubility is not greater than about one-half of this value. The solid phase was $CdCl_2 \cdot 6NH_3$. This follows from the results of Biltz and Mau,[2] on the equilibrium pressures of ammonia above the solid decammino and hexammino cadmium chlorides.

In Table I are presented the results of the electromotive force measurements made on the cell

$$\text{Zn(amalg., } N_2\text{), } ZnCl_2 \cdot 6NH_3\text{(s), } NH_4Cl \text{ (in } NH_3\text{(l), f.), } CdCl_2 \cdot 6NH_3\text{(s), Cd(amalg., } N_1\text{)} \quad (1)$$

for which the reaction is

$$\text{Zn(amalg., } N_2\text{)} + CdCl_2 \cdot 6NH_3\text{(s)} = ZnCl_2 \cdot 6NH_3\text{(s)} + \text{Cd(amalg., } N_1\text{)} \quad (2)$$

The activities of cadmium in its amalgams have not been calculated, but the electromotive forces of cells at 25.0° in which the following reactions take place are known.

$$\text{Zn(amalg. satd. with pure Zn)} = \text{Zn(amalg., } N_2\text{)}^3 \quad (3)$$

$$\text{Cd(2 phase)} = \text{Cd(amalg., } N_1\text{)}^4 \ (4), \text{ and Cd(2 phase)} = \text{Cd(s)}^5 \quad (5)$$

In the table E_1 is the electromotive force of the cell whose reaction is

$$\text{Cd(amalg., } N_1\text{)} = \text{Cd(s)} \quad (6)$$

and E_2 is that for the cell whose reaction is

$$\text{Zn(s)} = \text{Zn(amalg., } N_2\text{)} \quad (7)$$

It is assumed here that the electromotive force of the cell Zn(s) = Zn(saturated amalgam) is zero. In the last column of Table I are presented the values calculated from the relation $E^0 = E_{\text{obsd.}} + E_1 + E_2$, for the standard potential E^0 of the cell

$$\text{Zn(s), } ZnCl_2 \cdot 6NH_3\text{(s), } NH_4Cl \text{ (in } NH_3\text{(l), f.), } CdCl_2 \cdot 6NH_3 \text{ (s), Cd(s)} \quad (8)$$

for which the reaction is

$$\text{Zn(s)} + CdCl_2 \cdot 6NH_3\text{(s)} = ZnCl_2 \cdot 6NH_3\text{(s)} + \text{Cd(s)} \quad (9)$$

and the total pressure is the vapor pressure of the liquid ammonia solution at 25°.

Each cell required between four and five hours to attain equilibrium, after which time the elec-

tromotive force was constant to 0.1 millivolt or better for days. The cadmium electrode was always positive.

From the results of the measurements of the cell, it appears that the cadmium amalgam–hexammino cadmium chloride half-cell can be used to advantage as a reference electrode in liquid ammonia. Inasmuch as hexammino cadmium chloride is less soluble in liquid ammonia at 25° than thallous chloride, and since cadmium amalgams do not oxidize as readily as thallium amalgams, it would seem that this half-cell is superior to the thallium amalgam–thallous chloride half-cell.

Thermodynamic Constants of the Ammino Cadmium Chlorides and Cadmium Chloride.—The standard free energy increase accompanying reaction (9) was calculated from the relation $\Delta F^0 = -NE^0F$ to be $-16{,}637$ cal. The free energy of formation of $ZnCl_2 \cdot 6NH_3(s)$ at 25° is $-142{,}290$ cal.[6,7] and hence the free energy of formation of $CdCl_2 \cdot 6NH_3(s)$ at 25° is $-125{,}650$ cal.

The increase in heat content accompanying reaction (9) is -8060 cal., and it was calculated from the temperature coefficient of one of the cells $+0.000756$ volt/deg., and the partial molal heats of solution of zinc[3] and cadmium[4] in their amalgams. The heat of formation of $ZnCl_2 \cdot 6NH_3(s)$ at 25° is 250,840 cal.,[6] and consequently the heat of formation of $CdCl_2 \cdot 6NH_3(s)$ at 25° is 242,780 cal. This is a more reliable value than that given in the "International Critical Tables," namely, 237,000 cal.

From the results of other investigators, taken in connection with the above, the calculation of the free energies and heat contents of the other four ammoniated cadmium chlorides and cadmium chloride itself is possible. From the data of Biltz and Mau[2] the following equations have been derived.

$$CdCl_2 \cdot 10NH_3(s) = CdCl_2 \cdot 6NH_3(s) + 4NH_3(g) \qquad \Delta F^0_{298.2} = -6660 \text{ cal.} \quad \Delta H = 32{,}200 \text{ cal.} \tag{10}$$

$$CdCl_2 \cdot 6NH_3(s) = CdCl_2 \cdot 4NH_3(s) + 2NH_3(g) \qquad \Delta F^0_{298.2} = 2300 \text{ cal.} \quad \Delta H = 19{,}580 \text{ cal.} \tag{11}$$

$$CdCl_2.4NH_3(s) = CdCl_2 \cdot 2NH_3(s) + 2NH_3(g) \qquad \Delta F^0_{298.2} = 2350 \text{ cal.} \quad \Delta H = 32{,}660 \text{ cal.} \tag{12}$$

$$CdCl_2 \cdot 2NH_3(s) = CdCl_2 \cdot NH_3(s) + NH_3(g) \qquad \Delta F^0_{298.2} = 5681 \text{ cal.} \quad \Delta H = 10{,}800 \text{ cal.} \tag{13}$$

$$CdCl_2 \cdot NH_3(s) = CdCl_2(s) + NH_3(g) \qquad \Delta F^0_{298.2} = 10{,}700 \text{ cal.} \quad \Delta H = 23{,}510 \text{ cal.} \tag{14}$$

From these data, combined with those from the cell measurements, the thermodynamic constants of all the ammino cadmium chlorides and cadmium chloride have been computed, and are presented in Table II. In making the calculations, the free energy of formation of ammonia gas at 25° was taken as -3910 cal.[8] and its heat of formation as 10,940 cal.[9] The standard virtual entropies at 25° of cadmium,[8] chlorine,[10] nitrogen,[11] and hydrogen[12] are 11.80, 53.31, 45.79 and 31.23 cal./deg., respectively. The free energy and heat content values are referred to the elements in their standard states of 25° and one atmosphere. These free energy, heat content and entropy values for $CdCl_2(s)$ agree well with those obtained independently by Ishikawa, Kimura and Murooka,[13] namely $\Delta F^0_{298.2} = -81{,}857$ cal., $\Delta H_{298.2} = -92{,}149$ cal., and $S^0_{298.2} = 31.2$ cal./deg.

TABLE II

THE THERMODYNAMIC CONSTANTS OF THE AMMINO CADMIUM CHLORIDES AND CADMIUM CHLORIDE AT 25°

Substance	$\Delta F^0_{298.2}$, cal.	$\Delta H^0_{298.2}$, cal.	$S^0_{298.2}$, cal./deg.
$CdCl_2 \cdot 10NH_3(s)$	$-134{,}633$	$-318{,}741$	145.1
$CdCl_2 \cdot 6NH_3(s)$	$-125{,}653$	$-242{,}781$	90.8
$CdCl_2 \cdot 4NH_3(s)$	$-115{,}533$	$-201{,}321$	56.4
$CdCl_2 \cdot 2NH_3(s)$	$-105{,}363$	$-146{,}781$	65.7
$CdCl_2 \cdot NH_3(s)$	$-95{,}772$	$-125{,}041$	36.7
$CdCl_2(s)$	$-81{,}162$	$-90{,}591$	33.5

$S^0_{298.2}$ is the standard virtual entropy.

The Evaluation of the Standard Electrode Potentials Referred to the Standard Hydrogen Electrode.—In a former paper[6] were described briefly the attempts to measure the potential of the thallium amalgam–thallous chloride half-cell against a hydrogen half-cell in liquid ammonia. Due to experimental difficulties a completely satisfactory result was not obtained. It is now possible to calculate a value for the potential of the cell whose reaction is

$$Tl(s) + NH_4^+(a = 1, \text{in } NH_3(l)) + Cl^-(a = 1, \text{in } NH_3(l)) \qquad TlCl(s) + {}^1/_2H_2(g, 1 \text{ atm.}) + NH_3(l) \tag{15}$$

The standard free energies for all the substances entering into this reaction are known except that for ammonium chloride. Hunt and Larsen have determined the solubility of ammonium chloride in liquid ammonia as well as the vapor pressures of

ammonia above its solutions over a large range of concentrations.[14] These data permit the calculation of provisional values for the activities of the ammonium chloride by the graphical methods described by Lewis and Randall.[8] In Table III are presented the results of the calculations.[15] The lowest concentration at which Hunt and Larsen worked is 0.4 f, and for more accurate activity coefficients it is necessary to go to still lower concentrations.

TABLE III

ACTIVITY COEFFICIENTS OF AMMONIUM CHLORIDE IN LIQUID AMMONIA SOLUTIONS AT 25°

Formality, f, of NH_4Cl	Activity coefficient $\gamma = a_{NH_4Cl}/f$
1	0.25
5	.079
10	.068
15	.079
20	.17
24.4 (satd.)	.31

If the provisional values for the activity coefficients given in the table are accepted, and if it is also assumed that the solid phase present in the experiments of Hunt and Larsen is $NH_4Cl(s)$ and not $NH_4Cl{\cdot}3NH_3(2)$[16] then there results

$$\begin{aligned} NH_4Cl(s) &= NH_4Cl(a = 1, \text{ in } NH_3(l)) \\ \Delta F^0_{298.2} &= -1210 \text{ cal.} \end{aligned} \qquad (16)$$

The standard free energy of formation of NH_4Cl (s) at 25° is −47,810 cal.[17] The corresponding value for $NH_4Cl(a=1, \text{ in } NH_3(l))$ is therefore −49,020 cal. Taking −44,164 cal. as the standard free energy of formation of $TlCl(s)$[8] and −2620 cal. as that for liquid ammonia,[8] at 25°, we now have for reaction (15), $\Delta F^0_{298.2} = 2236$ cal., and $E^0_{298.2} = -0.10(00)$ volt. The experimental value becomes, when the differences between the concentrations used in the cell measured and those given for equation (15) are taken into account $E^0_{298.2} = -0.15$ volt. The agreement is satisfactory.

In Table IV are given the standard electrode potentials of three known half-cells referred to the standard hydrogen electrode in liquid ammonia as zero. The value for the half-cell involving zinc was derived from the measurements of Elliott and Yost[6] on the cell Zn(amalg.)-$ZnCl_2{\cdot}6NH_3(s)$, $NH_4Cl(\text{in } NH_3(l))$, $TlCl(s)$, Tl-(amalg.), and that for cadmium comes from the results presented above. These values are, of course, to be regarded as provisional.

TABLE IV

STANDARD ELECTRODE POTENTIALS IN LIQUID AMMONIA AT 25°

Half-cell reaction	$E^0_{298.2}$, volt
$Tl(s) + Cl^-(\text{liq. } NH_3) = TlCl(s) + E^-$	−0.10(00)
$Zn(s) + 2Cl^-(\text{liq. } NH_3) + 6NH_3(l) =$ $ZnCl_2{\cdot}6NH_3(s) + 2E^-$	+ .7293
$Cd(s) + 2Cl^-(\text{liq. } NH_3) + 6NH_3(l) =$ $CdCl_3{\cdot}6NH_3(s) + 2E^-$	+ .3688

When the solubilities and the activities of the solid substances are known it will, of course, be possible to estimate the molal electrode potentials.

Summary

In liquid ammonia solutions of ammonium chloride at 25° the potentials of the cell Zn(amalg., N_2), $ZnCl_2{\cdot}6NH_3(s)$, $NH_4Cl(\text{in } NH_3(l)$, f., $CdCl_2{\cdot}6NH_3(s)$, Cd(amalg., N_1) have been measured at several concentrations of the dissolved substances. The cell gives accurately reproducible and reversible e. m. f.'s. When zinc and cadmium are present as pure metals $E^0_{298.2} = 0.3605$ volt.

From the e. m. f. and the temperature coefficient of the cell, together with the results of other investigators, the standard free energies, heat contents and virtual entropies of the solid ammino cadmium chlorides and cadmium chloride were calculated and are presented in Table II.

Provisional values for the activity coefficients of ammonium chloride in liquid ammonia at 25° were calculated and the results, combined with free energy data, were used to evaluate the standard electrode potentials of three known half-cells with reference to the standard hydrogen electrode in liquid ammonia.

[14] Hunt and Larsen, *J. Phys. Chem.*, **38**, 801 (1934).

[15] After the present paper was submitted, an article by Larsen and Hunt, *J. Phys. Chem.*, **39**, 877 (1935), has appeared in which relative mean activity coefficients of ammonium chloride are given. Their values are not applicable to the type of calculation made here.

[16] No proof is given by Hunt and Larsen in their paper that the solid phase is $NH_4Cl(s)$. In a private communication Dr. Hunt states that the solid phase does consist of NH_4Cl. Moreover, an extrapolation of the equilibrium pressure data of Troust ("I. C. T.," Vol. VII, p. 240) for the reaction $NH_4Cl{\cdot}3NH_3(s) = NH_4Cl(s) + 3NH_3(g)$ gave 6.5 atm. for the pressure of $NH_3(g)$. The vapor pressure of ammonia above a saturated solution of NH_4Cl is 4.13 atm. This confirms the supposition that the solid phase is NH_4Cl.

The Accommodation Coefficient of Hydrogen on Iron

BY H. H. ROWLEY AND W. V. EVANS

Introduction

The concept of the accommodation coefficient as a measure of the completeness of heat exchange between a gas and a solid body was introduced by Knudsen[1] and has since been studied experimentally by numerous investigators. It was found that the accommodation coefficient is dependent not only on the nature of the gas but also to a large extent upon the condition of the solid surface.

Most of the previous experiments concerned the accommodation coefficient of light gases, such as helium and hydrogen, on the surfaces of heavy metals like platinum and tungsten. Earlier work[2] showed that the accommodation coefficient of hydrogen on a platinum surface freed from ordinary contamination was 0.22 at room temperature and that with decreasing temperature it rose to a value of 0.37 at 110°K. A similar rise was noted by Blodgett and Langmuir[3] for hydrogen on a tungsten surface. This negative temperature coefficient is contrary to the results obtained for helium[4] and to certain theoretical expectations.[5] The anomaly was explained by the presence of two types of adsorption layers: at room temperature the hydrogen was atomically adsorbed (active adsorption) giving rise to a more firm, rigid (smoother) surface and thus a lower accommodation coefficient; at the temperature of liquid air, the more loosely bound, molecular adsorption prevailed and the resulting rougher surface favored better heat exchange and consequently a higher accommodation coefficient.

The present work was undertaken to determine whether this rise was characteristic for hydrogen and also to determine whether a metal of lighter mass had any appreciable effect on the value of the accommodation coefficient. To determine this, the heat exchange of hydrogen at an iron surface was determined over a temperature range from 120–450°K. The method used was essentially the measurement of the amount of heat given up by an electrically heated wire at relatively low pressures of hydrogen.

Experimental

Apparatus.—The apparatus was practically the same as that used previously in determining the heat exchange of hydrogen on a platinum surface.[2] The cell consisted of a fine iron wire (over 99.9% pure) with a measured diameter of 0.0128 cm. stretched along the axis of a vertical Pyrex glass tube 1 cm. in diameter and about 23 cm. in length. The ends of the iron wire were silver soldered to 0.03-mm. tungsten leads which in turn were sealed through the glass. The lower lead-in wire was sealed through the side of the cell about 3 cm. from the bottom and the lower portion of the iron wire formed into a loop from which was suspended a glass weight filled with mercury. This weight not only served to keep the wire centered in the tube but also to take up the slack when the wire was heated and prevent its touching the walls and becoming contaminated.

The cell was sealed to a regular vacuum system containing a manometer, McLeod gage, hydrogen reservoir, mercury diffusion pump, Hy-vac oil pump, appropriate freezing-out traps and phosphorus pentoxide tubes. The hydrogen used was obtained by the electrolysis of dilute sodium hydroxide solution followed by diffusion of the hydrogen into the reservoir through an electrically heated palladium tube.

In order to eliminate the cooling effect of the tungsten leads, the resistance of the iron wire was not measured directly but the potential drop on the wire was determined between two potential leads of 0.05-mm. platinum wire firmly wrapped about the iron wire and connected to a Leeds and Northrup type K potentiometer through two extra tungsten leads sealed into the sides of the cell. The section of wire between the potential leads was 6.21 cm. in length and located in the middle of the wire as far removed from the lead in wires as possible.

The current passing through the wire was determined by means of an accurate milliammeter placed in the circuit. The temperature–resistance curve was determined by letting pure hydrogen at a pressure of 10–20 mm. into the cell which was immersed in a liquid bath at the proper temperature and passing a small current through the wire, sufficient to give an accurate potential reading but not enough to heat the wire above the temperature of the bath. Separate experiments showed that even with thirty milliamperes flowing, there was no appreciable rise of temperature. Twenty milliamperes was the current used for all calibrations.

Condition of the Wire.—The wire was carefully cleaned and placed in position, care being taken not to touch the wire with the fingers after cleaning. When the cell was constructed and sealed to the apparatus, the wire was

further cleaned by alternately heating in hydrogen and in vacuum at a temperature of not over 900°K., a treatment which should reduce any oxide formed and remove the resulting water. This cleaning process was repeated at frequent intervals throughout the course of experiments. This was the condition of the wire during most of the experiments and a wire so treated is referred to as a "normally" clean wire. The glass cell, freezing-out traps and connecting tubes were also baked out in electric ovens and frequently torched with a Bunsen flame in order to remove adsorbed and occluded gases that might affect the results.

Some later experiments were performed in which the wire was glowed for considerable time in vacuum just before the measurements in an effort to dislodge the adsorbed hydrogen layer which was believed to be present under the above conditions. It was found that after heating, the resistance of the wire at the bath temperature changed—sometimes considerably. At first, it was believed that this change was due to strains in the wire caused by uneven annealing and an attempt was made to relieve these by glowing at about 900–1000°K. in hydrogen for a period of several hours. This treatment did not seem to correct the difficulty. A separate series of experiments seemed to indicate very clearly that this change in resistance was not due to absorbed hydrogen, which is in agreement with work of Sieverts.[6] Inasmuch as the glowing wire reached a temperature of 1000–1200°K., the change in resistance was probably due to incomplete changes in the internal structure of the iron which is known to exist in at least three modifications, α-, β-, γ-iron and which have different resistances. This incomplete change caused different parts of the wire to have different resistances and hence when the wire was heated in vacuum (to avoid any possible Busch effect[7]) it glowed unevenly. This uneven heating might be due to variations in the diameter of the wire,[8] but since the dark places in the wire showing varying resistances shifted, this could not be the answer.

However, numerous calibrations of the temperature–resistance curve over the temperature range used for the experiments showed all these curves to have essentially the same slope, so that by determining the resistance of the wire at the temperature of the bath for each experiment, the temperature–resistance curve for that run could be found, even though the resistance of the wire at 274°K. varied from 0.110 ohm/cm. to 0.082 ohm/cm. Due to this irregularity, the temperature of the wire as read from the calibration curve was the average temperature of the section measured.

Calculation of the Accommodation Coefficient.—The method of calculation was the same as that used for determining the accommodation coefficient of hydrogen on platinum[2] and evolved the following formula

$$\alpha = \frac{\sqrt{2mk/\pi} \times 10^7}{dk\ 1332} \times \frac{W_c \sqrt{T_a}}{(\beta + {}^1/_2)p(T - T_a)}$$

where m is mass of molecule (3.32×10^{-24} g. for hydrogen), k is the Boltzmann constant (1.371×10^{-16} ergs/deg.), d is the diameter of wire (0.0128 cm.), p is pressure in mm., T is temperature of the wire, T_a is temperature of the incident gas molecules. Since, at the pressures used, the mean free path of the hydrogen molecules equals or exceeds the radius of the cell, the temperature of the incident molecules can be taken as equal to the temperature of the cell walls or the bath temperature. W_c is the energy loss per second from the wire in watts/cm. and is calculated from the potential drop along 6.21 cm. of the wire and the current flowing. βk is the specific heat at constant volume per molecule expressed in ergs/deg. K. When hydrogen is cooled to low temperatures, the specific heat approaches that of an ideal monatomic gas and β has the value 1.5 at 45°K.; at higher temperatures, the specific heat increases to values characteristic of diatomic gases and $\beta = 2.44$ at 273°K.[9] The values of β used when T_a was below 273°K. were those for the average temperature of the wire and the bath. Though β changes rather rapidly in this temperature range it was believed to be a better approximation of the true value than the value at either the wire or the bath temperature. It might be noted here that substitution of the other values did not materially change the type of curve obtained.

The pressure was measured with a McLeod gage, the mercury vapor being kept from the cell by means of liquid air or solid carbon dioxide–acetone traps. Since the measurements were never at room temperature, there is, according to Knudsen,[10] a pressure difference between the cell and the McLeod. In the pressure range used in these experiments where the quotient (diameter of connecting tube d)/(mean free path)λ has a value between 1.5 and 6, the following empirical formula holds according to Roberts[4]

$$p_1 - p_2 = (\lambda_0 \times 10^4/7.28\ d)\ (T_1 - T_2)$$

where λ_0 is the mean free path at 273°K. and 760 mm. and taken as 1.8×10^{-5} cm. for hydrogen. The pressures were corrected with this formula for all bath temperatures.

(6) A. Sieverts, *Intern. Z. Metallog.*, **3**, 37 (1913).

(7) H. Busch, *Ann. Physik*, **64**, 401 (1921); A. Farkas and H. H. Rowley, *Z. physik. Chem.*, **B22**, 335 (1933). This effect is frequently noted when a fine wire is heated in a gas at low pressures. Under certain conditions, the even temperature distribution along a wire becomes suddenly unstable and the wire takes on an uneven temperature; some sections may be glowing while others are at room temperature, though the average temperature of the entire wire may not change appreciably from its previous value.

(8) Actual measurements of sections of the wire taken at random failed to show any marked deviation from 0.0128 cm.

Experimental Procedure and Data

Surface of Wire "Normally" Clean.—After treating the wire and getting it in a "normally" clean condition, the cell was completely immersed in a constant temperature bath. Five different bath temperatures were used during the experiments: liquid air at 88°K., acetone–solid carbon dioxide at 195°K., ice water at 273°K., petroleum oil bath at 325 and 373°K. Pure hydrogen was let into the apparatus at a pressure of about 0.025 mm. of mercury and accurately measured with the McLeod gage. A known current from a six-volt storage battery was then passed through the cell and the potential drop along the wire measured. From these data the resistance and hence the temperature of the wire could be found. About five minutes was allowed for the cell to come to thermal equilibrium. Four or five measurements were made during each trial, the temperature of the wire ranging from 30 to 100° above that of the bath. Typical data for the various bath temperatures are given in Table I.

In a separate series of experiments, the heat lost from the wire by metallic conduction and radiation was determined for each bath by evacuating the cell and recording the energy necessary to bring the wire to a temperature 30–100° above that of the bath. Values from these curves were always subtracted from the total energy input in order to determine the amount of heat actually carried away from the wire by the gas molecules. Check determinations at various times indicated that this correction factor was constant for any one bath and wire temperature.

Attempts to Obtain Bare Surface.—It appears quite certain that the "normally" clean surface is actually covered with adsorbed hydrogen. Patterning after the work of Roberts[4] and Mann,[11] a similar technique was employed in attempting to obtain an iron surface free from adsorbed hydrogen. The wire which had been cleaned of ordinary contamination in the usual way, was glowed at 1000–1100°K. for varying periods of time in vacuum. The temperature of the wire was quickly lowered to a value about 80° above that of the bath and the time noted. Pure hydrogen at the proper pressure was introduced as soon as possible (within one minute) after re-

(11) W. B. Mann, *Proc. Roy. Soc.* (London), **A146**, 776 (1934).

ducing the current and readings taken at frequent intervals for twenty to thirty minutes. It was found that after about thirty minutes of glowing in vacuum the values of the accommodation coefficient dropped appreciably, giving 0.35 at 180°K. and 0.18 at 351°K. Further half-hour periods of heating at 1000–1100°K. failed to lower these values.

In an attempt to lower the values still further, the wire was heated to 1000–1100°K. in a vacuum for twelve hours. During this heating the resistance of the wire changed markedly as noted above. Using the same technique as before, the accommodation coefficient was found to be 0.21 at 346°K. and failed to change by further fifteen minute periods of heating in vacuum. The slightly higher value obtained might well be due to a change of surface caused by prolonged glowing.

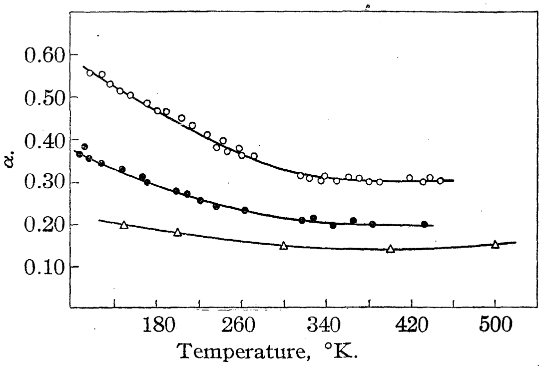

Fig. 1.—Change of accommodation coefficient with temperature: ○, iron wire saturated with hydrogen; ●, platinum wire recently glowed; △, tungsten wire specially cleaned.

Some runs were also made in which the wire was heated in hydrogen. In a typical experiment it was found that according to the measurements of the first few minutes, the accommodation coefficient rose quite rapidly. It is interesting to note that in some cases after this first sharp rise the values remained fairly constant for twenty to thirty minutes though showing a definite tendency to increase. In certain other cases, the increase was more rapid though nowhere near as great as during the first few minutes as shown in Table II. Upon letting the wire stand in contact with hydrogen at room temperature for several hours, the regular value of 0.31 was always obtained.

Table II

Increase of Accommodation Coefficient with Time

Bath temperature, 273°K.

Minutes	1	2	3	6	17
α	0.172	0.196	0.209	0.210	0.211
Minutes	1	2	3	4	6
α	0.130	0.205	0.228	0.236	0.238
Minutes	10	15	30	60	
α	0.245	0.250	0.263	0.278	

Discussion of Results

The values of the accommodation coefficient obtained for a "normally" clean iron wire follow quite closely those of hydrogen on a platinum surface, rising considerably as the temperature of the wire is decreased. The relatively higher values obtained with iron might be due to the smaller mass of the iron, since according to the theory of Baule[12] the energy exchange by collision between gas molecules and surface atoms of a solid body is more complete the smaller the difference in mass between the colliding particles. However, it seems more probable that the higher value is due to adsorbed layers on the surface. This is further substantiated by the fact that shortly after glowing the iron wire, the values of the accommodation coefficient are practically the same as those for a platinum surface which had been similarly treated.

With respect to the increasing accommodation coefficient with decreasing temperature, it is interesting to compare three different sets of values obtained at low temperatures. In Fig. 1 are plotted the values for a "normally" clean iron wire, a platinum wire that had been recently glowed[2] and a tungsten wire with which special pains had been taken to obtain a perfectly clean surface.[3] It is significant that in all cases there is a decided upward trend below 350°K., being greatest in the case of the iron and least in the case of tungsten. Recent work of Gregory[13] with platinum surface also shows a definite rise from 500 to 300°K. though not as great as that obtained at lower temperatures. This general rise in all cases would tend to substantiate the suggestion made in the previous paper[2] that two types of adsorption are causing this effect. According to certain theoretical considerations,[5] if the condition of the surface remains unaltered, the accommodation coefficient should decrease with decreasing temperature. That this is the case above approximately 500°K. appears to be shown by work of Blodgett and Langmuir[3] and others. In this range it might be assumed that the hydrogen was atomically adsorbed. Below

---

[12] B. Baule, *Ann. Physik*, **44**, 145 (1914).

[13] H. S. Gregory, *Proc. Roy. Soc.* (London), **A149**, 35 (1935).

this range, a second type of adsorption begins to take place, possibly a molecular adsorption on top of the atomic adsorption. This second type, being more loosely bound, would form a rougher surface and hence bring about a better exchange of energy between the gas molecules and solid. For a range of about 150°, this increasingly rough surface would offset the drop in the accommodation coefficient due to decreasing temperature and give values more or less constant such as actually found between 350 and 500°K. As the temperature was lowered still further, this molecular adsorption would become predominant and cause an actual rise in the accommodation coefficient. If such is the case, the values should reach a maximum and then drop sharply. Since no supply of liquid hydrogen was available, it was impossible to test this experimentally. The more ready adsorption of hydrogen on iron might explain the steeper rise at low temperatures than that observed with platinum or tungsten.

It might appear that this rise at low temperatures was caused by applying the pressure correction when the bath was not at room temperature. When the bath was below room temperature this correction, which amounted to 0.005 mm. at liquid temperatures, was subtracted from the pressure as read on the McLeod. This would tend to cause a rise in the calculated values. However, even if this correction were ignored, which we did not feel justified in doing, the curve still showed a decided upward trend giving values of 0.41 at 150°K.

It would appear that in all cases, even with the tungsten surface which had been carefully cleaned, there was adsorbed hydrogen on the wire to a greater or less extent. The value of 0.31 might be taken as the accommodation coefficient of hydrogen on a bright iron surface saturated with hydrogen at 350°K. It is interesting to compare values of the accommodation coefficient of hydrogen on various surfaces in this temperature range as shown in Table III. In all the cases chosen, the condition of the surface might be termed "normally" clean, *i. e.*, no special attempt had been made to get rid of adsorbed hydrogen. Considering the wide difference in the substances used and also the noticeable effect of rough surfaces, it is surprising to find the values of the accommodation coefficient so nearly the same. This fact seems to indicate that in all cases the solid surface was covered with adsorbed hydrogen and that the heat exchange was between hydrogen gas molecules and an adsorbed hydrogen surface. When a special technique is used to remove this hydrogen layer, lower values are always obtained, *i. e.*, 0.11 for platinum,[11] 0.14 for tungsten,[3] 0.18 for iron, but it is believed that even in these cases there is some adsorbed hydrogen. Langmuir[3] and others also postulated adsorbed layers in these cases.

TABLE III

ACCOMMODATION COEFFICIENT OF HYDROGEN ON VARIOUS SURFACES

Investigator	Surface	Temp. of surf. °K.	α
Knudsen[14]	Platinum	273	0.315
Knudsen[1]	Platinum	273	.26
Soddy and Berry[15]	Platinum	335	.25
Gregory[13]	Platinum	389	.25
Rowley and Bonhoeffer[2]	Platinum	350	.21
Soddy and Berry[15]	Palladium	(335)	(0.25)
Blodgett and Langmuir[3]	Tungsten	400	.22
Hughes and Bevan[16]	Nickel	437	.25
Chapman and Hall[17]	Silver	373	.25
Knudsen[1]	Glass	300(?)	.26
Rowley and Evans	Iron	350	.31

In the experiments where an attempt was made to dislodge this adsorbed hydrogen from the iron surface, the rapid rise of values during the first few minutes (see Table II) might be construed to mean a very rapid adsorption during the first few minutes such as Mann found on platinum.[11] Though this may be true, it appears certain that the wire and cell were not at thermal equilibrium much under three or four minutes after glowing the wire. Since the correct calculation of the accommodation coefficient by this method depends upon thermal equilibrium, values taken before this time have no great significance.

Summary

1. The accommodation coefficient of hydrogen on a bright iron surface saturated with hydrogen has been determined for the temperature range 120–450°K. and found to be 0.31 at the higher temperatures and rising steadily below 350°K. to 0.55 at 120°K.

2. This rise with decreasing temperature has been compared to similar results obtained with platinum and tungsten surfaces and discussed

Some Fluorinated Chlorobenzenes[1]

BY HAROLD SIMMONS BOOTH, HOWARD M. ELSEY[2] AND PAUL E. BURCHFIELD[3]

A survey of the literature revealed descriptions of the preparation of only ortho[4] and para-chlorofluorobenzene.[5] In order to complete the series of monochlorofluorobenzenes the preparation of meta-chlorofluorobenzene from meta-chloroaniline was undertaken.

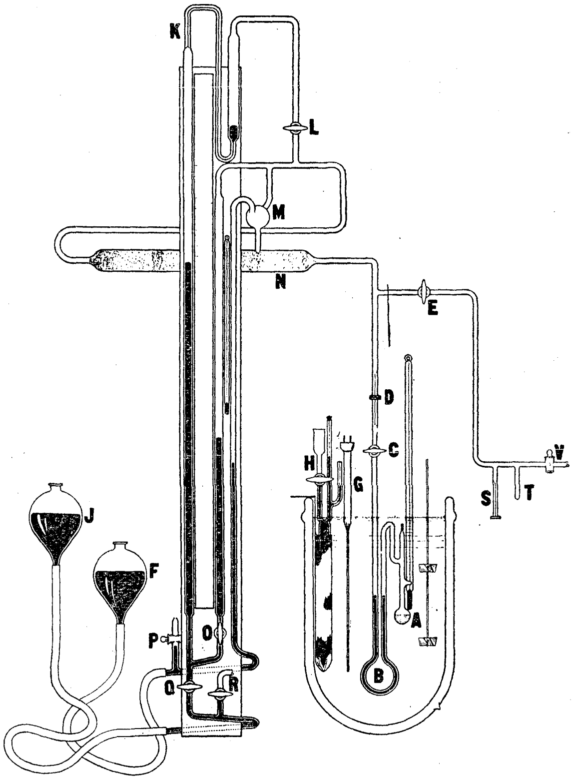

Fig. 1.

De Crauw[6] reported the preparation of 2,4,5-trichlorofluorobenzene from meta-fluoroaniline by several steps. De Crauw stated that a fluorine atom cannot be introduced into the benzene ring ortho to chlorine. The preparation of 2,4,6-trichlorofluorobenzene was attempted in order to extend the knowledge of this class of compounds and to discover whether or not the Balz and Schiemann reaction would effect the introduction of fluorine ortho to chlorine. In addition 2,4,6-trichlorofluorobenzene was successfully prepared from 2,4,6-trichloroaniline.

Experimental

Method of Determining Vapor Pressures

The apparatus for the determination of vapor pressure used in this research consisted of a modified "static isoteniscope,"[7] a suitable thermostat equipped with automatic and manual heat controls, and a modified Germann barometer,[8] shown in Fig. 1.

For the measurement of vapor pressure, a carefully purified sample was introduced into the bulb (A) the volume of which was approximately 2 cc. One arm of the bulb was connected to one side of the short U-manometer (B), the other arm was sealed to a tube (T) connected to a Hyvac pump. The second side of the U-manometer was provided with a stopcock (C) and a flat joint (D) and could also be connected by means of the flat joints (D) and (S) to the Hyvac pump. Both sides of the U-manometer were simultaneously evacuated for some time, and the mercury was carefully heated to its boiling point under the reduced pressure so that residual gases entrapped by the mercury were driven out.

When the mercury cooled, a small part of the sample was condensed on it in (B) and redistilled off in order to completely wash out any residual permanent gases in the sample chamber. The tube (T) connecting the sample bulb to the vacuum system was sealed off while the liquid in A was cooled in liquid air, and the other side of the small manometer was closed by means of stopcock (C).

[4] Rinkes, *Chem. Weekblad*, **11**, 360, 952 (1914).

[5] Wallach and Heusler, *Ann.*, **243**, 219 (1888); Swarts, *Rec. trav. chim.*, **35**, 131 (1915).

[6] De Crauw, *ibid.*, **48**, 1061 (1929).

[7] A. Smith and A. W. C. Menzies, THIS JOURNAL, **32**, 1412 (1910).

[8] A. F. O. Germann, *ibid.*, **36**, 2456 (1914).

The system was introduced into a clear mineral oil bath, contained in a 4-liter Dewar vessel, to such a depth that the space containing the sample was completely immersed. By means of the flat joint (D), the short manometer was connected to the manometer on which the vapor pressures were read.

The temperature was measured on a thermometer graduated to 0.1°. The thermometer, calibrated by the Reichsanstalt, was checked in this Laboratory against a precision platinum resistance thermometer and was found to be correct. The ice point was checked before each period of use. The necessary stem corrections were calculated and were added to the observed reading.

When the vapor pressure of the compound was to be measured, stopcock (C) was opened, and the mercury in the U-manometer (B) was brought to the same level by varying the pressure in the space connecting the large and small manometers by means of an air inlet (V) and a leveling bulb (F). The tube (N) was filled with barium oxide so that only dry air would come in contact with the mercury in the large manometer. When the mercury in (B) reached the same level the pressure was read on the large manometer at successive time intervals at constant temperature by a reading telescope until no change was observed in several observations. The observed pressure was corrected for the vapor pressure of mercury, and the necessary correction was applied to convert the observed pressure reading to the equivalent pressure at 0°, on the basis of a glass scale.

The boiling points of the compounds described below were read from the temperature–vapor pressure curves plotted on a large scale.

***m*-Chlorofluorobenzene.**—*m*-Chlorofluorobenzene was prepared from *m*-chloroaniline by the method of Balz and Schiemann.[9] The yield of *m*-chlorofluorobenzene was 60% calculated from the weight of chloroaniline used: b. p. 127.6° at 760 mm. (corr.); m. p. below −78°; d_{25} 1.221; $n^{27.0}{}_D$ 1.4911.

Analysis.—Chlorine was determined by the method of Chablay[10] as modified by Vaughn and Nieuwland.[11]

Anal. Calcd. for C_6H_4FCl: Cl, 27.17. Found: Cl, 27.15, 27.20.

Qualitative tests revealed the presence of fluorine.

Vapor pressure of *m*-chlorofluorobenzene and temperature are related by the equation $\log P$ (mm.) = $(-2342.4/T) - 2.4165 \log T + 15.017$. The average deviation of the calculated values from the observed values is ±1 mm.

2,4,6-Trichlorofluorobenzene was prepared from 2,4,6-trichloroaniline by the method of Balz and Schiemann.[9]

Twenty-four grams of trichloroaniline was added to 40 cc. of concd. hydrochloric acid. A concentrated solution of 8.4 g. of sodium nitrite was slowly added to the cold mixture. The diazonium solution was rapidly filtered to remove unreacted trichloroaniline, after which the diazonium fluoborate was precipitated by the addition of an excess of 45% fluoboric acid. After washing with alcohol and ether the salt was thoroughly dried at 70–80°. Efficient drying of the salt is necessary; otherwise the subsequent decomposition takes place with uncontrollable rapidity. The diazonium fluoborate was obtained in 75% yield.

The diazonium fluoborate was decomposed by heating in an evacuated system. Decomposition began at 187°, but it was necessary to heat to a considerably higher temperature to complete the decomposition. An appreciable quantity of tar was formed with each decomposition. From 13 g. of diazonium fluoborate 7 g. of crude trichlorofluorobenzene was obtained. The crude compound was washed successively with saturated sodium carbonate and 17% sodium hydroxide solutions, dried with barium oxide and repeatedly distilled under reduced pressure (10 mm.). Sixty grams of purified trichlorofluorobenzene was prepared in all: b. p. 208.4° at 760 mm. (corr.); m. p. 11.2°; d_{25} 1.530; $n^{27.2}{}_D$ 1.5429.

Anal. Calcd. for $C_6H_2Cl_3F$: Cl, 53.35. Found: Cl, 53.39, 53.22.

Qualitative tests revealed the presence of fluorine.

Vapor pressure of 2,4,6-trichlorofluorobenzene and temperature are related by the equation $\log P$ (mm.) = $-2452/T - 0.7316 \log T + 9.9389$.

The average deviation of the calculated values from the observed values is ±2.6 mm.

Instability of 2,4,6-Trichlorofluorobenzene.—The sample of 2,4,6-trichlorofluorobenzene on which the vapor pressures were run acquired a deep brown color after it was heated to 215.5°, which denoted thermal instability.

Summary

1. The preparation and properties of *m*-chlorofluorobenzene have been described.

2. 2,4,6-Trichlorofluorobenzene has been synthesized and the physical properties have been measured.

3. It has been demonstrated that a fluorine atom may be introduced ortho to chlorine in the benzene ring by means of the Balz and Schiemann procedure.

4. An improved precision technique for the determination of the vapor pressures of liquids has been devised.

Benzotrifluoride and its Halogenated Derivatives[1]

BY HAROLD SIMMONS BOOTH, HOWARD M. ELSEY[2] AND PAUL E. BURCHFIELD[3]

The purpose of this paper is to describe an improved method for the preparation of benzotrifluoride, the preparation and study of the isomeric monofluoro- and monochlorobenzotrifluorides, 3,4-dichlorobenzotrifluoride, and two mixtures of more fully chlorinated derivatives.

Wertyporoch[4] prepared the more or less impure monochlorobenzotrifluorides and small amounts of the dichloro derivative by the direct action of chlorine on benzotrifluoride in the presence of antimony pentachloride.

Since the investigation described in this paper was completed, Aelony[5] published a description of the preparation and properties of *m*-fluorobenzotrifluoride. The properties as described agree closely with our findings with the exception of the index of refraction.

Determination of Physical Properties.—Vapor pressures (Table I) were determined as described by Booth, Elsey and Burchfield.[6] The boiling points were read from the temperature–vapor pressure curves plotted on a large scale. The latent heats of vaporization were calculated from the Rankine and Clausius–Clapeyron equations. Melting points were determined as described by Booth and Stillwell.[7]

or combined fluorine. The resulting water and carbon dioxide were absorbed in a Fischer absorption bottle filled with calcium chloride and a Gomberg type absorber filled with 50% potassium hydroxide solution. The results of the analyses are given in Table II.

Experimental Part

(a) **Benzotrifluoride.**—Benzotrifluoride was prepared by the action on benzotrichloride of an excess of sublimed antimony trifluoride instead of the ratios recommended by Swarts[8] and by Aelony.[5] The reaction was initiated and carried to completion as quickly as possible and the product was distilled from the reaction vessel as fast as it was formed since antimony salts, etc., greatly decrease the yield of benzotrifluoride by the production of resinous products.

The distillate was washed successively with 6 *N* hydrochloric acid, sodium bicarbonate and 20% sodium hydroxide solutions, dried by shaking with barium oxide and twice distilled at a high reflux ratio through an insulated, electrically-heated column 2.5 cm. in diameter and 110 cm. high packed with jack-chain and surmounted by a Vigreux condenser.

(b) *o*-**Fluorobenzotrifluoride.**—An attempt was made to prepare *o*-fluorobenzotrifluoride by chlorinating *o*-fluorotoluene to *o*-fluorobenzotrichloride and fluorinating the side chain with sublimed antimony trifluoride.

Accordingly, one mole (110 g.) of *o*-fluorotoluene from the Eastman Kodak Co. was chlorinated until the system gained 95 g. The compound chlorinated very slowly, and phosphorus pentachloride as a catalyst does not increase the speed or the extent of chlorination. Fractionation yielded a liquid boiling at 215–223°, which supposedly was *o*-fluorobenzotrichloride.

Fluorination of the above liquid produced volumes of hydrogen fluoride, a large quantity of resin, but only a few grams of a compound boiling between 114 and 116°. The products of several fluorinations were combined, purified and fractionated. Approximately 10 cc. of a liquid was obtained which boiled at 113.8–114.3° at 740.6 mm., and which resembled benzotrifluoride in odor and physical properties. It was thought that the compound was *o*-fluorobenzotrifluoride.

Anal. Calcd. for $C_6H_4FCF_3$: C, 51.21; H, 3.45. Found: C, 47.1; H, 2.42.

These analyses revealed that the compound was not *o*-fluorobenzotrifluoride. Since the yields were so small this was probably some secondary decomposition product.

(c) *m*-**Fluorobenzotrifluoride.**—*m*-Fluorobenzotrifluoride ($C_6H_4FCF_3$) was prepared by the following reactions: benzotrifluoride was nitrated, the nitro group was reduced to an amino group[9] and the amino group was replaced by a fluorine atom by the method of Balz and Schiemann.[10]

m-Nitrobenzotrifluoride was prepared in 96% yield using a nitrating mixture composed of one part fuming nitric (sp. gr. 1.5) and 1.5 parts of concentrated sulfuric acids.

One mole (191 g.) of *m*-nitrobenzotrifluoride was reduced with tin and concd. hydrochloric acid with a yield of 154 g. of *m*-aminobenzotrifluoride corresponding to 95%.

A solution of the diazonium salt was prepared by the addition of a saturated solution containing 15 g. of sodium nitrite to 32 g. of *m*-aminobenzotrifluoride and 40 cc. of concentrated hydrochloric acid. The addition of an excess of fluoboric acid precipitated the diazonium fluoborate. There was obtained 46 g. of the salt corresponding to 87% yield. The decomposition taking place below 140° was effected by gentle heat. There remained in the flask a small amount of a slightly brown residue which was probably sodium fluoborate. From 166 g. of diazonium fluoborate 86 g. of fluorobenzotrifluoride was recovered—a yield of 82% calculated from the weight of the salt decomposed. The compound was chemically and physically purified in the usual manner.

(d) *p*-**Fluorobenzotrifluoride.**—One hundred and thirty grams of *p*-fluorotoluene[11] was chlorinated in the usual manner with phosphorus pentachloride as a catalyst. After eighteen hours of chlorination, the reaction stopped and the products were fractionated. There was obtained 220 g. of *p*-fluorobenzotrichloride ($C_6H_4FCCl_3$) which boiled at 212–213° (uncorr.) at 741.6 mm.; a yield of 76%.

Two hundred and twenty grams of *p*-fluorobenzotrichloride ($C_6H_4FCCl_3$) was converted into 130 g. of *p*-fluorobenzotrifluoride ($C_6H_4FCF_3$) in the usual manner by means of antimony trifluoride. This yield corresponded to 73%. After purification the compound had a boiling point range of 0.3°.

(e) *o*-**Chlorobenzotrifluoride.**—*o*-Chlorobenzotrifluoride was prepared from *o*-toluidine by replacing the amino group by chlorine, chlorinating and subsequently fluorinating the side chain.

One hundred and seventy-five grams of *o*-chlorotoluene[12] and 5 g. of phosphorus pentachloride were introduced into a suitable flask. A slow stream of chlorine was led into the flask, the contents of which were maintained at the boiling point throughout the chlorination. This treatment resulted in the formation of much tarry matter, but with small yield of the desired product. It was thought that possibly phosphorus pentachloride at the elevated temperatures may have caused the formation of the decomposition products.

Accordingly, 170 g. of *o*-chlorotoluene was chlorinated at 160–190° without a catalyst, with the formation of only traces of tarry products. Chlorination took place much less readily in the case of *o*-chlorotoluene compared with that of the para isomer.

Two hundred grams of *o*-chlorobenzotrichloride was obtained, corresponding to a yield of 64%.

Two hundred grams of *o*-chlorobenzotrichloride was mixed with 190 g. (excess) of sublimed antimony trifluoride. The mixture was heated rapidly until reaction set in. The product weighed 124 g. after washing several times with 6 *N* hydrochloric acid, corresponding to a yield of 85%, on the basis of *o*-chlorobenzotrichloride. After purifying and drying in the usual manner, the *o*-chlorobenzotrifluoride boiled at 148.2–148.7° (uncorr.) at 741 mm.

(12) Gattermann, *ibid.*, **23**, 1218 (1890).

(f) ***m*-Chlorobenzotrifluoride.**—The starting compound for the preparation of *m*-chlorobenzotrifluoride was *m*-aminobenzotrifluoride, the preparation of which was previously described.

The amino group was replaced by a chlorine atom by the method of Sandmeyer.[13] One hundred and thirty-eight grams of *m*-aminobenzotrifluoride was mixed with 200 cc. of concentrated hydrochloric acid in 180 cc. of water. The amine was diazotized by the addition of a concentrated solution of sodium nitrite which contained 60 g. of the salt. The diazotized solution was slowly poured into 400 cc. of boiling, 10% cuprous chloride solution. The resulting mixture was distilled with steam and the water–oil distillate was extracted with ether. The *m*-chlorobenzotrifluoride–ether solution was dried with anhydrous calcium chloride and was fractionated. There was obtained 110 g. of product which boiled between 136–140°, corresponding to a yield of 70%. The product was agitated with a saturated solution of sodium carbonate, dried by refluxing with barium oxide for five hours and was distilled through a column filled with glass beads.

(g) ***p*-Chlorobenzotrifluoride.**—In order to prepare *p*-chlorobenzotrifluoride it was necessary to prepare *p*-chlorotoluene, chlorinate the side chain to *p*-chlorobenzotrichloride, and replace the chlorine atoms in the side chain by fluorine atoms by means of antimony trifluoride.

p-Chlorotoluene was prepared by the Gattermann[12] method. One mole of *p*-chlorotoluene was introduced into a 500-cc. flask provided with conical ground glass joints for a chlorine inlet and a reflux condenser. Five grams of phosphorus pentachloride was added to serve as a catalyst for the chlorination of the side chain. The contents of the flask were heated to boiling and were maintained at the boiling point during the chlorination. A slow stream of dry chlorine was led into the liquid until the weight of the system gained 105 g. The chlorination process required ten hours. The product was fractionally distilled, and a yield of 215 g. of *p*-chlorobenzotrichloride (93%) boiling between 248–250° was obtained.

Two hundred and fifteen grams of *p*-chlorobenzotrichloride was mixed with 200 g. (excess) of sublimed antimony trifluoride and the mixture was heated rapidly to initiate the reaction. The reaction proceeded smoothly and rapidly. The product was washed several times with 6 *N* hydrochloric acid, followed by several washings with water. The compound thus treated weighed 148 g., a yield of 95% calculated on the basis of the weight of *p*-chlorobenzotrichloride used.

(h) **3,4-Dichlorobenzotrifluoride.**—The preparation of 3,4-dichlorobenzotrifluoride was carried out in a manner similar to that whereby the monochloro derivatives of benzotrifluoride were obtained. The starting compound was *p*-toluidine which was successively converted into 3,4-dichlorotoluene, 3,4-dichlorobenzotrichloride and 3,4-dichlorobenzotrifluoride. The preparation of 3,4-dichlorotoluene was carried out as described by Cohen and Dakin.[14]

The side chain of the above compound chlorinated readily at 160–190° without a catalyst. The chlorinated product was not distilled, but was fluorinated without further purification. The compound was fluorinated with resublimed antimony trifluoride with a yield of 59% of the desired product calculated on the basis of the dichlorotoluene used. The crude 3,4-dichlorobenzotrifluoride was purified in the usual manner. The final product had a boiling point range of 0.5°.

(i) **Exhaustive Chlorination of Benzotrifluoride.**—Two hundred grams of benzotrifluoride and several pieces of iron gauze were introduced into a flask provided with a reflux condenser. The temperature of the contents of the flask was maintained at 60–70° by means of a water-bath.

Volumes of hydrogen chloride were liberated when dry chlorine was bubbled through the mixture. After the system had gained 60–70 g. in weight the reaction slowed considerably. The temperature was then raised to 100°, with a noticeable increase in the speed of the reaction. The chlorination was continued for twenty-five hours until the system had gained 97 g.

The first distillation of the chlorinated product revealed a boiling point of 180–230°, with only 10–15 g. of a higher boiling liquid remaining in the distilling flask. The distillate had a dark brown color, which color changed to a light yellow when water was added. The compound was agitated with concentrated hydrochloric acid to remove traces of aluminum chloride or iron chloride, carefully washed with saturated sodium carbonate solution, 20% sodium hydroxide solution, followed by several treatments with distilled water. The clear yellow liquid was dried with calcium chloride and fractionated. The small amount of residue from this fractionation was liquid at 0° but partially solidified at −15°. The first fractionation gave a clear colorless liquid, boiling between 180 and 220° and melting below −15°.

From a comparison of the boiling points of the *o*-, *m*- and *p*-monochlorobenzotrifluorides and the 3,4-dichlorobenzotrifluoride, one would surmise that this mixture consists of dichlorobenzotrifluorides and trichlorobenzotrifluorides.

To introduce more chlorine into the ring, the contents of the flask were heated over a direct flame, below the boiling point of the contents but to such a temperature that crystals of ferric chloride formed in the flask, while a stream of dry chlorine was simultaneously led in. It was surprising to note that practically no decomposition products were formed by this drastic treatment. After purification in the usual manner the mixture boiled between 230 and 260° and crystals appeared if it cooled to 15°. On the basis of previous experience it seems reasonable to assume that this mixture consists of the isomeric tri- and tetrachlorobenzotrifluorides.

Discussion of Results

The physical properties of the compounds prepared and studied in this research are listed with their analyses in Table II.

The introduction of chlorine into the benzotrifluoride ring raises the boiling point of the original compound 35–37° for each chlorine atom replacing an atom of hydrogen, except in the case of the ortho compound where the elevation of the boiling point is decidedly higher. Practically the same elevation is noted when chlorine is introduced into the benzotrichloride ring, and the same inconsistency with the ortho chloro compound. These facts are shown in Table III.

The melting points of the compounds prepared in this investigation are in line with the generalization that the introduction of fluorine in place of hydrogen in the benzene ring lowers the melting point of the original compound. It should be noted that the chlorinated benzotrifluorides, with the exception of the ortho compound, have lower melting points than even the analogous chlorine derivatives of toluene, *o*-, *m*- and *p*-chlorotoluene, which melt at −34, −47.8 and 6.5 to 7.5°, respectively.

The latent heats of vaporization are in accordance with the values usually found in non-associated liquids of similar boiling points.

Summary

1. It was found that the best yields of benzotrifluoride were obtained when an excess of antimony trifluoride was distilled with benzotrichloride.

2. The preparation and properties of *p*-fluorobenzotrifluoride, *o*-, *m*- and *p*-chlorobenzotrifluoride and 3,4-dichlorobenzotrifluoride have been described.

3. The vapor pressures of benzotrifluoride, *m*- and *p*-fluorobenzotrifluoride, *o*-, *m*- and *p*-chlorobenzotrifluoride and 3,4-dichlorobenzotrifluoride were measured over temperature ranges.

4. The preparation and boiling point of *p*-fluorobenzotrichloride (unanalyzed) was described.

5. Two exhaustively chlorinated mixtures of benzotrifluoride were prepared.

Fluorination of Halogeno Methyl Ethers. I. Fluorination of Trichlorodimethyl Ether

BY HAROLD SIMMONS BOOTH AND PAUL E. BURCHFIELD[1]

This paper describes an investigation of the fluorination of, and the fluorinated products of, trichlorodimethyl ether.

Experimental

Monochlorodimethyl ether was prepared essentially as described by C. Friedel.[2] Continuous streams of chlorine and dimethyl ether were introduced into a reaction tube, in which a sufficient excess of dimethyl ether necessary to prevent flashing was maintained. Monochlorodimethyl ether was further chlorinated according to the method of A. de Sonay,[3] with the formation of dichloro-, trichloro-, and tetrachlorodimethyl ethers. The chlorinated products were readily separated by fractional distillation.

Fluorination of Trichlorodimethyl Ether

One-half mole (75 g.) of trichlorodimethyl ether (b. p. 130.6 corr., 748 mm.) was refluxed for two hours with 100 g. (excess) of sublimed anhydrous antimony fluoride only. There was obtained, after washing with water and drying with barium oxide, 50 g. of a mixture boiling between 30 and 55.3°. The components of the fluorinated mixture were separated by fractional distillation in a modified Dufton column and the mixture was shown to consist of two volatile liquids, difluoromonochloro- and trifluorodimethyl ether.

Analyses

Difluoromonochlorodimethyl ether: Calcd. for $C_2F_2ClH_3O$: mol. wt., 116.4; C, 20.6; H, 2.59; Cl, 30.5. Found: mol. wt. (Victor Meyer), 119.0; C, 20.47; H, 2.46; Cl (Carius), 30.7.

Trifluorodimethyl ether: Calcd. for $C_2F_3H_3O$: mol. wt., 100.0; C, 23.9; H, 3.0. Found: mol. wt. (Victor Meyer), 102.7; C, 23.85; H, 2.96.

Qualitative tests revealed the presence of fluorine in each of the above compounds.

Physical Properties

The physical properties of the compounds reported in this paper were determined as described by Booth, Elsey and Burchfield,[4] and are found in Table I.

TABLE I

PHYSICAL PROPERTIES OF $C_2F_2ClH_3O$ AND $C_2F_3H_3O$

Compound	B. p., °C. (corr.)	M. p., °C.	ΔH at b. p. Calcd.	Sp. gr. 25°C.
$C_2F_2ClH_3O$	55.3	−105.1	7650	1.370
$C_2F_3H_3O$	30.1	− 96.2	6990	1.328

Constants of the Rankine Equation

	A	B	C	Av. deviation of calcd. values from obsd. values—mm.
$C_2F_2ClH_3O$	−1649	0.1686	7.479	±1.6
$C_2F_3H_3O$	−2405	−6.661	27.344	±1.2

These compounds have a very faint odor somewhat resembling chloroform. They do not fume in air, but slowly hydrolyze in water.

Attempted Preparation of Monofluorodichlorodimethyl Ether

Rapid reaction of trichlorodimethyl ether with antimony fluoride and calcium fluoride, respectively, gave no indication of a fluorinated compound boiling above 55.3° in either case. In this fact, that a monofluoro compound could not be made and that antimony fluoride would fluorinate it without a catalyst, trichlorodimethyl ether resembles benzotrichloride, which until now has been the only organic chloride in the literature with this behavior. It would be interesting to see whether trichloromethyl phenyl ether would behave in the same way.

Summary

The fluorination of trichlorodimethyl ether by anhydrous sublimed antimony fluoride without a catalyst yields a mixture of difluoromonochlorodimethyl ether, m. p. −105.1° and b. p. +55.3°, and trifluorodimethyl ether, m. p. −96.2° and b. p. +30.1°. These compounds are only slowly hydrolyzed in water.

Transitions in Camphor and Chemically Related Compounds. I. Dipole Rotation in Crystalline Solids

BY W. A. YAGER AND S. O. MORGAN

The measurement of the dielectric constant may often provide a means of determining both the structure of molecules and the physical changes which take place in the material as it undergoes a phase change, either from liquid to solid or from one solid form to another. This paper points out how dielectric studies on certain solids have disclosed phase changes not heretofore known and how these phase changes contribute to our knowledge of dielectric behavior. In a companion paper[1] it is pointed out that the dielectric evidence of phase changes in these solids is confirmed by density and specific heat measurements and the nature of these changes is discussed in more detail.

The dielectric constant ϵ of a pure polar liquid which freezes sharply usually decreases abruptly, upon solidification, to a value equal to the square of the optical refractive index. For most organic materials this refraction value of ϵ is between 2 and 3. In nitrobenzene, an example of this class of material, which has been measured by several investigators,[2,3] ϵ decreases from 36 to 3 at the melting point, as a result of the inability of the polar nitrobenzene molecules to orient in the solid. The ability to orient is determined by the magnitude of the inner friction, which in normal crystalline solids becomes so high immediately on solidifying that orientation is impossible even at very low frequencies. Therefore in this class of materials the change from high to low ϵ is usually independent of frequency. In certain crystalline solids such as ice[4,5] and in some materials having water of crystallization,[6] as well as in substances such as glycerol[7] which solidify to glasses instead of crystallizing, the inner friction in the solid is still low enough to permit orientation at low frequencies. In these cases anomalous dispersion is always observed. Other crystalline solids are known in which the inner friction is so low that orientation is possible even at high radio frequencies. In these materials the dielectric constant characteristic of the liquid does not decrease to the refraction value at the freezing point but does so, without dispersion, at a lower temperature where a solid–solid transition occurs.

The significance of this behavior was made apparent by the work of Pauling[8] on the rotational motion of molecules in crystalline solids. As was pointed out by Pauling, the distinction between the two solid forms may be recognized, in the case of polar materials, by dielectric measurements. This fact has served both to explain the dielectric behavior of some crystalline materials and to provide a useful tool for the investigation of phase changes in solids. Since there are no very satisfactory criteria of the moments of inertia and intermolecular forces involved in the rotation of complex organic molecules, a convenient starting point for this dielectric investigation has been polar materials known to have solid–solid transitions. The work of Wallerant[9] on the crystal structure and Bridgman[10] on phase changes has shown that camphor is polymorphic. This paper discusses the interpretation of phase changes in camphor and some related compounds by means of dielectric measurements.

Experimental Details.—The experimental work to be described consists of measurements of the variation of dielectric constant and conductivity of camphor and some related compounds with frequency and temperature. The frequency range was from 1 to 100 kc. and the temperature range from liquid air temperature to somewhat above the melting points. Direct capacitance and conductance measurements were made with a capacitance bridge described by Shackelton and Ferguson.[11]

The original measurements on camphor in parallel plate and cylindrical condensers gave values of ϵ which were consistently about half those of corresponding measurements on pressed disks, due presumably to unusually great con-

traction on cooling from the liquid state, although precautions were taken to solidify the material as uniformly as possible. That the dielectric constant obtained for pressed disks of camphor was not due to any change produced by pressing was shown by a number of experiments on sheets pressed at different pressures, and by the fact that the high value was also obtained on a section cut from a cast specimen of the material. The dielectric data presented here are for pressed disks, except for camphoric anhydride, which pressed with such difficulty that recourse to melting the material into a cylindrical condenser was necessary.

Homogeneous disks 1.0 to 1.3 mm. thick and reasonably free from entrapped air were prepared by pressing the materials under 7.5 to 30 tons ram pressure in a 4.4 cm. circular mold. Tin foil disks were placed between the material and the plungers to facilitate removal from the mold and also to ensure good electrical contact between electrodes and dielectric. Two disks of each material, with tin-foil electrodes in place, were clamped one on top of the other between two brass disks 10 mm. thick and 6.35 cm. in diameter, by an arrangement of pins and springs as shown in Fig. 1. The object of the springs was to provide constant clamping pressure upon the disks of the dielectric so as to minimize void formation on cooling. The brass plates constituted the ground electrodes and the tin foil between the disks of dielectric the high tension electrode, which was connected to the bridge by a shielded lead insulated from the brass plates. The error due to edge effects in this arrangement was found to be negligible.

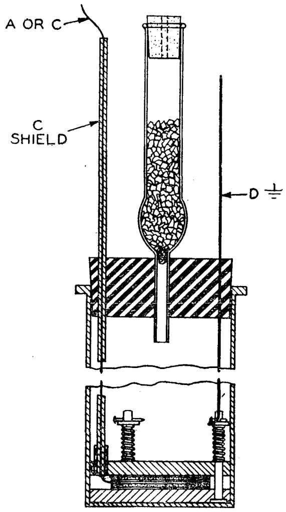

Fig. 1.—Arrangement of condenser for direct capacitance and conductance measurements on pressed disks of dielectric.

The cylindrical condenser employed for the measurements on camphoric anhydride is shown diagrammatically in Fig. 2. It was so designed that, by making direct capacitance and conductance measurements, all fixed and stray capacitances and conductances were eliminated.

The usual procedure in making preliminary measurements at low temperatures was to place the condenser containing the specimen in a Dewar flask, cool with liquid air, then remove the liquid air and allow the sample to warm up slowly. Capacitance and conductance were measured at 1 and 100 kc. alternately as the system warmed up, no attempt being made to hold the temperature constant. For bornyl chloride and *d*-camphor drifting measurements only were made with ascending temperatures. For the other materials measurements were made at constant temperature with both increasing and decreasing temperatures, the specimen being equilibrated in a simple liquid air thermostat. Good agreement was obtained between the values with a drifting temperature and those equilibrated at fixed temperatures. For measurements above room temperature an oil thermostat was used for the pressed disks and an aluminum block thermostat for measurements with the cylindrical condenser.

Materials.—The *d*-camphor was a refined commercial gum camphor which was recrystallized twice from absolute alcohol, dried and resublimed.

The *dl*-camphor was refined synthetic camphor from the du Pont Company and was used without further purification. A sample of refined synthetic camphor from the Eastman Kodak Company gave identical results and a sample of this camphor, which was recrystallized twice from alcohol and then resublimed, also gave the same dielectric constant, though slightly different dielectric loss.

Borneol and isoborneol from Fritzsche Brothers were measured as received.

d-Camphoric anhydride from Eastman Kodak Company was measured as received.

Eastman Kodak Company pinene hydrochloride (bornyl chloride)[12] was recrystallized from absolute alcohol and dried over calcium chloride.

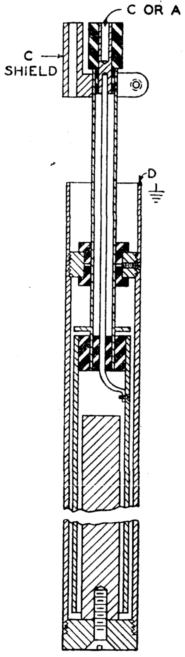

Fig. 2.—Cylindrical condenser for direct capacitance and conductance measurements on liquids or solids.

Experimental Results and Discussion

The temperature dependence of the dielectric constant of *d*-camphor is shown graphically in Fig. 3 for low temperatures. With descending temperature (Curve A) ϵ was found to increase to a maximum value of 14.9 at $-37°$. The temperature was maintained constant at $-37°$ for at least two hours, but ϵ retained its high value with no indication of falling off. On lowering the temperature a degree or two, however, ϵ decreased abruptly to a value of 2.82, which remained constant to liquid air temperature. With ascending temperature (Curve B) the same value of ϵ, independent of temperature, was observed up to $-32°$. At this temperature it increased rapidly to a maximum of 12.4 at $-25°$ and subsequently decreased with further increase in temperature. Within the experimental error the 1 and 100 kc. dielectric constants fall on the

---

[12] According to Brooks, "Non-Benzenoid Hydrocarbons," p. 438, what is commonly called pinene hydrochloride, m. p. 127°, is bornyl chloride.

same curves with no evidence of an anomalous dispersion even in the transition interval. The conductance, which is a more sensitive test for anomalous dispersion, was low so that changes could not be followed through the transition interval due to inability to balance the bridge, because of the rapidly changing capacity. It can be safely said, however, that the variation in conductance, if any, was extremely small. The dielectric constant at 18 megacycles, measured at room temperature, was also found to agree with the value at lower frequencies. It appears, therefore, that the relaxation time of the polarization which accounts for the value of ϵ above the transition is less than 9×10^{-9} seconds at room temperature.

The fact that the transition occurred at −37° on cooling, but at −32° on heating, can probably be attributed to an overstepping of the transition point in both directions as is often observed in solid–solid transitions.[13] The curve a-b of Fig. 3 was obtained by continuing the measurements which gave curve B from the point b, going first in the direction of descending and then in the direction of ascending temperature. The points all fall on the same curve, showing that after completion of the change to the high temperature form there is no hysteresis above the transition temperature.

The abrupt change in dielectric constant of *d*-camphor at the transition is accompanied by a large change in heat content, as revealed by heating and cooling curves. The first break in the heating curve occurred at −32° and the second at −27°, checking remarkably well the range determined from the dielectric data. On cooling, the transformation began at −37° and was practically complete at −40°, again in good agreement with the dielectric data.

