[a] Sinters at 95°, purified by high vacuum sublimation at 90°. [b] The carbon value of this compound was always found about 1% low. [c] Benzoyl and 3,5-dinitrobenzoyl derivatives of amino alcohols were prepared by allowing the hydrochlorides of the bases to stand with the calculated amount of the acyl chloride in pyridine solution at room temperature. [d] The crude hydrochloride was converted to the perchlorate or benzoate through the base and reconverted to the hydrochloride. It sinters at 138° and is completely melted at 156°. [e] Purified by high vacuum distillation at 90°, melts unsharply, begins to soften at 60°. [f] The amino ketone is sparingly soluble in benzene and separates from the reaction mixture. [g] Purified by high vacuum sublimation at 105°. Completely melted at 132°. Gives no benzoyl or dinitrobenzoyl derivative. [h] Gives no benzoyl derivative. [i] Formed as by-product in the preparation of No. 7 and in very small amount in that of No. 2, also in about 50% yield on boiling 2-bromo-1-tetranthrenone with diethylaniline for 4 hours. [j] Identical with 1-hydroxyphenanthrene obtained by heating 1-tetanthrenone with powdered selenium for fourteen hours at 295° (yield, 25%). [k] Molecular weight determination by the Rast method: found, 198, 189; by cryoscopic method in *p*-chlorotoluene, found, 193. Calculated for $C_{14}H_{11}O$, mol. weight 195. Semicarbazide acetate yields under the usual conditions, the semicarbazone of

1-tetanthrenone; 1-hydroxyphenanthrene is found in the mother liquors of the semicarbazone. Dilute potassium hydroxide solution extracts 1-hydroxyphenanthrene from the ethereal solution of the molecular compound decidedly slower than from an equally concentrated control solution of 1-hydroxyphenanthrene. Obtained also by boiling 2-bromo-1-tetanthrenone with diethylaniline as above (yield 30%). [l] Formed as by-product in the preparation of No. 23. [m] Prepared also by allowing molecular quantities of 4-hydroxyphenanthrene and 4-tetanthrenone to crystallize from methanol.

amino ketones are formed in yields of only about 20–30%. In the 1,2-series, 1-hydroxyphenanthrene and another nitrogen-free compound melting at 119° can be isolated from the reaction mixture in a total yield of about 25%. The compound of m. p. 119° sublimes readily at 90° in a high vacuum, and is converted to 1-hydroxyphenanthrene and 1-tetanthrenone by short warming with alcoholic potassium hydroxide. It is apparently a molecular compound and can also be obtained by crystallizing the two components in molecular quantities from methyl alcohol. The molecular compound shows a molecular weight corresponding to the simple formula $C_{14}H_{11}O$. The hydroxyphenanthrene is obviously formed by the loss of hydrogen bromide from the bromo ketone; we have no explanation at present for the formation of the tetanthrenone, the other constituent of the molecular compound. Auwers and Lämmerhirt[5] and later Krollpfeiffer and Schäfer[6] isolated from the reaction of α-halogenated ketones with diethylaniline, the corresponding bromine-free ketones in varying amounts, but offered no explanation for this peculiar reductive action of the amine. When we allowed 1,2-bromotetanthrenone to react with diethylaniline, 1-hydroxyphenanthrene (50%) and the molecular compound of m. p. 119° (30%) were formed. Neither in this reaction nor in that with diethylamine could any free tetanthrenone be found. The reaction of the 3,4-bromotetanthrenone proceeds throughout like that of the 1,2-isomer. In addition to the desired amino ketone, 4-hydroxyphenanthrene and a molecular compound (1 mole of 4-hydroxyphenanthrene with 1 mole of 4-tetanthrenone) can be isolated.

The amino ketones were reduced catalytically (platinum oxide) to the corresponding amino alcohols. In all cases only one of the two possible diastereomeric forms was obtained.

1,2,3,4-Tetrahydrophenanthrene is pharmacologically more effective in all respects, and especially in analgesic action, than either phenanthrene or 1,2,3,4,5,6,7,8-octahydrophenanthrene.[3] Of the two tetanthrenones the 1-keto isomer behaves quite unusually. In sufficient doses it shows a marked and mounting (up to five hours) analgesic action without showing much other effect. The 4-keto isomer is far less effective,[3] a relationship which is also known to hold true in the relative oestrogenic activity of these two isomers.[7]

The cyclic amino alcohols are generally more analgesic than the ones with the open side chain —CHOH—CH_2N= and  $\text{—CHOH—}\underset{\displaystyle CH_3}{\underset{|}{CH}}\text{—N=}$. It is remarkable that two of them approach and even excel some of the morphine derivatives. The effective analgesic dose of 2-piperidino-1-hydroxy-1,2,3,4-tetrahydrophenanthrene is 20 mg. per kg.; the corresponding dose of the 3-tetrahydroisoquinolino-4-hydroxy-1,2,3,4-tetrahydrophenanthrene is 15 mg. per kg., comparable with the effective doses of 10 and 20 mg. for codeine and pseudocodeine, respectively.[3]

We are indebted to Mr. Lyon Southworth of this Laboratory for the analyses appearing in this paper.

Experimental Part

Bromotetanthrenones.—Bromine (one mole) was added slowly to a solution or suspension of finely powdered tetanthrenone in absolute ether containing a few drops of ethereal hydrogen chloride. The bromine was taken up rapidly and the bromo ketone either crystallized out or was obtained by distilling the ethereal solution after washing it with water.

Amino Ketones.—A benzene solution of the bromo ketone (one mole) and the respective amine (3 moles) was allowed to stand in a stoppered flask at room temperature for two days. The color of the mixture became gradually yellow and deepened to dark red in some cases. The precipitation of the amine hydrobromide indicates the progress of the exchange. The reaction mixture was diluted with ether, the amine hydrobromide removed with water and the solution evaporated *in vacuo*. The residue was dissolved in acetone and the amino ketone hydrochloride precipitated with ethereal hydrogen chloride. The replacement of the bromine atom by the diethylamine residue proceeds only very slowly at room temperature. Therefore the benzene solution of the components was heated to 100° in a sealed tube for twenty-four hours, poured into dilute hydrochloric acid, and the non-basic reaction products were extracted into ether. The amino ketone hydrochloride crystallized partly from the aqueous solution.

(7) Cook, Dodds, Hewett and Lawson, *Proc. Roy. Soc.* (London), Series B, **114**, No. B, 788, 272 (1934).

Another portion of the amino ketone was obtained from the filtrate in the usual way. The amino ketone hydrochloride was separated from small amounts of high-melting, very insoluble, crystalline by-products by crystallization from alcohol. The ether–benzene solution of the indifferent by-products was evaporated and the residue sublimed in a high vacuum at 90–100°, whereby half of it remained as a tar in the distilling flask. The distillate was separated by crystallization from alcohol. The molecular compounds (m. p. 119 and 107°, respectively) are less soluble than the corresponding phenanthrols. In order to avoid distillation, the residue was repeatedly crystallized from alcohol and ligroin in another experiment; the results were essentially the same. The total yield of crystalline reaction products was about 50%.

Amino Alcohols.—The amino ketone hydrochlorides of the 3,4-series could be hydrogenated in methyl alcoholic solution with a platinum oxide catalyst to the corresponding amino alcohols without any complication. The success of the hydrogenation of the amino ketone hydrochlorides of the 1,2-series with platinum oxide depends apparently upon uncontrollable factors. In some cases the calculated amount of hydrogen was absorbed, and the amino alcohols could be isolated in a pure state; in other cases considerably more hydrogen, up to two moles, was absorbed and the amino alcohol hydrochlorides could be separated from the reaction mixture only in small amounts. However, satisfactory results were obtained consistently by hydrogenating the free amino ketones in methanol solution.

Summary

The synthesis of a series of amino alcohols derived from tetrahydrophenanthrene is described. This new type of amino alcohol is characterized by having the alcoholic hydroxyl and the nitrogen directly attached to the phenanthrene nucleus.

The synthesis is effected by exchanging the bromine atoms in 1-keto-2-bromo-1,2,3,4-tetrahydrophenanthrene and in 3-bromo-4-keto-1,2,3,-4-tetrahydrophenanthrene with the dimethylamino, diethylamino, piperidino and tetrahydroisoquinolino group, and reducing the resulting amino ketones catalytically to the corresponding amino alcohols.

The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. II. The Hydrocarbon Synthesis[1]

BY LOUIS F. FIESER AND EMANUEL B. HERSHBERG

The most prominent synthetical routes to members of the phenanthrene series were developed in order to provide methods of identifying degradation products of certain opium alkaloids, resin acids and natural products containing the aetiocholane ring system. The Pschorr synthesis,[2] the phenanthrene syntheses of Bardhan and Sengupta[3] and of Bogert,[4] which employ a common intermediate, and the method of cyclizing suitable arylbutyric acids, which has received particular elaboration in the hands of R. D. Haworth,[5] have been employed further by Cook, in the course of his important work on the cancer problem for the preparation of polynuclear hydrocarbons containing the phenanthrene nucleus.[6] The interest in synthetic compounds of possible sex hormone activity has provided a further impetus for the exploitation of the known methods and for the development of new avenues of approach.

The diene reaction of Diels and Alder has until very recently[6a] found little application to the problem.

Although hydrophenanthrene derivatives would be expected to result from the addition of dienes to β-naphthoquinones, a successful reaction of this type has been reported only in the case of one alkylated quinone,[7] and the reaction is not such as to lend itself to general application. A difficulty in the case of the ortho quinones is that they are perhaps too reactive, and too prone to enter into complicating side reactions. 3,4-Dihydronaphthalene-1,2-dicarboxylic acid anhydride (I), which is but one example of a class of compounds readily available by the Bougault synthesis,[8] is far more stable than the quinones, and, being a cyclic derivative of maleic anhydride, is of a type theoretically amenable to condensation with di-

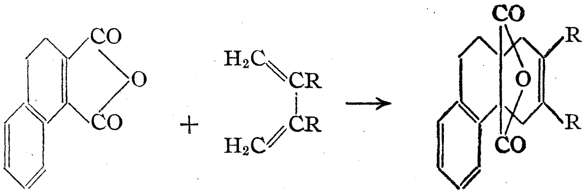
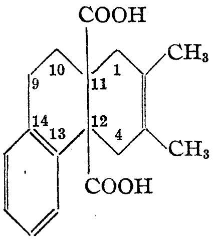
enes. It has been found that such condensations proceed in a highly satisfactory manner. The addition is rather slow, even with a large excess of diene and at a temperature of 100°, but the reaction proceeds smoothly to give in excellent yield nicely crystalline addition products of the type II.



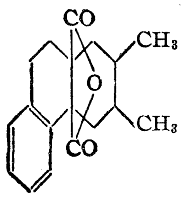
I II

The adducts from I with butadiene and 2,3-dimethylbutadiene have been prepared, together with the 2,3-dimethylbutadiene adducts from the anhydrides of 3,4-dihydrophenanthrene-1,2-dicarboxylic acid[8] and 1,2-dihydrophenanthrene-3,4-dicarboxylic acid.[8] The reaction appears to be one of quite general application.

Thus far we have studied most extensively the hydrophenanthrene derivative obtained from I with 2,3-dimethylbutadiene (II, R = CH_3), and the corresponding acid, 2,3-dimethyl-1,4,9,10,-11,12-hexahydrophenanthrene-11,12-dicarboxylic acid (III).



III



IV

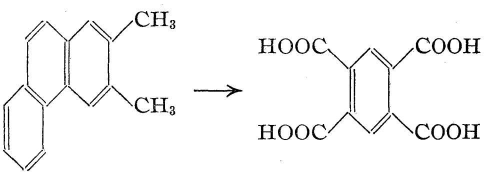
The di-potassium salt of the acid (III) is obtained by warming the anhydride with 6 *N* potassium hydroxide, the anhydride ring being rather resistant to hydrolysis. When the anhydride is heated with methyl alcoholic potassium hydroxide it is converted into a monomethyl ester of the acid III. The dimethyl ester, prepared with the use of diazomethane, is highly resistant to hydrolysis, as would be expected from the tertiary character of both ester groups. Attempts to differentiate between the two groups by partial hydrolysis have not yet been successful. The only method found suitable for effecting a hydrolysis is to fuse the ester with potassium hydroxide, and under these conditions both ester groups are hydrolyzed.

The double bond of the anhydride (II) is easily saturated by catalytic hydrogenation, giving IV. The properties of this substance and of the corresponding acid are similar to those of the unsaturated compounds.

The first attempts to eliminate the anhydride grouping of the adduct and to obtain an aromatic hydrocarbon met with little success. At the high temperature required for dehydrogenation with selenium a reversal of the Diels–Alder reaction apparently occurred, giving the original components or their products of dehydrogenation. The saturation of the double bond did not prevent this reversal, for similar results were obtained with the dihydro compound IV. The two additional hydrogen atoms may in this case be the first eliminated in the selenium treatment. Sulfur apparently is too active a reagent, for both the adduct (II) and its dihydro derivative were converted into a sulfur-containing compound of m. p. 73–74°. The dibasic acids could not be decarboxylated in quinoline solution with copper, for they lost water under these conditions and reverted to the anhydrides. The monomethyl ester of the adduct likewise lost methyl alcohol and suffered cyclization. It seemed necessary to conduct the decarboxylation in a strongly alkaline medium, and the desired result was achieved by fusing the adduct (II) with potassium hydroxide at 320–400° and distilling the product. Hydrocarbon fractions were obtained in this manner in good yield, but the reaction apparently does not follow a single course. Simple decarboxylation of the dipotassium salt would give a hexahydrophenanthrene derivative, but the preparations obtained boiled over a 9° range and the composition corresponded most closely to that of a mixture of the hexahydro and tetrahydro compounds. The material is resistant to hydrogenation in the presence of platinum, and there is but little absorption of hydrogen using palladium. We at first[1] took this as an indication that the principal hydrocarbon present is the 1,2,3,4-tetrahydro derivative, but although such a substance may indeed be present, we were unable to isolate a picrate and we are inclined now to regard the material as a mixture of tetra- and hexa-hydro compounds.

The nature of the gases evolved further points to the occurrence of reactions other than simple decarboxylation. When the dipotassium salt was fused with excess alkali a considerable amount of hydrogen was liberated; when the pure salt was subjected to dry distillation the formation of a large volume of carbon monoxide was noted. In the presence of an excess of potassium hydroxide at the high reaction temperature the cleavage of carbon monoxide, potassium formate or potassium oxalate from the molecule would be obscured by secondary changes, and the course of the reactions is still uncertain. The dihydro compound IV reacted with potassium hydroxide only at a considerably higher temperature, but it gave in good yield a mixture of tetra- and hexa-hydrophenanthrenes. The adduct from I and butadiene (II, R = H) gave a hydrocarbon boiling over a narrow range and having the composition of a hexahydrophenanthrene.

Although the method of fusion with alkali follows a complicated course and gives mixtures of hydrocarbons of varying degree of saturation, these mixtures are entirely suitable for the preparation of the completely aromatic hydrocarbons. The different fractions are dehydrogenated smoothly by selenium, giving pure phenanthrene derivatives in good yield. Phenanthrene itself was prepared by the present synthesis, and in the dimethyl series we obtained a hydrocarbon to which the structure of 2,3-dimethylphenanthrene (V) can be assigned on the basis of the oxidation of the substance to pyromellitic acid (VI).



V VI

Dr. R. D. Haworth has kindly compared our hydrocarbon with the material synthesized by Haworth, Mavin and Sheldrick,[9] and he reports that after further purification of the original sample the melting point is the same as for our material and that there is no depression on admixture.

Further studies of the diene addition products and further applications of the new phenanthrene synthesis are in progress.

Experimental Part[10]

1. The Diels–Alder Reaction

2,3 - Dimethyl - 1,4,9,10,11,12 - hexahydrophenanthrene-11,12-dicarboxylic Acid Anhydride.—For the condensation of 3,4-dihydronaphthalene-1,2-dicarboxylic acid anhydride with 2,3-dimethylbutadiene, 30 g. of the anhydride was heated in a sealed tube with 20–25 g. of the freshly distilled diene in a steam bomb at 100° for twenty to twenty-five hours. The anhydride soon went into solution and after the first five to ten hours it no longer crystallized on cooling the tube. At the end of the reaction the contents of the tube were taken up in ether, treated with Norite and the residue left on distillation of the solvent was distilled, b. p. 175–185° at 1 mm. The colorless oil obtained slowly crystallized, giving a solid, m. p. 92–94°; yield, 94–97%. Recrystallization from benzene–ligroin gave diamond-shaped prisms of the adduct, m. p. 95–96°. The anhydride is very readily soluble in benzene or ether and readily soluble in alcohol or ligroin.

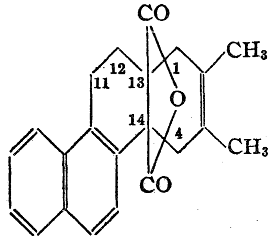
Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.45. Found: C, 76.56; H, 6.44.

The first experiment, identical with the above but carried out some months earlier, gave a product melting at 75–76°. The sample had been ground for analysis, and when it was reëxamined, subsequent to the later experiments, the melting point was found to have risen to 95–96°.

1, 4, 9, 10, 11, 12 - Hexahydrophenanthrene - 11, 12 - dicarboxylic Acid Anhydride.—The addition of butadiene was definitely slower and it was found advisable to use 5–6 molecular equivalents of the diene and to continue the heating for eighty-five hours. The anhydride distilled at 160–170° at 1 mm.; yield, 63%; colorless prisms, m. p. 83.5–84°, from benzene–ligroin.

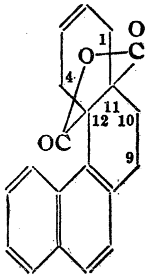
Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.56; H, 5.55. Found: C, 75.61; H, 5.97.

2,3 - Dimethyl - 1,4,11,12, 13,14 - hexahydrochrysene-13,14-dicarboxylic Acid Anhydride.—Because of the sparing solubility of the starting material the addition of 2,3-dimethylbutadiene was carried out in dioxane solution (45 hours). The yield in one small scale experiment was good; colorless prisms from cyclohexane, m. p. 196–196.5°. It is only slightly less soluble than the anhydrides described above.



Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.47; H, 6.07. Found: C, 79.51; H, 6.21.

5,6 - Benz - 1,4,9,10,11,12 - hexahydrophenanthrene - 11,12 - dicarboxylic Acid Anhydride.—A mixture of 10 g. of 1,2-dihydrophenanthrene - 3,4 - dicarboxylic acid anhydride, 15 cc. of dioxane and 14 g. of butadiene (added in portions on successive days) was heated in a sealed tube at 100° for 160 hours. The bright yellow color of the starting material faded during this time, but the solution retained a dull yellow color due to a by-product. A part of the adduct crystallized on cooling the tube and more was obtained by concentrating the mother liquor and adding petroleum ether; yield, 76%. The anhydride is readily soluble in benzene and crystallizes well from benzene–



---

[9] Haworth, Mavin and Sheldrick, *J. Chem. Soc.*, 454 (1934).

[10] See Note 4 of the first paper (Ref. 8).

ligroin, forming large, colorless prisms, m. p. 161.5–162°. On attempted distillation at the pressure of the oil pump the material became highly yellow-colored as the result of the partial reversal of the diene addition.

Anal. Calcd. for $C_{20}H_{16}O_3$: C, 78.92; H, 5.30. Found: C, 78.82; H, 5.39.

The 2,3-dimethyl derivative of the above compound was obtained in a similar manner in dioxane solution; yield, 68%, colorless prisms, m. p. 128–128.5°.

Anal. Calcd. for $C_{22}H_{20}O_3$: C, 79.49; H, 6.07. Found: C, 79.38; H, 6.40.

2. Characterization of the Anhydrides

2,3 - Dimethyl - 1,4,9,10,11,12 - hexahydrophenanthrene-11,12-dicarboxylic Acid (III).—A mixture of 2 g. of the anhydride and 15 cc. of 6 *N* potassium hydroxide was heated at the boiling point until the solid had dissolved (ten minutes), stronger alkali was added and the dipotassium salt was allowed to crystallize. On acidifying a solution of the salt in cold water the acid was precipitated. The acid is very readily soluble in alcohol and crystallizes only slowly on diluting the solution with water; it is very sparingly soluble in benzene. To obtain a pure sample the acid was dissolved in a small quantity of acetone and the solvent was largely displaced by adding successive portions of benzene and evaporating the solution. The acid then crystallized slowly as colorless microcrystals melting sharply at 176–177° with loss of water.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.95; H, 6.73. Found: C, 71.97; H, 6.81.

Monomethyl Ester.—The anhydride was recovered unchanged after being refluxed with methyl alcohol for four hours. To prepare the ester a solution of 3 g. of the anhydride in 150 cc. of methyl alcohol containing 1 equivalent of potassium hydroxide was refluxed for twelve hours. The solution was diluted with water and neutralized, the product separating as an oil which slowly solidified. Recrystallization from benzene–ligroin gave 2 g. of colorless prisms, m. p. 157–159° with loss of alcohol and formation of the anhydride.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.57; H, 7.07. Found: C, 72.52; H, 7.15.

Dimethyl Ester.—This was prepared by the action of diazomethane on either the acid or the monomethyl ester. Crystallized from methyl alcohol, in which it is moderately soluble, the ester formed prisms, m. p. 93.5–94°.

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.13; H, 7.37. Found: C, 73.20; H, 7.53.

The ester was not appreciably hydrolyzed by boiling a mixture of the material (0.2 g.) with 10 cc. of 6 *N* potassium hydroxide and 2 cc. of alcohol for four hours. A paste of the ester with 50% potassium hydroxide was heated carefully until the material was partially converted into a hard potassium salt. This was extracted with water from the unchanged ester, and the acid obtained on acidification was identified as the original dibasic acid in a very pure form.

2,3 - Dimethyl - 1,2,3,4,9,10,11,12 - octahydrophenanthrene-11,12-dicarboxylic Acid Anhydride (IV).—The hydrogenation of the addition product II proceeded smoothly in glacial acetic acid solution with Adams catalyst, the dihydro compound forming transparent octahedra from ligroin, m. p. 117–118°.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.00; H, 7.11. Found: C, 76.24; H, 7.17.

The **acid**, prepared and purified as above, crystallized with one-half molecule of benzene which was retained on drying the sample at room temperature. The substance melted at 183–184°; loss in weight on melting, 18.3% (calcd., 16.7%).

Anal. Calcd. for $C_{18}H_{22}O_4 \cdot (C_6H_6)^1/_2$: C, 73.81; H, 7.44. Found: C, 74.05, 74.06; H, 7.53, 7.70.

3. Decarboxylation

In a typical experiment a mixture of 5.7 g. of the (dimethyl) adduct II, 11 g. of potassium hydroxide, and 10 cc. of water in a Pyrex distilling flask with a sealed-on receiver was warmed until the at first molten anhydride had been converted into the solid potassium salt. The mixture was then heated in a nitrate bath to about 200° to distil off the bulk of the water and the temperature was raised to 325–350°, collecting the oily distillate and some water in the receiver. After bringing the bath to a temperature of 400–420° to complete the distillation, the product was dried in ether and fractionated. The total yield of colorless hydrocarbon suitable for dehydrogenation and boiling over a range of about 9° was 70–85% of the theoretical amount; middle fraction, b. p. 201–204° at 24 mm. The composition of the product was between that of the tetrahydro and hexahydro derivatives as shown in the following analyses of typical preparations.

Anal. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63; for $C_{16}H_{20}$: C, 90.50; H, 9.50. Found: preparation (a), C, 91.25, 91.31; H, 8.99, 9.12; (b) C, 90.86; H, 9.11.

No absorption of hydrogen by the hydrocarbon mixture was noted in alcoholic solution using Adams catalyst. With palladinized calcium carbonate the amount of hydrogen absorbed corresponded to approximately half that calculated for the presence of one reactive double bond, as in a pure hexahydro compound. The tetrahydro derivatives, if present, appear to resist hydrogenation.

The pyrolysis of the dry di-potassium salt (CO evolved) gave a yellow hydrocarbon fraction, b. p. 213–218° at 24 mm., in 64% yield.

When the dimethyloctahydrophenanthrene dicarboxylic acid anhydride (IV) was submitted to a similar fusion with excess alkali, the decomposition occurred only at a higher temperature (about 395°), and the reaction was conducted at a bath temperature of 400–420°. The hydrocarbon fraction, b. p. 200–210° at 24 mm., was obtained in 80% yield. The composition was about the same as above, indicating a mixture. (Found: C, 91.04, 91.02; H, 9.10, 9.24.)

The unmethylated adduct from butadiene (II, R = H) on fusion with alkali as above gave after redistillation a colorless liquid, b. p. 179–180° at 23 mm., in 55% yield. This apparently homogeneous **hexahydrophenanthrene** formed no picrate.

Anal. Calcd. for $C_{14}H_{16}$: C, 91.26; H, 8.74. Found: C, 91.23; H, 8.93.

On dehydrogenation of this material with selenium, there was obtained in 86% yield a hydrocarbon, m. p. 96.5–97.5°, identical with **phenanthrene** from coal tar.

4. Dehydrogenation

2,3-Dimethylphenanthrene.—Various hydrocarbon mixtures obtained as described above were submitted to dehydrogenation with entirely similar results. After heating 2.1 g. of a mixture of the tetra- and hexahydrides with 3 g. of selenium, added in portions, at 310° for twenty hours, the melt solidified completely on cooling. After extracting and distilling the product, one crystallization from methyl alcohol gave 1.6 g. (78%) of plates, m. p. 77–78°. On recrystallization from alcohol or petroleum ether the hydrocarbon formed fluorescent plates, m. p. 78–78.5°.

Anal. Calcd. for $C_{16}H_{14}$: C, 93.16; H, 6.85. Found: C, 92.86; H, 7.08.

The **picrate** formed light yellow needles from alcohol, m. p. 146–147°. The **quinone** crystallized from glacial acetic acid as glistening orange plates, m. p. 237.5–238.5° (**quinoxaline derivative,** m. p. 208–209°).

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.32; H, 5.13. Found: C, 81.23; H, 5.37.

In a letter to one of us Dr. R. D. Haworth states that the original specimen of 2,3-dimethylphenanthrene picrate prepared by his method[9] melts, after two recrystallizations from alcohol, at 144–145°; the regenerated hydrocarbon melts at 79–80°, and the styphnate (Found: C, 58.47; H, 3.95) melts at 137–148° (the m. p. given as 165–167° by a typographical error should have been 145–147°). Dr. Haworth compared his hydrocarbon, picrate, quinone and quinoxaline derivative with ours and observed no depressions; the constants are all in close agreement.

A mixture of 0.5 g. of 2,3-dimethylphenanthrene, 1 cc. of concentrated nitric acid, and 2 cc. of water was heated at 180–200° for twelve hours. As the reaction was not complete, an additional 1 cc. of acid was introduced and the tube was reheated. On concentrating the clear yellow solution and adding fuming nitric acid, the oxidation product was caused to separate. The crude acid was heated at 250° and the anhydride was sublimed in vacuum and crystallized from dioxane, giving prisms containing dioxane of crystallization. After drying at 150° in vacuum to remove the solvent, the substance melted at 277–279° and gave no depression when mixed with a sample of pyromellitic anhydride purified in the same way.

Summary

A new synthesis of phenanthrene has been developed which, in its simplest complete form, involves the following steps: (1) the preparation of γ-phenylbutyric ester, for example, by the condensation of benzene with succinic anhydride, followed by Clemmensen reduction and esterification; (2) condensation with oxalic ester; (3) cyclization to the anhydride of 3,4-dihydronaphthalene-1,2-dicarboxylic acid (the Bougault reaction, as applied by von Auwers and Möller); (4) the addition of butadiene (Diels–Alder reaction); (5) decarboxylation by fusion with alkali (a reaction which may yield a mixture of hydrophenanthrenes, but in which the carbon skeleton is not disturbed); (6) dehydrogenation.

The yields throughout are excellent, and pure products are obtainable at every step except (5). Some variation is possible in step (4), and the compounds required in (1) are already available in wide variety. Successful experiences with reactions (2), (3) and (4), using γ-arylbutyric esters of both the benzene and naphthalene series, indicate that the synthesis probably is capable of wide application.

The Oxidation of Carbon Monoxide Catalyzed by Nitrogen Dioxide[1]

BY R. H. CRIST AND O. C. ROEHLING

The oxidation of carbon monoxide is recognized as being of the chain type. The rate at high temperatures is explosive and exhibits the familiar pressure limits.[1] The explosive reaction as shown by Dixon, and Weston and Garner is changed by the presence of water vapor and hydrogen. A homogeneous reaction outside of the explosive region has not been measured. However, studies of a heterogeneous reaction have been made by Bodenstein and Ohlmer in a quartz vessel at 308°, the rate being proportional to the oxygen and inversely proportional to the carbon monoxide and by Langmuir, who found similar results with platinum at 700°. McKinney[2] studied the oxidation at 80° on platinum oxide. The explosive system has been shown by Semenoff and his co-workers[1] to be very sensitive to traces of nitrogen dioxide.

The present investigation is concerned with this reaction under conditions such that the rate of the oxidation in the presence of nitrogen dioxide is measurable. Preliminary experiments show[3]

---

that the rate increases very rapidly with the nitrogen dioxide pressure and after passing a maximum decreases rapidly. Hydrogen and water were also found to increase the rate.

Experimental Methods

Preparation of Gases.—The nitrogen dioxide was prepared from lead nitrate, pumped free from other oxides of nitrogen, redistilled, and stored as the solid by means of solid carbon dioxide. It was passed over phosphorus pentoxide before using.

The carbon monoxide was made by adding formic acid to concentrated sulfuric acid. The gas was passed through a solution of potassium hydroxide to remove carbon dioxide and dried by sulfuric acid and phosphorus pentoxide. When used it was passed through a liquid air trap.

Oxygen was taken from a commercial tank. The hydrogen was removed by passing it over hot copper oqide and then drying with magnesium perchlorate. The reaction was very sensitive to small traces of hydrogen so that the removal procedure had to be followed carefully.

Hydrogen was taken from a commercial cylinder and was dried before using.

Procedure.—The investigation was carried out at 527° in a Pyrex vessel of 260-cc. capacity. The vessel was put into the well of a sulfur boiler. The boiling point of the sulfur was controlled by maintaining a constant pressure of nitrogen over the sulfur vapor by means of a barostat arrangement.[4] The barostat consisted of a gas reservoir containing a heating element controlled by contact points on a manometer. The temperature variation on the boiler wall was less than 0.3°. The actual value of the temperature was read from a millivoltmeter giving a temperature accuracy of $\pm 2.5°$.

The measurement of the pressure of nitrogen dioxide was made by a Pirani type gage.[5] The filament consisted of a thin-walled U-shaped Pyrex capillary filled with mercury[6] with a total length of 20 cm. and a resistance of 31.2 ohms. The gage was calibrated against a McLeod gage using carbon dioxide. The pressure of a sample of nitrogen dioxide in contact with the solid at $-63.5°$ (melting chloroform) was read from the calibrated Pirani gage as 0.450 mm. while the value from the "International Critical Tables" is 0.467 mm. The error is thus 3.7%. The precision of measurement as determined from the instrument set-up was $10 \rightarrow 2.5\%$ for the pressure limits of $0.061 \rightarrow 1.53$ mm.

The nitrogen dioxide was measured in an auxiliary system and frozen into a capillary U-tube next to the reaction vessel and it was then carried into the reaction vessel by the carbon monoxide or oxygen.

The filling of the reaction vessel was first tried in the ordinary manner but certain mixtures were found to react so rapidly that it became difficult to determine the initial pressures. It was necessary, therefore, to use a special filling method for the last gas, usually the carbon monoxide. A vessel was filled to the required pressure and the gas was then forced into the reaction vessel by mercury through capillary connecting tubes. The known ratios of the volumes involved then enabled a satisfactory calculation of the initial pressures in the reaction vessel.

Experience showed that consistent results could be obtained only if a definite procedure for introducing the gases was carefully followed. The experiments with hydrogen in the reacting mixture were the most troublesome. The best results were obtained when the vessel was twice filled with hydrogen-free oxygen and evacuated. It was also found necessary to fill the system with dry oxygen before such operations as regreasing of stopcocks, for if filled with air several runs were required before consistent results could be obtained.

Results

Oxidation of Carbon Monoxide Catalyzed by Nitrogen Dioxide.—This study consisted in determining the rates of the reaction with different concentrations of nitrogen dioxide, the partial pressures of carbon monoxide and oxygen being kept approximately constant at 500 and 250 mm., respectively. The temperature was 527°. The highest pressure of nitrogen dioxide was 4.85 mm., this giving a rate that was as fast as could be measured reliably. The results are given in Table I and Figs. 1 and 2.

mm. shows that this should provide a satisfactory measure of the rate. Curve B of Fig. 2, where the conditions were the same as for Fig. 1, shows the very striking effect of nitrogen dioxide in the acceleration and the equally effective inhibition by the catalyst. This is similar to the catalysis by nitrogen dioxide of the hydrogen oxidation as found by Norrish.[7] In the case of carbon monoxide, however, an increasing rate is again observed with still higher concentrations of the catalyst.

The dependence of the reaction on the other components of the system was found by maintaining a constant pressure of nitrogen dioxide and varying in turn the carbon monoxide and oxygen. From these data and also from some additional runs, the effect of total pressure was obtained. The results are given in Tables II, III and IV, and in Fig. 3. The rate was estimated as before, no marked change in rate being observed in the course of the reaction during the five to thirty-five minute interval. In all cases the temperature was 527° and the pressure of nitrogen dioxide was constant at 0.585 mm.

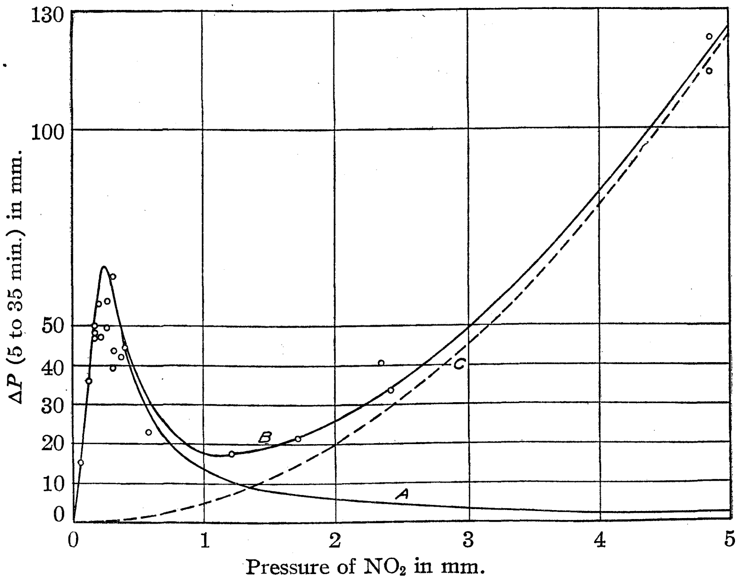

Fig. 2.—The rate of the oxidation of carbon monoxide as a function of the pressure of nitrogen dioxide; Curve B is the sum of A and C. A represents a chain process and C the trimolecular oxidation of nitric oxide.

---

[7] Norrish and Griffiths, *Proc. Roy. Soc.* (London), **A139**, 147 (1933).