In 1914, Wallerant,[9] studying the crystallography of *d*-camphor, found that if it is made to crystallize by fusion it assumes four different states. Upon first solidifying the crystals are cubic, transforming into rhombohedral at 97°. Small crystals, also rhombohedral, then develop on these large crystals and are to be considered the stable form as an inverse transformation never takes place at any temperature. Since these new crystals are produced by crystalline supercooling, the transformation takes place near 90° instead of 97°. Finally at −28° these crystals are again transformed into very birefringent crystals which are also rhombohedral. Bridgman[10] found that *d*-camphor is polymorphic with six possible solid phases depending upon the temperature and pressure. At atmospheric pressure a solid–solid transition was found at 87°, and another in the neighborhood of −40°. The dielectric data for camphor serve to define the lower of these phase changes more clearly than the earlier work, but tell very little about the change near 90°.

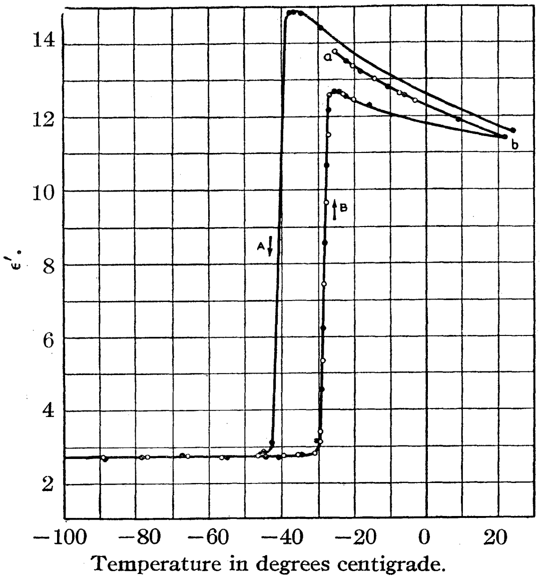

Fig. 3.—Dielectric constant of *d*-camphor as a function of temperature: Curve A, descending temperature; Curve B, ascending temperature. ○, 1 kc.; ●, 100 kc.

The temperature dependence of the dielectric constant of *d*-camphor at temperatures including the melting point and the transition in the neighborhood of 90° is shown in Fig. 4. A cylindrical condenser was employed for the measurements in the liquid state, and the disk condenser for the measurements in the solid state up to 168°. At these temperatures the vapor pressure of the camphor is so high as to cause excessive evaporation at the edges of the disks. To cover the range between 168° and the melting point (177.6°), the cylindrical condenser was again used, precautions being taken to solidify the material from the bottom up. The data up to 168° and above the melting point are shown as solid lines in the figure, and that of the intermediate region as dashed lines, there being some uncertainty as to the absolute values in this region.

---

[13] Findlay, "The Phase Rule and Its Applications," Longmans, Green and Co., New York City, 1923, p. 27.

The dielectric constant of solid *d*-camphor was observed to decrease with increasing temperature in a manner very similar to that of polar liquids, where the decrease is supposedly due to decreasing density and greater hindrance to dipole orientation. Up to approximately 75° ϵ is practically independent of frequency (between 1 and 100 kc.) and the dielectric loss may be accounted for entirely by direct current conductance. Between 90 and 100°, where the rhombohedral crystals should be transformed to cubic crystals, there is still no discontinuity in the higher frequency curves but the 1 kc. curve shows a slight break.

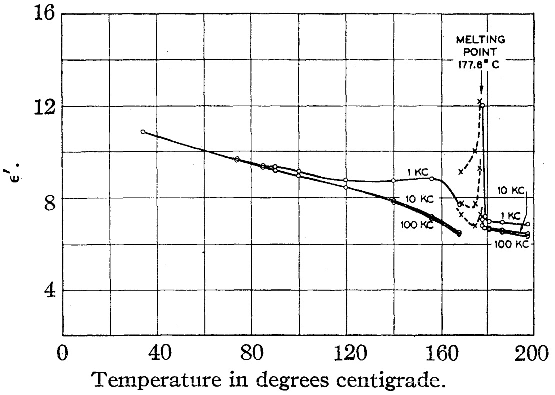

Fig. 4.—Dielectric constant of *d*-camphor as a function of temperature and frequency above room temperature.

The fact that ϵ at the higher frequencies decreases more rapidly as the melting point is approached than at lower temperatures, is probably due to the decrease in area of the test specimen as a result of evaporation. The 1 kc. value, although subject to the same percentage error, increases to a maximum at approximately 156° and then decreases rapidly. This maximum indicates the presence of an anomalous dispersion which, however, does not appear to be present at 10 and 100 kc. The conductivity data are too uncertain to assist in analyzing this behavior. In the neighborhood of the melting point there are two regions of anomalous behavior both of which are probably the result of interfacial polarizations due either to impurities or to the formation of two layers. The lower may be due to solid–air layers produced by contraction of the solid and the upper to the coexistence of a liquid and solid phase near the melting point.

Impurities present might give rise to a liquid phase just below the melting point but failure to attain temperature equilibrium is a more probable cause. As the system is allowed to cool gradually, a solid layer will form on the outer electrode giving in effect a two layer dielectric composed of a solid layer in series with a liquid layer. As cooling proceeds, the solid layer will increase in thickness at the expense of the liquid layer until the entire mass between the electrodes has solidified. The dielectric constants of the liquid and solid phases are essentially the same but the conductivity, γ, of the solid phase is less than that of the liquid phase so that the necessary condition for the existence of a Maxwell–Wagner interfacial polarization, namely, that $\epsilon_1\gamma_2 - \epsilon_2\gamma_1$ be either greater or less than but not equal to zero, is fulfilled. Furthermore, the conductivity is of the right order for the anomalous dispersion to occur in the frequency range of these measurements. It can be shown from the equations for a two-layer dielectric, that a behavior analogous to that observed may be obtained if the ratio of the thickness of the solid layer to the total electrode separation be allowed to increase progressively from 0 to 1. The reverse procedure of gradually heating the system through the melting point will give precisely the same results.

Apart from the uncertainties in the values near the melting point, the data indicate clearly that there is no appreciable change in value of ϵ for camphor on solidifying. They indicate that the same polarization which exists in the liquid state also is present in the solid. The melting point, usually supposed to represent the place where the molecules align themselves into a crystal pattern, does not introduce any appreciable interference with the ability of the molecules to orient. The restraint to rotation sets in at the transition point some 215° lower.

There is no evidence to indicate that any difference should have been expected between the dielectric properties of the natural *d*-camphor and the synthetic *dl*-camphor. Figure 5 shows that the two are very similar, though not identical. The transition for *dl*-camphor is displaced to lower temperatures, and ϵ undergoes but half the sharp drop shown by *d*-camphor at the transition. ϵ then decreases more gradually with descending temperature through a region of anomalous dispersion before finally reaching the state corresponding to the refraction polarization at −180°. There apparently is no temperature hysteresis in the region of anomalous dispersion as the data for ascending and descending temperatures fall on the same curves, but at higher temperatures a slight hysteresis appears, which is probably associated with the transition as in the case of *d*-camphor. The dielectric loss factor, ϵ', is shown for the region of anomalous dispersion below the transition temperature. At higher temperatures ϵ'' was too small to be significant.

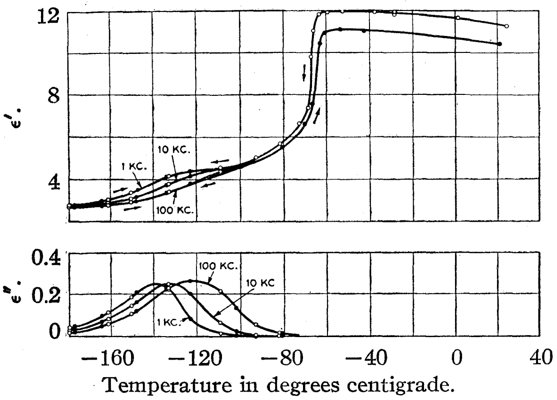

Fig. 5.—Dielectric constant and dielectric loss factor of *dl*-camphor as a function of temperature and frequency below room temperature; ●, ascending temperature; ○, descending temperature.

The anomalous dispersion below the transition was at first thought to be due to the presence of impurities. However, no systematic variation in ϵ'' with degree of purification was found. For a purified sample, which was recrystallized twice from absolute alcohol and then sublimed, ϵ'' was reduced somewhat in magnitude but by no means eliminated. The loss factor of a sample which, in addition to being recrystallized twice from absolute alcohol was recrystallized once from hexane, and subsequently sublimed, was higher than that of the unpurified sample and was shifted to somewhat higher temperatures. It appears that this dispersion below the transition is not entirely due to the presence of impurities in the usual sense of the term.

Heating and cooling curves for *dl*-camphor show breaks which are much less pronounced than those of *d*-camphor, in accord with the more gradual falling off of the dielectric constant in passing through the transition. From these data the transition interval appears to be between −65.7 and −66.7° on cooling and between −65.4 and −64.4° on heating, in fair agreement with the dielectric data.

A point of considerable interest is that the transition of *dl*-camphor occurs at a considerably lower temperature than that of *d*-camphor. Unpublished work in this Laboratory indicates that the transition of *d*-camphor is displaced to lower temperatures when it is one component of a solid solution, whereas its transition temperature is unaffected when it is one component of a eutectic mixture. This is in agreement with the usually observed behavior of transitions in metals. Whether or not the transition temperature is altered when it forms a compound with another material has not been determined. However, it appears that *dl*-camphor is either a racemic compound or a pseudo-racemic mixed crystal and[13] (p. 177) not a racemic mixture.

The dielectric data for samples of borneol and isoborneol are presented in Fig. 6. The data indicate a dielectric transition in borneol with a change in ϵ from 3.02 at 70° to 3.67 at 75°. The transition is less critical to temperature than those of the camphors as evidenced by the gradual increase in ϵ with temperature both above and below the transition proper. It is interesting to note that no temperature hysteresis was found in this case. There is also no evidence of an anomalous dispersion, between 1 and 100 kc., over the range of temperature shown, including the transition interval. Furthermore, ϵ'' and d. c. conductivity remained very low, even up to 100°.

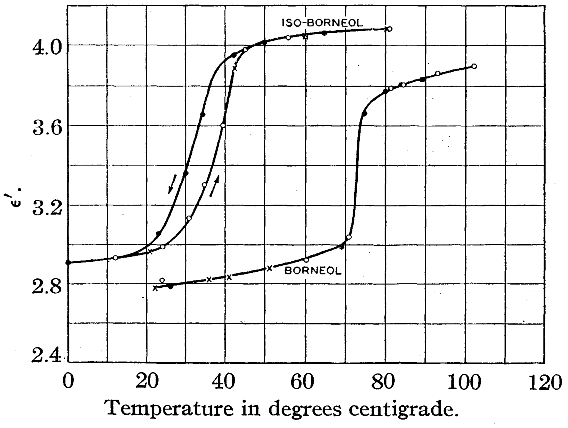

Fig. 6.—Dielectric constant of borneol and isoborneol as a function of temperature: x, ascending temperature—first run; ○, ascending temperature—second run; ●, descending run.

The data for isoborneol indicate a dielectric transition in which ϵ increases from 2.9 at 12° to 4.0 at 46° with a pronounced temperature hysteresis through this interval. There is no anomalous dispersion, between 1 and 100 kc., over the temperature range shown. In isoborneol also ϵ'' and the d. c. conductivity remain low, even up to 80°.

No transitions corresponding to those observed in borneol and isoborneol have been reported in the literature. As is shown elsewhere,[1] a change of volume accompanies this transition in both materials.

The fact that the dielectric constants of borneol and isoborneol decrease below their transition points to values somewhat higher than the refraction values (2.5 to 2.6) leads to further low temperature study of these materials. In both cases a second decrease of ϵ to the refraction value, and showing anomalous dispersion, was observed between about -50 and $-100°$. A similar small decrease of ϵ with a dispersion has also been observed in this Laboratory in other solids, particularly those having OH or OCH_3 groups. Since this change occurs at very nearly the same temperature in widely different compounds containing these groups it is believed that this is evidence of group rotation.

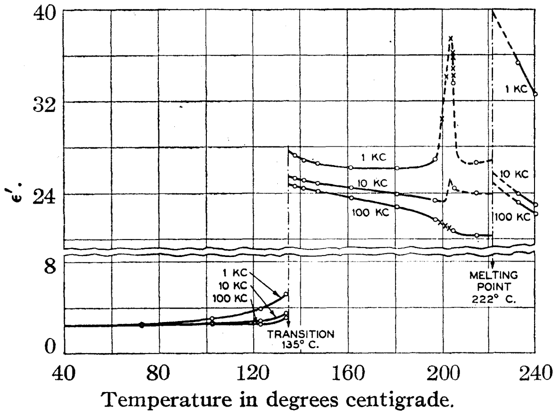

Fig. 7.—Dielectric constant of *d*-camphoric anhydride as a function of temperature and frequency.

The dielectric constant data for *d*-camphoric anhydride are presented in Fig. 7. They reveal a dielectric transition at 135°, at which ϵ suddenly increases, with no evidence of an anomalous dispersion, from a value of 3.2 to 24.8 at 100 kc., and to somewhat higher values at lower frequencies. Above 135° the dielectric constant at 1, 10 and 100 kc. shows the typical decrease with temperature characteristic of polar liquids, but between 190 and 210° some anomalous results are obtained. The 1-kc. dielectric constant increases rapidly to a maximum and then decreases again with equal rapidity. This anomalous behavior was much less pronounced at 10 kc. and apparently absent at 100 kc. The relative spacing of the 1, 10 and 100 kc. curves between 205° and the melting point suggests an anomalous dispersion. The d. c. conductivity in this range is so large as to mask the accompanying dielectric absorption so that the loss factor cannot be used to confirm the existence of the anomalous dispersion. At the melting point the dielectric constant increases somewhat, with no evidence of an anomalous dispersion, and exhibits the typical decrease with increasing temperature in the liquid state. There is, however, marked evidence of electrolytic polarization. The peculiar behavior of the dielectric constant some 20° below the melting point is similar to that observed for *d*-camphor about the same distance below the melting point. As in the case of camphor also, the change of ϵ at the melting point is so small compared to that at the transition as to indicate that dipole orientation is taking place in the solid, between the melting and transition temperatures.

The temperature dependence of the conductivity of *d*-camphoric anhydride is illustrated in Fig. 8. A discontinuity in the 1, 10 and 100 kc. curves is observed at both the transition and melting points, the conductivity increasing suddenly by a factor of approximately 10 in each case. However, the d. c. conductivity, measured with a microammeter after a one-minute application of 50 volts, apparently shows no discontinuity at the transition point. It seems, therefore, that the ionic conductivity which increases exponentially with temperature is essentially unaffected by the solid–solid transition. Above the melting point the conductivity is predominantly ionic and hence independent of frequency.

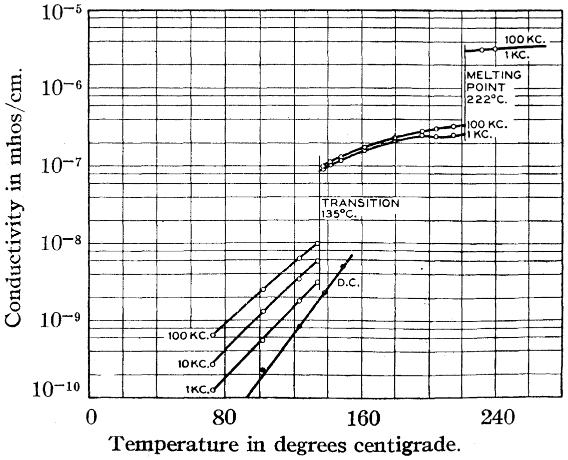

Fig. 8.—Conductivity of *d*-camphoric anhydride as a function of temperature and frequency.

The dielectric data for bornyl chloride are reproduced in Fig. 9. This behavior closely resembles that of *dl*-camphor, in that ϵ drops suddenly at the transition only part way to its refraction value and then passes through a region of anomalous dispersion with further decrease in temperature. ϵ'' curves of the same type as for *dl*-camphor are also obtained. The dispersion in bornyl chloride was very much altered by purification, a result contrary to that for *dl*-camphor. The unpurified sample showed an anomalous dispersion starting so close to the transition as to mask it.

The anomalous dispersion observed immediately below the transitions for *dl*-camphor and bornyl chloride probably arises from the restricted rotation of dipoles in the solid. Several causes of this restricted rotation suggest themselves. The initial decrease of ϵ without dispersion suggests that it may result from the separation of the material into two or more components, one of which has an inner friction of the correct magnitude to produce dispersion. Alternatively, it may be that following the transition of a part of the material to the low temperature form the resultant inner friction becomes large enough to restrict the rotation of the remainder. It must also be considered that the dispersion may be due to an interfacial polarization resulting from the existence of more than one solid phase. Since the free-ion conductivity of the solid phases is very low this explanation requires that there be a polarization conductivity of considerable magnitude. There appears to be little doubt that the high dielectric constants above the transition temperatures are a result of orientation of dipoles and that the inner friction opposing rotation is small compared to that below the transitions. The absence of an anomalous dispersion immediately above the transition temperature in the camphor compounds may be regarded as evidence of the sharpness of the change from the high temperature form, having low inner friction forces, to the low temperature form, where inner friction forces are too large to permit rotation.

The type of dielectric behavior described in this paper fits very closely into the picture provided by Pauling's theory. From consideration of the thermal properties, Pauling predicted that the polar hydrogen halides would have high dielectric constants in the solid state, the values and their temperature variation being those predicted by the Debye theory. Experimental study has confirmed this prediction.[14,15] In addition to hydrogen chloride, bromide and iodide this dielectric behavior has been reported for hydrogen sulfide, dimethyl sulfate and methyl alcohol.[16] All of these materials are known to show specific heat changes at their transition points, these changes, in fact, being used as an indication of expected dielectric constant change. The heat capacity measurements on the materials studied in this work, as far as they have been made, also show that a change of specific heat accompanies the solid–solid transitions.

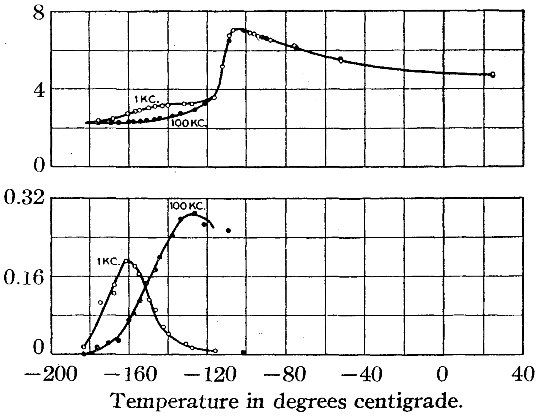

Fig. 9.—Dielectric constant and dielectric loss factor of bornyl chloride as a function of temperature and frequency.

The dielectric behavior of camphor and related compounds differs from that of many other crystalline solids, such as ice, for example, in the effect of frequency. In ice there is an anomalous dispersion at all temperatures below the freezing point. This has been observed by several experimenters.[2,4,5,17,18] Furthermore there is no discontinuity in the specific heat or density of ice which would lead to the prediction that the dielectric constant should change suddenly. It is to be expected that the gradual decrease in heat capacity and density would necessitate a gradual increase of the forces opposing dipole rotation and hence that anomalous dispersion should result.

The phase diagram of ice suggests the possibility that if the dielectric constant were studied with decreasing temperature at high pressure, a discontinuity might be expected at the temperature where a change from phase I to phase II takes place. This assumes that phase I is a high and

phase II a low dielectric constant form, which seems probable.

The molar polarization of these materials likewise undergoes a change at the transition point and is a linear function of $1/T$ in the range between the transition and melting temperatures. This is in agreement with the prediction of the Debye dipole theory but nevertheless is of doubtful significance except as qualitative evidence that a dipole polarization is present in these solids. Qualitative evidence that dipole rotation is contributing to the dielectric constant is also given by the correlation between the magnitude of ϵ and the dipole moment. No values are available for the moment of camphoric anhydride but it is safe to predict that it is the highest of this group of materials, probably between 4 and 5 *D*. The moment of camphor, 2.7 *D*, is higher than either bornyl chloride or borneol, as is its dielectric constant.

Summary

A study of the dielectric properties of *d*-camphor, *dl*-camphor, *d*-camphoric anhydride, borneol, isoborneol and bornyl chloride has shown that these materials undergo solid–solid transitions. These transitions have not been previously reported in the literature, except for *d*-camphor. Above the transition the value of the dielectric constant of the solid is that normally expected of the polar material in the liquid state. Below the transition the dielectric constant has a low value, approximately equal to the square of the optical refractive index. This dielectric behavior is explained by the rotation of dipoles in the solid.

Transitions in Camphor and Chemically Related Compounds. II. Vibration of Atomic Groups

BY ADDISON H. WHITE AND S. O. MORGAN

Introduction

In 1914 Wallerant[1] observed at −28° a transition of *d*-camphor from rhombohedral crystals of slight birefringence to similar crystals of pronounced birefringence, upon cooling. P. W. Bridgman[2] studied this transition at higher temperatures and pressures, and designated the solid phases stable above and below it as phase II and phase III, respectively.

Linus Pauling[3] has shown that some crystalline transitions accompanied by thermal phenomena may be explained by assuming that molecules or atomic groups begin to rotate at the transition when the crystal is heated. The possibility that a rise of molecular rotation is responsible for transitions occurring in crystals of complex organic molecules, as well as in the simple molecular lattices studied by Pauling, was the original subject of this investigation.[4] Activity was centered on the above-mentioned transition in *d*-camphor, at which dielectric constant undergoes a change similar to that predicted by Pauling for the transitions in crystals composed of simpler polar molecules.[5]

The molecule of *d*-camphor is so much more complex than that of hydrogen, which Pauling studied, that a mathematical discussion of the possibility of its rotation in the crystal would not be very informative. However, Pauling's theory suggests three lines of attack which should help to determine experimentally the mechanism responsible for the transition in *d*-camphor.

1. Heat capacity measurements through the transition should yield information as to any increase in mobility of units whose motion is restrained below the transition.

2. Specific volume and thermal expansion measurements should reveal any general loosening up of structure such as may accompany increased mobility of its units.

3. Dielectric measurements, interpreted in the light of the Debye[6] theory, should give some information as to the specific type of motion involved, and particularly as to whether the motion is rotational or translational.

Experimental Work

Thermal Measurements.—A modified Nernst vacuum calorimeter, modeled on that described by Southard and Andrews,[7] but greatly simplified, was used in this work. Measurements were made by the continuous heating method of Deese.[8] A large lag of temperature of the sample behind that of the container, to which the thermocouples were attached, undoubtedly resulted. Neither this error nor that of calibration of the container was important in work where the significant data are the increase of heat capacity at the transition and the heat of transition. However, the heat capacity of Schering–Kahlbaum calorimetric naphthalene as determined in this calorimeter at intervals between −180 and 0° was found to differ from the values of Southard and Andrews[7] by no more than 5%, being always lower than their more accurate measurements. The direction of the error agrees with that found by Deese.[8] It was concluded that despite its simplicity this calorimeter was capable of determining the increase of heat capacity and the heat of transition of *d*-camphor with the accuracy required.

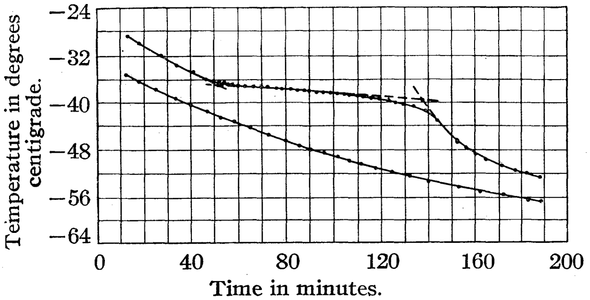

Fig. 1.—Cooling curve of *d*-camphor through the transition. The upper curve represents the temperature of the sample; the lower, that of the bath.

The *d*-camphor used in these measurements was purified as described by Yager and Morgan.[4]

Table I records the values of heat capacity found from the tangents of continuous heating curves taken at various temperatures and heating rates and for each phase of the *d*-camphor.

TABLE I

	t, °C.	V	C_p(cal./°C./mole)
Phase III	−56	1.86	39
	−49	1.86	42
	−40	1.86	40
	−31	1.86	40
		Average	40
Phase II	−30	1.57	58
	−28	1.39	59
	−16	1.86	58
	−14	1.86	58
		Average	58

The rate of heat input is proportional to the square of the applied voltage, which is listed in the third column of the table. The data show an increase of molar heat capacity of about 18 calories per degree accompanying the transition from phase III to phase II. The possibility that the high values observed in phase II are merely due to a further contribution of the heat of transition to the apparent specific heat is reduced by two considerations.

1. The heat capacity of phase II is relatively independent of temperature between −30 and −14°.

2. The value at −30° was obtained after cooling the sample only to −32°, where because of temperature hysteresis[4] the transition had not yet started. The cooling curve of the same sample shows in Fig. 1 that the transition does not begin above −36°. These data were not subject to temperature lag inasmuch as they were obtained with the thermocouple embedded in the sample.

The heat of transition was determined from continuous heating curves such as that illustrated in Fig. 2, where heat was applied to a sample of 6.871 g. of camphor at the rate of 0.1549 watt. The heat of transition was found from the time AB to be 1780 calories per mole. Two other measurements yielded the respective values of 1850 and 1950 for this quantity, whose best value was therefore taken to be 1860 calories per mole.

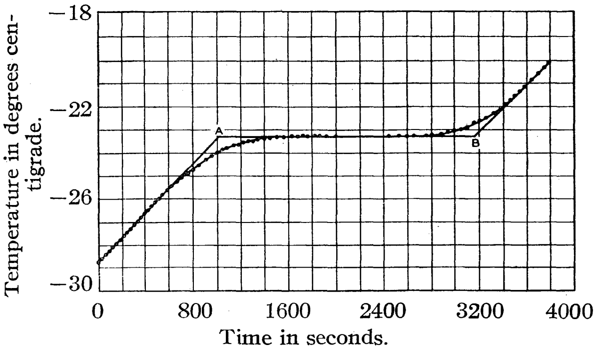

Fig. 2.—Calorimeter heating curve of *d*-camphor through the transition.

It will be noticed in Fig. 2 that the temperature of the transition as recorded thermally is about −23°, where Wallerant,[1] Bridgman,[2] and Yager and Morgan[4] place it between −28 and −40°. The difference is believed to be a rough measure of the temperature lag involved in making a continuous measurement in this calorimeter. Figure 3 shows, however, that the heat of transition thus determined falls on the same curve as those determined by the application of the Clapeyron–Clausius equation to Bridgman's data,[2] where the temperature of the transition is increased by the application of high pressures. This is regarded as evidence of the general accuracy of these thermal measurements.

Specific Volume.—A gas expansion volume meter similar in principle to that described by MacGee[9] was used to measure the specific volume of *d*-camphor through the transition. The apparatus differed from that of MacGee in that no mercury was allowed to enter the reference volumes, which were maintained at equal temperatures by means of a constant temperature bath. This modification was made necessary by the desirability of obtaining data below the freezing point of mercury. The random error of observation greatly exceeded errors from all other sources, being about ±0.5%.

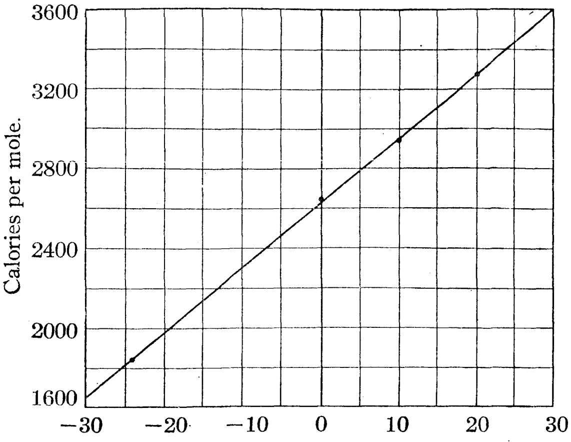

Fig. 3.—Heat of transition of *d*-camphor as a function of temperature.

The data thus obtained are represented in Fig. 4, and show a decrease of about 7% in the specific volume of *d*-camphor between −37 and −41°. The dielectric data are included for comparison. No temperature hysteresis of specific volume, analogous to those observed by thermal and dielectric measurements, could be detected. The discrepancy has not been satisfactorily explained, since equivalent precautions for obtaining thermal equilibrium were taken in the two series of measurements.

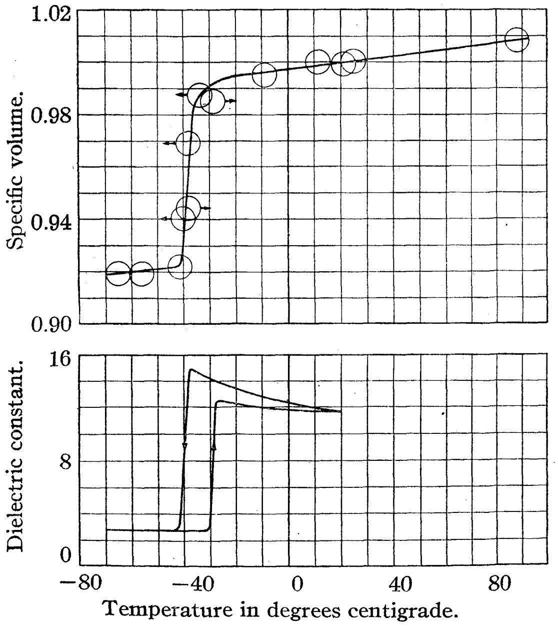

Fig. 4.—Specific volume of *d*-camphor compared with its dielectric constant.

Since dielectric measurements[4] had shown several closely related compounds to undergo dielectric transitions similar to that of *d*-camphor, the specific volume of these materials was measured in the hope of revealing a corresponding similarity in the behavior of this property. Figure 5 shows that a similar volume transition of about 4% is found in *dl*-camphor between −55 and −80°. Figures 6 and 7 portray data obtained for borneol and isoborneol by the much more sensitive method of observing the rise with temperature of a mercury meniscus in the calibrated capillary outlet of a dilatometer in whose bulb the sample had been solidified so as to be as free as possible from voids into which the mercury could not enter. Specific volume undergoes a small change at each of these transitions. The temperature hysteresis of dielectric constant observed in isoborneol[4] is reproduced by the specific volume data.

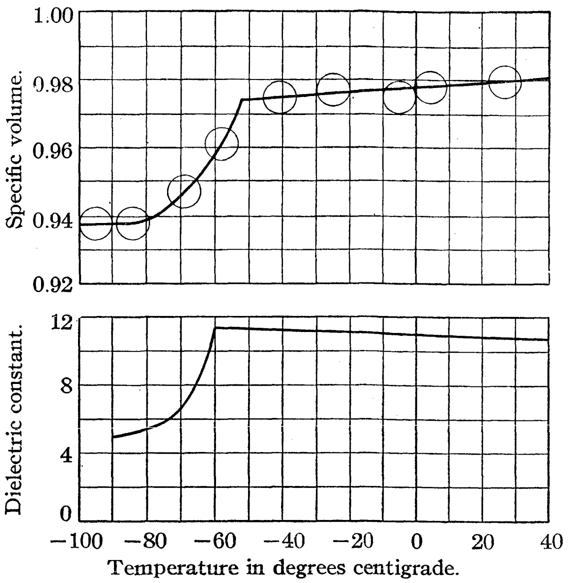

Fig. 5.—Comparison of specific volume and dielectric constant of *dl*-camphor.

Dielectric Measurements.—In seeking data on thermal transitions similar to that observed in *d*-camphor, it was found that in cyclohexanol there is a heat absorption of 1960 cal./mole and an increase of about five calories in C_p at a transition occurring at −10°.[10] Since these thermal data resemble those obtained for *d*-camphor, a corresponding similarity in dielectric properties was sought by measuring the variation of dielectric constant through this transition. Both cylindrical and parallel plate condensers were used to make grounded capacity measurements, which were in substantial agreement.

The results are shown for cyclohexanol in Fig. 8. Dielectric constant is, within the error of measurement, continuous through the melting point (+18°). It is possible to supercool phase I of the cyclohexanol far below the transition temperature;[10] below −25° an anomalous dispersion similar to that observed in supercooled liquids and involving nearly the whole polarization is observed. After the transformation to phase II, which occurred anywhere between −40 and −62°, heating failed to reverse the process until a temperature of about −25° was reached. Repeated distillation and drying of the cyclohexanol, which raised the melting point from 12 to 18°, and the boiling point to 161.0°, failed to change the upper temperature limit of this transition by any measurable amount. It is nevertheless thought to be essentially the

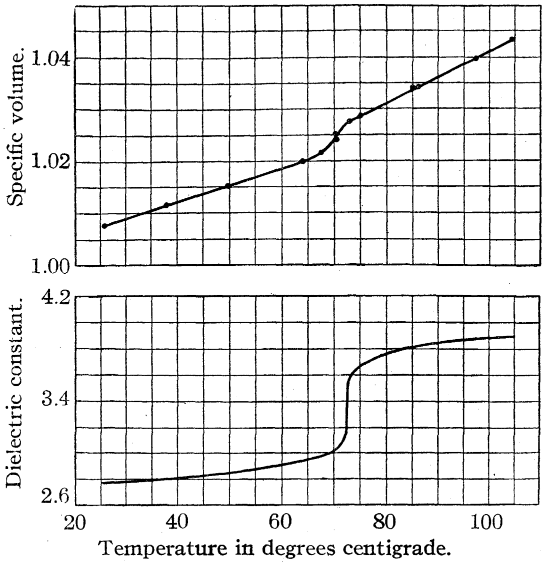

Fig. 6.—Specific volume and dielectric constant of borneol.

transition which Kelley[10] observed at −10°, especially considering the relative impurity of the samples as measured here; the melting point of the pure material is 24°, and its boiling point, 161.1°.

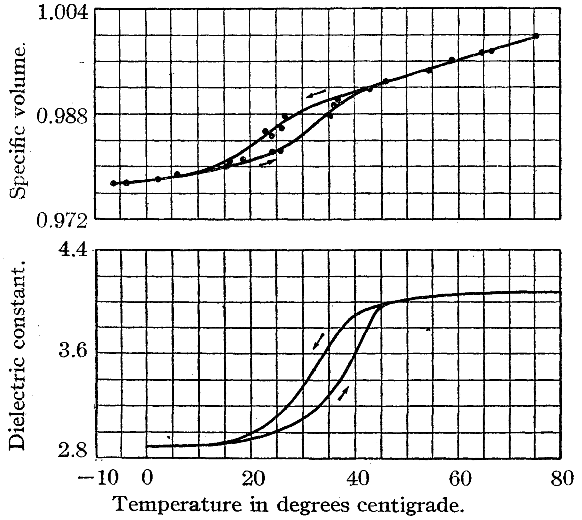

Fig. 7.—Specific volume and dielectric constant of isoborneol.

Measurements were also made on dilute solutions of the same sample of *d*-camphor in purified petroleum hexane, in order to calculate the dipole moment and atomic polarization of the *d*-camphor molecule according to the Debye theory.[6] Dielectric constant, density, and refractive index of each solution were measured by the method and with the equipment described by Morgan and Lowry.[11] Extrapolation of the refractive index measurements to low frequencies with respect to the optical showed the *d*-camphor to have as expected a molar refraction of 44.4 cc.

Density and dielectric constant data interpolated at 10° intervals from the experimental curves are plotted against concentration in Figs. 9 and 10. It is obvious that both variables are linear functions of concentration within the error of measurement. Thus it is possible accurately to calculate molar polarization of *d*-camphor at infinite dilution by the method of Hedestrand.[12] Such a calculation yields the curve of molar polarization against the reciprocal of absolute temperature shown in Fig. 11.

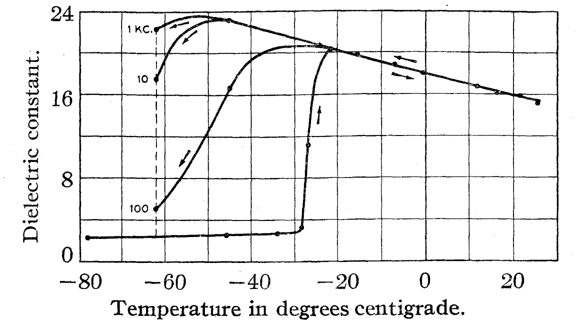

Fig. 8.—Dielectric constant of cyclohexanol as a function of temperature and frequency. The melting point of this sample is 18°.

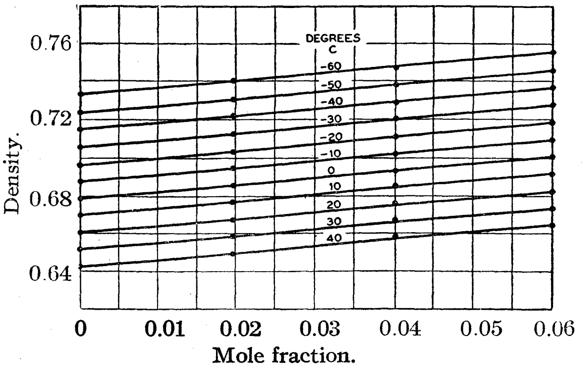

Fig. 9.—Density of solutions of *d*-camphor in petroleum hexane at various concentrations and temperatures.

Discussion of Results

From the theoretical point of view the significant increase of heat capacity at the transition in *d*-camphor is that at constant volume rather than the value experimentally determined at constant pressure. There are no compressibility data available for making the correction from C_p to C_v for the two phases of *d*-camphor. Andrews[13] has proposed the following approximation for this correction for organic lattices

$$C_p - C_v = 0.0214(T/T_M)\, C^2 \text{ (Molecule)}$$

where $C_p - C_v$ is expressed in calories per mole, C (Molecule) is the heat capacity at constant volume due only to translational and rotational

oscillations of the unit molecules, T_M is the melting point of the crystal, and T is its absolute temperature. Assuming C (Molecule) as calculated by Andrews[13] for benzene to be roughly typical of all organic lattices whose molecules are of similar complexity, this quantity should reach its classical value of about 12 calories in the crystal of *d*-camphor at some temperature between −170 and −120°. If then T_M is the same in both phases of *d*-camphor, $C_p - C_v$ does not increase at the transition, and the change of C_v should essentially correspond with that of C_p, being about 18 calories.

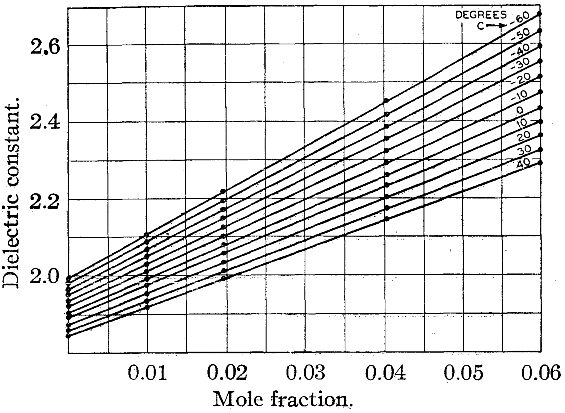

Fig. 10.—Dielectric constant of solutions of *d*-camphor in petroleum hexane at various concentrations and temperatures.

If the molecules of *d*-camphor are subject to a rotational oscillation capable, as inferred from Andrews' calculation for benzene, of absorbing heat above −120° at the classical rate of about six calories per degree per mole, the transition of this oscillation alone to free rotation should involve a decrease of specific heat, because of the loss of potential energy degrees of freedom. Even the transitions at much lower temperatures which are specified by Pauling[3] as involving molecular rotation are found to be characterized by only a very small increase of heat capacity. For example, the thermal transitions occurring at −174.6° in hydrogen chloride,[14] at −183.2° in hydrogen bromide,[15] at −207° in hydrogen iodide,[16] and −169° in hydrogen sulfide[17] all show a net increase of heat capacity of less than 1.5 calories per mole. Frenkel and his colleagues[18] have calculated that in hydrogen chloride the heat capacity should decline 1.32 calories per mole at the transition after correcting the observed values to constant volume. Each of the above-mentioned transitions involves so great an increase of dielectric constant over that normally observed in crystals that the rise of simple molecular rotation seems to be the best explanation.[19,20,21] It is therefore concluded that if C_v for *d*-camphor increases at the transition similarly to C_p, as has been assumed, the magnitude of this increase indicates that some change other than a simple rise of molecular rotation is occurring.

The observed heat of transition, 1860 calories per mole, also appears to be rather too large to be explained by the rise of molecular rotation alone. It is true that a three-dimensional molecule rotating in the crystal with so low an energy that its average potential and kinetic energy terms were nearly equal would have in the classical theory a total energy of $3RT$, which would be about 1500 calories per mole in *d*-camphor at 250 Å. However, all of this energy would have to be absorbed at the transition to explain the observed absorption of heat. This in turn would imply that below the transition temperature the rotational oscillation of the molecule is almost completely restrained. There is no reason to believe that this is true; Andrews' work[13] referred to above indicates that in the benzene crystal energy is absorbed by the degrees of freedom of rotational oscillation at the classical rate at tem-

peratures far below 250 Å. It therefore seems unlikely that the heat of transition can be completely accounted for by a rise of rotation of rigid molecules.

In terms of the current theory there is reason to believe that the rotation of so large and polar a molecule as *d*-camphor would not ordinarily be expected. Pauling's theory[3] shows that molecular rotation is unlikely where potential energy of restraint of molecular orientation and molecular moment of inertia are large. For a polar molecule Frenkel and his co-workers[18] state the potential energy to be

$$V = \mu E(1 - \cos \vartheta)$$

where μ is the dipole moment, at angle ϑ with the field E due to surrounding molecules. While nothing is known about E in the camphor crystal, μ is sufficiently large (at least 2.7 D) to indicate that the maximum value of V is not unusually small. On the other hand, the moments of inertia of the *d*-camphor molecule are far larger than those of the molecules which Pauling found able to rotate in the crystal. Mr. L. A. MacColl of these Laboratories has calculated the three moments of inertia of the camphor molecule from the accepted three-dimensional model, and finds the values 690, 600 and 510, all multiplied by 10^{-40} g. sq. cm. The moment of inertia of camphor about any axis of rotation is thus about 250 times as great as that of hydrogen chloride; molecular rotation in the crystal should therefore be considerably more difficult for the rigid *d*-camphor molecule than for hydrogen chloride, as far as the theory goes.

In general, any increase of C_v, at temperatures above 150 Å. and in crystals whose units are complex organic molecules, is due to atomic or group vibration within the molecule. When the heat capacity of such a crystal increases by about 50% it seems reasonable to ascribe most of that change to an abrupt increase of vibration of atoms or atomic groups. This should be particularly true when the molecule involved is completely saturated at all carbon to carbon bonds. Raman data show that vibration is more easily excited about single than about double bonds.[22] It is therefore proposed that unusually vigorous vibration of atoms or atomic groups arises in the molecule of crystalline *d*-camphor at the transition temperature.

If an increase of intramolecular vibration were the only significant mechanical feature of the transition in the *d*-camphor crystal, a certain increase of dielectric constant due to atomic polarization might be expected at the transition temperature, and a further large increase of dielectric constant due to free rotation of polar *d*-camphor molecules would be expected at the melting point of the crystal. Furthermore, the value of the atomic polarization would not in general be expected to decrease with increasing temperature.

Reference to the experimentally determined dielectric constant data for solid *d*-camphor[4] shows that neither of the above conditions is met. Dielectric constant rises sharply at the transition, subsequently declines rapidly with increasing temperature, and proves to be larger 20° below the melting point than immediately above it. These data lead Yager and Morgan to the conclusion that the dielectric properties of *d*-camphor in phase II are best explained by the assumption that the molecules rotate in the crystal lattice to much the same extent that they do in the liquid. Similarly, the dielectric constant of cyclohexanol, whose transition also seems to involve the rise of atomic vibration, changes so little at the melting point as to suggest that the rotation of polar molecules which is known to typify its liquid phase must continue below the freezing point.

The thermal data, dielectric measurements and Pauling's theory of molecular rotation in crystals may be reconciled by the following picture. As the crystal of *d*-camphor is heated through −30° the very marked increase of atomic vibration against reduced restoring forces suggested by the thermal data occurs rather generally throughout the crystal at the transition temperature. The accompanying reduction of the directional forces within the crystal should be large, as evidenced by a heat of transition larger than that of the fusion of *dl*-camphor[23] and by the 8% increase of specific volume. This reduction of internal forces together with the increased molecular pliability which should accompany the increased vibrational freedom would greatly reduce the magnitude of Pauling's potential hump $2V_0$, and permit the complex camphor molecules to rotate in the manner suggested by Pauling where molecules of more rigid structure might not be able to do so. This is of course only a rough

working hypothesis, as a detailed mathematical consideration of such a picture would become extremely involved. It seems to be useful, however, when the solution measurements are examined in the light of its implications.

Figure 11 shows that the measured molar polarization of *d*-camphor in dilute solution varies with temperature above $-10°$ ($(1/T) \times 10^3 = 3.81$) as predicted by the Debye theory, according to which

$$P = P_e + P_a + B/T$$

P_e the electronic polarization or molar refraction and P_a the atomic polarization are assumed to be independent of temperature, while the polarization of the rotating dipoles is a linear function of the reciprocal temperature, with tangent B related to the dipole moment μ by the expression

$$\mu = 0.0127\sqrt{B} \text{ Debye units}$$

From the tangent observed above $-10°$ the dipole moment is found to be 2.51 Debye units and from the intercept at $T = \infty$ the sum of P_e and P_a is found to be 113.3 cc. Since P_e is 44.4 cc., the value of P_a in the temperature range -10 to $+40°$ turns out to be 69 cc.

Jenkins[24] has recently shown that dilute solution measurements yield spuriously high values of atomic polarization unless the effect of temperature on the dielectric constant of the solvent is taken into account. At any given temperature the polarization of *d*-camphor calculated from the data of Figs. 10 and 11 is found to obey a modified form of Müller's[25] empirical formula for its variation with dielectric constant of the medium

$$P = A - B(\epsilon - 1)^2$$

where P is observed total polarization of *d*-camphor in solution and ϵ is dielectric constant of the solution. The constant A is taken to be the value of the solute polarization after correcting for all effect of the solvent. Within experimental error B was found to be independent of temperature in the case of *d*-camphor, having the mean value 20.78. Using this value of B, the accurately determined polarizations of Fig. 11 were then corrected for the effect of the dielectric constant of the solvent by finding the respective values of A in equation (2). The results thus obtained are shown in the second column of Table II; the nature of the P *vs.* $1/T$ curve is unchanged, although the part above $-10°$ which is linear shows a dipole moment of 2.69 D and an atomic polarization of about 69.6 cc. for the *d*-camphor molecule.

TABLE II

T, Å.	P	$P_0 = 43{,}600/T$	P_e	$P_a = P - P_0 - P_e$
313	253.3	139.3	44.5	69.5
303	258.2	143.9		69.8
293	262.8	148.8		69.5
283	268.3	154.1		69.7
273	273.9	159.7		69.7
263	279.9	165.8		69.6
253	285.5	172.3		68.7
243	291.5	179.4		67.6
233	297.1	187.1		65.5
223	302.7	195.5		62.7
213	308.5	204.7		59.3

This atomic polarization is very much higher than any reported in the reliable literature,[26] and would be regarded with extreme suspicion if there were no corollary evidence of unusual atomic vibration in the camphor molecule. The hypothesis proposed above for the mechanism of the crystalline transition, however, would require even freer atomic group vibration in the molecule when in the liquid state than when in the crystal lattice, since the restraints of the crystal forces on this vibration are eliminated in the former case. Van Vleck[27] has concluded that atomic polarization is negligible in stable diatomic molecules, but not necessarily so in those which are polyatomic. For a diatomic molecule he finds the contributions of atomic polarization to the total dielectric constant to be inversely proportional to the square of the natural frequency of the vibration involved. Applying this relation to the polyatomic camphor molecule, it is evident that an unusually large atomic polarization is required by our hypothesis that the intramolecular vibration is opposed by small restoring forces and therefore has an unusually low natural frequency.

Below $-10°$ this interpretation of the polarization data agrees with our picture in that the total polarization begins to decline below the value to be expected if the number of atomic groups engaged in unusual vibrations, and hence total atomic polarization, remained constant. The rate of decline of atomic polarization with temperature may be estimated by assuming that in this temperature range dipole moment remains

constant, as seems reasonable, since in the *d*-camphor molecule the effect of any atomic vibration on the time mean square of dipole moment would presumably be of the second order. Table II shows that the rate of decline of atomic polarization thus calculated is, as would be expected, less than that of the transition in the crystal, and seems to indicate that the maximum rate of this decline will occur below −100°. In a similar way the transition of *d*-camphor in *dl*-camphor[4] occurs at a lower temperature and over a broader range of temperatures than in pure *d*-camphor.

Donle and Volkert[28] and Wolf[29] agree in calculating a dipole moment of about 2.95 Debye units for camphor; the former investigators find a total polarization at 22° of about 234 cc. At 22° Fig. 11 shows a total polarization of 248 cc. for *d*-camphor. These values are in fairly good agreement, and the discrepancy between the accepted value of 2.95 Debye units for the dipole moment of camphor and the value of 2.69 presented here for *d*-camphor is mainly due to the large value calculated for P_a in the latter case. The older data were all obtained at single temperatures, no attempt being made to measure atomic polarization.

It is obvious that without independent evidence of great atomic vibration in *d*-camphor, the above interpretation of the polarization data would not be necessary, and that even with the corollary evidence it should be accepted with considerable caution until verified by measurements of the temperature variation of polarization of other compounds undergoing a similar crystalline transition, such as borneol,[4] isoborneol,[4] cyclohexanol and cyclohexanone.

The thermal and dielectric data indicate that the transition observed in cyclohexanol is due to the same mechanism as is the transition in *d*-camphor. Data to be published in the near future show similar dielectric transitions occurring in solid cyclohexene, cyclohexanone and chlorocylohexane. Now it is well known that there is possible in the cyclohexane ring a type of atomic group vibration which involves large amplitudes and large energy absorption, and which furthermore cannot occur in the benzene ring. Mohr's[30] modification of Sachse's[31] theory of strainless carbon rings predicted that the *cis*-form of the basic cyclohexane ring should be pliable and subject to large linear and rotational vibration of the methylene groups, while the *trans* form should be rigid. The possible amplitude of vibration of groups 2, 4 and 6 with respect to the plane of groups 1, 3 and 5 in the *cis* form of the ring is illustrated in Fig. 12. Henriquez[32] has shown mathematically that these vibrations may occur without bending or stretching any carbon valences which are directed away from each other at tetrahedral angles. It would therefore be expected that such a vibration would be possible in polar cyclohexane derivatives of the *cis* form, and would involve immensely greater displacements than would vibrations of equal energy but opposed by the elastic restoring forces of the valence bonds. A pliable polar molecule of this type should be unusually subject to deformation in an electric field, and hence should exhibit a large atomic polarization independent of temperature. This vibration would apparently account for part of the value of 1.6 found by O. Hassel[33] for the moment of 1,4-cyclohexadione.

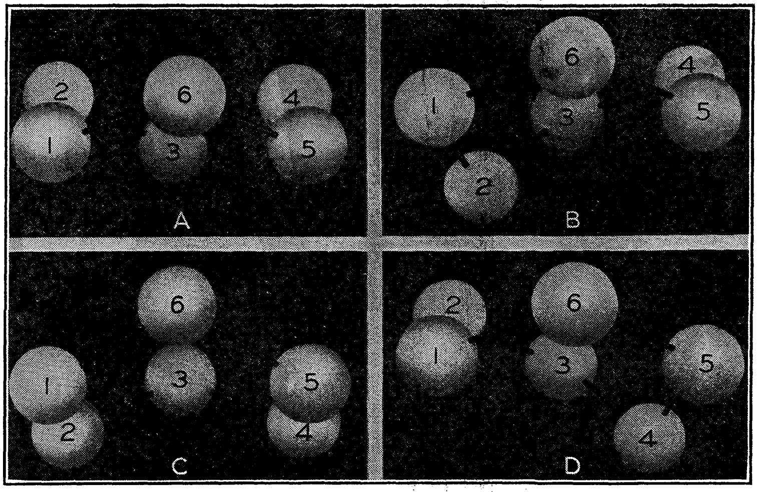

Fig. 12.—Strainless forms of the cyclohexane ring: A, the relatively rigid *trans* form; B, the pliable *cis* form obtained from A when atomic group No. 2 assimilates sufficient energy to change its position as indicated; C and D, further examples of the infinite series of equally probable configurations of the *cis* form.

The appearance of this vibration only above a transition in the cyclohexane derivatives would be explained if at low temperatures the *trans* form (Fig. 12) of the cyclohexane ring were the more stable. With rising temperature vibration of increasing amplitude might be expected to attain sufficient energy to carry some carbon over the potential hump between it and the pliable *cis* position. The difficulty of exciting atomic group vibrations should then decrease abruptly by a large factor, in line with the reduction of the Einstein parameter Θ. Absorption of energy and increased heat capacity would result. In a crystal the effect might spread from one molecule to another very rapidly, in the manner suggested by Pauling[3] for rotational transitions, because of the relaxation of crystal forces which might be expected to accompany a great reduction of the rigidity of the molecule, and an expansion of its "average volume." The same reduction of crystal forces should greatly facilitate the molecular rotation which is also believed to rise at the transition temperature.

An alternative possibility is that, even if the *cis* form were stable at the lowest temperatures, dipole forces, London forces and steric hindrance might prevent pliable rotation and vibration until a transition temperature was reached.

The accepted model of the *d*-camphor molecule is not pliable in the same sense as the cyclohexane ring, and hence gives very little indication of being subject to the type of extremely low frequency vibration required by our hypothesis. It is possible that the mechanical model does not reveal all types of vibration actually present in the molecule. However, the model does show that camphor contains a cyclohexane *cis* ring, whose tendency to pliable vibration would be elastically opposed only by the two bonds in the "bridge" of the molecule.

Summary

1. A rise of about 18 cal./°C./mole in the specific heat of *d*-camphor at the transition at −30° is observed and is explained by assuming that unusually energetic intramolecular vibration arises at the transition temperature.

2. The rise of molecular rotation at the transition which is evidenced by the dielectric data of Morgan and Yager is qualitatively explained in terms of Pauling's theory of molecular rotation in crystals, by assuming that the forces opposing this rotation are greatly diminished by a transition which reduces the rigidity of the molecules.

3. The behavior of total polarization of *d*-camphor in dilute solution is explained by assuming that at room temperature dipole moment is smaller and atomic polarization much larger than formerly supposed, and that the latter polarization begins to decline with temperature below −10° when the transition to the more rigid molecules begins.

4. Transitions very similar to that occurring in *d*-camphor are observed in crystals of derivatives of cyclohexane, whose carbon ring is supposed to be very pliable in the *cis* form and relatively rigid in the *trans* form. These transitions appear to be due to transformations from the rigid to the pliable forms of the molecules of which the crystals are composed.

A Quantum Mechanical Discussion of Orientation of Substituents in Aromatic Molecules

BY G. W. WHELAND AND LINUS PAULING

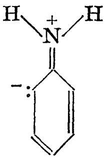
Introduction

When a substituent is introduced directly into an aromatic molecule, it may enter into certain of the available positions more readily than into others. This phenomenon of *orientation* has been exhaustively studied, and empirical rules have been found which describe the experimental results fairly satisfactorily. In a monosubstituted benzene C_6H_5R, for example, the introduction of a second substituent is governed by the nature of the atom or group, R, already present. Thus, for R = F, Cl, Br, I, OH, NH_2, and so on, the further substitution takes place largely in the ortho and para positions, while for R = COOH, CHO, NO_2, $(CH_3)_3N^+$, SO_3H, and so on, the substitution takes place largely in the meta position. Most ortho–para directing substituents, with the exception of fluorine, chlorine and bromine, activate the molecule so that the second substitution takes place more easily than in benzene itself. The meta directing substituents, on the other hand, produce deactivation. For other aromatic molecules similar rules have been found: in naphthalene substitution takes place largely at the α-position; in furan, pyrrole, and thiophene it takes place at the α-position; in pyridine it takes place at the β-position; and so on. In all the cases named except the last the molecule is more reactive than benzene.

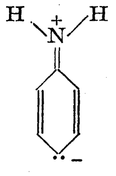
Several qualitative theories have been proposed to explain the phenomenon of orientation, but of these we shall mention only a single one, which has been developed during the last fifteen years. This theory, which has achieved a considerable measure of success, and which we believe to be essentially correct, presents the following picture of the process of directed substitution. For definiteness we shall consider a mono-substituted benzene, since this is the type of molecule which has been most carefully studied from both the experimental and the theoretical standpoints. In the molecule C_6H_5R, with R attached to carbon atom 1, the electron distribution may be such as to place an excess or a deficiency of electrons on the various carbon atoms 2–6. Moreover, the electron distribution may be changed somewhat on the approach of a group R′ to one of the carbon atoms ("polarization" of the molecule by the group). We assume that *the rate of substitution of R′ for hydrogen on the* i*th carbon atom increases with increase in the negative charge of the* i*th carbon atom when the group R′ approaches it.* We thus take into consideration, in addition to the permanent charge distribution, the changes in it caused by the approaching group.

There are two principal ways in which the charge distribution is affected by the substituent R. The first, called the *inductive effect,* results when the electron affinity of this group is appreciably larger, or smaller, than that of the hydrogen atom which it replaces. Thus, for example, if its electron affinity is larger, it will attract to itself a larger proportion of the electrons which form the bond between it and the carbon atom. This carbon atom will accordingly be left with a small positive charge, compared with the others, and its own electron affinity will be correspondingly increased. Consequently, it will tend to appropriate some of the electrons belonging to its neighbors, and so on around the ring. The net effect is, then, a transference of negative electricity from the ring to the substituent R. In an analogous manner, if R has a smaller electron affinity than the hydrogen atom which it replaces, it will give up negative electricity to the ring. In order to obtain agreement with experiment, it is necessary to assume that the *o*- and *p*-positions are affected by this redistribution of charge to approximately equal extents, and that the *m*-positions remain nearly unaffected. This is at variance with the simple classical picture, which predicts the order ortho > meta > para, but it finds its explanation in the quantum mechanical treatment given later.

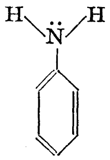
The second way in which the substituent R affects the charge distribution of the molecule is called the *resonance effect* (or sometimes the *tautomeric* or *electromeric effect*). This results when the molecule resonates among several electronic structures. For example, for aniline the structures



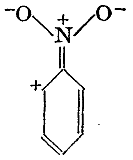
and



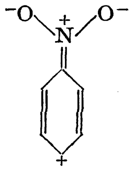
as well as



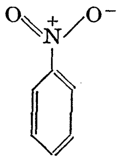
contribute to the normal state of the molecule, and for nitrobenzene



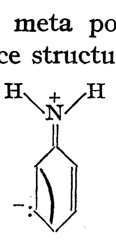
and



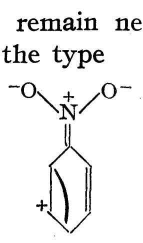
as well as



In the first molecule the resonance produces an increased concentration of electrons on the *o* and *p* carbon atoms, and in the second it produces a decreased concentration. As with the inductive effect, the meta positions remain nearly unaffected, since structures of the type



and



make relatively small contributions to the state of the molecule.

Some examples will illustrate the application of the theory to particular molecules. In toluene, the observed direction of the dipole moment shows that electrons have been transferred from the methyl group to the ring. Hence substitution takes place readily, particularly at the *o*- and *p*-positions, which have the greatest excess of electrons.

In nitrobenzene the nitro group has a large electron affinity, and accordingly draws electrons away from the ring. The resonance effect works in the same direction, and, as a result, all positions have a deficiency of electrons. The meta positions are least affected, and the substitution takes place there with difficulty. In aniline, the inductive effect and the resonance effect oppose each other, but the latter wins out, and very easy *o-p* substitution takes place.

These ideas have arisen through the combined efforts of a large number of different workers, among whom may be mentioned Fry, Stieglitz, Lapworth, Lewis, Lucas, Lowry, Robinson, and especially Ingold. For details the reader is referred to the excellent review articles of the last named author.[1]

With the development of a detailed quantum mechanical theory of the structure of aromatic molecules, it has become possible to attack the problem of orientation quantitatively. An attempt to do this was made by Hückel,[2] who showed that a polarizing substituent in benzene induces alternating charges in the ring. He limited his calculations, however, to the inductive effect, and neglected the resonance effect as well as the polarization of the molecule by the attacking group. As a result of these over-simplifications, he was led to make incorrect physical and chemical assumptions in order to obtain a rough correlation between his calculations and experiment. Thus, he assumed that "negative" groups, such as Cl, NH_2, and so on, increase the electron affinity of the attached carbon atom, while "positive" groups, such as NO_2, SO_3H, and so on, decrease its electron affinity. (Actually, all of the groups named tend to draw electrons away from the attached carbon atom, as far as the inductive effect alone is concerned, and hence to increase its electron affinity.) With this assumption, he then showed by a perturbation calculation that the negative groups induce positive charges on the *o*- and *p*-positions, while the positive groups induce negative charges there. This can be reconciled with the facts of orientation only if the ease of substitution is assumed to increase with increase of *positive* charge at the point of attack.

This is the exact opposite of the rule stated above, and appears to be in definite disagreement with other chemical evidence.[2] It is, furthermore, incapable of giving a consistent picture even of the process of orientation, as the following examples will show. (1) The observed direction of the dipole moment of toluene shows that electrons have been transferred from the methyl group to the ring. The methyl group is accordingly a positive one, in the sense of the foregoing discussion, and consequently should direct meta. Actually it directs ortho–para. (2) In pyridine the electron affinity of the nitrogen atom is larger than that of the carbon atoms. Consequently the charge distribution is the same as in benzene with a very strongly negative substituent. Substitution should accordingly take place in the α and γ positions (analogous to *o* and *p*) with great ease, but actually it takes place in the β position (analogous to *m*) with considerable difficulty.

The error in Hückel's treatment lies not in the quantum mechanical calculations themselves, which are correct as far as they go, but in the over-simplification of the problem and in the incorrect interpretation of the results. Consequently it has seemed desirable to us to make the necessary extensions and corrections in order to see if the theory can lead to a consistent picture. In the following discussion we have found it necessary to consider all of the different factors mentioned heretofore: the resonance effect, the inductive effect, and the effect of polarization by the attacking group. The inclusion of these several effects in the theory has led to the introduction of a number of more or less arbitrary parameters, and has thus tended to remove significance from the agreement with experiment which is achieved. We feel, however, that the effects included are all justified empirically and must be considered in any satisfactory theory, and that the values used for the arbitrary parameters are reasonable. The results communicated in this paper show that the quantum mechanical theory of the structure of aromatic molecules can account for the phenomenon of directed substitution in a reasonable way.

Outline of the Method

There are two principal methods available for the quantum mechanical treatment of molecular structure, the valence bond method and the molecular orbital method. In this paper we shall make use of the latter, since it is simpler in form and is more easily adapted to quantitative calculations.[3] We accordingly consider each electron

(2) E. Hückel, *Z. Physik*, **72**, 310 (1931). For criticism of this work from the chemical side see A. Lapworth and R. Robinson, *Nature*, **129**, 278 (1932); **130**, 273 (1932); see also E. Hückel and W. Hückel, *ibid.*, **129**, 937 (1932).

(3) For purely qualitative arguments, on the other hand, the former is quite convenient. The description of the theory up to this point has been, in fact, merely a statement of the qualitative conclusions of the valence bond theory.

to be moving essentially alone in a self-consistent field, which is produced by the nuclei and by all the electrons other than itself, and we approximate the individual one-electron wave functions, φ_j, by means of linear combinations of the orbitals, ψ_k, belonging to the different atoms.

$$\varphi_j = \sum\nolimits_k a_{jk}\,\psi_k \qquad (1)$$

In systems of the type under consideration the aromatic rings lie in a single plane. Consequently the atomic s and p orbitals, ψ_k, to which the present discussion will be limited, can be divided into two classes, depending upon whether they are symmetric or antisymmetric with respect to reflection in this plane. Since orbitals from one of these classes do not combine with orbitals from the other, each of the summations of Eq. 1 needs to be extended only over the members of a single class. Electrons will of course be assigned to molecular orbitals, φ_j, of both types, but it will be sufficient for our purposes to consider only the ones which are formed from the antisymmetric atomic orbitals—the $[p]_h$ orbitals in Hückel's nomenclature. In energy calculations this is a legitimate simplification, since it affects merely the arbitrarily chosen zero point of energy, but in the present treatment it requires further justification, since we are now interested in the charge distribution. There is, however, considerable experimental evidence to show that π bonds, such as are formed by the $[p]_h$ orbitals, are much more polarizable than σ bonds, such as are formed by the symmetric orbitals. This is in accord with their smaller binding energy, and also with the fact that orientation phenomena are not common in saturated systems. Consequently we shall assume that the inclusion of the polarization of the symmetric orbitals would result in only a negligibly small correction.

We return now to those molecular orbitals, φ_j, of Eq. 1 which are expressed in terms of the $[p]_h$ functions. The variation method shows that the best values of the coefficients a_{jk} are those which satisfy the equations

$$\sum\nolimits_{k=1}^{l} a_{jk}\,(H_{mk} - \Delta_{mk}\,W_j) = 0,\ j, m = 1,2,\ldots,l \qquad (2)$$

where l is the total number of $[p]_h$ functions (one for each atom present, except the hydrogens);

$$H_{mk} = \int \psi_m^*\,H\psi_k\,d\tau \qquad \Delta_{mk} = \int \psi_m^*\,\psi_k\,d\tau$$

and W_j is the energy of an electron occupying the molecular orbital φ_j.

For each value of j there is a set of equations, but the different sets are all identical except for the replacement of the subscript j by some other, say j'. The condition for the solubility of this set of equations is that their determinants vanish. The l roots of this secular equation, $W = W_j$ $(j = 1,2,\ldots,l)$ give the energies of the l molecular orbitals. We then assign two electrons (one with positive and one with negative spin) to the lowest root, two more to the next lowest root, and so on until all have been used up. The values of W_j found in this manner are then substituted back into the Equations 2, from which the ratios of the values of the coefficients a_{jk} can be derived. The absolute magnitudes of the coefficients are determined by the normalization condition, $\int \varphi_j^*\,\varphi_j d\tau = 1$.

$$|H_{mk} - \Delta_{mk}\,W| = \begin{vmatrix} H_{11} - \Delta_{11}W & H_{12} - \Delta_{12}W & \cdots & H_{1l} - \Delta_{1l}W \\ H_{21} - \Delta_{21}W & H_{22} - \Delta_{22}W & \cdots & H_{2l} - \Delta_{2l}W \\ \cdots & \cdots & \cdots & \cdots \\ H_{l1} - \Delta_{l1}W & H_{l2} - \Delta_{l2}W & \cdots & H_{ll} - \Delta_{ll}W \end{vmatrix} = 0 \qquad (3)$$

An electron occupying the molecular orbital φ_j will spend a fraction of its time given by the expression $|a_{jk}|^2$ in the atomic orbital ψ_k. Consequently the total average charge on atom k will be

$$C_k = e\sum\nolimits_j |a_{jk}|^2 \qquad (4)$$

where the summation is extended over all occupied orbitals φ_j (the orbital being counted twice if occupied twice),[4] and e represents the charge of the electron.