The Effect of Hydrogen and Water on the Catalyzed Oxidation of Carbon Monoxide.—It was found difficult to obtain a consistent set of data in this study. Some of the uncertainties may have been due to the time factors involved in introducing the gases. It was not possible to mix the gases prior to their introduction into the flask, because of the danger of explosion for which the apparatus was not designed. However, by a rigorous adherence to the definite procedure outlined in the first part it was possible to obtain fairly satisfactory data. The mixtures with more than 0.53 mm. of hydrogen had reacted completely by the time the gases were introduced, as was shown by the carbon dioxide obtained. In some cases, however, the initial rate was measurable but within a minute the manometer would drop suddenly and the reaction would be complete as evidenced by the total pressure change and by the yield of carbon dioxide. The pressures of water vapor were obtained by passing the carbon monoxide over ice at the required temperature. The results are shown in Figs. 4, 5 and 6. The carbon monoxide and oxygen pressures were approximately 500 and 250 mm. for all but Fig. 5, where the pressures were 270 and 230 mm., respectively. Figure 4 shows the relative effects of water vapor and hydrogen.

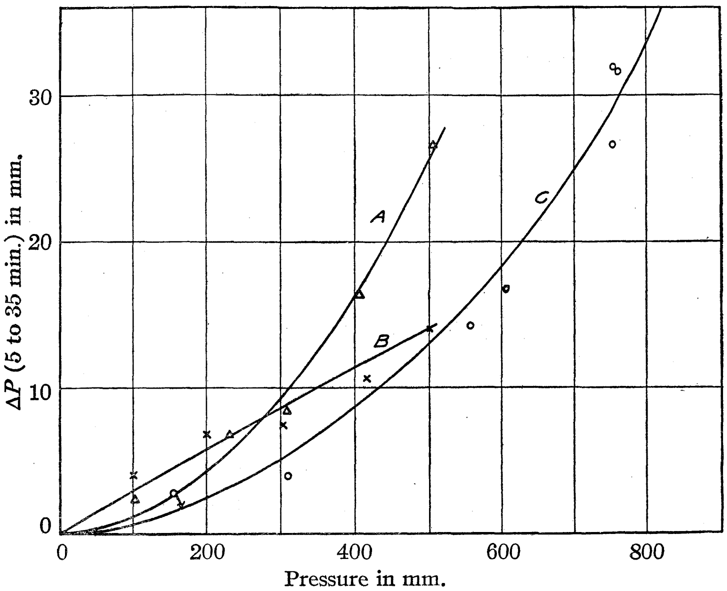

Fig. 3.—Curves A and B show the effect of carbon monoxide and oxygen, respectively. Curve C shows the rate as a function of the total pressure of carbon monoxide and oxygen. It is a composite of A and B. The pressure of nitrogen dioxide was 0.585 mm.

Discussion of Results

The Catalysis by Nitrogen Dioxide.—The character of the curve, Fig. 2 for the effect of nitrogen dioxide suggests that it is a composite of two separate processes. A formal mathematical analysis on any other basis is difficult. If the analogous nitrogen dioxide catalyzed hydrogen oxidation[7] is considered one process would be that represented by Curve A in Fig. 2, which is expressed by the equation

$$y = ax/(b - cx + x^2)$$

where x is the nitrogen dioxide pressure and y the rate. The other process is the remainder of the experimental curve and is shown as Curve C. This has the form, $y = k_3x^2$, where k_3 has the value of 5.0.

The nature of the second process can be understood by an examination of Experiment 21, Table I, where the pressure of nitrogen dioxide was 4.85 mm. The rate of this reaction was sufficiently rapid so that the course of the reaction was followed conveniently to three-fourths completion. This rate was found to be first order with respect to the oxygen. The constants given in Table V are calculated for the equation

$$k_2 = \frac{2.3}{t} \log \frac{(O_2)t_0}{(O_2)t}$$

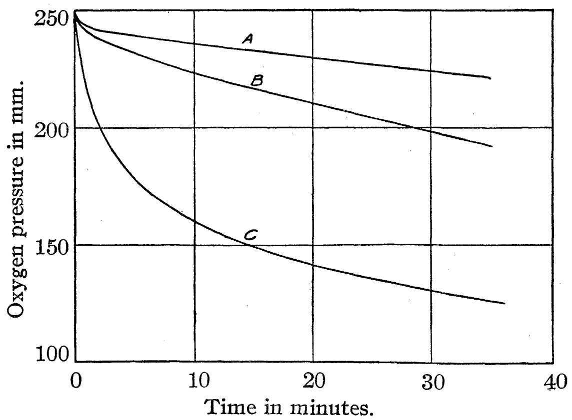

Fig. 4.—Individual runs to show the relative effect of water and hydrogen on the rate: A, no hydrogen or water; B, 0.100 mm. H_2O; C, 0.100 mm. H_2; pressure of nitrogen dioxide, 1.22 mm.; temperature, 527°.

The value for p_{O_2} at $t = 0$ was obtained from the plot of log p_{O_2} against time and is given in parentheses.

Table V

Rate of Reaction for $-d(O_2)/dt = k_2(O_2)$

t, min.	p_{O_2}	k_2
0	(248.3)	...
1	244.8	0.0143
2	237.0	.0234
5	217.0	.0269
10	186.6	.0285
15	161.2	.0288
18	147.6	.0289
22	132.2	.0286
35	93.8	.0278
40	82.8	.0274
45	73.8	.0270
53	61.2	.0264
63	51.2	.0251

Let it be assumed that the nitrogen dioxide is removed rapidly by the reaction

$$NO_2 + CO \longrightarrow CO_2 + NO$$

which is followed by

$$2NO + O_2 \longrightarrow 2NO_2$$

Then, if the second reaction determines the rate, the observed velocity would be

$$-d(O_2)/dt = k_1\,(NO)^2(O_2) \qquad (1)$$

Since the concentration of nitric oxide is kept constant by the first of the above reactions, the rate is then

$$-d(O_2)/dt = k_2\,(O_2) \qquad (2)$$

where $k_2 = k_1\,(NO)^2$. This is confirmed by the data of Table V. If the nitric oxide pressure (or nitrogen dioxide pressure) is varied and the oxygen pressure is kept constant, the rate is given by

$$-d(O_2)/dt = k_3(NO_2)^2$$

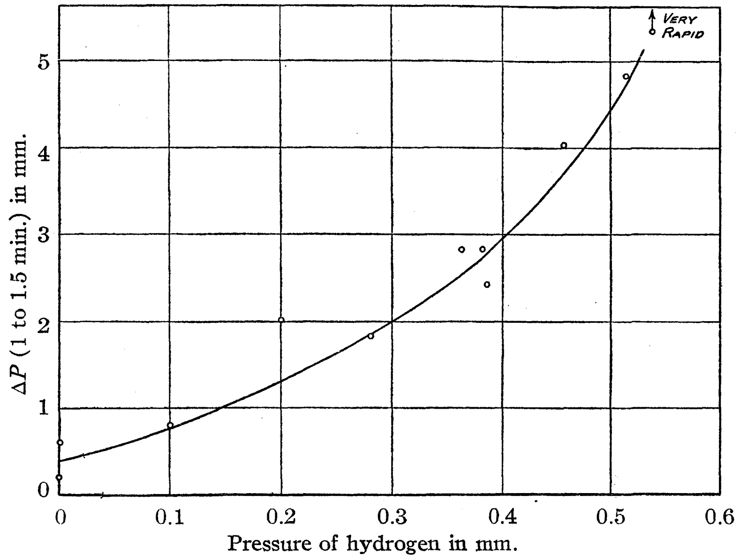

Fig. 5.—The effect of hydrogen: pressure of nitrogen dioxide, 1.22 mm.; temperature, 490°.

These are the conditions under which the data represented by Curve B of Fig. 2 were obtained and Curve C represents the equation, Rate = $5.0[NO_2]^2$.

The average value for k_2 from Table V is 0.0272 min.$^{-1}$ = 4.53×10^{-4} sec.$^{-1}$. By equations (1) and (2)

$$k_2 = k_1(NO)^2 \text{ or } k_1 = k_2/(NO)^2$$

Using (NO) = 4.85 mm. = 9.72×10^{-8} mole cc.$^{-1}$, $k_1 = 4.79 \times 10^{10}$ cc.^{2} mole^{-2} sec.$^{-1}$. A comparison of this value with previous experimental data on the oxidation of nitric oxide cannot be made since the highest temperature used for the direct measurement of the rate was 390°. From liquid air temperatures to this temperature the rate decreases about 16 fold, and present theories concerning the rate of this reaction[8] predict an increasing rate with temperature at high temperatures. For the temperature used in this investigation a rate of $1.3 \longrightarrow 9.8 \times 10^9$ cc.^{2} mole^{-2} sec.$^{-1}$ is predicted.[9] The experimental result put forward here is in line with this prediction.

It was found in this investigation that light of 3650 Å. in the first predissociation region of nitrogen dioxide had no effect on the rate. This result is rather surprising since Norrish[7] noticed a great increase in the rate of the oxidation of hydrogen catalyzed by nitrogen dioxide upon irradiation with such light. However, this negative result is in accord with the assumption that the nitrogen dioxide is removed rapidly by the carbon monoxide.

The next part of the discussion is concerned with Curve A of Fig. 2. The empirical equation for Curve A is

$$R = \frac{9.46\,(NO_2)}{0.0625 - 0.354\,(NO_2) + (NO_2)^2}$$

This equation can be derived on a formal chain theory. Thus, if (S) represents the number of chains in operation, then on the usual assumption of the steady state[10]

$$d(S)/dt = k_1(NO_2) + k_2(NO_2)(S) - k_3(S) - k_4(NO_2)^2(S) = 0$$

---

[8] Kassel, "Kinetics of Homogeneous Gas Reactions," Chemical Catalog Co., New York City, 1932, p. 168; Gershinowitz and Eyring, This Journal, 57, 985 (1935).

[9] Private communication from Dr. Gershinowitz.

[10] Nitrogen dioxide is used here to conform with the empirical equation. In the interpretation of this equation to follow we have used equations involving nitric oxide. We may assume that the nitric oxide concentration is proportional to the nitrogen dioxide concentration so that the equation here would be altered by the necessary proportionality factors.

From the equation we get $(S) = k_1(\mathrm{NO_2})/[k_3 - k_2(\mathrm{NO_2}) + k_4(\mathrm{NO_2})^2]$. If the rate is proportional to the number of chains (S), we have the equation of the rate as given above.

It is difficult to find an acceptable mechanism for this development. There is not sufficient information at hand to determine the nature of the initial process. The absence of a photochemical effect, which was explained previously, eliminates that as a clue to the initial step. In the case of the hydrogen–oxygen reaction catalyzed by nitrogen dioxide, the results obtained by Norrish were similar to those obtained here, showing the same kind of maximum. Also the rates were greatly enhanced by light of 3650 Å. From the known primary process on the absorption of light of wave length λ = 3650 Å. by nitrogen dioxide, namely

$$\mathrm{NO_2} + h\nu \longrightarrow \mathrm{NO} + \mathrm{O}$$

Norrish proposed a chain mechanism involving atomic oxygen in order to account for the kinetics of the light reaction. He suggested that since the thermal reaction is similar to the photo-reaction, the oxygen atoms for the thermal reaction could be provided by such reactions as

$$\mathrm{NO_2} \longrightarrow \mathrm{NO} + \mathrm{O} - 72.6\ \text{kcal.}$$
$$\mathrm{NO} + \mathrm{O_2} \longrightarrow \mathrm{NO_2} + \mathrm{O} - 44.4\ \text{kcal.}$$

With these considerations in mind the following mechanism can be suggested for the oxidation of carbon monoxide.

$$\mathrm{O} + \mathrm{O_2} \longrightarrow \mathrm{O_3} \qquad (1)$$
$$\mathrm{O_3} + \mathrm{CO} \longrightarrow \mathrm{CO_2'} + \mathrm{O_2'} \qquad (2)$$
$$\mathrm{O'} + \mathrm{CO} \longrightarrow \mathrm{CO_2} + \mathrm{O} \qquad (3)$$
$$\mathrm{NO} + \mathrm{O_2'} \longrightarrow \mathrm{NO_2} + \mathrm{O} \qquad (4)$$
$$\mathrm{NO} + \mathrm{NO} + \mathrm{O} \longrightarrow \mathrm{NO_2} + \mathrm{NO} \qquad (5)$$

The oxygen atoms could be supplied originally by nitrogen dioxide as above. Reactions (4) and (5) are set up in order to yield the equation for the Curve A of Fig. 2. Reaction (4) would require a very unusual stability to collision of the excited oxygen molecules with other molecules than the nitric oxide. Also, it would seem that any third body would serve as well as nitric oxide in (5). With regard to reactions (1) and (2), the recent work of Jackson[11] must be considered. He found that the illumination of oxygen–carbon monoxide mixtures with light of wave length λ = 1700 Å., which is capable of dissociating the oxygen molecules into atoms, produced ozone and little or no carbon dioxide at room temperature. At 500° only carbon dioxide was formed. The author does not discuss the mechanism of this formation of carbon dioxide, *i. e.*, whether it occurs directly with oxygen atoms or through the intermediate formation of ozone. The important facts of his paper in the present connection are: (1) his observation that the rate is independent of the total pressure, the ratio of the gases remaining constant; and, (2) the rate decreases if the carbon monoxide is increased, the total pressure remaining constant.

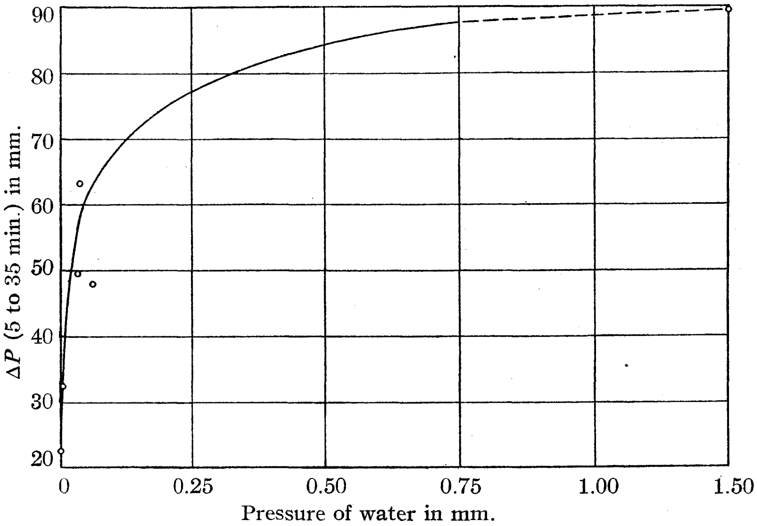

Fig. 6.—The effect of water: pressure of nitrogen dioxide, 0.585 mm.; temperature, 527°.

The study given in Tables II, III, IV and Fig. 3 shows the effect on the rate of the ratio of the gases and of the total pressure with constant pressure of nitrogen dioxide of 0.585 mm. The rate is directly proportional to the first power of the oxygen pressure and to the square of the carbon monoxide pressure, as is shown by Curves B and A of Fig. 3. Curve A is represented by the equation

$$R = 1.03 \times 10^{-4}(\mathrm{CO})^2$$

The effect of carbon monoxide is rather unusual, as all previous work has involved the first and negative powers of the carbon monoxide pressure. Curve C, which gives the effect of changing the total pressure with the ratio constant at 2:1, can be shown to be a composite of the separate oxygen and carbon monoxide curves.

---

(11) Jackson, THIS JOURNAL, **56**, 2631 (1934).

Some further information concerning the effect of total pressure of carbon monoxide and oxygen with the ratio constant at 2:1, can be obtained from a study of individual curves. In the case of No. 15, Table I, with nitrogen dioxide = 0.585 mm., the rate dropped to 59% when the reaction had progressed 20%, while curve C of Fig. 3 would predict a drop of 64%. This agreement is to be expected as all the data of Curve C are for conditions the same as No. 15. For No. 21, the nitrogen dioxide = 4.85 mm. and at 40% completion the rate has been reduced to 71%, while if this change in rate were due to change in carbon monoxide pressure only the prediction from Curve C would be 53%. This disagreement would be expected, if our earlier interpretation of the run is correct, namely, that the rate-determining step at these pressures of nitrogen dioxide is the trimolecular oxidation of nitric oxide. If we examine the results for a very low pressure of nitrogen dioxide as given by those runs on the rising part of Curve A, the one carried farthest (40% completion) was No. 8 and it was found to be linear throughout. This result would indicate that under these conditions the rate is independent of the total pressure of the reacting gases. The work of Jackson showed that the rate was independent of the total pressure and inversely proportional to the carbon monoxide pressure. It is found here that only at very low pressures of nitrogen dioxide is the rate independent of the total pressure and further that the rate increases with carbon monoxide pressure except for very low pressures of nitrogen dioxide, where it appears to be independent. This disagreement with the work of Jackson would indicate that an atomic chain is of some doubt though it is not definitely excluded.

The Effect of Hydrogen and Water Vapor.—The study of the effect of hydrogen on the nitrogen dioxide catalyzed oxidation of carbon monoxide is somewhat complicated by the formation of water which undoubtedly occurs during the progress of the reaction. This effect of the loss of "catalyst" has been largely eliminated in the results given in Fig. 5 by taking the rate as the pressure change from one to one and one-half minutes. The experimental points are considerably scattered and do not justify a thorough mathematical analysis, but the rate is approximately proportional to the square of the hydrogen pressure. The curve would rise much faster if tangents to zero time could be drawn. Whether the rates above 0.53 mm. of hydrogen were very rapid or explosive could not be determined.

In order to explain the effect of hydrogen, an atomic chain mechanism can be assumed. In the work of Norrish on the oxygen–hydrogen–nitrogen dioxide system, the atomic chains are assumed to be initiated by atomic oxygen. Recently Geib and Harteck[12] have shown that when hydrogen atoms are introduced into a mixture of hydrogen, oxygen and carbon monoxide, the ratio of the water to the carbon dioxide formed increases only slightly on going from room temperature to 100°. From a consideration of their results, and assuming that there is only a slight change in the ratio of water to carbon dioxide formed on further increase of temperature, the following mechanism is reasonable

$$
\begin{aligned}
O + H_2 &\longrightarrow OH + H + 0.8\text{ kcal.} && (1)\\
OH + CO &\longrightarrow CO_2 + H + 23.8\text{ kcal.} && (2)\\
H + O_2 + O_2 &\longrightarrow HO_2 + O_2 && (3)\\
H + O_2 + CO &\longrightarrow CO_2 + OH && (4)\\
HO_2 + CO &\longrightarrow CO_2 + OH && (5)\\
OH + OH &\longrightarrow H_2O + O && (6)\\
OH + H_2 &\longrightarrow H_2O + H + 31.1\text{ kcal.} && (7)
\end{aligned}
$$

(2), (6) and (7) are probably fast. (3) has a collision efficiency of about 1 and (4) has an efficiency of about 0.1 while (5) is somewhat less. In view of previous considerations, there is uncertainty about the initiation of the hydrogen chains as given in reaction (1).

The comparative effect of hydrogen and of water is given in Fig. 4; the former is seen to be very much greater. Now, if the hydrogen concentration were the most important factor in determining the rate, its complete disappearance in the formation of water would be indicated by a rate equal to that for water of the same concentration. This is indicated by the fact that the slopes of Curves B and C of Fig. 4, thirty minutes, are about the same. Final decision must be reserved until the effect of change in carbon monoxide and oxygen with water present is known. It is not possible to predict this from the earlier results, as we are now dealing with a very different mechanism. As a mechanism for the effect of water vapor, we may suggest

$$H_2O + CO \longrightarrow CO_2 + H_2$$

together with the hydrogen–oxygen–carbon monoxide mechanism previously discussed.

---

(12) Geib and Harteck, *Z. physik. Chem.*, **170A**, 1 (1934).

Summary

1. The oxidation of carbon monoxide catalyzed by nitrogen dioxide has been measured at 527°. The rate-determining reaction at low concentrations of the catalyst appears to be a chain mechanism, and at higher concentrations to be the trimolecular oxidation of nitric oxide.

2. The rate is first order with respect to oxygen at high concentrations of the catalyst and at low concentrations it is proportional to the oxygen and also to the second power of the carbon monoxide.

3. The initial rate is approximately proportional to the square of the hydrogen pressure and is infinite with the hydrogen greater than 0.53 mm.

4. The effect of water has been found.

5. The oxidation of nitric oxide at 527° has been discussed.

The Solubility of Ammonium Oxalate in Water

BY ARTHUR E. HILL AND EDGAR F. DISTLER[1]

The figures on the solubility of ammonium oxalate in water as given in "International Critical Tables,"[2] cover the range from 0 to 50°; they are based upon a small number of individual determinations[3] and lead to a curve with an estimated variation of ±3%. The present investigation was undertaken to extend the temperature range and to improve the probable accuracy.

For the experimental work, analyzed ammonium oxalate was recrystallized, giving a product which agreed upon analysis with the formula for the monohydrate. Samples were enclosed with water in glass-stoppered Pyrex vessels and rotated in thermostats; equilibrium was reached in a few hours with good stirring. The 0° temperature was obtained in an ice-bath, temperatures up to 45° in a water-filled thermostat, and higher temperatures in a glycerol-filled thermostat; the temperature variation was not greater than ±0.05° at the lower temperatures, about ±0.1° at 60 and 75° and about ±0.2° at 87 and 100°; the thermometer was compared with a standard and corrected for emergent stem. Samples for analysis were withdrawn through cotton and paper filters into pipets at the lower temperatures, and aspirated through heated tubes at the higher temperatures; the oxalate was determined by titration with 0.1 *N* potassium permanganate solution, using the method of McBride;[4] the permanganate was standardized with a sample of sodium oxalate from the Bureau of Standards.

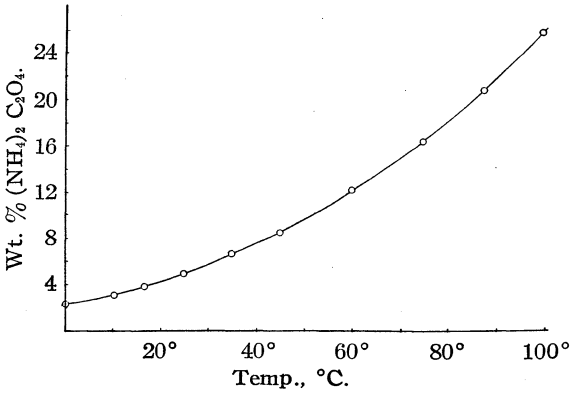

Fig. 1.

The results are shown in Fig. 1 and Table I. The curve shows no break to indicate the existence

of any solid phase other than the monohydrate; cooling curves also gave no indication of a change of phase down to the eutectic temperature, −0.75°.

By the method of least squares, the parabolic curve for the solubility was calculated with the following constants: wt. per cent. solubility = $2.314 + 0.06272t + 0.001714t^2$. The solubilities at round temperatures calculated by this equation are given in Table II. When compared with the figures of Table I, the solubilities calculated from the equation show an average deviation of ±0.073% with respect to the total solution, or ±0.84% with respect to the ammonium oxalate concentration; when comparison is made with the average curve given in "International Critical Tables,"[2] it is indicated that that curve is approximately 5% too low at 0° and 3.9% too low at 50°.

TABLE II

SOLUBILITY OF AMMONIUM OXALATE IN WATER

Calculated by equation:
Soly. = $2.314 + 0.06272t + 0.001714t^2$

T, °C.	Wt. per cent. $(NH_4)_2C_2O_4$	T, °C.	Wt. per cent. $(NH_4)_2C_2O_4$
0	2.314	50	9.735
10	3.112	60	12.25
20	4.254	70	15.10
25	4.953	80	18.30
30	5.738	90	21.84
40	7.565	100	25.73

Summary

The solubility of ammonium oxalate in water has been determined from 0 to 100°; the solid phase is the monohydrate throughout the entire range; the average figures in "International Critical Tables" are distinctly too low at 0 and at 50°.

The Catalytic Hydrogenation of Aldonic Acid Delta and Gamma Lactones and of the Aldoses

BY J. W. E. GLATTFELD AND G. WEBER SCHIMPFF[1]

These laboratories have been occupied for some time in the development of a practical method for the reduction of the C_4-saccharinic (dihydroxybutyric and dihydroxyisobutyric) acids to the corresponding aldehydes and also in the reduction of *dl*-erythronic lactone to *dl*-erythrose. The work reported in this paper was carried out chiefly in connection with the second of these problems. Since difficulties were encountered when the reduction of *dl*-erythronic lactone was attempted, a study was made of the reduction of similar but less expensive lactones. As a result of this work the conditions for the reduction of *dl*-erythronic butyl ester to crystalline erythritol in good yield have been established,[2] but, as yet, *dl*-erythrose has not been obtained. Efforts in this direction are being continued.

A preliminary study of the method of catalytic hydrogenation in the presence of platinic oxide as applied to the aldonic acids was made by Glattfeld and Shaver.[3] They found it possible to reduce *d*-gluconic acid, freshly liberated from its calcium salt by means of sulfuric acid, to *d*-glucose in 14–28% yield (measured as osazone).

In the present study the procedure used by Glattfeld and Shaver was modified and applied to the reduction of the delta and gamma lactones of certain of the aldonic acids, and it was further extended to the reduction of several of the aldoses. Efforts were made to determine the conditions for the production, in the first case, of a maximum yield of the corresponding sugar with a minimum of the corresponding alcohol (hereinafter called alcohol), and in the second, of a high yield of alcohol.

The work was begun with a study of the hydrogenation of the pure delta lactone of *d*-gluconic acid. This substance should upon reduction give the sugar with the 1,5-ring, which should be less easily reduced to the alcohol than the sugar with the 1,4-ring that would be expected to result from the reduction of the gamma lactone of the acid. Glacial acetic acid was the solvent first used, because it was thought that in this solvent the conversion of the delta lactone to gamma lac-

[a] A portion of the original solution was set aside; the rotations of this sample and of the reduced solution were observed in rapid succession at the close of the period of hydrogenation. [b] Catalyst was added in 0.3-g. portions, *t* = 0, 9, 15 hrs. [c] Addition of catalyst: 0.6 g. at 0 hrs.; 0.3 g. portions at 4, 9, 29, 31, 38 hrs. [d] This solution consisted of 30 ml. of the final solution from Experiment 7, diluted to a volume of 200 ml. [e] Glacial acetic acid was used as the solvent. The acid was removed by reduced pressure distillation before analyses were made.

tone and free acid[4] would be less rapid than in water. Although a reduction of 44.8% was obtained, this solvent was abandoned, because it was found that the use of aqueous solutions resulted in a greater reduction and permitted a simpler experimental procedure.

The effects of other variables—(1) concentration of solution, (2) amount of catalyst, (3) time of hydrogenation and (4) rate of agitation—on the reduction of *d*-gluconic delta lactone were also studied. It was found that an increase in the concentration of the lactone was attended by a marked decrease in the rate of reduction. A con-

centration of 0.2 molar was finally chosen as satisfactory, for it favored rapid reduction and at the same time permitted the treatment of rather large quantities of lactone. In regard to the amount of catalyst, it was observed that large quantities favored the production of alcohol, and small quantities necessitated an increase in the time of hydrogenation, a factor which in itself tended to increase the amount of alcohol formed. The rate of shaking of the solution was found to be a factor of the utmost importance. In solutions of approximately the same concentration, with equal quantities of catalyst, it was found that the time necessary to secure a 50% reduction was decreased from twenty hours to thirty minutes when the rate of shaking was increased from 120 to 350 cycles per minute (see experiments 1 and 10, Table I).

Various other lactones were then used in place of the delta lactone of *d*-gluconic acid. When the gamma lactone of *d*-gluconic acid was used, it was found that it was reduced more slowly than was the delta lactone and that it gave a higher yield of alcohol. Under conditions that resulted in an 80% yield of *d*-glucose with no alcohol from the delta lactone, there was obtained from the gamma lactone 23.4% sugar and 24% alcohol. In marked contrast was the behavior of the two lactones of *d*-mannonic acid. Both were reduced very readily. On the other hand, both lactones of *l*-rhamnonic acid were reduced slowly and both gave relatively high yields of alcohol; the gamma lactone gave three to four times as much alcohol as sugar, whereas the delta lactone gave approximately equal amounts of the two products. These results led to the same conclusion as did the work with the lactones of *d*-gluconic acid, *viz.*, the gamma lactone yields a sugar which is more readily reduced to the alcohol than the sugar from the delta lactone. In the case of lactobionic acid only the delta lactone is known. This substance was reduced to the extent of 79% in twenty minutes, with the production of practically no alcohol. The variations in experimental conditions with the results obtained are recorded in detail in Table I.

The method of catalytic hydrogenation developed for the aldonic acids was then applied to the reduction of aldoses in aqueous solution. It was found possible to reduce almost completely *d*-glucose, *d*-mannose, *l*-arabinose, *d*-xylose, *l*-rhamnose hydrate and lactose monohydrate. In several of the experiments the alcohols were isolated in yields varying from 63 to 80%. The results of these experiments are recorded in Table II.

Further work is in progress in these Laboratories both on the method herein described and on modifications which may render it applicable to reactions at high pressure and high temperature.

Experimental Part

Apparatus.—The apparatus possessed the essential features of the equipment used by Glattfeld and Shaver,[3] but the details of design were similar to those of the hydrogenation apparatus now manufactured by the Burgess–Parr Company of Moline, Illinois.

[a] The yield was calculated on the basis of the amount of alcohol theoretically present in the solution which remained at the end of the experiment, after various samples had been removed for analysis. [b] The reducing value of *d*-mannose was considered equivalent to that of *d*-glucose. [c] The dibenzaldehyde derivatives of the sirup and of *d*-sorbitol (Pfanstiehl) were prepared. Both derivatives, which were amorphous, melted at 195–200°. A mixture of the two products melted at the same temperature. [d] The conversion factor 0.92 was used [Vogel and Georg, "Tabellen der Zucker und ihrer Derivate," Verlag Julius Springer, Berlin, 1931, p. 9]. [e] The conversion factor of *l*-rhamnose was found to be 0.97. [f] A second crop could have been obtained, but time did not permit. [g] The conversion factor 0.655 was used [Vogel and Georg, *ibid.*, p. 49]. [h] The solutions of experiments 43 and 44 were combined for the isolation of the lactitol.

Materials.—(1) Commercial electrolytic hydrogen was used without purification. (2) Platinic oxide monohydrate was prepared according to the method described by Adams, Voorhees and Shriner.[5] However, it was found possible to prepare at a single fusion ten times the quantity specified. (3) *d*-Mannose was prepared according to the method of Clark;[6] $[\alpha]_D$ +14.1°. (4) *d*-Mannonic delta lactone was prepared from calcium *d*-mannonate dihydrate.[7] This salt was converted into the sodium salt by means of sodium oxalate. After the removal of the calcium oxalate, the filtrate was taken to dryness under diminished pressure at 50–60°. The solid residue was dried in a vacuum desiccator over concentrated sulfuric acid; yield, 96%. The sodium salt was then converted into the delta lactone according to the method of Brackenbury and Upson;[8] yield, 77.8%; m. p. 156–157°; $[\alpha]_D$ +113.4° (four min.). (5) *d*-Mannonic gamma lactone was prepared by an adaptation of the methods reported by Nef,[4a] by Hedenburg,[4b] and by Isbell and Frush.[9] A dry mixture of 23.32 g. (0.05 mole) of calcium *d*-mannonate dihydrate and 6.30 g. (0.05 mole) of powdered oxalic acid dihydrate was added to 24 ml. of boiling water. The hot thick paste was kept on a steam-bath with constant stirring for twenty minutes. The calcium oxalate was separated and washed with a total of 50 ml. of hot water. The washings and 4 drops of concentrated hydrochloric acid were added to the filtrate, and the entire solution was concentrated to a thick sirup at 50° under reduced pressure. This sirup was diluted with 20 ml. of water, transferred to a crystallizing dish, and placed in a vacuum desiccator over concentrated sulfuric acid. Crystals soon appeared; when the mass became solid, it was transferred to a Büchner funnel and the solid washed with about 200 ml. of absolute ethanol. The crystals were dried in a vacuum desiccator; m. p. 151–152°; $[\alpha]_D$ +51.7° (50 min.); yield, 12.1 g. (68%). (6) The delta and gamma lactones of *d*-gluconic acid were purchased from the Pfanstiehl Chemical Company, Waukegan, Illinois. (7) *l*-Rhamnonic delta lactone was kindly supplied by Professor Fred W. Upson, Department of Chemistry, University of Nebraska; m. p. 172–177°, $[\alpha]_D$ −97.9° (5 min.). (8) *l*-Rhamnonic gamma lactone was prepared by Mr. B. D. Kribben of this Laboratory from *l*-rhamnose monohydrate isolated from quercitrin; m. p. 147–149°; $[\alpha]_D$ −37.6° (20 min.). (9) Lactobionic delta lactone was kindly supplied by Dr. Horace S. Isbell of the Bureau of Standards, Washington, D. C.; m. p. (dec.) 195–196°; $[\alpha]_D$ +53.4° (2 min.). (10) *d*-Galactose, *l*-arabinose, *d*-xylose and lactose monohydrate were purchased from the Kahlbaum Chemical Company. (11) *l*-Rhamnose monohydrate was kindly supplied by Dr. M. E. Hanke, Department of Physiological Chemistry, University of Chicago; m. p. 101–103°; $[\alpha]_D$ +8.64° (final).

Reduction of Lactones.—An experiment with *d*-gluconic delta lactone (see experiment 3, Table I) will be described, since the operations are typical of those used in all the experiments conducted in aqueous solution. A 3.562-g. sample (0.02 mole) was dissolved in water and the volume made up to 100 ml. The solution was transferred to the reaction bottle and 0.2 g. of catalyst added; the bottle was thoroughly evacuated, filled with hydrogen until the gage registered a pressure of 35 pounds,[10] and shaken at the rate of 120 cycles per minute for thirty-three hours. At the end of that time the platinum black was allowed to settle; the rotation of the solution was observed; a sample was analyzed for reducing material by means of a micromodification of the Benedict method;[11,12] and a sample was titrated for total acidity. The percentage alcohol was calculated by subtracting from 100 the sum of the percentages of sugar and acid. In some experiments (see experiment 2, Table I) the shaking was interrupted, samples were removed for analysis, more catalyst was added and then the hydrogenation continued.

Isolation of *d*-Glucose.—In experiment 6 (Table I), the platinum black was removed by filtration after the final analysis, and the volume of the solution measured (84 ml. which contained 6.72 g. of *d*-glucose by analysis). The solution was diluted to 200 ml., warmed in a water-bath at 50°, and neutralized with calcium carbonate. The filtrate from the excess carbonate was concentrated to a thick sirup at reduced pressure (water-bath 50°). This sirup was diluted to 30 ml. with hot water and triturated with about 1200 ml. of absolute ethanol. The solid calcium *d*-gluconate which separated was powdered and washed with 200 ml. of absolute ethanol (weight 11.6 g., air dry). The ethanol solutions were combined and concentrated at reduced pressure to a volume of about 250 ml. (bath 40°). The volume was further reduced to about 30 ml. in a vacuum desiccator. The crystalline *d*-glucose was separated by filtration, washed with absolute ethanol and absolute ether, and dried in a vacuum desiccator; weight 5.2 g.; recovery 77.4%. After two recrystallizations from absolute ethanol, the m. p. was 145.5–146.6°; $[\alpha]_D$ +51.9° (17 min.).

Reduction of Aldoses.—The procedure used for the reduction of the sugars was practically identical with that outlined above, except that the process was usually interrupted at convenient intervals for the analysis of the solution and the introduction of catalyst. The process was discontinued when analysis showed 10% or less of sugar. The alcohol was usually isolated from the solution left after the removal of the platinum black, by the addition of an appropriate mixture of 95% ethanol and ordinary ether followed by storage of the solution in the refrigerator until crystallization had taken place. After the removal of the crystals, the mother liquor was concentrated under diminished pressure at 50° to a small volume, and the above treatment repeated for the obtaining of a second crop. It was not possible to obtain the *d*-sorbitol or the xylitol in crystalline form.