As usual in these calculations, we make the following assumptions in regard to the magnitudes of the integrals H_{mk} and Δ_{mk}.

$$\begin{aligned} H_{kk} &= q + \delta_k\beta \\ H_{mk} &= \beta,\ \text{if } \psi_m \text{ and } \psi_k \text{ are on adjacent atoms,} \\ &= 0,\ \text{otherwise, for } m \neq k \\ \Delta_{kk} &= 1 \\ \Delta_{mk} &= 0,\ \text{for } m \neq k \end{aligned}$$

Here q represents the coulomb energy of an electron occupying a definite $[p]_h$ orbital in unsubstituted benzene; its value has been estimated to be about -2.7 v. e. = -60 kcal./mole.[5] β is a *resonance integral* between adjacent orbitals; its value has been estimated to be about -0.85 v. e. = -20 kcal./mole.[5] δ_k is a constant, the purpose of which is to allow for the different electron affinities of the different atoms. For $\delta_k > 0$, the

---

(4) Strictly speaking, the complete eigenfunction for the molecule should be made antisymmetric before the charge densities at the various positions are calculated. It is easily shown, however, that this further refinement in the treatment does not alter the results obtained.

(5) G. W. Wheland, *J. Chem. Phys.*, **2**, 474 (1934).

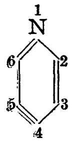
atom k has a larger, and for $\delta_k < 0$, a smaller electron affinity than a carbon atom in unsubstituted benzene.

We have attempted to estimate values of the δ's for the different kinds of atoms with which we will deal later, but we have not been able to arrive at any very consistent figures. Our procedure was to determine the values which would bring the calculated resonance energies into agreement with the empirical ones. The figures obtained in this way averaged about +4 for oxygen and +2 for nitrogen, and accordingly were of the correct sign, and of a reasonable order of magnitude, but the spread in both cases was quite large. Moreover, it is questionable if δ values obtained from energy calculations can be applied directly to calculations of charge distribution, when the method of treatment is as rough as the present. Accordingly we shall not choose a definite set of δ's which we shall use throughout, but instead shall allow the values to vary within fairly wide limits, in order to see the effect of such a variation upon the calculated polarization. Very fortunately it turns out that the decisive factor in most cases is not the magnitude of δ but its sign, which can be predicted with almost complete assurance.

Our method of calculation is now quite straightforward. We account for the permanent polarization resulting from the inductive effect by introducing suitable δ's upon the proper atoms; we account for that resulting from the resonance effect by explicitly including in the treatment all the $[p]_h$ orbitals of the problem, and not merely those on the atoms of the ring; and finally we account for the polarizing effect of the reacting group by introducing a small δ at the point of attack. For the sake of simplicity, we shall first treat only the permanent polarization, and then later consider the polarizability at the different positions.

Application to the Calculation of the Permanent Polarization

Pyridine.—We shall begin the discussion with pyridine rather than with a substituted benzene, since it offers a particularly simple example, in which only the inductive effect is operative. We number the atoms in order, beginning with nitrogen. Then δ_1, which takes into account the electron affinity of the nitrogen atom, will be positive in sign, and of the order of magnitude of perhaps 2; $\delta_2 = \delta_6$ will also be positive in sign as a result of induction, but will be much smaller in magnitude than δ_1; the remaining δ's can be considered negligibly small. The secular equation is then



$$\begin{vmatrix} x+\delta_1 & 1 & 0 & 0 & 0 & 1 \\ 1 & x+\delta_2 & 1 & 0 & 0 & 0 \\ 0 & 1 & x & 1 & 0 & 0 \\ 0 & 0 & 1 & x & 1 & 0 \\ 0 & 0 & 0 & 1 & x & 1 \\ 1 & 0 & 0 & 0 & 1 & x+\delta_6 \end{vmatrix} = 0$$

where, for simplicity in writing, we have divided each row by β and set $(q-W)/\beta = x$. We cannot solve this equation rigorously unless we put into it definite numerical values for δ_1 and δ_2 $(=\delta_6)$. The perturbation theory, however, gives a method by which we can expand both the solutions, W_j, and the eigenfunctions, φ_j, in rising powers of the δ's. If we carry the procedure only as far as the first order, we obtain linear expressions which represent approximately the variation of the different quantities of interest for small values of the δ's. The unperturbed secular equation, which is obtained by setting $\delta_1 = \delta_2 = \delta_6 = 0$, is just the same as the one which arises in the treatment of benzene. Its roots are

$$W_j^0 = q + 2\beta \cos (2\pi j/6)$$
$$j = 1,2, \ldots, 6$$

and the corresponding wave functions are

$$\varphi_j^0 = \frac{1}{\sqrt{6}} \sum_{k=1}^{6} e^{(2\pi i/6)jk}\, \psi_k \qquad i = 1,2, \ldots, 6 \tag{5}$$

The familiar equations of the first order perturbation theory now show that the corresponding perturbed quantities are

$$\left.\begin{aligned} W_j &= \int \varphi_j^{0*} H \varphi_j^0\, d\tau = W_j^0 + \int \varphi_j^{0*} H' \varphi_j^0\, d\tau \\ \varphi_j &= \varphi_j^0 + \sum_k{}' \frac{\int \varphi_k^{0*} H' \varphi_j\, d\tau}{W_j^0 - W_k^0} \varphi_k^0 \end{aligned}\right\} \tag{6}$$

where H' is the part of the complete Hamiltonian operator which refers to the perturbation, such that

$$\left.\begin{aligned} \int \psi_k^* H' \psi_l\, d\tau &= \delta_1\beta \text{ if } k = l = 1 \\ &= \delta_2\beta \text{ if } k = l = 2 \text{ or } 6 \\ &= 0 \quad \text{otherwise} \end{aligned}\right\} \tag{7}$$

and the prime on the summation sign indicates that the term with $k = j$ is omitted. When Eqs. 5 and 7 are inserted in Eq. 6 and use is made of Eq. 4, the following results are obtained.

$$C_N = C_1 = \left(1 + \frac{43}{108}\delta_1 - \frac{17}{54}\delta_2\right)e$$

$$C_\alpha = C_2 = C_6 = \left(1 - \frac{17}{108}\,\delta_1 + \frac{22}{54}\,\delta_2\right) e$$
$$C_\beta = C_3 = C_5 = \left(1 + \frac{1}{108}\,\delta_1 - \frac{14}{54}\,\delta_2\right) e$$
$$C_\gamma = C_4 = \left(1 - \frac{11}{108}\,\delta_1 + \frac{1}{54}\,\delta_2\right) e$$

(neglecting terms in δ_1^2, $\delta_1\delta_2$ and δ_2^2). These figures differ somewhat from the corresponding ones given by Hückel,[2] because he put $\delta_2 = 0$ and also, in applying the perturbation treatment, he made use of a rather different procedure which so complicated the calculations that he did not carry them through completely.

If, now, δ_2 lies within the limits $^1/_{28}\,\delta_1 < \delta_2 < ^1/_4\,\delta_1$, which seem quite reasonable, the over-all effect of the perturbation is a transference of negative electricity from the various carbon atoms to the nitrogen atom at position 1, with the consequence, in accordance with the rule formulated above, that the molecule is deactivated so that substitution is more difficult than in benzene; and furthermore the α and γ positions (2 and 6, and 4, respectively) are most affected by this transference of electricity, so that substitution will take place at the β positions (3 and 5), which have the smallest deficiency of electrons. Both of these conclusions are borne out by experiment.

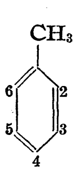
This calculation and its comparison with experiment hence provide us with a rough idea as to the magnitude of the inductive effect from atom to atom, as given by the ratio δ_2/δ_1. If this ratio were greater than $^1/_4$ the effect of δ_2 would overcome that of δ_1 and pyridine would substitute in the α and γ positions, whereas if it were less than $^1/_{28}$ substitution would occur in the β positions more readily than in benzene. A value of about $^1/_{10}$ for δ_2/δ_1 seems reasonable to us from a consideration of the electronic phenomena involved.

In order to see how accurate this perturbation treatment actually is, we have substituted numerical values for the δ's directly into the secular equation, and then solved it rigorously by numerical methods. The calculations are not given in detail, since they are quite straightforward and proceed along well-known lines. The results are shown in Table I.

TABLE I

δ_1	1	2	3	2
$\delta_2 = \delta_6$	0	0	0	0.2
$C_N = C_1$	1.37e	1.62e	1.79e	1.59e
$C_\alpha = C_2 = C_6$	0.85	0.76	0.71	0.83
$C_\beta = C_3 = C_5$	1.01	1.01	1.01	.96
$C_\gamma = C_4$	0.91	0.84	0.79	.82

It is seen that for $\delta_1 = 1$ the perturbation treatment is still fairly accurate, but that for larger values it is only qualitatively satisfactory. In any case, however, if we assume that the ease of substitution increases with increased negative charge at the point of attack, the calculations are in very good agreement with experiment; if, on the other hand, we follow Hückel in making the opposite assumption, the calculations can be reconciled with experiment only by making δ_1 negative, which seems highly improbable in view of the fact that the nuclear charge of nitrogen is greater than that of carbon.



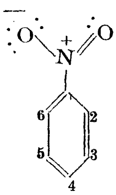
Toluene.—The toluene molecule is complicated in that it contains atomic orbitals (in the methyl group) which are neither symmetric nor antisymmetric with respect to reflection in the plane of the ring. However, since it seems very unlikely that there will be any appreciable resonance between the methyl group and the ring, we are able to avoid the difficulty by formally replacing the substituent by a small δ value on the adjacent carbon atom. The dipole moment of the molecule requires that this δ be negative in sign. It is also presumably small enough so that the same perturbation treatment as was employed in the case of pyridine will represent a good approximation.[6] The results are then just the same as those given in Eq. 8, except that C_α, C_β, and C_γ are to be replaced by C_{ortho}, C_{meta}, and C_{para}, respectively, in order to be in accord with the customary nomenclature. Here, as before, all the the δ's except δ_1 and δ_2 can be set equal to zero. Since δ_1 is negative, we see, neglecting δ_2, that the ortho and para positions have excess negative charges, in agreement with the experimental result that substitution takes place there very readily. This result is not changed by the consideration of δ_2 so long as the ratio δ_2/δ_1 is less than $^1/_4$.

Phenyltrimethylammonium Ion, $N^+(CH_3)_3$-C_6H_5.—In this ion, as in toluene, we ignore the electrons involved in bonds from nitrogen to the attached groups, and consider only the inductive effect. The positive charge on the nitrogen atom increases its electron affinity to a value still greater than that for neutral nitrogen, so that we

---

(6) For larger δ values, the results for toluene can be read off at once from those for pyridine (Table I); reversing the sign of the δ's in a given secular equation of the present type merely reverses the direction of the induced polarization, and leaves its magnitude unchanged.

introduce in the above expressions (for toluene) a large positive value for δ_1 (and a small value for δ_2). This leads to greatly decreased values of C for ortho and para carbon atoms, with smaller decrease for meta, and in consequence to meta directed substitution, in agreement with experiment.



Nitrobenzene.—In the treatment of nitrobenzene we must consider nine $[p]_h$ orbitals and ten electrons, including an unshared pair on the negative oxygen atom in the indicated structure and one electron for each of the remaining atoms. We assume the resonance integral β to have the same value for O-N and N-C as for C-C. The results of the calculation are given in Table II, the next to the last column of which corresponds to the δ values which seem reasonable to us. It is seen that all positions are deactivated, the deactivation occurring least at the meta positions, where substitution should take place. These conclusions are in agreement with experiment.

TABLE II

δ_O	0	0	4	4	4
δ_N (δ_C)	0	2	2	2	0.8
δ_1	0	0	0	0.2	0
C_O	1.50e	1.24e	1.95e	1.94e	1.92e
C_N (C_C)	1.00	1.53	1.37	1.32	0.68
C_1	1.00	0.96	0.62	0.70	.95
$C_{\text{ortho}} = C_2 = C_6$	1.00	1.01	.79	.79	.85
$C_{\text{meta}} = C_3 = C_5$	1.00	1.00	.95	.95	1.00
$C_{\text{para}} = C_4$	1.00	1.01	.63	.61	0.83

Benzoic Acid, C_6H_5COOH.—The treatment of benzoic acid is the same as for nitrobenzene except for the δ values. The results for $\delta_O = 4$ and δ_C (of the carboxyl group) $= 0.8$ are given in the last column of Table II; it is seen that the carboxyl group, like the nitro group, is meta directing, in agreement with experiment. The calculation, however, indicates a rather too small deactivation of the meta position. This effect appears only in the third decimal place of C_{meta}, and is consequently not shown in the table.

Benzaldehyde, C_6H_5CHO, **Acetophenone,** $C_6H_5COCH_3$, **and Benzonitrile,** C_6H_5CN.—The results obtained for these molecules by considering eight $[p]_h$ orbitals and eight electrons are given in Table III.

It is seen that the aldehyde, ketone and nitrile groups are all meta directing, in agreement with experiment.

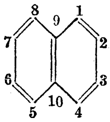
(X = O, S, NH)

Furan, Thiophene, Pyrrole.—The calculations for this case, with five orbitals and six electrons, show that when $\delta_2 (= \delta_5)$ (on the α carbon atoms) is neglected the β positions (3 and 4) are more strongly activated than the α. When, however, these δ's are given a reasonable magnitude, greater than $^1/_{25}\ \delta_1$, the situation is reversed, and the α positions are found to be the more strongly activated, as is demanded by experiment. Some calculated charge values are given in Table IV.

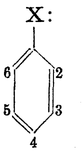
TABLE IV

δ_1	0.5	2.9	4	4	2	3
$\delta_2 = \delta_5$	0	0.29	0	0.5	0.25	0.375
$C_X = C_1$	1.38e	1.80e	1.88e	1.87e	1.69e	1.81e
$C_\alpha = C_2 = C_5$	1.14	1.08	0.98	1.13	1.10	1.13
$C_\beta = C_3 = C_4$	1.18	1.02	1.08	0.93	1.06	0.96



Naphthalene.—Naphthalene offers the first example of a molecule in which a consideration of the permanent polarization alone does not lead to the correct answer. Since this is a hydrocarbon, we might expect that no δ values would be necessary. In this case, however, the charge on each atom is found to be exactly 1.00e, so that substitution would take place at the α and β positions (1, 4, 5, 8 and 2, 3, 6, 7, respectively) with equal ease. If we attempt to avoid this difficulty by putting a δ upon the 9 and 10 carbon atoms, we find that its sign must be negative in order to produce an excess of electrons on the α positions. This seems unreasonable, however, since these carbon atoms carry no hydrogens, and would consequently be expected to have a larger rather than a smaller electron affinity than the others. We shall see later that a possible explanation of this discrepancy can be found by a consideration of the polarizing effect of the attacking group.

Aniline, Phenol, Fluorobenzene, etc.—The treatment of this group of molecules, involving seven $[p]_h$ orbitals and eight electrons, is comparatively unsatisfactory, in consequence of the fact that in them the inductive and the resonance effects work in opposite directions. In order to be able to predict which of the two will win out in any specific example, we need to have fairly accurate numerical values of the different δ's to be introduced in each case. In the absence of such information, the best we can do is to carry through a number of calculations, in order to see if any reasonable sets of values lead to agreement with experiment. The results are given in Table V.



($X = NH_2$, OH, F, etc.)

TABLE V

δ_X	0	2	4	6	2	4	6
δ_1	0	0	0	0	0.25	0.4	0.5
C_X	1.57e	1.91e	1.96e	1.98e	1.91e	1.97e	1.98e
C_1	1.00	0.93	0.95	0.95	1.02	1.10	1.15
$C_{\text{ortho}} = C_2 = C_6$	1.14	1.06	1.04	1.02	1.02	0.97	0.95
$C_{\text{meta}} = C_3 = C_5$	1.00	1.00	1.00	1.00	1.00	1.00	1.00
$C_{\text{para}} = C_4$	1.14	1.05	1.02	1.02	1.02	0.98	0.96

It will be seen that, as might be expected from purely qualitative considerations, the inductive effect, which deactivates the molecule and favors *m* orientation, is increased in importance with increase of the δ's, while the resonance effect, which activates the molecule and favors *o-p* orientation, is decreased in importance. This is in agreement with the fact that the *o-p* directing power of the halogens is in the order $F < Cl < Br < I$, which is the opposite of the order of electron affinities. On the other hand, it does not explain the marked difference between the halogens as a whole and the amino and hydroxyl groups—the former being relatively feeble in orienting power, and the latter being among the most powerful known. It also does not explain why the orders $NH_2 < PH_2 < AsH_2$ and $OH < SH$, which would be expected from analogy, are not correct.

It is possible that the explanation of these discrepancies is to be found in the fact that the resonance integral, β, may vary with the row and group of the periodic table. Such a variation must almost certainly exist, but it can be taken into account only with difficulty. Furthermore, the introduction of the large number of additional arbitrary parameters would deprive the whole procedure of much of its significance. A second possible explanation is that, with phenol for example, resonance with such structures as  and  may make relatively important contributions to the state of the molecule. The inclusion in the theory of such effects also would be difficult and would result in a further decrease in the significance of the treatment. Instead of resorting to such heroic measures to force the calculations into agreement with experiment, we prefer to let the matter stand as a possible weakness of the theory. It would not be surprising if our rough treatment should fall down in evaluating the relative importance of two opposed effects which differ so greatly in nature.

A further difficulty in the case of fluoro-, chloro- and bromobenzenes is that with them apparently no choice of the δ values seems to be reconcilable with the observed order of ease of substitution at the various positions: unsubstituted benzene > para > ortho > meta. Both the inductive and the resonance effects are seen to leave the charge on the *m*-position practically unchanged, and approximately equal to 1.00e, while the observed order demands a considerably smaller value. As in the case of naphthalene, however, we shall find later that this discrepancy can apparently be explained by taking into account the polarization of the molecule by the attacking group.

Polarization by the Attacking Group

The calculations so far have been concerned with the "permanent" charge distribution which the molecule would have when isolated, and which would be observed in its dipole moment. The factor that actually determines the orientation of the entering group, however, is the charge distribution at the instant of attack, which differs from the permanent charge distribution in consequence of polarization by the entering group. In most cases it is not necessary to take this latter effect into account explicitly, since it represents only a small correction. However, in certain cases it is apparently of decisive importance.[7]

In order to investigate the relative ease of substitution at the ith carbon atom, we shall introduce a small δ_i upon that atom, in addition

---

[7] This was suggested originally by Ingold, *cf.* Ref. 1.

to any other δ's that may be required by the permanent polarization. This δ_i will presumably be positive in sign in all cases, since the customary reacting groups are "electron-seeking" and will accordingly tend to increase by induction the electron affinity of the near-by carbon atom.

In benzene itself the charge at the point of attack will be not 1.00*e*, as has been assumed heretofore, but $(1.00 + (43/108)\delta_i)e$. (Since δ_i is small, the results of the perturbation treatment can be applied directly.) In other molecules the ease of reaction at the *i*th carbon atom will then be greater than that of benzene if the charge at that point is greater than $(1.00 + (43/108)\delta_i)e$, and conversely.

Let us apply these considerations to pyridine. If we set $\delta_N = \delta_1 = 2$, $\delta_\alpha = \delta_2 = \delta_6 = 0.2$, and $\delta_i = 0.2$, we obtain the results given in Table VI. As might be expected, the polarizability of the molecule at the various positions is practically constant, and is very nearly the same as that of benzene. Consequently the orientation is not affected by considering the polarization by the approaching group. This state of affairs can be expected to hold whenever the permanent polarization produces marked differences, as here, between the different positions.

TABLE VI

POLARIZABILITY OF PYRIDINE

i[a]	Charge at *i*th atom			Charge in benzene
	$\delta_i = 0$	$\delta_i = 0.2$	Difference	$(1.00 + \frac{43}{108}0.2)e$
2	0.831*e*	0.920*e*	0.089*e*	1.080*e*
3	.960	1.038	.078	1.080
4	.825	0.905	.080	1.080

[a] For the numbering of the different atoms see the diagrams given previously.

In naphthalene, on the other hand, the permanent polarization leaves all atoms with the same or very nearly the same charge, and as a result any small difference in polarizability has an opportunity to make its effect felt. The results of perturbation treatments are given in Table VII. With $\delta_i > 0$ the α position is activated, and substitution would take place there readily, as is demanded by experiment.

TABLE VII

POLARIZABILITY OF NAPHTHALENE

i	Charge on *i*th atom	Charge in benzene
1	$(1.00 + 0.44\delta_i)e$	$(1.00 + 0.40\delta_i)e$
2	$(1.00 + .40\delta_i)e$	$(1.00 + .40\delta_i)e$

In the halogen benzenes the ortho and para positions are found to be more polarizable than the meta, as is shown in Table VIII.

TABLE VIII

POLARIZABILITY OF $C_6H_5\ddot{X}$

$\delta_X = 4.0$, $\delta_1 = 0.4$

i	Charge at *i*th atom			Charge in benzene
	$\delta_i = 0$	$\delta_i = 0.2$	Difference	
2	0.975*e*	1.055*e*	0.080*e*	1.080*e*
3	1.002	1.069	.067	1.080
4	0.984	1.064	.080	1.080

With the particular choice of the δ's used in the calculation the observed order[8] unsubstituted benzene > para > ortho > meta is not obtained, but agreement can be achieved by a suitable readjustment of the parameter values. If, with δ_X held fixed and equal to 4, the charges at the different positions are assumed to be linearly dependent upon δ_1 and δ_i (as is the case when these quantities are sufficiently small), the results of Table VIII can be expressed as

$$\begin{aligned}\text{Charge on } 2 &= (1.036 - 0.152\delta_1 + 0.402\delta_i)e\\ \text{Charge on } 3 &= (0.998 + 0.009\delta_1 + 0.339\delta_i)e\\ \text{Charge on } 4 &= (1.024 - 0.099\delta_1 + 0.400\delta_i)e\end{aligned}$$

If we use the particular values $\delta_1 = 0.3$, $\delta_i = 0.2$ (any of several other sets would do as well), we find

$$\begin{aligned}\text{Charge on } 2 &= 1.071e\\ \text{Charge on } 3 &= 1.069e\\ \text{Charge on } 4 &= 1.074e\end{aligned}$$

These figures are now in agreement with the observed order given above. While it is doubtful if much significance can be attached to parameter values obtained in such an arbitrary and *ad hoc* manner, it is nevertheless gratifying to observe that the ones found are not unreasonable.

Conclusion

By introducing reasonable values (about 2 for nitrogen, 4 for oxygen) for the electron affinity parameter relative to carbon, δ, and for the induced electron affinity for adjacent atoms ($\delta_2/\delta_1 \simeq {}^1/_{10}$), we have shown that the calculated permanent charge distributions for pyridine, toluene, phenyltrimethylammonium ion, nitrobenzene, benzoic acid, benzaldehyde, acetophenone, benzonitrile, furan, thiophene, pyrrole, aniline, and phenol can be satisfactorily correlated qualitatively with the observed positions and rates of substitution. For naphthalene and the halogen benzenes this calculation does not lead to results

---

[8] Iodobenzene substitutes more easily than benzene. In this case, however, δ_X is comparatively small, and the discrepancy does not exist.

in complete qualitative agreement with experiment; agreement is obtained, however, by the consideration of the effect of polarization of the molecule by the attacking group. Because of the presence of several adjustable parameters, this treatment cannot be considered as a pure quantum mechanical theory of directed substitution in aromatic molecules. However, the various effects which we have considered are certainly real, and there is no reason to doubt that they act in the directions calculated, and are of the general order of magnitude assumed; the parameters introduced are not completely arbitrary in value, because they are related to definite and fairly well understood atomic and molecular quantities. Furthermore, in the cases in which only one effect is important, as in pyridine, or in which all effects act in the same direction, as in nitrobenzene, the calculations lead to completely unambiguous conclusions, which are dependent to only a small degree upon the particular parameter values chosen. We accordingly feel that the degree of success realized in these quantitative considerations provides strong support for the underlying ideas as to the nature of the effects involved.

Summary

Using the method of molecular orbitals, a quantitative discussion of the charge distribution in aromatic molecules undergoing substitution reactions is carried out, taking into consideration the inductive effect, the resonance effect, and the polarizing effect of the attacking group. It is shown that, with reasonable values for the parameters involved, the calculated charge distributions for pyridine, toluene, phenyltrimethylammonium ion, nitrobenzene, benzoic acid, benzaldehyde, acetophenone, benzonitrile, furan, thiophene, pyrrole, aniline, phenol, naphthalene, and the halogen benzenes are in qualitative agreement with the experimental results regarding position and rate of substitution, the auxiliary hypothesis being made that the rate of substitution of the group R′ for hydrogen on the *i*th carbon atom increases with increase in the negative charge of the *i*th carbon atom when the group R′ is in position to react.

Dibenzofuran. VII. Derivatives of Tetrahydrodibenzofuran

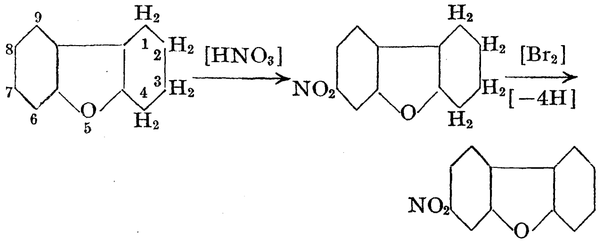
BY HENRY GILMAN, E. W. SMITH AND L. C. CHENEY

Introduction

The presence of a reduced dibenzofuran nucleus in morphine suggested an examination of nuclearly substituted reduced dibenzofurans. From the results of the present study on 1,2,3,4-tetrahydrodibenzofuran it appears (1) that the orientation of the parent dibenzofuran cycle is essentially unlike that of 1,2,3,4-tetrahydrodibenzofuran; (2) that the position assigned to the nitro group in nitro-1,2,3,4-tetrahydrodibenzofuran is incorrect; and (3) that the nuclear substituted *hexa*hydrodibenzofurans are in reality substituted *tetra*hydrodibenzofurans.

Nuclear substitution of dibenzofuran strikingly illustrates that the rule of conservation of the substitution type is not inviolate, and that the position assumed by substituents is significantly dependent on the kind of entering group. For example, with dibenzofuran, halogenation, sulfonation and the Friedel–Crafts reaction involve the 2-position; nitration involves predominantly the 3-position with only a small amount of 2-nitro compound being formed; and metalation (the replacement of hydrogen attached to carbon by a metal) takes place in the 4-position. With 1,2,-3,4-tetrahydrodibenzofuran, sulfonation, the Friedel–Crafts reaction and nitration involve the 7-(or 3′-)position; whereas metalation proceeds as with dibenzofuran to give a 6-(or 4′-) organometallic compound. Bromination may be difficult because bromine is at this time a reagent of choice for dehydrogenation of tetrahydrodibenzofurans to dibenzofurans.

The position of the nitro group in nitro-1,2,3,4-tetrahydrodibenzofuran was established as follows



Ebel[1] nitrated tetrahydrodibenzofuran and assumed that the nitro group was in the 8-position. Von Braun[2] assumed that his nitration product was 8-nitro-*hexa*hydibenzofuran. Through the kindness of Professor von Braun it was possible to show that a sample of his nitro compound was in reality the 7-nitro-1,2,3,4-*tetra*hydrodibenzofuran. The 8-position assigned to nuclear substituents by these earlier workers was predicated on the reasonable assumption of a *para*-orienting effect of oxygen.

The constitution of the sulfonation product as 1,2,3,4-tetrahydrodibenzofuran-7-sulfonic acid was established by the following sequence of reactions:

$$\begin{tikzcd}
C_{12}H_{12}O \text{ (tetrahydrodibenzofuran)} \arrow[d] & C_{12}H_8O \text{ (dibenzofuran)} \arrow[d] \\
7\text{-}(SO_3H)(C_{12}H_{11}O) \arrow[dd] & 3\text{-}(NO_2)(C_{12}H_7O) \arrow[d] \\
 & 3\text{-}(NH_2)(R) \arrow[d] \\
7\text{-}(SO_2Cl)(C_{12}H_{11}O) \arrow[d] & 3\text{-}(N_2X)(R) \arrow[d] \\
7\text{-}(SO_2NH_2)(C_{12}H_{11}O) \arrow[dd] & 3\text{-}(SO_2H)(R) \arrow[d] \\
 & 3\text{-}(SO_3H)(R) \arrow[d] \\
7\text{-(or 3-)}(SO_2NH_2)(C_{12}H_7O) & 3\text{-}(SO_2Cl)(R) \arrow[l]
\end{tikzcd}$$

A related procedure was used to identify the acetyl compound obtained by a Friedel–Crafts reaction:

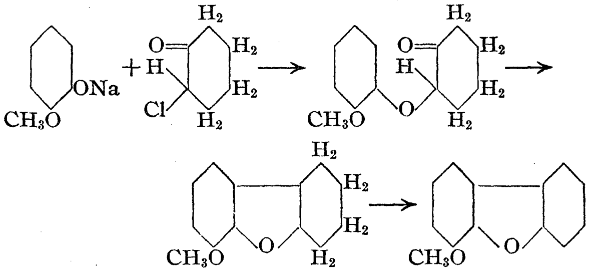
$$7\text{-}(CH_3CO)(C_{12}H_{11}O) \xrightarrow{I_2 + NaOH} 7\text{-}(CO_2H)(C_{12}H_{11}O) \xrightarrow[Br_2]{-4H} 7\text{- (or 3-)}(CO_2H)(C_{12}H_7O)$$

The 7-acetyl-1,2,3,4-*tetra*hydrodibenzofuran was shown to be identical with a supposed 8-acetyl-*hexa*hydrodibenzofuran.[2]

Metalation of *tetra*hydrodibenzofuran by means of phenyl-lithium or *p*-tolyl-lithium or *n*-butylsodium replaced a 6-hydrogen.

$$C_{12}H_{12}O \longrightarrow (C_{12}H_{11}O)(\text{Li or Na}) \xrightarrow{CO_2} (C_{12}H_{11}O)(CO_2H) \xrightarrow[Br_2]{-4H} 6\text{-(or 4-)}C_{12}H_7O(CO_2H)$$

The structure of 6-methoxy-1,2,3,4-tetrahydrodibenzofuran, prepared by the following interesting ring closure synthesis,[1] has been definitely established by dehydrogenation to 4-methoxydibenzofuran which in turn was made available by the recent unequivocal synthesis involving the metalation of dibenzofuran.[3]



An account of some reduction products of dibenzofuran is contained in the Experimental Part.

The pharmacological action of the several compounds will be reported by Dr. A. W. Dox and co-workers.

Experimental Part

1,2,3,4-Tetrahydrodibenzofuran.—The tetrahydrodibenzofuran used in all of the procedures, except when otherwise noted, was prepared according to the directions of Hönigschmid.[4] In a typical preparation 50 g. of dibenzofuran was reduced with 60 g. of sodium, a total of 400 cc. of absolute ethanol being used. The product was purified by distillation at atmospheric pressure, b. p. 270° (740 mm.), followed by a second distillation at reduced pressure, b. p. 145° (15 mm.), 135° (9 mm.), n^{20}_D 1.5795, sp. g.$^{20}_{20}$ 1.0938.

The reduction of 50 g. of dibenzofuran with 20 g. of sodium in boiling ethanol gave 25.7 g. of product distilling between 265–273° (740 mm.), and 15.4 g. boiling at 273–275° (740 mm.). Chilling the second fraction in an ice-salt bath yielded 3.6 g. of crystalline product which melted at 40–45° after one crystallization from ethanol. Several crystallizations from petroleum ether raised the melting point to 80° and this compound was shown to be dibenzofuran.

Nitration of Tetrahydrodibenzofuran.—Nitration by the method of Ebel[1] gave a nitro compound which melted at 124–125° when crystallized from ethanol. The material used was prepared both by ring closure and sodium–ethanol reduction. The compound was identical with the supposed 8-nitrohexahydrodibenzofuran[2] (mixed melting point). This substantiates Ebel's[1] surmise that his nitrotetrahydro compound was probably the same as von Braun's nitrohexahydro compound.

Anal. Calcd. for $C_{12}H_{11}O_3N$: C, 66.33; H, 5.11. Found: C, 66.02; H, 5.23.

A solution of 2.2 g. (0.01 mole) of the nitrotetrahydrodibenzofuran and 3.2 g. (0.02 mole) of bromine in 40 cc. of

glacial acetic acid was allowed to stand for fifteen hours at room temperature and then refluxed for one-half hour. On cooling, 0.75 g. or a 35% yield of 3-nitrodibenzofuran precipitated (mixed melting point).

The amine and the picrate of the amine prepared by reduction of 7-nitro-1,2,3,4-tetrahydrodibenzofuran were found by Mr. W. H. Kirkpatrick to have the same melting points as the reported amino-hexahydrodibenzofuran and its picrate, respectively.[2] However, the 7-acetamino-1,2,3,4-tetrahydrodibenzofuran was found to melt at 146° and not at 123°, which is the melting point reported for the acetamino-hexahydrodibenzofuran.[2] It is possible that the latter substance, for which no analysis was reported, is a mixture of mono-acetamino and di-acetamino compounds (acylation having introduced two acetyl groups).

Anal. Calcd. for $C_{14}H_{15}O_2N$: N, 6.11. Found: N, 6.31.

Friedel–Crafts Reaction.—The acetylation of tetrahydrodibenzofuran with acetyl chloride and aluminum chloride in carbon disulfide by Mr. J. A. V. Turck yielded an acetyltetrahydrodibenzofuran. The use of acetic anhydride and stannic chloride in benzene proved to be a better choice of reagents and gave the same product. Twenty and four-tenths grams (0.2 mole) of acetic anhydride was added dropwise with stirring to a solution of 34.4 g. (0.2 mole) of tetrahydrodibenzofuran and 104.4 g. (0.4 mole) of anhydrous stannic chloride in 150 cc. of dry benzene. At the conclusion of the addition the mixture was refluxed gently for ten hours and then hydrolyzed with cracked ice. The mixture was extracted with ether, the ether–benzene extract washed with 10% sodium hydroxide and then with water, and, finally, dried over anhydrous calcium chloride. The solvents were removed and the residue fractionated at reduced pressure. The fraction boiling at 200–217° (15 mm.) weighed 28.3 g., or a 66% yield. The solidified product crystallized from petroleum ether as colorless needles, m. p. 66–67°, b. p. 210° (15 mm.). A mixed melting point with an authentic sample of acetylhexahydrodibenzofuran[2] kindly supplied by Professor von Braun, and melting at 66–67°, showed no depression.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.46; H, 6.59. Found: C, 78.46 and 78.44; H, 6.25 and 6.74.

Dibenzofuran was also isolated from the reaction product.

The acetyl derivative supplied by Professor von Braun was also analyzed.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.46; H, 6.59. Calcd. for $C_{14}H_{16}O_2$: C, 77.73; H, 7.46. Found: C, 78.14; H, 6.64.

An aqueous solution of iodine in potassium iodide was added in small portions with shaking to a solution of 4 g. of acetyltetrahydrodibenzofuran in 100 cc. of dioxane and 40 cc. of 10% sodium hydroxide solution in accordance with Fuson's procedure. When the iodine color persisted at 60° for one minute, excess sodium hydroxide was added and the solution cooled. The supernatant liquid was decanted from the iodoform and acidified with sulfuric acid. The resulting precipitate was filtered and then washed. A 2.3 g. or 57% yield of 1,2,3,4-tetrahydrodibenzofuran-7-carboxylic acid was obtained which melted at 247–248° after crystallization from ethanol or glacial acetic acid. *Neutral equivalent:* calcd., 216.1; found, 213 and 213.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 72.07 and 71.90; H, 5.64 and 5.61.

Diazomethane was used to prepare the methyl ester, which melted at 72.5–73.5° after crystallization from dilute methanol.

One and six-tenths grams (0.01 mole) of bromine was added to a suspension of 1.08 g. (0.005 mole) of the above tetrahydrodibenzofuran-7-carboxylic acid in 25 cc. of glacial acetic acid at room temperature and the resulting solution was allowed to stand for ten hours. The solution was refluxed strongly until the evolution of hydrogen bromide ceased, and then cooled. A quantitative yield of dibenzofuran-3-carboxylic acid was obtained which melted at 271.5–272° after crystallization from glacial acetic acid. A mixed melting point with authentic dibenzofuran-3-carboxylic acid, m. p. 271.5–272°, showed no depression.

Diazomethane was used to convert the acid to the methyl ester which melted at 138.5° after crystallization from petroleum ether. A mixed melting point with authentic methyl dibenzofuran-3-carboxylate showed no depression. The methyl ester was prepared by the action of diazomethane on dibenzofuran-3-carboxylic acid, and melted at 138° after crystallization from petroleum ether.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.31; H, 4.46. Found: C, 74.31 and 74.67; H, 4.85 and 4.93.

Sulfonation of Tetrahydrodibenzofuran.—To a well-stirred solution of 34.4 g. (0.2 mole) of tetrahydrodibenzofuran in 100 cc. of carbon tetrachloride was added dropwise 23.4 g. (0.2 mole) of chlorosulfonic acid. The temperature was kept at 10°. At the conclusion of the addition the reaction was stirred for one hour at 0° and at room temperature for three hours. The reaction product was decomposed with cracked ice and the carbon tetrachloride layer separated. The aqueous layer was neutralized in the usual manner with barium carbonate and the slightly soluble barium sulfonate extracted with hot water. Concentration and cooling of the aqueous extract yielded 23.3 g. or a 36.3% yield of barium 1,2,3,4-tetrahydrodibenzofuran-7-sulfonate. The salt was crystallized several times from water prior to analysis.

Anal. Calcd. for $(C_{12}H_{11}O_4S)_2Ba$: Ba, 21.48. Found: Ba, 21.30 and 21.68.

On the basis of the formation of isomers in nuclear substitution reactions of partially reduced related systems, it is not at all unlikely that isomers may have formed in nuclear substitution reactions of 1,2,3,4-tetrahydrodibenzofuran.

Tetrahydrodibenzofuransulfonamide.—An intimate mixture of 21.5 g. (0.0785 mole) of crude sodium tetrahydrodibenzofuransulfonate and 12.3 g. (0.08 mole) of phosphorus oxychloride was allowed to stand for twenty-four hours at room temperature and then heated for one and one-half hours at 100–110°. The pasty reaction product was decomposed with cold concentrated ammonium hydroxide. The solid product was digested with fresh ammonium hydroxide and filtered to give a yield of 77%. The colorless flat plates melted at 207.5–208.5° after crystallization from ethanol and 60% acetic acid.

Anal. Calcd. for $C_{12}H_{13}O_3NS$: C, 57.33; H, 5.21. Found: C, 57.09; H, 4.92.

Dehydrogenation of Tetrahydrodibenzofuransulfonamide.—A solution of 1.28 g. (0.008 mole) of bromine and 1 g. (0.004 mole) of 1,2,3,4-tetrahydrodibenzofuran-7-sulfonamide in 25 cc. of glacial acetic acid was allowed to stand at room temperature for two days and then refluxed until the evolution of hydrogen bromide ceased. The chilled solution precipitated 0.55 g. of dibenzofuran-3-sulfonamide, which gave compact colorless crystals melting at 241–243° after crystallization from 60% acetic acid. A 10% yield of the same product was obtained when 1 g. of tetrahydrodibenzofuransulfonamide and 2 g. of sulfur was heated at 240–275° until evolution of hydrogen sulfide ceased. The product was extracted with and crystallized from 60% acetic acid. A mixed melting point of this compound with the authentic dibenzofuran-3-sulfonamide as prepared by the following sequence of reactions was not depressed.

Dibenzofuran-3-sulfonamide.—A solution of 4.4 g. of sodium nitrite in 20 cc. of water was added slowly to a suspension of 10 g. of 3-aminodibenzofuran in a solution of 40 cc. of concd. sulfuric acid in 150 cc. of water at 0°. The reaction mixture was stirred for one hour at 0° and allowed to stand at room temperature for twelve hours. The diazonium sulfate was saturated with sulfur dioxide at $-5°$, and then 40 g. of copper powder added in portions with vigorous stirring, the temperature being maintained at $-5°$. The resulting sludge was filtered off when the reaction was complete and both filtrate and precipitate were thoroughly extracted with ether. The ether extract, containing the sulfinic acid, was extracted several times with 6 *N* potassium hydroxide. The potassium sulfinate was immediately oxidized with permanganate in the usual manner to the potassium sulfonate which separated from the filtrate of the oxidation solution upon concentration and cooling. The yield of dry product was 10.2 g. or 65.3%, and the free acid was prepared by the acidification of an aqueous solution of this salt. Dibenzofuran-3-sulfonic acid sinters without melting; it was crystallized several times from water and oven-dried prior to analysis.

Anal. Calcd. for $C_{12}H_8O_4S$: S, 12.92. Found: S, 12.58 and 12.67.

An intimate mixture of 2.4 g. of potassium dibenzofuran-3-sulfonate and 5 g. of phosphorus pentachloride generated a considerable amount of heat and soon liquefied. The liquid was poured upon cracked ice, and the resulting precipitate melted at 148.5° after crystallization from benzene and petroleum ether.

Anal. Calcd. for $C_{12}H_7O_3ClS$: C, 54.02; H, 2.65. Found: C, 54.41; H, 2.91.

An ether solution of dibenzofuran-3-sulfonyl chloride was saturated with ammonia gas to yield dibenzofuran-3-sulfonamide melting at 241–242° after crystallization from 60% acetic acid.

Anal. Calcd. for $C_{12}H_9O_3NS$: C, 58.27; H, 3.67. Found: C, 57.87; H, 3.61.

Metalation of Tetrahydrodibenzofuran.—In this reaction it was necessary to use pure tetrahydrodibenzofuran prepared by ring closure.[1] Tetrahydrodibenzofuran prepared by the sodium–alcohol reduction of dibenzofuran contains sufficient impurity to cause the formation of 4-dibenzofurancarboxylic acid, which made isolation of the tetrahydrodibenzofurancarboxylic acid difficult. In a typical preparation, 0.5 mole of phenyl-lithium was prepared in the customary manner[5] from 7.6 g. of lithium, 78.5 g. (0.5 mole) of bromobenzene and 300 cc. of anhydrous ether. This preparation, after removal of the excess lithium, was gently refluxed with a solution of 86.0 g. (0.5 mole) of tetrahydrodibenzofuran in 200 cc. of anhydrous ether for fifteen hours. Carbonation was effected by slowly pouring the cooled reaction product on 500 g. of pulverized solid carbon dioxide. The mixture was allowed to stand overnight and was then extracted with two liters of water made alkaline with sodium hydroxide. Steam distillation of the ether layer resulted in the recovery of 41.4 g. of tetrahydrodibenzofuran. Acidification of the aqueous alkaline extract after decolorization with Norite yielded 18.1 g. of a resinous material. Crystallization of this product from ethyl acetate yielded 2.7 g. of crude 1,2,3,4-tetrahydrodibenzofuran-6-carboxylic acid which melted at 197° after further crystallization from the same solvent. This is a 4.8% yield based on the tetrahydrodibenzofuran used. *Neutral equivalent:* Calcd., 216.1; found, 216.8.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 71.92; H, 5.75.

The use of *p*-tolyl-lithium and *n*-butylsodium as metalating agents yields the same product, but in smaller yields. Metalations of substituted dibenzofurans will be reported later. Depending on the kind and position of substituents, it is possible to metalate in positions other than 4 and 6.

Dehydrogenation of 1,2,3,4-Tetrahydrodibenzofuran-6-carboxylic Acid.—A solution of 0.4 g. (0.00185 mole) of tetrahydrodibenzofurancarboxylic acid and 0.65 g. (0.004 mole) of bromine in 10 cc. glacial acetic acid was allowed to stand overnight at room temperature and then refluxed until the evolution of hydrogen bromide ceased. The solution was diluted to 250 cc., made alkaline with sodium hydroxide, decolorized with Norite and acidified. Dibenzofuran-4-carboxylic acid melting at 207–208° was obtained after crystallization of the resulting precipitate from ethanol. A mixed melting point with authentic dibenzofuran-4-carboxylic acid showed no depression.

In this connection, it is interesting to observe that the reduction of dibenzofuran-4-carboxylic acid by sodium and absolute ethanol gives a reduced acid which appears to be 1,2,3,4-tetrahydrodibenzofuran-4-carboxylic acid. The exact structure of this compound together with others prepared by reduction of substituted dibenzofurans will be described in a forthcoming article. This tetrahydro acid melts at 168° after crystallization from dilute acetone from which the acid separates as large silvery plates. *Neutral equivalent:* Calcd., 216.1; found, 216.3.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 71.89 and 72.42; H, 5.66 and 5.67.

Dehydrogenation of 1,2,3,4-Tetrahydro-6-methoxydibenzofuran.—An intimate mixture of 0.25 g. of the methoxytetrahydro compound[1] and 0.3 g. of sulfur was heated up to 275° until the evolution of hydrogen sulfide

---

(5) Gilman, Zoellner and Selby, THIS JOURNAL, **54**, 1957 (1932).

ceased. The solid melt was extracted with hot petroleum ether and the solvent evaporated to dryness. The residue was extracted with cold absolute ethanol and the extract concentrated to yield 4-methoxydibenzofuran[3] (mixed melting point).

Reduced Dibenzofurans.—There appears to be some confusion concerning variously reduced dibenzofurans. The 1,2,3,4-tetrahydrodibenzofuran was first prepared by Hönigschmid[4] by reduction of dibenzofuran with sodium in boiling ethyl or amyl alcohol. Extensive treatment with sodium and amyl alcohol did not yield a more completely reduced product, and when a lesser amount of sodium was used Hönigschmid isolated a compound melting at 43° which he assumed to be dihydrodibenzofuran. We repeated the work and obtained the same product melting at about 43°. However, several crystallizations from ethanol and petroleum ether raised the melting point to 80° and the compound as obtained was shown to be dibenzofuran.

The tetrahydrodibenzofuran has also been prepared by reduction of dibenzofuran with sodium and cyclohexanol.[6]

An entirely different procedure was used by Ebel,[1] who synthesized the tetrahydrodibenzofuran by a ring-closure reaction using 2-chlorocyclohexanone and sodium phenolate. This reaction together with oxidation of the tetrahydro compound to δ-(o-hydroxybenzoyl)-valeric acid leaves no doubt as to the constitution of the compound.

The hexahydrodibenzofuran of von Braun[2] was prepared by the catalytic reduction of o-biphenol. Ebel[1] introduced two atoms of hydrogen into tetrahydrodibenzofuran, using platinum–palladium black as a catalyst, and obtained a compound whose analysis and boiling point agreed with that of von Braun's hexahydrodibenzofuran.

We have found, however, that the picrates obtained from von Braun's hexahydrodibenzofuran, from Ebel's reduction product of the tetrahydrodibenzofuran and from the tetrahydrodibenzofurans prepared both by Ebel's and Hönigschmid's methods are identical, on the basis of mixed melting points.

The picrates were all prepared in the same manner and melted at 97–98° after crystallization from ethanol.[7] There were significant differences in yields of the picrates prepared from the variously reduced dibenzofurans. Incidentally, it might be added that the picrate prepared from von Braun's hexahydrodibenzofuran was decomposed by steam distillation of a suspension in sodium carbonate solution to yield a compound distilling at 145° (15 mm.) and having an index of refraction (1.5795 at 20°) identical with that observed with the tetrahydrodibenzofuran prepared by sodium reduction.

A dodecahydrodibenzofuran was described recently.[8] Mr. C. W. Bradley prepared this perhydrodibenzofuran by catalytic reduction of dibenzofuran at moderate temperatures and pressures using noble metal catalysts: b. p. 258–259° (740 mm.) and 108–110° (7 mm.); n^{20}_{D} 1.5023; sp. g. $^{20}_{20}$ 1.0312.

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.93; H, 11.19. Found: C, 80.37; H, 11.19.

An experiment by him to introduce 4 or 6 atoms of hydrogen by this method gave a product from which only dibenzofuran and perhydrodibenzofuran have so far been isolated. Mention should be made of the fact that hydrogenation of 2-hydroxydibenzofuran by Mr. Bradley also gave perhydrodibenzofuran.

The reduced dibenzofurans have been oxidized, von Braun obtaining δ-(o-hydroxybenzoyl)-valeric acid from his hexahydrodibenzofuran and chromic acid, and Ebel obtaining the same acid by ozonization of tetrahydrodibenzofuran. Mr. Bradley got a 16.7% yield of the acid by ozonizing the hexahydrodibenzofuran obtained in accordance with Ebel's directions for the reduction of tetrahydrodibenzofuran, an 87% yield of the same acid on ozonization under corresponding conditions of 1,2,3,4-tetrahydrodibenzofuran, and ozonization of the perhydrodibenzofuran gave an as yet unidentified product which is partly soluble in alkali.

From present evidence, there is no doubt concerning the existence of tetrahydrodibenzofuran and the perhydrodibenzofuran. No dihydrodibenzofuran has been definitely established.[7] The hexahydrodibenzofuran presents a different problem. This compound may be known as a parent type, but it seems quite clear that nuclear substitution reactions of it produce tetrahydro derivatives. The removal of two hydrogens from the hexahydro is not surprising with reagents like bromine, nitric acid, ozone and aluminum chloride. Possibly the picric acid also behaves as an oxidizing agent, and if so this would account for the apparent identity of the picrates prepared from the tetra- and hexahydrodibenzofurans.

The authors gratefully acknowledge the assistance of Mr. H. Oatfield with part of the sulfonation experiments and of Mr. W. Hoehn with some of the analyses.

Summary

A study has been made of variously substituted reduced dibenzofurans.

Metalation and nitration of 1,2,3,4-tetrahydrodibenzofuran involve the same relative positions observed with dibenzofuran. However, sulfonation and acetylation take place in the 7-(or 3′-) position, rather than in the 8-(or 2′-) position as in the case with dibenzofuran.

Some substituted *hexa*hydrodibenzofurans reported earlier have been shown to be substituted *tetra*hydrodibenzofurans, the substituents being in the 7- and not in the 8-position as assumed previously.

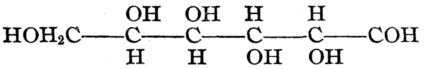
Crystalline *d*-Alpha-Galaheptose and Some of its Derivatives[1]

BY RAYMOND M. HANN, ALICE T. MERRILL AND C. S. HUDSON

In his pioneer studies of the two galaheptoses possible by addition of hydrocyanic acid to *d*-galactose, Fischer[2] isolated the *d*-[β-galaheptose] in crystalline condition, but was unsuccessful in his attempts to crystallize the isomeric *d*-[α-galaheptose]. He did, however, reduce the sirupy sugar with sodium amalgam and obtained the crystalline alcohol, *d*-[α-galaheptitol]. While Fischer recorded the rotation of this substance, it remained for Peirce[3] to point out that it is the antipode of *d*-[α-mannoheptitol] (perseitol), thus proving the configurations of the galaheptoses and the mannoheptoses.

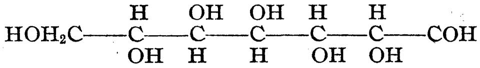
Recently the *d*-[α-galaheptose][4] has been obtained in crystalline condition as the monohydrate. The study of its derivatives has indicated that they crystallize with considerable difficulty, which was not unexpected because of the close similarity in configuration of the sugar to *l*-mannose. Incidental to the preparation of the lactone of *d*-[α-galaheptonic] acid, confirmation of the early work of Maquenne[5] and Kiliani[6] upon the isolation of crystalline *d*-[α-galaheptonic] acid has been obtained and a study of its rotational behavior has been made.

The data now at hand permit a good comparison of the properties of two aldoses which have very similar configurations, *l*-mannose and *d*-[α-galaheptose].



$$HOH_2C-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-COH$$

l-Mannose



$$HOH_2C-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\underset{H}{\overset{OH}{C}}-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-COH$$

d-Alpha-galaheptose

Because of the paucity of data in the *l*-mannose series the comparisons will be made upon substances of the *d*-mannose series, which are opposite in sign of rotation. On the plausible hypothesis that the physical and chemical properties (though not the biological) of an aldose and most of its derivatives are conditioned in first measure by the space configurations of carbons one to five inclusive, it is to be expected that *l*-mannose and *d*-[α-galaheptose] will be especially similar sugars. This inference is fully borne out by the facts now at hand. Considering first those properties which are the same for the *d*- and *l*-forms of a given sugar, it is noted that mannose is characterized by a readily crystallizable phenylhydrazone of unusually low solubility; the same applies to the phenylhydrazone of the heptose in question, as indeed was noted by Fischer before the configurations of the galaheptoses were established. Mannose is also peculiar among aldoses in that the equilibrium between its α and β stable methyl glycosides in acidified methyl alcohol is usually far toward its α form; the same is now found to hold for its heptose analog, though because of conventions of nomenclature, this heptoside is to be named the β-form.[7] Other paralleling characteristics which have been observed in the two series are the sparing solubilities of the amides and phenylhydrazides as well as the ease of crystallization of the

TABLE I

SIMILARITY OF SPECIFIC ROTATIONS ($[\alpha]^{20}_D$) OF SUBSTANCES IN THE MANNOSE AND ALPHA-GALAHEPTOSE SERIES

		d-Mannose series		*d*-Alpha-gala-heptose series
Sugar, (initial)	(α)	+34	(β)	−26
(final)		+14.6		−15.3
Sodium salt of aldonic acid		− 8.8[8]		+ 9.6
γ-Lactone		+51.8[9]		−52.3[2]
Aldonic acid phenylhydrazide		− 8.1[10]		+ 8.5[10]

γ-lactones in relatively pure condition, for the monobasic acids derived from the two aldoses.

In regard to optical properties, the data of Table I show a striking similarity in magnitude and full agreement in sign for substances of the two series. For reasons previously stated the values for mannose are taken from its *d*-series and hence for comparison the sign should be reversed.

The close similarity of properties in these particular sugar series is not limited to this pair but seems to be generally true, as can be readily verified by comparing known data,[15] and it appears to be of considerable practical value in furnishing a guide for preparative work and for studies of structure and configuration.

We express our appreciation to Dr. Reid Milner and Mrs. Mildred S. Sherman of the Fertilizer Investigations Laboratory, U. S. Department of Agriculture, for performing the micro analyses in connection with this work.

Experimental

Crude *d*-(α-Galaheptonic) Amide from *d*-Galactose.—To a solution of 500 g. of galactose in 750 cc. of water held at 0° in an ice–salt bath, 10 drops of concd. ammonia and 140 cc. of liquid hydrocyanic acid were added and the tightly stoppered flask allowed to stand in the ice box for two or three days, during which time the mixture set to a paste through crystallization of α-galaheptonic amide. It was thinned with 100 cc. of ice water, filtered on a large Büchner funnel and washed with three 50-cc. portions of ice water, dried for several hours at room temperature and finally in an oven at 60°. The yield varies according to the time necessary to obtain a satisfactory crystallization. In twenty-three experiments the lowest yield was 242 g. and the highest 355 g., an average yield of 47.5% being obtained. A considerable amount of α-galaheptonic lactone may be recovered from the filtrates by converting the soluble amides in solution to a mixture of α- and β-galaheptonic phenylhydrazides, separating by crystallization, and decomposing with copper sulfate as previously described.[16]

_d_-(α-Galaheptonic) Lactone from Crude _d_-(α-Galaheptonic) Amide.—A suspension of 500 g. of finely powdered amide in a solution of 300 g. of barium hydroxide octahydrate in 1000 cc. of water was boiled briskly under the hood for seven hours, water being added from time to time to replace that lost by evaporation. The barium was roughly precipitated with about 320 cc. of 6 *N* sulfuric acid and thereafter the solution balanced until free of barium and sulfate ions. The filtered solution was concentrated to a thick sirup and heated for six to eight hours on the steam-bath, 250 cc. of methyl alcohol was stirred in and upon standing overnight it crystallized to a solid mass; yield 380 g. (82.2%). The lactone can be conveniently recrystallized by dissolving 400 g. of crude lactone in 160 cc. of hot water, adding 1600 cc. of hot 95% alcohol and filtering through a preheated funnel. Overnight a yield of 285 g. of lactone (71.2%) showing a specific rotation[17] of −49.2° in water separates, and additional material may be recovered from the filtrate for further purification. One additional recrystallization from 3 parts of 90% alcohol yields the pure lactone, rotating −52.3° in water, in agreement with Fischer's[2] value.

_d_-(α-Galaheptonic Acid).—Under milder conditions of transformation the amide yields α-galaheptonic acid. A solution containing 138 g. of amide, 100 g. of barium hydroxide octahydrate and 500 cc. of water was boiled under reduced pressure at 60–70°, keeping the volume approximately constant by addition of water until ammonia could no longer be detected in the distillate. Sufficient 6 *N* sulfuric acid was added to the slightly warm solution to precipitate the barium exactly and upon filtering and cooling, a small amount of α-galaheptonic acid crystallized. The filtrate was concentrated *in vacuo* to 200 cc. and the main portion of the acid removed after cooling. The total yield of acid was 57.2 g. (41.3%). The mother liquor was heated in a shallow dish on the steam-bath for two days and yielded 33.5 g. of α-galaheptonic lactone.

α-Galaheptonic acid crystallizes from 100 parts of 95% alcohol in brilliant colorless leaflets melting at 143 to 147° (corr.) depending upon the rate of heating. A 5-g. sample heated under vacuum for one hour in a glycerol bath at 155–160° readily gave off water and the resulting melt, upon treatment with 10 cc. of methyl alcohol, deposited 2.8 g. of crystals. Examination of the recrystallized product showed it to be a mixture of needles and prisms, indicating a mixture of lactones. Confirmatory evidence was obtained on successive recrystallizations, the specific rotation decreasing in the order from −56.3, −54.2, −53.1 to −52.2° with disappearance of the needle form and separation of pure γ-*d*-[α-galaheptonic] lactone. Fresh solutions of the acid titrate immediately as an acid and upon standing they show the characteristic acid–lactone titration behavior. These solutions exhibit mutarotation and after the first twenty minutes closely follow a unimolecular course. Table II records the log of a typical rotation.

[15] A good example is the ease with which the ketose, sedoheptose, now known to be *d*-altroheptulose, passes in acid solution to a non-reducing anhydro form by a balanced reaction, which was unique in the sugar group until the recent discovery that *d*-altrose, of closely similar configuration, behaves in like manner [Richtmyer and Hudson, THIS JOURNAL, **57**, 1716 (1935)].

[16] Hann and Hudson, *ibid.*, **56**, 957 (1934).

[17] Throughout the article the rotations are specific rotations at 20° for sodium light.

d-(*α*-**Galaheptose**).—Forty-five grams of *α*-galaheptonic lactone was reduced in cold acid solution in the usual manner with 2000 g. of 2.5% sodium amalgam. Following removal of the sodium sulfate, the solution was freed of the sodium salt of *α*-galaheptonic acid by concentrating to a sirup and treating repeatedly with methyl alcohol. In one case treatment of this sirup with phenylhydrazine yielded 31.4 g. of hydrazone and 7.1 g. of osazone, equivalent to 38.5 g. of galaheptose, whereas the theoretical yield would have been 45.4 g. of sugar. The salt-free sirup was placed in a calcium chloride desiccator and treated repeatedly with small amounts of methyl alcohol; it finally crystallized as a monohydrate after about four months. The yield averaged about 25 g. The sugar may be recrystallized in a yield of 80% by solution in one-half part of water and addition of 5 parts of 95% alcohol, separating in glistening prisms melting at 77–78° (corr.) to a colorless sirup. The course of its mutarotation (Table III) is not unimolecular. The final specific rotation of the sugar, considered as anhydrous ($C_7H_{14}O_7$), is −15.3° and the initial rotation is approximately −26°.

Anal. Iodimetric Titration: 0.0519 g. consumed 4.56 cc. 0.1 *N* iodine equivalent to 0.0479 g. of heptose (92.3%): H_2O, 0.2632 g. lost 0.0214 g. (8.13%) on heating seven hours at 110° in Abderhalden drier. Calcd. for $C_7H_{14}O_7 \cdot H_2O$: C, 36.82; H, 7.07; sugar, 92.1; H_2O, 7.90. Found: C, 36.98; H, 7.13; sugar, 92.3; H_2O, 8.13.

Sodium *d*-[*α*-**Galaheptonate**].—This salt was obtained from the reduced solution following separation of the sodium sulfate by treatment of the sirup resulting upon vacuum concentration, with anhydrous methyl alcohol. It crystallized in clusters of glistening prisms showing a specific rotation of +9.7° in water. Recrystallized from one part of water by addition of one volume of methyl alcohol it rotated +9.5° (0.5265 g. in 10 cc. water in a 1-dm. tube rotated 0.50° to the right). Analysis showed it to be a monohydrate.

Anal. Calcd. for $C_7H_{13}O_8Na \cdot H_2O$: Na, 8.6; H_2O, 6.8. Found: Na, 8.6; H_2O, 6.7.

β-**Methyl** *d*-[*α*-**Galaheptoside**].—Ten grams of *α*-galaheptose monohydrate was refluxed for one hour with 100 cc. of methyl alcohol containing 1.5% of dry hydrochloric acid gas, when all reducing power disappeared. The solution was treated with 15 g. of dry silver carbonate and the halogen-free filtrate concentrated to a sirup and treated with about 20 cc. of ethyl alcohol, which induced crystallization readily. The substance was recrystallized from three parts of absolute alcohol; it separated in brilliant prisms rotating −70.1° in water. Upon recrystallization a rotation of −70.2° (0.2708 g. in 10 cc. of water in a 1-dm. tube rotated 1.90° to the left) was found. The compound melts at 132° (corr.); yield 6.4 g. (65%). The rate of hydrolysis in 0.05 *N* hydrochloric acid at 100° was 0.0004 (expressed in minutes and decimal logarithms), proving the glycoside to be of the stable type.

Anal. Calcd. for $C_8H_{16}O_7$: C, 42.83; H, 7.20. Found: C, 42.72; H, 7.19.

The substance is designated as the *β*-methyl glycoside because it is more negative in rotation than the *β*-form of the sugar, which belongs to the *d*-series. It has already been explained[7] how the accepted conventions of nomenclature led to this naming whereas the method of preparation and properties of the substance show it to be the analog of *α*-methyl *d*-mannoside. Likewise the crystalline form of *d*-*α*-galaheptose, for which the conventional naming is *β*, is the analog of the crystalline *α*-form of mannose.

Pentaacetyl *β*-**Methyl** *d*-[*α*-**Galaheptoside**].—Five and one-tenth grams of methyl-*α*-galaheptoside was dissolved in 30 cc. of pyridine and acetylated by adding an equal volume of acetic anhydride and allowing to stand overnight at room temperature. The solution was poured upon cracked ice and the gummy precipitate which formed was extracted with carbon tetrachloride and the dried extract concentrated to a sirup. It failed to crystallize by the usual procedure, but was finally obtained in crystalline condition by successive treatments with small amounts of absolute alcohol over a period of two months, yield 7.9 g. (80%). The compound may be recrystallized from two parts of 95% alcohol and separates in glistening plates. The specific rotation of −20.4° (0.2354 g. in 10 cc. of chloroform in a 1-dm. tube rotates 0.48° to the left) did not change appreciably upon recrystallization. The compound melts at 108° (corr.) to a colorless oil.

Anal. Calcd. for $C_{18}H_{26}O_{12}$: C, 49.74; H, 6.04. Found: C, 49.61; H, 6.11.

β-**Ethyl** *d*-[*α*-**Galaheptoside**].—This compound was prepared in an analogous manner to the methyl homolog and was obtained in a yield of 7.0 g. (67%). It was recrystallized from three parts of absolute alcohol as thin glistening plates, melting at 138° and showing a specific rotation of −65.4° (0.2310 g. in 10 cc. of water in a 1-dm. tube rotated 1.51° to the left), unchanged by recrystallization.

Anal. Calcd. for $C_9H_{18}O_7$: C, 45.35; H, 7.62. Found: C, 45.28; H, 7.70.

Pentaacetyl *β*-**Ethyl** *d*-[*α*-**Galaheptoside**].—This acetylated glycoside was obtained in a yield of 9.6 g. (85%) when 6.0 g. of the ethyl glycoside was acetylated with pyridine and acetic anhydride. It crystallized from five parts of 50% alcohol in long colorless needles melting at 92° (corr.) to a colorless oil. Its specific rotation was −24.9° (0.3570 g. in 10 cc. of chloroform in a 1-dm. tube rotated 0.89° to the left) after recrystallization to constancy.

Anal. Calcd. for $C_{19}H_{28}O_{12}$: C, 50.87; H, 6.30. Found: C, 50.81; H, 6.37.

d-[*α*-**Galaheptose] Benzyl Mercaptal.**—A solution of 5 g. of *α*-galaheptose monohydrate in 10 cc. of concd. hydrochloric acid was shaken with 10 cc. of benzyl mercaptan for ten minutes, when it set to a paste. After standing overnight at room temperature the solid was filtered, washed with 95% alcohol and dried, yield, quantitative. The mercaptal may be recrystallized readily from 75 parts of 95% alcohol, separating in small glistening plates, melting at 191° (corr.) and rotating +30.3° in pyridine (0.2212 g. in 10 cc. in a 1-dm. tube rotated 0.67° to the right).

Anal. Calcd. for $C_{21}H_{28}O_6S_2$: S, 14.56. Found: S, 14.50.

Hexaacetyl *d*-[*α*-**Galaheptose] Benzyl Mercaptal.**—A solution of 5 g. of mercaptal in 25 cc. of pyridine was treated with 25 cc. of acetic anhydride, allowed to stand overnight at room temperature and the acetate precipitated by pouring the solution over crushed ice. The compound crystallizes from 10 parts of 95% alcohol in clusters of elongated, very thin terminated plates, melting at 120° (corr.) and rotates −10.6° (0.2633 g. in 10 cc. in a 1-dm. tube rotated 0.28° to the left) in chloroform.

Anal. Calcd. for $C_{33}H_{40}O_{12}S_2$: S, 9.26. Found: S, 9.14.

Hexabenzoyl *d*-[*α*-**Galaheptose] Benzyl Mercaptal.**—A solution of 3 g. of mercaptal in 25 cc. of pyridine was treated dropwise with 11.5 g. of benzoyl chloride. The mixture became warm, developed a red color and soon became a mush of glistening crystals. The next day the mass was poured upon crushed ice, stirred and a red crystalline meal gradually formed. This was filtered off and recrystallized from 100 parts of 95% alcohol, the benzoate separating in clusters of colorless small prisms. The pure substance melts at 129° (corr.) and rotates −48.1° in chloroform (0.2950 g. in 10 cc. in a 1-dm. tube rotated 1.42° to the left).

Anal. Calcd. for $C_{63}H_{52}O_{12}S_2$: S, 6.02. Found: S, 6.03.

Summary

1. *d*-[*α*-Galaheptose] has been obtained in crystalline condition as the monohydrate of its beta form.

2. The rotational behavior of solutions of crystalline *d*-[*α*-galaheptonic] acid has been studied.

3. Methyl and ethyl glycosides of [*d*-*α*-galaheptose] and their acetates have been obtained in pure condition.

4. The benzyl mercaptal, its acetate and benzoate have been prepared and described.

5. Attention has been called to the parallelism of physical and chemical properties, as well as rotational behavior, of substances of configurationally related structure in the sugar group, as illustrated from substances of the mannose and *α*-galaheptose series.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, COLUMBIA UNIVERSITY]

The Determination of Ionization by Ultraviolet Spectrophotometry: Its Validity and its Application to the Measurement of the Strength of Very Weak Bases[1]

BY LEO A. FLEXSER,[2] LOUIS P. HAMMETT AND ANDREW DINGWALL

It has been amply demonstrated that most organic oxygen compounds are bases of the same kind as ammonia or aniline, but of a much less pronounced basicity.[3] Quantitative knowledge of the strength of these very weak bases is practically non-existent,[4] yet is of crucial importance for the understanding and interpretation of the phenomena of acid catalysis. One of the most promising methods for obtaining these data[4] involves the measurement of the extent of ionization of the base (that is to say, the extent of conversion of the base B to the cation or conjugate acid BH^+) in mixtures of sulfuric acid and water. Such measurements of extent of ionization have previously been made by the method of visual colorimetry;[5] we have now made the rather obvious extension[4] to spectrophotometry in the ultraviolet for cases where there is no visible change in color.

---

(1) This article is based upon the dissertation submitted by Leo A. Flexser to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, May, 1935. The material was presented at the New York meeting of the American Chemical Society, April, 1935. A preliminary Communication appeared in THIS JOURNAL, **56**, 2010 (1934).

(2) University Fellow in Chemistry, 1934–1935.

(5) (a) Hammett and Deyrup, THIS JOURNAL, **54**, 2721 (1932); (b) Hammett and Paul, *ibid.*, **56**, 827 (1934); (c) Hammett, *Chem. Rev.*, **16**, 67 (1935).

The simple fact that most organic acids and bases have absorption spectra which differ materially from those exhibited by the corresponding anions or cations has been so beclouded in the discussions of indicator theory that there has even been room to doubt the possibility of determining ionization by measurements of the absorption spectra of simple acids and bases. The method has indeed been successfully applied by Stenström and co-workers[6] to the measurement of the ionization of phenol, but they reported the method inapplicable to the ionization of benzoic acid, and no one else seems to have considered even the possibility of such measurements. Before attempting the determination of unknown constants we have therefore first verified the method on the constants in dilute aqueous solution of benzoic acid, dinitrophenol and aniline, which are known from more familiar methods of measurement.

Experimental

Apparatus.—All apparatus was calibrated either directly or indirectly against apparatus certified by the Bureau of Standards.

The absorption spectra were determined with a Hilger quartz sectorphotometer[7] and E-316 spectrograph using as a source of light a 25,000-volt condensed spark between tungsten electrodes in air. The ultraviolet spectrum down to 2000 Ångström units could be recorded on a single 10.2 by 25.4 cm. photographic plate. The wave length scale was calibrated by means of a copper arc and found to be correct within the error of visually determining match points, *i. e.*, better than 5 Å. throughout the ultraviolet and better than 10 Å. between 4000 and 5000 Å.

Moving pictures taken of the original photometer while the sectors were rotating showed that erratic slipping took place between the belts and the rotating sector disks. This was eliminated by cutting gears into the disks, and meshing them with one another. The upper and lower sectors could both be varied and were used on alternate exposures so that any error arising from initially imperfect matching of the upper and lower halves of the spectrum was automatically canceled out. The angular apertures of the sectors were measured and found to be correct within 5% up to sector settings of $-\log T = 1.3$. The sectors were never used above settings of 1.2 and since most settings were taken in half-unit steps on the less crowded portions of the scale between 0 and 1.0, it is probable that the error is in the neighborhood of 3%. The spark stand, photometer, and spectrograph were mounted on a heavy iron casting, which gave such stability that the instruments would keep their relative positions for several months.

As a check on the set-up, the percentage transmission of a piece of blue glass was measured and compared with the results obtained by the Bureau of Standards for the same piece of glass by an entirely different method, results herewith.

Wave length, Å.	% Transmission Obsd.	Bureau report
5200	80.0	80.6
5600	55.0	58.0
6000	34.0	34.5
6400	17.7	18.0

The agreement is surprisingly good considering the various sources of error inherent in the method.[8]

Two quartz cells were used, one to contain the solvent and the other the solution. The solvent cell was placed in front of the upper sector, the solution cell in front of the lower sector and settings of $-\log T = 0$, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, 0.80, 0.90, 1.0 and 1.2 were taken on the upper sector. The cells were then interchanged and settings of 0.05, 0.15, 0.25, 0.35, 0.45, 0.55, 0.65, 0.75, 0.85, 0.95 and 1.1 taken on the lower sector. A blank setting of 0 on both sectors with the cells removed was taken at the beginning and end of each plate as a check on the instrumental adjustment.

Although several types of cells were used, the most satisfactory were made by clamping two clear fused quartz circular disks to a fused quartz cylinder in a metal holder. The cylinder had a side-arm fitted with a ground silica stopper by which it could be filled and emptied without removal from the holder. The disks were 21 mm. in diameter and 1.5 mm. thick. The cylinder was 1.00 cm. long and had an outer diameter of 20 mm. The faces of the disks and the edges of the cylinder were polished optically plane and parallel. The fit was so good that no leakage was perceptible over a period of several hours. The cell holders could be securely mounted in the photometer by means of spring clips.

Considerable difficulty was encountered at the beginning of this investigation because of the fact that the more concentrated sulfuric acid solutions after standing in the cells for about an hour would begin to absorb ultraviolet light very strongly. The trouble was finally traced to the use of crystalline quartz disks. When fused quartz disks were substituted, the sulfuric acid solutions could be kept indefinitely in the cells without any change occurring. The crystalline quartz appeared to be of excellent quality, was very clear, and transmitted ultraviolet light down to the limit of sensitivity of the photographic plate, about 2000 Å., and the source of the difficulty is unknown. A soft glass cylinder also caused similar difficulty.

Materials.—The materials were of the highest commercially available purity (C. P. or C. P. analyzed grade).

Sulfuric acid solutions were prepared by dilution of the 95% acid. Analyses of weighed samples by titration with sodium hydroxide agreed to better than two parts per thousand. After standing for over a year in No-Solvit and in flint glass bottles, they were still transparent to ultraviolet light and showed no change in concentration greater than the error of analysis. One hundred per cent. sulfuric acid transparent to ultraviolet light was obtained by distilling sulfur trioxide from 60% fuming acid into the

95% acid in an all-glass apparatus. Benzoic acid and acid potassium phthalate were standard samples from the Bureau of Standards. 2,4-Dinitrophenol was twice crystallized from water after treatment with norite (m. p. 111°). Aniline sulfate was twice crystallized from approximately 1 *N* sulfuric acid after treatment with norite. *p*-Nitrobenzoic acid was twice crystallized from alcohol with one norite treatment, dissolved in 95% sulfuric acid and reprecipitated with ice, then slowly sublimed (m. p. 242°). After each step in the purification the absorption spectrum in 0.1 *M* hydrochloric acid was determined. It remained unchanged throughout the process. Phenylacetic acid was recrystallized from water several times (m. p. 77°). The acidimetric titers of these acids and of the aniline sulfate were found to be correct within two parts per thousand. Anthraquinone was crystallized from glacial acetic acid after treatment with norite; dissolved in 95% sulfuric acid and reprecipitated with ice, then crystallized again from acetic acid. Another sample was crystallized from benzene, then from alcohol, precipitated from 95% sulfuric acid, again crystallized from alcohol and finally crystallized from glacial acetic acid. Both products had identical absorption spectra in 95% sulfuric acid, and the spectrum of the second sample was not changed by the last crystallization.

The late Professor J. L. R. Morgan generously provided a sample of acetophenone which had been very carefully purified in the work of Morgan and Lammert,[9] and which had been kept in a paraffin sealed bottle in a dark closet since 1924. During this time its melting point had dropped from 19.65 to 18.9°. It contained a small amount of absorbing impurity because the spectrum in 95% sulfuric acid of the liquid residue remaining after some 98% had been slowly frozen out differed from that of the original sample. It was purified by twenty-five fractional freezings. These were carried out by slowly freezing (over a period of eight hours) all but 1 cc. of an originally 100-cc. sample, pouring off the liquid, and discarding it. The sample was preserved and the operations were carried out in the exclusion of daylight. The final sample had a melting point of 19.65 ± 0.02°, further fractional freezing had no effect on the melting point, and the spectrum of a small unfrozen residue was identical with that of the whole sample. The sample was carefully protected from moisture and light and its freezing point remained unchanged over a period of about a month.

Method

An approximately 0.002 *M* solution of the substance whose absorption spectrum was to be determined was made up by weighing out the calculated amount of solute and adding 50 cc. of solvent. Absorption spectra of this solution and of successive two or three fold dilutions of it were taken until the complete character of the absorption was brought out. This required from three to six plates. In the case of phenylacetic acid and aniline, a more concentrated original solution had to be made up because of the weak absorption of these substances. In all cases the plates were taken on the same day that the solutions were made up and usually within four hours. All measurements were made at room temperature, about 22 ± 5°.

The plates, which were the Eastman 33 type, were developed with a contrast developer, fixed with Eastman Acid Fixer, washed and dried. They were then mounted over an opal glass in an illuminated stand and match points were visually determined and recorded. The sector setting then gave immediately the value of the logarithm of the transmission T, and from this the extinction coefficient k for this wave length was obtained by Beer's law

$$k = -\log T/cl \qquad (1)$$

where c is concentration in moles per liter and l is the length (in this case 1.00 cm.) in centimeters of the path traversed by the light through the solution. The extinction coefficients were then plotted against wave length on semilogarithmic paper. Since at least twenty points were obtained from each plate, each absorption spectrum thus contained at least sixty points, in a fairly even logarithmic distribution. (See curve 8 in Fig. 4 where the experimental points are plotted.)

Inasmuch as some errors were likely to be introduced in the manipulative details of preparing the solutions in addition to the instrumental error of the apparatus itself, the error in the extinction coefficients is probably about 5%, and more often than not is less than this.

If Beer's law holds, the absorption spectrum from one solution should overlap and run smoothly into the absorption spectrum of its next dilution. This was always found to be the case within the experimental error. In those cases where dilution might change the amount of ionization and thereby result in failure of Beer's law, a buffer solution was used as the solvent in order to prevent this.

The calculation of acid or base strength was made as follows. If a solute exists in two forms, say B and BH^+, so that the total concentration c is equal to the sum of the concentrations of these two forms

$$c = c_B + c_{BH^+} \qquad (2)$$

and if, as seems generally to be the case, each substance absorbs independently of the presence of the other, then[7]

$$-\log T = (k_B c_B + k_{BH^+} c_{BH^+})l \qquad (3)$$

and it follows from equations (1), (2) and (3) that

$$(c_{BH^+})/(c_B) = (k - k_B)/(k_{BH^+} - k) \qquad (4)$$

In a dilute aqueous solution, k_B may be determined by reducing the acidity to the point where the concentration of BH^+ is vanishingly small; k_{BH^+} similarly by increasing the acidity. Knowing these, a measurement of k in some solution of intermediate acidity permits the calculation of c_{BH^+}/c_B and from this, if the *p*H of the solution is known, of the ionization constant of the base. The modifications of the above considerations necessary if the ionization constant of a weak acid HA which ionizes to H^+ and A^- is to be measured are obvious. In the measurement of the strengths of very weak bases in strong sulfuric acid solutions, certain complications, which will be discussed later, arise from the fact that the change of acidity involves necessarily a significant change in the nature of the medium with a concomitant change in the absorption spectrum.

Measurements in Dilute Aqueous Solution

The Acid Strength of Benzoic Acid.—The absorption of benzoic acid was determined in the

2609	675	620	640	..
2553	740	700	720	..
2500	1350	900	1050	3.92
2449	3050	1400	2350	4.35
2400	6450	2300	4500	4.27
2353	9200	4800	7200	4.30
			Average	4.16 ± 0.11

The logarithmic ionization constant pK was calculated by the equation

$$pK_{\text{HB}} = pK_{\text{HA}} + \log c_{\text{A}^-}/c_{\text{HA}} - \log (k - k_{\text{HB}})/(k_{\text{B}^-} - k) \quad (5)$$

derived from substitution of equation (4) in the equation

$$pK_{\text{HB}} = pK_{\text{HA}} + \log c_{\text{A}^-}/c_{\text{HA}} - \log c_{\text{B}^-}/c_{\text{HB}} \quad (6)$$

which is an obvious combination and transformation of the equilibrium expressions for the ionization of acetic and benzoic acids. The subscript A refers to acetate and the subscript B to benzoate. For the calculations values of k_{HB} were taken from curve 1, those of k_{B^-} from curve 3, and those of k from curve 2. The value of pK_{HA} was taken as 4.76.[10] This equation assumes that the quantity $f_{\text{A}^-}f_{\text{HB}}/f_{\text{HA}}f_{\text{B}^-}$ is unchanged by a transfer from infinite dilution to an ionic strength of 0.1. Within the precision of this assumption, therefore, the pK_{HB} obtained is the value in terms of activities referred to infinite dilution in water as the standard state

$$pK_{\text{HB}} = -\log a_{\text{H}^+}a_{\text{B}^-}/a_{\text{HB}} \quad (7)$$

Table I gives the values of pK thus obtained at various wave lengths, omitting those in the neighborhood of the isobestic point, the point where all three curves meet.[11] The average value of 4.16 thus obtained is in satisfactory agreement with the value of 4.20 found in the recent measurements by the conductivity method of Brockman and Kilpatrick[12] and of Saxton and Meier.[13]

The conclusion of Stenström and co-workers[6] that ultraviolet colorimetry cannot be applied to the measurement of the ionization of benzoic acid was apparently due to the limitations of their measurements. They did not determine the complete absorption spectra of benzoic acid but instead measured the wave lengths at which benzoic acid has an extinction coefficient of 800 (log k = 2.9). They thereby determined three points of the curve for benzoate ion and three for molecular benzoic acid. Four of these six points happen to fall on the isobestic point where of course no change takes place. The other two points are not in agreement with our measurements.

The Acid Strength of 2,4-Dinitrophenol.—The absorption spectra were determined in the

[10] (a) Harned and Ehlers, THIS JOURNAL, **55**, 652 (1933); (b) MacInnes and Shedlovsky, *ibid.*, **54**, 1429 (1932).

[11] The existence or non-existence of an isobestic point is a matter of considerable significance in studies of this sort. Suppose a given solute exists in two forms or reaction products (such as a base B and a cation BH^+) each of which possesses a characteristic absorption which is constant for a series of solutions. If both of the forms have equal extinction coefficients at some wave length, if, that is, the absorption curves of the two pure individuals intersect, then all of the solutions must likewise have the same coefficient at this wave length, because they contain only various mixtures of these individuals. The absorption curves of all the solutions, therefore, will pass through this intersection. Conversely, if two absorption curves intersect at a point which is not common to all the other curves, then it must be true either that more than two forms or reaction products of the solute must be present, or else that the change in conditions, for instance, in acidity, which produces the variation in proportion of the two forms also changes their specific absorption by what we have called a medium effect. See Clark, "The Determination of Hydrogen Ions," Baltimore, Md., 1928, pp. 153–154.

following solvents: (1) 0.1 *M* sodium hydroxide; (2) a buffer containing 0.55 *M* acetic acid and 0.10 *M* sodium acetate; (3) 0.1 *M* hydrochloric acid. The results are shown in Fig. 2 and Table II. In this case the absorption of the anion extends well into the visible, and this part of the spectrum as well as the ultraviolet is included. The average value of $pK = 4.10$ agrees excellently with the value of 4.09 obtained by von Halban and Kortum[14] and with the earlier conductivity results quoted in the Landolt–Börnstein "Tabellen."

(14) Von Halban and Kortum, *Z. Elektrochem.*, **40**, 502 (1934).

acid and 0.10 *M* sodium acetate; (3) 0.1 *M* sulfuric acid. For convenience the solutions were prepared from anilinium sulfate rather than from aniline. The results are shown in Fig. 3 and Table III.

In computing the base strength from these curves, it is not possible to correct for salt effects as simply as in the case of the acids because the activity coefficient terms do not cancel out. The base strength of aniline is defined by

$$\begin{aligned} pK'_A &= -\log a_{H^+}a_A/a_{AH^+} \\ &= pH - \log f_A/f_{AH^+} - \log c_A/c_{AH^+} \qquad (8) \\ &= pH - \log f_A/f_{AH^+} - \log (k - k_{AH^+})/(k_A - k) \qquad (9) \end{aligned}$$

The *p*H of the buffer was calculated from the tables of A. A. Green[15] and found to be 4.75. The activity coefficient term was computed from the formula based on the Debye–Hückel theory.

$$-\log f_A/f_{AH^+} = +\log f_{AH^+} = 0.5\sqrt{\mu}/(1 + \sqrt{\mu}) \qquad (10)$$

This gives a value of $\log f_{AH^+} = -0.12$, for the ionic strength of 0.1 which prevailed.

The average value of pK' obtained is in excellent agreement with the value of 4.66 given in the Landolt–Börnstein "Tabellen" and based upon hydrolysis measurements by both conductivity and indicator methods.

Some Cases of Small Change in Absorption.—It should not be concluded that spectrophotometry in the quartz ultraviolet is a perfectly general method for the determination of ionization. Thus the change in ultraviolet absorption when phenylacetic acid ionizes to phenylacetate ion is appreciable[16] but too small to permit a useful estimate of acid strength. Similarly, the conversion of *p*-nitrobenzoic acid to *p*-nitrobenzoate ion also results in only a small change in this part of the ultraviolet absorption (see Fig. 8). However, our results, together with data in the literature, tend toward the conclusion that with the majority of organic substances ionization results in a change in ultraviolet absorption above 2000 Å. and that ultraviolet spectrophotometry in the range accessible to an ordinary quartz spectrograph is a very general method for measuring ionization.

The Strengths of Some Very Weak Bases

Acetophenone.—Acetophenone has been shown to behave as a monobasic strong electrolyte when it is dissolved in pure sulfuric acid.[3a] The substance is therefore capable of undergoing the reaction

$$C_6H_5COCH_3 + H_2SO_4 = C_6H_5COH^+CH_3 + HSO_4^- \qquad (I)$$

For such a weak base, the work of Hammett and Deyrup[5] carried out by the methods of visual colorimetry lead one to expect the following changes in light absorption with varying concentration of sulfuric acid–water mixtures. Within a relatively narrow range of concentrations there will be a large change in absorption accompanying the ionization represented by equation I. Outside this range there will be a smaller change in absorption due not to a chemical reaction but to the gradual variation in the nature of the medium in which the substance $C_6H_5COCH_3$ or the substance $C_6H_5COH^+CH_3$ is dissolved. The absorption spectra of acetophenone shown in Fig. 4 and Table IV agree entirely with this prediction. There is only a small change in absorption, consisting essentially in a shift toward longer wave lengths in the range from 0 to 55% sulfuric acid (Curves 1 and 2). The same thing is true in the region above 86% sulfuric acid (Curves 8 and 9). In the intermediate region (Curves 2 to 8) there is a much more rapid change which is no longer of the nature of a lateral shift. It is rather of a sort which can hardly be attributed to any other cause than the presence in the solution in varying amounts of two substances, one of which has an absorption much like curve 2, the other one similar to curve 8. The composite nature of the intermediate curves is particularly apparent in curves 4 and 5.

The qualitative picture, that ionization according to equation I takes place in the region from 55 to 86% sulfuric acid, while only a medium effect—a slow lateral shift in the absorption curves—occurs at higher and lower concentrations, seems very well established. The quantitative treatment is more difficult because the same medium effect must be expected to exist also in the region of ionization. That it is present is demonstrated by the failure to obtain a true isobestic point.[11]

In order to calculate the base strength we use the values (taken from large scale plots) of the acidity function H_0 which have been obtained in previous work.[5] This acidity function has been shown[5] to be uniquely determined in these solutions by the equation

$$H_0 = pK'_B - \log c_{BH^+}/c_B \qquad (11)$$

where B is any base and

$$pK'_B \equiv -\log \frac{a_{H^+}a_B}{a_{BH^+}} \qquad (12)$$

2300	5700	4100	3800	2400	1800	1200	680	500	420	380

is the measure of the strength of the base in terms of activities. By combination of equations (11) and (4) we obtain

$$pK'_B = H_0 - \log (k - k_{BH^+})/(k_B - k) \qquad (13)$$

which is of course closely analogous to equation (9). Because of the medium effect, however, pure non-ionized acetophenone must have a different absorption in say 70% sulfuric acid from that which it possesses in water or even in 50% acid. We cannot, therefore, use the extinction coefficient of acetophenone in water solution as the value of k_B, nor can we use the coefficient in 100% sulfuric acid as the value of k_{BH^+}, even though we know that it is practically non-ionized in the former solvent and practically all ionized in the latter.

We have used two methods of correcting for this medium effect error, both dependent upon the assumption that the medium effect consists essentially in a lateral shift of the spectrum within the range of ionization as it does without this range. The first method was evolved from the following considerations. Suppose that in the neighborhood of some wave length at which the pK' is to be calculated, the reference curve for ionized acetophenone is very steep while the reference curve for non-ionized acetophenone is more or less flat. Now if the medium effect is causing the curves to shift, the reference curve for ionized acetophenone will be in great error because of its steepness, whereas the extinction coefficients of the curve for non-ionized acetophenone will be only slightly affected because of the flatness of the curve in the neighborhood of the wave length under consideration. Thus in calculating the pK' by means of formula (13), the error will be due primarily to the large error in k_{BH^+} resulting from the medium effect. There will, therefore, be considerable advantage if the pK' is calculated from experimental values of k and k_B alone in this range of wave lengths. There will be a similar advantage in using only k and k_{BH^+} in a range of wave lengths where the curve for ionized acetophenone is flat and that for the non-ionized compound is steep.

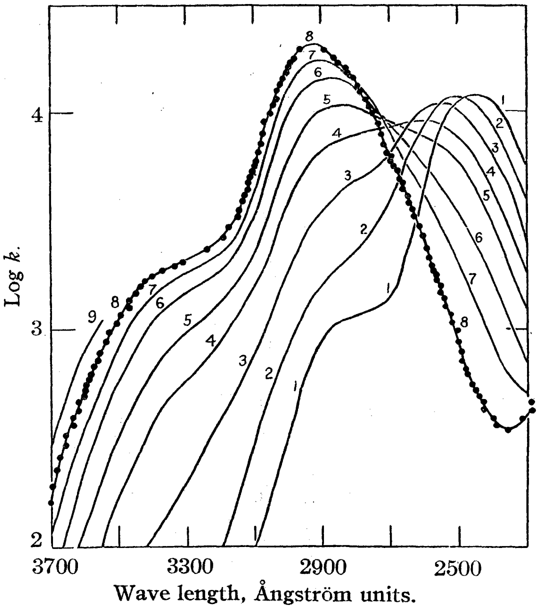

Fig. 4.—Ionization of acetophenone as a base: Curve 1, solvent is water; other curves sulfuric acid—2, 55%; 3, 65.15%; 4, 70.45%; 5, 73.65%; 6, 77.66%; 7, 80.40%; 8, 85.96%; 9, 95.99%.

For purposes of this calculation we transform equation (13) to the form

$$\text{antilog } (-pK'_{\text{B}}) \equiv K = \text{antilog } (-\text{H}_0) \times (k - k_{\text{BH}^+})/(k_{\text{B}} - k)$$

or

$$K = h_0\,(k - k_{\text{BH}^+})/(k_{\text{B}} - k) \qquad (14)$$

where

$$h_0 \equiv \text{antilog } (-H_0) \qquad (15)$$

Formula (14) may be put into two forms

$$K + k_{\text{BH}^+}[h_0/(k_{\text{B}} - k)] - h_0 k/(k_{\text{B}} - k) = 0 \qquad (16)$$

$$1/K + k_{\text{B}}[1/h_0(k_{\text{BH}^+} - k)] - k/h_0(k_{\text{BH}^+} - k) = 0 \qquad (17)$$

Both of these equations are of the form

$$a + bx - y = 0 \qquad (18)$$

where x and y are known quantities and a and b may be calculated, if two sets of values for x and y are known. If more than two sets of values of x and y are known, it is of course best to use a least squares solution. Formula (16) is to be used when the reference curve for non-ionized acetophenone is the flatter and formula (17) at those wave lengths at which the curve for ionized acetophenone is flatter. At those wave lengths where both curves are equally flat, formula (13) should give satisfactory values.

The reference curves for the ionized and for the non-ionized substance should obviously be taken as near the range of ionization as possible, yet sufficiently removed so that the substance is present essentially in one form, ionized or non-ionized only. To make this choice we have used the following procedure: a rough value of pK' was calculated using reference curves well outside the region of ionization. Using this approximate value, a calculation was made of the range of sulfuric acid concentration in which ionization of acetophenone would be less than 5% and greater than 95%. An appropriate safety factor was then allowed to take care of the error in the pK'. In this way, 55% sulfuric acid was chosen as the reference solvent for non-ionized acetophenone, and 86% sulfuric acid as the reference solvent for completely ionized acetophenone.

In deciding which reference curve is the flatter, the plot of log k against the wave length is misleading because of its logarithmic nature. Accordingly, the curves were replotted using k instead of log k as ordinate. Inspection of these curves revealed which reference curve and, therefore, which equation should be used for each wave length. The equations so chosen are listed in Table V which contains the results of the calculation.

[a] Omitted from final average.

The second method of calculation depends upon the principle that all of the absorption curves due to mixtures in varying proportions of two substances (in this case the base and the cation) must intersect in a single point if any two intersect and if there is no medium effect.[11] If the medium effect represents a shift in wave length only, without change in shape or height of the bands, it should be possible to compensate for its effect by shifting all of the absorption curves laterally to produce a single intersection, an isobestic point, somewhere in the middle of the ionization region. Inspection of the curves of Fig. 4 shows that Curves 4 and 5 are very close to what would be expected for approximately 50% ionization. We have, therefore, shifted the curves for other solvents laterally so that they all pass through the intersection of these two

TABLE VI

curves and have then calculated the pK' of acetophenone from these shifted curves. The results are given in Table VI.

The average values of pK' obtained by the two methods agree excellently. Furthermore, both methods show only a random variation of pK' with wave length. (This is most decidedly not the case if no account is taken of the medium effect.) All in all, it seems probable that this quantity, which has never before been measured in even the most approximate fashion, is now known within at least 0.1 unit.

A solution of acetophenone in 0.1 *M* aqueous hydrochloric acid would therefore be converted to the cation $C_6H_5COH^+CH_3$ to the extent of only one part in ten million. This is of course a figure of interest for the interpretation of such acid-catalyzed reactions of acetophenone as the bromination. The base acetophenone is nearly 10^{10} weaker than aniline; compared with nitrogen bases it is intermediate in strength between 2,4-dinitroaniline and 6-bromo-2,4-dinitroaniline, but is still over a thousand times stronger than 2,4,6-trinitroaniline; compared with other oxygen bases, its strength lies between that of β-benzoylnaphthalene and that of *p*-benzoyldiphenyl, and it is only about 0.4 logarithmic unit weaker than the familiar "halochromic" ketone benzalacetophenone.

Some Considerations about Indicators.—A medium effect was recognized in the colorimetric work in sulfuric acid–water mixtures of Hammett and Deyrup[5a] where it appeared as a variation in color intensity. There was no visible change in color quality which would have rendered a colorimetric match impossible. Yet the lateral shifts of the whole absorption curve toward longer wave lengths to which we now apply the same term, might, at first sight, be expected to result much more in a change in color quality than one in intensity. The explanation of the apparent contradiction derives from certain properties of human vision combined with the fact that the indicators studied were all of the colorless–yellow type. Their colorimetric behavior depends, therefore, upon the absorption by the yellow form of frequencies in the violet. In this range the human eye has little if any sense of color quality and it apprehends a shift in the absorption curve simply as a change in intensity without a concomitant change in color quality.[17] Thus the medium effect does not interfere with obtaining a colorimetric match, and all that need be corrected for is the change in intensity, which is not too difficult.

If, however, the indicator changed from colorless to let us say, blue, an evaluation of the medium effect would be very difficult because a small shift in the absorption spectrum due to the medium effect would not only change the intensity of the absorbed light but also its color, and it would be impossible to obtain a match in the colorimeter. This result has some application to colorimetric measurements in dilute aqueous solution, where medium effects due to changes in ionic strength or other variations in composition are larger than is sometimes appreciated. The nitrophenol indicators of Michaelis avoid color matching difficulties in this way, because they change from colorless to strong yellow.

An example of the difficulties which may result from the medium effect may be found in the work of Baker.[18] His work on the basic properties of organic oxygen compounds is of the greatest significance and interest, but he appears to have been misled by a medium effect in respect to the range of acidity in which acetophenone ionizes. He considered that the ionization occurs in the region in which the pale yellow color possessed by acetophenone in concentrated sulfuric acid is developing. Now in Fig. 4 the curves have been so drawn that an intercept on the ordinate of 3700 Å. corresponds to a visible yellow color in a solution containing a few thousandths molar acetophenone. It will be seen that the color does not appear until the acetophenone is practically completely converted to the ion and that the deepening of the yellow color with increasing concentration of sulfuric acid is due solely to the shift resulting from the medium effect. The change in absorption due to ionization occurs entirely in the ultraviolet.

Benzoic Acid.—This substance is also known to be a strong monoacid base in 100% sulfuric acid.[3] The absorption spectra were determined in sulfuric acid–water mixtures from 0.5 to 100% sulfuric acid. Some of the curves are given in Fig. 5. Only a medium effect shift to higher wave lengths appears between 0.5 and 70.20% sulfuric acid (Curves 1 and 2) and the large change corresponding to the basic ionization occurs between 70.20 and 95.65% sulfuric acid (Curves 3 to 5,

inclusive). Above 95.65% sulfuric acid there is again a shift corresponding to the medium effect. Curves 3 and 4 for the solvents 81.84 and 83.46% sulfuric acid correspond approximately to half ionization. The extinction coefficients for the various solvents are given in Table VII.

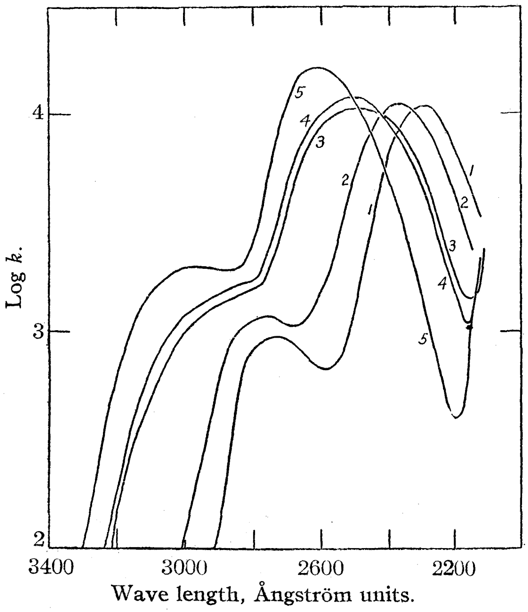

Fig. 5.—Ionization of benzoic acid as a base in sulfuric acid: Curve 1, 0.5% (0.1 N); 2, 70.20%; 3, 81.84%; 4, 83.46%; 5, 95.65%.

The pK' values computed by the least squares method (or by equation (13) where both reference curves are flat) are contained in Table VIII. The concentration of ion was assumed to be negligible in 70.20% acid, and the ionization was taken as essentially complete in 95.65% acid. Values were also computed by the second method, shifting the curves laterally so that they all passed through the intersection of Curves 3 and 4 at a wave length of 2430 Å. and an extinction coefficient of 10,000. This gave a value of -7.11 ± 0.10 from the data on 83.46% acid and -7.09 ± 0.04 from those on 81.84% acid. These are in fair agreement with the average of -7.26 ob-

tained by the least squares method, which should be considered the more reliable.

The base benzoic acid is from 1 to 1.5 logarithmic units weaker than the various phenyl ketones previously studied. The wide spread between the first and second acidity constants of the cation $C_6H_5C(OH)_2^+$ is worthy of note but not unexpected in view of the small distance between the two hydrogens. The acidity of a solution in which benzoic acid is half ionized to benzoate ion must be increased about 11.5 logarithmic units in order to convert it to a half ionized base.

Anthraquinone.—The base strength has previously been determined by the colorimetric method.[5a,b] Absorption curves are given in Fig. 6 and extinction coefficients in Table IX. The solubility in aqueous sulfuric acid of less than 85% concentration is so small that the determination of a reference absorption spectrum for the non-ionized base is impracticable. The pK' values must, therefore, be calculated from equation (17), which can be applied without serious error only in regions where the curve for BH^+ is flat. This limits us in this case to the region around 4000 Å. From the absorption at 100 Å. intervals between 4400 and 3900 we obtain an average pK' of -8.18 ± 0.19, which agrees well with the value of -8.15 from visual colorimetry.

TABLE IX

EXTINCTION COEFFICIENTS OF ANTHRAQUINONE IN $H_2SO_4 + H_2O$ MIXTURES

The low precision is due, at least in part, to the low dispersion of the spectrograph used in this range of wave lengths.

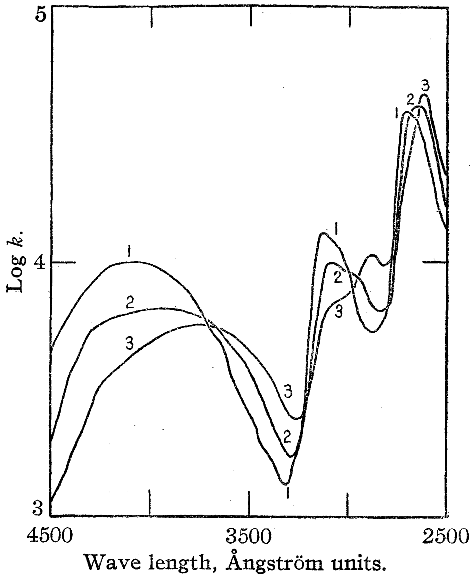

Fig. 6.—Ionization of anthraquinone as a base in sulfuric acid as solvent: Curve 1, 100.0%; 2, 90.52%; 3, 85.96%.

Phenylacetic Acid.—In spite of the fact that there is very little change in absorption when phenylacetic acid ionizes to phenylacetate ion,[16] there is a fairly large change when this acid gains rather than loses a hydrogen ion. Results of absorption measurements are shown in Fig. 7 and Table X.

TABLE X

EXTINCTION COEFFICIENTS OF PHENYLACETIC ACID IN $H_2SO_4 + H_2O$ MIXTURES

Wave length, Å.	% H_2SO_4 70.20	76.11	81.84	85.69	90.52

2200	1300	1430	1650	1600	1840

Above 90% sulfuric acid, the absorption changes rapidly with time, probably as a result of sulfonation. Thus the spectrum of a solution in 95.99% acid taken within an hour after prepa ration was similar in shape to curve 3 in Fig. 7 but displaced upward. The spectrum after three hours is shown in Curve 4. At 90% sulfuric acid or less the rate of this change is negligible. It is, therefore, impracticable to determine the absorption of the completely ionized form, and the pK' must be calculated from measurements on the non-ionized base and on partially ionized mixtures, using equation (16). The average value obtained from wave lengths of 2350, 2400, 2450, 2500 and 2550 Å., in the region in which the curve for the non-ionized base is flat, is -7.59 ± 0.13.

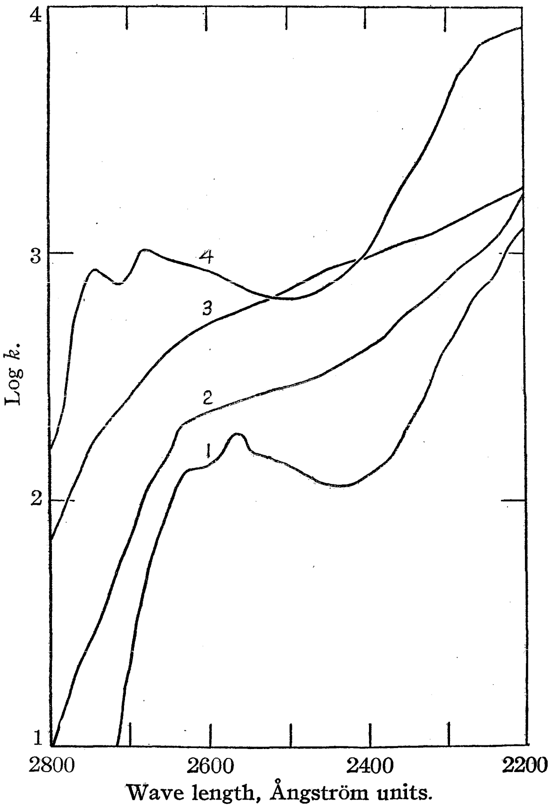

Fig. 7.—Ionization of phenylacetic acid as a base in sulfuric acid: Curve 1, 70.20%; 2, 81.84%; 3, 90.52%; 4, 95.99% (stood three hours).

It will be noted that base strength does not go inversely as acid strength. Phenylacetic acid is both a slightly weaker acid and a slightly weaker base than benzoic acid.

Although the base strengths of benzoic and phenylacetic acids are very nearly the same, the reaction rates of their acid catalyzed esterifications are very different.[19] Thus the esterification of phenylacetic acid with absolute ethyl alcohol in the presence of catalyzing hydrochloric acid is almost a hundred times faster than the corresponding esterification of benzoic acid.

It has not infrequently been implied in discussions of the acid catalysis of esterification that the rate should be uniquely determined by the base strength of the acid being esterified. This is evidently not the case.

***p*-Nitrobenzoic Acid.**—We have already pointed out that the change in ultraviolet absorption attending the ionization of this substance into *p*-nitrobenzoate ion is too small to permit measurement of the acid strength by this method (see Fig. 8). The ionization as a base also takes place with very little change in ultraviolet absorption. (It is completely ionized in 100% sulfuric acid.[3]) In fact the whole change in absorption from 0.1 *M* sodium hydroxide to 95.65% sulfuric acid might reasonably be attributed to medium effect alone. There is no obvious reason why this should be the case.

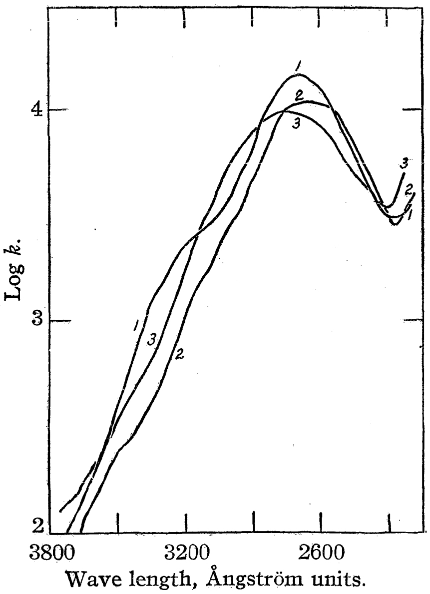

Fig. 8.—*p*-Nitrobenzoic acid: Curve 1, 95.65% H_2SO_4; Curve 2, 0.1 *M* HCl; Curve 3, 0.1 *M* NaOH.

We wish to acknowledge the kindness of Professors H. T. Beans and H. C. Urey, who made available for us apparatus which was indispensable for this work.

Summary

1. The ultraviolet absorption spectra in various solvents have been determined of benzoic acid, 2,4-dinitrophenol, aniline, acetophenone,

---

[19] Goldschmidt, *Ber.*, **28**, 3218 (1895).

anthraquinone, phenylacetic acid and *p*-nitrobenzoic acid.

2. The validity of ultraviolet spectrophotometry as a method of measuring ionization has been demonstrated for a carboxylic acid and a phenol, and for an oxygen and a nitrogen base.

3. Mathematical methods have been devised for taking into account the effect of changing solvent in measuring the strength of very weak bases.

4. Criteria have been established for the choice of indicators to be used in changing media.

5. The strengths of the following very weak bases have been measured: acetophenone, benzoic acid and phenylacetic acid.

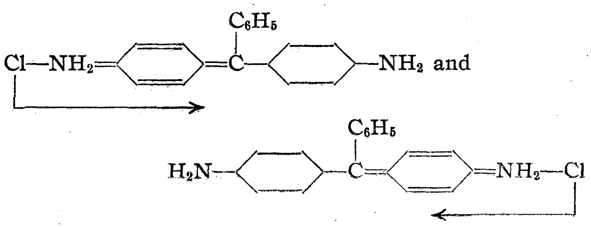
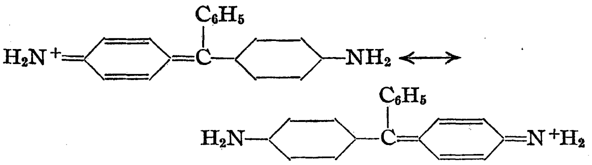
Auxochromes and Resonance

BY C. R. BURY

Baeyer[1] suggested that the color of the triphenylmethane dyes was due to the oscillation of an atom in the molecule. Döbner's violet (the hydrochloride of *p,p*-diaminotriphenylcarbinol) was considered to be in a state of oscillation between the two forms



Now that the distinction between electrovalent and covalent bonds is known, it is clear that the oscillation is purely structural

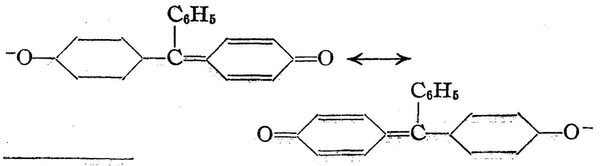


since change from one form to the other involves movement of electrons only, but no movement of atoms. Further, such an oscillation is to be expected: it is merely an example of resonance. Baeyer's hypothesis can be restated in terms of modern theory as follows. The intense absorption of light that characterizes dyes is due to an intimate association of a chromophore and of resonance in the molecule.

There is much indirect evidence that this hypothesis is true, not only for the triphenylmethane dyes, but also for most of the best investigated types of dyes. In particular, it gives some explanation of the function of an auxochrome. Willstätter and Piccard[2] called attention to the fact that certain simple compounds containing the quinonoid group were colorless, or very feebly colored: the development of color in these compounds depends on the introduction of certain substituent groups—auxochromes. In the light of the hypothesis put forward, the function of the auxochrome is to introduce the possibility of resonance. (Auxochromes also facilitate the attachment of the dye to the fabric, but this aspect is not considered further here.)

The hypothesis enables one to understand what groups can act as chromophores and what positions they must occupy. Thus, fuchsonimine $HN{=}C_6H_4{=}C{-}(C_6H_5)_2$ is colorless, though it contains the same chromophore as Döbner's violet. Introduction of an amino group in the *p*-position results in the development of color and the possibility of resonance. Other substituent groups are ineffective in producing color, though they may alter the shade of color of a dye that already contains an amino group. The amino group may be alkylated (—NR_2), but conversion to a trialkyl substituted group (—N^+R_3) renders resonance impossible and is found in practice to render it ineffective. The destruction of the color of methyl violet and similar dyes by excess concentrated acid can be attributed to the same change.

The color of the hydroxytriphenylmethane dyes is associated with a similar resonance, *e. g.*, the anion of benzaurin.



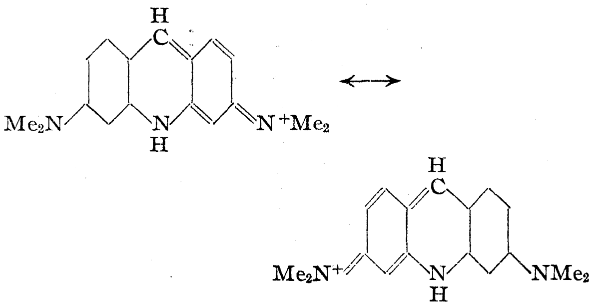
---

[1] Baeyer, *Ann.*, **354**, 152 (1907).

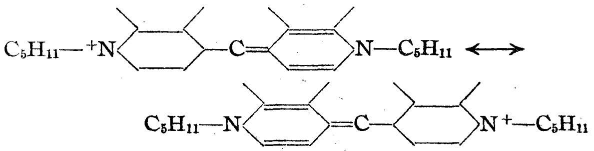
[2] Willstätter and Piccard, *Ber.*, **41**, 1458 (1908).

The hypothesis demands that the color of phenolphthalein in alkaline solution should be due to a dibasic ion, though most textbooks continue to attribute the color to a monobasic ion, which is adequate to explain the color on the usual theory, but is contrary to all experimental evidence.[3]

Resonance similar to that of the triphenylmethane dyes must also occur in the diphenylmethane dyes, the indamines, indophenols and auramines, and again in a group of dyes in which the two benzene nuclei are joined by a second bridge, such as the acridine, pyronine, azine, oxyazine and thiazine dyes. For instance, the colored cation of acridine orange can be represented.

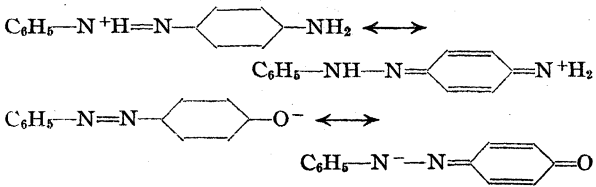


A closely related type of resonance is probable in the cyanines



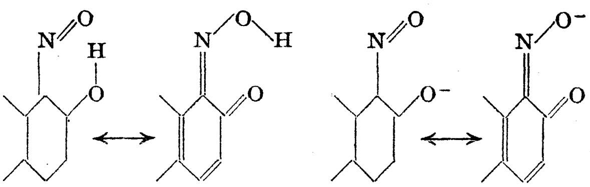
Mills and Ordish[4] have proposed tautomeric formulas, that are identical in principle with the resonance formulas of this paper, for the apocyanines.

Turning to a different type of dye, the azo dyes, it is well known that most molecules that contain the azo group are colored, but their color is feeble compared with that of the azo dyes; compare, for example, the color of methyl orange in alkaline solution with its color in acid. The resonance of this type of dye can be illustrated by formulas of the cation of aminoazobenzene and the anion of hydroxyazobenzene.

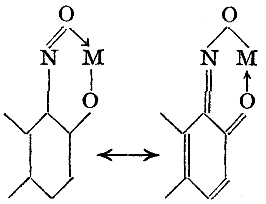


In support of these formulas is the fact that some syntheses and reactions of hydroxyazobenzenes suggest that they are really quinone phenylhydrazones. The change azo compound to hydrazone obviously occurs readily, but must be a slow reaction since it involves movement of a hydrogen atom. Change of the corresponding ions is, however, a purely structural change that involves no movement of atoms; the ions, therefore, may be expected to be in a state of resonance. Again, Hantzsch and Hilscher[5] have shown that the hydrogen ion introduced on formation of a salt of an aminoazobenzene is not attached to the amino group, but is probably in the position required by the above formula. Lastly, the hypothesis gives an explanation of the function of the auxochrome amino and hydroxy groups, and enables one to predict what substituent groups can act as chromophores, and what positions they must occupy. As with the triphenylmethane dyes, conversion of an amino group to a trialkylated group renders it ineffective.

A third important type of dye is the mordant or lake type, of which α-nitroso-β-napthol is a simple example. This type differs from previous examples in that the same resonance can persist in the neutral molecule I, in the ion II, and in the coördinate compound III which is the basis of the lakes.[6]



I II



III

Similar groups that can exhibit a similar resonance are IV, V and VI.

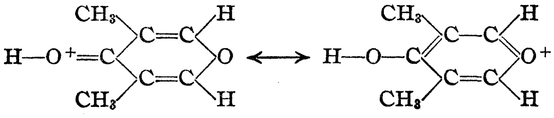
The physical properties of such *o*-disubstituted benzene derivatives are abnormal[7] compared with those of the corresponding *m*- and *p*-derivatives in such a way as to indicate that the *o*-substituents unite to form a second ring, a behavior that can only be explained by resonance.[8] Again, *o*-quinone monoximes are indistinguishable from *o*-nitrosophenols. With similar *p*-substituted compounds, resonance is restricted to the ion. Thus *p*-nitrophenol gives an intensely colored ion in alkaline solution, but is colorless in acid and in the solid state, whereas *o*-nitrophenol is colored in all conditions. The nitro dyes contain group IV, and the two most important types of mordant dyes, the hydroxyanthraquinones and the flavones, contain group V.

Some of the vat dyes contain similar groups and may be expected to exhibit similar resonance. Thus, alizarin yellow (gallacetophenone), which is probably the simplest vat dye, contains group V, and the side chain derivatives of anthraquinone that are vat dyes, and indanthrene, contain group VI.

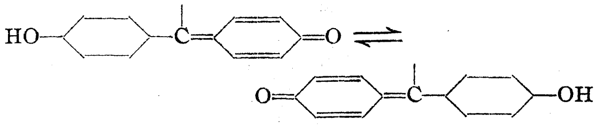
An interesting benzenoid–quinonoid type of resonance can occur in the dimethylpyronium ion.



This type of resonance was detected in dimethylpyrone by Sutton[9] from dipole measurements. The same grouping occurs in the flavones.

It is probable that more than one type of resonance is at work in the more complex dyes: thus two types of resonance have been postulated for the flavones. It is improbable, however, that resonance is extremely complex or the simple treatment applied above would be valueless. This implies that only resonance between states of nearly equal energy, or "complete" resonance, is effective in determining the structure that a molecule must have in order that it may be a dye.

There must, however, be more possibilities of resonance in the solid state than there are in solution. Thus, the change



involves movement of a hydrogen atom, and therefore cannot produce resonance. A similar change that does not involve movement of a hydrogen atom can, however, take place between suitably placed molecules in the solid state. This may account for the fact that rosolic acid is intensely colored in the solid state though it is colorless in neutral solution, but is given merely as an example of a phenomenon that must be expected frequently with dyes in the solid or in the colloidal state. Quinhydrone, the crystal structure of which has been elucidated by Foz and Palacios,[10] provides an example of exchange of hydrogen atoms between neighboring molecules in the solid state that involves no movement in space. The intense color of this compound may be attributed to the conjunction of resonance and of the chromophore in quinone.

The simple modes of resonance discussed above are sufficient to explain the phenomenon of auxochromes in the majority of the most thoroughly investigated dyes. Other probable modes can be devised for most other dyes the structure and reactions of which are known with any certainty; only the indigo dyes present any difficulty.

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF COLUMBIA UNIVERSITY]

An Investigation of Certain Sapinic Acids Obtained from Various Species of Pine and Spruce

BY TORSTEN HASSELSTROM AND MARSTON TAYLOR BOGERT[1]

It has been observed frequently[2] that when the solid portion of the oleoresins of pine and spruce is subjected to fractional crystallization from anhydrous solvents at temperatures below 60°, there are obtained the so-called sapinic acids. These are resin acids of the molecular formula $C_{20}H_{30}O_2$, with melting points in the neighborhood of 142–144°, which are very sensitive to oxidation, and easily isomerized by heat or by mineral acids to an abietic acid.[2e,g,h,3]

In optical rotation, they vary greatly, not only as between different tree species, but even in the case of different trees of the same species (see Table I).

The sapinic acids of *Pinus maritima*,[4] and of *Pinus Palustris*,[5] have been separated into *d*-pimaric and "*levo*-pimaric" acids. The former is stable;[6] whereas the latter is quite unstable, for it is easily oxidized, and is isomerized by heat or by mineral acids to abietic acids.[2c,3,4a,7]

This labile acid, however, is not the true optical antipode of the well-known *d*-pimaric acid. In fact, the real *l*-pimaric acid apparently has not yet been described. It has for some time been the approved usage of investigators in the resin acid field, to classify as "pimaric" acids only those resin acids which yield pimanthrene when fused with sulfur or selenium; and as "abietic" acids, those which when similarly treated give retene.

Since this so-called "*levo*-pimaric" acid yields retene when fused with sulfur,[4b] it belongs to the abietic and not to the pimaric class of resin acids. The name "*levo*-pimaric," originally given to it by Vesterberg,[8] therefore should be replaced by one more in agreement with our present knowledge, and we suggest in its place the designation "*l*-sapietic" acid. This name we have coined to recall its occurrence in the original sapinic acids of the gum and its belonging to the abietic group.

TABLE I

The optical rotations on the crude gums were determined upon selected samples carefully dried between filter papers.

Oleoresin	$[\alpha]_D$	Sapinic acid, m. p., °C.	$[\alpha]$	Calculated composition of the sapinic acids $[\alpha]_D$ +79.3 *d*-Pimaric acid	$[\alpha]_D$ −280.4 *l*-Sapietic acid	Reference

Picea excelsa	.....	142–143	−101.97	49.6	50.4	Nordström[3]

The crystals found by Köhler[2c] between the sapwood and the bark of *Picea excelsa* and which, therefore, had not been exposed to light and air, were probably fairly pure *l*-sapietic acid, containing relatively small amounts of *d*-pimaric acid. Köhler recorded their rotation as $[\alpha]^{20}_D$ −238° and, after four recrystallizations from methanol, as $[\alpha]^{20}_D$ −278°. Subsequent investigators have reported the rotation of the pure acid as $[\alpha]^{17}_D$ −279.4,[4b] −280.4,[9] and −274.5°.[5] Assuming

that the crude crystals contained only *l*-sapietic and *d*-pimaric acids, and taking Balas' figure[9] for the rotation of the latter ($[\alpha]_D + 79.3°$), their composition as calculated from Biot's relationship,[10] $-280.4x + (1-x)\ 79.3 = -238°$, would be approximately 88.2% of *l*-sapietic and 11.8% of *d*-pimaric acid.

It is the hypothesis of the authors that most of the so-called "sapinic acids" of the oleoresins of conifers are mainly isomorphous mixtures of *l*-sapietic and *d*-pimaric acids, the differences in optical rotation being due to the relative amount of *d*-pimaric present in the unoxidized and unisomerized acid mixture.

All of the sapinic acids examined by us, when hydrogenated in the presence of the Adams platinum oxide catalyst, yielded large quantities of dihydropimaric acid, which was easily isolated by virtue of its sparing solubility in methanol. Our experiments show that this is a satisfactory solvent for accomplishing the separation of a mixture of the dihydropimaric from the dihydroabietic type of acid.

Attempts to isolate dihydrosapietic acid,[4b,5] m. p. 144–146°, from the mother liquors were unsuccessful. There was obtained a low-melting acid mixture containing some dihydropimaric acid. As noted by previous investigators,[4a,5] catalytic hydrogenation even of pure *l*-sapietic acid yields a mixture of isomers difficult to separate.

As Palkin and Harris[5] have shown, and as we ourselves had observed in the course of some experiments carried out a year before the appearance of their paper, *d*-pimaric acid is readily identified by catalytic hydrogenation to its dihydro derivative.

The presence of *l*-sapietic in the original sapinic acid was established by refluxing the latter with glacial acetic acid, as described by Steele,[11] a treatment which isomerizes the *l*-sapietic to abietic, but leaves the *d*-pimaric acid unaltered. The solids obtained from the mother liquors of the abietic acid, when subjected to catalytic hydrogenation, yielded dihydropimaric acid in considerable amount.

It is generally recognized that the "abietic acids" constitute the major portion of ordinary colophony. Our demonstration of the occurrence of *d*-pimaric in the sapinic acids, indicates its presence also in rosins produced by the usual methods.

Acknowledgments.—For samples of oleoresins supplied, our thanks are due especially to Messrs. I. A. von Julin, Fiskars, Finland; William F. Allen, of Dr. Charles H. Herty's laboratory, Savannah, Ga.; and Edward A. Brennan, of the G. & A. Laboratories, Savannah, Ga.

Experimental

Preparation of the Sapinic Acids.—The semi-solid oleoresin, or the press-cake obtained therefrom by expressing, was dissolved in an anhydrous solvent (ethyl acetate), using approximately 1 part gum to 2–3 parts of solvent, at a temperature not exceeding 60°, and filtered from chips, bark, dirt, etc. The filtrate was concentrated to a sirup by evaporation under diminished pressure at a temperature below 60°, since above that temperature the *l*-sapietic acid begins to isomerize. This sirup was seeded with a few selected dry crystals of the sapinic acid obtained directly from the original gum and, on standing for from four to twelve hours, set to a semi-solid crystalline mass which was easily filtered. The crude sapinic acid so obtained was colorless. It was purified by successive crystallization from ethyl acetate, acetone and methanol.

The *Picea excelsa* oleoresin (from Finland) contained considerable oxidation products. These were removed by adding petroleum ether to the viscous ethyl acetate solution of the gum until no more dark colored precipitate separated. The filtrate from this precipitate was concentrated under reduced pressure at a temperature below 60°, and this process of purification was repeated thrice. The final sirup was then seeded and the crude product recrystallized as noted above.

Further details concerning the preparation of these sapinic acids and their properties, are given in Table II.

Hydrogenation of the Sapinic Acids.—To one part of sapinic acid in 20 of ethyl alcohol, there was added one-twentieth to one-tenth of a part of Adams platinum oxide catalyst and the hydrogenation was conducted at room temperature and a pressure of 7–25 lb. per sq. in. When approximately one mole of hydrogen per mole of acid had been absorbed, the hydrogenation was interrupted, the alcoholic solution concentrated to incipient crystallization and let stand for some time at room temperature. The separated solid was removed and crystallized from methanol until the product showed a m. p. of about 240°. Further crystallization to the m. p. of 249–250°, the figure given by Palkin and Harris[5] for pure dihydropimaric acid, was not undertaken since 240–241° has been generally accepted[12] as the m. p. of a practically pure acid.

From the mother liquors, by fractional crystallization, more dihydropimaric acid was recovered, but no constant melting product which could be identified as a dihydrosapietic acid.

The results of these hydrogenation experiments are presented in Table III.

By crystallization of a mixture of the oleoresins of *Pinus palustris* and *P. carribea*, Vocke[21] obtained a levo-

Dihydropimaric acid recovered from mother liquors		Yes	Yes	Not examined	Not examined	Yes	Not examined			

[a] The quantity of material available was insufficient for further recrystallization, but the presence of dihydropimaric acid seems evident from the analysis and from the fact that no dihydroabietic acid is known with a m. p. above 175°.[2e,2f,2g,5,13]

rotatory sapinic acid, m. p. 143°, which, on hydrogenation, yielded a dihydro acid. This latter was purified by crystallization from ethyl alcohol, in which it was but slightly soluble, and then melted at 195°. On further hydrogenation, there was obtained a tetrahydro acid (m. p. 173°, not sharp) which he assumed to be of abietic type. It is our belief that if Vocke had used methyl instead of ethyl alcohol for the purification of his dihydro acid, he would have discovered the presence therein of dihydropimaric acid.

Formation of Steele's Abietic Acid from Sapinic Acids.—A mixture of 10 g. of the sapinic acid with 10 cc. of glacial acetic acid was refluxed for four hours, then allowed to cool and left overnight at room temperature. The abietic acid which separated was purified by crystallization from alcohol.

The original acetic acid mother liquor was poured into water and the precipitated resin acid mixture removed and hydrogenated catalytically in alcoholic solution as described above. Dihydropimaric acid was thus secured, the mother liquors from which contained a low melting dihydro acid, which could not be obtained of constant melting point and was not identified. It may have been the dihydro Steele abietic acid described beyond.

The results of these experiments are given in Table IV.

TABLE IV

Hydrogenation of Steele's Abietic Acid.—Steele's abietic acid was prepared from the press-cake from sulfate "black liquor" tall oil[15] and the crude product was crystallized fifteen times from methanol, acetone and ethyl acetate. After eleven crystallizations, the melting point remained constant at 164.5–165.5°; $[\alpha]^{32}_{\mathrm{D}}$ −53.9°.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 79.41; H, 10.01. Found: C, 79.25; H, 10.03.

---

(13) (a) Johansson, *Arkiv f. kemi*, **6**, 19, 20 (1917); (b) Ruzicka and Meyer, *Helv. Chim. Acta*, **5**, 324 (1922).

(14) Ruzicka and Balaš, *Helv. Chim. Acta*, **6**, 677 (1923).

(15) Hasselstrom, U. S. Patent 1,986,817 (1934).

A solution of 3 g. of this acid in 50 cc. of alcohol was hydrogenated catalytically as described for the sapinic acids, interrupting the operation when one mole of hydrogen had been added (ten minutes). The product was worked up in the usual way, as in the case of the hydrogenated sapinic acids. The crude solid acid was crystallized first from methanol and then from acetone, six times in all. It formed colorless needles, m. p. about 154.5–157° (corr.), $[\alpha]^{32}_D$ +17.54°.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.88; H, 10.60. Found: C, 78.46; H, 10.50.

In view of the unsatisfactory melting point, it is unlikely that this is the pure dihydro derivative of Steele's abietic acid. More probably, it is a mixture of isomers.

Summary

1. The sapinic acids of *Pinus palustris*, *P. caribbea*, *P. taeda*, *P. serotina*, *P. silvestris* and *Picea excelsa*, consist chiefly of a mixture of *d*-pimaric and *l*-sapietic acids. This is in accord with the findings of Palkin and Harris[5] in the case of *P. palustris* and of Dupont,[4a] and Ruzicka, Balaš and Vilim[4b] for *P. maritima*.

2. The presence of the former is proved by the formation of dihydropimaric acid when the sapinic acids are hydrogenated catalytically; and, of the latter, by the fact that, when refluxed with glacial acetic acid, the sapinic acids yield Steele's abietic acid as one of the products.

3. The stability of *d*-pimaric acid and its existence in the sapinic acids explains its presence in ordinary colophony.[16]

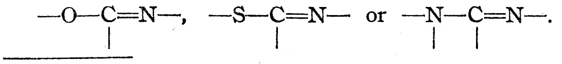
[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF COLUMBIA UNIVERSITY]

The Synthesis of Certain Phenylated Benzoxazoles and Derivatives[1]

BY VLADIMIR J. MIKESKA AND MARSTON TAYLOR BOGERT

The investigations of thiazole compounds conducted in these laboratories, especially on the connection between chemical constitution and tinctorial properties,[2] have made it seem worth while to carry out some similar studies in the closely related oxazole series.

The structural similarity between the oxazoles, thiazoles and imidazoles is paralleled by a close resemblance in methods of preparation and in properties of analogous compounds in the three series. Thus, in the basicity of their salts, the fluorescence of their solutions,[3] and odors, they are much alike. Auwers and Ernst,[4] who examined a large number of analogous compounds in the three groups in the helium region of the spectrum at 20°, found that their dispersion spectra corresponded closely, and that it seemed to make but little difference in the spectrum whether the grouping present in the cycle was



$-O-\underset{|}{C}=N-$, $-S-\underset{|}{C}=N-$ or $-\underset{|}{N}-\underset{|}{C}=N-$.

In all three series, the monocyclic types are most easily hydrolyzed, then the aliphatic 2-R derivatives of the benzo (dicyclic) type, the most stable derivatives being the 2-aryl compounds, like 2-phenylbenzoxazole. Of the three series, the oxazoles are most easily hydrolyzed,[5] even methylation breaking open the ring when 2-methylbenzoxazole is heated with methyl iodide.[6]

Clark[7] has carried out some interesting experiments on the opening of the cycle by the action of potassium hydroxide upon the methiodide.

Böttcher[8] was unable to effect ring closure by reduction of $CH_3COOC_6H_4NO_2$-(*o*), although this was accomplished easily by reduction of either C_6H_5-$COOC_6H_4NO_2$-(*o*) (2) or $C_6H_5COOC_{10}H_6NO_2$ (3).

For our attack upon the problem, the 2-R-5-phenyl and 2-R-7-phenylbenzoxazoles were used, because of the availability of the important industrial by-products *p*- and *o*-hydroxy diphenyls, from which they are easily synthesized. These syntheses are recorded in the present paper. The production of dyes from the phenylated benzoxazoles so obtained and a discussion of the tinctorial properties of these dyes, will form the subject of another communication.

For the synthesis of the 5-phenyl derivatives, 3-nitro-4-hydroxydiphenyl was reduced to the corresponding amine and this in turn was condensed with *p*-nitrobenzoyl chloride to the 2-*p*-nitrophenyl-5-phenylbenzoxazole, reduction of which yielded the corresponding amino derivative (A).

For the preparation of the analogous 7-phenylbenzoxazoles, 3,5-dinitro-2-hydroxydiphenyl was converted first to the benzoate and this then reduced, with simultaneous cyclization, to the 2,7-diphenyl-5-aminobenzoxazole (B).

Experimental

Raw Material.—In the manufacture of phenol by the fusion of sodium benzenesulfonate with sodium hydroxide and rectification of the crude product, there remain in the still residues certain higher boiling phenolic constituents, diphenylsulfone and other by-products. Through the courtesy of Weiss and Downs, Inc., of New York, and of The Bakelite Corporation of Bloomfield, N. J., we were provided with a supply of this crude still residue and also with a small quantity of a distillate composed mainly of a mixture of hydroxydiphenyls. To both of these firms we wish to express our thanks for their assistance. The crude still residue, which was our chief source material, was worked up as follows.

After adding an excess of dilute (about 10%) sodium hydroxide solution, the mixture was boiled and stirred vigorously for at least fifteen minutes, then diluted with about 2 volumes of cold water and filtered from the separated **diphenylsulfone** (I), which was purified by distillation under diminished pressure, crystallization of the distillate from alcohol and sublimation. The sublimed product melted at 128° (corr.), in agreement with the figure reported by Otto,[9] and this melting point was not altered when mixed with a sample of the pure sulfone, of the same melting point, prepared by the direct sulfonation of benzene as described by Mitscherlich.[10]

It was further identified by the production therefrom of a *dinitro derivative* (II), m. p. 197°, which figure agrees with that given by Gericke[11] for dinitrodiphenylsulfone.

The *o*- and *p*-hydroxydiphenyls were isolated from the alkaline filtrate from the diphenylsulfone.

When this filtrate was acidified with hydrochloric acid, both hydroxy derivatives were precipitated, as well as tarry material. On filtration, some of this tar ran through the filter in an emulsified or colloidal state, together with most of the phenol present. The precipitate of crude hydroxydiphenyls was washed, dried and distilled under reduced pressure (30 mm.), the distillation being continued until there was evidence of decomposition products coming over. The mixture of *o*- and *p*-hydroxydiphenyls so obtained was extracted with hot gasolene and the undissolved ***p*-hydroxydiphenyl** (III) was rectified. The distillate obtained in this rectification, when crystallized from alcohol, appeared in bunches of colorless minute silky needles or in flakes, both of which forms melted sharply at 164° (corr.). Raiford[12] reported the m. p. as 163°.

The product was further identified by the preparation therefrom of the following derivatives: *4-acetoxydiphenyl*, m. p. 88° (corr.), literature[12] m. p. 88°; *4-methoxy*, m. p. 89.5° (corr.), literature[13] m. p. 90°; *3-nitro-4-hydroxy*, m. p. 67° (corr.), literature[12] m. p. 66°; *3-amino-4-hydroxy*, m. p. 209° (corr.), literature[12] m. p. 208°.