Isolation of Lactitol.—After the removal of the platinum black, the solution was evaporated to dryness at reduced

[10] A pressure of two to three atmospheres was used throughout the work.

[11] Mathews, "Physiological Chemistry," William Wood and Company, Baltimore, Md., 5th ed., p. 1188.

[12] In the calculation of the percentage of reducing material, the molecular weights of the sugar and acid lactone were considered identical, even though their formulas differ by two hydrogen atoms.

pressure (bath 50°). The residue was triturated for several hours with absolute acetone. The resulting white solid, which was very hygroscopic, was carefully dried in a vacuum desiccator over phosphorus pentoxide (weight 8.0 g., 63%). A 0.900-g. sample was weighed rapidly, dissolved in water, and the solution diluted to 10 ml. The rotation of the solution in a 1-dcm. tube was found to be +1.48°; $[\alpha]_D$ +16.4°. The only value given in the literature is the one reported by Senderens,[13] who found $[\alpha]_D$ +12.2° for the monohydrate of lactitol. He reported the m. p. to be 78°. Our product melted to a milky liquid at 79–80° and increased in volume about five-fold; at 130–140° the mass turned to a yellow glass-like solid which decomposed at 190–200°. Neuberg and Marx[14] reported that anhydrous lactitol decomposed at 200°.

Summary

1. A method of catalytic hydrogenation has been developed whereby the delta lactones of aldonic acids are reduced in good yield to the corresponding sugars. The gamma lactones are also reduced, but they usually give lower yields of the sugars owing to the further reduction of the sugars to the corresponding sugar alcohols.

2. The method has been adapted to the reduction of the sugars to the corresponding sugar alcohols. It is possible to obtain practically complete reduction and to isolate the sugar alcohols in 63–80% yields.

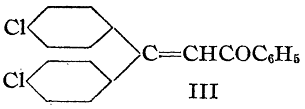
The Reversibility of the Friedel–Crafts Condensation. Hydrogenation Phenomena

BY L. L. ALEXANDER, A. L. JACOBY AND REYNOLD C. FUSON

It was to be predicted that the reversible addition of aromatic hydrocarbons to α,β-unsaturated carbonyl compounds[1] would be prevented by the presence of suitable substituents on the *beta* carbon atom. Several examples of conjugated systems have now been found which do not yield addition products but instead undergo hydrogenation. Thus, 1,1-diaryl-2-acylethylenes do not condense with benzene in the presence of aluminum chloride, but, instead, *are hydrogenated to the corresponding saturated diaryl ketones.*

$$\underset{\text{I}}{(Ar)_2C{=}CHCOR} \xrightarrow[AlCl_3]{C_6H_6} \underset{\text{II}}{(Ar)_2CHCH_2COR}$$

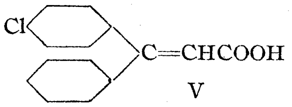
For example, 1,1-di-(p-chlorophenyl)-2-benzoylethylene (III) is converted to α-benzohydrylacetophenone (IV).



III

$(C_6H_5)_2CHCH_2COC_6H_5$

IV



V

$(C_6H_5)_2CHCH_2COOH$

VI

$(C_6H_5)_2C{=}CHCOC_6H_5$

VII

$(C_6H_5)_2C{=}CHCOC(CH_3)_3$

VIII

Similarly, β-(p-chlorophenyl)-cinnamic acid (V) gives β,β-diphenylpropionic acid (VI). In both of these examples replacement as well as hydrogenation is involved. However, the chlorine-free analog of III—1,1-diphenyl-2-benzoylethylene (VII)—appears to undergo only the latter change; it gives IV. In a similar fashion, 1,1-diphenyl-2-trimethylacetylethylene (VIII) is transformed into its hydrogenation product, α-benzohydrylpinacolone.

However, it seemed possible that this type of transformation might not be dependent on the presence of a hetero conjugated system, but might be simply a property of stilbenes. In order to clear up this point stilbene, p-bromostilbene and p,p'-dichlorostilbene were each subjected to treatment with benzene in the presence of anhydrous aluminum chloride. *In each case the product was dibenzyl.* The generalized form of the equation is $XC_6H_4CH{=}CHC_6H_4X + 2C_6H_6 + 2H = C_6H_5CH_2CH_2C_6H_5 + 2C_6H_5X$. It is seen that this process involves replacement of aryl groups as well as hydrogenation at the double bond.

The various mechanisms which suggest themselves for these processes raise the question as to whether the addition of benzene, the elimination of the substituted phenyl group and the hydrogenation are related processes and, if so, in what sequence they occur. The work is being continued from this point of view.

Experimental Part

α-Benzohydrylacetophenone (IV)

A. From 1,1-Di-(*p*-chlorophenyl)-2-benzoylethylene (III).—A mixture of 0.75 g. of the dichloro ketone, 1.5 g. of aluminum chloride and 20 cc. of dry benzene was saturated with dry hydrogen chloride and allowed to stand at room temperature for twelve hours. The product melted at 91.5–92°, and was shown by the method of mixed melting points to be α-benzohydrylacetophenone.

B. From 1,1-Diphenyl-2-benzoylethylene (VII).—α-Benzohydrylacetophenone was also obtained by applying the foregoing procedure to 1,1-diphenyl-2-benzoylethylene.

α-Benzohydrylpinacolone.—In a like manner, the interaction of 5 g. of 1,1-diphenyl-2-trimethylacetylethylene (VIII), 10 g. of aluminum chloride, 100 cc. of dry benzene, and dry hydrogen chloride gave 3.6 g. of α-benzohydrylpinacolone. The product melted at 83–84.5°, and the melting point was not depressed when this sample was mixed with an authentic specimen of the ketone.

Ethyl β-Phenyl-β-(*p*-chlorophenyl)-β-hydroxypropionate.—A mixture of 54.1 g. of *p*-chlorobenzophenone, 50 g. of ethyl bromoacetate and 225 cc. of dry benzene was treated with 19.6 g. of granulated zinc. The mixture was warmed and stirred for an hour and then decomposed with dilute acid in the usual manner. The product (from alcohol) melted at 79–80.5°; yield, 79%.

Anal. Calcd. for $C_{17}H_{17}O_2Cl$: C, 67.0; H, 5.6. Found: C, 67.3; H, 5.7.

β-Phenyl-β-(*p*-chlorophenyl)-β-hydroxypropionic acid was obtained by saponification of the ester. It crystallized from dilute alcohol in light yellow needles melting at 188.5–189°, with decomposition.

Anal. Calcd. for $C_{15}H_{13}O_3Cl$: C, 65.1; H, 4.7. Found: C, 64.9, 65.2; H, 4.9, 4.7.

β-(*p*-Chlorophenyl)-cinnamic Acid (V).—A mixture of 44.2 g. of β-phenyl-β-(*p*-chlorophenyl)-β-hydroxypropionic acid, 24.6 g. of acetic anhydride and 10.9 g. of freshly fused sodium acetate was heated for four hours under reflux. The solution was then poured into water and the mixture allowed to stand at room temperature for two weeks. The cinnamic acid was recrystallized from alcohol; m. p. 168°.

Anal. Calcd. for $C_{15}H_{11}O_2Cl$: C, 69.6; H, 4.3; neut. equiv., 258.5. Found: C, 69.6; H, 4.4; neut. equiv., 260.8.

β,β-Diphenylpropionic Acid (VI).—The chloro acid was shaken with a mixture of benzene, aluminum chloride, and hydrogen chloride over a period of twenty hours. The product (from an ether–petroleum ether mixture) melted at 151–152°, and was shown by the mixed melting point method to be β,β-diphenylpropionic acid.

Dibenzyl

A. From *p,p'*-Dichlorostilbene.—One and a half grams of powdered aluminum chloride was added to a mixture of 1 g. of *p,p'*-dichlorostilbene and 20 cc. of dry benzene. The mixture became dark red in color. Dry hydrogen chloride was bubbled through the mixture for thirty minutes. The reaction mixture was then stirred at room temperature for sixteen hours and poured on a mixture of ice and hydrochloric acid. The product melted at 51.5° and when mixed with *dibenzyl* did not depress the melting point; yield, 70%.

B. From Stilbene.—By a similar procedure involving stilbene and in which the reaction time was fifty-four hours, a 20% yield of dibenzyl was obtained.

C. From *p*-Bromostilbene.—In this experiment, in which the reaction time was seventeen hours, 2.9 g. of dibenzyl was obtained from 5 g. of the bromostilbene. The color change from brown to red was again noticed.

Summary

1. 1,1-Di-(*p*-chlorophenyl)-2-benzoylethylene and β-(*p*-chlorophenyl)-cinnamic acid react with benzene in the presence of aluminum chloride to give, respectively, α-benzohydrylacetophenone and β,β-diphenylpropionic acid.

2. Under the same conditions, 1,1-diphenyl-2-benzoylethylene and 1,1-diphenyl-2-trimethylacetylethylene undergo hydrogenation to α-benzohydrylacetophenone and α-benzohydrylpinacolone.

3. Similar treatment converts stilbene, *p*-bromostilbene and *p,p'*-dichlorostilbene into dibenzyl.

The Pyrolysis of Allyl-*p*-phenetidine

BY F. L. CARNAHAN

The predominating type of pyrolytic decomposition followed by the allylanilines has been shown[1] to differ from that encountered in the simpler allyl phenyl ethers. The allylanilines formed propylene, the corresponding primary amine and tarry material rather than products of allyl group migration from nitrogen to the aromatic nucleus. This behavior in some respects resembles that of 2,4-dimethyl-6-propylphenyl allyl ether,[2] which gave allene, diallyl, propylxylenol and resinous material. Previous work[1] on allylaniline, diallylaniline and diallyl-*p*-phenetidine has been extended to include allyl-*p*-phenetidine.

In connection with the proposed mechanism for the thermal decomposition of allylanilines, it is important to know if hydrogen is evolved at reflux temperatures. None was present in the gases from the diallylanilines, but some was found when allylaniline was heated at 600–700°. While allylaniline did not decompose at its reflux temperature (218°) it has been found that allyl-*p*-phenetidine is slowly decomposed on refluxing at 270°. Per mole of allyl-*p*-phenetidine, 0.465 mole of *p*-phenetidine was found, the loss in weight corresponded to 0.40 mole of propylene, resin equivalent to 0.447 mole was formed, and material equivalent to 0.10 mole was unidentified. No hydrogen was present. A search for 6-ethoxyquinoline and 6-ethoxytetrahydroquinoline failed to disclose either. At higher temperatures allylaniline gave some quinoline; this effect is extensive in the presence of lead dioxide.[3]

The most probable mechanism for these data is the one previously set forth wherein the initial step was formation of radicals

$$ArNHC_3H_5 \longrightarrow ArNH— + C_3H_5—$$

but instead of assuming that these radicals undergo disproportionation it is proposed that they become hydrogenated to *p*-phenetidine and propylene, respectively, by collision with neighboring undecomposed molecules. The latter molecules would thus be converted into an acrolein-anil, $ArN{=}CHCH{=}CH_2$, which is regarded as the forerunner of the resinous material. The absence of hydrogen as a reaction product makes it appear certain that molecular hydrogen plays no part in the reaction mechanism. It might be argued, for example, that molecules of $ArNHC_3H_5$ changed first into $H_2 + ArN{=}CHCH{=}CH_2$ with the hydrogen thus formed splitting another molecule of allyl-*p*-phenetidine into phenetidine and propylene. Three facts eliminate this possibility. Molecular hydrogen is sufficiently inert to escape partly as such but none is found. The mechanism would fail with the tertiary amines, diallylaniline and diallyl-*p*-phenetidine, which have been found actually to pyrolyze more readily than does allyl-*p*-phenetidine itself. Again, when hydrogen is removed from an allylaniline, especially by the aid of lead dioxide,[3] the product is related to quinoline and not a resin.

Experimental

Allyl-*p*-phenetidine.—Allyl-*p*-phenetidine was prepared by the general method of Hepp.[4] Allyl bromide was added to the reaction product of sodium on phenacetin; the thick oil resulting was hydrolyzed by sodium hydroxide in alcohol. Steam distillation of the product, followed by vacuum fractionation with a nitrogen leak gave allyl-*p*-phenetidine free from *p*-phenetidine. The yield was 31%; 37% if recovered *p*-phenetidine was taken into account.

The compound boils at 134.5° at 10 mm., 140° at 15 mm., and with decomposition at 265° at 745 mm. pressure. It shows $d^{20}{}_4$ 1.0096; $n^{20}{}_D$ 1.5493.

Anal. Calcd. for $C_{11}H_{15}ON$: C, 74.52; H, 8.53. Found: C, 74.55; H, 8.48.

Allyl-*p*-toluenesulfon-*p*-phenetidine.—Allyl-*p*-phenetidine was treated with 1.5 equivalents of *p*-toluenesulfonyl chloride and 5 equivalents of 2 *N* potassium hydroxide. The usual treatment gave crude alkali-insoluble material in a yield of 86% of the calculated amount. Crystallization from methyl alcohol and water accompanied by treatment with bone black gave the derivative in white needles melting at 81°.

An identical product was obtained by treating *p*-toluenesulfone-*p*-phenetidide[1] with an excess of allyl bromide in *N* potassium hydroxide solution at room temperature. Considering a small proportion of the starting material recovered unchanged, the yield was 99.5%.

Anal. Calcd. for $C_{18}H_{21}O_3NS$: C, 65.21; H, 6.39. Found: C, 65.49; H, 6.37.

Pyrolysis of Allyl-*p*-phenetidine by Refluxing.—Several runs were made with the same general results. The following experiment may be taken as representative.

[3] Koenigs, *Ber.*, **12**, 453 (1879).

[4] Hepp, *ibid.*, **10**, 327 (1877).

A 70.8-g. (0.4 mole) sample was placed in a 125-cc. flask to which was sealed 75 cm. of 1 cm. inside diameter tubing to serve as an air condenser. A thermometer rested on the bottom of the flask and extended into the condenser. Through a 15-cm. tube sealed to the flask nitrogen could be passed into the apparatus. Provision was made for the collection of gaseous products over water. The flask was heated in a fused salt bath to maintain a reflux about 15 cm. above the liquid level. The refluxing was continued for one hundred twenty hours with the temperature of the liquid in the flask averaging 270°.

During the pyrolysis gas was slowly evolved. Analysis showed 93.0% soluble in 85% sulfuric acid, 1.4% oxygen, 5.6% nitrogen. Passed through a solution of dry bromine in dry carbon tetrachloride, the gas formed propylene bromide, $n^{20}\text{D}$ 1.5181. The amount of gas over water was 965 cc. at 21° and 740 mm. equivalent to 0.035 mole propylene. The small amount collected is partly owing to the fairly high solubility of propylene in water (44.6 cc. per 100 cc. of water) and the long time of contact. The loss of weight in this experiment was 7.3 g. If this loss is considered to be represented by propylene evolved, it would correspond to 0.174 mole or 0.44 mole of propylene per mole of allyl-*p*-phenetidine. Another experiment in which the loss of weight of the refluxed material was ascertained quantitatively indicated 0.404 mole of propylene per mole of the amine.

Liquid products of the pyrolysis were poured while hot into a 200-cc. balloon flask with a side-neck carrying a nitrogen leak. Distillation through a 1.5 × 38 cm. packed column was carried out at 9 mm. pressure. The first fraction was colorless, boiled at 114–116°, and weighed 20.5 g. The second fraction was also colorless, boiled at 116–130°, and weighed 5.05 g. Both these fractions gave *p*-toluenesulfone-*p*-phenetidide,[1] m. p. 108°, in yields as high as obtained from pure *p*-phenetidine. Melting points in mixture with an authentic specimen of the derivative were unchanged.

When distillation through the column became impossible, the procedure was continued in a Claisen flask. The deep yellow liquid collected through the range 160–235° at 19 mm. weighed 6.75 g. Of this liquid, 40% was soluble in 3 *N* hydrochloric acid. In the soluble portion attempts were made to identify 6-ethoxyquinoline[5] (b. p. 290–292°) and 6-ethoxytetrahydroquinoline[6] (b. p. 164–166° at 17 mm.). On account of their high boiling points, these compounds should be present in this fraction rather than one composed predominantly of *p*-phenetidine. The procedures of Sonn and Benirschke[6] were followed in the preparation of 6-ethoxyquinoline and 6-ethoxytetrahydroquinoline. The methiodide of the former melted at 193–194°, that of the latter at 208–209°. A search for the two compounds in the acid-soluble material above as well as in the intermediate (116–130° at 9 mm.) fraction did not disclose either of them.

The non-basic material was not further investigated. Possibly it may represent a lower stage of polymerization than the resin itself.

The residue from the distillation procedures was a dark brown brittle resin weighing 31.25 g., m. p. 68–88°.

The resin was soluble in ether, acetone, benzene, xylene and concentrated sulfuric acid, giving in each case a solution with a green-blue fluorescence. This phenomenon may indicate the presence of nitrogen rings in the resin since certain salts of 6-ethoxyquinoline and quinine exhibit fluorescence. On long boiling with 3 *N* hydrochloric acid about 6% of the resin dissolved. No simple water-insoluble material such as *p*-phenetidine was produced by boiling 5.0 g. of the resin with 25 cc. of 25% hydrochloric acid for twenty-seven hours. Likewise, boiling for twelve hours with 60% sulfuric acid effected no decomposition.

Summary

1. Allyl-*p*-phenetidine and allyl-*p*-toluenesulfon-*p*-phenetidide have been prepared and characterized.

2. Allyl-*p*-phenetidine has been found to decompose on refluxing at atmospheric pressure into *p*-phenetidine, propylene and resinous material. The initial step of this process appears to be a splitting into radicals at the carbon-to-nitrogen bond.

The Induction Period in Gaseous Thermal Explosions[1]

By O. K. Rice,[1a] Augustine O. Allen and Hallock C. Campbell

We have recently studied the explosions of azomethane[2a] and ethyl azide,[2b] and have shown that they are probably thermal explosions, due to self-heating of the gas on account of the exothermicity of their slow decompositions. In these papers we have compared our results with the theory of Semenoff,[3] which gives the critical explosion pressure as a function of the temperature. Now it is observed when the gases are admitted to the reaction vessel that an appreciable time elapses before the explosion occurs. These lag times or induction periods have been measured in many cases, and in this paper we shall present these data, and discuss the theory. We shall see that this enables us to make an estimate of the heat of decomposition.

The basis of the theory which we shall present consists in following the change of temperature of the gas as reaction proceeds. An equation giving the amount, T, by which the temperature of the reacting gas exceeds that of its container as a function of the time and from which the induction period can be obtained has been given by Allen and Rice.[2a] The rate of production of heat is given by the expression $QknV$, where Q is the heat of reaction per mole of gas decomposed, V the volume of the reaction vessel, n the number of moles of reacting gas per unit volume, and k the rate constant. $k = Ae^{-E/R(T + T_0)}$, A being a constant, R the gas constant, E the activation energy for the unimolecular decomposition, and $T + T_0$ the temperature of the gas; T_0 is the temperature of the reaction vessel. We may write $n = n_0e^{-kT}$, where n_0 is the initial value of n and t is the time, provided we assume as an approximation that k is constant during the induction period. Heat is removed from the gas by conduction and convection at the rate axT, a being the wall area and x a constant. Subtracting the rate of loss of heat from the rate of production and dividing by C, the total heat capacity of the gas in the vessel, we get the rate of change of the temperature of the gas; making a slight reduction we obtain the equation

$$\mathrm{d}T/\mathrm{d}\tau = e^{-E/R(T + T_0)}\, e^{-k(C/B)\tau} - (ax/B)T \quad (1)$$

where $B = QAn_0V$ and $\tau = tB/C$; here t is measured from the moment the gas is admitted to the vessel, assuming that it warms up instantly to the temperature T_0, an assumption that will be discussed later. Since C as well as B is proportional to n_0, we may, for any given series of runs involving a definite substance and reaction vessel at a definite external temperature, T_0, but with varying pressure, consider τ to be a measure of the time from the start of the experiment expressed in a special set of units. Likewise the quantity B/ax, assuming that x is independent of the pressure, is a measure of the pressure used in a given experiment, and its value determines whether or not an explosion occurs in an experiment performed at a given temperature, T_0. In a case in which an explosion occurs integration of (1) will show that the temperature rises very suddenly after a lapse of time, and the time at which this sudden rise occurs may be set equal to the induction period,[4] while if explosion does not occur the temperature merely rises to a maximum and falls off again.

The differential equation (1) cannot be integrated analytically, but it may be solved numerically by the use of the Runge–Kutta formula.[5] In order to compare with the experimental data it is necessary to go through this process for different values of T_0 and ax/B. When this is done the value of τ at which the explosion occurs is known for any given conditions; this may be compared with the observed induction period t and B/C found. Now $B/C = QAn_0V/n_0VC_\mathrm{M} = QA/C_\mathrm{M}$ where C_M is the heat capacity per mole of azomethane; as A is known, we can calculate Q/C_M which should be practically constant for all experiments with a given composition of gas. If there are r moles of inert gas per mole of azo-

[4] The same principles have been used by Tizard and Pye [*Phil. Mag.*, **44**, 79 (1922)] in discussing the oxidation of certain hydrocarbons, but their experiments were of a different type than ours, and their equations cannot be used in treating the experiments of the type considered here.

[5] Scarborough, "Numerical Mathematical Analysis," The Johns Hopkins University Press, p. 273.

methane, then $C_M = C_A + rC_G$, where C_A is the molal heat capacity of azomethane and C_G that of the inert gas.

In order to take into account the correction factor $e^{-k(C/B)\tau}$, which allows for the amount of gas decomposed before explosion takes place, and which affects the induction period near the explosion limit and also changes the value of the critical explosion pressure somewhat, it is necessary to assume a preliminary value of C/B, which is precisely the quantity we are trying to obtain. One is thus required to make a series of successive approximations, a very long process on account of the tedious calculation involved in the use of the Runge–Kutta formula. This fact, together with the desirability of having an easy way to perform the integration for a considerable range of values of the constants involved, has led us to seek an approximate method of calculation. This will be presented in §2. It is first necessary, however, to carry out the more exact integration of Equation (1) for some special values of the constants involved, in order to gain some information about the general character of the solutions of (1) and to be able to verify the accuracy of the approximate method.

For this purpose we have taken among others the case where T_0 = 630°K. and $kC/B = 1.27 \times 10^{-21}$ and E = 51,200 calories per mole. These values were estimated to correspond roughly to the situation with azomethane at 630°K. Figure 1 shows the calculated T *vs.* τ curves for various values of ax/B. It is seen that, as expected, the curves are definitely of two classes, the curves for small values of ax/B (large values of the pressure) being such as one would expect to correspond to an explosion, while the curves for large values of ax/B correspond to a quiet decomposition in which the temperature reaches a relatively low maximum, and then drops off. In the case of the explosive curves, the theory does not predict an exact instant for the explosion to occur, but certainly fixes it within an interval of time much smaller than the experimental error in determining the induction period. The critical value of ax/B appears to lie between 2.86×10^{-19} and 2.87×10^{-19}. It is, however, not certain that this value can be determined as closely as indicated by these figures, for very close to the explosion limit the curves are very sensitive to slight inaccuracies in the calculation, and it is quite possible that one which appears to be explosive actually should not be, or *vice versa.* But if the curve is only so far from the explosion limit as the one for $ax/B = 2.84 \times 10^{-19}$ in Fig. 1, the critical τ for explosion is no longer sensitive to slight errors. For values of the pressure very near the explosion limit very large values of τ are theoretically possible, but experimentally these have not been realized. It is, in general, impossible to adjust the pressure closely enough to get within the critical range of pressures, and it is also probable that the theory fails in this region, as k is not actually constant as we have assumed.

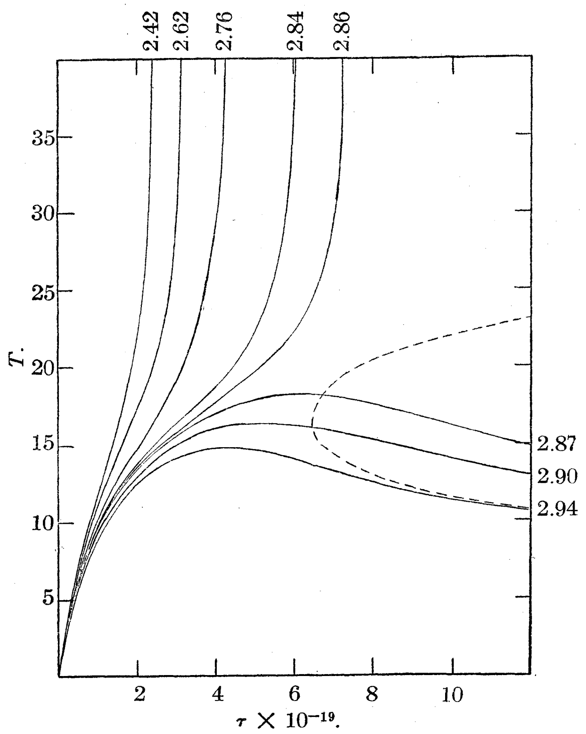

Fig. 1.—Theoretical temperature time curves at 630°K. for various values of $(Ax)/B(\times 10^{19})$.

In spite of the probable failure of the theory for pressures very close to the explosion limit it will not be without interest to examine a little more closely the nature of the solutions of the differential equation (1). Every one of the T *vs.* τ curves will ultimately reach a maximum, even though it be of the explosive type. This maximum will necessarily lie on the locus

$$(kC/B)\tau = -E/R(T + T_0) - \ln(ax/B) - \ln T \quad (2)$$

which makes $dT/d\tau$, as given by Equation (1), zero. The locus defined by Equation (2) for $ax/B = 2.86 \times 10^{-19}$ is shown (broken curve) in Fig. 1; the loci for other values of ax/B near this will be of just the same shape, but displaced along the τ axis a short distance. These loci are s-shaped, starting at $\tau = \infty$ for $T = 0$ and eventually reaching $\tau = -\infty$ for $T = \infty$. There are two points where the locus (2) has a vertical slope; one is shown, the other one is at a value of T approximately equal to

E/R, which is of the order of 25,000°, and a value of τ approximately $(B/kC)\ (E/RT_0 - 1 + 2\ \ln(RT_0/E))$, or about 32×10^{19}, greater than the value of τ for the first point of vertical slope. This value of τ gives the longest theoretically possible induction period. The explosive curves theoretically reach the upper branch of (2), that is, the part of the locus defined by (2) which is going out to $\tau = -\infty$; the values of T thus theoretically attained are greater than 25,000°. Such values will obviously not actually be reached, for one reason because k will not actually be independent of T and therefore the azomethane is used up before such temperatures are reached. The curves which have their maxima on the lower and middle branches of (2), up to the second point of vertical slope, where the locus defined by (2) turns around and heads toward $\tau = -\infty$, are the non-explosive curves. Theoretically there is a perfectly continuous transition between explosive type and non-explosive type curves, the transition occurring in an astonishingly small range of values of ax/B.

§2. Approximate Integration of Equation (1)

In order to get an approximate integration of Equation (1) we first see what can be done if the term $e^{-k(C/B)\tau}$ is set equal to 1. Under these circumstances we may, from Equation (1), write for τ_c, the critical value of τ at which explosion takes place

$$\tau_c = \int_0^{2RT_0^2/E} [e^{-E/R(T + T_0)} - (ax/B)T]^{-1}\,\mathrm{d}T \qquad (3)$$

The upper limit in this integral is obtained in the following way. In the theory of Semenoff the rise in temperature at the explosion limit is equal approximately to[2a] RT_0^2/E, this being also very approximately the temperature at which the locus defined by Equation (2) has infinite slope, as shown in Fig. 1. From Fig. 1 it is obvious that, though τ_c cannot, as we have said, be exactly defined, it will be very reasonable to determine a value by integrating to the temperature where T is equal to twice the value RT_0^2/E.

If we make the allowable approximation[6] $(1 + T/T_0)^{-1} = 1 - T/T_0$ then we may write Equation (3) in the form

$$\tau_c = \int_0^{2RT_0^2/E} [e^{-E/RT_0}\, e^{ET/RT_0^2} - (ax/B)T]^{-1}\,\mathrm{d}T \qquad (4)$$

If we set $y = ET/RT_0^2$ and $f = (ax/B)\ (RT_0^2/E)\ e^{E/RT_0 - 1}$ this takes the form

$$\tau_c = (RT_0^2/E)e^{E/RT_0 - 1}\, I_0 \qquad (5)$$

where

$$I_0 = \int_0^2 (e^{y - 1} - fy)^{-1}\,\mathrm{d}y \qquad (6)$$

I_0 may be evaluated as a function of f from Equation (6) by numerical integration. By its definition, f is inversely proportional to P, the pressure, x being assumed independent of pressure.

Now the equation for the critical explosion pressure[7] is also based on the same approximations made so far in the considerations of this section. Using this equation we see that at the critical explosion pressure f is equal to 1 and we may set

$$f = P^*/P \qquad (7)$$

where P^* is the critical explosion pressure of the approximate theory. For explosive runs, of course, $f < 1$.

Allowance for the term $e^{-k(C/B)\tau}$ of Equation (1) may be made in an approximate manner as follows. In the actual calculation of the curves in Fig. 1 one finds that the value of τ at which the curve begins to rise rapidly is largely determined by its behavior in the neighborhood of the inflection point, which occurs at a value of τ very near to $\tau_c/2$ and a value of T very near RT_0^2/E. This suggests that we replace the exponential term in question by a sort of average value, namely, $e^{-k^*(C/B)\tau_c/2}$, where k^* is the value of the rate constant at the temperature $T_0 + RT_0^2/E$. We then get in place of Equation (4), the equation

$$\tau_c = \int_0^{2RT_0^2/E} [e^{-E/RT_0}\, e^{ET/RT_0^2}\, e^{-k^*(C/B)\tau_c/2} - (ax/B)T]^{-1}\,\mathrm{d}T \qquad (8)$$

in which τ_c is involved inside the integral sign as well as on the left-hand side of the equation. This equation is to be solved for τ_c. It is convenient to define a quantity I, similar to the quantity I_0 of Equation (5) by the relation

$$\tau_c = (RT_0^2/E)e^{E/RT_0 - 1}\, I \qquad (9)$$

the difference between the value of τ_c obtained from Equation (8) and that given by Equation (4) being expressed by the difference between I and I_0. If we make the substitutions following Equation (4) and, further, set

$$\Theta = k^*(C/2B)(RT_0^2/E)e^{E/RT_0 - 1} \qquad (10)$$

then it is readily seen from Equations (8) and (9) that

$$I = e^{\Theta I} \int_0^2 (e^{y - 1} - e^{\Theta I} fy)^{-1}\,\mathrm{d}y \qquad (11)$$

---

(6) We may note that under this approximation Equation (1) may be written in the form

$$\mathrm{d}y/\mathrm{d}J = e^{y - 1}\, e^{-\phi J} - fy$$

where

$$J = \tau(E/RT_0^2)e^{1 - E/RT_0}$$
$$\phi = k(C/B)(RT_0^2/E)e^{E/RT_0 - 1}$$

and y and f are defined just following Equation (4). This would make the Runge–Kutta calculations much easier, for the effects of T_0 and $k(C/B)$ are both taken care of essentially by the one parameter ϕ. This would greatly lessen the number of calculations needed, but they are still sufficiently laborious to make it seem worth while to develop the approximation method of this section.

(7) Ref. 2a, Equation (5).

Now the integral appearing in Equation (11) is simply the integral I_0 with the argument $fe^{\Theta I}$ appearing in place of f. We can thus write a functional equation connecting I and I_0

$$I(f) = e^{\Theta I(f)} I_0(fe^{\Theta I(f)}) \qquad (12)$$

in which the quantity in parentheses following an I or I_0 is the argument of which that I or I_0 is a function. This functional equation for I may be solved and I found as a function of f by the method presented in the Appendix. The results of these calculations for a number of different values of Θ are shown in Fig. 2. (The values given on the curves are 1760 Θ.)

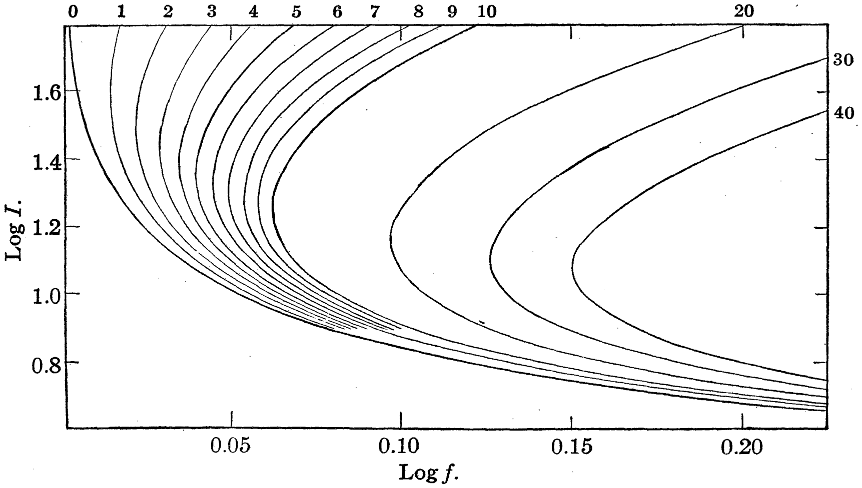

Fig. 2.

Now the fact that the curves bend back indicates that for any given value of Θ there is a certain largest value of f above which there are no real solutions of the functional Equation (12). This suggests that this largest value of f corresponds to the corrected explosion limit. Equation (7) gives f in terms of P and P^*, the latter being the uncorrected critical pressure. If we wish to get I for any Θ as a function of P/P_1^* where P_1^* is the corrected critical pressure we can do this by noting that[8]

$$P/P_1^* = f_\Theta/f \qquad (13)$$

where f_Θ is the largest value of f for the given Θ. Thus, to get I as a function of P/P_1^* or f_Θ/f we simply move the curves of Fig. 2 to the left till the point of infinite slope touches the axis, $\log f = 0$. The result is shown in Fig. 3. The real justification of this procedure is that in special cases the curve obtained agrees with the result obtained by integrating Equation (1) directly, using the Runge–Kutta formula. This is shown in Fig. 3. The circles and triangles represent the values $\tau_c/(RT_0^2/E)e^{E/RT_0 - 1}$, where τ_c has been calculated by means of the Runge–Kutta formula from (1), and P/P_1^* has been set equal to the critical value of Ax/B divided by the value of Ax/B corresponding to the particular value of τ_c. It is seen that the agreement is very good, especially when one bears in mind that the Runge–Kutta method does not give the explosion limit very accurately, and that all points of a given set of calculations should be shifted horizontally by an amount corresponding to the error in the explosion limit. We may therefore use the the approximation developed in this section with some confidence, except very close to the explosion limit where all calculations break down. Since all our calculations do break down near the explosion limit it is not surprising that an attempt to go beyond the explosion limit results in the upper branches of the curves of Fig. 2, which can have no physical meaning.

In an experiment we have a measurement of the time lag, which we may call t_c and which we may assume gives us $(C/B)\tau_c$. Furthermore, we know the ratio of the pressure to the critical pressure, which gives P_1^*/P. We also know T_0 and k^*. We therefore choose from among the curves of Fig. 3 that one which gives us the correct value of $(C/B)\tau_c = 2\Theta I/k^*$ (see Equations (9) and (10)) at the given value of P_1^*/P. We thus find the value of Θ corresponding to the particular experiment, and from this we can get Q/C_M, where C_M is the heat capacity of the reacting gas per mole of azomethane. This quantity is obtained from Θ by noting that $k^* = Ae^{-E/R(T_0 + RT_0^2/E)}$, which is approximately equal to $Ae^{1 - E/RT_0}$. Substituting this into Equation (10), and remembering the definitions of C and B we get

$$\Theta = (C_M/Q)(RT_0^2/2E) \qquad (14)$$

Since Q/C_M will not be expected to vary very much over the range of temperatures which can

---

[8] Equation (13) can be used to correct the critical pressure given by the Semenoff theory. However, Equation (14) shows that Θ should be practically constant for any given explosive reaction over the range of temperatures in which it can be studied. The correction to $\log P^*$ is therefore essentially a constant independent of the temperature, and hence is of no practical importance. However, for purposes of notation, it is assumed hereafter in this paper that the experimental critical pressure gives a measure of P_1^*.