The gasolene filtrate from the *p*-isomer was concentrated to one-fourth its volume or less and, as it cooled, the ***o*-hydroxydiphenyl** (IV) separated in colorless crystals which were purified by distillation at 30 mm. pressure. The fraction collected at about 190° was nearly pure *o*-hydroxydiphenyl. Crystallized from alcohol, it formed massive colorless glassy crystals, m. p. 67.5° (corr.), which coincides with the figure reported by Norris, Macintire and Corse.[14]

For further identification, the *3,5-dinitro derivative* prepared from this product melted at 204° (corr.), as compared with a m. p. of 203–204° recorded by Borsche and Scholten.[15]

Summarizing our results, the yields of the various products isolated from this particular still residue were approximately as follows: diphenylsulfone 33%, *p*-hydroxydiphenyl 10%, *o*-hydroxydiphenyl 11%; phenol, water, unidentified higher-boiling constituents, tar and loss 46%.

Derivatives of *p*-Hydroxydiphenyl

3-Nitro-4-hydroxydiphenyl Sulfonic Acid (V).—A solution of 20 g. of 3-nitro-4-hydroxydiphenyl (m. p. 67°, corr.) in 60 cc. of concentrated sulfuric acid was stirred for three hours at 70°. There resulted a water-soluble sulfo acid, whose barium salt gave a yellow solution, unless barium entered the phenolic group also, when a red precipitate separated. Excess of sulfuric acid was precipitated by titration with barium hydroxide solution, the appearance of the yellow barium sulfonate changing the color of the solution and giving a clear end-point. A slight excess of barium hydroxide was used. The mixture was heated, allowed to stand for twenty-four hours and filtered. The filtrate containing the barium sulfonate was then titrated with more barium hydroxide solution, giving a deep canary yellow solution. The end-point in this titration was the appearance of the red color, or red precipitate, due to the entrance of the barium into the phenolic group also. By concentration of the yellow solution, the barium sulfonate crystallized in bright canary-yellow flakes; yield, 80%.

3-Nitrodiphenyl-4-*p*-toluene sulfonate (VI) was prepared by treating 5 g. of 3-nitro-4-hydroxydiphenyl with a solution of 5.2 g. of *p*-toluenesulfochloride in 5 g. of dimethylaniline and heating the mixture for a day at 100°. It was then acidified, the precipitate collected, dried, pulverized and extracted with 1% caustic alkali, to remove traces of unchanged initial materials. The residual ester was then purified by crystallization from alcohol and decolorization. The product formed bright yellow flakes, m. p. 114.8° (corr.); yield, 66%.

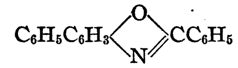
3-Nitrodiphenyl-4-*p*-nitrobenzoate (VII).—To a solution of 60 g. of 3-nitro-4-hydroxydiphenyl in 250 cc. of pyridine, there was added slowly, with stirring, 55 g. of well ground *p*-nitrobenzoyl chloride, keeping the temperature of the mixture below 25°. The reaction was completed in three hours and the mixture was poured into 400 cc. of 10% caustic alkali solution, let stand for an hour and filtered. Decolorized and crystallized from alcohol, the product appeared in colorless silky crystals, m. p. 169° (corr.); yield, 82%.

Reduced in glacial acetic acid solution by stannous chloride and hydrochloric acid, it yielded the 2-*p*-aminophenyl-5-phenylbenzoxazole.

3-Amino-4-hydroxydiphenyl was obtained by reduction of the corresponding nitro derivative, as reported by Raiford,[12] and formed minute colorless scales, m. p. 209° (corr.), in agreement with the literature;[12,16] yield, 65%.

3-(*p*-Nitrobenzoylamino)-4-hydroxydiphenyl (VIII).—In the synthesis of 2-*p*-nitrophenyl-5-phenylbenzoxazole from 3-amino-4-hydroxydiphenyl and *p*-nitrobenzoyl chloride (see beyond), the crude oxazole was extracted with warm normal sodium hydroxide, to remove by-products and unchanged initial materials. These alkali extracts were treated with a current of carbon dioxide, which precipitated the phenol and not the *p*-nitrobenzoic acid. This precipitate, when decolorized and crystallized from alcohol, gave the hydroxydiphenyl derivative in canary-yellow flakes, m. p. 249.3° (corr.); yield, 12%.

2,5-Diphenylbenzoxazole, (5)



$C_6H_5C_6H_3{<}\overset{O}{\underset{N}{}}{>}CC_6H_5$

(IX).—A mixture of 3 g. of finely ground 3-amino-4-hydroxydiphenyl with 5% more than the calculated quantity of benzoyl chloride was boiled for thirty minutes and then distilled. After removal of the excess benzoyl chloride, the benzoxazole distilled and congealed as it cooled. It was pulverized, digested for three hours with 2% sodium hydroxide to eliminate contaminants, washed thoroughly, decolorized and crystallized from alcohol, when it appeared in colorless silky flakes, m. p. 132.8° (corr.); yield, 1.5 g., **or** 35%.

2 - (*p* - Nitrophenyl) - 5 - phenylbenzoxazole (X).—An intimate mixture of 3.3 g. of 3-amino-4-hydroxydiphenyl with 4 g. of *p*-nitrobenzoyl chloride was heated for thirty minutes at 210°. The cooled melt was pulverized and extracted with warm normal sodium hydroxide, to remove by-products and unchanged initial material. The residue was washed thoroughly, dried and extracted repeatedly with small amounts of toluene. The crude oxazole recovered from these toluene extracts was decolorized and crystallized twice from glacial acetic acid, giving a colorless pulverulent solid, m. p. 288.8° (corr.); yield, 52%.

2 - (*p* - Aminophenyl) - 5 - phenylbenzoxazole (XI).—A solution of 8 g. of 3-nitrodiphenyl-4-*p*-nitrobenzoate in 200 cc. of glacial acetic acid at 100° was treated gradually with a solution of 60 g. of stannous chloride in 130 cc. of concentrated hydrochloric acid and the mixture was boiled for six hours. The complex tin salt which separated was removed, washed with water, dried, pulverized, and digested for six hours at 40° with normal sodium hydroxide, to decompose the tin complex and eliminate the tin. The crude oxazole when decolorized and crystallized from alcohol, formed pale yellowish needles, m. p. 174.2° (corr.); yield, 63%.

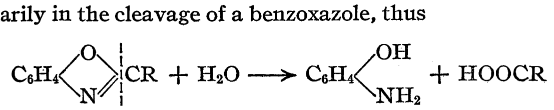
The same product was obtained by reduction of the 2-(*p*-nitrophenyl)-5-phenylbenzoxazole in a similar manner; yield, 75% (XII).

The alcohol solution of this compound exhibited a beautiful violet fluorescence, scarcely distinguishable from that produced by dehydrothio-*p*-toluidine.

2 - (*p* - Benzenediazochloride) - 5 - phenylbenzoxazole Hydrochloride (XIII).—The general method of Erdmann[17] was followed. A suspension of 1.5 g. of 2-*p*-aminophenyl-5-phenylbenzoxazole in 5 cc. of concentrated hydrochloric acid was cooled to 0–10° and diazotized by the gradual addition of the requisite amount of a 10% sodium nitrite solution. The mixture was allowed to stand (at room temperature) until a clear solution was secured, when it was diluted carefully until a precipitate appeared which was removed and dried. This diazochloride hydrochloride formed a yellow amorphous solid, m. p. 130.5° (corr.); yield, 42%. Boiled with dilute sulfuric acid, it gave the 2-*p*-hydroxyphenyl-5-phenylbenzoxazole.

2 - *p* - Aminophenyl - 5 - phenylbenzoxazole Disulfonic Acid (XIV).—A solution of 4 g. of 2-*p*-aminophenyl-5-phenyl-benzoxazole in 10 cc. of concentrated sulfuric acid was cooled to 20° and treated gradually with 15 cc. of fuming (60% free SO_3) sulfuric acid, maintaining the temperature below 55°, and protecting the solution from absorption of moisture by calcium chloride guard tubes. After stirring the mixture for twelve hours, it was cooled and poured upon ice. The colorless precipitate was removed, dissolved in dilute ammonium hydroxide, the solution filtered and the filtrate precipitated by acidification with hydrochloric acid. The precipitated sulfo acid was colorless and amorphous; yield, 80%.

When this disulfo acid was fused with caustic alkali, all of the products isolated were soluble in water but not in neutral organic solvents. Since this reaction results ordinarily in the cleavage of a benzoxazole, thus



$$C_6H_4{<}\overset{O}{\underset{N}{}}{>}\vdots CR + H_2O \longrightarrow C_6H_4{<}\begin{matrix}OH\\NH_2\end{matrix} + HOOCR$$

it follows that both cleavage products in the case of our disulfo acid carried a sulfonic acid group. *p*-Aminobenzoic acid dissolves quite readily in ether, but ether extraction of our products yielded nothing.

These results indicate that the original disulfo acid, like the corresponding thiazole compound,[18] carries one sul-

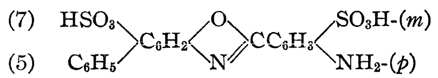
fonic acid group on each of the two benzene nuclei, the most likely structure being the following.



2-*p*-**Hydroxyphenyl-5-phenylbenzoxazole** (XV).—When a solution of 2 g. of the diazo chloride (XIII) in a liter of 20% sulfuric acid was boiled for twelve hours and then cooled, this phenol separated. From alcohol, it crystallized in cream colored flakes, which were dried at 120° and then melted at 270° (corr.); yield, 65%. Its solution in concentrated sulfuric acid exhibited a sky-blue fluorescence. Under identical conditions, the corresponding amine gave a lighter violet blue fluorescence.

Derivatives of *o*-Hydroxydiphenyl

3,5-Dinitrodiphenyl-2-benzoate (XVI).—A solution of 10 g. of sodium 3,5-dinitrodiphenyl-2-phenolate[15] in acetone was stirred for two hours with an excess of benzoyl chloride. The precipitated benzoyl derivative was removed and a second crop obtained by the addition of water and ether to the filtrate. The combined precipitates, after thorough washing with water, alcohol and ether, were crystallized from alcohol and pale yellowish crystals obtained, which melted at 119.5° (corr.); yield, 65%.

2,7-Diphenyl-5-aminobenzoxazole (XVII) was obtained by reduction of the above benzoate in essentially the same way as the 2-*p*-aminophenyl-5-phenylbenzoxazole (XI) was prepared from the corresponding benzoate (VII). Decolorized and crystallized from alcohol, it formed pale yellowish needles, m. p. 220.8° (corr.); yield, 61%. Its alcoholic solutions exhibited a greenish fluorescence.

Sulfonic Acid (XVIII).—To a solution of 8 g. of the above oxazole (XVII) in 20 cc. of concentrated sulfuric acid at 20°, 40 cc. of fuming (50% free SO_3) sulfuric acid was added at such a rate that the temperature did not rise above 55°. After the initial reaction was over, the temperature of the solution was held at 55° until the sulfonation was complete (six hours). The mixture was then poured upon ice, the white precipitate collected, washed, dissolved in sodium carbonate solution, reprecipitated by hydrochloric acid, this solution and reprecipitation repeated. The product crystallized with one molecule of water and decomposed above 375°.

When fused with potassium hydroxide at 250–270° for ten minutes, the only product isolated and identified was benzoic acid. It seems probable, therefore, that the sulfo group was on the benzoxazole portion of the molecule.

Summary

1. From commercial phenol still residues, *p*- and *o*-hydroxydiphenyls have been isolated and converted into the new dye intermediates, 2-*p*-aminophenyl-5-phenylbenzoxazole, 2,7-diphenyl-5-aminobenzoxazole, and their sulfo acids.

2. A number of new intermediate and final products have been synthesized and their properties recorded.

Preparation and Properties of Acetyl Dextro- and Acetyl Levo-β-methylcholine Chloride

BY RANDOLPH T. MAJOR AND HOWARD T. BONNETT

Acetyl β-methylcholine chloride[1] has recently been shown to be a useful therapeutic agent.[2] It has been carefully studied pharmacologically and has been found to possess a strong muscarine-like action with none of the nicotine-like action observed with choline and many of its derivatives.[3]

An examination of the chemical formula of acetyl β-methylcholine chloride, $(CH_3)_3NClCH_2CH(CH_3)OCOCH_3$, reveals the fact that it contains one asymmetric carbon atom. Theoretically it should be possible to prepare two optically active forms of this compound. It is generally recognized that one of the optical isomers of a drug is usually much more active physiologically than the other.[4] In order to determine this in the case of acetyl β-methylcholine chloride the optical isomers of the compound have been prepared.

Dextro-dimethylaminoisopropanol was obtained by resolving the *dl* amine with bromocamphorsulfonic acid. Methyl iodide reacted with this to give dextro-β-methylcholine iodide from which acetyl dextro-β-methylcholine chloride was obtained by standard procedures.

Levo-dimethylaminoisopropanol was obtained by resolution of the *dl* amine with *d*-tartaric acid. Acetyl levo-β-methylcholine chloride was obtained by procedures similar to those indicated above for the dextro isomer.

PREPARATION AND PROPERTIES OF ACETYL DEXTRO AND ACETYL LEVO β-METHYLCHOLINE CHLORIDE

[a] A mixed melting point of equal quantities of the *d*- and *l*-forms melted at 172–174°. Major and Cline [THIS JOURNAL, **54**, 247 (1932)] give 172–173° for *dl*-acetyl-β-methylcholine chloride.

Dr. Hans Molitor, Director of the Merck Institute for Therapeutic Research, has tested these compounds pharmacologically and reports that the muscarine-like action on the blood pressure of acetyl *l*-β-methylcholine chloride is one one-hundredth of that of acetyl *dl*-β-methylcholine chloride. The action of the former on isolated intestine was considerably less than the action of the latter. The muscarine-like action on the blood pressure of acetyl *d*-β-methylcholine chloride is somewhat greater than the action of the *dl* form. The action on isolated intestine is comparable to that of the *dl* form.

Experimental Part

Preparation of *d*-Dimethylaminoisopropanol.—Dimethylaminoisopropanol (b. p. 124–126°) was treated with a 5% excess of bromocamphor sulfonic acid in ethyl acetate solution. The salt was recrystallized from a mixture of 5 cc. of ethyl acetate and 1 cc. of absolute alcohol per gram of salt. Its rotation attained a value of +83.5° after five recrystallizations and was unchanged by additional recrystallizations. The amine was obtained from the salt by treating the latter with excess sodium hydroxide, extracting with ether, drying the ether solution with anhydrous potassium carbonate and distilling at atmospheric pressure; b. p. (770 mm.) 124.5–126°; $[\alpha]^{25}_D$ +17.1°.

Anal. Calcd. for $C_5H_{13}ON$: N, 13.59. Found: N, 13.61, 13.48.

Preparation of *l*-Dimethylaminoisopropanol.—Dimethylaminoisopropanol (b. p. 124–126°) was treated with 1.05 moles of *d*-tartaric acid in 95% alcohol solution. The salt was recrystallized from 6 cc. of 96% ethyl alcohol per gram of salt. A series of fifteen recrystallizations gave a salt having $[\alpha]^{25}_D$ −10.7°, the last four crystallizations changing the rotation from −10.3 to −10.7°. The amine was obtained from the salt as described above; b. p. 125°, $[\alpha]^{25}_D$ −14.8°.

Anal. Calcd. for $C_5H_{13}ON$: N, 13.59. Found: N, 13.00, 12.96.

Preparation of Acetyl *d*- and Acetyl *l*-β-Methylcholine Chlorides.—The methiodides of the optically active am-

ines were prepared in the usual manner. They were recrystallized from hot absolute alcohol to which about 30% of acetone was added after solution, and were obtained as white non-hygroscopic crystals. The optically active β-methylcholine iodides were converted to the corresponding chlorides using silver chloride in alcohol according to standard procedures. The chlorides were recrystallized from butyl alcohol,[5] and were obtained as white hygroscopic crystals. The optically active β-methylcholine chlorides were acetylated according to the method of Major and Cline.[5] The acetyl esters thus obtained were white hygroscopic crystalline solids. The properties and analyses of the above-mentioned compounds are recorded in the table.

The authors wish to express their appreciation to Messrs. Douglass F. Hayman and Sol Adler for the analyses recorded in this paper.

Summary

1. *dl*-Dimethylaminoisopropanol has been resolved into its optically isomeric forms.

2. The dextro and levo isomers of β-methylcholine iodide, β-methylcholine chloride, and acetyl-β-methylcholine chloride have been prepared and characterized.

Potassium Thiocyanate as a Primary Standard Substance

BY I. M. KOLTHOFF AND J. J. LINGANE

Although potassium thiocyanate has long been used as a reagent in the classical Volhard method for the titration of silver, the use of the pure salt as a primary standard substance in argentimetry has been discouraged in the literature.[1]

The initial purpose of the present investigation was to investigate the possibility of preparing the pure salt for use as a standard substance. A secondary purpose was to determine the *accuracy* of the potentiometric and the Volhard methods for the titration of thiocyanate with silver, which has never been established, although the *precision* of the titration has been the subject of several studies.[2]

The second part of this work has led to the discovery of a hitherto unsuspected side reaction (or reactions) that takes place when thiocyanate is precipitated with silver.

Preparation of Pure Potassium Thiocyanate

Potassium thiocyanate from Kahlbaum and the reagent quality product of the Mallinckrodt Company have both been used in this study, and except for a considerable amount of hygroscopic water, the salts were found to be quite pure and suitable starting materials.

Samples of the salt were repeatedly recrystallized from water, ethanol and methanol. Recrystallization from the alcohols is somewhat simpler than from water, with respect to the manipulative details, but we have found that removal of chloride is incomplete on crystallization from alcohol and therefore it is preferable to recrystallize from water when the original salt contains appreciable amounts of chloride. The yield in either case is approximately 50%.

Other samples of the pure salt were prepared by fractional precipitation from a saturated ethanol solution by the addition of ether; four successive fractions were collected.

In all cases, the crystals were collected on a Büchner funnel without paper, the adhering mother liquor was removed by suction, and the products were dried in a desiccator at room temperature. The samples were then heated for an hour at 150° and were finally heated to 200° (m. p. 172°) and kept melted for ten to twenty minutes, to remove the last traces of solvent.

Experiments were made to determine whether chloride and ammonium thiocyanate can be removed completely from potassium thiocyanate by recrystallization from water or alcohol. A sample to which 1% of potassium chloride had been added still contained 0.6% after three recrystallizations from alcohol, but after three recrystallizations from water the final product contained less than 0.005% of chloride.

A sample to which 1% of ammonium thiocyanate had been added contained less than 0.005% of ammonia after three recrystallizations from alcohol or from water.

It was found occasionally that the salt became colored yellow on heating and melting. Systematic study showed that this yellow discoloration was only obtained when the salt was heated in an atmosphere that was slightly contaminated by acid vapors. The discoloration also takes place at room temperature when the dried salt is exposed for some time in an acid contaminated atmosphere. The yellow coloration was more frequently observed with products that had been recrystallized from alcohol, even though the atmosphere in which the salt was heated was entirely free from acid fumes.

The yellow coloration is probably due to the formation of isoperthiocyanic acid ($H_2C_2N_2S_3$) and isodithiocyanic acid

---

[2] *Cf.* I. M. Kolthoff and L. H. van Berk, *Z. anal. Chem.*, **70**, 369 (1927).

$(H_2C_2N_2S_2)$[3] or a mixture of these with the yellow oxidation products described by Offord.[4]

If reasonable care is taken to heat and melt the salt in a pure atmosphere, and to store the dried salt in glass-stoppered bottles in the dark, no trace of the yellow discoloration is formed. Samples prepared in this way are stable indefinitely. In direct sunlight the colorless crystals become yellow fairly quickly. Solutions of the pure salt in pure water are entirely stable, when protected from light. We have kept a solution of the pure salt for eleven months with no detectable change in titer.

Test for Impurities

Water (Alcohol).—Ten grams of the salt should not decrease in weight by more than 1 mg. (0.01%) when melted for ten minutes at 200°.

Chloride.—The test given by Murray[5] was found to be entirely satisfactory. One gram of the salt is dissolved in 50 cc. of water and 20 cc. of chloride-free concentrated nitric acid is added. The solution is heated for two to three hours at 90 to 95° under reflux, and after cooling and addition of a few drops of 0.5 *N* silver nitrate solution, no opalescence due to silver chloride should be observable.

Ammonia.—One gram of the salt is placed on a watch glass and 1 cc. of 4 *N* sodium hydroxide solution is added. The watch glass is covered with a second inverted one of the same size which has a strip of moistened litmus paper adhering to its under side. The presence of 0.001% of ammonia is easily detectable by a blue coloration of the litmus paper after the apparatus has stood for fifteen minutes. The products used by us contained less than 0.001% of ammonia.

Other Impurities.—Other tests given by Murray were found to be satisfactory.

The samples of potassium thiocyanate used in the titrations against silver were pure white, and tests showed that they were entirely free from heavy metals, alkaline earth metals, chloride, ammonia, sulfate, sulfur, cyanate and cyanide.

Drying of Potassium Thiocyanate and Hygroscopicity of the Dried Salt

Three 23-g. samples of potassium thiocyanate, which had been thrice recrystallized from water and dried for a week over phosphorus pentoxide at room temperature, were ground to a fine powder in an agate mortar and placed in large tared weighing bottles with well fitting stoppers. The samples were then subjected to the drying treatment described in Table I. The results with the three samples agreed within the limits of the possible error in weighing, and we therefore give only the data obtained with one sample for the sake of brevity.

TABLE I

LOSS IN WEIGHT OF POTASSIUM THIOCYANATE ON HEATING

Treatment	Wt. of salt, %	Total change in weight, g.
25 hrs. over P_2O_5 at room temp.	23.6163	(0.000)
45 hrs. over P_2O_5 at room temp.	23.6170	+ .003
1 hr. at 100–105°	23.6136	− .011
4 hrs. at 100–105°	23.6125	− .016
1 hr. at 150–155°	23.6083	− .032
3 hrs. at 150–155°	23.6072	− .038
5 hrs. at 150–155°	23.6069	− .039
10 min. at 200–210° (m. p. 172°)	23.6055	− .045
30 min. at 200–210°	23.6036	− .053
1 hr. at 200–210°	23.6065	− .041
1 hr. 40 min. at 200–210°	23.6087	− .032

It is evident from these experiments that no more than 0.02% of water is retained by the salt after heating for one to two hours at 150°. The last trace of water is removed by melting for a short time at 200°.

It will be observed that there was a slight, but definite, increase in weight on prolonged heating of the molten salt at 200°. This increase in weight is probably caused by a slow air oxidation and for this reason the melting period should not be unduly long.

Samples heated in the molten state for fifteen hours at 195° gained 0.05% in weight. Subsequent titration with pure silver solutions as described later showed that the effective strength of these samples was 0.04% less than samples which had been melted for only ten minutes at 200°.

Experiments were next made to determine the hygroscopicity of the dried salt. Twenty-three-gram samples of the solid melts from the drying experiments were crushed and ground to a fine powder in an agate mortar, and, after transferring to tared weighing bottles, they were redried at 150° to remove the water taken up during grinding (0.08%).

After standing for a week over deliquescent calcium chloride hexahydrate (relative humidity, 0.30), and for a week longer over deliquescent potassium carbonate dihydrate (r. h. 0.45), the weight of the dried samples remained unchanged. A sharp increase in weight, which increased rapidly with time, was found when the samples were placed over deliquescent sodium bromide dihydrate (r. h. 0.57). Therefore the dried salt is not hygroscopic at a relative humidity less than 45% but deliquesces rapidly at relative humidities greater than about 50%. This result is in accord with measurements of N. Schoorl (private communication), who found that the aqueous vapor pressure of a saturated potassium thiocyanate solution corresponds to a relative humidity of 0.50 at 13.5°.

Potentiometric Comparison of Potassium Thiocyanate against Silver.—We have studied the accuracy of this titration by direct comparison of pure potassium thiocyanate against pure silver.

Materials

Silver.—Pure silver was prepared according to the classical method of Richards and Wells[6] by reducing twice recrystallized silver nitrate with redistilled ammonia and pure formic acid. Several samples of the metal so obtained were further purified by melting into buttons on charcoal, and electrolyzing these buttons in the usual way.

Silver Nitrate.—Mallinckrodt reagent quality silver nitrate was twice recrystallized from nitric acid and after

drying at 110° the samples were melted for fifteen minutes at 225 to 250° in an electric oven, in platinum.

Water.—Twice distilled water was used for all standard solutions. All other materials used in this work were of a degree of purity consistent with the purposes for which they were used, as shown by appropriate tests.

Standard Solutions.—Standard solutions were prepared by weight, using a large Bunge balance which had a sensitivity of 1 mg. with a full load of two kilograms. Weighings below 200 g. were performed on an ordinary analytical balance. The set of weights used (10 mg. to 1000 g.) was carefully calibrated by the substitution method. Weighings were corrected to vacuum on the following density basis; weights 8.4, air 0.0012, potassium thiocyanate 1.91, silver nitrate 4.35 and silver 10.5 g. per cc.

The stock solutions were prepared and stored in specially constructed one-liter Erlenmeyer flasks, provided with finely ground glass stoppers carrying sealed-in delivery tubes similar to an ordinary wash bottle. The ends of the delivery tubes were closed with ground glass caps. These storage flasks were modeled after the storage bottles described by Lange and Schwartz.[7]

Potassium thiocyanate and neutral silver nitrate solutions were prepared from samples of the pure fused salts.

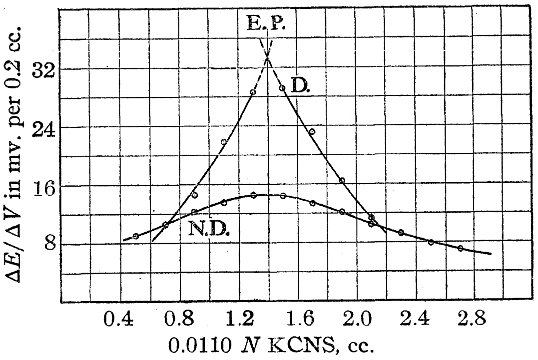

Fig. 1.—$\Delta E/\Delta V$ curves in region of equivalence point in final titrations of a digested and undigested precipitate: D., digested; N. D., not digested.

Acid silver solutions were prepared by dissolving carefully weighed buttons of the purified metal in an excess of 6 *N* nitric acid in a Kjeldahl flask. After diluting and heating to remove residual oxides of nitrogen, the solution was transferred to a previously weighed storage flask, diluted to *ca.* 800 cc. and weighed. The free acid concentration of these silver solutions (*ca.* 0.02 *N*) was determined by titrating suitable samples with standard sodium hydroxide, using brom cresol green indicator.

The standard stock solutions were approximately 0.2 molal. Twenty times diluted solutions (*ca.* 0.01 *N*) of each of the stock solutions were prepared using calibrated volumetric apparatus.

Apparatus and General Procedure of the Titrations

The usual potentiometric apparatus was used, allowing e. m. f. readings to ±0.1 mv. The silver electrodes were prepared by plating small platinum gauze electrodes (cylinders of 1 cm. diameter and 1 cm. in length) with silver from a potassium argenticyanide bath at low c. d. The saturated calomel and saturated mercurous sulfate reference electrodes were of the simple bottle type recommended by Müller.[8] The bridge tubes were of the inverted U-type, filled with a gel of saturated potassium sulfate in 3% agar.

The titrations were performed in very faint diffuse daylight in a room with closely drawn shades. As a further precaution against light decomposition, the 250-cc. titration beaker was placed in a closely fitting brown glass jar. Efficient mechanical stirring was employed in all measurements and titrations, using a small electric induction motor and a glass stirrer of the propeller type.

The general procedure of titration consisted in weighing out 40 to 50 g. of the stock silver solution into a small tared and stoppered flask directly from the storage flask (silver solutions cannot be dispensed from weight burets with greased stopcocks), transferring to a 250-cc. beaker and diluting to 125 cc., with or without the addition of nitric acid. The stock thiocyanate solution was then added from a weight buret over a period of three to five minutes, with constant stirring, until the measured e. m. f. indicated close approach to the equivalence point.

In some titrations it was desired to add the titrating solution very slowly over a period of fifteen to thirty minutes and for this purpose a special dropping funnel, without a stopcock, similar to the one described by Johnson[9] was used.

In some titrations a slight deficiency of potassium thiocyanate solution was added, and in others a slight excess was added. The titration was finally finished with the appropriate dilute solution (*ca.* 0.01 *N*), added from a 5-cc. microburet. The location of the equivalence point was found in the usual manner by calculating the point at which $\Delta E/\Delta V$ attained a maximum value.

The final titration was made very slowly, with care to obtain constant potential before adding successive increments of the dilute titrating solution. It required about one to one and a half hours for the final titration.

It was found that the titration could be made more quickly, and a more pronounced maximum in $\Delta E/\Delta V$ was obtained, when the mixture was heated to 70 to 90° for ten minutes after the addition of the stock thiocyanate solution, and cooled to room temperature again before the final titration. In this way the bulk of the precipitate is subjected to a drastic aging which causes a marked decrease in its adsorptive properties toward silver and thiocyanate ions.[7] In Fig. 1 the data of two final titrations in the region of the equivalence point have been plotted to illustrate this difference in the behavior of digested and undigested precipitates. In both cases the maximum in $\Delta E/\Delta V$ comes at the same place, but the break is more pronounced with digested precipitates.

Considerable time is required to obtain constant e. m. f. readings during the titration, especially with undigested precipitates. Constant potential was obtained more quickly when an excess of thiocyanate solution was added, and the final titration was made with the dilute silver solution, than when the reverse procedure was employed. Ad-

dition of barium nitrate as recommended by Müller[8] was not conducive to more rapid attainment of steady potential, the drift in potential, and the time required for the drift to decrease to a negligible magnitude, were practically the same as when no barium nitrate was present.

In order to show the precision of the comparisons the data of a typical titration are given in Table II.

TABLE II

DATA OF A TYPICAL TITRATION

52.476 grams of 0.17828 molar silver nitrate solution diluted to *ca.* 125 cc. and 1 cc. of concd. nitric acid added. 48.729 grams of 0.19131 molar potassium thiocyanate solution (salt recryst. once from alcohol) added from weight buret at room temperature. Mixture heated to 70 to 90°, digested ten minutes, and cooled to room temperature. Titration completed with 0.00955 M thiocyanate solution from microburet. Saturated mercurous sulfate reference electrode.

0.00955 N KCNS, cc.	E, volts	$\frac{\Delta E}{\Delta V}$	$\frac{\Delta^2 E}{\Delta V^2}$
0	+0.0800		
3.4	.1411		
3.6	.1558	147	
3.8	.1774	216	+68
4.0	.2058	284	−23
4.2	.2319	261	
4.4	.2519	200	

$V = 3.8 + 68/(68 + 23) \times 0.2 = 3.95$ cc. Correction to thiocyanate solution, +0.197 g. Total thiocyanate solution, 48.729 + 0.197 = 48.926 g. wt. $AgNO_3$ soln./wt. KCNS soln. = 52.476/48.926 = 1.0725 (calcd. 1.0731.) Effective strength of KCNS, 99.94%.

Five other titrations, using the same sample of potassium thiocyanate, yielded the following results, in terms of the effective strength of the salt: 99.96, 99.93, 99.90, 99.90 and 99.93%, or an average of 99.93% for the six titrations.

Products recrystallized two to five times from water and alcohol, and the samples obtained by fractional precipitation of a saturated alcohol solution of the salt with ether, were tested in a similar way.

The detailed results of these titrations are not given here but may be found in the thesis of the junior author.[10] It suffices here to state that the final average obtained with twelve different products corresponded to an effective strength of 99.92% for the potassium thiocyanate.

Titrations carried out in neutral solution at room temperature, and with varying concentration of nitric acid (0–0.5 N), indicated that the acidity did not influence the results. However, when the potassium thiocyanate was added to a hot (80–90°) neutral or acid (nitric) silver solution, the average effective strength of the potassium thiocyanate was 100.05%. When the hot silver solution was acidified with sulfuric acid (0.06 N) the effective strength of the potassium thiocyanate was several tenths of a per cent. too high.

The reverse order of precipitation was also used in several titrations in neutral and dilute nitric acid solution; *i. e.*, the silver nitrate solution was added to the thiocyanate solution. The results agreed with the data of the former experiments, which showed that the order of the precipitation is without influence in the titrations.

Titration to the Equivalence Potential.—Since the precision of this method is dependent on an exact knowledge of the equivalence potential, it is of prime importance to determine this value in an accurate way. A simple method has been proposed by Kolthoff[11] for determining the equivalence potential by titration. The method consists in performing a titration with very dilute solutions of known concentration, calculating an empirical equilibrium constant for the reaction from the titration data, and finally calculating the equivalence potential from the equilibrium constant. In this way the solubility product of silver thiocyanate in neutral 0.05 N potassium nitrate solution was found to be 3.2×10^{-12} at 24°, and the corresponding equivalence potential against the saturated mercurous sulfate electrode was +0.176 v., which agrees well with the value +0.175 v. found from the maximum in $\Delta E/\Delta V$. By a similar titration it was found that the equivalence potential in a solution 0.05 N in potassium nitrate and 0.032 N in nitric acid (which duplicates the conditions in the titrations described below) was +0.187 ± 0.002 v.

Titrations were performed by adding thiocyanate solution to a slight excess of silver solution, and finally adding dilute thiocyanate solution until the measured e. m. f. remained constant at +0.187 ± 0.002 v. for at least fifteen minutes. In four such titrations to the equivalence potential, the average effective strength of the potassium thiocyanate was found to be 99.92%. These results are in exact agreement with those obtained by locating the equivalence point from the maximum in $\Delta E/\Delta V$.

Titration by the Volhard Method.—Some titrations were made by the classical Volhard method employing ferric iron as indicator. The thiocyanate solution was added to a slight excess of silver solution and the excess was titrated back with the *dilute thiocyanate solution. The indicator* blank was found to be 0.10 cc. of 0.01 N thiocyanate, using 4 cc. of a saturated ferric alum solution as indicator, in a final volume of 200 cc., and this value was applied as a correction in the titrations. A comparison flask, containing the same amount of precipitate and ferric alum indicator with a slight excess of silver present, was used to assist in locating the color change. The end-point was taken when the yellowish-brown coloration persisted after a minute or two of vigorous shaking.

The results showed an effective strength for the potassium thiocyanate that varied between 100.01 and 100.05%, the average being 100.02%. These results, 0.10% higher than the potentiometric comparisons, indicate that adsorption equilibrium is not reached in the relatively rapid Volhard titration, and that an excess of silver is retained by the precipitate at the visual end-point. In the potentiometric titrations, which require more than an hour, the silver nitrate, co-precipitated by the precipitate, is given off during the time required to obtain constant e. m. f.

The correctness of this conclusion was verified by adding a slight known excess of silver nitrate to the suspension remaining after potentiometric titrations in which the pre-

(11) I. M. Kolthoff, *Rec. trav. chim.*, **47**, 397 (1928).

cipitate had been digested. The slight excess of silver was then titrated back with the dilute thiocyanate solution after the addition of 4 cc. of saturated ferric alum indicator. The effective strength of the potassium thiocyanate calculated from the results of two such titrations was only 0.01% higher in both cases than the value determined from the potentiometric end-point.

A Side Reaction During the Precipitation of Thiocyanate with Silver.—Although the methodical precision of the potentiometric titrations was better than 0.01%, the results frequently varied by as much as 0.05% under identical conditions of titration. Furthermore, the effective strength of the various preparations of potassium thiocyanate was consistently in the neighborhood of 99.92% instead of exactly 100.00%, although no impurities could be found in any of the products. These facts pointed to the occurrence of a side reaction (or reactions) accompanying the precipitation of silver thiocyanate.

When a hot, acid silver solution was precipitated with thiocyanate the effective strength of the thiocyanate was definitely greater than 100%. Further, when a hot, neutral silver solution was treated with thiocyanate, the precipitate was colored a light tan, even when the precipitation was made in the dark. From hot dilute sulfuric acid solution the precipitates were pure white, but the effective strength of the potassium thiocyanate was several tenths of a per cent. greater than 100%.

Some of the tan precipitates from hot neutral solution were washed with water and suspended in a weak acetic acid solution containing excess potassium iodide. A strong odor of hydrogen sulfide was observed and a test for hydrogen sulfide was obtained with a moistened lead acetate paper placed in the mouth of the flask.

It was thought that an air oxidation of thiocyanate might have been induced during the precipitation, but the results obtained in potentiometric titrations in an atmosphere of nitrogen were the same as in air, and tan colored precipitates were also obtained in the absence of air.

Another possibility was that silver, being a rather strong oxidizing agent under certain conditions, might oxidize a minute fraction of the thiocyanate with the formation of cyanide, or cyanate, and thionic acids. A test was developed which was capable of detecting as little as 0.01% of cyanide in the precipitate but no indication of the presence of cyanide was obtained.

It was thought that some cyanate might be formed according to the reaction

$$2\text{CNS}^- + \text{O} + 2\text{H}_2\text{O} \longrightarrow 2\text{CNO}^- + 2\text{S}^{=} + 4\text{H}^+ \quad (1)$$

with the simultaneous precipitation of the sulfide by silver or its oxidation to thionic acids or sulfate, depending on the conditions. Cyanic acid is a weak acid which decomposes very easily

$$\text{HCNO} + \text{H}^+ + \text{H}_2\text{O} \longrightarrow \text{NH}_4^+ + \text{CO}_2 \quad (2)$$

Thus, if cyanate were an intermediate product of the side reaction, ammonia should be present in the final solution. This was actually found to be true.

The traces of ammonia, formed under various conditions of precipitation of thiocyanate with silver, were determined in the supernatant solution by making alkaline with ammonia-free sodium hydroxide, distilling in an all-glass apparatus and collecting the distillate in 10 cc. of 0.001 *N* sulfuric acid. The amount of ammonia in the distillate was estimated colorimetrically with Nessler's reagent. Ammonia-free reagents were used. According to the procedure developed, 0.005 mg. of ammonia in 90 cc. of solution could be detected with certainty.

Table III

Formation of Ammonia During Precipitation of Silver Thiocyanate

1.75 g. of AgNO_3 in 100 cc. of water and 0.97 g. of KCNS in 75 cc. of water for each experiment. 1 cc. excess of 4 *N* NaOH added to 90 cc. of supernatant solution and distilled for 30 min. in current of pure air.

	Conditions of precipitation	NH_3 in 10 cc. of distillate, mg.
1	KCNS $\longrightarrow$ AgNO_3, 0.2 *N* in HNO_3, room temp.	0.03
2	As (1), except at 80–90°	.07
3	As (1), except both solutions boiled 2 min. before mixing, and boiled during precipitation	.04
4	As (1), except air displaced with NaHCO_3	.03
5	KCNS $\longrightarrow$ AgNO_3, neutral, room temp.	.03
6	KCNS $\longrightarrow$ AgNO_3, neutral, 80–90°	.05
7	As (5), except 0.5 g. of borax present	.03
8	As (7), except AgNO_3 $\longrightarrow$ KCNS	.02
9	KCNS $\longrightarrow$ AgNO_3, 0.2 *N* in H_2SO_4, room temp.	.03
10	As (9), except at 80–90°	.07

It will be observed that practically the same amount of ammonia was formed in the absence as in the presence of air. More ammonia was found when the precipitation was made in hot solution than when the precipitation was made at room temperature.

Discussion of Results

Although the end-point of the potentiometric titration can be found with a precision of better than 0.01%, the titration of silver with thiocyanate is not suited to work of a highly exact nature. As a result of the side reactions, the variations between duplicate titrations at room temperature may amount to as much as 0.05%, the average result corresponding to an effective strength of the potassium thiocyanate of 0.08% less than the theoretical.

The Volhard method of locating the end-point leads to the same result when the precipitate is digested with a slight excess of silver before the final titration. In the ordinary Volhard method at room temperature without digestion, the average effective strength of the potassium thiocyanate is 0.02% higher than the theoretical, and 0.10% greater than the effective strength found potentiometrically or after digestion, because 0.10% of the silver nitrate is still adsorbed or occluded by the precipitate at the end-point. The relatively good results obtained by the ordinary Volhard method are thus due to a compensation of errors.

Potassium thiocyanate may be recommended as a standard substance in work of ordinary accuracy.

Summary

1. Potassium thiocyanate is easily obtained in a pure state and is a suitable standard substance for work of ordinary accuracy (±0.1%).

2. During the precipitation of silver with thiocyanate, or the reverse, slight side reactions occur in which cyanic acid is an intermediate product decomposing to ammonia and carbon dioxide. When a hot neutral silver solution is precipitated with thiocyanate the precipitate is colored tan by silver sulfide. The side reactions also take place in the absence of oxygen.

3. As a result of the side reactions, the average effective strength of the potassium thiocyanate in the potentiometric titration with silver at room temperature is only 99.92%.

4. If titrated at 70 to 90° an effective strength slightly greater than 100% is found. If the precipitation is carried out in hot dilute sulfuric acid (0.06 *N*), the deviation is several tenths of a per cent. greater.

5. The ordinary Volhard titration at room temperature leads to an effective strength 0.10% greater than the potentiometric titration, due to occlusion of silver nitrate at the end-point. If the precipitate is digested just before the end-point, the Volhard method gives results practically identical with the potentiometric method.

6. The solubility product of silver thiocyanate at 24° in 0.05 *N* neutral potassium nitrate solution is equal to 3.2×10^{-12}.

The Formation of Zirconeate Hydrosols and their Disintegration by Certain Neutral Salts

BY ARTHUR W. THOMAS AND HARRY S. OWENS

In a previous publication,[1] the *p*H raising action of neutral salts upon basic zirconium chloride (sometimes designated as "zirconium oxide") hydrosols was ascribed to the replacement of OH groups from the polyolated micelles by the anions of the added neutral salts. If the strongly coördinatively bound OH group can thus be displaced from the central metallic atom by added anions, one would expect other coördinatively bound groups also to be displaceable.

Increases in chloride ion activity of "oxide" hydrosols have been reported to result upon addition of neutral salts.[2] Inasmuch as the order of effectiveness of the anions of the salts in raising the chloride ion activity is in general similar to those reported from this Laboratory for displacing OH groups from the micelle, the writers submit this as evidence for the expected displacement of chlorido groups. Removal and replacement of aquo groups from the central metallic atom by

---

[1] A. W. Thomas and H. S. Owens, THIS JOURNAL, **57**, 1825 (1935).

[2] (a) P. S. Wassiliev and A. J. Rabinowitch, *Kolloid Z.*, **56**, 305 (1931); (b) H. B. Weiser, *J. Phys. Chem.*, **35**, 1, 1368 (1931); (c) A. Lottermoser and T. Chang, *Kolloid Z.*, **65**, 62 (1933); (d) W. Pauli and E. Valkó, "Elektrochemie der Kolloide," Julius Springer, Vienna, 1929, p. 527.

added anions would likewise be expected. If so, then the positive charge of the micelle would be reduced and perhaps reversed.

The reversal of the sign of charge of cationic "metallic oxide" micelles by added electrolytes has been ascribed by some investigators to the adsorption of the added ions to the surface of the micelle. These investigators, reasoning from the physical point of view, base their arguments on *zeta* potential measurements such as those of Powis[3] with oil emulsions and of Kruyt[4] with glass–water interfaces. Their work has led to the following conclusion which is the main tenet of the adsorption advocates: "if the *zeta* potential is positive, it is influenced more by anions and the influence increases with the valency of the effective ions, unless the ion is strongly adsorbed."[5] Since the degree of adsorption of organic ions increases with valence and molecular complexity, one would not expect simple univalent organic anions to be as potent as divalent in reversing the charge of the cationic micelle. However, inasmuch as glycolate and lactate readily reverse the charge of basic zirconium chloride micelles while succinate or oxalate either do not or only under limited experimental conditions the weakness of the adsorption argument is apparent.

A chemical type of explanation has been suggested by Pauli,[6] who explains irregular series formation with "iron oxide" hydrosols by assuming that stable complex formers such as pyrophosphate or ferrocyanide react with the surface bound basic ferric chloride in the following way

$$\mathrm{Fe(OH)_2Cl + Na_4P_2O_7 \longrightarrow (FeP_2O_7)^-Na^+ + 2NaOH + NaCl}$$

while trivalent ions of the same type do not form negative particles since they can react to form neutral molecules[7]

$$\mathrm{Fe(OH)_2Cl + K_3Fe(CN)_6 \longrightarrow Fe[Fe(CN)_6] + 2KOH + KCl}$$

Further, he claims, with alkaline hydrolyzing salts like phosphates and citrates, the reversal always results with an excess of OH^- ion, whereas at lower concentrations the discharging by means of OH^- takes place with salts with high valence anions through the simultaneous action of the anion and OH^-. A model for this discharging and reversal reaction is

$$\mathrm{Fe(OH)_2Cl + KOH \longrightarrow Fe(OH)_3 + KCl}$$
$$\mathrm{Fe(OH)_3 + KOH \longrightarrow (Fe(OH)_4)^-K^+}$$

The charge on the sols can be due to ions varying in nature from $(Fe(OH)_4)^-$ to $(FeAnOH)^-$ in which "An" is a trivalent anion.

Inasmuch as the writers have in the case of basic zirconium chloride sols succeeded in reversing the micellar charge by the addition of certain acids, and addition of salts with anions of various valencies while maintaining the *p*H value below 7, the explanation by Pauli does not apply.

The writers have found that the anions listed in "Group A" of Table I reverse cationic basic zirconium chloride micelles to anionic zirconeate micelles while those in "Group B" do not.

TABLE I

Group A	Group B
Citrate[a]	Acetate
Glycolate[a]	β-Hydroxybutyrate
Lactate[a]	Chloride
Malate[a]	Ethoxyacetate
Mucate[a]	Ferricyanide
Pyruvate	Ferrocyanide
Tartrate[a]	Formate
Dihydrogen phosphate[b]	Fumarate
Pyrophosphate[b]	Glycine
	Maleinate
	Monochloroacetate
	Monohydrogen phosphate
	Oxalate
	Phosphate
	p-Hydroxyphenylglycine
	Propionate

[a] These salts were also found to peptize freshly prepared hydrated zirconium oxide to zirconeate hydrosols. The three salts in Group A not marked [a] were not tried. The salts in Group B would not, of course, be expected to peptize the oxide. [b] Provided medium was not too alkaline.

The conditions necessary for reversal of cationic to anionic micelles by added salts are: (1) ability of the salt anion to displace aquo groups from the cationic micelle, (2) the formation of a soluble anionic complex and (3) the equilibrium constant of the anionic complex must be near to or less than the solubility product of zirconyl hydroxide.

The first is essential to reversal of charge and inasmuch as the majority of anions in Group B possess known coördinative binding powers, they

(7) Pauli and Neurath[6] state that because the stabilizing agent is distributed over the surface of the oxide micelle, it is impossible for the stabilizing agent to react with quadrivalent radicals to yield neutral complexes.

must be able to displace aquo groups. If they do displace a number sufficient to reverse the charge, their failure to repeptize the precipitated cationic basic zirconium complexes resulting upon their additon to the hydrosol means that the complexes either are insoluble or unstable, or both.

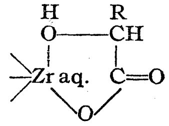
The anions in Group A must fulfill the conditions stated. The range of concentration in which charge reversal is effected is always very narrow. For example, the case of addition of potassium malate to Sol E[8] may be cited. At a malate concentration of 0.0035 *N* its micelles were positively charged, its *p*H was 4.65 and it was clear. At a malate concentration of 0.005 *N* it was a slightly turbid malato zirconeate hydrosol with a *p*H value of 7.40. Between these concentrations of malate the dispersed phase was all precipitated. Calculations show that more than 90% of the added malate was available to maintain equilibrium conditions and to react with the cationic micelle in some way other than displacement of OH groups. With the exception of the possible action of a small part of the malate in displacing chloride groups, part of the balance must have displaced aquo groups in order to confer the negative charge.

Inasmuch as hydrolysis (conversion of aquo to hydroxo groups) lowers the positive charge of basic metallic salt micelles, boiling of a sol (which process also favors olation and oxolation) should reduce the amount of added anion required to precipitate and reverse the charge of the micelles. A typical case may be cited. Sol E required (a) a concentration of 0.005 *N* potassium tartrate for precipitation and (b) 0.0088 *N* for conversion to tartrato zirconeate sol. After boiling under a reflux condenser for one hundred and ninety-two hours (a) = 0.0025 and (b) = 0.005.

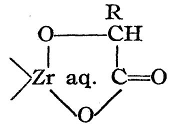
The zirconeate sols formed by addition of the Group A (Table I) salts to basic zirconium chloride sols were very stable, being unaffected by addition of alkali (excepting phosphate and pyrophosphate) and it is significant that all are α-hydroxy compounds.[9] It is interesting in this connection to refer to the chemistry of crystalloidal zirconium compounds. De Boer[10] has shown that the ability of ions to form complex compounds with zirconium is in the following order: α-hydroxy organic salts[11] (in alkaline solution) $> OH > C_2O_4 > SO_4 > Cl$ (in acid solution) and Mandl[12] found a similar order: α-hydroxy organic salts $> C_2O_4 >$ maleinate $>$ saturated monobasic or dibasic organic acid salts.

The stability of metal–α-hydroxy complexes has for many years been ascribed to the ability of the α-hydroxy group to react with the metallic ion. There are two possible types of compounds (1) comparable to the β-diketone chelates[13] and (2) one in which the hydroxy group acts as an acid.[14]

These types would be formulated as follows.



I



II

In "type I," negative micellar formation should be possible with radicals like monochloroacetate or ethoxyacetate, yet each of these acts like acetate when added to basic zirconium chloride sols. Evidently, ability of the α-substituted group to act as a donor of electrons to the metal has little effect on its ability of causing reversal of charge.

If "type II" illustrates the compound formed during chelation, then hydrogen ion should be liberated. An indication that such a reaction takes place is obtained from OH displacement experiments with salt mixtures, typical results of which are given in Table II. It is striking that mixtures of anions which do not reverse the charge of the micelles produced nearly the same *p*H values, while oxalate–lactate and oxalate–tartrate mixtures gave lower *p*H values. Chelation as illustrated by type II would account for the *p*H differences found and for the stability of the zirconeate hydrosols. Oxalate precipitates basic zirconium chloride sols without reversing the charge but subsequent addition of a salt of an α-hydroxy acid peptizes the precipitate to a complex zirconeate sol. Further, if sufficent α-hydroxy salt is first added to a basic zirconium chloride sol, subsequent addition of oxalate produces no precipitate. These behaviors are entirely in accord with the properties of crystalloidal zirco-

---

(8) Sol E had a *p*H value of 3.50 (at the time of this experiment), its total Zr and total Cl contents were 126.2 and 11 milliequivalents per liter, respectively. Its micelles were cationic.

(9) The enol form of pyruvate exists in increasing concentration as the *p*H is raised.

nium solutions where in almost every case α-hydroxy groups form more stable complexes than any other groups.

TABLE II

EFFECT OF ADDITION OF SALT MIXTURES TO SOL B[a]

(I)[b]	(II)[b]	pH
..	0.05 Oxalate	7.42
0.001 Tartrate	.05 Oxalate	7.23
.005 Tartrate	.05 Oxalate	7.01
.05 Tartrate	.05 Oxalate	6.86
.05 Lactate	.05 Oxalate	7.02
.05 Acetate	.05 Oxalate	7.34
.05 Sulfate	.05 Oxalate	7.34
.05 Oxalate	.05 Tartrate	6.88

[a] "B" was a basic zirconium chloride hydrosol, pH value = 3.22, total Zr and total Cl = 89.1 and 11.2 milliequivalents per liter, respectively. [b] (I) Solid potassium tartrate, acetate, sulfate or an 85% solution of potassium lactate was first added to the hydrosol. Then (II) a solution of potassium oxalate (or of tartrate) equal in volume to the hydrosol was added and the pH value of the mixture determined. The numbers in Columns I and II denote the normality of the salts in the resulting mixture of hydrosol and salt solution.

Ability to chelate does not necessarily mean that the anion will be capable of reversing the sign of the charge on the cationic sol particles, as illustrated by the case of glycine. This compound readily chelates with metallic ions in solution;[15] however, it affects basic zirconium chloride sols to but a slight extent. The authors were unable to precipitate a dilute sol containing cationic micelles with a large excess of glycine. Weitz and Conrad[16] report similar findings with glycine and aminobenzoic acids mixed with basic ferric chloride ("ferric oxide") hydrosols.

Deolation to the Crystalloidal State.—Since powerful coördinative binding ions weaken the ol linkage,[17] the α-hydroxy organic salts might be expected ultimately to effect disruption of ol bonds. According to the postulates from this Laboratory that "metallic oxide" hydrosols are polyolated structures, the salts mentioned should decompose an "oxide" sol to the crystalloid state. This postulate was tested in the following manner. To each of three portions of a basic zirconium chloride hydrosol was added, respectively, an equal volume of 0.1 N potassium citrate, tartrate and glycolate. The resulting zirconeate hydrosols were dialyzed in nitrocellulose bags against distilled water at room temperature. The diffusate contained zirconium (tested by the phosphate method) in each case but not in the instance of a control dialysis of the untreated basic zirconium chloride sol. As the dialysis continued the amount of zirconium diffusing decreased, but on further addition of the original salt solution to the dialysate more diffusible complexes were formed. These diffusions and additions of salt were continued until there was but a trace of zirconium left in the dialysate. With the potassium citrate the time of dialysis required to disintegrate the colloidal micelles was three hundred and fifty to four hundred hours,[18] with potassium tartrate four hundred to five hundred hours,[18] with potassium glycolate the time required was still longer. This order of ability to deolate the colloidal micelles, citrate > tartrate > glycolate, is the same as the tendency for these anions to become coördinatively bound with zirconium, as shown by titration experiments with basic zirconium chloride hydrosols.[1]

Zirconeate Hydrolysis of Low pH Value.—Basic zirconium chloride sols (Zr in the cationic micelle) which are of low pH value can be changed to zirconeate sols (Zr in the anionic micelle) by the careful addition of any of the following acids: citric, glycolic, lactic, oxalic, pyruvic,[19] sulfuric and tartaric. Zirconeate sols thus formed can exist only on account of the strong tendency of basic zirconium complexes to oxolate.[1] The oxo linkages are resistant to acids and thus render possible the existence of polynuclear complexes. The micelles are negatively charged because the anions of the acids named, strong coördinative binders, replace aquo groups from the central metallic atoms.

Acid zirconeate hydrosols may be prepared also by the action of acids (with powerful coördinative binding anions) upon hydrated zirconium dioxide. In studying the course of the peptization of such an oxide by tartaric acid, both positive and negative zirconium micelles arose in the same solution. This is so contrary to the accepted notions of colloid chemistry that a description of the experimental procedure is important.

A solution of $ZrOCl_2 \cdot 8H_2O$ was treated with ammonium hydroxide to complete precipitation of the zirconium. The precipitate was washed

(19) Pyruvic acid acts very slowly.

at room temperature by means of centrifugal decantations until the supernatant liquid was free from chloride ion. It was then suction filtered and air dried at room temperature for twenty-four hours. Portions of this hydrated oxide equal to 1 g. of zirconium oxide were immediately[20] placed in 200-cc. portions of water to which the amounts of tartaric acid reported in Table III were added. Then, with the exception of the last stated case in Table III, the systems were rotated at 7 r. p. m. at 25 ± 0.2° for twenty-four hours. In the last stated case, the system was boiled under a reflux condenser for twenty-four hours. Then all were centrifuged to throw down the unpeptized oxide. The supernatant liquids which were turbid to reflected light while clear to transmitted light were subjected to the tests recorded in Table III.

TABLE III

PEPTIZATION OF A HYDRATED ZIRCONIUM OXIDE BY TARTARIC ACID

Tartaric acid, g.	Temp., °C.	Dispersed zirconium calcd. as milliequiv. ZrO_2 per liter	*p*H	Migration in electric field[a]
0.08	25	6	4.95	+ and −
.16	25	9	4.41	+ and −
.62	25	15	2.80	+ and −
.62	100[b]	112	2.27[c]	.....

[a] Migration of zirconium-containing micelles; + to cathode, − to anode. [b] In this instance, instead of agitating the system at 25°, it was boiled in a Pyrex glass reflux condenser apparatus for twenty-four hours. [c] In this case, the *p*H of the hydrosol was lower than of the original tartaric acid solution.

The startling fact shown in the table is the coexistence of cationic and anionic micelles. This fact was demonstrated by electrophoresis measurements upon the freshly prepared sols in a Coehn tube. The cationic micelle migrated faster than the anionic, thus indicating a greater charge density for the former. Probably none of the anionic micelles (tartrato zirconeate) would have been present were the systems allowed to stand for a longer time, as in the case of the peptization carried out at boiling temperature. The basic zirconium tartrate (cationic) micelles arise owing to the combination of H^+ ions with hydroxo groups of the hydrated oxide, forming aquo groups and thus conferring a positive charge upon the polynuclear complex. The tartrato zirconeate (anionic) micelles arise owing to the preponderant coördinative binding of tartrate ions over H^+ ions through displacement of aquo groups. The polynuclear zirconium or zirconeate complex would ultimately disintegrate to small particles if the complexes were not highly oxolated.

This is probably the first reported instance of the occurrence of positive and negative micelles in the same solution. The sols were rather dilute, however, and hence one can conclude that the solubility products of the sundry complex basic zirconium zirconeates present were not exceeded.

The subject of these acid dispersions of zirconeate micelles is being investigated further by one of us (H. S. O.).

Summary

Certain neutral salts convert basic zirconium (cationic) micelles to zirconeate (anionic) micelles while others do not. Certain neutral salts disintegrate basic zirconium ("zirconium oxide") micelles to the crystalloidal state. Zirconeate hydrosols of low *p*H value may be formed by the action of certain acids upon hydrated zirconium oxide. The possibility of the coexistence of positively and negatively charged micelles has been demonstrated. The polyolation and oxolation theory of the structure of "metallic oxide" hydrosol micelles proposed by this Laboratory renders possible the prediction and understanding of these behaviors.

NEW YORK, N. Y.

RECEIVED JULY 9, 1935

---

[20] This hydrated zirconium oxide becomes refractory on aging, presumably due to oxolation. After forty-eight hours of standing at room temperature the amount peptizable by tartaric acid was decreased to about one-third of its former value. A specimen six months old was resistant to the action of boiling concentrated hydrochloric acid.

Titrimetric Determination of Water and Alcohols by their Acid Catalyzed Reactions with Acetic Anhydride in Organic Media

BY GERRIT TOENNIES AND MARGARET ELLIOTT

The present work is an outgrowth of earlier observations on the acid catalyzed hydration of acetic anhydride in acetonitrile[1,2] and of a non-aqueous titration method[2] developed in this connection. For a review of the pertinent literature on the determination of water and alcohols reference is made to two papers by Smith and Bryant[3] which appeared while the present study was in progress. The method reported here is different in principle and scope from that of Smith and Bryant so that depending upon the nature of the analytical problem the one or the other will be preferable.

It was previously[2] shown that acetic anhydride can be titrated accurately in organic media by sodium methylate in methyl alcohol with thymol blue as an indicator according to

$$(CH_3CO)_2O + OCH_3^- \longrightarrow CH_3COOCH_3 + CH_3COO^- \quad (1)$$

while after hydration double the amount of methylate is consumed.

$$(CH_3CO)_2O + H_2O \longrightarrow 2CH_3COOH \quad (2)$$

$$2CH_3COOH + 2OCH_3^- \longrightarrow 2CH_3OH + 2CH_3COO^- \quad (3)$$

It was observed in this connection also that reaction (2) in dilute solution in acetonitrile is extremely slow, while in the presence of perchloric acid (0.1 M as cystine perchlorate) the reaction is complete in less than one hour. On account of certain disadvantages of perchloric acid (its liquid nature, uncertain degree of hydration and tendency to decompose with oxidation in the dehydrated state) in the present study 2,4-dinitrobenzenesulfonic acid was used as the acid catalyst. This acid was shown by Elgersma[4] to be comparable in acid strength with the strong mineral acids, it is easily obtained in a non-hygroscopic crystalline form with 2 molecules of water and it appears stable in a dehydrated solution. A concentration of this acid of the order of 10^{-3} M is sufficient catalytically to complete the above reaction (2) in organic media within from one hour to one day, depending on the nature of the medium. The reactions

$$(CH_3CO)_2O + ROH \longrightarrow CH_3COOR + CH_3COOH \quad (4)$$

($R = CH_3^-, C_2H_5^-$) were found to be accelerated to a similar degree, while the ester reaction

$$CH_3COOH + ROH \rightleftarrows CH_3COOR + H_2O \quad (5)$$

in both directions proved to be very slow under similar conditions compared with reactions (2) and (4). These circumstances permit determination of water by its acid catalyzed reaction with an excess of acetic anhydride according to equation (2), the molar amount of water present being equal to the increase in titration value compared with a blank, according to equations (1) and (2, 3). Alcohol can be determined by first letting reaction (4) go to completion in presence of excess anhydride and then decomposing the unused anhydride by excess water according to equation (2), while in a blank the same amount of anhydride is made to react directly with excess water. The difference between the two titrations is equal to the molar amount of alcohol present since each hydrolyzed molecule of anhydride consumes two equivalents of base while each alcoholized molecule consumes only one. Comparison of equations (1) and (4) will also show that in the water determination the presence of alcohol does not interfere since in the methylate titration acetic anhydride uses the same amount of base whether it has reacted with an alcohol previous to the titration or not.

The present investigation has been limited to establishing the principles and practicability and examining the accuracy and limits of sensitivity of the proposed method. The technique to be followed varies according to the problem at hand, and the examples given further on will enable the reader to adapt the method to his needs.

Experimental

Reagents.—2,4-Dinitrobenzenesulfonic acid was prepared according to Elgersma.[5] By dissolving 100 g. of the crude trihydrate in 440 cc. of acetonitrile and precipitating with 7.5 volumes of benzene the dihydrate was obtained in almost colorless crystals; equivalent weight by aqueous titration: found, 284.2, 283.8; calcd., 284.15.

The yield is at least 50% in terms of initial chloro-2,4-dinitrobenzene. The dihydrate should not be stored in a closed container until acetonitrile has been very completely removed as the latter will react on standing with the crystal water with resulting odor of acetic acid.

$$CH_3CN + H_2O \longrightarrow CH_3COONH_4 \qquad (6)$$

$$CH_3COONH_4 + RSO_3H^{6} \longrightarrow RSO_3NH_4 + CH_3COOH \qquad (7)$$

A 0.1 *M* solution of the acid in dry acetonitrile (Merck Reagent) undergoes a slow change according to equations (6) and (7) (*cf.* also Ref. 2), but if kept at 0° can be used for several weeks.

A 1 *M* solution of acetic anhydride (Merck Reagent, about 95% $(CH_3CO)_2O$) in dry acetonitrile remains unchanged for months at room temperature.

A 1 *M* solution of water in acetonitrile is also stable for months.

A 0.1 *M* solution of sodium methylate in methyl alcohol (Merck Reagent) keeps a stable titer if it is set up in a closed titration system, protected against carbon dioxide and evaporation. Its absolute value is established by comparing it with standard sodium hydroxide in presence of an equal methanol concentration (about 15%) by titration against hydrochloric acid, using a (minor) correction for the effect of the methanol on the methyl red end-point. Regarding the standardization of sodium methylate *cf.* also Reference 2.

Thymol blue (Hynson, Westcott and Dunning) was used in a 0.125% methyl alcohol solution neutralized with 1 mole equivalent of sodium methylate solution. Approximately 10 drops per 20 cc. end-volume were used in the titrations.

General Technique.—The initial concentration of acetic anhydride preferably should be not higher than about 0.2 *M* in experiments extending over a few hours, or 0.04 *M* in experiments of one day or longer duration. After reaction with the water or alcohol present (including the crystal water of the catalyst and other water present in the blank) not less than 0.01 *M* acetic anhydride should be left. Also, in the alcohol determination the amount of water added to decompose the excess acetic anhydride is regulated so as to leave an unused excess of about 0.01–0.1 *M*. The sulfonic acid concentration of the test is made 0.002–0.004 *M*. Care must be taken to maintain a sufficiently high acetonitrile concentration to prevent crystallization of the sulfonic acid. In the case of ether 5% acetonitrile is sufficient with 0.004 *M* sulfonic acid, even though an opalescence may appear, on standing, while for benzene 10% acetonitrile is necessary.

Suitable amounts of acetic anhydride and sulfonic acid solution are combined immediately before the start of the experiment and equal amounts of the mixture are pipetted for tests and blanks. Glass-stoppered Erlenmeyer flasks, in case of the water determinations dried for several hours in high vacuum in the presence of calcium chloride, should be used. Suitable amounts of the liquid to be analyzed are added to the tests, and after sufficient time has elapsed both tests and blanks are titrated with the 0.1 *M* sodium methylate to a blue end-point. In the alcohol determination, after completion of the alcohol–acetic anhydride reaction excess water solution is added to tests and blanks and allowed to decompose the unused acetic anhydride before the titration is made. After adding to the solutions sufficient methylate to neutralize the sulfonic acid, thereby stopping the catalytic action, the solvent composition of all tests and the blanks is made the same by addition of the required amounts of the liquid used in the tests, and, after addition of indicator, the titration is finished. By this procedure perfect compensation[7] for medium effects on the end-point is obtained, and the absolute color of the end-point is immaterial as long as it is the same in blank and test.

Reaction Times.—No exact kinetic measurements were made in this study since it was realized that each analytical problem would present a different situation with regard to medium and concentration of reagents. It was established, however, that at ordinary temperatures a period of two hours is ample for the completion of the reactions of water, methyl and ethyl alcohol with acetic anhydride under the specified conditions in acetonitrile or a 4:1 mixture of benzene and acetonitrile, while in ether–acetonitrile (20:1 to 10:1) the reactions are approximately ten times slower. In presence of a catalyst concentration of the order of 10^{-2} *M* the water reaction in acetonitrile is complete in less than ten minutes, but as this concentration is, for reasons of solubility, too high for use in the presence of ether and similar solvents, catalyst concentrations about ten times lower were chosen throughout. Completeness of the reaction is made certain by running several tests with varying amounts of solution, varying excesses of acetic anhydride, or for different periods of time.

Practical Examples

Determination of Water. **(a) In Acetonitrile.**—Blanks: 0.045 millimol. RSO_3H + 1.25 mml. $(CH_3CO)_2O$ in

---

[6] RSO_3H is used throughout as a symbol for 2,4-dinitrobenzenesulfonic acid.

[7] For maximal compensation the methyl alcohol content of blank and test should also be made equal at the end-point.