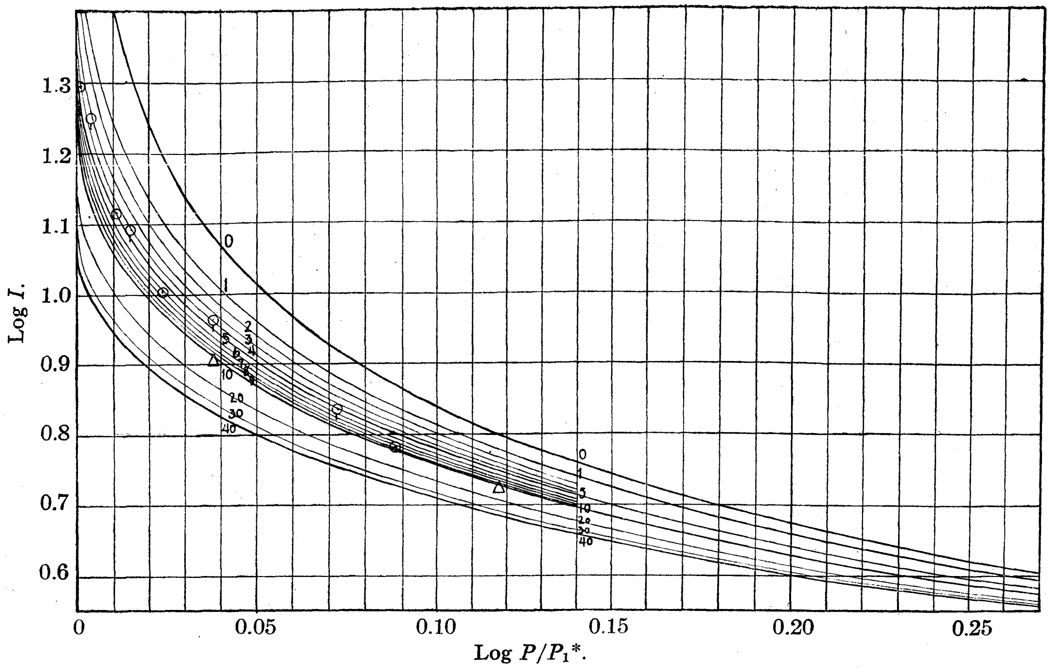

Fig. 3.—Data for Runge–Kutta points: ♀, E = 51,200, T_0 = 630°K., 1760 θ = 3.66; ○, E = 51,200, T_0 = 614°K., 1760 θ = 6.66. △, E = 41,500, T_0 = 553°K., 1760 θ = 7.82.

be studied, we should get the same value for all experiments with a given substance or mixture, and this will be a test of the theory

§3. The Heating of the Gas

In the above discussion we have neglected the time it takes to heat up the gas when it enters the reaction vessel. It is rather difficult to make an exact calculation of this quantity because the gas enters the reaction vessel through a hot tube where it receives a preheating, in what is probably a negligible length of time. If this heats the gas to a temperature equal to $T_0 - T'$, then the time (multiplied by B/C) for the gas to heat up to the wall temperature, T_0, is, from Equation (1) (which should hold for this process as it does for the heating up of the gas after the temperature T_0 has been reached)

$$\tau' = \int_{-T'}^{0} [e^{-E/R(T+T_0)} - (ax/B)T]^{-1}\,dT \qquad (15)$$

In this we have set the term $e^{-k(C/B)\tau}$ equal to 1, which is surely reasonable in this case. τ' determines the time which elapses before "zero time," that is before the time at which the gas is at the temperature T_0, and it is to be added to τ_c before comparing with the experiments. Making the same substitutions as were made to get τ_c in the form (5) we find

$$\tau' = (RT_0^2/E)e^{E/RT_0} - 1\,I' \qquad (16)$$

where

$$I' = \int_{-T'/T^*}^{0} (e^y - 1 - fy)^{-1}\,dy \qquad (17)$$

where $T^* = RT_0^2/E$. We have evaluated I' for a number of values of f for $T'/T^* = 5$ and for $T'/T^* = 10$. These values are given in Table I together with values of I_0. It will be seen from this table that I' is not very sensitive to T'/T^* when the latter is as great as 5, and all our subsequent calculations have been carried out using this value.

Table I

Values of I_0 and I'

f	I_0	$I'(T'/T^* = 5)$	$I'(T'/T^* = 10)$
0.99	40.81	3.091	3.791

.50	3.819	5.152	...

§4. Comparison with Experiment

Tables II and III show all measurements of the induction period with azomethane and all of those made with ethyl azides No. 5 and No. 8,[9]

---

[9] See the discussion by Campbell and Rice, Ref. 2b, of the various samples of azide used.

with the exception of some in which the temperature was uncertain. These runs are arranged in groups, all in any group having been done at the same time and at very approximately the same temperature, and the data for the highest pressure non-explosive run in each group are also given at the beginning of each group. These non-explosive runs are designated by the symbol ∞ in the "t_c, obs." column. In Table IV we give some examples illustrating the method by which Q/C_M is calculated from the observed time. The first row gives the absolute temperature; the second the logarithm of the ratio of the pressure P of the particular experiment to the critical explosion pressure P_1^*; the third row gives the observed induction period in seconds; the fourth row gives log A, which differs in different cases because of the falling off of the rate constant

The apparently anomalous value of t_c for Expt. 217 as compared with Expts. 191 and 192 is due to the former having been performed with a different preparation (probably slightly impure) which gave a higher explosion limit than the preparation used in the latter two experiments.

k^*	0.083	0.049	0.0313
17.6 Θ	.09–0.10	.09–0.10	.08–0.09
I	7.60–7.50	5.61–5.56	10.22–10.02
$-\log f$	0.107–0.111	0.165–0.169	0.074–0.079
I'	3.69–3.71	4.08–4.11	3.49–3.52
t_c (calcd.)	1.39–1.54	2.02–2.24	3.98–4.43
17.6 Θ expt.	0.091	0.089	0.080
Q/C_M	1560	1530	1580

the induction period, obtained from the formula $t_c = 2\Theta(I + I')/k^*$; from these we obtain by comparison with the observed value of t_c and by interpolation the experimental value of 17.6 Θ, and this enables us to calculate Q/C_M from Equation (14). Table IV shows the order of magnitude of the various quantities involved. The first run presented is an extreme case as regards the relative importance of I' and I. In all others, I is considerably larger than I', the other examples given being typical.

In Table V we give in condensed form the results of all calculations of Q/C_M. This table covers all experiments given in Tables II and III in which the pressure was more than 1.04 times the critical pressure. In most cases the critical pressure used was simply the average of the pressures of the highest non-explosive and the lowest explosive runs of the particular group of experiments to which the run belonged, all runs having been made primarily to determine the explosion limits; but in the case of pure azomethane it was considered more accurate (on account of temperature fluctuations in a given series) to draw a smooth curve through the values of P_1^* plotted as a function of T and then to read P_1^* from the curve.

TABLE V

CALCULATION OF Q/C_M AND Q

Expt.	T_0, °K.	Log P/P_1^*	Log A	t_c, obsd., sec.	Q/C_M	C_M cal./mole deg.	Q cal./mole

In order to get Q we have made an attempt to estimate roughly the specific heats of azomethane and ethyl azide. Though the Raman spectra of these substances have apparently not been obtained, we may nevertheless assign approximate frequencies to each of the bonds or modes of vibration in these molecules, on the basis of the Raman spectra of similar compounds.[10] These can then be translated into contributions to the specific heat. Table VI gives the results. The degeneracy values in the second column were obtained from simple geometrical considerations. The azide radical was assumed to be linear. The frequencies in the third column are estimated, following Kohlrausch. The N=N frequencies in both azomethane and ethyl azide are assumed equal to the C=O frequency in ketones. The "skeleton bending" frequencies are merely a very rough guess; but their values are undoubtedly lower than the other frequencies, and since at the temperatures used such low frequencies are nearly fully excited, their exact value does not matter much. Contributions to C_v (fourth column) are calculated for each vibrational de-

---

(10) Kohlrausch, "Der Smekal–Raman Effekt," Verlag Julius Springer, Berlin, 1931, especially pp. 154, 157, 206, 314; *Z. Elektrochem.*, **40**, 429 (1934).

gree of freedom by the formula $C_v = R(h\nu)^2 e^{h\nu/kT}/(kT)^2\,(1-e^{h\nu/kT})^2$, with T taken as 620°K. for azomethane and 550°K. for ethyl azide. The result can lay no great claim to accuracy; we should expect, however, that its probable percentage error is no greater than that of our determination of Q/C_M. In view of the other uncertainties involved we have not thought it worth while to consider the change of specific heat with temperature for the small temperature range available.

TABLE VI

CALCULATION OF SPECIFIC HEATS

Degree of freedom	Degeneracy	ν, cm.$^{-1}$	C_v, cal. per mole
	Azomethane		
Translation	3		2.98
Rotation	5		4.96
C—H stretching	6	2940	0.62
C—N stretching	2	1035	2.52
N=N stretching	1	1714	0.62
C—H bending	10	1430	8.94
Skeleton bending	3	600	5.10
Total C_v for azomethane =			25.7
	Ethyl azide		
Translation	3		2.98
Rotation	5		4.96
C—N stretching	1	900	1.28
C—C stretching	1	1050	1.08
N=N stretching	2	1800	0.81
C—H stretching	5	2940	.27
C—H bending	7	1430	4.87
C—H bending	2	1200	1.83
Skeleton bending	4	400	7.23
Total C_v for ethyl azide =			25.3

Using these values of C_v, we have calculated Q for azomethane and ethyl azide. For the mixtures the formula of §1 for C_M is used, C_G being taken as 3.0 cal. per mole for helium, and 4.9 for nitrogen.[11] The results are given in the last column of Table V.

Over the temperature range for which it is possible to make measurements Q should be approximately constant. It will be seen that the values actually obtained vary considerably, but in view of the considerable errors necessarily involved the variation does not seem excessive. Errors may occur in the actual measurement of the induction period, which is very short, and may also be due to slight changes in temperature during a series of runs, which causes the explosion limit to be determined for a slightly different temperature than that at which the given run was made. Any error in the explosion limit due to this or any other cause produces a relatively large error in Q. But perhaps the greatest source of error is the finite time which is required for the gas to enter the reaction vessel. This was especially great in the case of ethyl azide, as noted in the preceding paper,[2b] and the pressure in the reaction bulb had not, in general, become quite equalized with the storage bulb before the stopcock was closed. However, since the largest portion of the gas undoubtedly rushes in almost immediately, and since in almost all cases the stopcock can be closed before the explosion occurs, we believe that the results are of significance even though considerable error can no doubt be caused, and the effect should be partly neutralized by the fact that the same error enters into the determination of the explosion limit. In general, the variations in Q seem to be quite random, the only apparent exception being the values of Q for azomethane in the presence of nitrogen. It is impossible to say whether this variation, for which no obvious explanation is available, is real or not.

The final average values of Q are 43,000 calories per mole for azomethane and 42,000 for ethyl azide. It is possible that these values not only are subject to the errors inherent in the experiments, but also contain systematic errors due to the assumptions made in the theory, particularly the assumption that the rate at which heat is removed from the vessel is simply proportional to the difference in temperature between the gas and the wall of the vessel. However, since the proportionality constant in this expression does not enter into the final results at all, it seems likely that the result will not be very sensitive to the form of the expression, either. We believe that the values of Q given are probably correct to within about 10,000 calories per mole.

§5. The Attainment of Temperature Equilibrium in a Reaction which Is Not Exothermic

When the rate of an ordinary non-explosive reaction is measured, the gas is admitted to a heated reaction vessel at a certain time, and it is assumed that the time required to heat it to the temperature of the vessel is negligible. The considerations of the present paper give us the possibility of discussing this assumption; we can learn something about heat transfer in non-explosive gases, whose decompositions are slightly exothermic or endothermic (or which do not react at all) by in

---

(11) "International Critical Tables."

ference from the properties of the explosive gases as deduced in the preceding sections of this paper.

The results of the last section show that the length of time required to heat the gas up to the temperature of the vessel is generally only a fairly small fraction of the entire induction period. This is due in part to the fact that, as the temperature of the vessel is approached, the gas begins to decompose, giving out heat and warming itself up. If the reactions were not so exothermic it would take considerably longer for the final temperature adjustment to occur, and if it were endothermic the situation would be even less favorable. In the case in which the reaction neither gives out nor absorbs heat, the rate of increase of temperature is given by Equation (1) with the first term on the right-hand left out, and, using t instead of τ, we see that the time required to heat up the gas from a temperature $T_0 - T'$ to a temperature, $T_0 - T''$, say, is given by

$$t = -\int_{-T'}^{-T''} \frac{C}{ax}\frac{\mathrm{d}T}{T} = \frac{C}{ax} \ln T'/T'' \qquad (18)$$

If we could determine x it would thus be possible to find how long it takes for a gas to heat up to within, say, 1° of the temperature T_0 from a temperature, say, 100° below. Now x can be determined for the explosive gases from the value of f, and we may reasonably assume that it is the same order of magnitude for all gases. From the definitions of f (following Equation (4)) and B, we have

$$\frac{ax}{Qn_0} = VA \frac{E}{RT_0^2} e^{1 - E/RT_0} f = \frac{VEk^*}{RT_0^2} f \qquad (19)$$

Remembering that $C = C_{\mathrm{M}} n_0 V$ we have

$$\frac{ax}{C} = \frac{Q}{C_{\mathrm{M}}} \frac{Ek^*}{RT_0^2} f \qquad (20)$$

Taking, for example, the data from the first run in Table IV we get $ax/C = 6.3$ sec.$^{-1}$, while if $T'/T'' = 100$ then t from Equation (18) is equal to about 0.7 second. In this case the total pressure is about 32 mm. and the experiment was done with a 200-cc. flask. Since C is proportional to n_0 and V it is seen that this time would be increased at higher pressures and with larger vessels. The matter is somewhat complicated by the fact that the results of our previous work[2] indicate that x is not a true constant, but it is fairly obvious that with pressures up to an atmosphere and with conditions under which reaction rates are usually run, the gas will come to nearly the temperature of the flask within at most half a minute. It may be well to note that this is far faster than equilibrium could be established by heat conduction alone, and convection must play an important role in the mechanism of heat transfer.

In the case of a non-explosive run of a gas which does react exothermally, the time necessary to reach what is essentially a steady state temperature should require a length of time of the order of magnitude of the induction period in an explosive run. According to the simple Semenoff theory the temperature rise T should never reach a value greater than $T^* \cong RT_0^2/E$ in a non-explosive run. An examination of Fig. 1 shows that actually in a run near the explosion limit the temperature surges up above that value and then drops back again. Excepting for a run exceedingly close to the explosion limit we may judge from Fig. 1 that all this will take place in a time not more than two or three times that occupied by the actually observable induction periods. Since this time is, in general, small compared to the half life of the decomposing substance, the calculation made in §5 of the paper of Allen and Rice[2a] should be valid in almost all cases.

Appendix

The solution of the functional equation (12) may be obtained by a series of successive approximations in the following manner. We define a quantity f' by the equation

$$f = f' e^{-\Theta I_0(f')} \qquad (\mathrm{A})$$

and take as a first approximation to $I(f)$ the quantity $I_1(f)$ defined by

$$I_1(f) = e^{\Theta I_0(f')} I_0(f') \qquad (\mathrm{B})$$

We then insert this quantity $I_1(f)$ into the right-hand side of Equation (12) in place of $I(f)$ to get a second approximation

$$I_2(f) = e^{\Theta I_1(f)} I_0(f e^{\Theta I_1(f)}) \qquad (\mathrm{C})$$

We now insert $I_2(f)$ into the right-hand side of Equation (12) and continue the process, getting finally for the nth approximation

$$I_n(f) = e^{\Theta I_{n-1}(f)} I_0(f e^{\Theta I_{n-1}(f)}) \qquad (\mathrm{D})$$

If the process converges, that is, if $I_n(f)$ approaches a limit as n becomes large, then it is easily seen that the limiting value of $I_n(f)$ satisfies Equation (12) and may thus be identified with $I(f)$. That the process does converge readily appears when one attempts to carry it out; in fact, I_1 is a sufficiently good approximation for our purposes and has been used in Fig. 2. The easiest way to get I_1 as a function of f is to start with given values of f' and Θ. Equation (A) then determines a value of f and Equation (B) gives the corresponding value of I_1; together they give a point on the curve for the given value of Θ.

Summary

When the differential equation connecting temperature with time in an exothermic gas reaction is integrated, a sudden temperature rise, corresponding to an explosion, is found to be indicated above a certain sharply defined pressure. From curves of this type, an approximate method for calculating the induction period in thermal explosions has been obtained, and has been applied to the explosions of azomethane and ethyl azide. Rough values of the heats of decomposition of these compounds are thereby obtained. A discussion is given of the rate at which a gas not reacting exothermically comes into thermal equilibrium when admitted to a heated vessel.

The Hydrogenation of Carbon Dioxide and a Correction of the Reported Synthesis of Urethans

BY MARK W. FARLOW AND HOMER ADKINS

In an attempt to prepare N-pentamethylene salicylamide through the reaction of methyl salicylate and piperidine at 250° under hydrogen, Wojcik and Adkins[1] obtained a product which they reported as phenyl N-pentamethylene urethan, *i. e.*, $C_6H_5OC(O)NC_5H_{10}$. They suggested that the supposed urethan might be formed through the decarboxylation of salicylic acid followed by the reaction of phenol, carbon dioxide and piperidine. They apparently confirmed this hypothesis by obtaining the same product from phenol, carbon dioxide and piperidine as from methyl salicylate and piperidine. A further study of the postulated reaction has shown that the alleged urethan was a mixture of phenol and formylpiperidine, $C_5H_{10}NC(O)H$. An equimolecular mixture of these two compounds has a constant and narrow boiling range about 10° higher than either component and shows an analysis for nitrogen very nearly the same as for the urethan. Similarly, the products reported as phenyl N-*n*-amyl and *n*-butyl-N-pentamethylene urethans have been found to be mixtures of formyl amines with phenol or butanol-1.

The identification and isolation of formylamines from the reaction products of hydrogen, carbon dioxide, amines and alcohols led to a study of the hydrogenation of carbon dioxide. The significant numerical results are given in the table and may be summarized as follows.

The hydrogenation of carbon dioxide to formic acid in the presence of an amine takes place at 80° or less over Raney nickel.

$$CO_2 + H_2 \longrightarrow HCO_2H$$
$$HCO_2H + RNH_2 \longrightarrow HCO_2NH_3R$$

For example, after one hour at 80° 1-Ph-2-aminopropanol-1 was converted to the formate in a yield of 55% based upon the amine, the carbon dioxide and hydrogen being in excess. The rate and temperature necessary for hydrogenation apparently varies with the structure of the amine as well as with the catalyst. At a sufficiently high temperature (250°) sheet brass, such as has been used in this Laboratory for fabricating liners for steel reaction vessels, is an active catalyst for the hydrogenation. If the hydrogenation is carried out at a temperature much above 100° in the presence of a primary or secondary amine, the formate is dehydrated and the amide (formylamine) is obtained.

$$HCO_2NH_3R \longrightarrow HC(O)NHR + H_2O$$

Since a variety of substances may be present under the conditions used for the hydrogenation, it is not possible to formulate with certainty the course of the reaction. Carbon dioxide might react with a primary or secondary amine with the formation of a carbamate

$$2R_2NH + CO_2 \longrightarrow R_2NC(O)ONH_2R_2$$

or since traces of water are present a carbonate might be formed

$$R_2NH + CO_2 + H_2O \longrightarrow (R_2NH_2)_2O_2CO$$

Dehydration of the carbonate would give the

TABLE I

HYDROGENATION OF CARBON DIOXIDE IN PRESENCE OF AMINES[a]

	T, °C.	Time, hours	G. catalyst	Moles	Yield of products
2,2,6,6-Tetra-Me-4-OH piperidine (in EtOH)	100	6	5 Ni(R)	0.10	57% formate of amine
2,2,6,6-Tetra-Me-4-OH piperidine (in EtOH)	100	3	5 Ni(R)	.10	47% formate of amine
Piperidine (in EtOH)	150	9	5 Ni(R)	.25	76% N-formyl-piperidine[b]
n-Amylamine (in EtOH)	150	5	5 Ni(R)	.25	45% N-formyl-*n*-amylamine
1-Ph-2-aminopropanol-1 (in EtOH)	80	1	5 Ni(R)	.04	55% formate of amine
α-Oximinopropiophenone (in EtOH)	80	1	5 Ni(R)	.10	[c]Formate of 1-Ph-2-NH_2-propanol-1
N-*n*-Bu-2-Me-piperidine (in EtOH)	100	6	5 Ni(R)	.10	[c]Formate of amine
Piperidine (in phenol)	250	5	Brass	.50	50% N-formylpiperidine
β-Ph-Et-amine (in phenol)	250	4	Brass	.50	35% N-formyl-β-Ph-Et-amine
n-Amylamine (in phenol)	250	5	Brass	.50	33% N-formyl-*n*-amylamine

[a] Carbon dioxide was admitted to the amine dissolved in EtOH or PhOH until the pressure was constant at about 60 atm. Hydrogen was admitted until the total pressure was 100 to 200 atm. The bomb was then heated to the indicated temperature, the pressure being then 200 to 400 atm. [b] The percentage yield as given is based upon analysis for nitrogen of the product which was made up of the formylpiperidine and phenol. [c] Formic acid was identified but the formate was not isolated in sufficient purity to justify the calculation of a % yield.

TABLE II

PROPERTIES AND ANALYSES OF PRODUCTS

Name	B. p. or m. p., °C.	Formula	Analyses, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found

N-Formyl-β-phenylethylamine	180–181 (14 mm.)	$C_9H_{11}NO$	72.4	72.4	7.45	7.54
N-N′-Di-*n*-amyl urea	88 (m. p.)	$C_{11}H_{24}N_2O$			N, 14.00	14.01
β-Phenylethylamine formate	128–129 (m. p.) (dec.)	$C_9H_{13}NO_2$	64.7	64.65	7.84	7.89
2,2,6,6-Tetramethyl-4-hydroxypiperidine formate	207 (m. p.) (dec.)	$C_{10}H_{23}NO_2$	59.1	59.2	10.43	10.35
1-Phenyl-2-aminopropanol-1 formate	160 (m. p.) (dec.)	$C_{10}H_{15}NO_3$	60.9	60.8	7.69	7.67

carbamate and further dehydration a disubstituted urea. The latter type of product was actually isolated in two instances. The action of hydrogen upon these various types of compounds might well result in the formation of a formyl amine. However, since formates were obtained even with primary amines and since a tertiary amine was as effective as primary and secondary amines in facilitating the hydrogenation of carbon dioxide there seems no reason to assume that the amine plays any other role than to neutralize the formic acid produced by direct hydrogenation.

The formyl derivatives reported in Table I were isolated by fractionation of the reaction mixture through a Widmer column. These various formyl derivatives showed the physical properties and analyses given in Table II. Formylpiperidine[2] was also identified through the preparation of a double salt with mercuric chloride, m. p. 147–148°. The derivative was prepared by heating 5 g. of mercuric chloride and 1 ml. of formylpiperidine in 100 ml. of water until solution was complete. The derivative crystallized out upon cooling the solution and was recrystallized from a mixture of ethyl acetate and petroleum ether. Since formylpiperidine and phenol cannot be separated by fractional distillation the mixture was dissolved in alkali and the amide extracted with ether. The mercuric chloride derivative was then prepared from the material extracted by ether.

The formates were isolated by crystallization from mixtures of alcohol and ether or alcohol and ethyl acetate. Because of the solubility of these salts the yields reported in Table I are in all cases considerably less than the amount of amine formate produced. This is especially true of the formate of 1-Ph-2-amino-propanol-1. The formates were identified by analysis and by comparison with authentic specimens prepared from equimolecular quantities of amine and formic acid in ether.

Diamyl urea $(C_5H_{11}NH)_2CO$ (4.5 g.) and *sym*-diphenylethyl urea[3] $(C_6H_5CH_2CH_2NH)_2CO$ (5.0 g.) were isolated from the reaction products of the last two experiments recorded in Table I.

Summary

Carbon dioxide may be hydrogenated to formic acid in the presence of a variety of amines. If the hydrogenation is carried out at a temperature much above 100°, the formate of the amine may be dehydrated to the substituted formamide.

Surface Potentials and Force–Area Relations of Monomolecular Films. II. *d*-Pimaric Acid and Tetrahydro-*d*-pimaric Acid

BY WILLIAM D. HARKINS, HERMAN E. RIES, JR., AND EVERETT F. CARMAN

I. Introduction

Through the kindness of Professor Ruzicka the writers have been able to investigate the surface potentials and force–area relations of *d*-pimaric acid, an unsaturated compound, and tetrahydro-*d*-pimaric acid, the corresponding saturated compound. These compounds contain a phenanthrene residue, and are related to certain hormones and vitamins. The carboxyl group is displaced one position from the hydroxyl group of cholesterol, and the area for the pimaric acid is slightly larger.

II. Apparatus and Procedure

The apparatus and general procedure are essentially the same as described by Harkins and Fischer.[1] The modifications that have been introduced will appear in a paper which is now being prepared for publication. A more recent improvement will be discussed here in connection with the method adopted to obtain "zero" or clean surface potentials. It has increased the accuracy of the surface potential values.

The procedure is as follows. The trough is filled with the aqueous solution (0.01 molal hydrochloric acid in these experiments) and the surface swept several times to remove initial contamination. The electrode is then lowered into a position 2 to 3 mm. above the surface and the cage closed. The system is allowed to remain in this condition for about one hour. It seems that during this time most of the additional contamination settles out from above the surface and rises from below. At the same time the surface of the silver–polonium electrode reaches equilibrium with the water vapor.

One of the features of the procedure involves the use of mechanical arms to perform the final sweepings without opening the cage or otherwise disturbing the immediate surroundings of either the surface or the electrode. It is unnecessary to raise the electrode in order to accomplish the final sweepings as thin barriers have been constructed which easily pass under the lowered silver–polonium disk. After the hour has elapsed, the surface is swept until the potential is constant to within 1 mv. for periods of ten to twenty minutes. Readings are taken immediately after the individual sweepings to ensure a clean surface during the measurement. The additional barriers for the final sweepings are taken from racks conveniently suspended above the two ends of the tray.

The importance of an accurate clean surface potential cannot be overemphasized, as it is obvious that an error here vitiates all of the film potential values. It might be added in connection with these precautions that capillary active contamination falling on the spread films has a negligible effect on the potential compared to the change introduced by the same contamination on a cleaned surface.

The films were spread from redistilled benzene solutions on 0.01 molal aqueous hydrochloric acid. Surface potential and pressure measurements were made simultaneously at minute intervals. The experiments were carried out at room temperature (28 to 30°).

III. Pressure–Area Relations and Thickness of the Films

The saturated and unsaturated compounds form monomolecular films, which give almost identical pressure–area curves until collapse begins (Figs. 1, 2 and 3). The film which is composed of the unsaturated compound withstands higher pressures than that of the saturated, and its maximum pressure is about 17 dynes on 0.01 molal hydrogen chloride. The film pressure of the unsaturated compound approaches a state of equilibrium. The maximum thickness of the mono-layer is about 12 Å. for both compounds, or slightly less than half that for a similar film of stearic acid. These compounds exhibit orientation of the perpendicular type. The films are much thicker than those in which a single chain lies flat in the surface.

The films are highly compressible, and the coefficient $[a_0 - a_1)/a_0]/(f_1 - f_0)$ has a value of 0.0068 for the saturated acid and 0.010 for the unsaturated compound.

The extrapolated molecular area at zero pressure for both the saturated and unsaturated compounds is about 53 sq. Å. but it seems possible to compress the films to an area of about 43 sq. Å. before collapse occurs. This is practically the area of two hydrocarbon chains. Our unpublished data on large rings up to thirty-four carbon atoms in the ring, and the values of Büchner, Katz and Samwel[2] on rings up to thirty carbon atoms, also give minimum areas equal to that exhibited by two single oriented hydrocarbon chains.

---

[1] Harkins and Fischer, *J. Chem. Phys.*, **1**, 852 (1933).

[2] Büchner, Katz and Samwel, *Z. physik. Chem.*, **B5**, 327 (1929).

The work of Harkins and Morgan[3] showed that phenanthrene spreads on water only when much salt is present. The compounds used in our work are much more saturated, which probably reduces resonance in the molecule, but has only a minor effect on the polarity. However, the presence of the dipole due to the carboxyl group, as is usual, orients the molecule with this group toward the water.

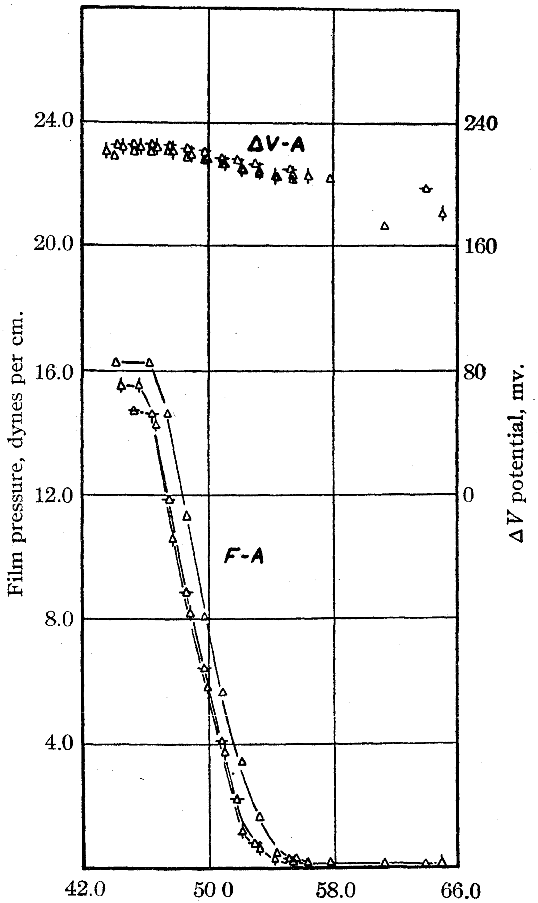

Fig. 1.—Tetrahydro-*d*-pimaric acid on 0.01 molal hydrochloric acid.

	Expt.	Temp. °C.
Δ	199	28.0
Δ̩̍	200	28.0
-Δ-	206	29.5

IV. Structure and Orientation of the Pimaric Acids

It is of interest to compare the structures and orientations in films of the pimaric acids with those of cholesterol. If the side chains, which, due to interpenetration of the molecules probably contribute very slightly to the cross-sectional area, are neglected the similarity between the pimaric acid nucleus (phenanthrene residue) and the A, B, C ring structure of cholesterol (Fig. 4) is obvious. The significant point of difference is the location of the polar, water-attracting group.

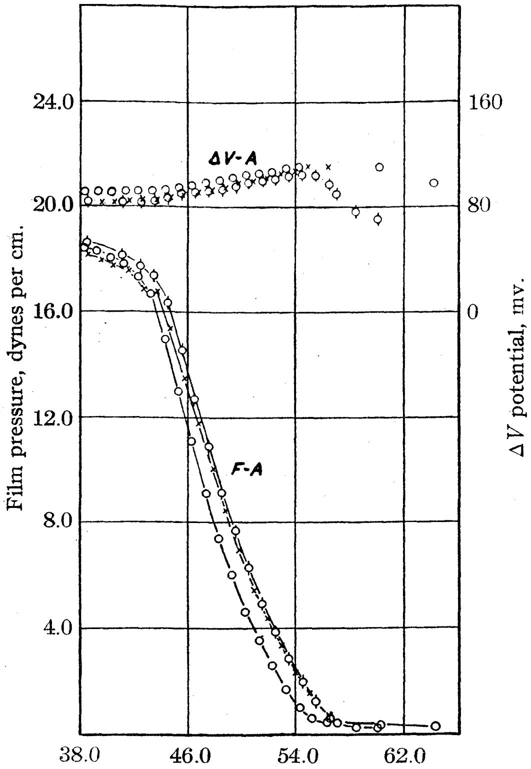

Fig. 2.—*d*-Pimaric acid on 0.01 molal hydrochloric acid.

	Expt.	Temp. °C.
×	197	30.0
ϕ	198	28.0
○	205	28.0

In pimaric acid the carboxyl group is on carbon atom number 4, whereas in the cholesterol compound the hydroxyl group occupies position number 3. It is evident that if the molecule is oriented so that the polar group is located at the lowest point, one would expect the pimaric acids should be tilted in such a way as to occupy more area in the surface than the vertically oriented cholesterol. The cross-sectional area of a molecule obtained from film balance measurements is of course dependent on the orientation.

Measurements of molecular models indicate that for oriented sterol ring systems with the polar group in position 3, the cross-sectional area should be about 37 sq. Å. and for the same system with the polar group in position 4 about 42

---

(3) Harkins and Morgan, *Proc. Nat. Acad. Sci.*, **11**, 637 (1925).

sq. Å. Measurements on models and the effects of the positions of polar groups in similar compounds have been discussed in a paper by Danielli and Adam.[4] The calculations agree quite well with the film areas per molecule at the collapse pressure. The area obtained for the unsaturated acid at the collapse pressure is about 43 sq. Å. The extrapolated area, 53 sq. Å., is considerably greater because of the expanded nature of the film.

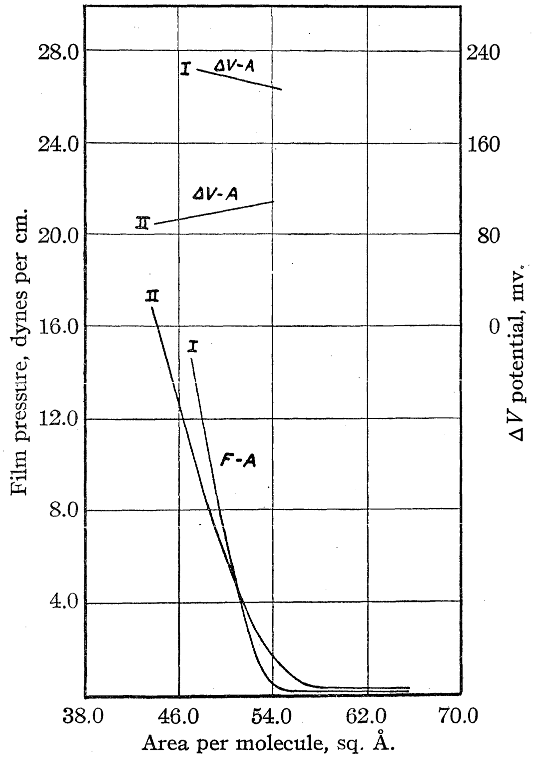

Fig. 3.—Average curves: I, tetrahydro-*d*-pimaric acid; II, *d*-pimaric acid.

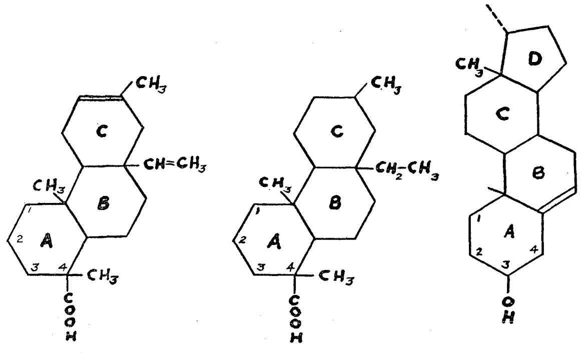
It may be noted here that the curve of the more condensed film of tetrahydro-*d*-pimaric acid crosses the curve for the unsaturated acid. Consequently, the reduced compound has a larger area at the collapse point and a smaller extrapolated area at zero pressure than does the unsaturated acid. The increased polarity of the unsaturated compound is probably the cause of the expanded nature of the film. This will also account for the greater adhesion to the water surface and the resultant higher pressure.

V. Surface Potentials

The surface potential (ΔV), defined as the difference in the contact potential when the film is present and when it is absent, exhibits some anomalies not previously found. The surface potentials of the condensed films are low, with a value of about 100 mv. for the unsaturated and about 200 mv. for the saturated compound. The film of *d*-pimaric acid exhibits a behavior heretofore unobserved in that the surface potential of the condensed film *decreases* as the film is compressed.



(a) (b) (c)

Fig. 4.—Vertical orientation of molecules at air–water interface: (a) *d*-pimaric acid; (b) tetrahydro-*d*-pimaric acid; (c) cholesterol (chain omitted).

In connection with the surface potential of tetrahydro-*d*-pimaric acid, it should be noted that the measurements for this compound gave about 200 mv., which is approximately half of the value obtained for a straight chain acid of the type of stearic acid. This is largely because the area per molecule or area per polar group for this reduced pimaric acid is roughly twice that of the stearic acid type, so its polar group surface density is approximately half that of condensed stearic acid films. However, there are a number of complicating factors which include effects due to orientation of adjacent dipoles, water dipoles, and shifts of electrolyte ions.

As indicated above the surface potential of the unsaturated *d*-pimaric acid is about 100 mv., or one-half that of the saturated compound, although the two substances have practically the same molecular surface density. One would therefore be led to believe that the dipoles associated with the double bond in the ring or in the side chain or possibly in both are oriented in such a way as to oppose the dipole of the carboxyl group, even at the initial stages of the compression. Then, on compression, further internal opposition or compensation of the dipoles may be said to result in the decreasing surface potential observed. As shown by Harkins, Ries and Carman[5] the surface

---

[5] Harkins, Ries and Carman, This Journal, **57**, 776 (1935).

potential (ΔV) may rise considerably less rapidly than the surface density of the film (13% less rapidly in the case of certain polymers of ω-hydroxydecanoic acid). This is usually attributed to the mutual effect of the surrounding dipoles. However, it is quite probable that in the case of the *d*-pimaric acid, the conspicuous *decrease* in the surface potential with increased surface density is due to a changing orientation of the individual molecules in such manner as to further the opposition or compensation of the intramolecular dipoles.

Additional studies relating potential variations to temperature changes are now in progress.

VI. Summary

1. Surface potential and force–area relations for monomolecular films of a saturated and unsaturated pimaric acid were studied. The corresponding curves are shown.
2. An improved procedure for obtaining more accurate clean-surface potentials is described.
3. The maximum thickness of the mono-layer is about 12 Å. for both compounds. The coefficients of compressibility are calculated.
4. The structures of the pimaric acids are compared with that of cholesterol, and their orientations in surface films are related to the different positions in which the polar groups are located. The experimental data compare favorably with the results to be expected from model measurements.
5. The surface potential of the tetrahydro-*d*-pimaric acid is about 200 mv., whereas that of the unsaturated compound is about 100 mv. An unprecedented decrease in the surface potential on compression was observed in the case of the unsaturated acid films. It is considered probable that these facts may be related to an increasing intramolecular dipole compensation on compression.

Heterogeneous Reaction Kinetics. The Effect of Light Exposure on the Kinetics of Thermal Decomposition of Silver Oxalate

BY ARTHUR F. BENTON AND GEORGE L. CUNNINGHAM

In reactions of the type A(s) = B(s) + C(g), which are normally autocatalytic in nature, existing evidence shows that the rate depends on two separate factors, formation of nuclei of product and subsequent growth of these reaction centers. However, a satisfactory quantitative treatment of the kinetics has not yet been attained. With this objective in view we have studied, both experimentally and theoretically, the rate of decomposition of a light-sensitive solid on which nuclei have previously been produced by controlled irradiation.

Silver oxalate was chosen as a suitable material, since it decomposes at convenient temperatures and apparently yields only silver and carbon dioxide, uncomplicated by side reactions. MacDonald and Hinshelwood[1] found the reaction to be autocatalytic, and the rate sensitive to adsorbed ions and to oxygen. Sheppard and Vanselow[2] showed that sulfur compounds greatly accelerate the reaction. Arens and Eggert[3] found that silver oxalate–gelatine plates were made developable by exposure, and resembled silver chloride emulsions both in sensitivity and spectral range.

Experimental Methods

Approximately 1-g. samples of silver oxalate were decomposed in the dark in Pyrex bulbs heated by suitable vapor baths provided with electric heating and regulated pressure. The evolved gas was continuously removed by means of a Sprengel pump and fed into the lower end of a water-jacketed, mercury-filled buret, where its volume was measured at regular intervals. Absence of leaks in the all-glass apparatus was assured by overnight test before each experiment.

In the later experiments (Oxalate II), samples were illuminated when desired with light from a 1000-watt tungsten-filament lamp provided with a reflector. The light, after traversing in order a lens system, 6 cm. of running water, a suitable color filter and a shutter, was reflected downward to the bulb by a metallic mirror. The filter was Corning G586AW, which transmits from about 320 to 400 mμ, with a maximum at 370 mμ. All exposures were made with the oxalate at room temperature. The

sample was contained in a cylindrical bulb 4 cm. in diameter, closed at the top by fusing to a plane disk of Pyrex glass. At its lower end the bulb was drawn down to a funnel shape, terminating in a 2-mm. capillary, through which air or other gas was drawn in, to stir the sample during exposure. This procedure occasioned only a negligible loss of sample, *e. g.*, 1.7% in eight hours.

The light absorbed by the oxalate was measured by surrounding the reaction bulb with a 2-mm. layer of a 1% solution of *o*-nitrobenzaldehyde in purified acetone. Based on the measurements of Hyman, quoted by Weigert and Brodman,[4] this arrangement absorbed 99.6% of λ 366, and thus substantially all the light in our experiments, centering at 370 mμ. The light absorbed by the solution, at least between λ 366 and λ 436, produces 0.5 molecule of *o*-nitrosobenzoic acid per quantum.[5] The acid was determined by conductance measurements, with known mixtures of aldehyde and acid containing a constant total amount (1%) of the two isomers as standards. For stirred samples 40 to 50% of the incident light was absorbed.

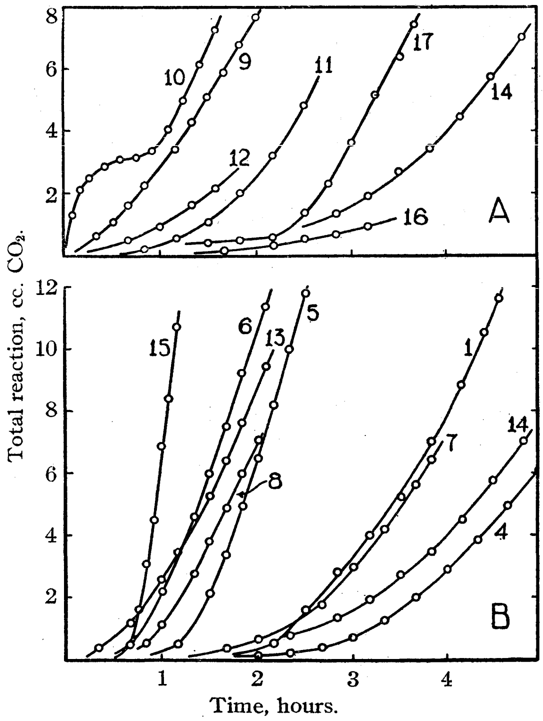

Fig. 1.—Decomposition of oxalate I: effect of various factors (Table I).

Materials.—The first batch of silver oxalate (Runs 1–17) was prepared by continuously adding, during seventy-five minutes, a solution of 25 g. of C. P. silver nitrate in one liter of distilled water to a solution containing 20 g. of C. P. sodium oxalate dissolved in 3 liters of water, with vigorous mechanical stirring. After ten thorough washings the precipitate was dried in a vacuum desiccator over sulfuric acid. Exactly the same procedure was followed for the second batch. The oxalate was prepared and stored in a dark room, only a minimum of red light being used when necessary.

Experimental Results

In the data given below, the course of reaction is expressed as total cc. of carbon dioxide evolved by the whole weight of sample as a function of time. The gas volumes represent an average temperature of 26° and an average pressure of 750 mm. (at 0°). Since we were primarily interested in the earlier stages, the reaction was usually followed only to 5–10% of completion, except at higher temperatures.

Silver Oxalate I.—The experiments with this preparation were designed to show the influence of various factors on the course of decomposition. All except Run 15 were made at 100 ± 0.2°. The results are shown in Fig. 1 (A and B), and the necessary data in Table I. All exposures were made with a 100-watt tungsten filament lamp at a distance of 20 cm. The numbers listed in Column 4 of Table I give the disposition of the samples during exposure: (1) spread out in thin layer in air, (2) stirred magnetically in vacuum, (3) stirred in water, then dried in air. Color filters were used only in Run 11 (Wratten 16, passing λλ > 520 mμ) and Run 12 Wratten 47A, passing λλ 360–520).

oxalate, by the presence of carbon dioxide, or by contact of the sample with *foreign* particles of silver. The rate was somewhat increased by fine grinding. Previous exposure to light greatly increased the rate, the effect being relatively greater for shorter exposures. Wave lengths longer than 520 mμ were surprisingly effective, but the effect per quantum was undoubtedly much greater for shorter wave lengths.

After the last point shown for Run 7, a twelve-hour exposure at room temperature produced 0.06 cc. of gas. That light alone could effect decomposition was also indicated by the discoloration from exposure in Run 10. On carrying Run 8 to completion the evolved gas was 99.6% of theoretical; not more than 0.04% was unabsorbed by potassium hydroxide.

Silver Oxalate II.—With this material all exposures were conducted as described under "Methods." The results of a series of runs at 100°, with different stirring gases during exposure, are shown in Fig. 2A, and the pertinent data in Table II. It may be observed that the unexposed sample (19) decomposed much more slowly than Oxalate I, in spite of the identical method of preparation. Another run (18) under the same conditions gave results practically identical with 19. Contact with air (Run 22) retarded the initial decomposition, doubtless due to the strong chemosorption of oxygen by silver,[6] but this effect was later overcome. During the exposure in Run 26 the sample evolved 0.05 cc. of gas, or 0.12 molecule per quantum absorbed.

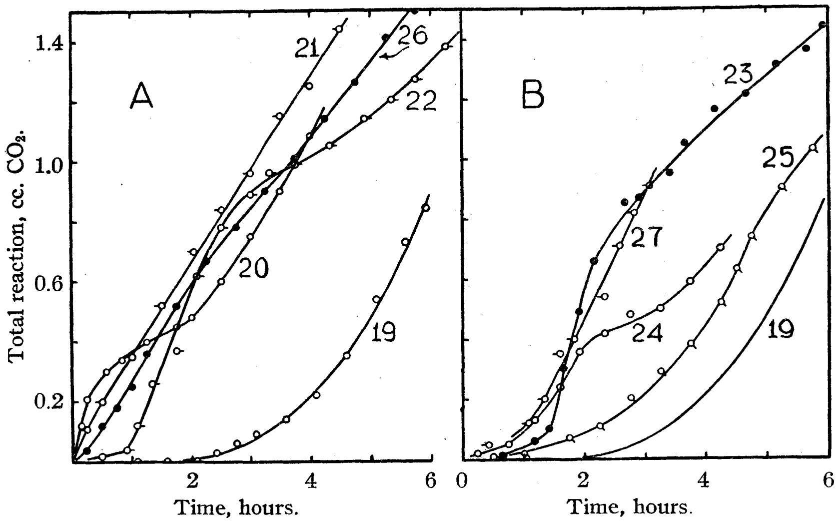

Fig. 2.—Decomposition of oxalate II at 100°: A, effect of gas used for stirring during exposure (Table II): B, effect of exposure time (Table III).

TABLE II

RUNS AT 100° FOLLOWING EXPOSURE IN DIFFERENT GASES

Run	Wt., g.	Gas	Exposure, hr.	Quanta absorbed × 10⁻¹⁸
19	1.42	None	0	0
20	0.91	CO_2	8	7.1
21	1.02	N_2	8	8.7
22	1.09	Air	8	5.5
26	1.42	None	20	11.9

Figure 2B shows the results obtained at 100° with samples previously exposed for varying times, all being stirred with air. Table III gives the necessary data. It is evident that while these early stages of the reaction are more rapid with increasing exposure, the effect is relatively much less for the longer exposures.

A series of runs at 118°, following varying exposure with air stirring, is detailed in Table IV and in Fig. 3, where *rate* is plotted against time. At this temperature exposure evidently has relatively little effect, but the actual increase in total reaction at any time, as compared with unexposed samples, is much greater than at 100°.

(6) Benton and Drake, THIS JOURNAL, **56**, 255 (1934); Drake and Benton, *ibid.*, **56**, 506 (1934).

In Run 44 the unexposed sample was subjected to occasional rapid changes in temperature between 117 and 100°. Comparison of the average of the rates at 117° before and after each temperature change with the intervening rate at 100° gives ratios of 5.1, 3.9 and 4.5, or an average of 4.5. The general effect of a wider range of temperature on unexposed samples is shown in Fig. 4, to which the following data apply.

Run	19	42	34	37	30
Wt., g.	1.42	1.38	0.90	0.92	1.30
Temp., °C.	99.9	109.8	118	131	138

At the upper limit of the curves shown for Runs 30 and 37 the samples exploded.

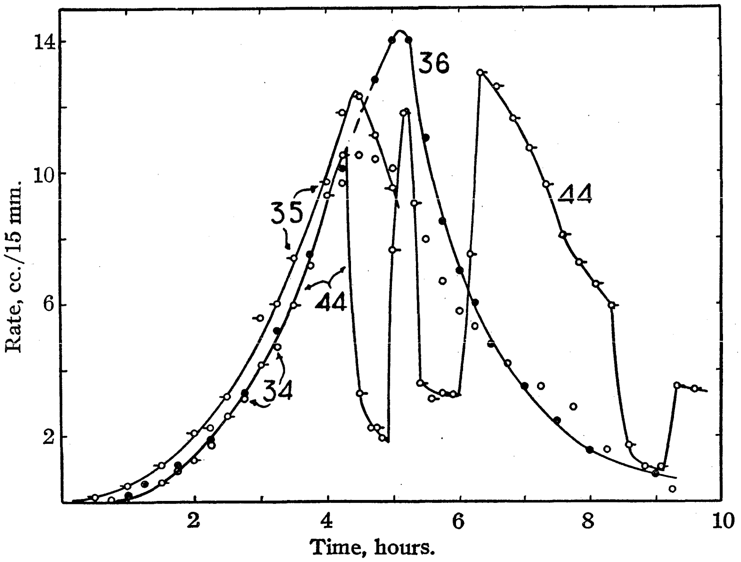

Fig. 3.—Rate of decomposition of oxalate II at 118° (Table IV).

At 80° a 1.53-g. sample gave no measurable evolution of gas in thirteen and one-half hours. Another sample (1.20 g.) gave no gas in seven hours at 80°; on changing the bath temperature to 100°, the course of reaction was practically identical with that in Run 19 where the sample had not been preheated. Hence the rate of formation of nuclei at 80° must be inappreciable. A third sample (1.15 g.) was exposed to room light for thirty minutes and then heated for two and three-tenths hours at 80°, during which time not more than 0.01 cc. of gas was evolved. When the temperature was raised to 100° decomposition began at once in the normal manner for exposed samples. After 0.6 cc. had been given off, the temperature was brought back to 80°, where in two and one-half hours only 0.02 cc. was evolved. Thus the rate of growth of nuclei at 80° is extremely small, but appreciable.

A single granule of Oxalate II, weighing perhaps 1 mg., was decomposed at 118° in a tiny bulb protected from light (Run 45). The evolved gas was measured by the depression of the mercury level in an adjoining 1-mm. capillary, the pressure being maintained at 1 mm. When readings (cm.) on the capillary are plotted against time, the curve is almost identical with that shown in Fig. 4 for Run 42.

Silver Oxalate III.—This material was prepared in exactly the same manner as I and II except that, instead of a slight excess of sodium oxalate, a 100% excess of silver nitrate was used. In a run at 100° an unexposed sample (1.27 g.) gave yields only about half as great as Oxalate II (Run 19). Another sample (1.11 g.), exposed for one hour exactly as in Run 24, gave rates at 100° practically identical with the latter. Although it is possible that adsorbed silver nitrate retards the reaction, the much greater difference in activity between Oxalate I and II, which were prepared alike, renders this conclusion doubtful.

Theoretical Results

The following considerations are based on the assumption that the formation of nuclei and their subsequent growth are essentially independent processes. Without sharply defining the size of a "nucleus," we may let the number of them which have formed up to time t equal n. Let the volume of the solid which has reacted around a particular nucleus be $x = f(t - \tau)$, where τ is the time at which the nucleus came into existence, and f is some function. Then at any time the number $\mathrm{d}n$ of nuclei which appeared in the interval $\mathrm{d}\tau$ will have spread through a volume $x\mathrm{d}n$, and the total volume decomposed at time t will be

$$V = \int_{\tau=0}^{\tau=t} x\mathrm{d}n \qquad (1)$$

To integrate this expression it is necessary to make assumptions regarding the variation of x and n with time.

Solutions of the problem for certain special cases have already been given. Thus Topley and Hume[7] assumed that reaction in each particle spread from a single nucleus, and that all particles were nucleated simultaneously at zero time. Bradley, Colvin and Hume,[8] assuming nucleation according to a probability law, treated the case in which the reaction, once started on a particular granule, spreads instantaneously over its whole surface. In each case the relations obtained were successful in reproducing the later stages in the decomposition of certain salt hydrates, but failed to account adequately for the earlier stages. It is our belief that the early stages of interfacial reactions are particularly amenable to a general treatment, such as that which follows.

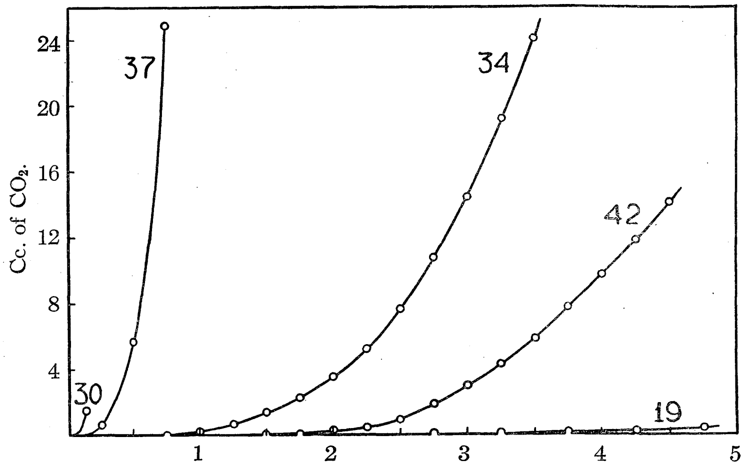

Fig. 4.—Decomposition of oxalate II (unexposed) at different temperatures.

In single crystals decomposition, once started, has been found to progress in directions parallel to prominent lattice planes,[9] and with a *constant* velocity characteristic of each direction.[10] The porous, disperse product remaining usually retains the gross size and shape of the original material, and exerts no retarding effect on the rate. Let u be the *mean* linear velocity of advance of the interface. Then the volume decomposed at any time becomes $u^3(t - \tau)^3$ if the nucleus appeared at a corner, twice this if the start occurred on an edge, and four times if it began on a face. If reaction is assumed to spread out with a spherical front, these values must be multiplied by $\pi/6$. In general we may write for the volume decomposed

$$x = Bu^3(t - \tau)^3 \qquad (2)$$

Since most workers have observed that nucleation occurs preferentially at corners, B will doubtless be near unity. Even for a typical microcrystalline material, complicated by intergrowths and other irregularities, Eq. 2 might be expected to hold for a given granule until the reaction zones spreading from two or more neighboring nuclei begin to overlap.

The problem of the rate of formation of nuclei is less clear. An obvious assumption is that $\mathrm{d}n = k(N - n)\mathrm{d}\tau$, where n is the number formed up to time τ, and N is the total number of potential nuclei in the whole sample (possibly "active spots"), all assumed equally active. This expression leads to $\mathrm{d}n = k(N - n_0)e^{-k\tau}\mathrm{d}\tau$, where n_0 is the number of nuclei, if any, present at the start.

With these values inserted in Eq. 1 the total volume decomposed at time t becomes

$$V = \int_{\tau=0}^{\tau=t} Bu^3(t - \tau)^3 k(N - n_0)e^{-k\tau}\mathrm{d}\tau$$
$$= k(N - n_0)Bu^3\,[6e^{-kt}/k^4 + (t^3/k)(1 - 3/kt + 6/k^2t^2 - 6/k^3t^3)]$$

If the exponential term is now expanded as a power series in t, all terms below t^4 cancel, and

$$V = (k/4)(N - n_0)Bu^3t^4(1 - kt/5 + k^2t^2/5\cdot 6 - \cdots)$$

But this does not include the reaction due to growth of the n_i nuclei, such as those produced by irradiation, which were present at zero time. Including these, and multiplying by the ratio r of measured product (in our case cc. of carbon dioxide) to the volume of solid reactant, we have for the total yield

$$Y = r[(k/4)(N - n_0)Bu^3t^4(1 - kt/5 + \cdots) + n_iBu^3t^3 - v_0n_i] \qquad (3)$$

n_i and n_0 will be equal provided photochemical and thermal nucleation involve the same "active spots." The last term, representing the purely photochemical yield in the production of the n_i nuclei, each of volume v_0, may be neglected. Unless the rate of nucleation k is very great, the higher terms in the parentheses are also small; thus when $n = N/3$, $kt/5$ is only 0.08. Hence, as a fair approximation for the earlier stages, the yield for unexposed samples (n_i and $n_0 = 0$) should vary nearly as t^4, with a smaller average

power of t for exposed samples. These relations will of course fail to hold after the time when the first granules nucleated have been completely decomposed.

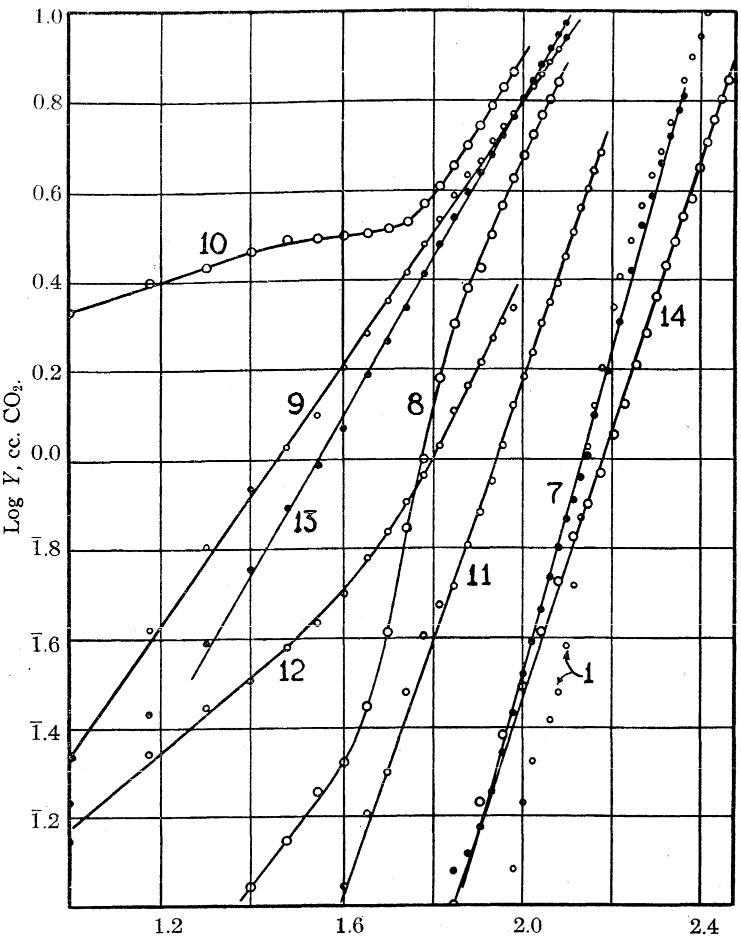

Fig. 5.—Log–log plot for decomposition of oxalate I at 100°.

TABLE V

OBSERVED AND CALCULATED YIELDS IN RUN 44

$Y = 1.176 \times 10^{-7}t^{3.60}$

Time, min.	Y, obsd., cc.	Y, calcd., cc.
60	0.21	0.30
75	.69	.66
90	1.29	1.28
105	2.24	2.22
120	3.52	3.59
135	5.47	5.49
150	8.07	8.03
165	11.4	11.3
180	15.6	15.5
195	20.5	20.6
210	26.4	26.9
225	34.3	34.6
240	43.6	43.6
255	54.1	54.2

It has been assumed that the reaction, even though its early rate may be very small, actually begins at zero time, in other words there is no "incubation" period. This is the case for silver oxalate decomposition and nearly all other interfacial decompositions. The mechanism of nucleation here assumed cannot be applied to cases, such as many reduction reactions, where a real incubation period occurs.

Discussion

The above development suggests that plots of log Y *versus* log t should give nearly straight lines for the earlier stages of decomposition. (Complete decomposition of a 1-g. sample is equivalent to Y = 160 cc.) Such plots for representative runs are shown in Figs. 5 and 6. In the majority of cases the curves closely approximate straight lines. Prolonged exposure tends to make the early yield relatively too large. In a few cases the curves are S-shaped, particularly in Run 8 (also 5 and 6) where the sample was exposed in air without stirring. The gaps in Curves 14 and 19 represent overnight interruptions with the sample at room temperature. Table V indicates the extraordinary fidelity with which the results for an unexposed sample (44) may be repro-

duced by the simple expression $Y = at^m$. The last observed value represents 28% of the total reaction.

In Table VI are recorded the values of m and a (cc. at 26°, 750 mm.) in the equation $Y = at^m$, for all runs in which this relation was followed over a major part of the observed data.

Runs are listed downward in order of increasing exposure to the active wave lengths. In general, the requirements of Eq. 3 are qualitatively fulfilled, that is, m decreases and a increases with increasing exposure. It is noteworthy that for unexposed samples, m is close to 3.5, for both batches and for different temperatures, whereas the corresponding values of a differ widely. The difference from the theoretical value of $m = 4$ might be ascribed to a fraction of the crystals having one very small dimension, or to a variation among the N "active spots" in ability to form nuclei. The most probable explanation, however, is to be found in a continuing exhaustion of those granules which happened to be nucleated early, any sharp change in rate being obscured because of variation in particle size.

Likewise, for exposed samples, Eq. 3 calls for $m = 3$ near the start of reaction, whereas slopes only half of this value were occasionally found. It is proper to note here, however, that slopes much below 3 were found only when the exposed sample had been in contact with air before decomposition (Runs 12, 9, 10) or when, as in Run 13, the illumination was nonuniform due to inadequate stirring.

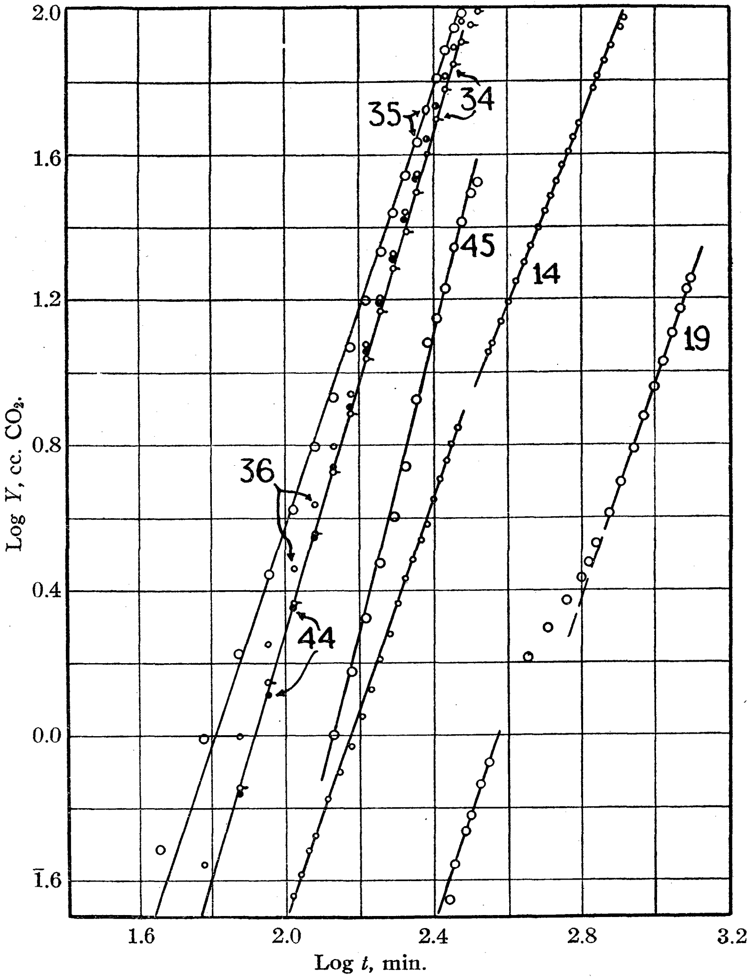

Fig. 6.—Log-log plot for decomposition of oxalate II.

In cases of short exposure (n_i and $n_0 \ll N$) the yield from thermally produced nuclei will be the same with or without exposure, so that ΔY, the increase due to exposure, should be proportional to the n_i photonuclei. This relation is roughly valid for exposures up to one hour (Fig. 2B). The increasing importance of n_0 may explain the relatively smaller effect of longer exposures, or it may be that the number of photonuclei increases less rapidly than the number of quanta absorbed.

For a given (short) exposure and time the values of ΔY at two temperatures should be proportional to the corresponding values of u^3. For Oxalate II a quantum absorption of 0.5×10^{18} produced at t = two hours a ΔY of about 0.15 cc. at 100° (based on Runs 24 and 25), and 0.77 cc. at 118° (Run 36). Hence u^3 increased by a factor of 5.1 and u by a factor of 1.7, corresponding to an activation energy E_u of 8600 cal. An independent value of E_u may be obtained from the relative rates at 117 and 100° in Run 44 (Fig. 3)—a procedure which is justified because at 100°, as Run 19 shows, new nuclei make no appreciable contribution to Y for at least two hours. Over the 17° interval in Run 44 u increased by a factor of $\sqrt[3]{4.5} = 1.65$, equivalent to $E_u = 8500$ cal., in agreement with the former value.

For the early stages of reaction with unexposed samples the relative yields at a given time should vary as kNu^3, and the yields per gram of sample as ku^3. For Runs 34 and 19 the relative yields per gram at twenty-five-minute intervals from $t = 195$ to $t = 300$ min. were 300, 280, 290, 290, 260. Hence, in this 18.5° interval ku^3 increased by a factor of 290, so that k increased by a factor of $290/5 = 58$, equivalent to an activation energy E_k of 64,000 cal. for the nucleation process. The conclusion that the temperature coefficient of nucleation is much greater than that of growth of nuclei is confirmed by the qualitative experiments at 80°.

An E_k of 64,000 cal. is equivalent to an einstein of λ 445 mμ. With Oxalate I wave lengths $>$ 520 mμ caused nucleation, but the much greater rates of decomposition of this material suggest that its E_k may have been less than 64,000.

Summary

In the decomposition of solid silver oxalate variations in rate due to long drying, preparation with excess of one or the other reagent, or fine grinding, were scarcely greater than the differences between two samples prepared and treated alike. Exposure to light, particularly to λλ $<$ 520 mμ, greatly increased the rate of the subsequent thermal reaction. Contact with oxygen during exposure resulted in a marked initial poisoning as compared with exposure in nitrogen, carbon dioxide or vacuum. The increase in yield at any time over that for unexposed samples was roughly proportional, for the shorter exposures, to the number of quanta absorbed, but relatively much less for longer exposures. The effect of exposure was relatively less at higher decomposition temperatures. In the exposure itself λ 370 mμ produced about 0.1 molecule of carbon dioxide per quantum absorbed.

The earlier stages of decomposition have been found to be in fair agreement with a quantitative formulation of the kinetics (Eq. 3), based on simple assumptions regarding the formation of nuclei of product and their subsequent growth. In agreement with the theory, the extent of reaction at any time t, in the earlier stages, is approximately proportional to t^m, where m is found to be 3.5 for unexposed samples, but progressively less for increasing exposure.

For a particular sample of oxalate the activation energy of nucleation is about 64 kcal., while that for growth of nuclei is 8.5 kcal.

The Molecular Rearrangement of Sulfanilides. II

BY MAURICE L. MOORE[1] AND TREAT B. JOHNSON

In a previous paper[2] on this subject we have discussed the rearrangement of certain aromatic sulfanilide compounds of type I. We have shown

I

II

that on heating these alone or in the presence of an excess of the corresponding amine they undergo rearrangement to the corresponding aromatic para-amino sulfides II. In this paper we shall describe a second type of rearrangement characteristic of sulfanilides which is brought about by the action of alcoholic sodium hydroxide solution.

Smiles and his co-workers,[3] who have recently investigated the chemical behavior of *o*-amino sulfones and sulfides, have made the interesting observations that certain representatives of both series undergo molecular rearrangement in alkaline media to form the corresponding sulfinic acid and mercaptan derivatives of diphenylamine, respectively. The same type of rearrangement was also found to take place with the *o*-hydroxy sulfones.[4] The amino sulfide compound shows an irregularity in chemical behavior as is illustrated by the following observation. It was found that the acetyl and the 2-nitrobenzoyl derivatives of 2-nitro-2′-aminodiphenyl sulfide, for example, would undergo rearrangement to the corresponding diphenylamine structures, whereas under the same conditions the parent amine itself, the picryl and the benzenesulfonyl deriva-

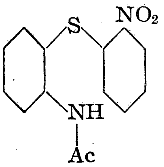
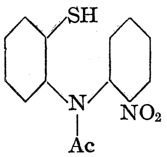
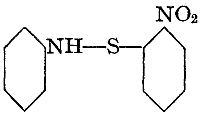
tives were not altered. A theory coördinating the factors influencing this rearrangement was proposed by Smiles[3b] in which he postulated that the rearrangement of III to IV was favored in cases of substituted derivatives when the acyl groups were derived from relatively weak acids. It was later found that the formyl[3c] derivative of VI rearranged with deacylation to form the mercaptan derivative VII.