4 cc. acetonitrile. Tests: the same as the blank, + 5 cc. acetonitrile. Titration after four hours. Difference between tests and blanks (2 of each): 0.1555 ± 0.003 (average deviation from mean) mml. methylate. The same amounts of RSO_3H and $(CH_3CO)_2O$, 5 cc. and 10 cc. of acetonitrile. 2 blanks. Titration after twenty hours. Difference from blanks: for 5 cc. 0.156 ± 0.002, for 10 cc. 0.311 ± 0.002 mml. Result: the water content of the acetonitrile is 0.0311 ± 0.0003 *M*. Similar determination on another batch of acetonitrile gave (4 blanks, 1 test with 5 cc., 2 with 10 cc., reagents as before, three hours): 0.0143 ± 0.0005 *M* H_2O. The water concentration of the former acetonitrile was increased by 0.0206 *M;* found (4 blanks, 1 test with 10 cc.; 2 with 5 cc., reagents as before, three hours) 0.053 ± 0.001 *M;* calculated 0.052 *M.*

(b) In Ether.—For the determination of the minute residual water content of ether treated exhaustively with sodium the following technique was used: 0.225 mml. RSO_3H + 1.4 mml. $(CH_3CO)_2O$ in 5 cc. of acetonitrile, +50 cc. (2 blanks) and +100 cc. (2 tests) ether. Titration after twenty-four hours (1 pair) and after forty-eight hours (1 pair). Difference after twenty-four hours 0.040 mml., after forty-eight hours 0.035 mml. Result: the water content of the dried ether is 0.00075 ± 0.00005 *M*. The water concentration of the ether was increased by 0.00060 *M;* found by the same technique 0.0011, 0.0012 *M;* calculated 0.0013 *M*. A solution of water and alcohol in ether was made: 0.5644 *M* in water and 0.5241 *M* alcohol (0.2332 *M* C_2H_5OH + 0.2909 *M* CH_3OH). 0.045 mml. RSO_3H + 2.25 mml. $(CH_3CO)_2O$ in 10 cc. of acetonitrile, +4 cc. acetonitrile (blanks), and +5 cc. acetonitrile containing 1 cc. of the ether solution (tests). Titration after three hours (2 blanks and 2 tests): difference 0.567 ± 0.005 mml., after four hours (2 blanks and 2 tests): 0.568 ± 0.005 mml.; calculated 0.5644 mml.

Determination of Alcohols. (a) In Acetonitrile.—0.11 mml. RSO_3H + 2.1 mml. $(CH_3CO)_2O$ in 10 cc. of acetonitrile, +2 cc. 1 *M* H_2O in acetonitrile (4 blanks), and +25 cc. of acetonitrile (4 tests). After twenty minutes 2 cc. 1 *M* H_2O in acetonitrile were added to 2 tests and after an additional eighty minutes they were titrated together with two of the blanks. Blanks minus tests = 0.002 ± 0.005 mml. 2 cc. 1 *M* H_2O in acetonitrile was added to the other two tests after one hour's standing and they were titrated, together with two blanks, after an additional two hours. Blanks minus tests = −0.004 ± 0.004 mml. Results: less than 0.005 mml. of alcohol is present in 25 cc. of acetonitrile, *i. e.*, the alcohol concentration is less than 0.0002 *M*. A 0.00142 *M* solution of C_2H_5OH in acetonitrile was made. Analysis as above gave 0.035 ± 0.001 and 0.033 ± 0.005 mml.; found 0.0014 ± 0.0002 *M* alcohol; calculated 0.0014 *M*.

(b) In Ether.—The same dried ether that was used in the water determination was tested for alcohol as follows: 0.225 mml. RSO_3H + 1.8 mml. $(CH_3CO)_2O$ in 5 cc. of acetonitrile, +50 cc. (5 blanks), and +100 cc. (5 tests) ether. 2 blanks and 2 tests to which 2 cc. 1 *M* H_2O in acetonitrile was added after one day were titrated after another day (I). Of 3 blanks and 3 tests to which water solution was added after two days, one pair was titrated after one additional day (II) and two pairs after two days (III). Blank minus test = −0.004, −0.007 mml. (I); −0.010 mml. (II); −0.022, −0.015 mml. (III). The reaction with acetic anhydride of any alcohol should produce a positive difference between blanks and tests. A faint yellow discoloration observed during these protracted periods suggests that the slight tendency toward a difference in the opposite direction is caused by a minor polymerization or decomposition of the acetic anhydride. Tentatively the conclusion is drawn that the alcohol content of the ether is at the most 0.0001 *M*. A solution of 0.00058 *M* C_2H_5OH in this ether is made and analyzed in the same manner. Found after one + one day: +0.023, +0.028 mml., after two + two days: +0.017, +0.013 mml. By using the negative differences obtained in the previous experiment as corrections (−0.006 ± 0.002 mml. for one + one day and −0.019 ± 0.004 mml. for two + two days) one obtains 0.00061 ± 0.00006 *M* and 0.00068 ± 0.00010 *M*, or an average result of 0.00065 ± 0.0001 *M* alcohol; calculated 0.00058 *M*. The synthetic solution of water, methyl and ethyl alcohol mentioned above (under Determination of Water (b)) was analyzed for alcohol. 0.045 mml. RSO_3H + 2.26 mml. $(CH_3CO)_2O$ in 10 cc. of acetonitrile, +4 cc. of acetonitrile (4 blanks), and +5 cc. of acetonitrile containing 1 cc. of the ether solution (4 tests). Two cc. of 1 *M* H_2O in acetonitrile was added to two blanks at once and to two tests after thirty minutes. All were titrated after a total of two hours. Blanks minus tests = 0.526 ± 0.002 mml. Another 2 blanks and 2 tests, after addition of water after two and a half hours, were titrated after a total of six hours. Blanks minus tests = 0.524 ± 0.002 mml. Found 0.525 ± 0.003 mml.; calculated 0.524 mml.

Scope and Limitations.—The method seems primarily suited for the determination of small and moderate concentrations of water and alcohol in solvents that are inert against acetic anhydride and low concentrations of a strong acid, and that have no pronounced acidic or basic properties. As two extreme examples acetonitrile and ether, the one with an exceptionally high dielectric constant and the other with a low one, have been studied in detail. By proper modifications benzene (found 0.014 ± 0.001 *M* H_2O and less than 0.001 *M* alcohol; added C_2H_5OH 0.0602 *M*, found 0.0595 *M*) and chloroform (found 0.049 ± 0.002 *M* H_2O and 0.20 *M* alcohol) were studied.

The experiments show a maximum practical error of 0.010 mml. for a tested volume of 50 cc. equal to 0.0004% H_2O (by volume) and similarly for the alcohol determination a maximum error of 0.005 mml. for 50 cc. equal to 0.0004% C_2H_5OH or 0.0003% CH_3OH, while for tested volumes of 1 cc. the respective maximum errors encountered were 0.006% H_2O and 0.005% C_2H_5OH.

Substances that under the influence of acid split off water, such as for instance formic acid or acetone (mesityl oxide, phorone and mesitylene formation) should be expected to cause errors in the water determination. While these reactions prevent application of the method to the determination of water in acetone, acetone concentrations of the order of 0.1% or less cause only minor errors when the reaction medium is chiefly acetonitrile. In the water determination of acetonitrile (5 cc. of $RSO_3H - (CH_3CO)_2O$ mixture and 10 cc. of acetonitrile, titrated after three hours) to which 0.1 and 0.01% of acetone had been added, less than 1 mole per cent. of the added acetone reacted as water. In the case of the more protracted reaction in ether the error is more serious so that the presence of acetone should be excluded by specific tests. The fractions of the added acetone reacting as water were, with ether as the medium

Vol. % acetone added		1	0.1	0.01
Mol. % acetone reacted after	1 day	4.7	31	—
	2 days	5.2	37	85

In the case of the 1 and 0.1% acetone concentrations a yellow deposit was formed in the solutions and a very rapid fading of the blue titration end-point took place. It seems probable that the precipitation phenomenon contains the explanation for the inverse variation of the extent of the pseudo water reaction with the acetone concentration.

The question as to how far the respective reaction kinetics make the alcohol method practicable for higher alcohols, phenols, thiol compounds, etc., has not been covered in the present work, as the method is primarily intended for determining the purity of inert solvents with respect to their more common contaminants water and lower alcohols. For the same reason application to the water determination in alcohols has been left in abeyance for the present.

Thanks and appreciation are expressed to Merck and Company, Rahway, N. J., who generously supplied the acetonitrile used in this investigation.

Summary

The vigorous catalytic acceleration by strong acids in non-aqueous media, of the hydrolysis and alcoholysis of acetic anhydride is shown to be useful as a basis for the separate determination of water and alcohols in inert solvents. The error in concentrations of the order of one per cent. is less than ±1%. The lower limit of response is less than 0.001%.

Application of the Glass Electrode to Unbuffered Systems

BY SAMUEL B. ELLIS AND SAMUEL J. KIEHL

Introduction

In the realm of unbuffered or very weakly buffered systems the measurement of hydrogen-ion concentration or *p*H value becomes exceedingly difficult and involves considerable uncertainty. Most of the familiar methods of determining the *p*H value have been modified for use in such systems, but complete success can hardly be claimed for practical accurate measurement. For application of the hydrogen electrode to unbuffered systems reference may be made, among others, to the work of Beans and Hammett,[1] Kolthoff and Kameda,[2] and Hammett and Lorch.[3] Similar use of the quinhydrone electrode is described by Best.[4] Colorimetric methods have been discussed by numerous workers, among whom are Stern,[5] Acree and Fawcett,[6] and Kolthoff and Kameda.[2b]

The glass electrode with its obvious adaptability for use in unbuffered systems appears to have received definite attention only recently. Burton, Matheson and Acree,[7] who used a Thompson glass electrode, have given a brief account of some measurements on dilute buffers and distilled water. The development of glass electrode technique to its ultimate refinement has, however, been merely started and the field offers many possibilities for further research.

Accordingly, an extension of the use of the glass electrode and the development of methods whereby the accurate determination of the *p*H

value may be made conveniently in the most difficult of unbuffered systems—highly purified water itself—were undertaken.

The Glass

The very soft glasses of low electrical resistance which have met with considerable favor for making glass electrodes have the serious disadvantage of being relatively soluble and of causing weakly buffered solutions with which they are in contact to become more alkaline, as the following experiment will illustrate. Three glass electrodes made of Corning 015[8] glass and of the type, to be described, were soaked in water for five weeks; then, under protection from atmospheric contamination, they were filled with distilled water and the *p*H value determined at intervals; at first the *p*H rose rapidly—approximately one *p*H unit per hour; even after twelve hours with a *p*H of 9, there was still a slow drift. In general the behavior of Corning 015 glass with unbuffered solutions was found to be quite erratic and unsatisfactory.

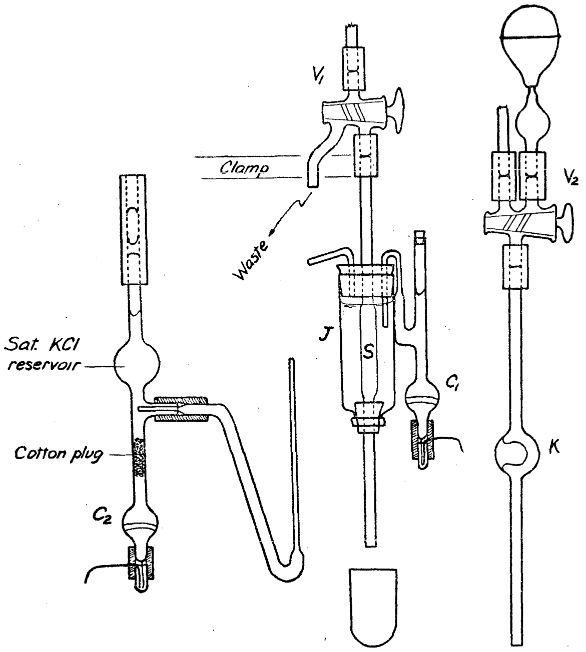

Fig. 1.—Glass electrode assembly.

From the standpoint of solubility, the ordinary soft (soda-lime) glass is much to be preferred to any of the special glasses. Electrodes made from it have much higher resistances, but a suitably designed electrical circuit will meet this difficulty.[9] Asymmetry potentials are also higher than those of Corning 015 glass, but in our experience they were just as constant—the important consideration. Again, ordinary soft glass does not agree with the hydrogen electrode over as wide a range as does Corning 015 glass. The work of Hughes,[10] of MacInnes and Dole,[8] of Sokolov and Passinski,[11] and of Lengyel and Blum,[12] in alkaline solutions indicate this. The matter of agreement with hydrogen electrode and the consistency of glass electrode measurements at extreme *p*H values and under varying conditions have not, however, been studied sufficiently to warrant the adoption of any particular glass to the exclusion of all others.

The measurements recorded in the work which follows were obtained by use of ordinary soft glass electrodes which had been carefully checked against the hydrogen electrode by use of phosphate and borate buffers over the *p*H range of 4 to 9.

Glass Electrode Assembly

The device used for measuring electromotive force was a sensitive vacuum tube potentiometer described by the authors elsewhere.[9]

The glass electrode, Fig. 1, was designed especially for convenient application to unbuffered solutions. The solution being measured is either sucked or siphoned into the tube, S, which drawn out thin in its central portion constitutes the glass membrane. This membrane of cylindrical shape is made by simultaneously blowing and drawing the central portion of an ordinary soft glass tube (6–7 mm. diameter). It is important and a little difficult to blow a sufficiently thin membrane. The required thinness however may be judged roughly by its flexibility when the membrane is depressed by a pointed instrument. Thicker membranes, even when their resistance is not exorbitant, are more likely to be erratic and unsatisfactory. The fixed portion of the system in the jacket surrounding the membrane is 0.1 *N* hydrochloric acid connected directly to a 0.1 *N* hydrochloric acid calomel cell C_1 of Hughes.[10] The liquid junction of the solution with a second calomel cell C_2 (saturated potassium chloride type) is effected either at the bottom of the tube S or at a point inside it, depending upon circumstances.

An easier method of forming the thin glass membrane is indicated by K of Fig. 1, which will be recognized as the familiar sucked-in-bulb type of Kerridge.[13] Although easier to make, the Kerridge bulb electrodes compared with the cylindrical type have several disadvantages: (1) their asymmetry potentials are less stable; (2) they are less easily washed, rinsed, and flushed free of air bubbles; (3) the Kerridge electrodes are more fragile and are easily broken by a sudden movement of the liquid inside; (4) the junction with a reference electrode must be formed somewhere below or above the active membrane, which, as will be shown later, is sometimes undesirable. With one exception, included for illustrative purposes, all the measurements reported in the following pages were obtained by use of the cylindrical type of electrode.

A rigid mounting of the membrane within a jacket by use of rubber or cement is more desirable and trustworthy than a glass seal because even slight heating produces noticeable deterioration of the glass electrode. The permanent combination on the outside of the membrane, including hydrochloric acid and hydrochloric acid–calomel cell C_1 is used merely to complete the electrical circuit and ensure constancy of e. m. f.—the prime consideration.

The second calomel cell C_2 of the saturated potassium chloride type requires no other comment than to call attention to its removable (interchangeable) tip (Fig. 1) of which several may be available for special requirements. The tip is used to form the liquid junction inside the glass electrode tube during flow of the liquid being measured.

Of the various devices available for filling the glass electrode the two which have been found most satisfactory are illustrated by the sketch of Fig. 1. A three-way stopcock located at the top of the glass electrode may be employed in either of two ways, V_1 or V_2. By use of V_1 the electrode filled through the top may be kept full of liquid at all times. To eliminate all air bubbles from the electrode tube itself, from which expulsion is sometimes difficult, and rigorously to avoid atmospheric contamination, a preliminary flushing through the waste tube is necessary. By V_2 the glass electrode may be rinsed and filled either from the top by means of a siphon tube or from the bottom by means of suction. Either entrance may be reserved for the standard reference buffer, while the other is used for the solution of which the *p*H value is desired. Thus for a continuous record a solution may be passed through the siphon tube with an interruption of flow only for purposes of comparison with a standard buffer during which the rubber bulb or a second siphon tube may be utilized. As another alternative, the top entrance may be used for rinse water through the siphon tube, while all solutions to be measured are admitted at the bottom. By this scheme the electrode may be washed with distilled water by a turn of the stopcock and may be filled ready for a measurement by squeezing the bulb a few times. The rubber bulb may, however, be displaced by another siphon tube. For rigorous exclusion of atmospheric contamination the electrode must always be filled through a closed tube.

In supporting any glass electrode assembly it is important to insulate very carefully one side of the membrane. The outside of the membrane therefore was insulated by means of a Bakelite support which clamped the electrode at the top only (Fig. 1). The HCl–calomel cell C_1 was connected by a short lead directly to the highly insulated terminal of the vacuum tube potentiometer.

Measuring Technique

In making a measurement the procedure is essentially that of comparing the solution of unknown *p*H with a standard reference buffer by means of their respective potentials in the glass electrode. The simple mathematics described by Clark[14] and Britton[15] needs no discussion. The reference buffer was without exception 0.05 molar potassium acid phthalate, *p*H 3.97.

Solutions having a small buffering capacity (*e. g.*, 0.01 *M* disodium hydrogen phosphate) are very easily measured by almost any technique which might be suggested in connection with the glass electrode assembly described above. However, if the liquid or solution being measured (*e. g.*, potassium chloride solution) has little or no buffering capacity, the contamination occurring at the glass surface may change the e. m. f. and produce erroneous results. Even though the ordinary soft glass used for all electrodes in the present work is very much better than Corning 015 or other similar electrode glass as regards solubility, it is still not ideal.

The most obvious procedure for sensitive unbuffered solutions is to complete the measurement as quickly as the system could be expected to reach equilibrium under ordinary circumstances and disregard subsequent drifting. Since glass electrodes do not always reach their stable equilibrium potentials in the same length of time, the question of how soon to accept such a reading is difficult to answer. Readings should be repeated, however, until successive trials check each other. When this procedure is used with solutions of appreciable conductivity, fair results may be obtained—results which check within possibly a millivolt of those obtained by the improved technique to be described below.

Even if one is satisfied, however, to accept an e. m. f. reading which is in the initial stages of a steady drift, the method has further faults when applied to a liquid of relatively low conductivity like purified water.[16] After the glass electrode is flushed and filled with highly purified water,[16] the electromotive force shows various anomalous effects which indicate the generation and subsequent slow dissipation of electrical charges. The time required for apparent dissipation of the charges is variable, but in general the effects last for a sufficient time (a few minutes to half an hour) to vitiate the measurement. The trouble is very much less pronounced with water of less purity.

To satisfactorily overcome the alkaline effects due to the glass, the contents of the electrode should be continuously renewed by flow while the measurement is being made When very dilute solutions or purified water are measured, such flow may cause trouble with streaming potentials,[17] unless the liquid junction is established at the center of the glass electrode. By moving the liquid junction (tip of calomel cell C_2) to different positions within the glass electrode and the tube below it, the presence or absence of streaming potentials may be readily determined.

When the liquid junction is located at the center of the cylindrical membrane S (Fig. 1), it seems highly unlikely that any streaming potential of appreciable magnitude may be superimposed upon the measured electromotive force. This theoretical conclusion is supported by subsequent experimental evidence that the electromotive force is independent of the rate of flow when other factors are eliminated. As the liquid junction is moved downward below the membrane, streaming potentials increase rapidly (water charged positively with respect to the glass). Near the center of the cylindrical membrane, however, a small displacement of the potassium chloride junction causes little change in the measured electromotive force. Therefore the liquid junction need not be located with extreme accuracy; the central position as judged by the eye is entirely satisfactory.

With the Kerridge sucked-in-bulb type of electrode, unless it is of distorted and impractical proportions, the liquid junction cannot be located at a central position with regard to the active membrane. The best that may be

done is to bring the junction to a point immediately under the thinnest portion of the membrane. It is therefore difficult if not impossible to eliminate small streaming potentials when the Kerridge electrode is used for measuring a liquid whose conductivity is unusually low (*e. g.*, highly purified water).

Typical Measurements

When electromotive force (or *p*H) is determined at different rates of flow, the results depend in general upon the type of solution. A number of typical examples of this are illustrated by Figs. 2 and 3. The data for the most part are given in graphical form only because the exact numbers are of little consequence to the present discussion. In Fig. 2, curve A illustrates the general behavior of highly purified water when it is measured in an electrode (C5) of the cylindrical type. The horizontal portion of the curve indicates the *p*H of the water. The fairly sudden break in the curve at a flow of about 25 cc./min. is typical of such systems, and the behavior is suggestive of a transition from streamline to turbulent flow. However, that such a transition did not occur was proved by several experiments in which a fine colored band of methylene blue was used. Turbulence did not commence until a flow of about 150 cc./min. was reached.

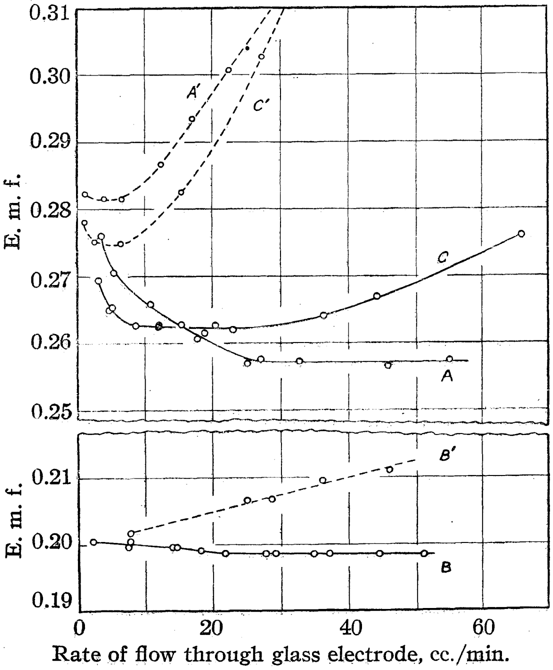

Fig. 2.—A and A', purified water measured in cylindrical electrode, C5; B and B', Columbia distilled water measured in C5; C and C', purified water measured in Kerridge electrode K10. Dashed curves indicate streaming potentials; data obtained by same method as for solid curves except that the potassium chloride junction was located 9 cm. below the bottom of the membrane.

Curve B of Fig. 2 represents the behavior of the stock distilled water^{18} in the same cylindrical electrode, C5. The pronounced difference between curves B and A illustrates a perfectly general behavior which is of considerable interest and importance. The stock distilled water, a high grade commercial distilled water, is practically unaffected at low rates of flow by alkali from the glass, whereas the highly purified water shows a large increase in *p*H value. The stock distilled water in comparison with the purified water is evidently buffered by minute traces of carbon dioxide and ammonia, evidence and confirmation for which appear in another paper.^{16}

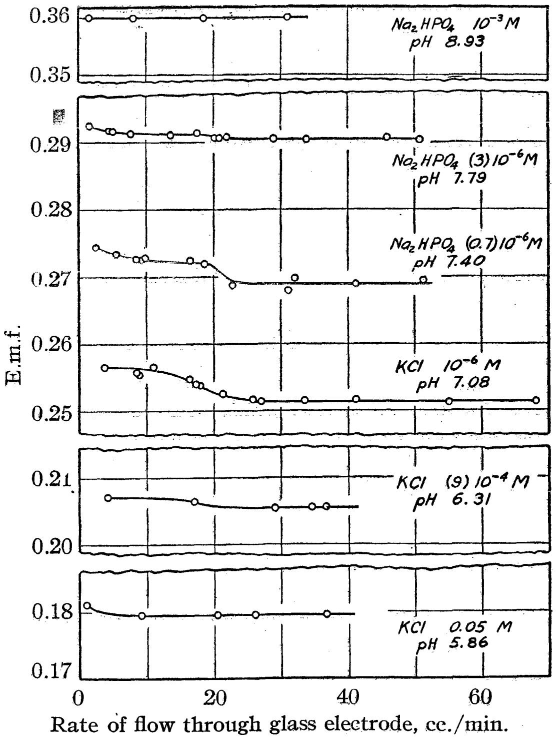

Fig. 3.

When an electrode made of Corning 015 glass was used for measuring the stock distilled water, the curve (not shown) was similar to A of Fig. 2 except for the horizontal portion which it lacked. If the flow was increased to 60 cc./min. the *p*H value was still decreasing but was nevertheless

---

(18) "Stock distilled water" refers to the distilled product furnished in the Havemeyer Chemical Laboratories of Columbia University; specific conductivity in the neighborhood of 10^{-6} reciprocal ohms and *p*H from 6.1 to 6.5.

0.16 *p*H unit higher than that obtained by use of the ordinary soft glass electrode. By this experiment the stock distilled water was shown to be very sensitive to changes of *p*H value which were caused by the solubility of Corning 015 glass.

The dashed curves A′ and B′ of Fig. 2 were obtained in exactly the same way as A and B, except that the potassium chloride junction was moved down to a position about 9 cm. below the bottom part of the active membrane. The measured e. m. f. in this case included a streaming potential superimposed upon the same e. m. f. previously shown in A and B. The difference between the ordinates of A and A′ gives the streaming potentials for purified water; the difference between B and B′ gives the streaming potentials for the stock distilled water.

Curves C and C′ of Fig. 2 illustrate the use of a Kerridge type of electrode for the measurement of purified water. Its general characteristics are similar to those of the cylindrical electrode but its shape prevents centering of the potassium chloride junction and, consequently, there is definite evidence of streaming potentials at the higher rates of flow.

In Fig. 3 some typical curves are shown illustrating the measurement of dilute salt solutions. The solutions were very carefully prepared by distilling highly purified water[16] directly into "No-solvit" and Pyrex glass receivers, containing a weighed quantity of purified salt.

A very pure potassium chloride was further purified by three crystallizations from distilled water and dried at 100°. The disodium hydrogen phosphate, of very good quality, was crystallized four times and dried under vacuum at 30°. For the more dilute solutions a 2-liter quantity of water was used and the salts were weighed out by means of a micro-balance. Rigorous protection from acid or basic constituents of the atmosphere was maintained in all cases, just as was done with purified water itself.

The curves in the center of Fig. 3 for the most dilute solutions show the alkaline effect of the glass at the lower rates of flow, but their shape is different from that obtained when purified water was measured. The characteristic inflected form of the curves indicates that the buffering capacity of these extremely dilute solutions is less if they are relatively pure (flowing rapidly) than they are if contaminated by alkali from the glass. This is to be expected since it is a familiar fact that weak acids or bases show less resistance to *p*H change (smaller buffering capacity) if pure than if partially neutralized. The exact nature of the material dissolved from the glass and the detailed mechanism of the buffering reactions, are investigations beyond the scope of the present problem.

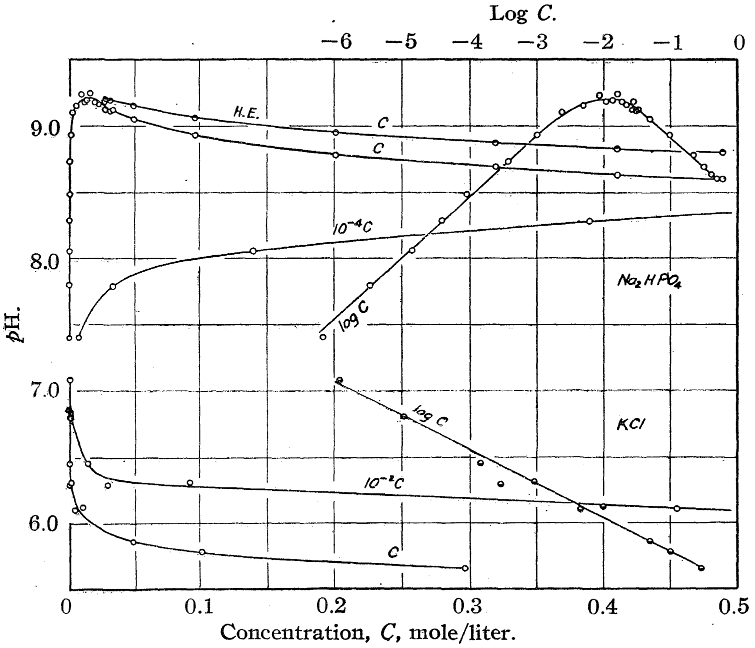

Fig. 4.

As the solutions of Fig. 3 are made more concentrated the alkaline effect from the glass rapidly becomes less pronounced, and the inflection of the curves disappears. It is quite evident from the experiments that even such a solution as potassium chloride has a definite, though very small, buffering capacity which increases with the concentration.

The *p*H values of the salt solutions, potassium chloride and disodium hydrogen phosphate, were measured over a wide range of concentrations, extending from millionth molar to half molar. The results listed by Tables I and II are shown graphically by Fig. 4, where *p*H is plotted against concentration (C) and also against log C. In the curves marked 10^{-4} C and 10^{-2} C the abscissas should be multiplied by 10^{-4} or 10^{-2}, respectively, in order to obtain the correct scale. These two curves afford a magnified view of the extremely dilute region and include only the first few points which on the normal scale of abscissas (C curves) appear as vertical lines.

The upper curve for disodium hydrogen phosphate marked H. E. (Fig. 4) shows some measurements made in the more concentrated region by means of the hydrogen electrode. The discrepancy between the hydrogen and the glass electrode measurements is about what should be expected on the basis of the investigations of MacInnes and Belcher.[19] As the phosphate solutions are made more dilute, however, the discrepancy rapidly decreases. The agreement would probably be very close in the dilute region, which is most difficult for application of the hydrogen electrode. Calibration of the glass electrode against the hydrogen electrode in various buffers indicated that there was no significant difference at *p*H values less than 8 (extreme acid range not included).

The definitely acidic character of the purified potassium chloride merits notice. If this behavior could be substantiated with samples of the salt purified with extreme precaution, it would be of considerable interest. Perhaps of even greater interest is the shape of the disodium hydrogen phosphate curve, reported by Kiehl and Loucks,[20] with a maximum *p*H at a concentration of approximately 0.015 molar. The straight line character of the respective logarithmic curves, with two branches for the disodium hydrogen phosphate is of singular interest.

The curves of Fig. 4 are presented for the purpose of illustrating the practical possibility of making consistent *p*H measurements in extremely dilute weakly buffered systems. The consistency of the measurements over the entire range of concentration is best demonstrated by the logarithmic curves.

The data of Fig. 4 support the other data of this investigation in proving beyond question that the glass electrode offers important opportunities for research in unbuffered systems.

The authors take this opportunity of expressing their appreciation to Professor John R. Dunning of the Physics Department, for his many helpful suggestions and advice during the development of the electrical measuring circuit.

Summary

The practical measurement of *p*H in the most difficult of unbuffered aqueous systems has been accomplished by means of the glass electrode. General technique has been developed, and some examples are given.

The Purification of Water and its pH Value

BY SAMUEL B. ELLIS AND SAMUEL J. KIEHL

A series of experiments relative to purification of water and the determination of its pH value by the glass electrode[1] is described in this article.

The Still.—The still (Fig. 1) was designed to incorporate the principles both of Bourdillon[2] and of Weiland.[3] In the still of Bourdillon purified air is passed upward through a long condenser tube, countercurrent to the condensing water. In Weiland's still purified air is passed through the hot boiler before the actual distillation is started. Thus the combination of Weiland's method with that of Bourdillon allows volatile impurities to be partly or largely driven from the boiler before or during distillation while the remainder is removed as far as possible in the condenser tube.

The condenser, including joints, was made entirely of block tin. The tapered delivery tip and the small side tube near it were cast, machined to the required dimensions, and sealed to the main condenser tube. Two water jackets of brass were joined to the condenser tube by means of solder. The top water jacket was constructed so that cold water could enter at the top and provide more efficient condensation while the one at the bottom served to control the temperature of the dsitillate. The boiler, a round-bottomed Pyrex flask of 12-liter capacity, with long ring neck ground flat on top, was joined to the machined surface of the condenser by clamps. Heat was supplied by a gas hot-plate.

The neck of the flask, inclined and filled with glass beads, served as a very efficient spray arrester. The angle of inclination left most of the cross-section fairly dry and open for the free passage of steam and air. By this method the elimination of all spray, an absolute necessity in work of this type, was accomplished satisfactorily.

The glass tube through the top of the boiler was used for three purposes: (1) for filling the boiler *in situ;* (2) for eliminating volatile impurities with purified air; (3) for the prevention of bumping. As all three purposes are important, combined they make this tube indispensable.

Purification of Air.—The air was passed through the following train: (1) a capillary flow-meter; (2) four gas washing bottles (5 cm. × 18 cm.) half full of glass beads, the first three of which contained, respectively, sulfuric acid about 6–10 normal, sulfuric acid about 1 normal, sodium hydroxide about 6–10 normal, the final bottle being used to catch spray; (3) a series of five towers (3.5 × 29 cm.) each containing soda-lime, 8–14 mesh, 15% moisture; (4) a final tower (3.5 cm. × 29 cm.) containing a filter of tightly packed glass wool and cotton.

From this purification train the air passed directly to the still through glass tubing, connected by short lengths of extra heavy-walled rubber tubing. The rubber tubing and stoppers were steamed for half an hour and impregnated with castor oil *in vacuo* at 60 to 90°.

Receiving Vessels.—Walker and Smither[4] in a study of the characteristics of various glasses, concluded that Pyrex and Libbey varieties are about equally insoluble in water, and that in this respect they both excel "Non-sol," Jena, and all the other resistance glasses studied. Pyrex has been very popular as a container for very pure water.[5]

Other materials (*e. g.*, quartz, platinum, silver, and tin) have been used occasionally as containers, but there has been no definite comparison with glass.

In these experiments three different kinds of receiving vessels were used: (1) Pyrex Erlenmeyer flasks of 500-cc. capacity with Pyrex siphons; (2) "No-solvit" bottles of 2-liter capacity with Pyrex siphons; (3) silver flasks of 1-liter capacity with silver siphons.

In general, if the container is suitable, the pH value of the purified water will not change on standing, or will change very slowly. Also, if the pH values of water collected in containers of different material agree, this confirms the conclusion that none of them contaminate the water appreciably. By both of the above criteria, the three materials used were found reasonably satisfactory. Further refinement of the experiments would justify investigation of other materials. Tin especially, should be used since the condenser itself is made of tin.

Preliminary cleaning of all vessels was accomplished by scrubbing with soap solution, rinsing thoroughly, and steaming for an hour. Siphon tubes were similarly treated. This method of cleansing was found to be more satisfactory than the other well known methods.

Collecting a Sample.—The sample was collected and kept in a purified atmosphere at all times. To accomplish this, the receiver was closed with an impregnated rubber stopper through which the delivery tip of the condenser extended (Fig. 1), so as to avoid contact of water with the rubber. Purified air passed through the siphon tube into the receiver at a rate of 20–25 liters per hour and thence up through the condenser tube by way of the by-pass and stopcock V instead of the delivery tip of small bore, 2.5 mm. On account of the small bore of the tip and the continually renewed water held therein, atmospheric contamination of the lower condenser was prevented during times that the receiver was disconnected. A very slow distillation was sufficient to keep fresh relatively pure water at the bottom of the tip.

Before the receiver was connected to the condenser, it was flushed with purified air for a period of time. For this purpose, the hose was connected at both i and o; the unoccupied hole in the stopper, ultimately occupied by the delivery tip, was closed with a glass plug; and the

three-way stopcock, V, was turned so as to discharge directly into the atmosphere instead of through the condenser. After thus flushing the receiver, stopcock V was turned so as to pass the purified air stream through the condenser again. After ten minutes longer the glass plug was removed, and the receiver quickly attached.

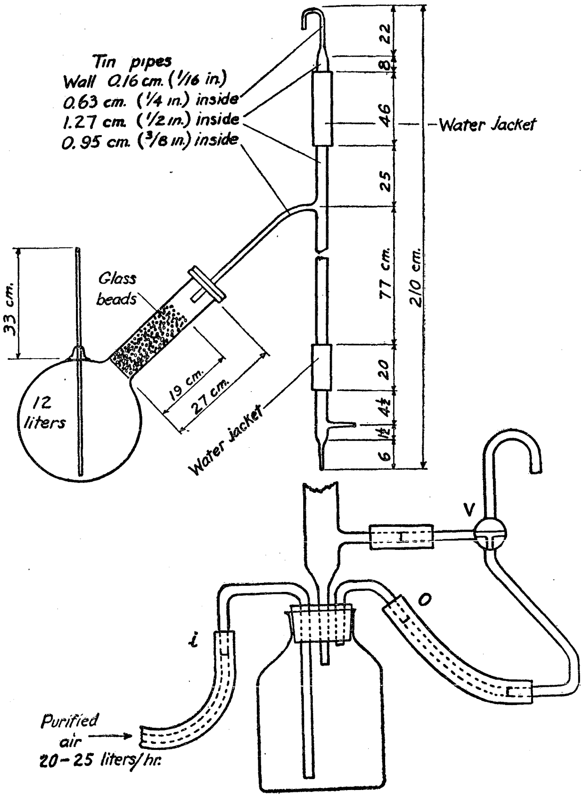

Fig. 1.

During and after disconnecting the receiver the air, uninterrupted, was forced through the hole previously occupied by the delivery tip. A three-way T-bore stopcock was then inserted and closed after the expulsion of the impure air. The hose connection at o was then broken and the glass tube tightly stoppered with a small impregnated rubber stopper or a paraffined cork. Hose connection i on the siphon tube was finally broken. The sample of purified water was then ready for use. A pressure of purified air through the three-way stopcock was used to obtain a portion of the sample through the siphon tube. The impure air was expelled from the stopcock through its side-tube, before the pure air passed into the receiver. The siphon tube in all experiments was attached directly to the top of the glass electrode.

Preliminary Experiments.—The once distilled water furnished to the chemical laboratories of Columbia University was always used for filling the boiler. This water which will be conveniently referred to as the stock distilled water, had a specific conductivity of roughly 10^{-6} reciprocal ohms, and a *p*H value of 6.1 to 6.5. Upon standing in the open, the *p*H soon dropped to approximately 5.8. A carefully conducted Nessler test on this water indicated that ammonia was present to approximately 0.004 part per million. Ammonia-free water prepared by distillation from phosphoric acid was used for comparison and for making all test solutions and standards of reference. "Aeration" of the stock distilled water by purified air caused its *p*H value to change in general from 6.3 to beyond 8.0. Continued aeration then caused this value to drop very slowly. The water contained both carbon dioxide and ammonia. Carbon dioxide is easily eliminated by aeration. Ammonia is removed very slowly. Table I illustrates the type of data which were obtained.

Table I

Aeration of Columbia Distilled Water

Hours aerated	0	6	8	9.5	12	19.5	21
*p*H	6.3	8.05	8.13	8.18	8.22	8.17	8.13

Thirty to forty per cent. of the stock distilled water had to be distilled before a Nessler test of the distillate became negative or uncertain. The first fractions from the Bourdillon–Weiland apparatus always contained ammonia (0.1–0.2 part per million) and had a high *p*H (8.5 or more). Therefore from these experiments it appears that the Bourdillon still is capable of eliminating carbon dioxide but not ammonia.

Aeration of various fractions (32 in all) obtained from the Bourdillon–Weiland still, confirmed in a very conclusive way the general picture already described. The first fractions, those of *p*H higher than about 7.5, gave without exception a drop in *p*H when aerated. The later fractions of lower *p*H value showed very little change during prolonged aeration. Those samples with a *p*H value of 7.2 or less had a tendency slowly to become more alkaline, but seldom greater than 0.1 *p*H unit in twenty-four hours.

The *p*H values of water samples such as the above which are freed of volatile impurities may change during aeration because of contamination from containing vessels or the air stream, or because of an imperfectly closed container. The fact that very little change was actually observed over periods as long as forty-eight hours indicated that these combined effects were very small.

Purification of Water

The best method of procedure for preparing water of high purity is indicated by the data of Table II, shown graphically in Fig. 2.

When the stock distilled water was used in the boiler either alone (curve A) or with sodium hydroxide (curve B), the *p*H value of the first distillate was high (presence of ammonia). As distillation proceeded the *p*H value dropping finally tended to become constant at a value slightly higher than 7. Constancy was approached only after 50% of the charge in the boiler had been distilled. Even then there was probably a tendency to change as distillation proceeded. The *p*H value of the last fraction tended, in general, to be slightly higher than that of water distilled from phosphoric acid, which, as will be seen from curve

E, was constant throughout the distillation. It seems perfectly logical on this basis to conclude that the samples distilled from alkali or from water alone were never entirely freed of ammonia.

Confirmation of this conclusion is afforded by a study of the curves shown in Fig. 3 for the different fractions distilled from alkali. E. m. f., or apparent *p*H, is plotted against rate of flow through the glass electrode.[1] The first fraction distilled contained sufficient ammonia (easily verified by a Nessler test) to make the solution definitely alkaline and to render its measurement in a glass electrode very easy—curve A of Fig. 3. The second fraction gave a curve (not shown) very similar to A with the horizontal part not quite so perfect at lower rates of flow. The third fraction, curve B of Fig. 3, began to show a slight somewhat doubtful inflection, and a definite indication that the glass was contaminating the water at lower rates of flow. The fourth fraction gave a typical inflected curve C, with a considerable alkaline effect from the glass at lower rates of flow. Curve C remained more or less representative of all subsequent fractions—the last of which was taken when 92% of the water in the boiler had been distilled. A comparison of the curves of Fig. 3 with the types described in the previous paper[1] demonstrates their similarity to those obtained with contaminated water (*e. g.*, millionth molar KCl or Na_2HPO_4). None of them have the same shape as that for highly purified water distilled from phosphoric acid. Hence, this evidence contributes further to the conclusion that ammonia was not entirely eliminated at any time during the distillation of neutral or alkaline water.

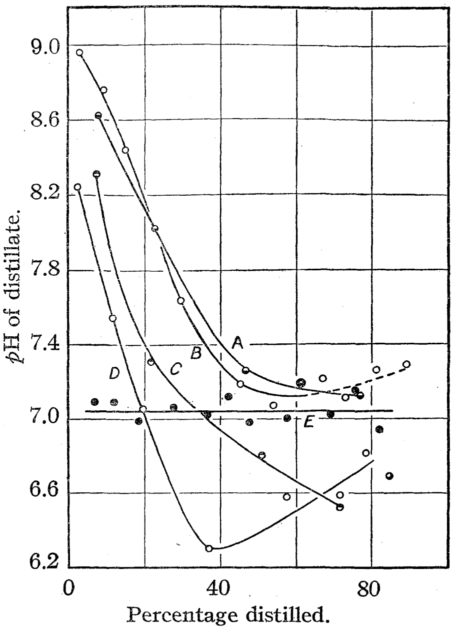

Fig. 2.—Distillations with various reagents in boiler (*cf.* Table III).

Any non-volatile reagent, which added to the boiler could hold or destroy both carbon dioxide and ammonia, would obviously be a valuable aid in purifying water. For this purpose Kendall,[6] and Fales and Nelson[7] have used Nessler reagent. Some data for Nessler reagent are plotted in curve C of Fig. 2. That it failed to hold ammonia was demonstrated not only by the high initial *p*H values, but also by direct Nessler tests for ammonia which were made on the distillate. Furthermore, as distillation proceeded, the *p*H of the supposedly purified water continued to drop. The most reasonable explanation for this anomalous gain of acidity seems to be that a small amount of iodine set free from the Nessler reagent was carried over with the current of air and steam.

After the distillation from the Nessler reagent, the boiler was disconnected from the condenser and cleaned by thorough rinsing with distilled water (a dozen or more separate rinsings). Stock distilled water was then added and a distillation completed as shown by curve D of Fig. 2. Ammonia came over with the first fractions as usual,

---

[6] Kendall, THIS JOURNAL, **38**, 2460 (1916).

[7] Fales and Nelson, *ibid.*, **37**, 2782 (1915).

but the *p*H of the distillate continued to drop to a minimum value of 6.3, after which it rose again to about 6.8. From this behavior it would seem reasonable, as a speculation, that sufficient iodine had accumulated in the condenser from the previous distillation to contaminate the water for a considerable time afterward. In any event the experiments (C and D of Fig. 2) leave no doubt concerning the utter futility of attempting to use Nessler solution in the boiler. In consequence of the experiments with Nessler reagent it was necessary to cleanse the system thoroughly. To accomplish this the still was operated for a whole day with the cooling water off part of the time.

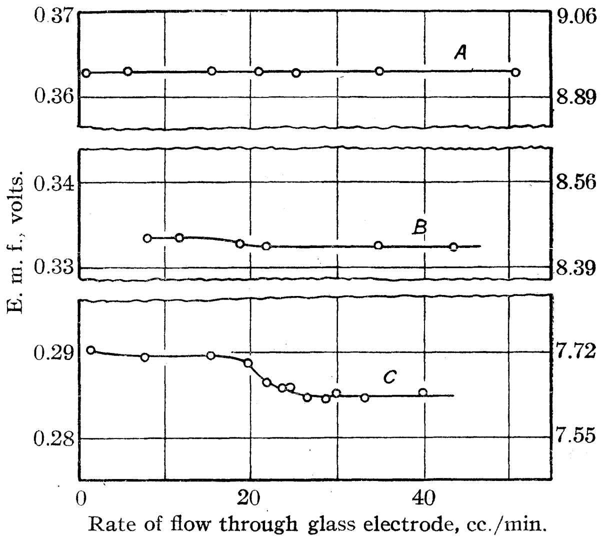

Fig. 3.—Samples of water distilled from NaOH (Table III) and measured with cylindrical glass electrode C5: A, first fraction collected, boiler emptied 1–5%; B, third fraction, boiler emptied 13–18%; C, fourth fraction, boiler emptied 20–39%.

The horizontal line E of Fig. 2, representing a distillation from phosphoric acid, shows that the acid retained all ammonia in the boiler, and that the modified Bourdillon still was capable of eliminating the carbon dioxide. The first fraction distilled had the same *p*H as the later fractions, and upon the rough basis of streaming potentials measured in the glass electrode,[1] they had about the same low conductivity. During the entire course of the distillation, samples of high purity could be collected. The superiority of such a distillation over the others is strikingly emphasized by the curves.

To eliminate volatile matter, the phosphoric acid was carefully heated for twenty minutes with the evolution of white fumes. Phosphorus pentoxide used without preliminary treatment was satisfactory.

Potassium permanganate both in acid and alkaline solution has been very commonly used in boilers for the purification of water. When permanganate was added to the boiler in the presence of alkali, curve B of Fig. 2 remained essentially unchanged; in other words ammonia was not thus eliminated by oxidation. When permanganate was used in the presence of acid, it likewise served no useful purpose; the acid held the ammonia in any case. The situation as regards the use of permanganate may be different if the boiler water contains appreciable quantities of organic or other oxidizable impurity. No such water has, however, been used in this research.

The *p*H of Purified Water

A series of measurements, summarized by Table III, was undertaken for the purpose of estimating as accurately as possible by the technique previously described the *p*H of purified water. During a series of four complete distillations at the rate of 800 cc. per hour from phosphoric acid (20 g. of P_2O_5 in the boiler) samples were collected in Pyrex, "No-solvit" and silver containers. The lower water jacket on the condenser was used to control the temperature of the condensate and keep it as nearly as possible that of the room. Hence the *p*H values could be measured immediately. Although more samples were collected in silver than in glass, the data for silver, nevertheless, cover exactly the same series of distillations as are covered by the two kinds of glass. Therefore, differences between the various containers cannot be due to differences between successive distillations. The four distillations themselves showed no significant difference of any kind.

A single glass electrode of cylindrical shape[1] made of ordinary soft (soda-lime) glass was used for all the measurements of Table III. Potassium acid phthalate (0.05 molar, *p*H 3.97) was employed as the reference buffer, and the difference of potential (ΔE) between it and the water is listed in the second column of the table. The buffer and the glass electrode were both checked by means of the hydrogen and quinhydrone electrodes. All measurements were made with the purified water flowing through the glass electrode[1] and each value listed in the table is the

MEAN VALUES

Containers	Average temp., °C.	Average, pH	Average deviation from mean pH
Pyrex	27.9	7.11	0.024
"No-solvit"	28.4	7.07	.039
Pyrex and "No-solvit" comb.	28.0	7.09	.034
Silver	27.4	7.01	.045

mean of two or three (sometimes more) readings taken at different rates of flow. Obviously only rates of flow on the straight horizontal part of the e. m. f.–flow curve were used.

The significant difference between measurements made in silver and those made in glass (Table III) indicates that the glass contributes a very small alkalinity to the water. Whether or not the silver likewise contributes alkalinity is left in doubt. However, the results of experiments previously described in which samples of water were kept for comparatively long periods in the various containers would indicate that if any such effect is present it must be very slight.

The most probable pH value of water to be deduced from the data of Table III is undoubtedly the mean of the silver series, namely, 7.01 at approximately 27.5°. The precision of this figure is about 0.01 pH unit, measured in terms of the so-called "average deviation of the mean," commonly abbreviated A. D. The fluctuations of temperature as they ordinarily occur in a room could account for a greater pH change than this, but it is probable that successive series of nineteen measurements would give averages that were consistent within the meaning of this precision.

The value for the pH of water here obtained is in substantial agreement with accepted figures and with the best previous direct measurements.[4,5,8,9] The present measurements, however, are unique in that they represent a direct determination made upon a highly purified water to which no foreign material of any kind had been added, neither "isohydric" indicator nor gaseous hydrogen with platinum black.

Summary

1. Methods for the purification of water have been investigated and important information concerning this general problem has been obtained.

2. The pH value of the purest water, collected in silver vessels, has been measured directly by means of the glass electrode and found to be 7.01 at 27.5°.

[CONTRIBUTION FROM THE LABORATORY OF THE CORNING GLASS WORKS]

Extraction and Analysis of Gases from Glass[1]

BY R. H. DALTON

Introduction

In the course of a study of gases in glass there arose the problem of working out an apparatus for extracting and quantitatively analyzing the gases from molten glass. A fairly successful system has been developed and thoroughly tested in use. Since the procedures differ considerably from any previously described and involve some points of general interest in high temperature technique it was thought worth while to publish a brief description of them. To illustrate the behavior of the apparatus it was also decided to include the results of some test analyses and of some determinations on typical glasses that are of general interest.

Various other investigators have studied the gases in glass, but most of them have confined their observations to temperatures below the softening point. At these lower temperatures the quantity and nature of the gas is different, as is also the procedure necessary for extraction, so it is beyond the scope of this paper to discuss these investigations. The earliest work at high temperatures was that of E. S. Shepard mentioned in an article by Allen and Zies.[2] This was followed by the more extensive work of Washburn, Footitt and Bunting.[3] Both of these investigations failed to provide for the detection and estimation of water vapor, which is almost always an important constituent of gases coming from glass. A more complete investigation has been reported by Salmang and Becker.[4] The results of the present work are in general agreement with theirs, although the analytical and extraction methods differ considerably in the two cases.

Some earlier experiments by the author[5] indicated that water, carbon dioxide, sulfur dioxide and oxygen were the principal gases to be expected. It was also apparent that it would be an advantage from the viewpoint of extraction to keep the size of the glass samples down to a gram or so. This meant dealing with gas samples averaging around 0.5 cc. in volume but falling as low as 0.01 cc. in special cases.

The apparatus divides itself naturally into two parts, the extraction apparatus and the analytical apparatus. The extraction is carried out by melting the glass in vacuum and pumping off the gases. The analysis is carried out at low pressure using physical methods of separation where possible.

Extraction Apparatus

The general problem in the extraction process is that of designing an apparatus which will be gas tight at 1400° in vacuum and which can be baked out so that it will not itself give off appreciable quantities of gas. Sillimanite has been found to be the material most nearly fulfilling these conditions.

Figure 1 shows a cross section of the apparatus. The outgassing takes place in the sillimanite (Champion 6060) tube (F). Fortunately this can be sealed directly to "Pyrex" brand chemical glass of which the whole apparatus is constructed, thus making it possible to eliminate all wax and greased joints. This porcelain to glass seal is easily made in diameters up to 1.3 cm. and is quite useful for vacuum technique at high temperatures. Sillimanite tubes up to 1.3 cm. diameter and 1.6 mm. wall will stand a full atmosphere at 1450° without appreciable collapse. A new tube is used in each determination.

The heating is done by means of a winding of 75 mil tantalum wire embedded in alundum. Tantalum has been found superior to molybdenum as its oxide is not volatile and the wire is more easily bent into form (when new). The heater (H) is surrounded by two concentric cylindrical shields (C_1) and (C_2) of tantalum or molybdenum to act as radiation reflectors. To protect the metals from oxidation the whole furnace system is enclosed in an evacuated glass tube (D). This serves the additional purpose of eliminating any possibility of gases getting into (F) and of cutting down heat loss from the furnace. The tube (D) has its own vacuum pump and there is no connection with the main vacuum system. The ground glass joint (J) is sealed with wax and the whole tube is surrounded by a water jacket (not shown). A sample tube (G) with magnetic plunger furnishes a means of introducing the sample which is in the form of short lengths of rod. This is done after the apparatus has been evacuated and baked out. The bake out is continued until tests show that the gas evolved is negligible compared to that expected from the glass. This normally requires about a thirty-minute

treatment at 50° above the temperature at which the glass is to be outgassed. The temperature is measured through the window (W) by means of an optical pyrometer and any temperature up to the melting point of sillimanite can be attained. The glass samples are usually outgassed at 1400°, however. The tube (L) leads to the pumps and the analytical apparatus. The pumping system consists of a two stage mercury vapor pump backed by an oil pump.

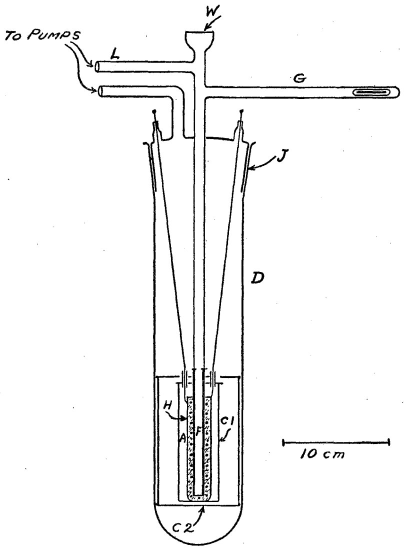

Fig. 1.—Outgassing furnace.

There is one serious source of error in this method of extraction which we have found no way to eliminate entirely. This error is due to the volatilization of oxides such as Na_2O, B_2O_3, etc., which condense in the tubing just above the furnace and reabsorb part of the gases before they reach the analytical apparatus. In view of this, coupled with the fact that the work is in a fairly new field where it is of greater interest to obtain approximate results on a number of glasses than very accurate results on a few, no attempt has been made to push the accuracy of the analytical part of the apparatus to the limit.

Analytical Apparatus

The analytical apparatus must provide means of pumping the gases from the furnace and of analyzing for water, carbon dioxide, sulfur dioxide and oxygen. It was desired also to provide for hydrogen and carbon monoxide in case these should be present. Nitrogen plus other inert, non-condensable gases could be determined together as a residue. The fact that the gas samples come from glass at 1400° simplifies the problem in that oxidizing and reducing gases cannot come off together. The procedure consists in general of freezing out the water, sulfur dioxide and carbon dioxide in the order named, then removing oxygen by hot copper and finally oxidizing carbon monoxide and hydrogen with copper oxide.

A brief mention will be made of an early form of the apparatus as it worked fairly well and had a great advantage in simplicity. This apparatus is shown diagrammatically in Fig. 2. The gas evolved from the molten sample enters the system through the special stopcock (S_1) which is in position to connect 1 and 2 and close off 3. The gases then pass through the trap (T) where water is frozen out by cooling with solid carbon dioxide and thence into the bulb (B). From here the gas can be pumped into the space between (S_1) and (S_2) by raising the mercury from the reservoir (R_2). In this way the bulb (B) acts as a form of Toepler pump, withdrawing the gas from the furnace and transferring it to the small volume above (S_2). The water that has been collected in (T) is determined by confining it between the points (AA) and measuring the pressure that develops when the trap and connecting tubes are completely immersed in boiling water. The volume between (AA) is accurately known and is such that the water vapor is always well below the saturation pressure at the temperature of the surrounding bath. The total volume of gas other than water is measured by letting the gas expand back into B, and measuring the pressure at one of the points of known volume (V_0–V_5). This measurement is in error, of course, by the ratio of the volume (S_1–S_2) to the total volume above (P), but this error can be made smaller than that from other sources.

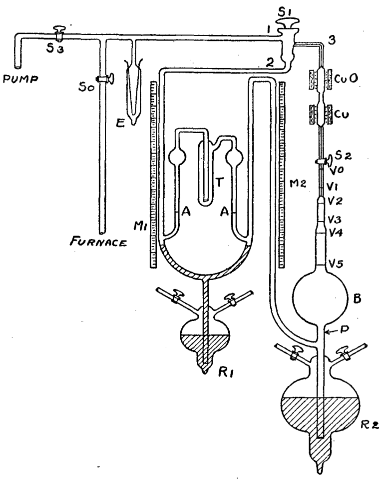

Fig. 2.—Analytical apparatus.

To determine the other gases the sample is recirculated through appropriate refrigerants and reagents as will be described in detail later in connection with final form of the apparatus.

This simple apparatus worked quite satisfactorily in most respects but in order to eliminate occasional trouble with leaking and plugging at the stopcock (S_2) it was decided to go over to a system in which there were no stopcocks. This would have the additional advantage of avoiding any contamination by vapors of stopcock grease. The method of determining water was simplified at the same time and the error due to the volume (S_1–S_2) was eliminated. The final form of the apparatus is shown in Fig. 3. In order to show things clearly the small parts have been drawn to a magnified scale so no indication of relative size is given by the diagram. Also the whole thing has been compressed vertically to save space.

The apparatus is best understood by tracing through the procedure, which is as follows. After the reading of the Pirani gage (E) indicates that a good vacuum has been obtained the mercury is raised in (H_1) and (H_3), thus cutting off the pumps and the reagent tubes. The glass sample is then added to the extraction furnace and the Toepler pump (B_1) is operated thus drawing the gas from the furnace through the trap (T) and compressing it into the gas buret (G) where the volume can be measured. The water vapor is removed from the gas as it passes through (T) which is cooled with solid carbon dioxide. When the major part of the gas has been extracted, which takes usually around half an hour, the furnace is closed off at (H_2) and the water is allowed to vaporize, filling the space between (H_1), (H_2), (H_3) and the trap in the capillary leading to (G). The volume of this space is known, and from the pressure reading on the Pirani gage which has been calibrated for water vapor, the quantity of water can be determined. The electrical circuit is that suggested by Campbell[6] in which the gage is in one arm of a Wheatstone bridge, the three other resistances of which have fixed values such that the bridge balances when the filament is around 100°. The bridge voltage necessary to obtain a balance is a measure of the gas pressure in (E).

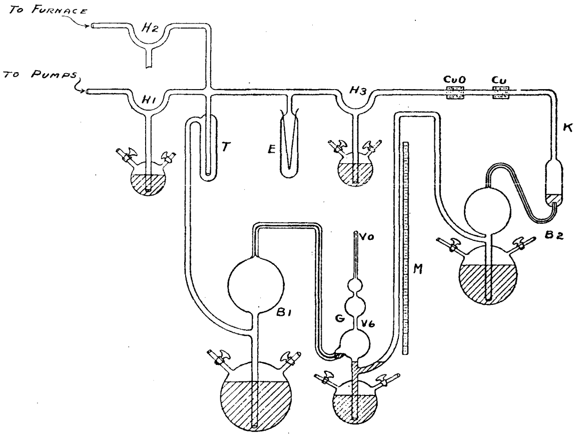

Fig. 3.—Analytical apparatus.

Using a gage with a filament of 28 cm. of 2 mil platinum wire, the voltage reading ran from 1 volt in vacuum to about 9 volts with a pressure of 4.59 mm. of water vapor. The voltmeter reading could be made to 0.01 volt. This method of determining water vapor has proved fairly satisfactory and is much easier and quicker than that described before. It has a disadvantage, however, in that there is sometimes a gradual drift in the gage reading, probably due to changes in the adsorbed gases on the filament surface. In this case it is necessary to wait until a steady value is reached before making the reading. The gage is immersed in a water-bath (not shown) maintained at an approximately constant temperature. After being determined, the water is removed from the apparatus by opening (H_1) to the pumps.

Sulfur dioxide is determined next by cooling (T) to −140° with a special bath and pumping the gas around with the Toepler pumps (B_2) and (B_1). The cut-off (H_1) is, of course, closed and (H_3) open. The cooling bath consists of petroleum ether in a heavy copper tube, the lower end of which terminates in a copper rod dipping in liquid air. The tube is wound around with a resistance heater. By properly balancing the cooling effect of the liquid air and heating effect of the current it is possible to hold the temperature of the bath within two or three degrees, which is close enough for our purpose. Temperature is measured with a small thermocouple immersed in the ether. The decrease of pressure in (G) when all the gas has been returned gives the sulfur dioxide content. If the Pirani gage were calibrated for this gas, it could also be determined in the same way as water.

For carbon dioxide the gases are circulated again as above except that the trap is cooled in liquid air. To be sure of the nature of the gas frozen out, the vapor pressure may be followed as the trap is allowed to warm up gradually. The vapor pressure of a gas is a fairly characteristic property and in a case like the present where only a few gases can conceivably be present it serves as a satisfactory identification.

Oxygen is determined by heating the tube containing metallic copper to around 350 or 400° and recirculating the gases. Before the gases are admitted, the reagent tube is given a good bake-out while open to the pumps. This is necessary to avoid errors due to gases given off by the hot glass or by the copper itself. As an additional precaution (T) may be immersed in liquid air, as most of the evolved gas is removed at that temperature. If only a small quantity of oxygen is expected the gas can be compressed over the reagents by closing (H_3) and filling the trap and tube (K) with mercury from (B_2). This accelerates the reaction.

For the measurement of carbon monoxide and hydrogen the gases are circulated over hot cupric oxide. The oxidation is quite slow in the case of carbon monoxide so the gas must be compressed as much as possible and left in contact with the cupric oxide for some time. In this case the previous outgassing of the reagent tubes must be particularly thorough as water vapor is the principal gas given off by the glass walls of the tube. Any water formed is collected in (T) by cooling with solid carbon dioxide and measured as before. It could also be obtained by the drop in pressure in the gas buret provided, as in our case, oxidizing and reducing gases cannot be present together. The carbon dioxide is measured as was that in the original sample.

Any inert, non-condensable gas which remains in (G) after the analysis would probably be nitrogen or one of the inert gases. In the samples we have run which came from glass there has never been any appreciable residue at this point.

The complete analysis of a gas sample requires about half a day. This does not include the time for outgassing the glass sample.

Analytical Results

The results of some test analyses are given in Tables I and II. Table I gives the results with the first form of the apparatus and Table II with the present one. With the latter, the errors vary from 0.5% or less in samples of 1 cc. or so up to several per cent. in small samples.

Since the apparatus was completed gas analyses have been run on several hundred glass samples. All samples except those that had been

---

(6) Campbell, *Proc. Phys. Soc.* (London), **33**, 287 (1921).

previously outgassed gave off appreciable quantities of gas. On the average it may be said that the volume of gas at standard conditions is at least as great as the volume of the glass sample. Table III gives some typical results obtained by three different analysts. A separate glass sample was used in each check analysis. The symbol R stands for residue of inert gas.

As may be seen from the table, it is impossible to check successive samples as closely as would be anticipated from the results of test analyses. This is due to difficulties in the extraction apparatus, previously mentioned, the principal of which is reabsorption of the gases by materials that are volatilized from the glass and condense in the cool upper section of the furnace tube. Sodium oxide probably causes the most trouble. Ways have been found to diminish this effect, but so far no way has been found to eliminate it. The best system is to clean the furnace tube thoroughly after each run, use a new crucible, and pump the gases away from the furnace as rapidly as possible.

VIII	Soda-lime (expt.)	1.41	28	28		10	8		62	64	..	..
IX	Borosilicate (heat resistant)	0.44	93	93		2	4		5	3	..	..

The table gives, in addition to the composition of the gas, the general type of the glass and the volume of gas at standard conditions obtained from a gram of sample. The latter is many times that obtained at low temperatures where the glass is still solid. All glasses examined contained water and this was usually the most abundant constituent. Carbon dioxide is also nearly always present though often only in small quantities. Sample No. 1 contained a large volume of carbon dioxide due to the basic character of barium oxide. Glasses which contain sodium sulfate give off sulfur dioxide, and those containing higher oxides of arsenic or iron give off oxygen. The gases carbon monoxide and hydrogen were rarely found present, and there was never an appreciable residue of inert gas. Glasses VI to IX may contain some sulfur dioxide but no test was made for this gas so the figure given represents the sum of sulfur dioxide and carbon dioxide. Sample No. VIII was an experimental glass of unusually high arsenic content.

In conclusion the author wishes to express his thanks to Messrs. W. C. Taylor and H. P. Hood for supervising the work and to A. Jacoby for valuable assistance in carrying out the experiments.

Summary

An apparatus is described for collecting and analyzing the gases evolved by glass when heated in vacuum. The apparatus takes samples of from 1 cc. to 0.01 cc. and analyzes for H_2O, CO_2, SO_2, O_2, H_2, CO and N_2, etc. (by difference). Results of test analyses and results with some typical glasses are given.

Heats of Adsorption of Gases and Vapors upon Crystallogenetic Adsorbents

BY ARTHUR B. LAMB AND EDWIN N. OHL

The heats of adsorption of many gases and vapors upon amorphous substances and particularly upon charcoal have been measured and a number of relationships affecting them have been discovered.[1] No such measurements have been made, so far as we are aware, upon *crystallogenetic* adsorbents, *i. e.*, adsorbents whose interior architecture retains to a greater or less degree the original structure of the crystalline material from which they have been prepared.[2]

Information on this score is of particular interest not only because of the high adsorptive capacity which certain of these adsorbents exhibit, for instance chabasite, but also because the greater uniformity in the fineness of the porosity of these adsorbents might well lead to heats of adsorption more divergent among themselves, *i. e.*, more specific, but individually less variable with the amount adsorbed than is the case with ordinary amorphous adsorbents.

We have therefore undertaken the measurement of the heats of adsorption of a number of gases and vapors upon three crystallogenetic adsorbents: chabasite, brucite and thomsonite.

Experimental Procedure

The Adsorbed Substances.—Samples of the best commercially available grades of the substances to be adsorbed were tested to ensure the absence of recognized impurities and were then subjected to further appropriate purifications. If the substance was liquid at ordinary temperatures, the final step in every case was distillation through an efficient fractionating column, only the middle fraction, boiling always within a range of 0.05°, being used in our measurements; if it was a gas, it was condensed either to a liquid or a solid and volatile impurities removed by evacuation, after which the condensed gas was allowed to warm up and to evaporate into the apparatus.

The *methyl alcohol* was twice redistilled over sodium. The absolute *ethyl alcohol* was refluxed for several hours over quicklime. The *carbon disulfide* was shaken exhaustively with mercury and distilled over sodium.

The *methyl chloride* was passed through two washbottles containing a concentrated solution of potassium hydroxide and then over phosphorus pentoxide. It was thereafter liquefied with carbon dioxide snow, evacuated for some time and then allowed to evaporate into the apparatus. The *ethyl chloride* and the *hydrogen sulfide* were dried over phosphorus pentoxide and repeatedly recrystallized by means of liquid nitrogen and then subjected to a high vacuum. In the case of the ethyl chloride freshly purified samples were employed for each run to avoid the presence of impurities which might have resulted from the action of diffuse light.