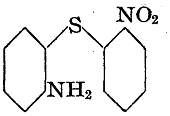
III



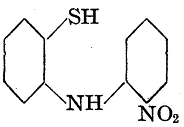
IV



V



VI



VII

As our rearrangement of the sulfanilides of type I by application of heat appeared to be predominately of the para type, it was of especial interest to determine their behavior when warmed in alcoholic sodium hydroxide solution. We found that 2-nitrophenylsulfanilide, V, gave an excellent yield of the sodium salt of the aromatic mercaptan, VII, by heating it in sodium hydroxide solution for three hours. This rearranged product, VII, was isolated as a red crystalline compound, and was converted easily into the corresponding thiomethyl ether previously described by Smiles. This investigator prepared this thioether by methylation of the compound resulting by the rearrangement and deacylation of 2-nitrophenyl-2′-formamido-diphenyl sulfide.[3c] 2-Nitrophenylsulf-*o*-toluidide and the *p*-toluidide give the corresponding mercaptodiphenylamines by rearrangement when treated under similar conditions with sodium hydroxide. These results show conclusively that the 2-nitro-sulfanilides are capable of undergoing both ortho and para types of rearrangements. The first change is favored by the alkali treatment according to the technique of Smiles, leading to the formation of a mercaptodiphenylamine derivative, VII, while direct heating causes rearrangement to a stable para-substituted amino sulfide II. In the case of 2-nitrophenyl-5′-methyl-2′-aminophenyl sulfide, however, we obtained no rearrangement of the diphenylamine type after refluxing in alkaline solution for six hours. 2-Nitrophenyl-4′-aminophenyl sulfide and 2-nitrophenyl-3′-methyl-4′-aminophenyl sulfide obtained by rearrangement of the corresponding sulfanilides by heat underwent no further change by action of sodium hydroxide, as was to be expected. These observations are in accord with the results obtained by Smiles. In regard to the mechanism of the transformation of nitrosulfanilides V to diphenylamines VII it would appear that intermediates of the structure of ortho-amino sulfides VI are first formed which then undergo the second type of rearrangement in presence of alkali, giving the final product of reaction, VII. We have at present, however, insufficient evidence to substantiate such a conclusion and further research on the subject will be conducted in this Laboratory.

Experimental Part

Procedure for Rearrangement.—The necessary sulfanilide (5 g.) as previously prepared[2] was placed in alcohol (25 ml.) containing 20% sodium hydroxide (5 ml.) and refluxed until a given sample shows that all of the material has rearranged, usually after about three hours of heating. After allowing to cool, the solution was then diluted to twice its volume with water and upon chilling in an ice-bath the sodium salt of the mercaptan derivative was obtained as a red, glistening, crystalline mass. The mother liquor on concentration yielded a further quantity of the same material. The sodium salt was soluble in alcohol and

[a] Smiles reports m. p. 98° for the same compound prepared from the formamido derivatives of the residue.

water but insoluble in ether and benzene. Upon dissolving in water and neutralizing with dilute hydrochloric acid, the free mercaptan was obtained as an oily precipitate which was very difficult to purify.

Methylation of the Mercaptan.—The sodium salt from above operation (2 g.) was dissolved in alcohol (10 ml.) and refluxed for one hour with an excess of methyl iodide (2 ml.). The solution was then diluted with water, when the required thioether crystallized out upon cooling. The wall of the container was rubbed vigorously with a glass rod to facilitate crystallization. The methyl sulfides prepared were soluble in ether, alcohol and benzene but insoluble in water.

In the table are recorded the results of the different products obtained by rearrangement of different sulfanilides under the influence of alkali.

Summary

Certain sulfanilides have been rearranged by digestion in alcoholic sodium hydroxide solution to give the corresponding *o*-mercaptodiphenylamines, whereas, upon heating alone, the same compound gives *p*-amino sulfides. The free *o*-amino sulfides, so far as examined, do not suffer a rearrangement under the same conditions, hence, the question arises, do the sulfanilides pass through this intermediate stage before forming the *o*-mercaptan derivative. As yet this point has not been clarified.

Chloroform-d (Deuteriochloroform)[1]

BY F. W. BREUER

As part of the program on organic compounds of deuterium in progress in this Laboratory,[2] the reaction of chloral with sodium deutroxide has been studied. Chloroform-d, $CDCl_3$, is formed exclusively as shown by the Raman spectrum.[3] The boiling point and freezing point were about 0.5° higher and lower, respectively, than those of ordinary chloroform. No difference was found in the refractive index, $n^{20}\text{D}$ 1.4450. The most significant difference other than the Raman spectrum is in the density, d^{20}_4 1.5004 as compared with 1.4888 for ordinary chloroform determined in an identical manner. Assuming identical molecular volumes for $CHCl_3$ and $CDCl_3$, the calculated value is 1.5013.

Experimental

The various manipulations for making chloroform were first carefully worked out with ordinary water.

Chloral Deuterate, $Cl_3CCH(OD)_2$.—Chloral (E. K. Co.) was distilled through a still head (30 × 0.9 cm.) packed with glass helices[4] to give a middle fraction which was redistilled, the vapors being passed over anhydrous calcium sulfate (Drierite)[5] kept at 100°. After a third distillation, the middle cut ($n^{20}\text{D}$ 1.4568) was used. To 14.72 g. (0.1 mole) of the purified chloral was gradually added with cooling 5.47 g. (0.22 mole) of deuterium oxide (d^{20}_{20} 1.1079).

Reaction of Chloral Deuterate and Sodium Deutroxide.—In a container permitting the interaction of water vapors with metallic sodium a solution of sodium deutroxide in deuterium oxide was prepared from 2.2 g. (0.096 g. atom) of C. P. sodium metal and 5 g. (0.25 mole) of the deuterium oxide. The oxide was added slowly from a dropping funnel and the deuterium gas evolved collected under a pressure slightly below atmospheric. At first the reaction seemed to proceed at about the same rate as with ordinary water, as evidenced by the amount of gas formed. Soon, however, a coating of sodium deutroxide formed on the metal and the reaction rate decreased considerably. After five days the volume of gas remained constant during a period of twenty hours. A white crystalline precipitate had formed, whereas with ordinary water a clear solution was obtained. Apparently, sodium deutroxide or a deuterate of it is less soluble in deuterium oxide than the proto compounds in ordinary water. This is in accord with the decreased solubility of the chlorides of sodium and barium in heavy water.[6] In the present study chloral deuterate was found to be considerably less soluble in deuterium oxide than chloral hydrate in natural water.

In order to condense vaporized heavy water the reaction flask was cooled to −78° and the gas container heated for five hours with a stream of warm air.

After connection between the two vessels had been severed the reaction flask was equipped with a reflux condenser and the chloral deuterate solution was admitted from a dropping funnel over a period of five hours, the flask being kept below 5°. The first few drops caused a rather vigorous reaction; afterward the formation of chloroform-d continued smoothly. After standing overnight the reaction was completed by gentle warming of the flask for ten minutes. Complete separation into two layers, which occurs with the proto compounds, did not

occur even after two days. The separation was finally effected by centrifuging. The reaction product was dried over freshly ignited calcium oxide, distilled, and redistilled. The yield of $CDCl_3$ was 7.85 g.

Boiling Point, Freezing Point, Density, Refractive Index and Raman Spectrum of Chloroform-d.—The difference in boiling points of the product and of ordinary chloroform prepared by the same reaction was determined with a set of two micro Cottrell apparatus,[7] each of a capacity of 5 cc., one junction of the thermopile being inserted in each of the instruments. At 732 mm. the deuteriochloroform boiled 0.5° higher than its light analog. Good checks were obtained with Emich's micro boiling point determination.[8]

In order to ascertain the degree of purity of the compound freezing and melting point determinations on a 1.5-cc. sample were run, and compared with the constants of highly purified chloroform and also of ordinary chloroform prepared from chloral hydrate and sodium hydroxide. The determinations were carried out in a double-jacketed container with air insulation. A copper–constantan thermopile of 2 couples enclosed in a flattened platinum tube was used with a glass container of similar shape which by the reduced volume allowed the entire thermopile to be covered with the liquid. The determinations were carried out under a pressure of 3 mm. to ensure removal of all gases which might have been formed by partial decomposition of chloroform during the Raman exposure.

	M.p. or range, °C.	F. p., °C.	
$CHCl_3$, esp. pure	−63.62	....	
$CHCl_3$, from chloral hydrate	−63.77 to −63.33	−63.49	−63.62
$CDCl_3$	−64.69 to −64.15	−64.12	−64.12

The melting range of the samples of light and heavy chloroform prepared on a small scale indicates that these compounds are not quite pure. Refractionation was not possible because of the small quantities obtained.

However, the observed values indicate that the deuteric compound melts definitely lower, which is in accordance with the lower melting points of other organodeuterium compounds.

A density determination of a middle fraction, using a 0.5-cc. pycnometer, gave d^{20}_4 1.5004.

The index of refraction was determined by means of a new carefully calibrated Bausch and Lomb refractometer of the Abbe type with temperature control at 20 ±0.05°: n^{20}_D for $CDCl_3$ 1.4450, for $CHCl_3$ 1.4450.

Because of the close similarity in properties of $CHCl_3$ and $CDCl_3$ it would have been most difficult to determine the nature of the product except for the Raman spectrum obtained and analyzed by Professor R. W. Wood of Johns Hopkins University and Dr. D. H. Rank of this Laboratory.[3] All lines appearing on the plates correspond to those for $CDCl_3$. No evidence of any $CHCl_3$ lines was detected.

Grateful acknowledgment is made to Professor Wood and Dr. Rank and to Mr. G. H. Fleming of this Laboratory for his help in portions of the work.

Summary

1. Chloroform-d, $CDCl_3$, free from ordinary chloroform, has been prepared.
2. The properties of the new substance closely resemble those of ordinary chloroform.

The Preparation of Dialkylmagnesium Compounds from Grignard Reagents

BY ARTHUR C. COPE

Schlenk's dioxane precipitation method[1] for the removal of the RMgX and MgX_2 components of the Grignard reagent $2RMgX \rightleftharpoons R_2Mg + MgX_2$ is now in common use for the preparation of ether solutions of dialkylmagnesium compounds. There is need for proof that the system is in mobile equilibrium, however, and for evidence concerning the accuracy of the dioxane method of analysis, since the equilibrium may shift during precipitation. Research in this Laboratory on these problems has revealed several factors which affect the yield of R_2Mg obtainable from Grignard reagents. They are reported in this communication.

The amount of R_2Mg obtained from all of the Grignard reagents investigated increased with increasing temperature. Thus the data summarized in Table I show that the amount of diphenylmagnesium present in solutions of phenylmagnesium bromide increased by about 10% for a 50° temperature rise. The point of equilibrium was also determined in *n*-butyl ether, in order to determine the effect of still higher temperatures. Both phenylmagnesium bromide and methylmagnesium iodide proved to be much less disproportionated in butyl ether than in ethyl ether at the same temperature. The data are recorded in Table II. Preliminary experiments at low temperatures showed a continued decrease in the amount of R_2Mg present and an apparently rapid rate of equilibration, for in solutions of ethylmagnesium iodide, ethylmagnesium bromide and phenylmagnesium bromide the amount of R_2Mg present decreased by approximately 30, 20 and 10%, respectively, on cooling from room temperature to −20 to −30° in forty to fifty seconds.

TABLE I

EFFECT OF TEMPERATURE ON THE DISPROPORTIONATION OF C_6H_5MgBr

Concn. of C_6H_5MgBr[a]		Basic Mg present as $(C_6H_5)_2Mg$, % at *T*, °C.			
Basic Mg, *N*	Br^-, *N*	−15	0	20	35
0.1325	0.1381	59.5	62	67	69
.2178	.2257	62	64	68	70
.2772	.2897	61.5	65	69	70

[a] The slight apparent increase in $(C_6H_5)_2Mg$ with increasing concentration may be due to a rise in temperature during precipitation, which in the case of the most dilute of the above solutions amounted to 5°.

TABLE II

DISPROPORTIONATION OF C_6H_5MgBr AND CH_3MgI IN BUTYL ETHER

RMgX	Concentration		Basic Mg present as R_2Mg, % at *T*, °C.			
	Basic Mg, *N*	X^-, *N*	20	60	100	140
C_6H_5MgBr	0.1108	0.1752	24	39	56	65
CH_3MgI	.2803	.2739	0.2			20

Another factor influencing the yield of R_2Mg obtainable from phenylmagnesium bromide is the reversibility of the precipitation; the yields of diphenylmagnesium increased if the precipitate with dioxane was allowed to stand in contact with the solution. Thus a 0.1818 *N* solution of phenylmagnesium bromide was found to contain 67% of diphenylmagnesium by the usual method of analysis. On allowing the precipitated samples to stand for one, two, three, twenty-four and seventy-two hours before separation of the precipitate by centrifuging, however, the amounts of diphenylmagnesium increased to 72, 73, 74, 75 and 75%, respectively. This reversibility of the precipitation is not general, for the yields of dimethylmagnesium from methylmagnesium iodide and methylmagnesium chloride did not increase on allowing the precipitated solutions to stand.

From these results, in the preparation of dialkylmagnesium compounds from Grignard reagents for synthetic purposes, the precipitation should be made by the addition of dioxane to refluxing solutions of the alkylmagnesium halides in order to obtain maximum yields. Due to the high disproportionation of the common Grignard reagents[1b,2,3] (especially the chlorides), all of the ordinary dialkylmagnesium compounds with the exception of dimethylmagnesium are thus available for practical synthetic use. Methylmagnesium iodide and methylmagnesium bromide are not highly disproportionated, however, so that Bartlett[4] was able to obtain dimethylmagnesium from methylmagnesium bromide in only 4% yield. Investigation of the disproportionation of methylmagnesium iodide at higher tempera-

tures and of methylmagnesium chloride showed that dimethylmagnesium can also be prepared in the fair yield of 50% from the chloride (Table III).

TABLE III

EFFECT OF TEMPERATURE ON THE DISPROPORTIONATION OF CH_3MgX

	Concentration		Basic Mg present as $(CH_3)_2Mg$, % at T, °C.			
CH_3MgX	Basic Mg, N	X^-, N	20	35	80 (in benzene)[a]	100[b]
CH_3MgI	0.2232	0.2331	2	10	17.5	44
CH_3MgCl	.2418	.1894	47	50		54

[a] The benzene solution was obtained by dissolving the liquid residue of methylmagnesium iodide etherate remaining after distilling off the ether in benzene. Note that the disproportionation is higher in benzene at 80° than in ether at 35°. The use of benzene as a solvent at 80° was recently assumed to decrease the disproportionation of cyclohexylmagnesium bromide by Miller and G. B. Bachman [*ibid.*, **57**, 767 (1935)]. Further work on the effect of solvents on the equilibrium was discontinued following the notice by these authors that they intended to study the problem.

[b] The samples at 100° were obtained by distilling off the ether and heating the residue at 100°. The methylmagnesium iodide etherate was a liquid, the chloride a white crystalline solid and mechanical difficulties probably account for the relatively low yield in the latter case.

All of the solutions of methylmagnesium chloride prepared contained more basic magnesium than chloride ion. Consequently the precipitate always formed in the preparation of this reagent is magnesium chloride etherate, not only from the Wurtz reaction, but also from the Grignard equilibrium. Thus, in the solution of methylmagnesium chloride described in Table III, 21.5% of the total basic magnesium was present as dimethylmagnesium regardless of any disproportionation of the methylmagnesium chloride remaining in solution. This amount was fairly constant for several preparations which had the following concentrations: (a) basic Mg, 0.2481 N, Cl^-, 0.1963 N (therefore 21% $(CH_3)_2Mg$; (b) basic Mg, 0.5404 N, Cl^-, 0.4168 N (therefore 23% $(CH_3)_2Mg$). A similar precipitation of magnesium chloride etherate was observed by Schlenk[1a] from benzylmagnesium chloride but precipitation was slow in that case, beginning only after several days, while with methylmagnesium chloride, concentrations similar to the above are observed immediately after preparation of the reagent.

Experimental Part

The Grignard reagents used in this investigation were prepared and stored under nitrogen. They were filtered through a plug of asbestos inserted in a stopcock sealed to the side of the flask in which they were prepared. If they were allowed to stand for a short time before filtering (or twelve hours in the case of methylmagnesium chloride), most of the filtration amounted to a decantation and could be made quite rapidly. The analyses for percentage R_2Mg were made as previously described.[3] The amount of dioxane used in each case to precipitate the halides was four moles to each mole of halide ion in the sample, made up to 10 cc. with the ether used in preparing the Grignard reagent. This amount was an excess, and apparently the excess employed does not affect the results given by the method. In all cases, the dioxane solution was at the same temperature as the solution being precipitated. In making the rapid cooling measurements, the samples were immersed in a carbon dioxide–ether mixture. In the other cases, since the equilibria appear to be established rapidly, the solutions were held at the recorded temperature for only fifteen minutes. The removal of halide ion from the solutions was practically complete in all cases, no more than 0.4% of the original quantity remaining in any case. For the measurements in which the ether was removed, the centrifuge tubes were fitted with a small dry exit tube and heated to the indicated temperature (80 or 100°) while the ether distilled off. In the measurements in benzene 20 cc. of dry benzene was then added and the tubes stoppered, while in the 100° determinations the tubes were stoppered and the residues heated at that temperature for fifteen minutes. The precipitation was made by adding 2 cc. of pure dioxane in each of these cases. In the samples precipitated in the absence of a solvent, dry ether was added to the tubes as soon as the rather vigorous reaction with dioxane was over and the rest of the determination made as before. Since heat is evolved during the precipitations, no attempt was made to control the temperature with an accuracy greater than 1°. The order of accuracy of the measurements is indicated by the average deviation of the duplicate analyses which were made in each case, which was 0.5% for basic magnesium; 0.2% for halide ion; 1% for per cent. R_2Mg.

Summary

The extent of the disproportionation $2RMgX \rightleftharpoons R_2Mg + MgX_2$ depends upon the solvent

employed and increases with increasing temperature, as determined by the dioxane precipitation method.

The precipitate formed during the preparation of the Grignard reagent from methyl chloride contains magnesium chloride etherate from the disproportionation of methylmagnesium chloride, so that the reagent contains 20% of dimethylmagnesium in addition to that formed by the disproportionation of the methylmagnesium chloride remaining in solution.

The Photobromination of Tetrachloroethylene and of Chloroform with Special Reference to the Effects of Oxygen

BY JOHN WILLARD AND FARRINGTON DANIELS

Oxygen, present as an incidental impurity, is known to have a marked effect on the rate of certain chemical reactions,[1] and very likely it is a factor in others where its influence has not yet been suspected. The matter is of interest both from a theoretical and from a practical standpoint.

The photobromination of cinnamic acid has been under investigation in this Laboratory for several years[2] and it seemed desirable to investigate also the photobromination of the very simple molecules, tetrachloroethylene for addition, and chloroform for substitution. These two substances are valuable for investigational purposes not only on account of their simple structure but also on account of the fact that they have high vapor pressures and can be studied in the gas phase as well as in the liquid phase.

All of the photochemical work described here was carried out with a large quartz monochromator and capillary lamps of high intensity,[3] and a large area thermopile.[4]

Photobromination of Tetrachloroethylene

Experimental Procedure

Tetrachloroethylene.—Chlorine was passed into Eastmen tetrachloroethylene and exposed to light.[5] After washing several times with sodium hydroxide and with water the liquid was dried with calcium chloride and twice distilled through a Widmer column in an all-glass still, the middle fraction being retained. It was further purified by freezing in an all-glass reservoir equipped with a dozen taps which could be opened with magnetically operated hammers.

Bromine.—Merck reagent quality bromine was distilled from potassium bromide onto phosphorus pentoxide which had been resublimed in a stream of oxygen. It was then fractionally distilled four times and fractionally crystallized three times, all steps in the purification process being carried out in an all-glass system. After degassing in the manner to be described shortly, it was distilled into a dozen small bulbs.

Oxygen.—Commercial tank oxygen was liquefied in a liquid air trap and the middle-boiling fraction was used to fill a series of bulbs of 1 cc. or less in volume. The pressure of oxygen was determined with a glass manometer.

Degassing Liquids.—Dissolved oxygen was removed from the reservoirs of liquid tetrachloroethylene and bromine by a repeated cycle of freezing with liquid air, evacuation with a mercury vapor pump, melting and brief boiling. When gas from the frozen liquid was no longer able to support a discharge from a Tesla coil, the material was deemed to be sufficiently free from oxygen. It was usually necessary to go through a series of six or seven freezings and evacuations before the oxygen and other permanent gases were sufficiently removed to meet this criterion.

Apparatus.—The experiments were carried out in a fused quartz cell 1 × 2 cm. in cross section and 8 cm. deep. The cell was equipped with a head as illustrated in Fig. 1. Side arm A contains bulbs of reactants which may be shaken into depression C to be broken by the glass-enclosed hammer B. D-E-G is a sealed-in, magnetically-operated stirrer designed to give efficient stirring in the illuminated portion of the cell, without interrupting the beam of light. It consists of the quartz-enclosed iron core D, the quartz landing button E and the quartz rod which terminates in the stirring button G. When an experiment is in progress the circuit through the solenoid M is opened and closed about twice a second by means of a contact operated by a metronome or by a cam on a pulley wheel. This jerks the stirrer up several centimeters and then allows it to fall under its own weight to the point where E is stopped by the quartz platform, F. In falling rapidly the button G sets into motion a body of liquid which travels on into the illuminated region of the cell. The button G has to be 5 mm. or less in diameter, in order to pass through the neck

of the cell and its shape makes little difference in the effectiveness of stirring.

Part H of the cell-head is a quartz-to-Pyrex graded seal which allows the cell to be sealed to Pyrex systems.

To fill the cell it was first sealed through the outlet K to the glass tap M of a reservoir of purified and degassed tetrachloroethylene. It was then evacuated by a mercury vapor pump through J and protected by a liquid air trap. While evacuation was taking place all portions of the cell except that containing the bulbs of reactants were flamed. The pump was then sealed off at J, the tap M was broken by the hammer L and tetrachloroethylene was distilled into the cell and sealed off at P and at K. The glass tap I allowed the cell to be opened without contamination of air, for addition of materials or removal of the reaction mixture for analysis. When the cell had been filled with tetrachloroethylene and sealed, its light transmission was compared with that of a similar blank cell. A bromine bulb was then broken in C. The bromine vaporized and was quickly absorbed by the tetrachloroethylene. The solution was then illuminated and readings of the light transmitted by the reaction cell and by the blank were taken at frequent intervals in order that the reaction might be followed by Beer's law. When a sufficient number of readings had been taken to show the course of the reaction in the absence of oxygen a bulb of oxygen was broken in C and the readings were continued. At the end of each experiment three graphs were made in which light absorption, concentration and quantum yield were plotted against time.

Measurements were confined to 4360 Å. because liquid tetrachloroethylene itself showed absorption for the ultraviolet lines of the mercury spectrum. The absorption at 3650 Å. was very slight. It was determined qualitatively, that light of 3650 and 5780 Å. causes the addition of bromine when oxygen is absent. It was shown experimentally that absorption of light at 4360 Å. by the product is negligible.

Calculations

A straight line was obtained when the logarithm of the transmission of light of 4360 Å. was plotted against the concentration of bromine used in the solutions. The averaged value of E, defined by the relation $E = 1/lc \log I_0/I$, was 197 ± 3 where l is the length of the light path in cm. and c is the concentration of bromine in moles per liter. This value is the same as that obtained by Bauer and Daniels[6] for the extinction coefficient of bromine dissolved in carbon tetrachloride, namely, 195 ± 3.

From the transmission of light by the reaction mixture the concentration of bromine at any time was determined by reference to the logarithmic plot. Transmissions were determined by readings of the galvanometer deflections when the light passed through the reaction cell, when it passed through a blank cell and when it was cut off by a shutter. All readings were corrected for reflection losses at the several windows. The same galvanometer readings, calibrated in terms of a U. S. Bureau of Standards standard radiation lamp, permitted a calculation of the number of ergs and the number of quanta absorbed.

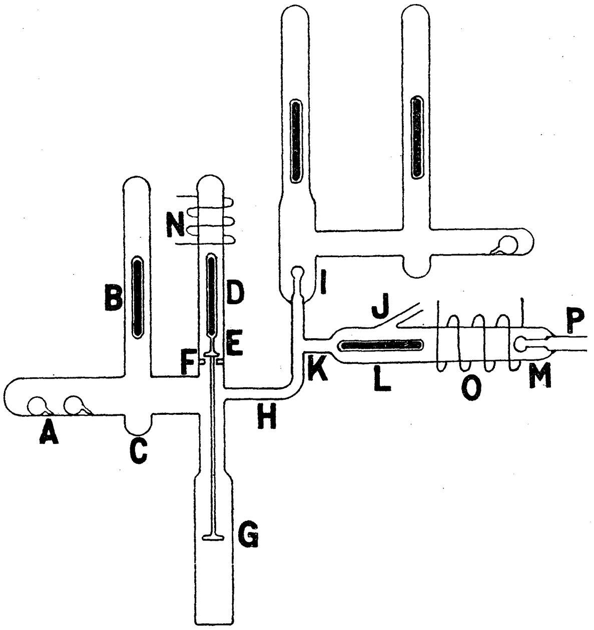

Fig. 1.—Reaction cell.

The concentration of bromine was plotted against time of illumination and the slope of the smooth curve, determined with a Richards–Roope tangent meter, gave the rate of the reaction at any time. The quantum yield at any time was determined by expressing this rate of reaction in terms of the number of molecules reacting per second and dividing by the number of quanta absorbed per second.

Results

Effect of Oxygen.—When reaction mixtures of bromine and tetrachloroethylene, which had been treated to free them from oxygen, were illuminated bromine was consumed at a readily measurable rate. When a bulb of oxygen was broken in the reaction chamber, giving a partial pressure of 20 to 50 mm. of the gas, the rate showed a sharp increase, indicating that small amounts of oxygen accelerate this reaction. Curves E and H of Fig. 2 illustrate this fact. Curves for other experiments indicate that the accelerating oxygen is gradually used up during the exposure to light. When oxygen at one atmosphere pressure was admitted to the cell the reaction was almost com-

pletely inhibited as shown in Fig. 3, where the readings which give the curve A were made with a reaction mixture from which oxygen had been removed and those for part B were made with the same mixture after oxygen at one atmosphere pressure had been admitted to the cell. Many experimental measurements were made which cannot be recorded here in detail,[7] but it should be emphasized that the results are all in substantial agreement even though the purification and procedures were considerably altered.

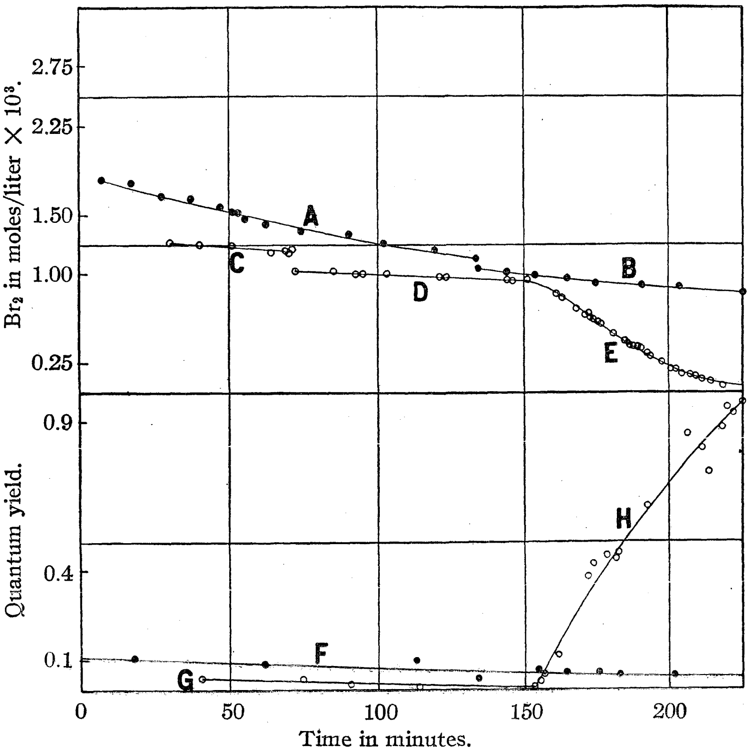

Fig. 2.—A, plot of concentration of bromine against time for reaction mixture in which considerable concentration of product has previously been built up. B, continuation of A after nine hour dark interval. C, continuation of B after breaking a fresh bulb of bromine in the reaction chamber; 225 minutes should be added to the time scale for curves C, D, E, G and H. D, continuation of C after a thirty-seven hour dark interval. E, continuation of D after breaking bulb containing about 1.5×10^{-5} mole of oxygen in the cell of 35-cc. capacity. F, plot of quantum yield against concentration corresponding to curves A and B. G, plot of quantum yield against concentration corresponding to curves C and D. H, curve showing increase in quantum yield after breaking oxygen bulb.

Inhibition by Products.—The two curves in each section of Fig. 2 represent the reactions which occurred after the breaking of two different bromine bulbs in the same solution of tetrachloroethylene. Since the concentration of tetrachloroethylene may be considered to remain essentially constant during these experiments, the fact that the slope of curves C and D in Fig. 2 is less than that of curves A and B at points of equal bromine concentration, indicates that the apparent rate of reaction has been decreased by the accumulation of products in the reaction mixture. This inhibition is also shown by the fact that curve G shows lower quantum yield values than does curve F.

Stirring.—If, during the course of an experiment, the stirrer was operated only during alternate intervals of illumination, the plot of concentration against time was of a sawtooth nature, indicating that bromine was consumed in the path of the light much more rapidly than it diffused in from the surrounding solution. If, however, a complete experiment was carried out without stirring, a smooth curve resulted, but such experiments differed from those in which stirring was used, in that the plot of percentage of incident light absorbed against time which they gave was convex to the axes of the plot while that for the stirred solutions was concave. This difference can probably be ascribed to the accumulation of the reaction product in the illuminated region of the unstirred reaction mixtures.

Temperature Effect.—One experiment was made with a deoxygenized system, in which readings were taken first at 0 and then at 25°. The quantum-yield values for the 0° illumination were extrapolated over a seven-minute interval of illumination which occurred between the last 0° reading and the first 25° reading. The value thus obtained divided into the quantum yield corresponding to the first reading of the 25° illumination gave a 25° temperature factor of 1.33. This gives a 10° temperature factor of $\sqrt[2.5]{1.33}$ or 1.12.

Concentration of Tetrachloroethylene.—Two experiments were carried out with carbon tetrachloride solutions of bromine and tetrachloroethylene. The amount of bromine consumed was determined by volumetric analysis after several

---

(7) Complete details may be found in part of a Ph.D. thesis filed in the Library of the University of Wisconsin by John Willard in August, 1935.

hours of illumination and quantum yields were calculated. The bromine concentrations, the light intensities and the amounts of bromine consumed were of the same order of magnitude in the two cases. One reaction was carried out at 0° and the other at 25°, and the concentration of tetrachloroethylene was about 0.17 mole/liter in one case and about 5 moles/liter in the other. When the quantum yield for the reaction at 0° was corrected to 25° by means of the temperature factor given above, it was found that the yield for the solution of higher tetrachloroethylene concentration was only about 2.5 times greater than for the solution in which the concentration was one twenty-fifth as great. Both yields were of the same order of magnitude as those obtained with solutions of bromine in tetrachloroethylene which were not diluted with carbon tetrachloride. These facts indicate that the concentration of tetrachloroethylene is not important in determining the rate of the bromination reaction.

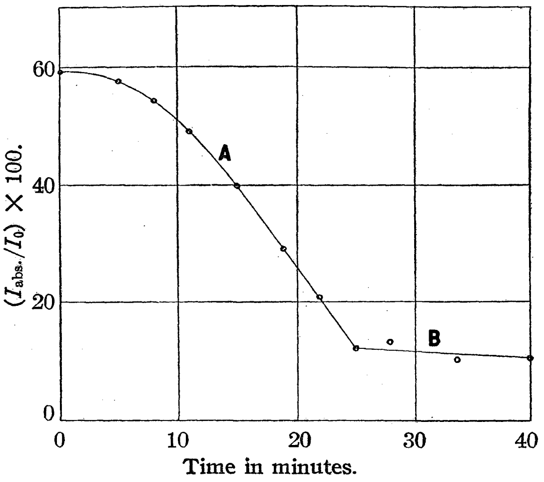

Fig. 3.—Inhibition of the photobromination of tetrachloroethylene by an excess of oxygen.

Dark Reaction.—The vertical drops between curves A and B and between curves C and D in Fig. 2 show that a slight dark reaction occurred over dark intervals of nine and thirty-seven hours. The rate of the dark reaction thus observed and also that observed when mixtures of bromine and tetrachloroethylene were allowed to stand in the dark while exposed to air was very much less than the rate reported by Herz and Rathmann.[8]

Gas Phase.—A few experiments were made on the gas phase reaction of bromine and tetrachloroethylene at temperatures between 50 and 60°. In one case a curve showing decreasing concentration of bromine with time of illumination was observed. In another, crystals of product formed on the windows of the reaction cell. In two others there was no indication of a bromination occurring even after long-continued illumination. These two experiments, however, showed a decrease in light absorption after the contents of the cell had been frozen out and then allowed to return to room temperature. When the cell was illuminated after such a treatment the light absorption increased from its reduced value to a rather definite maximum. This phenomenon is illustrated in Fig. 4 where A, B, C and D represent periods of illumination at 50° separated by dark periods in which the temperature was lowered. A three-hour period intervened between B and C. A bulb of oxygen was broken between C and D at the lower temperature. These facts may be explained by the assumption that during the liquefaction and freezing a small amount of dibromotetrachloroethane is formed and that on illumination of the revaporized mixture it is decomposed through a bromine sensitized photodecomposition of the type shown to exist by the recent work of Carrico and Dickinson,[9] which was published after the present research was completed.

Quantum Yields.—The quantum yields observed in the liquid phase experiments dropped rapidly during the first periods of illumination of a given reaction mixture. The quantum yield represented by the lowest point of curve G, Fig. 2, is 0.009. This is the lowest observed in any experiment. In the experiments shown in Fig. 2

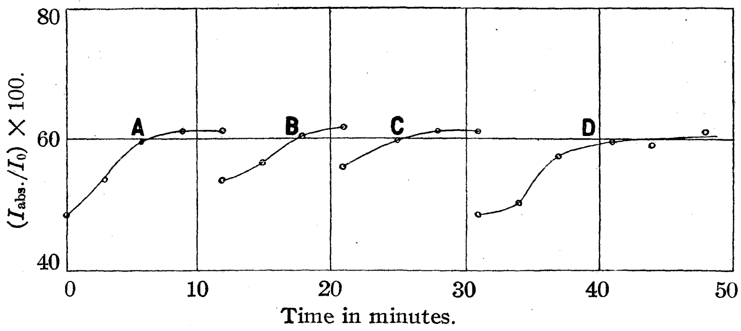

Fig. 4.—Influence of alternate periods of low temperature (dark), and high temperature and light on the concentration of bromine in gaseous mixtures, with tetrachloroethylene.

(9) Carrico and Dickinson, THIS JOURNAL, **57**, 1343 (1935).

the solution originally contained an excess of bromine which was removed by illumination before the transmission measurements were begun, with the result that a concentration of the reaction product had been built up. This fact accounts for the low values of the quantum yields and for the fact that the yield is decreasing only slowly with time as contrasted to its rapid rate of change when the concentration of product is smaller.

The quantum yields varied with the individual fillings of the cell and with the concentration of products. The highest quantum yield observed was 24 molecules of bromine disappearing for each quantum absorbed; the lowest was 0.009. Under the conditions of most of the experiments with the removal of oxygen but with the accumulation of some dibromotetrachloroethane, quantum yields from one to five were commonly obtained.

It is clear that both the straight addition of bromine to the double bond in tetrachloroethylene, and also the oxygen-accelerated reaction, involve chains. Large quantities of oxygen cause a different reaction to take place, in which the bromine is not consumed.

Mechanism

Carrico and Dickinson have established the fact that in the gas phase at temperatures between 100 and 135° the photobromination of tetrachloroethylene occurs only slightly if at all but that the bromine-sensitized photodecomposition of dibromotetrachloroethane occurs through reaction chains which may be as much as 45 molecules long. This fact may be correlated with the characteristics of the addition reaction in the liquid phase at room temperatures by a mechanism which postulates that a bromine atom may react with either tetrachloroethylene or dibromotetrachloroethane to form a mono-bromo free radical, C_2Cl_4Br. This radical may either undergo a unimolecular decomposition to form tetrachloroethylene and a bromine atom as suggested by Carrico and Dickinson, or it may react with a bromine molecule to form dibromotetrachloroethane and a bromine atom. The first possibility is a step in a dibromotetrachloroethane decomposition chain, the second is a step in a chain causing the addition of bromine to tetrachloroethylene. Decomposition predominates when the life of the radical is short; addition predominates when the life is long enough to give opportunity for radicals to undergo collision and reaction with a bromine molecule. The rate of decomposition of this free radical is assumed to have a high temperature coefficient, an assumption which is in agreement with the value of about 2 for the 10° temperature factor of the decomposition reaction which may be calculated from the data of Carrico and Dickinson. As a result only the decomposition reaction is observed at high temperatures while the addition reaction is the one experimentally apparent at low temperatures. This hypothesis is in accord with a test made since the publication of the results of Carrico and Dickinson, which shows that if a liquid reaction mixture that has been illuminated until it becomes nearly colorless at 25° is then illuminated at 65° a distinct bromine coloration reappears.

The accelerating effect of oxygen on the addition reaction may possibly be accounted for by the formation of a monobromoperoxy free radical which is capable of reacting with a bromine molecule but which is capable of existing longer without decomposition than is the mono-bromo free radical. The formation of peroxy free radicals by the reaction of oxygen with free radicals has been suggested by Haber and Willstätter,[10] and by Ziegler.[11] The latter author conceives these peroxy free radicals to be capable of giving off their oxygen and being regenerated as the original free radical which is then capable of taking on more oxygen.

The inhibition of the photobromination of tetrachloroethylene by large quantities of oxygen and the fact that small accelerating quantities of oxygen are gradually used up in the photochemical reaction may be well explained by the assumption that a bromine-sensitized photo-oxidation takes precedence over the addition of bromine, just as the chlorine-sensitized photo-oxidation takes pre-

(11) Ziegler and Ewald, *Ann.*, **504**, 162 (1933).

cedence over the chlorination of tetrachloroethylene as shown by Dickinson and Leermakers.[5]

In a system containing bromine, tetrachloroethylene, dibromotetrachloroethane and oxygen the reactions indicated may occur according to the mechanisms already discussed.

All the reactions at the right are capable of continuing chains which can be stopped by the reaction

$$\mathrm{Br} + \mathrm{Br} + \text{third body} \longrightarrow \mathrm{Br_2}$$

The bromine-sensitized oxidation reaction may be represented by

$$\mathrm{Br^*} + \mathrm{O_2} \longrightarrow \mathrm{Br} + \mathrm{O_2^*}$$
$$\mathrm{O_2^*} + \mathrm{C_2Cl_4} \longrightarrow \text{oxidation products}$$

The asterisk which passes from the bromine atom (or molecule) to the oxygen is used to indicate the fact that the bromine has been made incapable of reacting with tetrachloroethylene while making the oxygen capable of doing so.

Other mechanisms may be developed for this reaction some of which involve the concept of transitory bromine oxide, or of a peroxide formed on the double bond. The one which has been presented seems, however, to be the most serviceable in accounting for the characteristics of both photobromination and bromine sensitized photochemical decomposition.

This hypothesis, that the life period of the free radical $\mathrm{C_2Cl_4Br}$ is the factor which determines the relative amount of decomposition and addition, suggests possibilities for explaining the facts of certain iodination and chlorination reactions.

The Photobromination of Chloroform

The photobromination of liquid chloroform was studied at room temperatures with light of wave length 2650 Å. from the large monochromator using reaction mixtures with concentrations of bromine sufficient to absorb 100% of the light. Bromine was introduced from weighed capillaries which could be sealed in the side-arm of a quartz reaction cell and broken by heating. The bromine consumed was determined by volumetric analysis after several hours of illumination; and quantum yields were calculated.

When it was desired to carry out experiments in the absence of oxygen the reaction cell was filled with chloroform; this was partially boiled away, and the cell was sealed while the boiling continued. In cases where this technique was used practically no bromination occurred during long periods of illumination. In other cases approximately known amounts of oxygen were obtained in the cell by first boiling the chloroform and then allowing a chloroform vapor and air or oxygen equilibrium to be attained in the cell at a temperature at which the vapor pressure of chloroform was known. The outlet from the cell to the air or to an oxygen tank led through a tube of phosphorus pentoxide.

When pressure of oxygen of about 30 mm. was present above the liquid reaction mixture in the cell, quantum yields of about 2 were obtained. When a pressure of 660 mm. of oxygen was present the yields dropped to negative values, indicating that halogen had been liberated by an oxidation of chloroform.

Tests to determine at what wave lengths the bromination would take place in the presence of air showed negative results at 3650 and 3130 Å. but bromine was used up at 2850 and 2650 Å.

Summary

1. It has been found that photobromination of tetrachloroethylene is inhibited by the product of the reaction, that the concentration of the tetrachloroethylene is not an important factor in the rate, and that the temperature effect is small.

2. Small amounts of oxygen accelerate the photobromination of tetrachloroethylene. When large amounts of oxygen are present, the rate of bromination approaches zero, probably on account of a competing bromine-sensitized photooxidation.

3. Mixtures of liquid chloroform and bromine do not react appreciably in the absence of oxygen when illuminated at 25° with light of 2650 Å. Reaction occurs in the presence of oxygen.

4. A mechanism postulating a bromo free radical is suggested to account for the characteristics of the photobromination of tetrachloroethylene and for the fact that the reaction is reversed at higher temperatures. It is assumed that the life period of this radical is dependent on temperature and that the radical is partially stabilized by oxygen.

5. An effective method for degassing liquid systems is described.

6. A magnetically-operated, sealed-in stirrer for use in photochemical work is described.

A Study of the Kinetics of the Permanganate–Oxalate Reaction. I. The Effect of Various Salts upon the Rate of Reaction[1]

BY R. W. FESSENDEN AND BRYAN C. REDMON

Since the classical work of Harcourt and Esson[2] the kinetics of the reaction between permanganate and oxalate ions in acid solution have been studied by several investigators.[3,4,5] The development of a sound theory of kinetic salt effect by Brönsted[6] offers another method of investigating the mechanism of this reaction. Launer[5a] has shown that a positive salt effect is found when the reaction occurs in the presence of relatively large concentrations of oxalate and of added manganous ion.

A mechanism for the reaction is presented here as a basis for discussion.

$$x\mathrm{MnO_4^-} + y\mathrm{Mn^{++}} + 8x\mathrm{H^+} \longrightarrow z\mathrm{Mn^{++++}} + [(x+y) - z]\mathrm{Mn^{+++}} + 4x\mathrm{H_2O} \quad (1)$$

(Sum of series of rapid reactions)

$$\mathrm{Mn^{++++}} + \mathrm{Mn^{++}} \rightleftarrows 2\mathrm{Mn^{+++}} \text{ (rapid, reversible)} \quad (2)$$

$$\mathrm{Mn^{+++}} + 3\mathrm{C_2O_4^{=}} \rightleftarrows \mathrm{Mn(C_2O_4)_3^{\equiv}} \text{ (rapid, reversible)} \quad (3)$$

$$\mathrm{Mn^{++}} + 2\mathrm{C_2O_4^{=}} \rightleftarrows \mathrm{Mn(C_2O_4)_2^{=}} \text{ (rapid, reversible)} \quad (4)$$

$$\mathrm{Mn^{++++}} + \mathrm{C_2O_4^{=}} \longrightarrow \mathrm{Mn^{+++}} + \mathrm{CO_2} + \mathrm{CO_2^-} \text{ (measurable)} \quad (5)$$

$$\mathrm{Mn^{++++}} + \mathrm{CO_2^-} \longrightarrow \mathrm{Mn^{+++}} + \mathrm{CO_2} \text{ (rapid)} \quad (6)$$

$$\mathrm{Mn^{+++}} + \mathrm{C_2O_4^{=}} \longrightarrow \mathrm{Mn^{++}} + \mathrm{CO_2} + \mathrm{CO_2^-} \text{ (measurable)} \quad (7)$$

$$\mathrm{Mn^{+++}} + \mathrm{CO_2^-} \longrightarrow \mathrm{Mn^{++}} + \mathrm{CO_2} \text{ (rapid, slower than (6))} \quad (8)$$

If the reduction of the permanganate ion to the intermediate valences occurs in a series of rapid bi-molecular reactions, as seems probable to the authors, both $\mathrm{Mn^{++++}}$ and $\mathrm{Mn^{+++}}$ ions are produced. Due to the existence of the equilibrium represented by equation (2), this point is not easily demonstrated and is not essential to the rest of the mechanism.

The formula of the manganic oxalate complex ion in equation (3) differs from that proposed by Launer.[5a] Evidence for the formula $\mathrm{Mn(C_2O_4)_3^{\equiv}}$ will be presented in another paper. The existence of the equilibrium represented in equation (4) is shown by the work of Scholder and Linström.[7]

Equations (5), (6), (7) and (8) are those proposed by Launer and Yost.[5b] The existence of reaction (7) is difficult to prove because of the existence of the equilibrium represented by equation (2) and reaction (5).

From an inspection of the mechanism it is evident that, if the rate-determining equation is either (5) or (7), the salt effect should be negative according to the Brönsted theory. Launer[5a] in his investigation of the salt effect used a relatively high concentration of the oxalate ion and added manganous ion. Under these conditions, the reactions from left to right in the equilibria represented by equations (2) and (3) are favored, and the rate of reaction becomes inversely proportional to the concentration of the manganic oxalate complex ion. The effect of added salts on this equilibrium would be to increase the dissociation of the manganic oxalate complex ion and so increase the rate of reaction. From these considerations the positive salt effect found by Launer is apparently not a kinetic salt effect, but a salt effect on the equilibrium represented by equation (3) or a secondary salt effect according to the Brönsted theory.

If the reaction is carried out in the presence of relatively low concentrations of oxalate and no added manganous ion, the reactions from left to right in equations (2) and (3) will be greatly decreased, and it might be expected that the true kinetic salt effect on equations (5) or (7) would not be hidden by the secondary salt effect on the equilibrium (3). The purpose of this investigation was to study the salt effect under these conditions.

Experimental Procedure.—The velocity of the reaction was measured iodimetrically by adding aliquots drawn from the reaction mixture to a solution containing excess potassium iodide and titrating the liberated iodine immediately with standard thiosulfate solution. According to Launer[5a] this method is not accurate unless care is taken to exclude oxygen from the reaction

mixture. In determining the relative rates of reaction in solutions which are identical except for added electrolytes, such an error is not believed to be important.

The procedure used in making the rate measurements was as follows. The permanganate solution was placed in one flask and the remaining constituents of the reaction mixture in a second flask. The two flasks were placed in a thermostat and allowed to reach thermal equilibrium. The contents of the two flasks were poured together and then poured from one flask to the other to complete mixing as rapidly as possible. A stop watch was started simultaneously with the first mixing of the solutions. The reaction mixture, now contained in one flask, was replaced in the thermostat and aliquots withdrawn at suitable time intervals. The pipet used to remove the aliquots was a 5-ml. Mohr, with the tip cut off to ensure rapid delivery. The total time necessary for complete delivery of the sample was not more than three seconds. Calibration of the pipet showed an average deviation from the mean delivery of 1.2% in eight trials.

A good grade of C. P. chemicals was used without further purification, except for a sample of sodium oxalate from the Bureau of Standards which was used as the primary standard for the permanganate and oxalate solutions. All solutions were prepared and standardized by accepted quantitative methods.

All experiments were conducted at a temperature of 25.00 ± 0.05°.

Experimental Results.—The results of the investigation of the kinetic salt effect are given in Table I. The reaction mixture used in all experiments recorded in Table I was made up to be 0.01 molar with respect to sodium oxalate, 0.00241 molar with respect to potassium permanganate and 0.0965 molar with respect to sulfuric acid. The values of x, the loss in oxidizing value in time t, are given in milliliters of 0.005 M sodium thiosulfate solution. Values listed in columns 2, 3, 4, 5 and 6 are averaged from two or more determinations. Duplicate experiments agreed very closely.

The data contained in Table I are plotted in Fig. 1. A comparison of the curves for the rate in the absence of added salts, and for the rate in the presence of added sodium or potassium sulfate demonstrates the existence of a negative kinetic salt effect. The curve for the rate in the presence

of magnesium sulfate also shows a negative effect, but the effect is less than might be expected from the concentration and valence type of this salt.

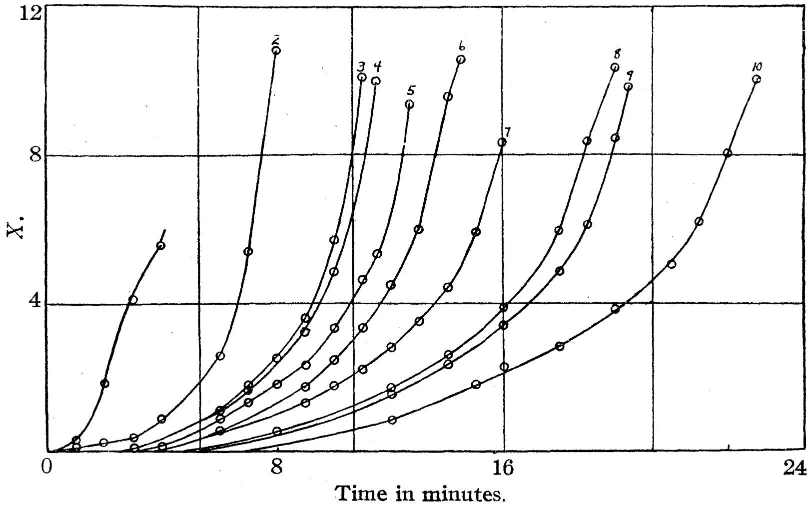

Fig. 1.—The effect of various salts on the rate of the permanganate–oxalate reaction: (1) 0.125 *M* $Al_2(SO_4)_3$; (2) 0.125 *M* $ZnSO_4$; (3) 0.05 *M* $ZnSO_4$; (4) 0.259 *M* $CdSO_4$; (5) 0.155 *M* $CdSO_4$; (6) no added salt; (7) 0.258 *M* $MgSO_4$; (8) 0.125 *M* Na_2SO_4; (9) 0.111 *M* K_2SO_4; (10) 0.222 *M* K_2SO_4

All of the remaining salts studied show a positive salt effect. The case of the aluminum ion is peculiar in that the initial rate is very rapid, but after about one-half the oxidizing value has disappeared, a precipitate of manganese dioxide forms and the reaction becomes heterogeneous.

These apparently contradictory results may be explained by the kinetics of the reaction and the chemistry of the cations of the added salts. The velocity of the reaction is inversely proportional to the concentration of the oxalate under the conditions of these experiments as is shown by the data in Table II. The data in this table are the results of experiments in which the concentration of the sodium oxalate was varied as indicated, while the concentrations of the other reactants were the same as in the experiments given in Table I. Considering the portions of the curves shown in Fig. 2, for the induction period,[4] where the rate is rapid and the greater part of the reaction takes place, it is evident that the velocity of the reaction is inversely proportional to the concentration of sodium oxalate from 0.00753 molar to 0.0301 molar. From 0.0301 molar to 0.301 molar, the rate increases with the concentration of the oxalate. The concentration of oxalate used in the experi-

ments on salt effect, 0.010 molar, falls in the range where the rate varies inversely with the oxalate concentration.

The cations of the salts showing a positive salt effect are known to form oxalate complexes. In the case of the zinc ion, two complex ions, $Zn(C_2O_4)_3^{\equiv}$ and $Zn(C_2O_4)_2^{=}$ depending on the concentration of the oxalate ion, are reported.[8] Kohlschütter[9] postulates the existence of cadmium oxalate complexes, notably the $Cd(C_2O_4)_2^{=}$ ion. Peters,[10] working on the quantitative separation of cadmium from copper, found that copper oxalate was much less soluble than cadmium oxalate in acid solution, which may indicate the formation of a cadmium acid oxalate complexion. Salts containing stable alumino-oxalate anions of the types $Al(C_2O_4)_3^{\equiv}$ and $(Al(C_2O_4)_2(H_2O)_2)^-$ have been prepared by Burrows and Lauder.[11]

The apparent positive kinetic salt effect may thus be explained as due to the decrease in the concentration of the oxalate ion resulting from the formation of oxalate complexes. The fact that the effect of the magnesium ion is less than expected may be explained in a similar manner as magnesium oxalate is known to be weakly dissociated.[12]

The reversal of the effect of oxalate ions on the rate, as demonstrated by the data in Table II and Fig. 2, seems to be due to reaction (4). The removal of the manganous ion to form the manganous oxalate complex ion should decrease the rate in the incubation period. In accord with this reasoning the rate during this part of the reaction for concentrations of oxalate greater than 0.0301 *M* decreases with increasing oxalate ion concentration as is shown in Fig. 2.

Furthermore, the decrease in the concentration of manganous ion by reaction (4) decreases the reaction from left to right in equation (2) and consequently decreases the effect of the reaction from left to right in equation (3). Therefore, the rate during the induction period varies directly with the oxalate ion concentration in accordance with the mass effect.

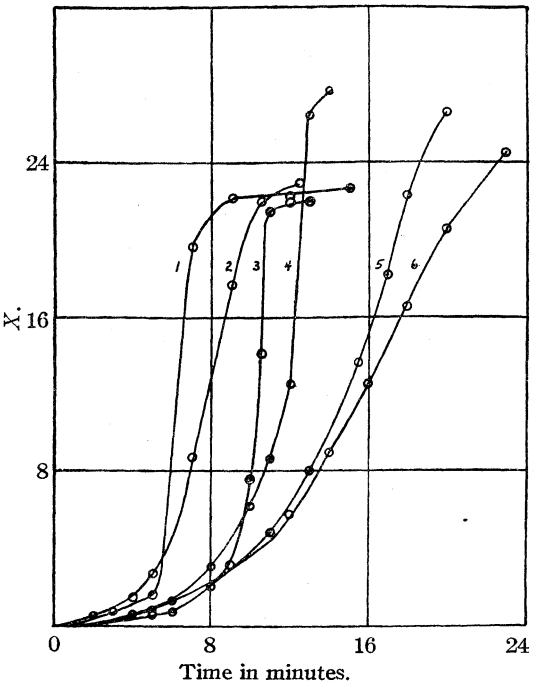

Fig. 2.—The effect of the variation of the concentration of sodium oxalate upon the rate of reaction: (1) 0.1506 *M* $Na_2C_2O_4$; (2) 0.0753 *M;* (3) 0.301 *M;* (4) 0.00753 *M;* (5) 0.01506 *M;* (6) 0.0301 *M.*

The reason that the equilibrium (4) does not seem to be important in the lower concentrations of oxalate is believed to be due to the instability of the $Mn(C_2O_4)_2^{=}$ ion in these low concentrations.

Summary

A negative kinetic salt effect has been found in the case of the permanganate–oxalate reaction.

The effect of oxalate upon the rate of reaction varies with its concentration.

An explanation is offered for the apparent positive salt effect found with certain cations which form oxalate complexes.

Equilibrium Studies on the Exchange Reaction between Acetylene and Heavy Water[1]

By L. H. Reyerson and Bruce Gillespie

As a result of the discovery in this Laboratory that an isotopic exchange occurs between acetylene and alkaline solutions of heavy water, it was decided to study the equilibria involved. The reaction takes place due to the ionization of the acetylene, but the determination of the change in the density of the heavy water makes it possible to calculate K_X. The results here reported give the values obtained at 0, 25 and 100° using water containing 9.77 and 18.97% deuterium oxide.

Experimental Procedure

A calibrated liter bulb was attached to the high vacuum line shown in Fig. 1, and then thoroughly evacuated and flamed. Dry carbon dioxide-free air was admitted to the bulb before and after flaming. Opening A was stoppered during evacuation but a slow stream of this same air was passed in through A during the cooling of the bulb. About 1 g. of N alkaline solution of known percentage of D_2O was then introduced from a pycnometer through A and A immediately sealed off in such a way that no water from the flame could condense inside the bulb. Part C of the bulb was then immersed in liquid air for from twenty to thirty minutes, after which the bulb was carefully evacuated. Tests made at this point showed no dissolved air. The bulb was now placed in an ice-bath and carefully purified acetylene run in through B from storage bulb Q to the desired pressure. This acetylene was prepared by the action of carefully purified water vapor on the purest of calcium carbide. The gas was further purified by the method recommended for acetylene. After pressure equilibrium had been established the pressure was read, B closed and the contents frozen out at C with liquid air. The bulb was sealed off at D, placed in a thermostat at the desired temperature and occasionally removed and rotated to redistribute the solution over the walls. At the close of the reaction E was sealed to the vacuum line and the system exhausted. The contents of the bulb were frozen out with liquid air and the capillary F broken. The liquid air bath was then transferred to H and about half of the acetylene was distilled over to H. At this point a salt–ice bath of −20° was placed about C and the remaining acetylene distilled. At this point the manometer reading was found to be approximately zero. About a liter of dry carbon dioxide was then condensed in J by a bath of liquid air and all of the non-condensable gases pumped from the system. The carbon dioxide was allowed to warm up and expand into the reaction bulb to a pressure of about 1 atmosphere, when B was closed. The carbon dioxide remained in the bulb for several hours during which time C was warmed to 70–80° occasionally. This treatment converted the sodium hydroxide to sodium carbonate, restoring the combined water.

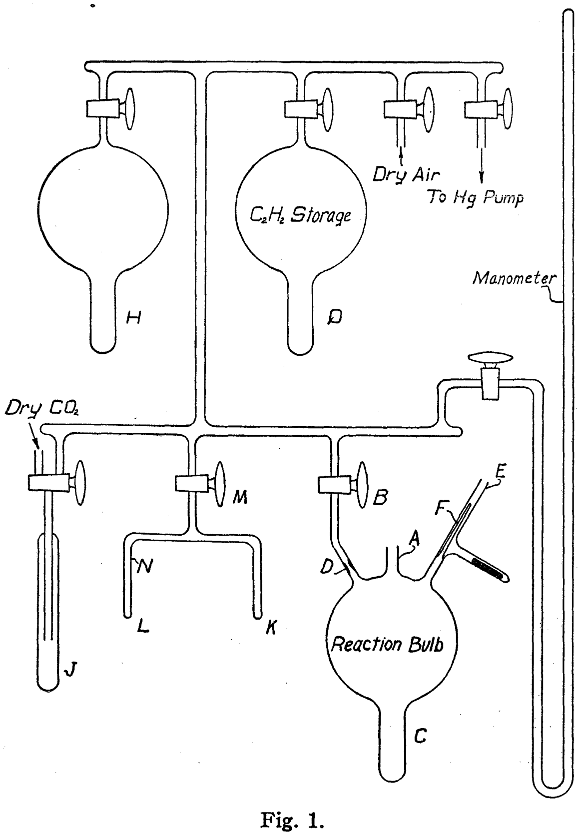

Fig. 1.

The carbon dioxide was removed in the same manner as the acetylene. With K immersed in liquid air the water was then carefully distilled into K from C. K was warmed until the water had melted. With K held at 0° M was cautiously opened to a pressure of about 1 cm. to remove any dissolved carbon dioxide. The pressure external to M was lowered slowly until the water at 0° just started to boil when M was closed, and the water distilled from K to L. Dry carbon dioxide free air was admitted at atmospheric pressure to K and L and L then removed from the system at N and thermostated to constant temperature. The density of the water was determined in a pycnometer of 0.55 cc. capacity. With care the loss of water in the whole operation was of the order of magnitude of 0.1 to 0.15 cc. Finally the reaction bulb was removed, opened at A and D, and the contents washed out with from 8 to 10 small portions of hot freshly distilled water. The washings were combined and titrated with 0.1 N hydrochloric acid using methyl orange as indicator. This gave the amount of alkali used in the original solution.

Results

From the change in density of the water during a given run the amount of deuterium that had reacted with the acetylene could be determined. Table I gives the results of several experiments at the temperatures indicated. The moles of initial and final products of the principal reaction are given and K_X values are calculated for the reaction $C_2H_2 + HDO \rightleftharpoons C_2HD + H_2O$. While there are four possible reactions between solutions of deuterium oxide and acetylene, the concentrations of deuterium oxide justified the calculation for the above reaction alone. Practically all of the deuterium was in the form of HDO at these concentrations. Furthermore, mass spectral analysis of the acetylene at equilibrium showed only a trace of C_2D_2 while the amount of C_2HD present agreed well with the value calculated from the density change. The authors do not attach much significance to the second figure of the K_X values. The averages of the K_X values at the three temperatures are as follows: at 0° K_X is 0.365, at 25° K_X is 0.45 and at 100° K_X is 0.51.

In connection with this investigation, it should be noted that R. P. Bell,[2] as a result of experiments performed at Oxford, questioned the exchange reaction which we had previously reported.[3] In addition to the evidence for this exchange reported in the above equilibrium studies, we have obtained positive proof of the existence of the molecule C_2HD in the equilibrium gas. This was obtained by mass spectroscopic investigation and the amount found compared favorably with the amount determined from the equilibrium study. Furthermore, Glockler and Morrell[4] obtained lines in the Raman spectra for the molecule C_2HD in a sample of gas taken from one of our equilibrium reactions. We feel therefore that the above equilibrium studies represent real equilibrium values within the limit of error of our experimental technique.

The authors wish to acknowledge the valuable suggestions of R. S. Livingston and the assistance of S. T. Yuster which aided greatly in the investigation. Further studies are being carried on at higher deuterium concentrations.

Summary

1. Equilibrium studies have been carried out at 0, 25 and 100° between acetylene and solutions of heavy water.

2. Average values of K_X for the reaction $C_2H_2 + HDO = C_2HD + H_2O$ were found to be 0.365 at 0°, 0.45 at 25° and 0.51 at 100°.

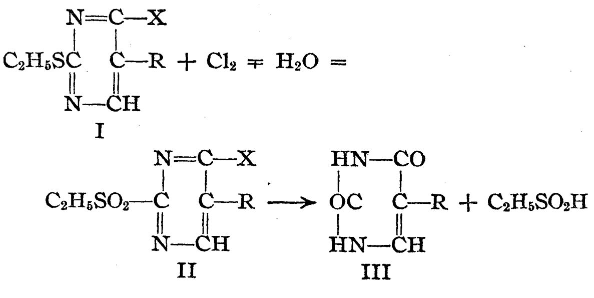
Researches on Pyrimidines. CXLVIII. Action of Chlorine on Mercaptopyrimidines

BY JAMES M. SPRAGUE[1] AND TREAT B. JOHNSON

Although considerable work has been done on the application of mercaptopyrimidines to synthesis in the pyrimidine series,[2] no extensive investigation has been made of reactions in this heterocyclic series involving changes in the mercapto group. The chief reactions, in which the mercapto grouping functions, have been its replacement by a hydroxyl group by hydrolysis, and by its substitution with an amino radical by interaction with various amines.[2] Recent developments in the field of "vitamin chemistry" have induced the authors to undertake an exhaustive study of characteristic reactions of the mercapto grouping in different heterocyclic combinations. Because of the postulated existence of a pyrimidine nucleus in the sulfur containing vitamin B_1,[3] a better knowledge of the chemistry of different types of mercapto- and thiopyrimidines becomes very important. A study has been made, therefore, of the behavior of several mercaptopyrimidines toward such reagents as alkalies, sodium alkoxides, nitric acid and chlorine. In this paper the authors will discuss fundamental changes resulting from the action of chlorine upon some ethylmercaptopyrimidines.

When a 2-ethylmercaptopyrimidine (I) is suspended in water and treated with chlorine gas at a low temperature, a pyrimidine sulfone compound is formed (II).

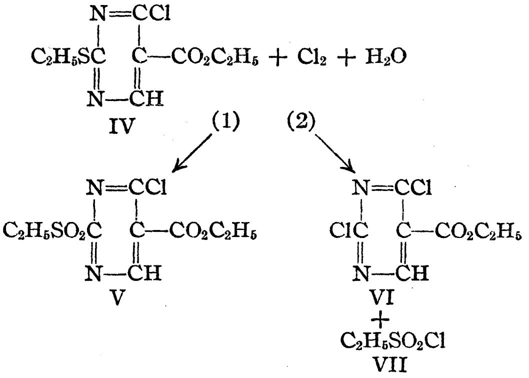


I

II

III

This reaction was applied with success to a series of 2-ethylmercapto-4-ethoxy- (I, X = OC_2H_5), and 2-ethylmercapto-4-chloropyrimidines (I, X = Cl) where R was hydrogen, methyl and bromine. With a slight modification of experimental conditions we also succeeded in synthesizing the 2-ethyl sulfone derivative of 2-ethylmercapto-4-amino-5-carbethoxypyrimidine (I, X = NH_2, R = $CO_2C_2H_5$). The results of our experiments are recorded in Table II. When 2-ethylmercapto-4-chloro-5-carbethoxypyrimidine (IV) is treated with chlorine according to the above technique the pyrimidine VI and ethylsulfonyl chloride (VII) together with the corresponding pyrimidine sulfone (V), were obtained.



IV

V

VI

VII

The relative amounts of the products of these two reactions depended largely upon the temperature. When the treatment with chlorine gas was carried out below 5°, a 60% yield of the sulfone (V) was obtained. Nevertheless, at this temperature, a 15–20% yield of the product of the second reaction was also obtained. When the chlorination was conducted at a higher temperature, 30–40°, reaction 2 predominated and 2,4-dichloro-5-carbethoxypyrimidine (V) (69–75%), and ethylsulfonyl chloride (VII) (47–75%) were obtained. Under these conditions the yield of the sulfone (V) was reduced to 7%.

That the sulfone (V) is not an intermediate in the formation of compounds (VI) and (VII) through a cleavage by chlorine is shown by its inertness toward chlorine in either water or benzene. This behavior is analogous to that observed in the case of diethyl-sulfone, which remained unaffected while the corresponding diethyl sulfoxide was readily cleaved by chlorine to ethylsulfonyl chloride and ethyl chloride.[4] This suggests that the pyrimidine sulfoxide derivative of the original mercaptopyrimidine is an inter-

mediate in both reactions 1 and 2.[5] Conditions have not yet been found which will yield pyrimidine sulfones from 2-ethylmercapto-4-oxypyrimidine (I, X = OH) by the action of chlorine.

That an ethylmercapto group occupying the 4-position of the pyrimidine nucleus may also be converted into a sulfone was shown with 2,4-diethylmercaptopyrimidine (I, $X = SC_2H_5$, R = H). This compound, on treatment with chlorine, gave smoothly the disulfone, 2,4-diethylsulfonylpyrimidine (II, $X = SO_2C_2H_5$, R = H). Although 2,4-diethylmercapto-5-methylpyrimidine (I, $X = SC_2H_5$, $R = CH_3$) gave a product insoluble in petroleum ether, it could not be crystallized or distilled. Similar results were obtained with 2-ethylmercapto-4-ethoxy-5-carbethoxypyrimidine.

To establish definitely the point of attack of the chlorine, as well as to establish the structure, our sulfones were subjected to hydrolysis. On refluxing with 20% hydrochloric acid, there were obtained, beside the corresponding dioxypyrimidine, sulfur dioxide and a small amount of ethylsulfonic acid.

Ethylsulfonic acid was found to be stable under the conditions of hydrolysis; this fact, coupled with the production of a 2,4-dioxypyrimidine (III) rather than a monoxypyrimidine, suggests that the immediate product of the hydrolysis was probably ethylsulfinic acid. Although most of this acid decomposed to sulfur dioxide a small amount underwent oxidation to ethylsulfonic acid during the working-up process.

Experimental Part

2 - Ethylmercapto - 4 - chloropyrimidines.—These compounds, 2-ethylmercapto-4-chloropyrimidine,[6] 2-ethylmercapto-4-chloro-5-methyl pyrimidine,[6] 2-ethylmercapto-4-chloro-5-bromopyrimidine,[6] and 2-ethylmercapto-4-chloro-5-carbethoxypyrimidine[7] have all been previously prepared in this Laboratory, but largely by the use of phosphorus pentachloride. For this investigation they were all prepared in the usual manner[8] from the corresponding 4-oxypyrimidine by action of phosphorus oxychloride.

2-Ethylmercapto-4-ethoxypyrimidines.—An alcohol solution of the 2-ethylmercapto-4-chloropyrimidine was added slowly to a well-cooled solution of sodium (10–20% excess) in dry ethanol. The reaction mixture was allowed to stand at room temperature for three or four hours and the reaction completed by heating on a steam-bath for ten minutes. The alcohol was then removed under diminished pressure. Water was added to the residue and the reaction product of 2-ethylmercapto-4-ethoxypyrimidine extracted with ether. After drying over calcium chloride, the ether extract was distilled. The results of the experiment are collected in Table I. 2-Ethylmercaptopyrimidine had been prepared previously by a different procedure.[9]

In the preparation of 2-ethylmercapto-4-ethoxy-5-carbethoxypyrimidine (I, $X = OC_2H_5$, $R = CO_2C_2H_5$) it was necessary to modify the above procedure since in alcohol solution there was a loss of ethylmercaptan. The corresponding 4-chloropyrimidine in boiling benzene was treated with an equivalent amount of sodium ethoxide prepared in benzene from powdered sodium and the calculated amount of dry ethanol. The rate of addition of the sodium ethoxide was adjusted so that the reaction mixture was never alkaline to moist litmus. After heating for an additional fifteen minutes, the reaction was worked up as described below for the diethylmercaptopyrimidines.

2,4-Diethylmercaptopyrimidine.—A solution of 2,4-dichloropyrimidine[10] in toluene was added to a suspension of sodium ethylmercaptide (10% excess) which had been prepared in toluene from powdered sodium and ethyl mercaptan. After heating on a steam-bath for four hours, water was added and the toluene layer was dried and distilled. 2,4-Diethylmercapto-5-methylpyrimidine was prepared by the same procedure from 2-ethylmercapto-4-chloro-5-methylpyrimidine and sodium ethylmercaptide (Table I).

Ethylsulfonylpyrimidines. General Procedure.—The liquid 2-ethylmercaptopyrimidine (1–5 cc.) was suspended in water (20–75 cc.) and chlorine gas vigorously passed into the mixture which was well cooled in ice. Heat was evolved but the temperature did not rise above 20°. Most of the mercaptopyrimidine went into solution which immediately became turbid and a heavy oil precipitated. This gradually solidified and the treatment with chlorine was continued until the reaction mixture had a distinct green color of excess chlorine. The solid sulfone was filtered off, and, after drying over phosphorus pentoxide, recrystallized from a mixture of benzene and petroleum ether. These sulfones were readily soluble in the common organic solvents except petroleum ether in which they were practically insoluble. The purified sulfones may be kept over phosphorus pentoxide for several months without decomposition. However, in moist air they decompose rapidly.

Occasionally difficulty was experienced in obtaining the sulfones as solids on the first preparation. Usually this was due to incomplete chlorination or insufficient cooling during the reaction. However, the solid sulfone was obtained when an ether extract, which had been washed with sodium thiosulfate and dried over calcium chloride, was evaporated. If the residue from the ether extract did not solidify, it was triturated with petroleum ether. Subsequent preparations of the sulfone were obtained as solids directly from the reaction by seeding with a solid sulfone.

2-Ethylsulfonyl-4-ethoxypyrimidine (II, $X = OC_2H_5$, R = H) was a liquid which, when pure, distilled without decomposition.

---

[5] The mechanism of these transformations is being investigated and the results will be discussed in a future paper.