The *ethylene* and *nitrous oxide* were passed over phosphorus pentoxide and liquefied. They were then boiled for some time under reduced pressure, frozen with liquid nitrogen and the solid subjected to pumping for some time. The ethylene was further purified by repeated melting and recrystallization. The gas gave no condensate when chilled with solid carbon dioxide. Analysis by absorption in fuming sulfuric acid showed a purity of 99.7%.

The *carbon dioxide* was from a selected cylinder and contained by analysis only 0.12% of impurity. It was dried by passage over phosphorus pentoxide and introduced into the apparatus.

The *methane* was a sample specially purified by Dr. Woodhouse, which is described elsewhere.[3] Analysis by combustion indicated a purity of 99.0–99.4%, but it was probably purer than this.

The Adsorbents

Chabasite.—This was in every case material said to have been collected in the vicinity of Aussig, Bohemia. The clear samples were freed from adventitious material, crushed, sorted to pass a 14- and be retained on a 20-mesh screen, and equilibrated over 24% sulfuric acid for at least two weeks according to the procedure described elsewhere.[3] The activation of the chabasite by dehydration at 500–550° has been described elsewhere. In four representative cases the losses of water were as follows:

Sample no.	9	11	14	16	Average
Loss, %	21.62	21.35	21.37	21.38	21.42

These values agree closely with those obtained by Lamb and Woodhouse with comparable material similarly treated. They found that chabasite dehydrated under these conditions and to this extent had the maximum adsorptive capacity for a variety of gases. Exhaustive dehydration at a higher temperature, accompanied by a marked loss of adsorptive capacity, gave a total water content of 22.3%, so that the activated material can be taken as 96.0% dehydrated.

Brucite.—Our material was all from one lot collected near Cleevelah, Washington. It was cleaned, pulverized, and sorted by the same procedure used with chabasite and was dehydrated at 550° at a pressure of 2–5 mm. Two samples showed a loss of water amounting to 27.33 and 27.15%, average 27.24%, which agrees closely with the values obtained by Lamb and Woodhouse under similar

(2) The heat of adsorption of water vapor on dehydrated chabasite has recently been measured by Tiselius and Brohult, *Z. physik. Chem.*, **A168**, 248 (1934).

(3) Lamb and Woodhouse, THIS JOURNAL (to appear).

conditions. They found that brucite dehydrated to this extent (88.3% of complete dehydration) exhibited maximum adsorptive capacity.

Thomsonite.—This material came from Table Mountain, Golden, Colorado, and was prepared and activated in the same way as the chabasite. Two samples heated at 550° to constant weight lost 13.17 and 13.20%; average 13.19%. Since the original material contained 13.72% of water, these samples were dehydrated to 96.0 and 96.2% of completion.

Apparatus and Manipulation.—Following the lead of Titoff[4] and many subsequent investigators in this field, we have employed the ice-calorimeter in our measurements. This and the accessory apparatus are shown in Fig. 1.

The adsorption cell L had a volume which never differed greatly from 6.5 cc. and was connected to the buret A and the manometer N·P by capillary tubing of 1 mm. bore. L was surrounded by mercury in the inner tube of the ice-calorimeter proper, F, which was completely covered by a mixture of washed ice and distilled water in the Dewar flask H which in turn was surrounded by ice and water in a large, tall beaker, G. A drop of alcohol was added, as usual, to the water-filling of the ice-calorimeter.

The position of the mercury thread in the capillary tube J was read by means of an attached millimeter scale and a suitable telescope with micrometer eyepiece, to within 0.1 mm. The tube was carefully calibrated throughout its whole length and corrections to within 0.1 mm. were applied when required.

The weight of mercury per centimeter length of thread in this capillary was determined in three successive measurements to be 20.48, 20.51 and 20.47 mg.; average 20.49 mg. Taking 0.01546 g. as the weight of mercury corresponding to one calorie,[5] one centimeter length of thread corresponds to 1.325 cal.

The gas buret was provided with a water jacket which could be stirred with a current of air and was calibrated throughout its length to 0.01 cc. The volume of the capillary tube between the buret and the fiduciary mark in N was 0.24 cc.

The thermometers were calibrated to 0.01°, at the ice-point and at the transition temperature of sodium sulfate decahydrate.

The rate of heat-leak was determined before and after each measurement of the heat of adsorption. Usually it amounted to about 1 mm. per hour, but it was frequently even less. Since the heat evolution accompanying adsorption was usually complete within about fifteen minutes, the heat-leak could often be neglected. The room temperature was usually about 23°; no measurements were carried out when it exceeded 29° or was less than 15°.

The pressure in the system was measured by observing the difference in height of the mercury surfaces in the two limbs of N by means of a cathetometer reading to 0.05 mm. For high pressures the right-hand limb was open to the atmosphere; for low pressures it was exhausted to a negligible pressure as determined by the McLeod gage P. In every case the mercury level in the left-hand limb was brought to the fiduciary mark just below the beginning of the capillary tube.

Preparation of the Adsorbent.—A fresh adsorption cell was used for each new sample of adsorbent. These cells, before they were filled, consisted of a tube about 12 mm. in bore and 60 mm. long sealed on one end to a short length of capillary tubing and on the other to a short length of tubing with a bore of about 3 mm. bearing a mark near the seal. The volume of the cell from the capillary tube to the mark in the other tube was first carefully measured. The cell was then dried, filled with the granular adsorbent, the small tube sealed off sharply at the mark without heating the absorbent, and the capillary tube of the cell sealed onto the capillary tube of the apparatus.

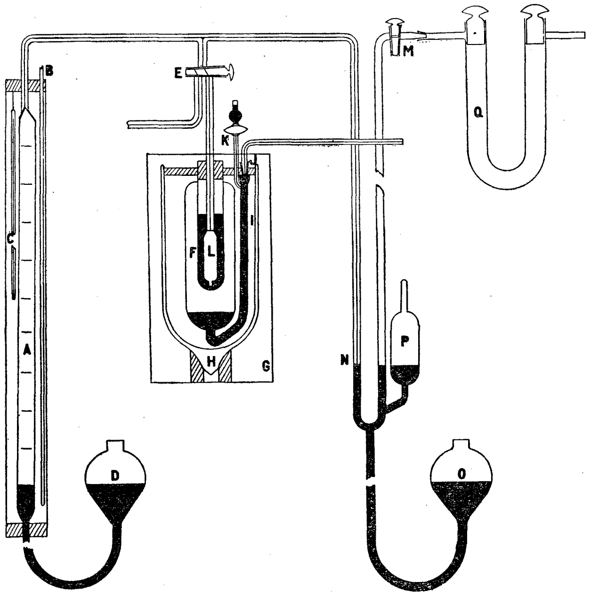

Fig. 1.

The phosphorus pentoxide tube Q was then attached and the whole system evacuated through it with a mercury diffusion pump. A cylindrical furnace was placed around the adsorption cell and its temperature raised gradually to 300° and then more rapidly to 500–550° as indicated by a mercury-in-quartz, nitrogen-filled thermometer with its bulb beside the cell. The pressure was maintained at 0.03 mm. After a suitable interval the stopcocks were closed, the furnace was removed and the tube Q disconnected and weighed.

Calorimetric Measurements.—The ice-calorimeter assembly was now raised by a jack so as to surround the adsorption cell, the position of the mercury thread was adjusted by means of the stopcock K and the measurement of the initial heat-leak was commenced. The tube Q was re-

(5) Ostwald-Luther, "Physiko-chemische Messungen," 1925, p. 397.

placed, the system exhausted, the mercury in N brought to the fiduciary mark, the buret charged with gas and its temperature and pressure accurately ascertained.

After a constant heat-leak had been maintained for at least twenty minutes, gas was introduced into L and G, the stopcock E was closed and the pressure and volume in the buret were measured. A constant heat-leak was in general reestablished in about fifteen minutes, but observations were usually continued for an additional half hour.

After one such determination of the heat of adsorption, an additional amount of gas was admitted to the adsorbent and the resultant heat evolution again measured. This procedure was repeated until the rate of the adsorption became unduly slow.

Computation of the Results.—The observed pressures of the gases before and after adsorption were corrected to 0° by the usual formula applicable to mercury and a brass scale. They were also corrected for molecular attraction by means of the values of the term *a* in the van der Waals equation as listed in the Landolt–Börnstein tables. From these corrected pressures and the observed temperatures the volumes under standard conditions of the gas in the buret were computed by means of the simple gas law. Their difference, corrected for the dead space, gave the volume of gas actually taken up by the adsorbent.

The total excursion of the mercury thread corrected for the heat-leak and for any inaccuracies in the bore of the capillary multiplied by the above mentioned factor gave the apparent heat of adsorption. From this was subtracted the relatively small amount of heat given off by the gas in cooling from the observed room temperature to zero degrees as computed from the known specific heat of the gas. Finally, dividing by the weight of the adsorbent, the heat of adsorption per gram of adsorbent was obtained.

Reliability of the Measurements.—The volume of gas taken up by the adsorbent could be ascertained to within about 0.02 cc. and since volumes of 10 cc. or more were usually involved, the error on this score would amount to about 0.2%. Usually the uncertainty due to the unknown volumes created by the removal of water from the adsorbent was considerably less than this, but in some instances where the saturation pressure was high and the amount adsorbed small, an additional error of about the same magnitude was introduced. The thermal measurements were subject to an experimental uncertainty of about 0.02–0.03 cal., and since heats of 5–10 cal. were usually evolved, the error here was about 0.3%. The over-all error attached to a typical measurement of the heat of adsorption can therefore be estimated as about 0.5%. An examination of the plotted results (see Fig. 3) indicates that the average deviation from a smooth curve of the measurements within the above ranges is no greater than this estimate.

Results

Heats of Adsorption.—The experimental data and the results computed therefrom for a single measurement of the heat of adsorption of carbon dioxide upon chabasite are given in full in Table I in order to illustrate the procedure followed in all of our measurements and in the computations based upon them.

sent the corrected volumes of gas adsorbed per gram of *completely* dehydrated adsorbent, those under $h_{\text{obsd.}}$ the heat evolutions accompanying these adsorptions.

In Fig. 2 the heats of adsorption are plotted against the amount adsorbed. Most of the curves differ but slightly, and in two cases not at all, from straight lines. This means that the heat of adsorption per cubic centimeter of adsorbed gas is nearly or quite independent of the amount adsorbed. This is the same behavior previously observed with charcoal.[6] Indeed, the empirical equation, $h = ax^n$, which was there found to express the experimental results satisfactorily is equally applicable here, as is shown by Fig. 3 where these deviations are plotted on a large scale against the amount adsorbed. It can be seen that the deviations are usually small and for the most part lie upon smooth curves to within the previously estimated accuracy of our

measurements irrespective of the sample taken and of the number of times it had been re-evacuated. The only marked exception to this is with carbon dioxide where the measurements with sample No. 8 give definitely different results than those with sample No. 16. The values of the constants in these formulas are collected in Table V and it can be seen that here, as in the case with charcoal, the value of *n* is usually not far from unity.

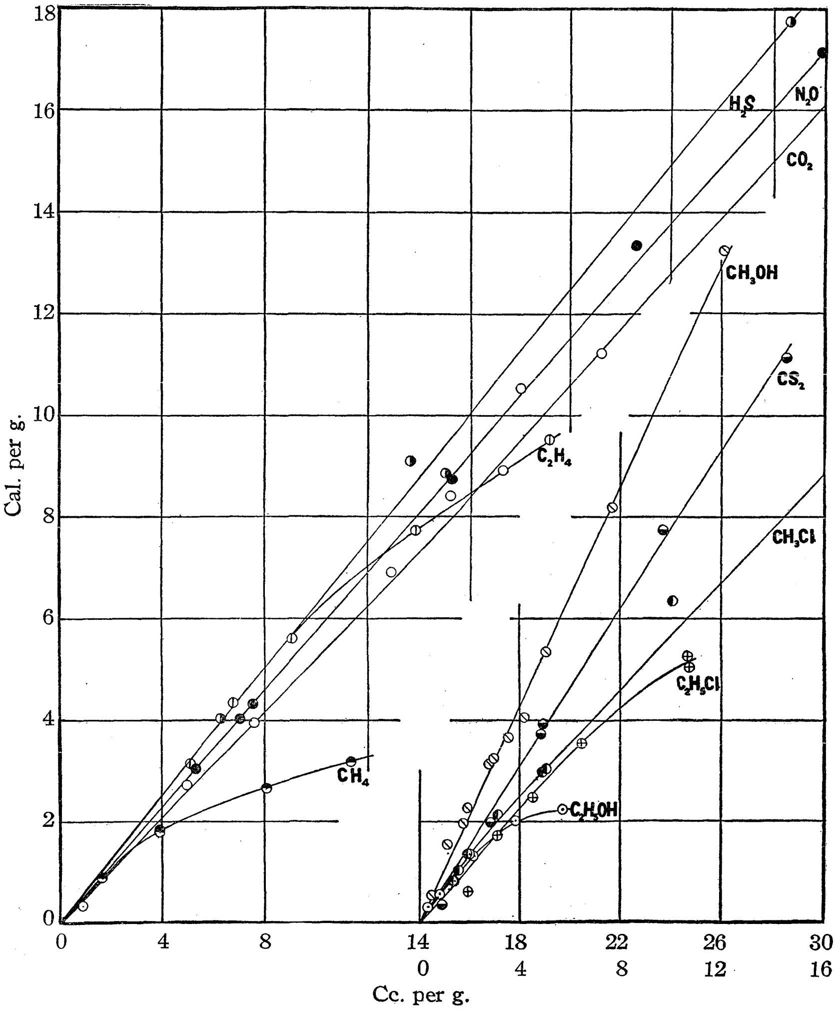

Fig. 2.—○, CO_2; ⦶, C_2H_4; ⊘, CH_3OH; ⊕, C_2H_5Cl; ⊙, $C_2H_5O_4$; ◑, H_2O; ◐, CH_3Cl; ◒, CS_2; ●, N_2O; ⊖, CH_4.

Molar Heat of Adsorption.—The empirical formulas permit a convenient calculation of the molar heats of adsorption of the respective gases at the same molar concentration in the adsorbent. Values thus computed for 11 cc. of gas per gram (0.0005 mole per gram), which is in general within the range of the empirical equations, are given in the fourth column of Table V. It is interesting that these values are not very different from those previously found for adsorption upon charcoal (Col. 5).

The curves in Fig. 4 present our results for the heat of adsorption of carbon dioxide on dehydrated chabasite, thomsonite and brucite along with corresponding results of others with charcoal and silica gel. The constants of the empirical formulas which express these results and the molar heats of adsorption calculated from them are collected in Table VI.

It is clear that the crystallogenetic adsorbents show a considerably greater heat of adsorption for carbon dioxide than do charcoal and silica gel.

It is of interest that while most of the curves in Fig. 4 are straight lines (and the exponent *n* in the empirical equation nearly unity), that of dehydrated brucite has a marked curvature showing that the molar heat of adsorption increases decidedly for small amounts adsorbed. The heat of reaction of magnesia and carbon dioxide to form massive magnesium carbonate is 26.7 kg. cal. and is represented by the dotted line shown in Fig. 4. It can be seen from the position of this line that the molar heat of adsorption for small amounts adsorbed is as great or greater than this heat of reaction. A similar behavior has been reported in other cases.[7]

Effect of Dehydration on Heat of Adsorption.—In order to ascertain the relation between the extent of dehydration of these adsorbents and the heats of adsorption to which they give rise, we have measured the heat evolved when methyl alcohol is adsorbed on chabasite and on brucite after successive portions of water have

been removed from them. The procedure was the same as in the preceding measurements except that at the completion of a run the phosphorus pentoxide tube was attached and the alcohol was pumped off at room temperature, *after* which additional quantities of water were removed by gradual and gentle heating and pumping.

It proved to be impossible at low degrees of dehydration to remove all of the alcohol in this way without removing some of the water at the same time. The stated values for the degree of dehydration must therefore in these cases be considered as only approximate. At higher degrees of dehydration no such effect was detected. The experimental results are collected in Fig. 5.

It can be seen from these figures that the heats of adsorption on the slightly dehydrated material are decidedly less than on the more completely dehydrated material; however, the difference is proportionately smaller as the water content becomes less. The relationship is brought out even more clearly by Fig. 6, where the heats of adsorption of 0.000178 mole per gram, expressed as percentages of the maximum heat of adsorption, are plotted against the percentage of complete dehydration. It is evident that the points, with a single exception, for both adsorbents lie on a single curve which is nearly a straight line.

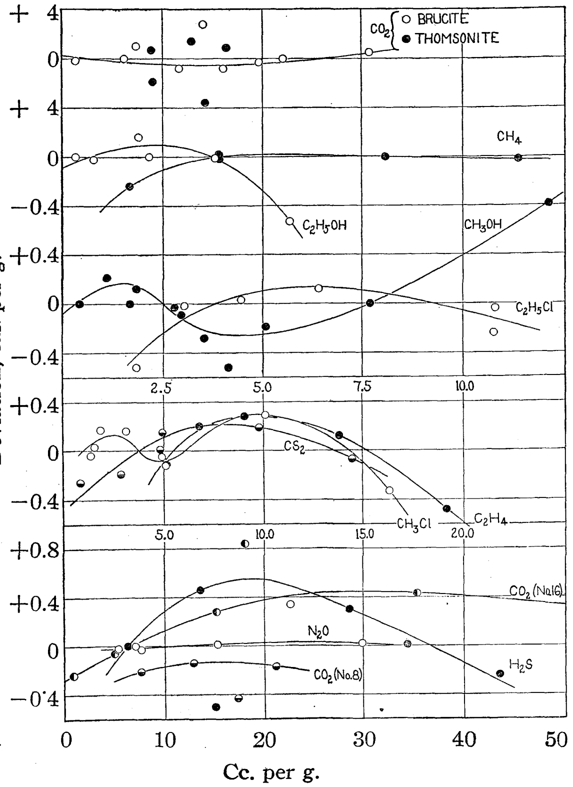

Fig. 3.—Deviations from empirical equation.

These effects would appear to indicate that the heat of adsorption per mole is decidedly greater at high degrees of dehydration than at low. On the other hand, since water is certainly desorbed from the slightly dehydrated adsorbents along with alcohol on pumping at room temperatures, it is probable that some desorption of water occurs under these conditions when the alcohol is adsorbed in the calorimeter and this would diminish the true heat of adsorption of the alcohol by the (negative) heat of desorption of the water. The observed heat of adsorption would therefore be too small by the amount of this disturbing factor. It is unlikely, however, that this can have affected the points for the more completely dehydrated samples or that it would give curves that are so nearly linear.

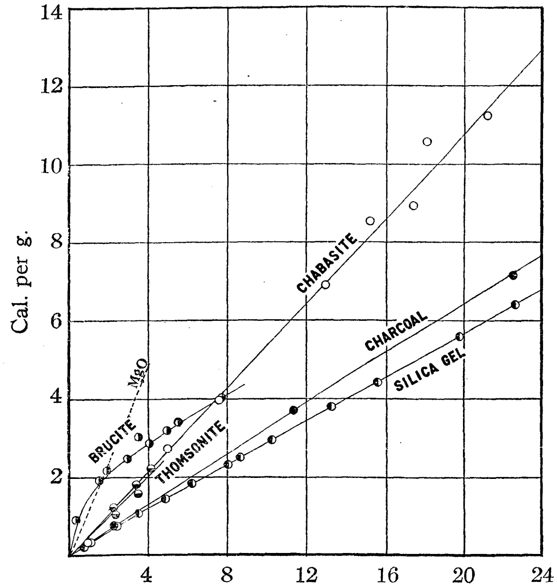

Fig. 4.—Heats of adsorption of carbon dioxide on various adsorbents.

Net Heats of Adsorption.—The *net* heats of adsorption have been obtained by subtracting from the molar heats of adsorption (h_m) the molar latent heats of vaporization of 0° (ϕ). The resulting values listed in the seventh column of Table V are, except for the value for methane which was obtained by using the empirical equation far beyond its range and those for ethyl chloride and ethyl alcohol which are aberrant for other reasons to be explained later, not very divergent among themselves and are in general considerably larger than the corresponding values upon charcoal at the same concentration (Column 8).

It has been shown[6] in the case of eleven volatile organic liquids, first, that while the net *molar* heats of adsorption vary considerably among themselves (from 6.22 to 10.65 kg. cal.) the net heats of adsorption per cubic centimeter of the *liquid* are nearly identical (0.0877 kg. cal. ±7.4%) and second, that the pressures which would be required to produce, by compression, heats equal to these net heats of adsorption are even more nearly identical (28,100 atmospheres ±4%).

To test the first relationship by the present data we have computed the net heats of adsorption per cubic centimeter of the liquids by dividing the net heats of adsorption per mole by the molar volumes of the liquids at zero degrees. The resulting values, given in Column 10, while they are all of about the same magnitude (average deviation from the mean ±25%) are by no means as concordant as in the case of the abovementioned organic liquids adsorbed on charcoal and are indeed less concordant than the net molar heats. This is, however, not surprising, for this relationship would only be expected to hold closely when the molar volumes are measured under the high virtual pressures prevailing in the adsorption layer or when they are proportional to the molar volumes at zero degrees measured at atmospheric pressure. In the case of the organic liquids with similar critical temperatures and compressibilities this proportionality probably exists, but in the case of the substances here studied with quite different critical temperatures and compressibilities it presum-

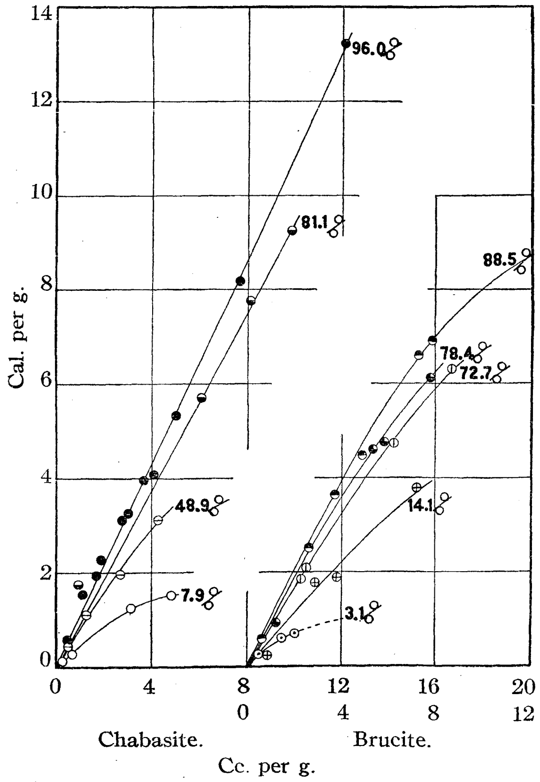

Fig. 5.—Methanol on partially dehydrated adsorbent.

ably does not and hence no such close concordance is to be expected.

We have not been able to test the second relationship since the data necessary to compute the heats of compression are lacking. It is clear, however, that in order to produce by real or virtual compression of the adsorbed layer, the considerably greater net heats of adsorption observed in these crystallogenetic adsorbents, the adsorptive pressure must be correspondingly greater than was found for charcoal.

The marked difference in the behavior of ethyl chloride and ethyl alcohol as compared with the other substances which we have studied should also be remarked. These substances are adsorbed but slightly, their heats of adsorption vary considerably with the amount adsorbed and their net heats of adsorption are small; indeed, that of ethyl alcohol is apparently negative. The explanation of this behavior is doubtless to be found in the decidedly greater dimensions of the molecules of these substances computed from known atomic radii and atomic distances, as compared with those of the other substances that we have studied. As has been pointed out previously,[8] molecules larger than a certain size are apparently unable to enter the fine pores of these crystallogenetic adsorbents, and the slight adsorption observed in these instances is presumably chiefly confined to the outer surfaces and to the inter- rather than intra-crystalline porosity. It is not surprising that this slight and mostly unoriented adsorption should evolve less heat than the more extensive and oriented adsorption within the dehydrated crystals.

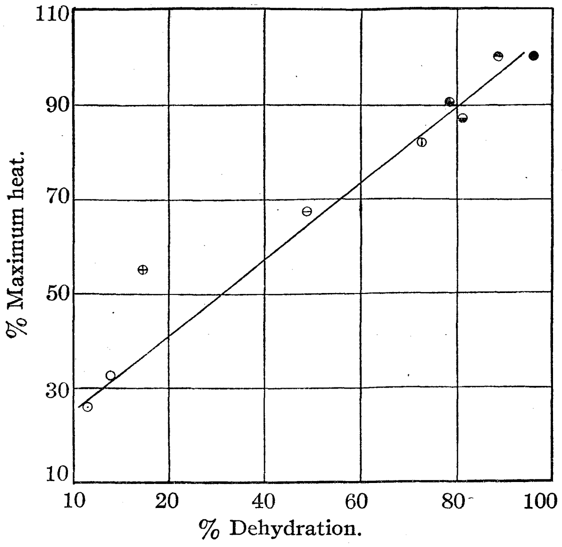

Fig. 6.

Summary

1. The heats of adsorption of a number of gases and vapors on dehydrated chabasite, thomsonite and brucite have been measured at 0°.

2. The molar heats of adsorption of such of these substances as are copiously adsorbed by these materials are in general somewhat larger than those previously observed on charcoal and silica gel but, like them, vary only slightly with the amount adsorbed and can be represented by the same empirical equation.

3. The net heats of adsorption are also considerably greater than those previously observed with charcoal and this indicates that the adsorbate on these adsorbents is subjected on the average to a more intense adsorptive and compressive force than on charcoal.

The Configuration of the Mercuric Halides

BY W. J. CURRAN AND H. H. WENZKE

The Raman spectra of the mercuric halides have been interpreted[1] to indicate a linear structure for these compounds. Bell[2] calculated the moments of the mercuric halides from solubility data. He obtained 4.0, 5.7 and 6.6 × 10^{18} for the chloride, bromide and iodide, respectively. Braekken and Scholten[3] concluded from x-ray data that the molecular configuration of mercuric chloride was linear but that of mercuric bromide was not. The solubility of the mercuric halides in benzene is so small that it is difficult to use this solvent in the determination of electric moments. These halides are more soluble in dioxane and it is for this reason that the latter solvent was used. In order to determine whether or not the dioxane formed a coördinate compound with the mercury, it was used as a solvent in the determination of the moment of mercury diphenyl. The moment of mercury diphenyl had already been determined in benzene by Hampson.[4] He obtained the value 0.41.

TABLE II

POLARIZATIONS AND MOMENTS OF MERCURIC COMPOUNDS

Comopund	P_∞	P_E[a]	P_{A+0}	$10^{18}\ \mu$
Mercury diphenyl	69.02	65.30[4]	3.72	0.42
Mercuric chloride	65.03	30.36[5]	34.67	1.29
Mercuric bromide	78.63	55.30[5]	23.33	1.06
Mercuric iodide	101.40	94.28[5]	7.12	0.58

[a] The electronic polarizations were obtained from the literature according to the references given.

Discussion of Results

The value of 0.42 obtained for the moment of mercury diphenyl in dioxane is practically the same as that obtained by Hampson[4] in benzene, namely, 0.41. This shows that the oxygen of the dioxane does not form a coördinate covalent link with the mercury and that the dioxane is a satisfactory solvent for these compounds. It is apparent from the moments of these compounds that the mercuric halides are not linear in structure. The decrease of the moment with increase in atomic weight of the halogen is no doubt due in part to steric effects which cause a widening of the valence angle of the mercury as the atomic weight of the halogen increases. It is no doubt also true that the moment of the mercury-to-halogen linkage decreases with increase in size of the halogen atom. Unfortunately the electric moment data do not permit the calculation of the valence angle of the mercury in these halides. The measured moments are very much smaller than those obtained in the calculations of Bell.[2] The force relationships existing between the solute and solvent are of such a complex nature that at present no quantitative relation between them and dipole moments is known.

Summary

1. Electric moments have been determined for mercury diphenyl, mercuric chloride, mercuric bromide and mercuric iodide.

2. The configuration of the mercuric halides is not linear, as has been sometimes assumed from other lines of investigation.

(5) Bergmann, Engel and Wolf, *Z. physik. Chem.*, **B17**, 81 (1932).

3. The moments obtained by direct measurement are much smaller than has been calculated from solubility data. While dipole forces undoubtedly play a part in determining solubility, apparently not enough is known about them to permit an even semi-quantitative calculation of electric moments by this method.

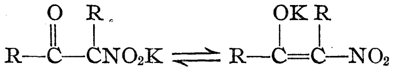
Asymmetric Syntheses. IV. The Action of Optically Active Nitrates on 2-Bromofluorene

By J. T. Thurston and R. L. Shriner

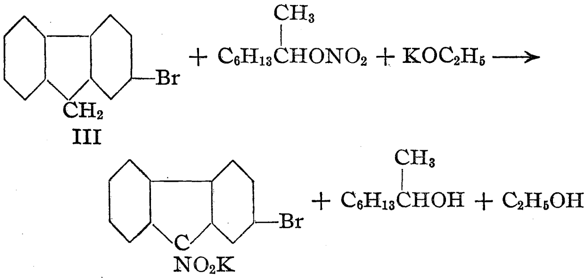
The reaction between optically active nitrates and cyclic ketones[1] led to the formation of salts which could possess either structure[2] I or II. In order to avoid this, a study has been made of the action of optically active nitrates on an active methylene compound which cannot undergo such tautomerization.



$$\mathrm{R{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}NO_2K \rightleftharpoons R{-}\overset{\overset{OK}{|}}{C}{=}\overset{\overset{R}{|}}{C}{-}NO_2}$$

I II

Since Wislicenus and Waldmüller[3] showed that fluorene would react with ethyl nitrate in the presence of potassium ethoxide to give the potassium salt of 9-nitrofluorene, it was decided to study the reaction between the optically active 2-octyl nitrates and 2-bromofluorene (III).

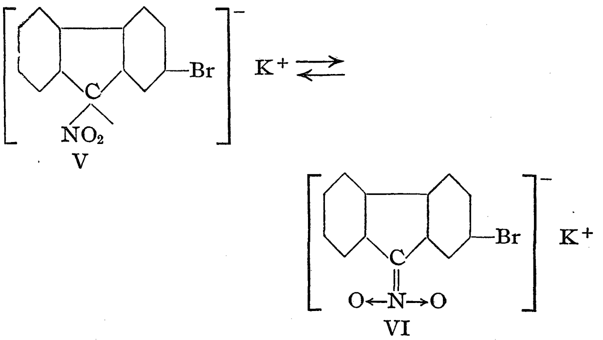


III

IV

The latter compound (III) contains an active methylene group but cannot undergo enolization. The presence of the bromine in one ring renders the molecule unsymmetrical so that carbon atom 9 in the product (IV) may be asymmetric.

Treatment of 2-bromofluorene with *d*-2-octyl nitrate in the presence of potassium ethoxide yielded the potassium salt of 9-nitro-2-bromofluorene which possessed a very slight optical activity. Two independent preparations gave specific rotations[4] of +4.48 and +4.33°. The observed rotations were very low, +0.06 ± 0.01° and +0.05 ± 0.01°, but the absolute alcohol solutions of the salts were distinctly optically active. The *l*-2-octyl nitrate gave a very low specific rotation of −1.71°. The salts racemized readily. The activity of these salts indicates that at least a partial asymmetric synthesis was achieved by the optically active reagents. At least part of the salt must exist as the asymmetric ion (V) since the other form of the ion (VI) is not asymmetric.



V

VI

Immediate treatment of the *d*-potassium salt with acid gave the *aci*-9-nitro-2-bromofluorene (VII) which was optically inactive. This *aci*-form (VII) was a solid, m. p. 132°. It was readily soluble in sodium carbonate solution, and gave a green color with ferric chloride. This *aci*-form was transformed into the *normal*-nitro compound (VIII) by heating it in alcoholic solution. The *normal*-nitro compound (VIII) gave

(2) Horne and Shriner, *ibid.*, **55**, 4652 (1933).

(3) Wislicenus and Waldmüller, *Ber.*, **41**, 3334 (1908).

(4) All specific rotations reported in this paper were determined at 25° with sodium D light.

no color with ferric chloride, and was insoluble in sodium carbonate solution. These two compounds, therefore, constitute another case in which both the *aci*- and *normal*-forms have been isolated. It is worth pointing out that there should be two geometric isomers of the *aci*-form (VII); one, in which the hydroxyl is *syn* to the bromine in the ring, and a second in which the hydroxyl is *anti* to the bromine. Only one form of VII was obtained in the present work.

Air oxidizes these potassium salts to 2-bromofluorenone and potassium nitrite, a reaction which has been observed previously by Wislicenus and Waldmüller in the case of the salts of 9-nitrofluorene.[3] Bromine converted the *d*-potassium salt into 9-nitro-2,9-dibromofluorene, which was optically inactive. A quantitative bromine titration of the potassium salt, according to the general procedure of Meyer and Wertheimer,[5] showed that 90% of the theoretical amount of bromine was taken up. Titration of the *aci*-form VII gave a 50% absorption of bromine, whereas the *normal*-nitro form VIII did not absorb bromine at all under the conditions of the titration. The fact that the *aci*-form changes over to the *normal*-form probably accounts for the bromine titration value of 50%. These results are of importance since they constitute some evidence against the cyclic structure, IX, which was originally proposed for the *aci*-form by Holleman,[6] and Hantzsch and Schultze.[7] The ready formation of the bromonitro compound from the salt and the absorption of bromine by the *aci*-form are best explained by the structure X for the *aci*-modification rather than by IX. These *aci*-forms parallel the nitrogen alkylated ketoximes which have been shown[8] to possess the structures XI and XII. As mentioned above, none of the *syn* and *anti* forms of *aci*-nitro compounds have been obtained as yet.

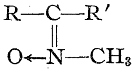
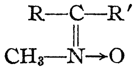
$R-C(=N(\rightarrow O)-OH)-R'$

X



$R-C(=N(\rightarrow O)-CH_3)-R'$

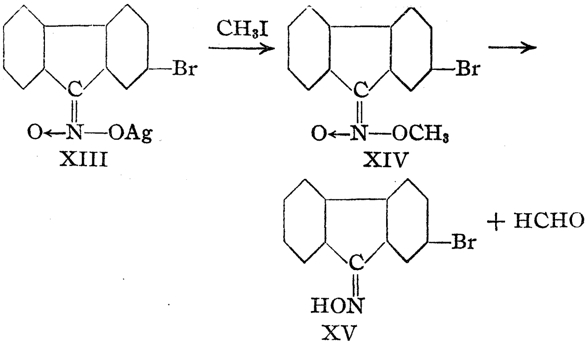
XI



$R-C(=N(\rightarrow O)-CH_3)-R'$

XII

Nenitzescu and Isacescu[9] have found that alkylation of sodium or potassium salts of nitro compounds leads to degradation products which may be best explained by an intermediate nitronic ester. In the present study it was found possible to obtain the methyl nitronic ester (XIV) by treating the silver salt of 9-nitro-2-bromofluorene (XIII) with methyl iodide.



This nitronic ester (XIV) was very unstable, and readily decomposed into 2-bromofluorenone oxime (XV) and formaldehyde. This decomposition is characteristic of nitronic esters[10] and shows that alkylation occurred on the oxygen atom, and not on the carbon atom.

Experimental

2-Bromofluorene.—To 125 g. of fluorene and about 1 g. of iodine, dissolved in 350 cc. of boiling benzene, was added during the course of three hours 120 g. of dry bromine dissolved in 200 cc. of cold benzene. This solution was refluxed for another hour, cooled, washed with water and finally with sodium bisulfite solution. After distilling the benzene and water, the product was fractionated twice. About 20 g. of unchanged fluorene, 75 g. of product boiling at 157–162° (1–2 mm.) and 40–50 g. of undistillable tar were obtained. The crude product was recrystallized from three 500-cc. portions of alcohol, and melted sharply[11] at 113°. The yield was 65 g., or 35% of the theoretical.

Anal. Calcd. for $C_{13}H_9Br$: Br, 32.65. Found: Br, 32.66.

***dl*-, *d*- and *l*-2-Octyl Nitrates.**—These were prepared according to the method previously described.[1] *dl*-2-Octyl nitrate boiled at 92–94° (17 mm.); n^{20}_D 1.4240. *d*-2-Octyl nitrate boiled at 96–97° (16 mm.; $[\alpha]^{25}_D$ +16.00°; n^{20}_D 1.4270. *l*-2-Octyl nitrate boiled at 95–97° (20 mm.); $[\alpha]^{25}_D$ −15.28°; n^{25}_D 1.4292.

Condensation of 2-Bromofluorene with *dl*-2-Octyl Nitrate.—A solution of 5.6 g. of *dl*-2-octyl nitrate and 6 g. of 2-bromofluorene in 80 cc. of absolute ether was added to a solution of potassium ethoxide prepared from 1 g. of potassium, 7 cc. of absolute ethyl alcohol and 25 cc. of absolute ether. The reaction mixture was maintained at 45° by means of a water-bath; after about two hours half of the ether was distilled. The remaining solution was filtered and poured into 200 cc. of low-boiling petroleum ether. The yellow, precipitated potassium nitro salt was purified by dissolving in a very small amount of ethyl

acetate and reprecipitated with equal parts of benzene and petroleum ether. The product, which gave a green color with a drop of ferric chloride, was obtained in yields of 62.5% of the theoretical.

Anal. Calcd. for $C_{13}H_7O_2NBrK$: K, 11.89; Br, 24.36; N, 4.27. Found: K, 12.11; Br, 24.50; N, 4.05.

Condensation of 2-Bromofluorene with *d*-2-Octyl Nitrate.—The same general procedure as above was followed, using *d*-2-octyl nitrate. However, the temperature was maintained at 35°, and the ether was removed at diminished pressure. The yield of the crude salt, giving an immediate specific rotation[4] in absolute alcohol of +4.33°, was 1.5 g. Another sample of the salt, prepared in the same manner, gave an immediate specific rotation in absolute alcohol of +4.48°. Below 30° the reaction did not take place, and between 30 and 35° the yields were very small. The order of addition or molar ratio of the reactants had no effect on the yield or optical activity of the salt.

Anal. Calcd. for $C_{13}H_7O_2NBrK$: K, 11.89. Found: K, 11.51.

Condensation of 2-Bromofluorene with *l*-2-Octyl Nitrate.—Exactly the same procedure as above was followed using *l*-2-octyl nitrate, and the specific rotation[4] of the salt in absolute alcohol was immediately determined and found to be −1.71°.

Reaction between *dl*-2-Octyl Nitrate and Potassium Ethoxide.—A control experiment identical with the above procedure except that the 2-bromofluorene was omitted showed that the potassium 2-octoxide was soluble in the concentrations of alcohol, ether and petroleum ether used in the above reactions, and, therefore, could not contaminate the salts of the nitro compounds.

2-Bromofluorenone from the Potassium Nitro Salt.—The potassium nitro salt in alcohol solution on exposure to air for several days was oxidized to potassium nitrite and 2-bromofluorenone melting at 146°. The latter yielded an oxime which melted at 196°, while the recorded[12] melting point is 194–195°.

Anal. Calcd. for $C_{13}H_7OBr$: Br, 30.88. Found: Br, 31.49.

Aci-9-Nitro-3-bromofluorene.—The bright yellow precipitate, obtained by the action of dilute acetic acid upon an aqueous solution of the *dl*-potassium nitro salt, after recrystallization from hot alcohol, melted at 132°. It was soluble in dilute alkalies and gave a green color with a drop of ferric chloride. The optically active salts gave the same optically inactive *aci*-form.

Anal. Calcd. for $C_{13}H_8O_2NBr$: N, 4.83; Br, 27.55. Found: N, 5.01; Br, 27.78.

9-Nitro-2-bromofluorene.—When an alcoholic solution of the *aci*-nitro form was boiled it was converted into the normal nitro form which crystallized when the solution cooled. The colorless plates, after recrystallization from ethyl acetate, melted at 170°, were insoluble in dilute alkalies and did not give a color with a drop of ferric chloride. On longer standing, the original filtrate deposited crystals of 2-bromofluorenone, melting at 146°.

Anal. Calcd. for $C_{13}H_8O_2NBr$: N, 4.83; Br, 27.55. Found: N, 4.84; Br, 27.59.

2,9-Dibromo-9-nitrofluorene.—An alcoholic solution of the *dl*-potassium nitro salt on treatment with a solution of bromine in absolute alcohol gave the dibromo compound, which was precipitated by the addition of water. After recrystallization from an alcohol–ethyl acetate mixture, the yellow needles melted at 139°.

Anal. Calcd. for $C_{13}H_7O_2NBr_2$: Br, 43.32; N, 3.79. Found: Br, 43.38; N, 4.03.

The *d*-potassium nitro salt, by exactly the same procedure as above, gave the same dibromo compound, which was washed with a small amount of alcohol, dried in a vacuum desiccator and the optical rotation immediately taken. It was optically inactive.

Methylation of the Silver Salt.—The silver salt was prepared in almost quantitative yields by the addition of silver nitrate solution to an aqueous solution of the potassium salt. To 2 g. of the dried silver salt suspended in 5 cc. of ether cooled to −10° was added 3 cc. of methyl iodide dissolved in 6 cc. of ether. After shaking the suspension for six hours, the mixture was filtered and the filtrate evaporated at diminished pressure. After four recrystallizations from a mixture of ether and petroleum ether the product still melted over a wide range, 72–80°. When stored in a desiccator the odor of formaldehyde was noted in a short time. The analysis for nitrogen was high indicating the presence of some of its decomposition product, 2-bromofluorenone oxime.

Anal. Calcd. for $C_{14}H_{10}O_2NBr$: N, 4.60. Found: N, 4.96.

When the above nitronic ester was dissolved in alcohol and warmed for about thirty minutes, the transformation into the oxime was complete. The 2-bromofluorenone oxime melted at 195° and a mixed melting point with an independently prepared specimen showed no depression.

Bromine Titrations.—The general procedure of Meyer and Wertheimer was followed, using a weighed amount of the *dl*-potassium nitro salt, which was dissolved in cold alcohol and quickly titrated with a freshly prepared methyl alcohol solution of bromine. The excess bromine was removed by adding 2–3 cc. of 10% β-naphthol solution. After excess 20% potassium iodide solution was added and warmed for twenty minutes, the liberated iodine was titrated with 0.1 *N* thiosulfate solution using starch as an outside indicator.

Compound	Bromine absorption % of calcd.
dl-Potassium salt	89.2–90.4
Aci-nitro form	50.4
Normal nitro form	0.0
Nitronic ester	48.8–53.5
2-Bromofluorenone oxime	50.76

Since the nitronic ester breaks down into the oxime, the values for these two compounds are similar.

Summary

The condensation of 2-bromofluorene with *d*- or *l*-2-octyl nitrate produced the potassium salts of 9-nitro-2-bromofluorene. These salts were slightly optically active.

Acidification of the salts gave optically inactive

---

(12) Courtot, *Ann. chim.*, [10] **14**, 62 (1933).

aci-9-nitro-2-bromofluorene. Treatment with bromine gave 9-nitro-2,9-dibromofluorene which was also optically inactive.

Methylation of the silver salt of 9-nitro-2-bromofluorene gave an unstable nitronic ester which readily decomposed into 2-bromofluorenone oxime and formaldehyde.

The *aci*-nitro form of 9-nitro-2-bromofluorene readily rearranged to the *normal* form. The latter did not absorb bromine whereas the *aci*-form absorbed 50% of the theoretical amount.

Some Derivatives of *p*-Fluorophenyl Sulfinic Acid[1]

BY RAYMOND M. HANN

In connection with a study of the action of certain sulfur compounds as possible chemotherapeutic agents in the treatment of pneumonia, a series of derivatives of *p*-fluorophenyl sulfinic acid has been prepared. The sodium salt of *p*-fluorophenyl sulfinic acid was readily obtained from fluorobenzene by the synthesis of Knoevenagel and Kenner[2] and proved to be a suitable material for the introduction of various substituents in the sulfinic acid group. Such compounds as were applicable in regard to solubility and toxicity were tested upon pneumococcus infections in mice by Dr. Sanford Rosenthal, of the Division of Pharmacology, National Institute of Health, but proved to be without therapeutic effect.

Experimental

Sodium *p*-Fluorophenyl Sulfinate Dihydrate.—Dry hydrochloric acid gas was bubbled through an ice-cold suspension of 15 g. of anhydrous aluminum chloride in a solution of 10 g. of fluorobenzene in 25 cc. of carbon disulfide until it was saturated. Dry sulfur dioxide was then introduced in a slow steady stream until the crystalline aluminum chloride was completely changed to a heavy green oily layer (three hours), which became crystalline on standing overnight at room temperature. The reaction mixture was decomposed with 200 cc. of ice water, 20% sodium hydroxide added to strong alkalinity (about 70 cc.), the suspension digested for an hour on the steam-bath, filtered, the soluble aluminum precipitated by passing in carbon dioxide, and, following a second filtration, the mother liquor concentrated to a volume of 50 cc. when a first crop of 12.7 g. of pure salt separated. A second crop, upon further concentration, brought the total yield to 17.0 g. (75% based on dihydrate). Recrystallized from one part of hot water it separated in glistening diamond shaped crystals of the dihydrate.

Anal. Calcd. for $C_6H_4O_2SNaF \cdot 2H_2O$: Na, 10.5; H_2O, 16.5. Found: Na, 10.4; H_2O, 16.7.

Benzyl-ψ-thiourea Salt of *p*-Fluorophenyl Sulfinic Acid.—Cold solutions of 1 g. of benzyl-ψ-thiourea hydrochloride in 10 cc. of 0.25 *N* hydrochloric acid and of 0.9 g. of sodium *p*-fluorophenyl sulfinate in 10 cc. of water were mixed, the resulting thiourea salt filtered and recrystallized from 25 cc. of 0.25 *N* acid, when it separates in elongated prismatic columns showing a melting point of 161° (corr.).

Anal. Calcd. for $C_{14}H_{15}O_2N_2S_2F$: N, 8.6. Found: N, 8.7.

Benzyl-ψ-thiourea Salt of *p*-Fluorophenyl Sulfonic Acid.—A solution of 1 g. of sodium *p*-fluorophenyl sulfinate in 5 cc. of *N* sodium hydroxide was treated dropwise with 5 cc. of 30% hydrogen peroxide, and following the original heating up and gas evolution, it was heated on the steam-bath for one-half hour to complete the oxidation. The oxidized solution was carefully neutralized with *N* hydrochloric acid and added to a solution of 1.1 g. of benzyl-ψ-thiourea hydrochloride in 10 cc. of 0.25 *N* hydrochloric acid. The precipitated salt was filtered and recrystallized from 15 cc. of 0.25 *N* hydrochloric acid, being obtained in brilliant plates, melting at 166° (corr.).

Anal. Calcd. for $C_{14}H_{15}O_3N_2S_2F$: N, 8.2. Found: N, 8.3.

***p*-Fluorophenylphenacyl Sulfone.**—A solution of 1 g. of sodium *p*-fluorophenyl sulfinate in 5 cc. of water and 15 cc. of 95% alcohol was refluxed for fifteen minutes with 1.1 g. of ω-bromoacetophenone and the precipitate which separated on cooling was recrystallized from 30 cc. of 95% alcohol. The sulfone separates in large elongated colorless plates melting at 151° (corr.).

Anal. Calcd. for $C_{14}H_{11}O_3SF$: S, 11.5. Found: S, 11.3.

***p*-Fluorophenyl *p*-Nitrobenzyl Sulfone.**—This sulfone was obtained from the sulfinate and *p*-nitrobenzyl chloride and crystallized from 95% alcohol in slightly yellow brilliant plates melting at 185° (corr.).

Anal. Calcd. for $C_{13}H_{10}O_4NSF$: N, 4.8. Found: N, 5.0.

***p*-Fluorophenyl Sulfone Acetic Acid.**—A solution of 3 g. of sodium *p*-fluorophenyl sulfinate and 1.6 g. of monochloroacetic acid in 15 cc. of water was neutralized with *N* sodium hydroxide, evaporated over a free flame to crystallization and then to dryness on the steam-bath. The dry salt was taken up in 10 cc. of water, acidified to Congo red

with hydrochloric acid, extracted with ether and the residue remaining after evaporation of the ether recrystallized from benzene when the free acid was obtained in colorless needles melting at 110–111° (corr.).

Anal. Calcd. for $C_8H_7O_4SF$: S, 14.7. Found: S, 14.4.

Benzyl-ψ-thiourea Salt of *p*-Fluorophenyl Sulfone Acetic Acid.—This salt was obtained in microcrystalline glistening prismatic needles melting at 144° (corr.) with decomposition.

Anal. Calcd. for $C_{16}H_{17}O_4N_2S_2F$: N, 7.3; S, 16.7. Found: N, 7.7; S, 16.6.

***p*-Bromophenacyl Ester of *p*-Fluorophenyl Sulfone Acetic Acid.**—This ester crystallizes from 95% alcohol in colorless glistening needles melting at 126° (corr.).

Anal. Calcd. for $C_{16}H_{13}O_5SBrF$: S, 7.7. Found: S, 8.0.

***p*-Fluorophenylsulfonyl Acetone.**—A suspension of 5.5 g. (10% excess) of finely powdered sodium *p*-fluorophenyl sulfinate in 25 cc. of 95% alcohol containing 2.1 g. of monochloroacetone was refluxed for one-half hour, the alcohol driven off by an air current and the oily residue crystallized by trituration with water; yield quantitative.

The sulfonyl acetone was obtained in elongated needle-like plates melting at 66° (corr.) by recrystallization from 10 parts of 95% alcohol.

Anal. Calcd. for $C_9H_9O_3SF$: S, 14.8. Found: S, 14.7.

α-γ-Di-*p*-fluorophenylsulfonyl Acetone.—The difluorophenylsulfonyl ketone was similarly prepared from α-γ-diiodoacetone and crystallized from 95% alcohol in long colorless needles melting at 144° (corr.).

Anal. Calcd. for $C_{15}H_{12}O_5S_2F_2$: S, 17.1. Found: S, 16.8.

Summary

A series of derivatives of *p*-fluorophenyl sulfinic acid has been prepared and characterized.

The Chemistry of the Acetylenes. II. Pharmacological Properties of the Acetylenic Linkage

BY G. BRYANT BACHMAN

Although the number of medicinals containing acetylenic linkages which have been prepared is relatively small, the available evidence points to a lesser pharmacological activity for these substances than for the corresponding olefinic and saturated isologs. Shonle[1] has found this to be true of a group of hypnotics of the barbital series, and Gilman and Pickens[2] still earlier report β-diethylaminoethylphenyl propiolate to be intensely irritating rather than anesthetic in its action. In order to investigate this lesser activity of acetylenic compounds more thoroughly and to study further the relative values of aliphatic novocaine analogs,[3] a number of amino esters of α-octynoic, α-octenoic and octanoic acids have been prepared and tested for local anesthetic action on the sciatic nerves of frogs. From the results obtained it may be said that in so far as sensory anesthesia is concerned, the same order of activity holds for these anesthetics as holds for the hypnotics tested by Shonle. On the motor and sensory nerves of frogs the compounds tested exhibited a potency comparable to or slightly better than that of novocaine. The octanoic acid esters, however, were the best and the octynoic esters the poorest of the entire group. All of the esters were somewhat irritating although not intensely so. Of the esters of any single acid, those were best having the greatest molecular weight and those poorest having the least molecular weight. On the basis of these results it appears that the local anesthetic effectiveness of novocaine analogs in the aliphatic series is directly proportional to the molecular weight of the alcohol portion of the molecule (probably within limits) and inversely proportional to the degree of unsaturation in the acid portion of the molecule. None of the compounds tested in this work exhibited anesthetic action on mucus membranes.

Experimental

The esters were prepared by cautiously adding a slight excess of the acid chlorides in an equal volume of benzene to the amino alcohols also in benzene. The mixture was then refluxed for one hour, poured into water and made alkaline with aqueous potassium hydroxide. The benzene solution of the ester was separated, dried and then distilled under diminished pressure.

α-Octenic acid chloride, a new compound, was prepared by reaction of the acid with thionyl chlo-

ride and has the constants: b. p. 109–111° (30 mm.); n^{20}_D 1.4649; d^{20}_4 0.9841. *Anal.* Calcd. for $C_8H_{13}OCl$: Cl, 22.13. Found: Cl, 22.10, 22.21.

The table lists the properties and analyses of the compounds prepared and shows their relative anesthetic activity as measured by the time elapsed between contact with the drug and complete anesthesia.[4]

Some difficulty was experienced in obtaining satisfactory aqueous solutions of the compounds tested. Apparently excess acid (hydrochloric) was necessary to attain complete solution and undoubtedly this contributed to the irritating qualities noted for each compound. Novocaine is included in the table for the sake of comparison.

Summary

1. A number of amino esters of octanoic, α-octenoic, and α-octynoic acids have been prepared and their local anesthetic powers reported.

2. Within the limits of the compounds here described it appears that the anesthetic power of these amino esters is directly proportional to the molecular weight of the amino alcohol part of the molecule and inversely proportional to the degree of unsaturation of the acid.

Thermodynamical Calculations of Solubilities of Nitrogen and Hydrogen in Water at High Pressures

BY I. R. KRICHEVSKY AND J. S. KASARNOVSKY

Much attention is given nowadays to the experimental investigation of solubilities of gases at high pressures in liquids, chiefly in water and liquid ammonia. This paper gives a method of calculation of solubilities of gases in one special, but very important, case where the solubility of gas is small and the vapor pressure of solvent is not great. The solubilities in water of such important technical gases as hydrogen, nitrogen, carbon oxide, methane, oxygen and helium fall in this classification.

When the concentration of a solute is small the fugacity of the solvent can be calculated by means of Raoult's law, the fugacities of the components being connected according to the equation of Gibbs–Duhem

$$N_1 \mathrm{d} \ln f_1 + N_2 \mathrm{d} \ln f_2 = 0 \qquad (1)$$

(N_1, N_2 and f_1, f_2 are mole fractions and fugacities of either solvent and solute); it is not difficult to prove that there exists direct proportionality between f_2 and N_2, known as Henry's law

$$f_2 = KN_2 \qquad (2)$$

where K is Henry's coefficient.

Wiebe, Gaddy and Heins[1] nevertheless have shown that their experimental data on the solubility of nitrogen in water are poorly expressed by the equation (2). This is also true for the data on the solubility of hydrogen in water. The solubilities of these gases in water are so small, even at a pressure of 1000 atmospheres, that the fugacity of water in solution can be calculated according to Raoult's law. From this, however, it would seem to follow as a thermodynamical

---

[1] Wiebe, Gaddy and Heins, THIS JOURNAL, **55**, 947 (1933).

consequence that Henry's law would be obligatory for the dissolved gas. But the experimental data are evidently in contradiction to this theoretical deduction.

We shall prove that the stated contradiction occurs on account of erroneous application of the Gibbs–Duhem equation. This equation assumes that the pressure remains constant throughout the integration. In case the pressure changes but little it is possible to disregard this change as is usually done, sometimes unconsciously, when examining, for instance, the solubilities of gases at small pressures. On the contrary, when the solubilities of gases are measured at high pressures there can be no question of disregarding its influence.

It is easy to show how the usual equation of Henry has to be corrected in order to predict the solubilities of gases even at very high pressures.

When the concentration of dissolved gas changes from $N_2 = 0$ to a certain N_2, the pressure rises from $p_1°$ to P, where $p_1°$ is the vapor pressure of the pure solvent, and P is the total pressure at a concentration N_2. Agreeing that the vapor pressure of the solvent is not great, the total pressure can without any sensible error be identified with the partial pressure of gas. In order to eliminate the influence of the change of pressure on the solubility, we shall expose the solution to tension (negative pressure) which is every moment equal to $P - p_1°$. The tension must naturally affect only the solution, and not the gas phase. At such a compensation the pressure upon the solution remains constant and equal to the primary pressure $p_1°$. The integration of the Gibbs–Duhem equation becomes lawful, and supposing that the fugacity of the solvent is submitted to Raoult's law, we must obtain for the dissolved gas Henry's law

$$f_2 = KN_2' \qquad (3)$$

N_2' is, certainly, not the experimentally measured concentration of the soluted gas. N_2' is the concentration which could be obtained through compensation of the gas pressure by means of corresponding tension of the solution. K is the usual Henry's coefficient, because it is in principle determined at the zero partial pressure of gas.

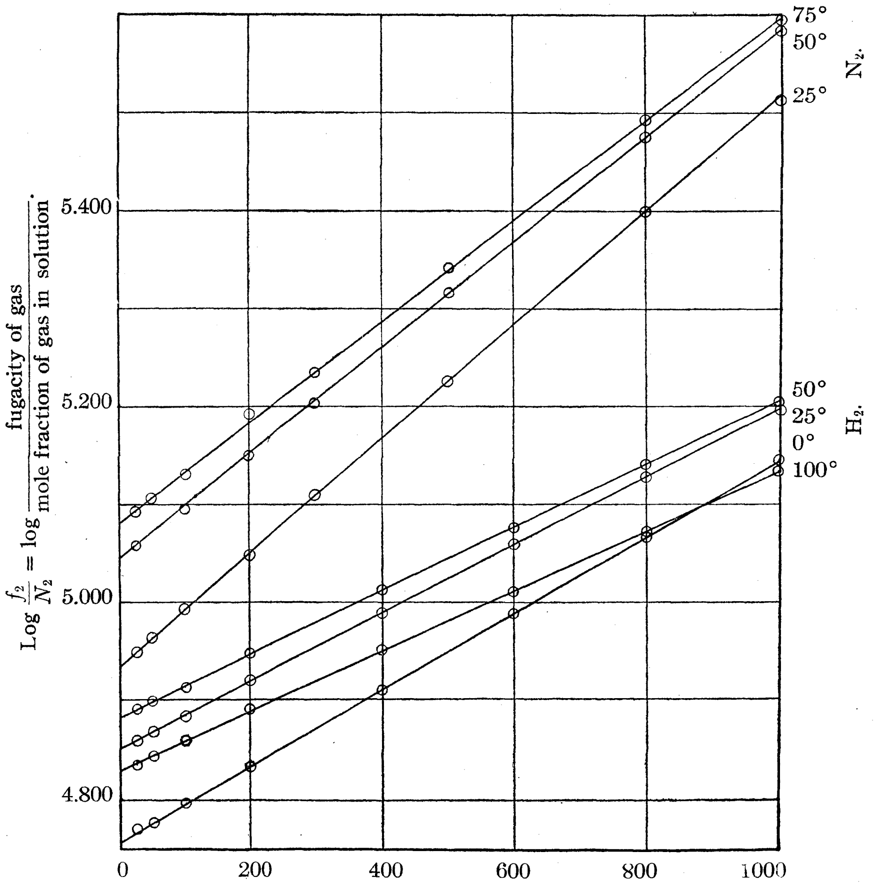

Fig. 1.

The transition from N_2' to N_2 can be made by means of the well known equation

$$\left(\frac{\partial \overline{F}_2}{\partial p}\right)_T = \bar{v}_2 \qquad (4)$$

where $\overline{F}_2$ is the partial molal free energy of the dissolved gas and $\bar{v}_2$ is its partial molal volume.

Since the concentration of gas in solution is small

$$\mathrm{d}\overline{F}_2 = RT\,\mathrm{d}\ln N_2 \qquad (5)$$

Substitution from equation (5) in the equation (4) gives us

$$\left(\frac{\partial \ln N_2}{\partial P}\right)_T = \frac{\bar{v}_2}{RT} \tag{6}$$

Integration of equation (6) by the supposition of independence of $\bar{v}_2$ from pressure gives

$$\ln N_2 = \ln N_2' - \frac{\bar{v}_2 P}{RT} \tag{7}$$

From equations (3) and (7) we receive

$$\lg \frac{f_2}{N_2} = \lg K + \frac{\bar{v}_2 P}{2.303\ RT} \tag{8}$$

[a] From $\lg f_2/N_2 = 4.7569 + 0.0003866\ P$. [b] From $\lg f_2/N_2 = 4.851 + 0.0003465\ P$. [c] From $\lg f_2/N_2 = 4.8822 + 0.0003210\ P$. [d] From $\lg f_2/N_2 = 4.8307 + 0.0003035\ P$.

The experimental data on the solubilities of nitrogen[1] and hydrogen[2] in water agree very well with equation (8) (see Tables I and II and Fig. 1). The values of the fugacities of nitrogen and hydrogen are taken from the papers of Deming and Shupe[3] and Ångström[4] measured the increase of the volume of water due to solubility of nitrogen and hydrogen in water at 1 atmosphere.

We have calculated from his data the partial molal volumes of nitrogen and hydrogen in water solution and they are in good agreement with the values calculated from equation (8) (Table III).

For the integration of equation (6) we assumed the partial molal volume of dissolved gas to be independent of pressure, and the errors caused by this assumption appeared beyond the range of the accuracy of experimental measurements. Generally $\bar{v}_2$ is to be regarded as a function of pressure. For instance, it may be assumed to follow the simple equation

$$\bar{v}_2 = \bar{v}_2{}^\circ - \beta P \tag{9}$$

where $\bar{v}_2{}^\circ$ is the partial molal volume at zero pressure and β is the coefficient of compressibility. Differently from pure substances β can have for the partial molal volume a negative value.[5]

TABLE III

PARTIAL MOLAL VOLUMES OF NITROGEN AND HYDROGEN IN WATER SOLUTION

	0°	25°	50°	75°	100°
			Nitrogen, cc.		
$\bar{v}_2$ obsd.	32.5				
$\bar{v}_2$ calcd.		32.8	33.4	34.1	36.2
			Hydrogen, cc.		
$\bar{v}_2$ obsd.	23.9				
$\bar{v}_2$ calcd.	20.0	19.5	19.6		21.4

In view of the accuracy of determination of the solubility of gases, it may not be very advisable

---

(2) Wiebe and Gaddy, THIS JOURNAL, **56,** 76 (1934).

(3) Deming and Shupe, *Phys. Rev.*, **37,** 638 (1931); **40,** 848 (1932).

(4) Ångström, *Wied. Ann.*, **15,** 297 (1882).

(5) Adams, THIS JOURNAL, **53,** 3769 (1931); **54,** 2229 (1932).

to use equation (9) for the purpose of integrating equation (6).

It may be pointed out that our use of Raoult's law necessitates the independence of $\bar{v}_2$ from N_2.[6]

Equation (8) can also be applied to calculate the mixed solubility of slightly soluble gases, such as the solubility in water of a 3:1 mixture of hydrogen and nitrogen. In such a case in equation (8) f_2 is the fugacity of one of the gases, N_2 is its mole fraction in solution and P is total pressure. Having no experimental data about the mixed solubility of gases, we are unable to verify equation (8) by concrete examples.

Equation (8) can be used also to solve the inverse problem of calculating the fugacity of pure and mixed gases.

Summary

1. A thermodynamical equation is given which allows the calculation of the solubility of slightly soluble gases in solvents with small vapor pressure.

2. The deduced equation is verified in examples of solubilities of nitrogen and hydrogen in water at a pressure up to 1000 atmospheres and temperatures from 0 to 100°.

3. Partial molal volumes of nitrogen and hydrogen in their water solutions are calculated.

4. The possibility of calculation of the fugacity of gases on account of their solubility is shown.

Partial Molal Quantities in an Infinitely Dilute Solution

BY I. R. KRICHEVSKY AND J. S. KASARNOVSKY

The partial molal quantities g_1 and g_2 and the composition of a binary solution, expressed in mole fractions, N_1 and N_2, are connected with each other by a well-known equation, which it will be convenient for the purpose of further argumentation to set forth as follows

$$\frac{\partial \bar{g}_1}{\partial N_2}\Big/\frac{\partial \bar{g}_2}{\partial N_2} = -\frac{N_2}{N_1} \qquad (1)$$

This equation has been submitted by Lewis and Randall for the case of an infinitely dilute solution to a special analysis. "In an infinitely dilute solution of X_2 in X_1, where we may write $N_2/N_1 = 0$, it is evident that either $\partial\bar{g}_1/\partial N_2$ is zero, or $\partial\bar{g}_2/\partial N_2$ is infinite. In other words, when N_2 is zero either the curve $\bar{g}_1$ becomes horizontal, or the curve of $\bar{g}_2$ becomes vertical."[1]

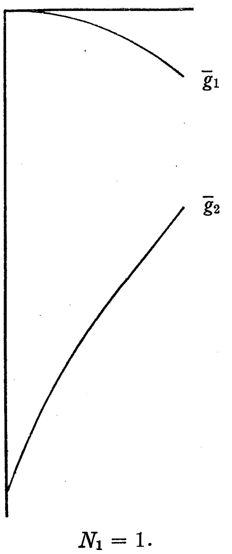

Fig. 1.

The analysis given by Lewis and Randall does not exhaust the question, inasmuch as mathematically (equation (1) is not a thermodynamical one) three other cases are possible: (1) $\partial\bar{g}_1/\partial N_2$ is zero and $\partial\bar{g}_2/\partial N_2$ is zero; (2) $\partial\bar{g}_1/\partial N_2$ is zero and $\partial\bar{g}_2/\partial N_2$ is infinite; (3) $\partial\bar{g}_1/\partial N_2$ is infinite and $\partial\bar{g}_2/\partial N_2$ is infinite.

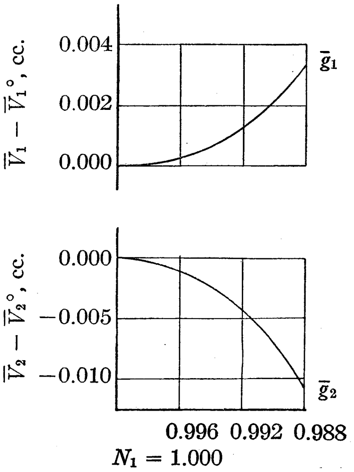

Fig. 2.—Partial molal volumes of water and ethyl alcohol at 40°.

Notwithstanding the fact that, if such allowances are made, the left part of equation (1) turns into indefiniteness, the latter at $N_2 = 0$ may have for its limit zero.

---

[1] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923.

When $\partial \bar{g}_1/\partial N_2$ is tending to attain zero as the first degree of N_2, then at $N_2 = 0$, $\partial \bar{g}_2/\partial N_2$ differs from zero, as it is to be seen from equation (1) (Fig. 1).[2] This is one of the two cases pointed out by Lewis and Randall.

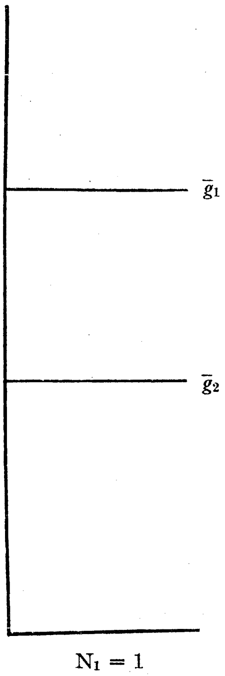

Fig. 3.

When $\partial \bar{g}_1/\partial N_2$ is tending to attain zero as the higher degree of N_2, then $\partial \bar{g}_2/\partial N_2$ is likewise tending to attain zero, but the left part of the equation (1) has for its limit zero (Fig. 2).

Figures 1 and 2 correspond to such partial molal quantities, as for instance the volume (or heat capacity or heat content). According to Fig. 1 in the infinitely dilute solution only the partial molal volume of the solvent is constant. According to Fig. 2 in the infinitely dilute solution the partial molal volumes both of the solvent and solute remain constant. Hence it is natural to turn to such a case, when this constancy extends into the field of finite concentrations (Fig. 3).

As the temperature is rising, *i. e.*, when the abnormality of the solutions is decreasing, it may be expected that the trend will be from Fig. 1 via Fig. 2 to Fig. 3.

The partial molal volumes for the system water–ethyl alcohol[1] (apparently for the temperature 20–25°) calculated by Lewis and Randall correspond to Fig. 1. The calculations made by us of the partial molal volumes for 40° are given in Fig. 2.

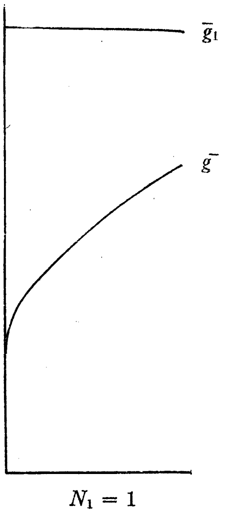

Fig. 4.

With a further rise of temperature it is likely that we shall arrive at Fig. 3.

When $\partial \bar{g}_1/\partial N_2$ is approaching zero as N_2 in a degree below one, then at $N_2 = 0$, $\partial \bar{g}_2/\partial N_2$ is infinite (Fig. 4). The partial molal volumes of the system water–strong electrolyte[3] correspond to this case.

The third case when at $N_2 = 0$, $\partial \bar{g}_1/\partial N_2$ and $\partial \bar{g}_2/\partial N_2$ are infinite, is apparently of no practical value.

---

Amides Obtained from Benzenesulfinic Acid

By L. Chas. Raiford and Stewart E. Hazlet

A large number of aryl sulfinic acids have been prepared[1] but few of them have been converted into the corresponding acid chlorides, while the behavior of the latter toward amino compounds has received very little attention.

Hilditch and Smiles[2] obtained benzenesulfinyl chloride in rectangular plates that melted at 38°. Braun and Kaiser[3] may have obtained this product as a solid, but they recorded no melting point. Although they used specially purified starting material, Whalen and Jones[4] could not duplicate Hilditch and Smiles' results, and they did not obtain crystals when they followed Braun and Kaiser's directions. Their product was an oil with a boiling range of 85–90° at 3 to 4 mm.

In the present work, the purpose of which was to test further the action of benzenesulfinyl chloride on amino compounds, the "crude" acid chloride was obtained in nearly quantitative yield by treatment of benzenesulfinic acid[5] with thionyl chloride at room temperature. Distillation, when successful, gave about 83% of a yellow oil at 80–85° and 2 mm. Often rapid and violent decomposition of material took place. Comparison of products obtained by the action of "crude" chlo-

ride and distilled material showed that little purification was accomplished by distillation.

With the exceptions noted below the sulfinamides listed were obtained by treatment of two molecular proportions of the required amine, dissolved in about three volumes of dry ether, with 1.25 proportions of "crude" benzenesulfinyl chloride in two volumes of ether, with continuous agitation at 0°. The solid that separated was shaken with water to remove amine salt, the residue, if any, was mixed with the ether filtrate and from this the amide was isolated. Analytical

[a] Crystallized from alcohol; in other cases dilute alcohol was used. [b] Chloroform-ligroin (60–80°). [c] Morgan and Micklethwait [*J. Chem. Soc.*, **89**, 1294 (1906)] found 172° and satisfactory analysis for a product obtained by boiling a toluene solution of the amine and acid chloride for three hours, evaporating the mixture to dryness, extracting the residue with sodium carbonate solution and precipitating the amide by acid. No yield was given. In the present work heating ether solution of the reactants, followed by standing, gave no change. Pyridine was then used as a solvent. [d] Determination made by semimicro Dumas method. [e] Reaction carried out in ether solution. [f] The reaction carried out in pyridine. [g] Previously obtained and analyzed by Hinsberg [*Ann.*, **265**, 184 (1891)] who recorded no yield. It was prepared in the present work for comparison with the sulfinamide of the same base, m. p. 124–125°. A mixture of the two melted at 85–95°.

data for these products are given in Table I.

For purposes of comparison of physical properties a number of corresponding sulfonamides were prepared. Data for them are given in Table II.

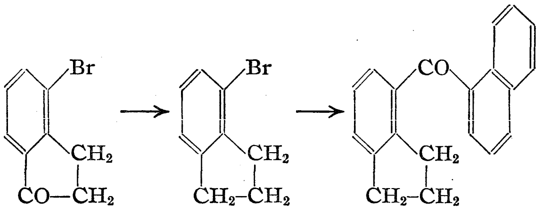
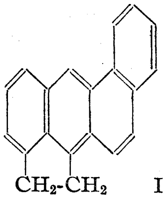
Cholanthrene and Related Hydrocarbons

BY LOUIS F. FIESER AND ARNOLD M. SELIGMAN

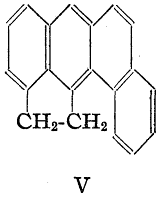
The synthesis of cholanthrene by three different methods has been reported recently by Cook and his associates.[1] We have found that the modified Elbs synthesis[2] provides still another route to this interesting hydrocarbon. The ketone III was prepared from the known 4-bromohydrindone-1 (I)[3] as indicated, and on pyrolysis there was obtained a hydrocarbon corresponding to the description[1] of cholanthrene, IV. From the ketone resulting from the reaction of the Grignard compound of II with β-naphthoyl chloride, the isomeric hydrocarbon V was obtained.



I II III



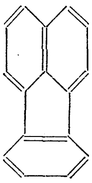
IV



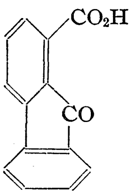
V

Dr. M. J. Shear has observed that crystalline cholanthrene injected subcutaneously in mice produced effects similar to those obtained with methylcholanthrene and in approximately the same time. The hydrocarbon induced ulcerations beginning with the fortieth day and the first tumor, noted on the sixty-second day, took successfully on transplantation. From these preliminary results it appears that a methyl group at C_{20} is of less influence in determining the carcinogenic activity than might have been expected on the basis of the available data.[4]

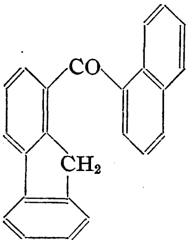
Another hydrocarbon having the cholanthrene ring system was obtained very easily starting with fluoranthene (VI) from coal tar. By the methods of Fittig and Liepmann,[5] modified in some details, fluorene-1-carboxylic acid can be prepared in any desired quantity by the oxidation of fluoranthene, followed by the reduction of the resulting keto acid VII. 1-(α-Naphthoyl)-fluorene (VIII) was obtained from α-naphthylmagnesium bromide and fluorene-1-carboxylic acid chloride, and on pyrolysis it yielded the hydrocarbon IX.



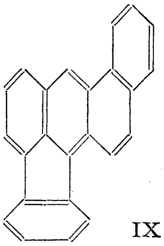
VI



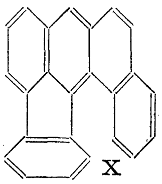
VII



VIII



IX



X

To indicate the relationship to the carcinogenically active parent hydrocarbon, this substance may be called 15,16-benzdehydrocholanthrene.[6]

The Friedel and Crafts reaction of the above acid chloride with naphthalene was investigated, with rather unexpected results. The condensation proceeded poorly in carbon bisulfide, probably because of the sparing solubility of the com-

plex compounds, and there was obtained a mixture which was not separated, but which was found by pyrolysis experiments to contain a considerable proportion of the α-ketone VIII. Using tetrachloroethane the chief reaction product was the higher melting 1-(β-naphthoyl)-fluorene. The results were about the same with nitrobenzene as the solvent. Pyrolysis of the β-ketone afforded the hydrocarbon X.

Experimental Part[7]

4-Bromohydrindone-1 (I) was prepared from *o*-bromohydrocinnamic acid, using the method of ring-closure described by Hoyer,[8] but employing more thionyl chloride. In large-scale experiments the yield of pure ketone, m. p. 97°, was only 70% of the theoretical amount, based on the acid.

Various methods of preparing *o*-bromohydrocinnamic acid were investigated, the one found most satisfactory consisting in the catalytic hydrogenation of *o*-bromocinnamic acid prepared from *o*-bromotoluene by the convenient method of Reich and Chaskelis.[9] The yield reported by these workers (26%) was confirmed. Using material which had been sublimed *in vacuo* the hydrogenation with Adams catalyst proceeded smoothly in absolute alcoholic solution, the acid being largely esterified during the process; yield, 85%. *o*-Bromocinnamic acid was also prepared from *o*-nitrocinnamic acid according to Gabriel,[10] the yields being 89% in the reduction and 67% in the Sandmeyer reaction, but the method requires a much more expensive starting material.

We also investigated the preparation of the desired acid from *o*-bromobenzyl chloride and malonic ester, following the procedure employed previously.[2] The yields were good but the commercial *o*-bromobenzyl chloride, even after repeated careful fractionation, gave rise to unhomogeneous products at every step. The impure *o*-bromohydrocinnamic acid gave a hydrindone preparation which crystallized well but melted persistently low (88°). 4-Bromohydrindene was obtained in a pure condition by repeated fractionation of the mixture obtained on reduction, but with considerable loss of material.

4-Bromohydrindene was prepared in 77% yield by the Clemmensen reduction of pure 4-bromohydrindone-1 by the usual procedure;[2] b. p. 118° at 18 mm.

Anal. Calcd. for C_9H_9Br: C, 54.83; H, 4.60. Found: C, 54.55; H, 4.48.

4-(α-Naphthoyl)-hydrindene (III) was obtained in a form (A) suitable for pyrolysis in 50% yield by the Grignard procedure.[2] On further distillation in vacuum it was obtained as a viscous yellow oil.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.93. Found: C, 87.75; H, 5.90.

4-(β-Naphthoyl)-hydrindene was prepared similarly, using β-naphthoyl chloride, in 46% yield: small colorless needles, m. p. 68–69°, from ether–petroleum ether.

Anal. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.93. Found: C, 88.25; H, 6.05.

Cholanthrene (IV).—On pyrolysis of the partially purified ketone III (A) at 400–405° for twenty-five minutes there was obtained, after vacuum distillation and one crystallization from ether–benzene, a pale yellow product melting at 170°; yield, 34%. This material was altered but little on further purification. After passage of a benzene solution through four adsorption towers containing activated alumina, the hydrocarbon was obtained as very faintly yellow plates, m. p. 173–173.5°, corr.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.51; H, 5.65.

The *picrate* crystallized from benzene as small, reddish-purple needles, m. p. 169–170°, corr.

Anal. Calcd. for $C_{26}H_{17}O_7N_3$: N, 8.69. Found: N, 8.75.

8,9-Dimethylene-1,2-benzanthracene (V) was prepared similarly, the melting point at various stages of purification being as follows: one crystallization, 172°; chromatographic purification, 173°; treatment with sulfuric acid in benzene solution, very faintly yellow plates from benzene–ether, m. p. 174° (176.5–177°, corr.).

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.48; H, 5.65.

The *picrate* forms purple-black needles from benzene, m. p. 158–159°, corr.

Anal. Calcd. for $C_{26}H_{17}O_7N_3$: N, 8.69. Found: N, 8.86, 8.98.

Fluorenone-1-carboxylic acid[5] was prepared by adding slowly a solution of 340 g. of chromic anhydride in 300 cc. of water and 200 cc. of glacial acetic acid to a solution of 100 g. of fluoranthene in 2.5 liters of glacial acetic acid, keeping the mixture just below the boiling point. After standing for several hours the solution was heated to the boiling point for one hour and then diluted with about 15 liters of water. The crude acid was collected and extracted with cold alkali, precipitated, and heated with an aqueous suspension of barium carbonate until no further material could be extracted. On acidifying the filtrate, 56 g. (48%) of orange, crystalline material, m. p. 191–193°, was obtained. For reduction to *fluorene-1-carboxylic acid*, 60 g. of the keto acid was added in portions to a mixture of 1920 g. of 4% sodium amalgam and 2 l. of water, heated on the steam-bath. The solution was kept near the neutral point by the frequent addition of hydrochloric acid, a fresh portion of keto acid being introduced only after the precipitate which formed on acidification was nearly colorless. The mixture was heated for two hours after the addition was complete, when it was cooled and filtered. The crude acid which precipitated on acidification was extracted as the barium salt, from which it was recovered in a colorless condition; yield 47.5 g. (84%). After sublimation *in vacuo* the acid (m. p. 245°) was refluxed with a large excess of thionyl chloride for two hours, the excess reagent was removed and the acid chloride was distilled at diminished pressure; yield, 83%.

1-(α-Naphthoyl)-fluorene (VIII).—A solution of the Grignard reagent from 15 g. of α-bromonaphthalene in 70 cc. of ether was added slowly to 26.5 g. of fluorene-1-car-

boxylic acid chloride in 250 cc. of dry benzene and 50 cc. of ether at 0°. The mixture was slowly brought to 35–40° and kept at that temperature overnight. The crude ketone was subjected to thorough steam distillation from an alkaline medium and then extracted with ether–benzene, distilled at the oil pump, and crystallized from ether–petroleum ether; colorless needles, m. p. 108–110°; 12.3 g. (56% yield, 10 g. of fluorene-1-carboxylic acid being recovered from the alkaline solution).

The ketone is very readily soluble in benzene, moderately soluble in ether, and sparingly soluble in alcohol. Recrystallized from benzene–ether it formed slender needles, m. p. 113–114°.

Anal. Calcd. for $C_{24}H_{16}O$: C, 89.97; H, 5.04. Found: C, 90.02; H, 5.15.

15,16-Benz-dehydrocholanthrene (IX).—Four grams of the above ketone was heated for twenty-five minutes at 415° under nitrogen and the product was distilled in vacuum and crystallized once from benzene; yield, 2.25 g. (60%) of orange-red material, m. p. 177°. Purification by chromatographic adsorption was more tedious and wasteful than with sulfuric acid and gave no better material. On shaking a dilute benzene solution of the hydrocarbon with small portions of sulfuric acid until the acid acquired only a yellow color, the extraneous red material was removed with little loss of product. The purified hydrocarbon crystallized from benzene, in which it is only moderately soluble, as bright yellow, cottony needles, m. p. 181–181.3° corr.

Anal. Calcd. for $C_{24}H_{14}$: C, 95.33; H, 4.67. Found: C, 95.23; H, 4.98.

The *picrate* crystallizes from benzene as small, brick-red needles, m. p. 174.5–175.5°, corr.

Anal. Calcd. for $C_{30}H_{17}O_7N_3$: N, 7.91. Found: N, 8.22.

1-(β-Naphthoyl)-fluorene was the chief product of the reaction of 14.5 g. of fluorene-1-carboxylic acid chloride with 9 g. of naphthalene, and 9.2 g. of aluminum chloride in 300 cc. of tetrachloroethane, the mixture being initially at 5–10°, then at room temperature. The crude ketone was heated with acetone and alkali in order to hydrolyze unchanged acid chloride, 3.9 g. of acid being recovered after distilling the solvent and extracting the ketone with ether–benzene. After distillation *in vacuo*, one crystallization from benzene–ligroin gave 8 g. of the nearly pure β-ketone, m. p. 145–150°; total yield, 12.5 g. (84%). After several crystallizations of the first crop from benzene–ether the substance formed clusters of pale yellow needles, m. p. 159–162°. The compound is considerably less soluble than the α-isomer.

Anal. Calcd. for $C_{24}H_{16}O$: C, 89.97; H, 5.04. Found: C, 89.97; H, 5.25.

1′,2′-Naphtho-1,2-fluoranthene (X).—The pyrolysis of the above ketone proceeded as in the case of the α-isomer, but the hydrocarbon, which is considerably more soluble than IX, is best purified with the use of an adsorption tower. It crystallized from benzene–ether in the form of flat, golden yellow needles, m. p. 178–179°, corr.

Anal. Calcd. for $C_{24}H_{14}$: C, 95.33; H, 4.67. Found: C, 95.25; H, 5.04.

The *picrate* crystallizes from benzene in the form of crimson needles melting at 181–182° corr.

Anal. Calcd. for $C_{30}H_{17}O_7N_3$: N, 7.91. Found: N, 8.16.

Summary

Cholanthrene and three additional hydrocarbons of the 1,2-benzanthracene series have been prepared by the modified Elbs synthesis.

Halogenation of Phenolsulfonic Acids in Nitrobenzene

BY RALPH C. HUSTON AND ARTHUR H. NEELEY[1]

The replacement of sulfonic acid groups of phenols with nitro groups or halogen takes place with rapidity in the presence of aqueous acid.[2,3] If, however, the reaction is carried on in alkaline solution this group is rendered stable and serves as an effective blocking agent.[4,5]

Fuming sulfuric acid has been used with more or less success in the preparation of 2-nitroresorcinol[6] and to protect the four and six positions of *m*-cresol during nitration.[7,8] Good yields of 2-bromo-*m*-cresol[9] and 2-chloro-*m*-cresol[10] were obtained in this Laboratory by brominating or chlorinating *m*-cresol directly with one mole of halogen in four volumes of fuming sulfuric acid and then removing the sulfonic acid groups by hydrolysis with superheated steam at 180–200°.

Numerous attempts to adapt this method to the preparation of 2,6-dibromophenol and 2-

bromophenol failed to give satisfactory yields of either compound but indicated that the halogenation might take place as desired if carried out in an inert anhydrous solvent. Accordingly a number of runs were made in various solvents including petroleum ether, gasoline, kerosene and nitrobenzene. It was found that freshly distilled nitrobenzene was very well suited to the purpose and the following procedure was developed which gave excellent yields of 2,6-dibromophenol. Slight modification gave satisfactory yields of 2-bromophenol, 2,6-dichlorophenol or 2-chlorophenol.

2,6-Dibromophenol and 2-Bromophenol.—A mixture of 31.3 g. (one-third mole) of phenol and 50 g. of concentrated sulfuric acid (d. 1.84) was heated with stirring at 100–110° for two hours on an oil-bath. It was cooled and 100 g. of freshly distilled nitrobenzene added. Cooling was continued while 15 g. of fuming sulfuric acid (49%) was added at such a rate that the temperature did not rise above 10°. One hundred seven grams (two-thirds mole) of bromine and 50 g. of nitrobenzene was added dropwise over a period of two hours and stirring was continued for an hour to complete bromination. One liter of water, in which 5–10 g. of sodium bisulfite had been dissolved, was added. The water and reaction mixture was thoroughly stirred for fifteen minutes to facilitate extraction of the brominated phenol sulfonic acids. For the most part, the tribromophenol remained in the nitrobenzene. This was drawn off by means of a separating funnel and the solution of sulfonic acids was evaporated from a 2-liter flask, suitably equipped for steam distillation, on an oil-bath maintained at 200°. The distillate obtained during the evaporation contained a small amount of nitrobenzene and was discarded. When the temperature of the sulfonic acid solution reached 115°, steam, superheated in a copper coil, was passed through it. The temperature of the oil-bath was maintained at 200, while the temperature of the contents of the flask continued to rise to 175–180° during hydrolysis. The brominated phenols were extracted from the distillate with ether and the phenol residue, after evaporation of the ether, was distilled under reduced pressure 4 mm.) from a modified Claisen flask having a 35 cm. column. Under these conditions a 10.4% yield of 2-bromophenol boiling at 55–60° (4 mm.)—190–191° (740 mm.)—and a 72.7% yield of 2,6-dibromophenol (m. p. 55–56°) boiling at 80–90° (4 mm.)—255–256° (740 mm.)—were obtained. Increasing amounts of sulfuric acid used in succeeding runs gave increasing amounts of 2-bromophenol and decreasing amounts of 2,6-dibromophenol. With 95 g. of sulfuric acid a minimum yield of 9.5% of 2,6-dibromophenol and a maximum yield of 46.5% of 2-bromophenol were obtained. Gradual reduction of bromine as the amount of sulfuric acid was increased did not change the yields.

2,6-Dichlorophenol, 2-Chlorophenol.—Reactants were used in the same quantities and under the same conditions as in the preparation of bromo derivatives except that 200 g. of nitrobenzene was used and the nitrobenzene solution of sulfonic acids was maintained at 55° while chlorine was passed in until no further reaction took place. A number of runs made with increasing amounts of sulfuric acid, gave increasing amounts of 2-chlorophenol and decreasing amounts of 2,6-dichlorophenol. The use of 68 g. of sulfuric acid gave a maximum yield of 70.3% of 2,6-dichlorophenol (m. p. 66–67°) boiling at 80–85° (4 mm.)—219–220° (740 mm.)—and a minimum yield of 17% of 2-chlorophenol boiling at 50–55° (4 mm.)—177–178° (740 mm.). Minimum yields of 24% of 2,6-dichlorophenol and maximum yields of 72% of 2-chlorophenol were obtained when 100 g. of sulfuric acid was used.

Anal. Calcd. for $C_6H_4OCl_2$: Cl, 43.5. Found: Cl, 43.4.

6-Bromo-*o*-cresol.—Bromination of 36 g. of *o*-cresol at 5–10°, using 55 g. of concentrated sulfuric acid, 100 g. of nitrobenzene and 60 g. of bromine in 50 g. of nitrobenzene, gave a 60% yield of crude 6-bromo-*o*-cresol boiling at 55–65° (4 mm.) which contained about 8% *o*-cresol. When redistilled through a 90-cm. column (surrounded by an evacuated jacket) a pure product was obtained, b. p. 206–207° (740 mm.).

Anal. Calcd. for C_7H_7OBr: Br, 42.77. Found: Br, 42.3.

A small amount of 4,6-dibromo-*o*-cresol (13%), which boiled at 105° (4 mm.), was obtained.

6-Chloro-*o*-cresol.—Thirty-six grams of *o*-cresol chlorinated at 55°, using 60 g. of concentrated sulfuric acid and 200 g. of nitrobenzene, yielded 30% of 6-chloro-*o*-cresol boiling at 45–50° (4 mm.)—188–189° (740 mm.)—and 12% of 4,6-dichloro-*o*-cresol boiling at 73–78° (4 mm.).

2-Bromo-*m*-cresol, 4-Bromo-*m*-cresol and 2,6-Dibromo-*m*-cresol.—Several runs were carried out using 36 g. of *m*-cresol, 36 g. of concentrated sulfuric acid[11] and other reagents in the amounts given in the procedure for bromophenols. It was found necessary to brominate at 55–60° to prevent precipitation of the sulfonic acids before the reaction was completed. Two fractions were obtained. The first, boiling at 60–70° (4 mm.)—214–215° (743 mm.)—was identified as 2-bromo-*m*-cresol. (6-Bromo-*m*-cresol, which boils at approximately the same temperature, was probably present but was not isolated.) It was obtained in an average yield of 7% and solidified on standing in the receiver. When crystallized rapidly from a small amount of petroleum ether it formed a sheaf of tetragonal crystals. Slower crystallization from a greater amount of solvent gave large solid prisms, m. p. 61–62°.[9]

Anal. Calcd. for C_7H_7OBr: Br, 42.77. Found: Br, 42.4.

The second fraction boiling at 102–105° (4 mm.) also solidified in the receiver. However, toward the end of the distillation a small amount of material came over at about the same temperature which did not solidify. (This mixture was assumed to contain 4-bromo- and 2,4-dibromo-*m*-cresol[12] which have boiling points very near that of 2,6-dibromo-*m*-cresol.) The solid fraction was obtained in about 23% yield and was shown by analysis and the following series of reactions to be 2,6-dibromo-*m*-cresol. It crystallized from petroleum ether in clusters of needles which melted at 36.5–37.5° and formed a *p*-toluenesulfonyl ester[13] melting at 131–132°.

Proof of Structure of 2,6-Dibromo-*m*-cresol.—Pure 4-nitro-*m*-cresol prepared by the method of Staedel and Kolb[14] was brominated with two moles of bromine in glacial acetic acid and the resulting 2,6-dibromo-4-nitro-*m*-cresol was reduced by means of stannous chloride and hydrochloric acid.[15] The hydrochloride of 2,6-dibromo-4-amino-*m*-cresol was diazotized by the procedure of Bigelow, Johnson and Sanborn[16] and an unsuccessful attempt was made to prepare 2,6-dibromo-*m*-cresol by reducing the diazonium group with alcohol in the presence of finely divided copper. The first fraction obtained by the steam distillation of the reaction mixture remained an oil, while subsequent fractions solidified in the receiver and were shown by analysis to be 2,6-dibromo-4-chloro-*m*-cresol. Recrystallization from petroleum ether gave needle clusters melting at 68.5–69.5°. Analysis of the liquid fraction coming over in the first stages of the steam distillation for halogen indicated a mixture of 2,6-dibromo-*m*-cresol and 2,6-dibromo-4-chloro-*m*-cresol. Direct chlorination of this fraction in chloroform, after repeated attempts to purify it had failed, gave 2,6-dibromo-4-chloro-*m*-cresol melting at 68.5–69.5°. The *p*-toluene sulfonyl ester[13] recrystallized from alcohol melted at 108–109°.

Conclusive proof of the structure of the 2,6-dibromo-*m*-cresol was obtained by chlorinating it directly in chloroform to the 2,6-dibromo-4-chloro-*m*-cresol, which was also prepared by the bromination of 4-chloro-*m*-cresol with two moles of bromine. In all cases the identity of the products was checked by melting point, ester formation and analysis.

An attempt to prepare 2-bromo- and 6-bromo-*m*-cresol was made by brominating 36 g. of *m*-cresol (one-third mole) and 36 g. of concentrated sulfuric acid in nitrobenzene at 5–10°. However, the reaction was found to yield a mixture of 25 g. (40%) of 2-bromo-*m*-cresol boiling at 60–65° (4 mm.) and 5 g. (8%) of 4-bromo-*m*-cresol boiling at 103–104° (4 mm.). The latter compound formed a mass of very fine needles when recrystallized from petroleum ether which melted at 58.5–59.5°. Its *p*-toluene sulfonyl ester[13] melted at 112–113°. Recrystallization of 4-bromo-*m*-cresol, prepared by Huston and Hutchinson[12] from the same solvent, gave the same melting point and its *p*-toluene sulfonyl ester also melted at 112–113°. To further prove the structure of this (higher) fraction, 4-nitro-*m*-cresol was reduced by tin and hydrobromic acid in alcoholic solution and the hydrobromide diazotized in hydrobromic acid solution. Replacement of the diazonium group with bromine by the Sandmeyer reaction[17] yielded 4-bromo-*m*-cresol, which was identified by the melting point and that of its *p*-toluene sulfonic ester.

2-Chloro-*m*-cresol, 2,4-Dichloro-*m*-cresol and 2,6-Dichloro-*m*-cresol.—Adaptation of the method to the chlorination of *m*-cresol gave 2-chloro-*m*-cresol (m. p. 49–50°) boiling at 53–57° (4 mm.)—195–196° (740 mm.)—2,4-dichloro-*m*-cresol (m. p. 58–59°) boiling at 75–80° (4 mm.)—235–236° (745 mm.)—and 2,6-dichlorophenol boiling at 80–85° (4 mm.)—239.5–240.5° (745 mm.). The presence of 2,4-dichloro- and 2,6-dichloro-*m*-cresol in the same reaction is not surprising since Haworth and Lapworth[18] report a mixture of the 4 and 6 sulfonic acids of *m*-cresol when it is sulfonated at 100–120°.

The structure of 2,4-dichloro-*m*-cresol was proved by brominating it in chloroform to the corresponding 2,4-dichloro-6-bromo-*m*-cresol (m. p. 58–59°), which was also prepared by chlorinating 6-bromo-*m*-cresol in chloroform. In order to prepare this in a pure state 6-nitro-*m*-cresol[19] was reduced[20] and the resulting amino group was diazotized and replaced by bromine.[18] It boiled at 70–73° (4 mm.)—210–212° (745 mm.)—and solidified upon standing in the receiver. When crystallized from petroleum ether it melted at 38.5–39.5°.

Similarly, the structure of 2,6-dichloro-*m*-cresol was proved by brominating it to 2,6-dichloro-4-bromo-*m*-cresol[21] (m. p. 64–65°), which was also prepared by chlorinating 4-bromo-*m*-cresol directly.

Summary

1. Bromination of *p*-phenol sulfonic acid in anhydrous nitrobenzene gave excellent yields of 2,6-dibromo- and 2-bromophenol.

2. Chlorination of *p*-phenol sulfonic acids under similar conditions gave 2,6-dichloro and 2-chlorophenol.

3. Bromination or chlorination of the *p*-sulfonic acid of *o*-cresol in anhydrous nitrobenzene gave 6-bromo-*o*-cresol or 6-chloro-*o*-cresol.

4. Bromination or chlorination of the 4- and 6-sulfonic acids of *m*-cresol in anhydrous nitrobenzene gave 2-bromo-*m*-cresol, 2,6-dibromo-*m*-cresol and 4-bromo-*m*-cresol or 2-chloro-*m*-cresol, 2,4-dichloro-*m*-cresol and 2,6-dichloro-*m*-cresol.

5. Sulfonic acid groups on the benzene ring of phenol and phenol derivatives were shown to be stable toward halogenation in the presence of acid if carried out in an inert *anhydrous* solvent.

Occurrence of Decomposition Products of Chlorophyll. III.[1] Isolation of Pyrroporphyrin from Beef Bile[1a]

BY PAUL ROTHEMUND

Since the discovery of the presence of phylloerythrin in beef bile by Löbisch and Fischler,[2] bile has been the source for the preparation of this decomposition product of chlorophyll. The original method of isolation has been improved by different authors[3] and leads to a beautifully crystallized product. Depending upon the method used, one obtains phylloerythrin either in form of $C_{33}H_{34}N_4O_3$, or with one molecule of chloroform of crystallization for every two molecules of phylloerythrin, $(C_{33}H_{34}N_4O_3)_2CHCl_3$. Synthetic phylloerythrin was first prepared by Fischer,[4] but beef bile is still the best source for its preparation, due to the low cost and the ready availability of this starting material.

Using the methods referred to above, large quantities of bile were worked up in our laboratory for the preparation of phylloerythrin. The data of the elementary analyses, as reported in the literature for the product thus prepared, as well as the analyses of our product, showed small but consistent deviations from the theoretical values for phylloerythrin. In some cases, the examination of a solution in pyridine–ether with the Zeiss pocket spectroscope with wave length scale and comparison prism, revealed a faint but distinct absorption band at approximately 625 mμ.

Some time ago, we had demonstrated the occurrence of a number of chlorophyll derivatives in the stomach contents, in the stomach walls, and in the digestive system of herbivorous animals;[5] the presence of other substances of porphyrin character besides phylloerythrin in beef bile could, therefore, be assumed, and the spectroscopic finding proved this assumption to be correct. The method of fractionation of an ether solution of the bile pigments with hydrochloric acid was used for the separation.

Coproporphyrin, which is a physiological constituent of *human* bile[6] and is formed there from the protoporphyrin of the red blood cell,[7] was found in the 0.5% hydrochloric acid fraction only in traces. This finding is interesting in the light of the fact that coproporphyrin can always be detected spectroscopically in cow's milk; the volume of bile necessary to obtain a positive test for this substance is much larger than that of milk.

The chlorophyll porphyrins phyllo- and rhodoporphyrin could not be found in bile; it was, however, possible to demonstrate the presence of pyrroporphyrin. This porphyrin was responsible for the spectroscopic finding mentioned above; the position of its main red absorption band, measured on a large grating spectroscope, is 623.1 mμ in ether. It was isolated from the 3% hydrochloric acid fraction and analyzed. The methyl ester was prepared.

The 10% hydrochloric acid fraction yielded phylloerythrin in approximately the same quantity as obtained by the chloroform/pyridine–alcohol method in which fractionation is omitted.

Two fractions were separated using higher concentrations, 15 and 20% hydrochloric acid, but the quantity of pigment in each of these fractions was too small to permit the isolation. The absorption spectra of these two fractions in ether are given in the experimental part.

Experimental

Twelve liters of beef bile was evaporated to a volume of 1.5 liters, and transferred into a 5-liter separatory funnel by means of 750 cc. of water. After acidification with 10 cc. of concd. hydrochloric acid and thorough shaking, the bile was extracted with a mixture of 1800 cc. of chloroform and 300 cc. of pyridine. The chloroform–pyridine layer was filtered and the chloroform distilled off. To the recovered chloroform about one-tenth of its volume of pyridine was added, and a second extraction of the bile solution was performed with this mixture. The extract was added to the residue from the first extraction, and the chloroform recovered. The combined material from six extractions was concentrated *in vacuo* to a volume of 150 cc., and transferred into 2 liters of ether by means of 200

(7) Hijmans van den Bergh, *Nederland. Tijdschr. Geneeskunde*, **76, I**, 120 (1932); Hijmans van den Bergh, Grotepass and Revers, *Klin. Wochschr.*, **11**, 1534 (1932).

cc. of pyridine; 500 cc. of water was added, and shaken, until the precipitate was dissolved. The water layer was separated, diluted with 500 cc. of water, and extracted with 250 cc. of ether. The combined ether solutions were washed with 150-cc. portions of water, until the water layer showed only slightly yellow color (3 to 6 washings were usually sufficient). The dark red-brown ether solution was subjected to fractionation with hydrochloric acid by Willstätter's method.[8]

0.5% Hydrochloric acid was used in seven portions of 100 cc. each for the first fraction. The pigment from the combined extracts was transferred into 500 cc. of ether by means of concd. sodium acetate solution. This ether was washed acid free and evaporated to a small volume; the coproporphyrin was refractionated with 0.1% hydrochloric acid and identified spectroscopically only. Fifty liters of bile did not yield enough material for esterification and determination of the melting point of the ester.

Ten 100-cc. portions of the 3% hydrochloric acid fraction were combined, the pigment transferred into ether in the usual manner, the ether washed and refractionated with 1.5% hydrochloric acid. The porphyrin was brought back into ether with sodium acetate. Direct spectroscopic comparison with an ether solution of pyrroporphyrin from pheophytin showed identity. The hydrochloric acid number was 1.5. The porphyrin was quantitatively removed from the ether by means of 0.1 *N* potassium hydroxide or a 10% sodium carbonate solution. Esterification with methanolic hydrochloric acid yielded pyrroporphyrin methyl ester of m. p. 241°, spectroscopically identical with the free porphyrin. No depression of the melting point was observed with pyrroporphyrin ester prepared from pheophytin.

Anal. Micro Kjeldahl determinations: pyrroporphyrin (material from 100 l. of bile recrystallized from pyridine–methanol). Calcd. for $C_{31}H_{34}N_4O_2$: N_2, 11.34%. Found: N_2, 11.2%. Pyrroporphyrin methyl ester (recrystallized from pyridine–methanol). Calcd. for $C_{32}H_{36}N_4O_2$: N_2, 11.02. Found: N_2, 10.9.

Phylloerythrin was extracted from the ether solution with 10% hydrochloric acid. In addition to the normal absorption bands of phylloerythrin, a weak band at 656.0 $m\mu$ was observed in the ether solution of phylloerythrin, which had been subjected to hydrochloric acid fractionation. The substance to which this band is due, remained in the mother liquid, when the phylloerythrin was recrystallized from pyridine.

The 15% hydrochloric acid fraction was transferred to ether and exhibited then the following absorption bands: I, 664.4–(656.6)–648.8---635.7; II, 608.0---597.0–(592.3)–587.5---580.0; III, 566.0–(555.7)–545.4; IV, 534.8–(530.8)–526.8; V, 507.2–(499.2)–491.1; E. A. 465. Intensity: I, II, III, IV, V.

The spectrum of the 20% hydrochloric acid fraction in ether was: I, 601.6–(589.3)–577.0; II, 563.4–(558.5)–553.7; III, weak band with its maximum approximately at 521; E. A. 442. Intensity: I, II, III.

Summary

1. Pyrroporphyrin was found in beef bile under physiological conditions; its quantity changed only very slightly with the season of the year. Traces of coproporphyrin were also always present.

2. The separation from phylloerythrin, and from other pigments in bile, was performed by fractionation of an ether extract of the pigments with hydrochloric acid.

3. It is assumed that the occurrence of pyrroporphyrin in beef bile is due to decomposition of chlorophyll, while the presence of coproporphyrin is accounted for by the decomposition of hemoglobin.

4. No evidence for the presence in bile of other chlorophyll porphyrins (phyllo- or rhodoporphyrin) could be obtained; neither was it possible to demonstrate the occurrence of other porphyrins from blood pigment (*e. g.*, proto- or deuteroporphyrin).

Identification of Carboxylic Acids as Carboxylates of Benzylamine and Alpha-Phenylethylamine

BY C. A. BUEHLER, LOUISE CARSON AND RACHEL EDDS

Although simple addition compounds are not regarded generally as being suitable derivatives for the identification of organic compounds, those which benzylamine and α-phenylethylamine form with solid carboxylic acids are exceptions. These amines, with dissociation constants of the order of ammonia,[1] unite with both aliphatic and aromatic carboxylic acids to form stable compounds, but, unfortunately, the derivatives of some of the liquid aliphatic acids are difficult to isolate because of their low melting points, their deliquescent nature, and their tendency to supercool when in the liquid state. It is interesting to note, however, that these carboxylates, melting near room temperature, are of sufficient stability to withstand vacuum distillation. Among the solid derivatives prepared, the stability is such that various solvents such as ethyl acetate or absolute alcohol may be used for purification, although the former is to be preferred because of the lower solubility of the carboxylates in it. The compounds thus obtained are white in color, unless a group such as the nitro or amino is present, and they possesss two easily found constants, the melting point and the neutralization equivalent. The latter was determined by the method[2] recommended for the salts of aliphatic amines. All the compounds listed in Tables I and II are new, and of a 1:1 molecular ratio.

TABLE I

BENZYLAMMONIUM CARBOXYLATES

Acid	Formula	Melting point., °C. Obsd.	Corr.	Neut. equiv. Calcd.	Found	Nitrogen, % Calcd.	Found

---

(1) *K*, for benzylamine, "International Critical Tables," Vol. VI, p. 281, is 2.0 × 10^{-5}; the value for α-phenylethylamine is not available, but, by analogy with the effect of the substitution of a methyl group in the alpha carbon in other cases, it would be expected to be similar to that of benzylamine.

Experimental

The benzylamine was the best Eastman grade while the α-phenylethylamine was prepared by the reduction of acetophenone oxime.[3] The fraction of the latter used boiled at 184–187°. Melting points were determined by the method of Mulliken[4] in which a thermometer calibrated by the Bureau of Standards was employed.

To form the carboxylates of the solid acids, 0.01 mole of the acid was dissolved in the smallest possible amount of boiling ethyl acetate, and then a slight excess of the hot solvent was added. Into this hot solution 0.01 mole of the amine was stirred in, after which the resulting solution was poured quickly on a watch glass for crystallization. After the bulk of the crystals had formed, the mother liquor was poured off and the crystals were dried first for a short time in the air and finally between filter paper. For the liquid acids, with the exception of those cited below, equimolecular amounts were mixed, in the absence of any solvent, on a watch glass in which crystallization was induced by gentle tapping at room temperature, or, if necessary, at the lower temperature of an ice–salt mixture. The separation and drying of the crystals were accomplished as before. Final purification in either case was realized by crystallization from ethyl acetate.

Some of the carboxylates in the neighborhood of *n*-butyric acid (see Tables I and II) possess such low melting points that they could not be obtained satisfactorily by crystallization methods. These were prepared by distilling equimolecular amounts of the amine and acid under reduced pressure.

Summary

A series of carboxylates of benzylamine and α-phenylethylamine has been prepared. Those of the solid carboxylic acids are particularly suitable for identification purposes.

Observations on the Rare Earths. XLVI. The Atomic Weight of Gadolinium[1]

BY C. R. NAESER WITH B. S. HOPKINS

The object of the work described in this paper was to determine the atomic weight of gadolinium by the gadolinium chloride-to-silver ratio. Several previous determinations have been made, but none by this method. Marignac,[2] the discoverer of the element, assigned the "equivalent" of 120.5 to it. This was equal to an atomic weight of 156.75. It is probable that this equivalent was referred to sulfur trioxide, which was assumed to have a molecular weight of 80. Bettendorf[3] was the first to publish the determinations with their individual data. He effected the synthesis of the sulfate from the oxide, and obtained 156.75 for the atomic weight. Benedick[4] and Marc,[5] also using the sulfate-to-oxide ratio, obtained 156.52 and 156.39, respectively. Brauner's[6] single determination, made with material contaminated with samarium, may be disregarded. The material used by Urbain[7] in 1905 was probably the purest of all. He calcined the octahydrated sulfate to the oxide and obtained 157.24 as the average of two series of determinations. Feit and Przibylla,[8] using a volumetric method of sulfuric acid against gadolinia, obtained 157.377 and 157.398. The value adopted by the International Union of Chemistry[9] is 157.3. This value, of course, is based on the oxide-to-sulfate ratio. The disadvantages of the oxide-to-sulfate ratio have been discussed critically by Hopkins and Balke[10] and Brauner and Svăgr.[11] Because of these disadvantages and the large difference between the atomic weight of europium and that of gadolinium, it was thought advisable to redetermine the atomic weight of gadolinium, and to use the chloride-to-silver ratio.

Purification of Gadolinium Material

The original source of the gadolinium material was Brazilian monazite and Norwegian gadolinite. The gadolinite ore was broken up and taken into solution at this Laboratory, and the Brazilian monazite was obtained as the crude rare earth oxides from the Welsbach Company. The cerium was removed by the permanganate–phosphate method.[12] The cerium-free material was then converted to the double magnesium nitrates and fractionated as such. The samarium–europium–gadolinium fractions at the more soluble ends of the series were set aside and then put into a new series.[13]

The major part of the fractionation was carried out as described by Meyers and Hopkins[14] in their recent paper on the atomic weight of europium. The resulting fractions which were gadolinium rich and europium poor were run for a time as the double magnesium nitrates with bismuth[15] magnesium nitrate as the separating agent. After 150 fractionations in this fashion the gadolinium material was converted to the simple nitrates and again run with bismuth nitrate present.

At the conclusion of the fractionation, eight fractions were obtained, six of which were used for the atomic weight work. A portion of the bismuth was removed by hydrolysis, and the remainder was precipitated as the sulfide with hydrogen sulfide gas. This procedure was carried out six times to ensure complete removal of the bismuth. The gadolinium material was purified further by five alternate precipitations of the hydroxide and the oxalate. All of these precipitations were carried out in conductivity water. The final oxalate obtained from each fraction was ignited to the oxide in a platinum crucible at 800°.

A spectroscopic analysis of each sample was made, using an E_1 Hilger spectrograph and pure graphite electrodes. The first six fractions, GD-7 to GD-12, showed only gadolinium lines. Fractions GD-13 and GD-14 showed very faintly the most persistent lines of europium. No evidence of either bismuth or magnesium was found in any of the fractions. Similarly, no evidence of platinum was found.

Purification of Reagents

The purification of the reagents was carried out in a manner similar to that described in earlier publications from this Laboratory.[16] The purified gadolinium oxide was dissolved in redistilled hydrochloric acid and twice recrystallized.

Formation of Anhydrous Gadolinium Chloride[17]

The purified gadolinium chloride was transferred to a quartz reaction flask and dissolved in redistilled hydrochloric acid and conductivity water. A mixture of nitrogen and hydrogen chloride was then passed in from a purifying train while the flask was maintained at a temperature of 95°. When the gadolinium chloride began to crystallize, the stream of nitrogen was stopped, and only hydrogen chloride was allowed to pass into the flask. The temperature of the flask was slowly raised to 110° and kept there until the first five molecules of water of crystallization were removed. The temperature was then gradually raised to 180°, at which point the last molecule of water of crystallization began to be evolved. The dehydration was complete when a temperature of 225° was reached. To ensure complete dehydration, however, the temperature was raised to 350° and maintained there for one hour. Then, with hydrogen chloride still passing through the flask, the gadolinium chloride was fused by means of a Bunsen burner. After the flask had cooled, the stream of hydrogen chloride was stopped, and nitrogen was passed through until the exit gas gave no test for a chloride. The nitrogen was then displaced by dry air and the stoppered flask was placed in the balance case, where it was allowed to hang for three hours before being weighed.

The Ratio of Gadolinium Chloride to Silver

After it had been weighed, the gadolinium chloride was dissolved in conductivity water and transferred to a 1.5-liter glass-stoppered bottle. An approximately equivalent amount of silver was weighed out and etched with nitric acid. The silver was then washed, dried and carefully weighed again. After weighing, it was dissolved in redistilled nitric acid, diluted with conductivity water, and added slowly, with constant shaking, to the gadolinium chloride solution. The glass-stoppered flask was placed in a shaking machine for six hours and was then allowed to remain undisturbed for twenty-four hours. After this period of standing, a portion of the clear liquid was removed and tested in the nephelometer for excess of silver or chloride. Weighed portions of 0.01 *N* silver nitrate or sodium chloride solution were added until the nephelometer indicated equivalence. After each addition of the standard solution, the bottle was shaken for an additional six hours and allowed to stand for twenty-four before testing for equivalence again.

In the following table the fraction number in the series, the determination number, and the weight of the anhydrous chloride and silver, ratio of weights, and the atomic weights are given.

Detn.	Fraction number	$GdCl_3$, g.	Ag, g.	Ratio $GdCl_3/3Ag$	Atomic weight of gadolinium
I	GD-7	0.38265	0.47047	0.813333	156.86
II	GD-7	.82483	1.01416	.813311	156.85
III	GD-8	1.56656	1.92608	.813344	156.86
IV	GD-8	0.63482	0.78060	.813247	156.82
V	GD-9	.68899	.84716	.813304	156.85
VI	GD-9	2.27153	2.79249	.813442	156.89
VII	GD-10	1.89197	2.32637	.813289	156.84
VIII	GD-10	1.41902	1.74486	.813262	156.83
IX	GD-11	1.23485	1.51829	.813317	156.85
X	GD-11	1.61684	1.98796	.813315	156.85
XI	GD-12	1.72986	2.12689	.813329	156.86
XII	GD-12	2.48952	3.06091	.813326	156.85
				Average	156.85

All weighings were made by the method of substitution. The tare flask was made of quartz and differed from the reaction flask by only a few milligrams. The balance used was sensitive to 0.01 mg. and the weights were carefully standardized against a set recently checked by the Bureau of Standards. All weighings were corrected to vacuum standard. A sample of thorium oxide was kept in the balance case to eliminate all electrostatic charges.

The density of gadolinium chloride was determined by displacement of xylene and carbon tetrachloride, and checked the value given by Bourion,[18] namely, 4.52. The atomic weight of silver was taken as 107.88, and that of chlorine as 35.457. Other density values used were: silver, 10.49; platinum weights, 21.5; platinum-plated brass weights, 8.4. Since both platinum and platinum-plated brass weights were used, the two densities were used in reducing the weighings to vacuum standard. Both densities were also used in standardizing the weights.

Discussion of Results

The value of 156.85 ± 0.011 is lower than the accepted value for the atomic weight of gadolinium by 0.45 units, but is in good agreement with Aston's[19] latest determination with the mass spectrograph, namely, 156.9 ± 0.2.

Summary

1. The ratio of gadolinium chloride to silver is found to be 156.85, with a mean deviation of 0.011. This is lower by 0.45 than the present accepted value, but is in good agreement with the latest determination made with the mass spectrograph.

2. The density of anhydrous gadolinium chloride is found to check with the value given in the literature, 4.52.

Observations on the Rare Earths. XLV. Preparation of Rare Earth Amalgams by Displacement[1]

BY D. H. WEST WITH B. S. HOPKINS

Rare earth metal amalgams have been prepared by direct combination[2] and by electrolysis[3] in non-aqueous solvents using a mercury cathode. Amalgams prepared electrolytically have been decomposed thermally to obtain metallic lanthanum, cerium and neodymium.[4]

Barium amalgam is conveniently prepared[5] by allowing sodium amalgam to react with aqueous barium chloride solution. Barium is quite closely related to the rare earths, being slightly more active. Since such a method might have advantages over the electrolytic preparation, an investigation of this possibility was entered upon to find out whether displacement can be used and if so to ascertain the most favorable conditions for the reaction.

Experimental

Preparation of Anhydrous Chlorides.—Anhydrous chlorides of the rare earth materials were prepared by the method of Reed[6] with some changes. The dry oxides were first ground in a large mortar with twice the calculated weight of ammonium chloride. Instead of heating this mixture in open casseroles and stirring by hand it was found convenient to carry out the operation in a Pyrex flask. This was slowly rotated at an angle of thirty degrees with the horizontal in an air-bath which was heated to 225–250° until the reaction was complete. The removal of excess ammonium salts was carried out by heating to 300–320° in the evacuated Pyrex apparatus described by Reed.

In this way the anhydrous chlorides of neodymium, a didymium mixture, samarium and yttrium were prepared without difficulty, the product in most cases being free from oxide or basic chloride as shown by complete solubility in water. Cerium dioxide reacted much more slowly with the ammonium chloride but by adding a three or four-fold excess of the latter and continuing the reaction for ten to twelve hours it was possible to prepare a product containing only a small amount of unconverted oxide.

Preparation of Amalgams.—It was found that sodium amalgam would react with the rare earth chlorides in alcohol solution forming the rare earth amalgam according to the equation

$$3NaHg_x + RCl_3 \longrightarrow 3NaCl + RHg_y$$

The sodium chloride is precipitated as is also some rare earth chloride. The displacement reaction begins rapidly forming an amalgam which contains a preponderance of rare earth metal. Although the reaction goes nearly to completion there is always a trace of sodium left in the amalgam. After a time there is a tendency for the amalgam to decompose, both sodium and rare earth metals resulting. Analysis of the amalgams was carried out by allowing them to decompose in air for three to five days and treating the residue with dilute hydrochloric acid. The soluble material was filtered off, evaporated and converted to the nitrate. From this solution the rare earth was precipitated as the oxalate and ignited to the oxide. The filtrate from the latter operation was fumed down with sulfuric acid and the sodium was weighed as the sulfate after ignition in platinum to red heat.

The sodium amalgams used were prepared in pulverized form by direct combination of the metals. Concentrations of 2–2.5% by weight of sodium gave the best results. More concentrated amalgams were so hard that they reacted very slowly with the rare earth chlorides. The sodium amalgam was agitated with the alcohol solutions by means of a stirrer driven by compressed air. The containers used were either large test-tubes or Erlenmeyer flasks.

With cerium, neodymium and "didymium" mixture, one hour was sufficient time to allow for the formation of good amalgams containing 3 to 3.5% rare earth metal and a small amount of sodium. The reaction was slower in the case of yttrium, two to three hours of stirring being required. Yttrium amalgams and amalgams of a mixture containing about 70% yttrium with erbium and other yttrium group earths were prepared in concentrations of 2 to 2.5% rare earth metal. Results of typical runs are given in Table I. In all cases a three to four fold excess of the rare earth salt was used.

TABLE I

Material	Time, min.	% Na in starting amalgam	Wt. Hg recovered, g.	Metals in final amalgam	
				% R. E. metal	% Na
Didymium	21	1.24	105.45	1.74	0.274
Didymium	35	1.63	16.72	2.20	.038
Didymium	60	2.68	6.83	3.38	.141
Didymium	40	2.50	27.07	3.15	.085
Didymium	20	19.60	5.31	3.20	.500
70% Yttrium	60	2.50	23.71	2.58	.342
Yttrium	90	1.76	35.03	1.56	.271
Cerium	45	2.50	22.52	3.40	.120
Neodymium	35	1.88	25.42	3.20	.370

Rare earth amalgams have been prepared electrolytically from water solution. However, no success was encountered by the authors in attempting to carry out the displacement reaction in water solution or in alcohol solutions containing appreciable amounts of water. Methyl

alcohol was satisfactory but best results were obtained with absolute ethyl alcohol saturated with the rare earth salt.

It was found best to cool the reaction tube with tap water since heat is developed by the reaction and at the higher temperature the tendency toward decomposition of the amalgam increases.

Potassium amalgams reacted with the anhydrous rare earth chlorides similarly to the sodium amalgams but were not as satisfactory. Barium amalgam gave partial displacement of the cerium group elements but did not react at all with the yttrium chlorides.

Yttrium amalgam was readily decomposed by heating in an evacuated Pyrex distilling bulb, the product being a pyrophoric powder which contained a small amount of mercury. Attempts to obtain yttrium metal entirely free from mercury have thus far been unsuccessful. The removal of all the mercury from the amalgams of the cerium group metals was successfully accomplished by placing the amalgams in an alundum crucible which had a lining of rare earth oxides and heating in a steel vacuum chamber by means of an electric furnace.

Summary

1. Amalgams of cerium, neodymium, didymium and yttrium have been prepared by displacement from the alcohol solution of their chlorides by sodium amalgam.

2. The most successful runs were made by suspending powdered sodium amalgam, containing 2–2.5% sodium, in a saturated alcoholic solution of the rare earth chlorides. The mixture was thoroughly agitated; the time required varied with the rare earth used.

3. This method takes much less time than the electrolytic method and gives a considerably more concentrated amalgam in the case of yttrium. The amalgams always retain a trace of sodium.

4. Metals of the cerium group were obtained free from the mercury by heating their amalgams in an evacuated chamber. This method did not yield yttrium which was entirely free from mercury.

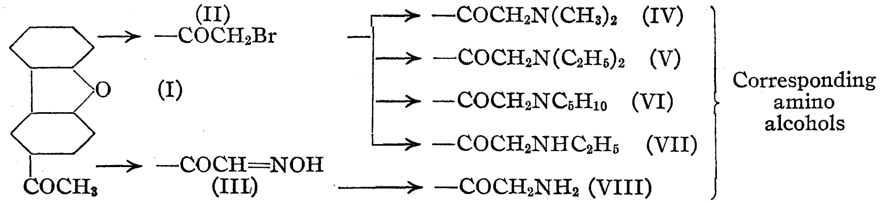
Amino Alcohols Derived from Dibenzofuran[1]

BY ERICH MOSETTIG AND RICHARD A. ROBINSON

The structural similarity of dibenzofuran to 4,5-phenanthrylene oxide has led us to the study of dibenzofuran derivatives[2] as a part of our search for morphine substitutes. The present communication deals with dibenzofuran alkamines containing the characteristic side chain —CHOH—CH$_2$—NR$_2$; these compounds were selected for comparison with amino alcohols of the phenanthrene series which have been found to resemble morphine somewhat in physiological action.[3] Such comparison of dibenzofuran and phenanthrene analogs may yield information as to whether the phenanthrene nucleus contributes an essential part to the total physiological action of morphine, or whether it can be replaced by another polynuclear system.

Starting from the known 2-acetyldibenzofuran, the synthesis of the alkamines was accomplished as outlined in the diagram.



The tertiary amino ketones IV, V and VI were prepared by a method similar to that used for the synthesis of their respective phenanthrene analogs.[3] The primary amino ketone VIII was obtained by reduction of the isonitroso compound III according to the method of Hartung and Munch.[4]

The exchange of the bromine atom in II with ethylamine yields only about 30% of the expected ethylamino ketone VII. The yield of the corresponding monomethylamino ketone does not exceed 5%. In the latter case a small amount of

[a] Prepared by bromination of 2-acetyldibenzofuran in absolute ether at 0°. The bromo ketone was purified by recrystallization from benzene–ligroin mixture or from acetic acid. The yield of pure substance was 55%; soluble in benzene. The residue, a lower-melting fraction, could not be greatly purified by further recrystallization and probably consisted of nuclear bromination products. In order to prove that the bromine atom was located in the side chain, the bromo ketone was oxidized with sodium hypochlorite to dibenzofuran-2-carboxylic acid. The 2-acetyldibenzofuran was prepared by the method of Friedel and Crafts.[5] The reaction was carried out at room temperature with nitrobenzene as the solvent (duration of reaction, forty-eight hours). The crude ketone was purified by vacuum distillation (pressure approximately 1 mm.). The unchanged dibenzofuran can be easily separated in this way but the acetyl derivative so isolated is contaminated with about 5% of a compound of m. p. 148–149° that cannot be removed efficiently by distillation. This compound is probably identical with the 2,8-diacetyldibenzofuran reported by Borsche and Schacke.[5] The separation of this impurity from the 2-acetyldibenzofuran is best effected by several crystallizations from ether or isopropyl ether; yield of pure 2-acetyldibenzofuran, 32%, m. p. 82°; in addition, 24% of practically pure substance (m. p. 74–79°).

[b] Five grams of (1), finely pulverized and thoroughly dried, was suspended in 25 cc. of absolute ether and mixed immediately with a solution of 2.2 g. of dimethylamine in 60 cc. of absolute ether (temperature approximately 0°). The powdered bromo ketone, which gradually dissolves, is replaced by a precipitate of dimethylamine hydrobromide. The transformation is complete in one hour. The amino ketone was worked up as the hydrochloride, yield 90%. The free base is moderately stable but becomes colored on long standing or in ethereal solution.

[c] Soluble in water; precipitates almost quantitatively from dilute hydrochloric acid as white needles containing one mole of water of crystallization. *Anal.* Calcd. for $C_{16}H_{16}O_2NCl \cdot H_2O$: H_2O, 5.85. Found: H_2O, 6.57.

[d] Prepared from diethylamine and the bromo ketone by the method given for (2); yield, 97%; soluble in water and ethanol. The transformation is complete in one hour, and coloration of the products can be avoided by working up immediately at this point. With dimethylamine and piperidine there is very little tendency for the reaction products to become colored. The free diethylamino ketone base is a colorless oil. K. and P prepared this substance from chloroacetyldibenzofuran and state as melting point for the hydrochloride 204–206°.

[e] Prepared from piperidine and the bromo ketone by the method given for (2); yield, 96%. The free base is moderately stable but becomes yellow on long standing. It softens at 97–100° and melts over a wide range.

---

(5) Galewsky, *Ann.*, **264**, 187 (1891); Borsche and Schacke, *Ber.*, **56**, 2498 (1923).

Moderately soluble in water; K. and P. give m. p., 270–271°.

[g] Prepared from ethylamine and the bromo ketone by the method given for (2). The transformation is complete in one and one-half hours and the reaction mixture always becomes highly colored. The amino ketone was extracted from the filtered ether solution with dilute acetic acid and precipitated as the hydrochloride by the addition of concd. hydrochloric acid to the acetic acid solution; yield, 30%, difficultly soluble in water and alcohol. From 5 g. of bromo ketone, 0.5–1 g. of dibenzofuran-2-carboxylic acid was found as a by-product. The remainder of the material was a highly sensitive substance. The freshly precipitated free base soon turns pink. It melts at 65–75°.

[h] Prepared by reducing 2-isonitrosoacetyldibenzofuran by the method of Hartung.[4] The solvent was prepared by mixing 150 cc. of methanol with 40 cc. of concentrated hydrochloric acid. The amino ketone hydrochloride precipitates after about 90% of the calculated amount of hydrogen has been absorbed and absorption stops completely at this point; yield, 64%. The salt is sparingly soluble in alcohol, moderately soluble in water. It turns pink in warm alcohol or water, but is stable in dilute hydrochloric acid. The free base becomes pink immediately when liberated from the hydrochloride. The isonitroso compound was obtained from 2-acetyldibenzofuran by the method of Claisen and Manasse[6] in a yield of 60%. It is soluble in alcohol and benzene, and was crystallized once from dilute alcohol and reduced without further purification. It decomposes over a wide temperature range starting at 171°.

[i] Prepared by reducing (2) (free base or hydrochloride) in absolute alcohol solution with platinum oxide catalyst; yield, 90%, soluble in alcohol.

[j] Soluble in alcohol and water.

[k] Prepared by the method of Schotten–Baumann.

[l] This compound could not be obtained by reducing the free base of (3). The amino ketone solution became colored during preparation and would not reduce. In two cases the hydrochloride was successfully reduced in absolute ethanol. Exactly one mole of hydrogen was absorbed and the expected compound obtained. In other experiments, when reduced in absolute ethanol, the hydrochloride absorbed 2 to 3 moles of hydrogen, yielding about 25% of unchanged amino ketone hydrochloride and an oily hydrochloride which became colored. By using 70% ethanol we were able to obtain consistently, with the absorption of one mole of hydrogen, the desired amino alcohol in a yield of 80–90%. It is soluble in ethanol and benzene. This amino alcohol and its hydrochloride as well as all other members of this series are, in contrast to the amino ketones, very stable compounds.

[m] Very soluble in ethanol and water. K. and P. give m. p. 137°.

[n] Obtained from (4) (free base) by reducing in absolute ethanol with platinum oxide catalyst; yield 90%; moderately soluble in ethanol. K. and P. state m. p. 103–104°.

[o] Sparingly soluble in water, moderately soluble in alcohol. K. and P. give m. p. 242°.

[p] Prepared by the method of Schotten–Baumann.

[q] Obtained by reducing (5) (hydrochloride) in dry methanol with platinum oxide catalyst; soluble in benzene and alcohol.

[r] Moderately soluble in ethanol, soluble in methanol and water.

[s] Obtained from (6) (hydrochloride) by reduction in dry methanol; yield 90%, soluble in ethanol. If traces of free hydrochloric acid are present (originally added to suppress coloring of the hydrochloride solution) 2 to 6 moles of hydrogen are absorbed. The addition of water in this case does not stop the reduction at one mole of hydrogen.

[t] Soluble with difficulty in water and alcohol.

[u] Obtained from 2-acetyldibenzofuran by reduction in absolute ethanol with platinum oxide catalyst; yield, 90%, soluble in benzene and alcohol. *Anal.* Calcd. for $C_{14}H_{12}O_2$: hydroxyl, 8.02. Found: hydroxyl, 10.3.

[v] A solution of 35 g. of aluminum chloride in 75 cc. of anhydrous nitrobenzene was added slowly at room temperature to a solution of 20 g. of dibenzofuran and 12.5 g. of propionyl chloride in 25 cc. of anhydrous nitrobenzene. The mixture was allowed to react at room temperature for sixty hours and was then worked up in the usual way. For purification the crude ketone was distilled in a vacuum of about 5 mm. and then recrystallized from 95% ethanol; yield of pure substance, 11 g.; moderately soluble in ethanol. For constitutional proof the propionyldibenzofuran was oxidized by means of sodium hypochlorite to dibenzofuran-2-carboxylic acid.

[w] Soluble in water.

[x] Soluble in water and alcohol with difficulty.

Compounds 5, 6, 10, 11, 14 and 15 were extremely difficult to burn even when mixed with copper oxide.

the tertiary amine, methyl-bis-[-(2-dibenzofuroyl)-methyl]-amine, formed by the reaction of one mole of methylamine with two moles of the bromo ketone, could be isolated. In both cases 2-dibenzofurancarboxylic acid could be separated from the reaction products. Its formation in the reaction is as yet unexplained. Attempts to increase the yield of the secondary amino ketones by variation of experimental conditions failed. The amino ketones IV, V and VI were obtained in almost quantitative yield.

While the dimethylamino and piperidino ketones IV and VI can be reduced without any complications, the amino and diethylamino ketones VIII and V absorb two to six moles of hydrogen unless certain conditions are strictly observed.

Dibenzofuran shows as little physiological activity as phenanthrene; with the introduction of simple groups such as —$COCH_3$, COC_2H_5, mild depressant action becomes apparent. The amino alcohols do not give a morphine-like picture in the cat, but are generally more analgesic and more toxic than the corresponding amino alcohols in the phenanthrene series.[3b]

---

[6] Claisen and Manasse, *Ber.*, **20**, 2194 (1887).

Experimental Part

The compounds marked with an asterisk have been recently prepared by Kirkpatrick and Parker.[7] We have included descriptions of them here because of some differences in physical properties. The authors will be referred to as K. and P.

Summary

The preparation of a series of amino alcohols derived from dibenzofuran is described. From 2-acetyldibenzofuran derivatives carrying the side chain —CHOH—CH_2NR_2 (NR_2 being the amino, dimethylamino, ethylamino, diethylamino and piperidino group) are obtained.

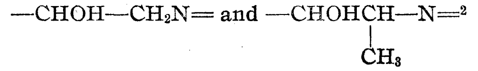
Studies in the Phenanthrene Series. IX. Amino Alcohols Derived from 1,2,3,4-Tetrahydrophenanthrene[1]

BY ERICH MOSETTIG AND ALFRED BURGER

Morphine and most of its derivatives may be considered essentially as amino alcohols having the secondary alcoholic hydroxyl and the tertiary nitrogen attached to a partially hydrogenated phenanthrene nucleus. This consideration has led us in the past few years to the synthesis of a series of derivatives of phenanthrene and of partially hydrogenated phenanthrene carrying the side chains



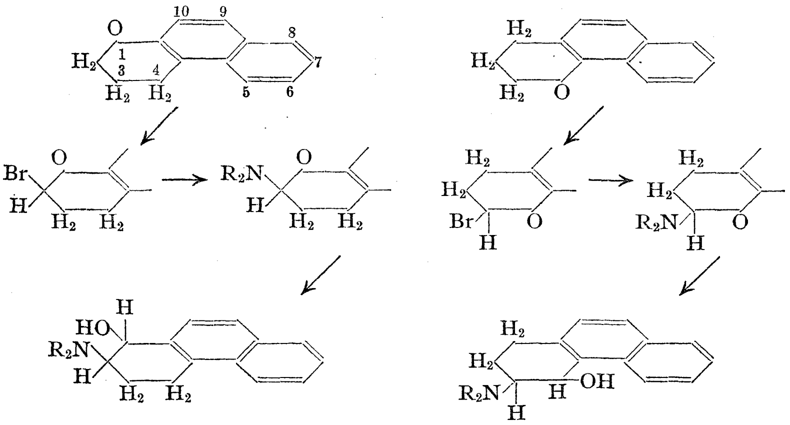
$$\text{—CHOH—CH}_2\text{N= and —CHOH}\underset{\displaystyle\text{CH}_3}{\text{CH}}\text{—N=}^2$$

Some of the amino alcohols of this type show a decided pharmacological resemblance to morphine.[3]

This communication deals with a series of amino alcohols which differ principally from those mentioned above in that the alcoholic hydroxyl and the nitrogen are not located in a side chain, but are attached directly to carbon atoms of the phenanthrene nucleus itself, which must necessarily be hydrogenated in the ring carrying the substituents. It is apparent that the amino alcohols of this type are structurally somewhat more closely related to morphine and hence might be expected to show a morphine-like effect more pronounced than that of the open-chain amino alcohols.

The known 1-keto-1,2,3,4-tetrahydrophenanthrene ("1-tetanthrenone"[4]) and the 4-isomer are convenient starting materials for the synthesis of a series of these new amino alcohols. The synthesis is outlined in the diagram.

The bromination of the tetanthrenones proceeds smoothly. The dimethylamino- and piperidino- ketones are formed in yields of over 80%, the corresponding tetrahydroisoquinolino compounds in yields of 60–70%. It is noteworthy that all attempts to exchange the bromine in the bromotetanthrenones with tetrahydroquinoline were without much success. In the reaction with diethylamine, whether carried out at room temperature or at elevated temperatures, the expected



NR_2 = dimethylamino-, diethylamino-, piperidino- and 1,2,3,4-tetrahydroisoquinolino-.