2-Ethylsulfonyl-4-chloro-5-carbethoxypyrimidine.—To obtain this sulfone (II, X = Cl, R = $CO_2C_2H_5$) in practical yields it was necessary to carry out the chlorination in an ice–salt bath (−10°). The temperature of the reaction was not allowed to rise above 5°. Even at this temperature 15–20% of the cleavage product (reaction 2) was obtained by extracting the reaction mixture with petroleum ether (see below). This sulfone is very unstable and decomposes rapidly even over phosphorus pentoxide, giving a product insoluble in benzene.

The cleavage reaction of 2-ethylmercapto-4-chloro-5-carbethoxypyrimidine was carried out as follows. Five cubic centimeters (6.3 g.) of 2-ethylmercapto-4-chloro-5-carbethoxypyrimidine was suspended in 60 cc. of warm water (30–40°) and chlorine rapidly passed into the mixture. The temperature was kept within the above limits by cooling in water. When the oil had separated completely, the mixture was shaken with petroleum ether and the sulfone derivative which separated as a solid at the water–petroleum ether interface was removed by filtration (0.5 g., 7%). After washing with dilute sodium thiosulfate and drying over calcium chloride the petroleum ether extract was fractionated with the following results: fraction 1, b. p. 68–74° (18 mm.) 1.5–2.5 g. (47–75%); fraction 2, b. p. 118–120° (4 mm.) 3.9–4.2 g. (69–75%).

Fraction 1.—This was redistilled, b. p. 67–68° (17 mm.), $n^{21.50}_D$ 1.4520 and identified as ethylsulfonyl chloride (VII) by formation of ethylsulfonamide[11] (m. p. 59–60°), ammonium ethylsulfonate[12] (m. p. 208–209°), and aniline hydrochloride.

Fraction 2.—This solidified on cooling and was recrystallized from ether, m. p. 36–37°, and was identified as 2,4-dichloro-5-carbethoxypyrimidine (VI) by analysis and hydrolysis with hydrochloric acid to uracil-5-carboxylic acid.[13]

Anal. Calcd. for $C_7H_6O_2N_2Cl$: N, 12.67; Cl, 32.09. Found: N, 12.63; Cl, 31.88.

2-Ethylsulfonyl-4-amino-5-carbethoxypyrimidine (II, X = NH_2; R = $CO_2C_2H_5$).—Five grams of 2-ethylmercapto-4-amino-5-carbethoxypyrimidine (m. p. 102°) was suspended in 60 cc. of water and concentrated hydrochloric acid (8 cc.) added. A small amount of solid remained undissolved but went into solution when treated with chlorine. The chlorination was carried out in an ice-bath. The yield was 5.3 g.

Hydrolysis of Pyrimidine Sulfones.—The sulfones (1–2 g.) were refluxed with 20% hydrochloric acid and the evolved gases swept into solutions of potassium permanganate, bromine water, or iodine–potassium iodide solution. The test solutions were decolorized and gave tests for sulfate. The acid solution was then evaporated to dryness on a steam-bath. The residue was triturated with alcohol and the filtered solid identified as a dioxypyrimidine by analysis and by comparison with authentic

preparations. The alcohol filtrate was evaporated and the residue was freed of solid by triturating with alcohol or water, filtering and evaporating to dryness. This was repeated several times and the residual sirup treated with concentrated ammonium hydroxide. The solid obtained on evaporation was then recrystallized from an alcohol-ethyl acetate mixture and identified as the ammonium salt[12] of ethylsulfonic acid.

The sulfone (2 g.), 2-ethylsulfonyl-4-ethoxy-5-methylpyrimidine (II, X = OC_2H_5, R = CH_3), on refluxing for several hours with 2.5% sodium hydroxide in 90% alcohol gave 2,4-diethoxy-5-methylpyrimidine.[14] The diethoxypyrimidine (0.9 g.) was extracted with petroleum ether after removal of the alcohol under diminished pressure.

Summary

The action of chlorine gas on ethylmercaptopyrimidines has led to the preparation of nine ethylsulfones in the pyrimidine series.

It has been shown that this method is applicable to ethoxy-, chloro-, amino- and carbethoxy-ethylmercaptopyrimidines.

On acid hydrolysis the pyrimidine sulfones yield the corresponding oxypyrimidines.

Acetylene Polymers and their Derivatives. XXIII. The Preparation and Polymerization of Oxyprenes

By Harry B. Dykstra

Recent studies[1] have revealed that of the various derivatives of butadiene-1,3 which are known, those having a single substituent in the 2-position have outstanding properties from the standpoint of rubber synthesis. The term orthoprene has been suggested for compounds of this type.[2] Only a few orthoprenes are known. Prior to the discovery of the haloprenes, chloro-2-butadiene-1,3[3] and bromo-2-butadiene-1,3,[4] isoprene and ethylbutadiene were the only members of this class which had been described. To this list have recently been added the butyl, *t*-butyl, hexyl, phenyl and benzyl butadienes,[5] and the formoxy, acetoxy, chloroacetoxy and butyroxy butadienes.[6]

The interesting properties of the orthoprenes, particularly those containing a negative substituent, have prompted the preparation and examination of other members of this class. The present paper is concerned with orthoprenes in which the substituent is an ether group. The designation "oxyprene" is suggested for these compounds. They are obtained by the series of reactions illustrated below for ethoxyprene (V).

$$\underset{\text{I}}{CH_2{=}CHC{\equiv}CH} + H_2O \longrightarrow \underset{\text{II}}{CH_2{=}CHCOCH_3}$$

$$\text{II} + C_2H_5OH \longrightarrow \underset{\text{III}}{C_2H_5OCH_2CH_2COCH_3}$$

$$\text{III} + HC(OC_2H_5)_3 \longrightarrow \underset{\text{IV}}{C_2H_5OCH_2CH_2C(OC_2H_5)_2CH_3} + HCOOC_2H_5$$

$$\text{IV} \longrightarrow \underset{\text{V}}{CH_2{=}CHC(OC_2H_5){=}CH_2} + 2C_2H_5OH$$

The hydration of vinylacetylene to methyl vinyl ketone[7] and the addition of alcohols to methyl vinyl ketone[8] are recorded elsewhere and will not be described in detail. The conversion of the ether ketones (III) into the ether ketals (IV) by means of orthoformic esters takes place almost quantitatively at room temperature in the presence of alcohol and hydrogen chloride. Physical and analytical data for the ether ketals are given in Table IA.

At sufficiently high temperatures, generally above 130°, the decomposition of the ketal (IV) to the oxyprene (V) is fairly complete, but at lower temperatures intermediate compounds involving the elimination of only one molecule of alcohol are formed. These are the unsaturated ketals (VI) formed when acidic catalysts are used, and the unsaturated ethers (VII) formed with basic catalysts. By further heating, these compounds, particularly VI, are in turn converted to the oxyprenes. Physical and analytical data for the intermediates VI and VII are given in

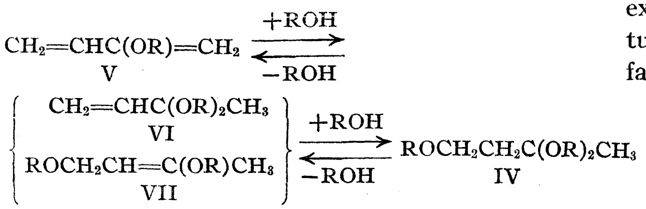
[8] Rothrock, U. S. Patent 2,010,828 (1935).

Table IB and IC. Similar data for the oxyprenes are recorded in Table ID.

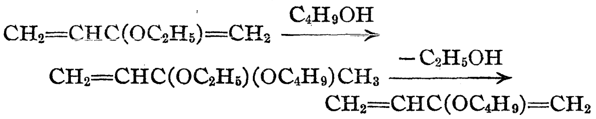
Below the dissociation temperatures any of the compounds V, VI and VII will reunite with alcohols yielding the ketals (IV). The reaction therefore is reversible as illustrated in the equations



$$\underset{\text{V}}{CH_2{=}CHC(OR){=}CH_2}\ \underset{-ROH}{\overset{+ROH}{\rightleftarrows}}$$
$$\left\{\begin{array}{c} CH_2{=}CHC(OR)_2CH_3 \\ \text{VI} \\ ROCH_2CH{=}C(OR)CH_3 \\ \text{VII}\end{array}\right\} \underset{-ROH}{\overset{+ROH}{\rightleftarrows}} \underset{\text{IV}}{ROCH_2CH_2C(OR)_2CH_3}$$

The unsaturated compounds also unite with phenols and mercaptans.

The ease with which compounds, such as V, VI and VII, add alcohols or phenols makes it possible to prepare mixed ethers and ketals of types IV, VI and VII. This also provides a method for converting one oxyprene into another as illustrated in the following scheme.



$$CH_2{=}CHC(OC_2H_5){=}CH_2 \xrightarrow{C_4H_9OH} CH_2{=}CHC(OC_2H_5)(OC_4H_9)CH_3 \xrightarrow{-C_2H_5OH} CH_2{=}CHC(OC_4H_9){=}CH_2$$

The oxyprenes which have been prepared are clear, mobile liquids having ethereal odors. The structures assigned to these products are based on the following reactions observed for the ethoxy derivative. On treatment with dilute mineral acids the ethoxy derivative is converted into methyl vinyl ketone which has been identified by its odor and its reaction product with phenylhydrazine, namely, methyl-3-phenyl-1-pyrazoline.[9] The structure of the ethoxy derivative has been further confirmed by its reaction with naphthoquinone (Diels–Alder diene reaction) to yield, after oxidation, ethoxy-2-anthraquinone.[10] In carbon tetrachloride solution the ethoxy derivative absorbs four atoms of bromine, the end-point being fairly sharp. On hydrogenation at room temperature with a platinum black catalyst it absorbs but two atoms of hydrogen, forming what appears to be ethoxy-2-butene-2. Its behavior toward alcohols and phenols has already been indicated.

Under ordinary conditions the oxyprenes show much less tendency to polymerize than chloroprene. Samples can be stored in the laboratory for several months without the formation of more than a few per cent. of polymer. Polymerization is greatly accelerated by light, heat and various catalysts, such as peroxides, sodium, metallic halides, iodine and certain acids, including acetic and hydrocyanic. The polymers may be liquids, resins or rubber-like products, depending upon experimental conditions. Use of low temperatures and the absence of diluents and catalysts favor the formation of rubber-like polymers. Thus, a 20% yield of rubber-like polymer comparatively free from liquid and resinous polymers is obtained by exposing ethoxyprene to ultraviolet light at room temperature for one week. Elevated temperatures promote the formation of liquid polymers. At 100° a 15% yield of polymer is obtained in six days, the product consisting of about 25% of liquid polymer (largely dimer) and 75% of rubber-like resin. At 130° substantially complete polymerization occurs in two weeks, the amounts of liquid and rubber-like polymer being approximately equal. A comparison of these data with those reported for isoprene[11] and for chloroprene[1] would indicate that ethoxyprene polymerizes about one-third as fast as isoprene and $^1/_{2000}$ as fast as chloroprene. Certain catalysts, notably iodine and hydrogen cyanide, bring about rapid polymerization of ethoxyprene to liquid polymers of low molecular weight. On the other hand, metal halides and acetic acid cause polymerization to resinous polymers. The polymerization of oxyprenes, like that of vinyl ethers,[12] takes place almost explosively in the presence of metal halides, such as stannic chloride.

The rubber-like polymer derived from ethoxyprene (and other oxyprenes) is plastic and readily soluble in ethyl acetate and in benzene. It is elastic and resilient but lacks the snap and high tensile strength of natural rubber or polymerized chloroprene. On heating with dilute hydrochloric acid the polymer is hydrolyzed to a polymeric ketone, identical in composition with methyl vinyl ketone.

As already indicated two types of intermediates, VI and VII, are formed in the preparation of the oxyprenes. Compounds VI are assigned the unsaturated ketal formula, $CH_2{=}CHC(OR)_2CH_3$, on the basis of the following reactions of the diethoxy derivative. On treatment with dilute acids, the diethoxy derivative is readily hydrolyzed to methyl vinyl ketone.

Unlike vinyl ethers, it is not polymerized appreciably by iodine. It reacts with hydrogen in the presence of platinum black to form the diethyl ketal of ethyl methyl ketone.

The structure of compounds VII has not been established with absolute certainty. Structure $ROCH_2CH{=}C(OR)CH_3$ appears most probable on the basis of the following data. The diethoxy derivative yields beta-ethoxyethyl methyl ketone (III) on hydrolysis with dilute acid. It is readily polymerized by iodine. On oxidation with potassium permanganate it yields ethyl acetate and acetic acid.

Experimental Part

Triethoxy-1,3,3-butane.—A mixture of 232 g. of beta-ethoxyethyl methyl ketone, 315 g. of ethyl orthoformate, 282 g. of absolute alcohol and 0.136 g. of hydrogen chloride was placed in a stoppered flask. After four days the mixture was made alkaline with ammonium hydroxide, dried over magnesium sulfate and distilled. The yield of the triethoxy compound, boiling at 72–75° at 9 mm., was 351 g. or 92% of the theoretical. This compound can also be prepared directly from methyl vinyl ketone and ethyl orthoformate.

The corresponding trimethoxy and tributoxy compounds were prepared in a similar manner.

Ethoxy-2-butadiene-1,3.—During the course of about four hours triethoxy-1,3,3-butane was dropped slowly into a heated distilling flask containing 0.01 g. of potassium bisulfate. The triethoxy compound was added at such a rate that approximately 20 g. was present in the flask at all times. The temperature of the flask was maintained at 120–140° to cause steady distillation of the decomposition products, *i. e.*, ethyl alcohol and ethoxy-2-butadiene-1,3. Some of the intermediate, diethoxy-3,3-butene-1, also distilled off. The decomposition products were collected in dilute potassium carbonate solution and were worked up by further washing with potassium carbonate solution, followed by drying and distilling. From 126 g. of the triethoxy compound there was obtained in this manner 39 g. of ethoxybutadiene (59% conversion) and 12 g. of diethoxybutene (13% conversion). The latter can be returned to the process to yield more ethoxybutadiene.

Methoxybutadiene and butoxybutadiene were similarly prepared. Other catalysts which have been used in the preparation of the oxyprenes are magnesium sulfate, *p*-toluenesulfonic acid and *d*-camphorsulfonic acid. When aluminum oxide is used as catalyst, the chief product is dialkoxy-1,3-butene-2.

Butoxy-2-butadiene-1,3.—A mixture of 15 g. of ethoxy-2-butadiene-1,3 and 11 g. of butyl alcohol was heated in a distilling flask until the temperature of the distilling vapors reached 95° and then distillation was continued under reduced pressure. The distillate consisted of 2 g. of ethyl alcohol, 6 g. of butyl alcohol and 6 g. of dibutoxy-3,3-butene-1. The residue in the flask was a viscous brown oil. On heating the dibutoxybutene with potassium bisulfate it decomposed into butyl alcohol and butoxy-2-butadiene-1,3.

Ethoxybutadiene plus Alcohols.—Seven grams of ethyl alcohol and 3.5 g. of ethoxy-2-butadiene-1,3 were heated together in a sealed glass tube at 100° for twenty-four hours and then distilled under 10 mm. pressure. The products consisted chiefly of ethyl alcohol (4.5 g.), triethoxy-1,3,3-butane (4 g.) and polymerized ethoxybutadiene (1 g.). When the reaction was carried out at 130°, only a small amount of the triethoxy compound was obtained, the chief product being diethoxy-3,3-butene-1. The latter compound adds alcohol at 100° to form the triethoxy compound.

A mixture of 14.7 g. of ethoxy-2-butadiene-1,3 and 12.4 g. of ethylene glycol was heated in a sealed tube for twenty-four hours at 110°. Distillation of the homogeneous reaction mixture thus obtained gave 9 g. of ethyl alcohol, 12 g. of a compound boiling at 56° at 100 mm. and 5 g. of resinous product. The compound boiling at 56° at 100 mm. gave methyl vinyl ketone on hydrolysis with dilute acid, indicating that it was either $CH_2{=}CHC(OCH_2CH_2OH){=}CH_2$ (VIII) or $CH_2{=}CH{-}\overline{C(CH_3)OCH_2CH_2{-}O}$, (IX). The product showed no tendency to polymerize. These data, together with the following, favor structure IX: d^{20}_4 0.9547; n^{20}_D 1.4213; MR calcd. for VIII, 33.24; MR calcd. for IX, 31.63; MR found, 30.32.

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.11; H, 8.83. Found: C, 63.39; H, 8.58.

Phenol and thiophenol add readily to ethoxy-2-butadiene-1,3 at ordinary temperatures.

Reaction of Ethoxybutadiene with Naphthoquinone.—A mixture of 12 g. of ethoxy-2-butadiene-1,3, 10 g. of 1,4-naphthoquinone and 15 g. of benzene was refluxed for six hours and then allowed to stand overnight. The yellow crystalline mass which separated was dried in air. This caused the mass to become gray. The product was next suspended in a water–alcohol mixture containing sodium hydroxide, and air was passed through the dark colored mixture until it took on a yellowish-orange appearance. The solid was separated and recrystallized twice from acetic acid. The product, ethoxy-2-anthraquinone, melted at 136° as compared with 135° reported by Liebermann and Hagen.[10]

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.16; H, 4.80. Found: C, 76.01; H, 4.68.

The identity of the ethoxy-2-anthraquinone was further established by heating it with concentrated sulfuric acid as described by Liebermann and Hagen. The product, hydroxy-2-anthraquinone, melted at 302° as reported by these authors and gave a red coloration with alkali.

Hydrolysis of Ethoxybutadiene.—A small amount of ethoxy-2-butadiene-1,3 was added to dilute hydrochloric acid. Solution took place readily and the sharp odor of methyl vinyl ketone developed. On reaction of this mixture with phenylhydrazine, methyl-3-phenyl-1-pyrazoline was obtained, melting at 75–76° as compared with a value of 76–77° reported by Maire.[9]

Hydrogenation of Ethoxybutadiene.—A solution of 14.4 g. (0.147 mole) of ethoxy-2-butadiene-1,3 in 30 cc. of absolute alcohol was hydrogenated in a Burgess–Parr apparatus using 0.2 g. of platinum oxide as the catalyst. Reaction ceased within one and one-half hours after 0.17 mole of hydrogen had been absorbed. Addition of fresh catalyst failed to bring about further absorption. The hydrogenated product boiled almost completely from 88 to 93° and had a refractive index of n^{20}_D 1.4006. These properties suggest that the product is ethoxy-2-butene-2, ethoxy-2-butene-1 or a mixture of these compounds.[13] In a similar experiment using acetone as solvent, 0.117 mole of ethoxybutadiene absorbed 0.129 mole of hydrogen.

Polymerization of Ethoxybutadiene.—Forty grams of ethoxy-2-butadiene-1,3 was heated in a sealed glass tube at 130° for thirteen days. The product consisted of 20 g. of liquid polymer (mainly dimer, b. p. 105–125° at 5 mm.) and 17 g. of solid polymer. The latter was a light-colored, soft, rubber-like resin soluble in acetone, ethyl acetate and benzene, but insoluble in water and in alcohol.

A few drops of a 25% solution of stannic chloride in benzene was added to 5 g. of ethoxybutadiene. A vigorous reaction occurred which converted the ethoxybutadiene into a dark viscous mass within a few minutes. Acetic acid also converted ethoxybutadiene into resinous products, but the reaction was less violent and gave a lighter-colored product. When iodine was used as catalyst, 65% of the polymer consisted of liquid dimer and trimer and the remainder of soft resin.

Polymerization of Butoxybutadiene.—Exposure of butoxy-2-butadiene-1,3 in a quartz tube to ultraviolet light from a mercury arc for one week resulted in a 13% yield of polymer. The polymer was a white, opaque, fibrous solid which was somewhat sticky and elastic. It was insoluble in alcohol, acetone and ethyl acetate; in chloroform and benzene it lost its opacity but did not dissolve.

Diethoxy-3,3-butene-1.—This product, obtained in yields of 10–30% when triethoxy-1,3,3-butane was heated in the presence of acidic catalysts, was readily hydrolyzed by shaking with dilute hydrochloric acid. The product of the hydrolysis, methyl vinyl ketone, was characterized by its odor and reaction product with phenylhydrazine.

An ethanol solution of the diethoxy compound was treated with hydrogen in the presence of platinum oxide in a Burgess–Parr apparatus. Approximately 0.7 equivalent of hydrogen was absorbed. Distillation of the hydrogenated products showed that side reactions had occurred; only a 40% yield of the expected $CH_3CH_2C(OC_2H_5)_2CH_3$ was obtained. Properties observed for this product are: b. p. 68–69° at 100 mm.; d^{20}_4 0.8423; n^{20}_D 1.4012; MR calcd., 42.43; MR found, 42.18. A boiling point of 68° at 100 mm. is reported for this compound.[14]

Diethoxy-1,3-butene-2.—A mixture of 57 g. of $C_2H_5OCH_2CH_2C(OC_2H_5)_2CH_3$ and 0.1 g. of aluminum oxide was heated in a distilling flask. Decomposition started at about 110° and proceeded smoothly at 110–165° with the removal of alcohol. On distilling the residue in the flask under diminished pressure, 41 g. (95% yield) of product believed to be diethoxy-1,3-butene-2 was obtained.

Ten grams of this diethoxy compound was treated with 20 cc. of 1% hydrochloric acid and shaken for a few minutes. The product (6 g.) of the hydrolysis, separated by extraction with ether, proved to be beta-ethoxyethyl methyl ketone, identical with that obtained by addition of ethyl alcohol to methyl vinyl ketone. Some of its properties are: b. p. 57° at 24 mm.; d^{20}_4 0.9024; n^{20}_D 1.4089.

A mixture of 58 g. of the diethoxy compound and 600 g. of water was treated with potassium permanganate (350 g.) until no further reaction occurred. From the oxidation products, there was separated in the usual way 40 g. of an acetic acid–ethyl acetate mixture. The acetic acid was identified by its *p*-toluidide (m. p. 145–147°) and the ethyl acetate by its physical properties (odor, b. p. 78°; n^{20}_D 1.3780).

The author wishes to express his thanks to Dr. Wallace H. Carothers for his interest in this work and for his helpful suggestions.

Summary

The methyl, ethyl and butyl ethers of hydroxy-2-butadiene-1,3 have been prepared and characterized. The designation oxyprene is suggested for products of this structure. The oxyprenes

---

[13] Lauer and Spielman, This Journal, **53**, 1533 (1933).

[14] Reitter and Hess, *Ber.*, **40**, 3020 (1907).

polymerize slowly to rubber-like products, but as substitutes for rubber these products are inferior to polychloroprene.

A method for the synthesis of oxyprenes from vinylacetylene has been described which involves as its final step the thermal decomposition of compounds of the formula $ROCH_2CH_2C(OR)_2CH_3$. A number of intermediates of types $ROCH_2CH_2COCH_3$, $ROCH_2CH_2C(OR)_2CH_3$, $ROCH_2CH{=}C(OR)CH_3$ and $CH_2{=}CHC(OR)_2CH_3$ have been prepared and characterized.

Alkyl Ethers of 2,2-Bis-(4-hydroxyphenyl)-propane. I. Some Dialkyl Ethers[1]

BY G. R. YOHE AND J. F. VITCHA

The condensation of two molecules of phenol with one of acetone in the presence of hydrogen chloride or sulfuric acid yields 2,2-bis-(4-hydroxyphenyl)-propane, $HOC_6H_4C(CH_3)_2C_6H_4OH$. This compound, with some of its simple derivatives, has been described in the literature.[2] Of the ethers of this compound only the dimethyl ether has been described.[2a,2b,3]

Some time ago the writers began the preparation of a series of the monoalkyl ethers of this dihydric phenol. The preparation of these monoalkyl ethers resulted in the incidental formation of the corresponding dialkyl ethers as well; several of these are described herewith. The monoalkyl derivatives will be described in a subsequent communication.

The general method followed was to allow an excess of the phenol in aqueous sodium or potassium hydroxide solution to react with the suitable dialkyl sulfate. Commercial dimethyl and diethyl sulfates were used, *n*-propyl and *n*-butyl sulfates were prepared by the method of Barkenbus and Owen,[4] while *n*-amyl sulfate was prepared by the action of sulfuryl chloride on *n*-amyl alcohol[5] and used without being isolated for the alkylation reaction. The ethers described herein were isolated from the alkali-insoluble portions of the reaction mixtures and purified by distillation or by recrystallization from methanol or ethanol solution cooled with a solid carbon dioxide–ether mixture; in some cases both distillation and crystallization procedures were used. In general the yields were low and the compounds rather difficult to purify.

The di-*n*-propyl ether gave the most difficulty in purification. It was contaminated with a rather large amount of a substance of similar boiling point, but of higher refractive index. Isolation was finally accomplished by dissolving the crude compound in petroleum ether (b. p. 40–60°) and cooling the solution with solid carbon dioxide–ether mixture, whereupon the impurity separated out as a gum, leaving the desired dipropyl derivative in solution. The identity of the impurity has not been established.

The solid dialkyl ethers of 2,2-bis-(4-hydroxyphenyl)-propane are white needle crystals; in the molten state they may be easily supercooled to liquids of moderate viscosity. These compounds are soluble in the usual organic solvents; the higher members of the series are only sparingly soluble in methanol.

The properties of these *n*-alkyl ethers through amyl are listed in Table I.

The reactions described below are typical of the relative amounts and conditions used in all reactions. No doubt higher yields of the dialkyl derivatives could have been obtained by using the alkyl sulfates in excess. This, however, would have minimized the formation of the monoalkyl ethers.

Experimental Part

Dibutyl Ether of 2,2-Bis-(4-hydroxyphenyl)-propane. Use of the Dialkyl Sulfate.—A mixture of 114 g. (0.5 mole) of 2,2-bis-(4-hydroxyphenyl)-propane, 60 g. (1.5 moles) of sodium hydroxide and 300 cc. of water was heated to boiling, 42 g. (0.2 mole) of di-*n*-butyl sulfate added,

and the heating continued for three hours. The alkali-insoluble portion of the reaction product was isolated by ether extraction, and the dibutyl derivative obtained by distillation of this solution. The yield was 35 g., or 51% of the theoretical, assuming the utilization of only one of the alkyl groups of the sulfate. It was necessary to further purify this material.

Diamyl Ether of 2,2-Bis-(4-hydroxyphenyl)-propane. The Alcohol–Sulfuryl Chloride Method.—One mole (88 g.) of pentanol-1 was cooled with an ice-bath, and 0.5 mole of sulfuryl chloride added slowly so that the reaction mixture remained cold. This was allowed to stand protected from moisture for one week. It was then neutralized with sodium hydroxide solution (approximately 0.75 mole in the form of a 10 *N* solution was needed), and a solution of 0.5 mole of 2,2-bis-(4-hydroxyphenyl)-propane in 150 cc. of potassium hydroxide (500 g. per liter) added. This was then treated and worked up as described above. The yield was 24 g., or 26% of the theoretical, assuming the formation of 0.5 mole of diamyl sulfate and the utilization of one of the alkyl groups of this sulfate in the alkylation. The product was further purified by recrystallization from methanol.

The writers wish to thank E. I. du Pont de Nemours and Co. and The Goodyear Tire and Rubber Co. for supplying certain of the materials used, and Mr. C. A. Sluhan for help with the experimental work.

Summary

This paper describes the preparation and properties of the di-*n*-alkyl ethers of 2,2-bis-(4-hydroxyphenyl)-propane from methyl to amyl.

The Chemistry of the Tetrose Sugars. I. A Crystalline Triacetate of *d*-Threose from the Degradation of Strontium Xylonate with Hydrogen Peroxide. Nomenclature in the Tetrose Group[1]

BY ROBERT C. HOCKETT

Within recent years so many sugars previously prepared by synthetic methods in the laboratory have been found playing an important role in natural processes that new attention is focused upon the necessity of filling those gaps which still remain in the sugar family. Particularly does this necessity apply to the sugars of low carbon atom content which are those most likely to be encountered as intermediates in the physiological degradation of glucose. The tetroses are still among the least known members of the sugar group despite the fact that the first efforts toward their preparation were made nearly fifty years ago.[2] The general methods of degrading sugars devised by Wohl and Ruff seemed at first to furnish a very promising means of attacking the problem, and centered an interest upon the tetroses particularly from 1899 to 1901,[3] but the results proved disappointing in that all the classic methods of preparing sugars are beset by special difficulties when applied to this group, so that very few crystalline compounds were prepared and few data recorded. Except for the later application of Weerman's[4] method of degradation

which resulted in little actual new success, the field was abandoned until recent years.

In January, 1931, we decided to undertake a complete resurvey of the known methods of degradation to determine whether advancing knowledge would now permit some of the difficulties to be surmounted. *d*-Threose was chosen as the object of search because it has received much less attention than the erythroses, and the Ruff degradation was selected as a method. In the undertaking, we had certain advantages over predecessors. (1) Xylose, our starting material, once very rare, is now available in quantity. (2) Our independent preparation of crystalline strontium xylonate[5] made possible the use of a pure anhydrous salt in the oxidation experiments. The results were far superior to those obtained by using amorphous calcium xylonate. (3) The announcement by Isbell and Frush[6] of their electrolytic oxidation of aldoses provided us with a method which proved very efficient when applied to the preparation of strontium xylonate. (4) A new method of making the ferric acetate catalyst proved to be very rapid and reliable.[7]

With these advantages, colorless strontium-free *d*-threose sirups were prepared in relatively good yield. One of these which was acetylated, after a year or more yielded crystals of the acetate which is fully described in the experimental part, and which thereafter was obtained readily. It represents a substance which can be highly purified, weighed and deacetylated almost quantitatively to give an aqueous solution of the tetrose whose concentration is pretty accurately known, thus making the sugar available in a form suitable for a variety of chemical investigations and for biological experiments, some of which are in progress.

This acetate was rigidly identified by the determination of carbon, hydrogen, acetyl and molecular weight, while the free sugar was converted into four known crystalline derivatives: erythrosazone, dibenzylidene-*d*-threitol, brucine *d*-threonate and potassium levo-bitartrate.

A standard aqueous solution of the free sugar prepared as described was used for determining its equilibrium specific rotation, which was found to be approximately[8] $-12.3°$. This result was surprising because W. Freudenberg[9] had meanwhile announced the preparation of a crystalline *d*-threose showing a positive specific rotation in water of $+19.59°$. Deulofeu[10] had also announced the preparation of *l*-threose diacetamide rotating $-7.68°$ in cold $N/3$ sulfuric acid, which changed to $-24.6°$ after heating for forty-five minutes to remove the acetamide groups. His conclusion was that the latter value represents the rotation of *l*-threose. These two reports, harmonious with one another and opposite to our result, suggested the possibility that an acetyl group had failed to be dislodged by our method of saponification with sodium methylate. Experiments involving two successive deacetylations or the use of other agents such as barium hydroxide, however, all gave us levorotatory solutions of the sugar. The discrepancy was therefore left to be explained when a totally different method of preparing *d*-threose could be carried out and the products compared. The second paper of this series will discuss this work.

It was observed that the deposition of the crystalline threose acetate always leaves a levorotatory mother liquor which suggests the presence of isomeric acetates as in the case of higher-carbon sugars. Stronger evidence is provided by the fact that a threose sirup prepared by saponification of pure acetate, when reacetylated, yields only one-third of the original acetate and two-thirds of a levorotatory sirup rotating roughly $-19.4°$ in chloroform. When the deacetylation and reacetylation is repeated upon this sirup, again one-third is recovered as the crystalline acetate and two-thirds as levorotatory sirup, strongly suggesting the existence of two (or more) closely related isomers of which at least one presumably is a ring form.

A dried *d*-threose sirup when treated with 2% dry hydrogen chloride in methanol, loses all reducing power and reaches a constant rotation in about twenty minutes at room temperature. Such behavior is to be expected of a sugar whose chain is too short for the formation of methyl pyranosides and which must form either methyl furanosides or a dimethyl acetal (Fig. 1).

Nomenclature in the Tetrose Group

Several errors and inconsistencies have arisen in the nomenclature of substances in the four-

carbon group owing in part to the small attention they have received during developments elsewhere.

In 1906, Rosanoff[11] proposed certain reforms in Fischer's nomenclature involving a change in the name of dextrorotatory xylose from *l*- to *d*-xylose. This change, promptly accepted by American[12] and British chemists in the interest of logical harmony within the system, came into general acceptance about 1923.[13] It has repercussions among names formerly assigned to certain derivatives of xylose which should be brought into conformity, as will be shown.

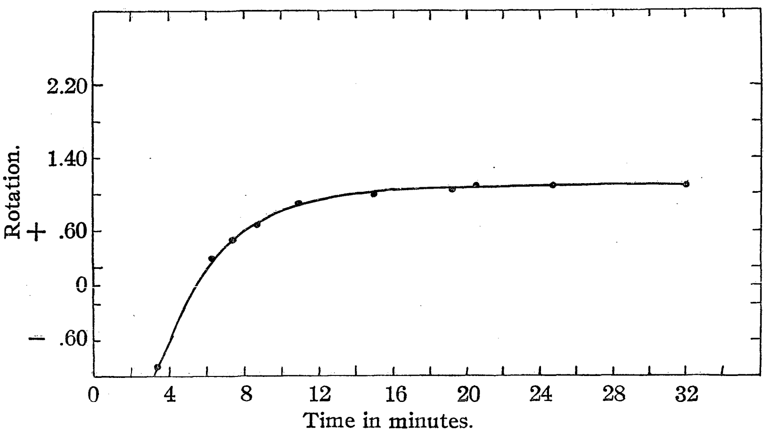

Fig. 1.—The action of 2% hydrogen chloride in methanol upon threose.

Maquenne,[3] by degrading what we now call *d*-xylose, prepared a sirup of *d*-threose (Fig. 2, I) which he erroneously called *l*-erythrose. By reducing this sugar, he obtained the alcohol which should be known as *d*-threitol (II), but which he called *l*-erythritol. Bertrand[3] meanwhile made a four-carbon ketose by the action of sorbose bacteria on the natural inactive erythritol (III). His product might *a priori* have been either *d*- or *l*-erythrulose depending upon which carbon was attacked (IV or V). That he actually obtained *l*-erythrulose (V) is indicated by the behavior of the ketose on reduction. We should expect two products, the original inactive erythritol (III) and an active alcohol either identical or enantiomorphous with Maquenne's *d*-threitol (II or VI). The products actually obtained were inactive erythritol and *l*-threitol (VI)[14] (which they called *d*-erythritol). In no text or reference work that we have examined has Bertrand's name "*d*-erythrulose" been corrected to "*l*-erythrulose" as required by consistency.

Consistency also strongly urges limiting the term "erythritol" to the natural inactive alcohol (m. p. 120–121.3°) which may also be obtained by reduction of either *d*- or *l*-erythrose, and using the terms "*d*-threitol" (rotating +4.33° in water) and "*l*-threitol" (rotating −4.4° in water) for the active tetritols derived, respectively, from the two threoses, since elsewhere in the sugar group, only enantiomorphous alcohols bear the same name, being distinguished by prefix, and forms of different configuration bear different names.

On oxidation with nitric acid, *d*-threose is converted into a dibasic acid which might consistently be called *d*-threodihydroxysuccinic acid were it not already well known as *l*-tartaric acid (VII). The latter, long ago named from its actual rotation, is not in harmony with the arbitrary standard set up by Fischer for assignment of prefixes in the sugar group, and appears destined to constitute a permanent anomaly in our nomenclature.

Experimental

Strontium *d*-xylonate.[5]—One hundred grams of xylose, 20 g. of sodium bromide, 130 g. of strontium carbonate and two liters of water are warmed to 60°, placed in a glass cell equipped with carbon electrodes providing about 200 sq. cm. of anode surface, and electrolyzed with the current from a tungar battery charger at about 10 volts and 2.6 amperes for twenty-four hours with good mechanical stirring. Another 100 g. of xylose is added each twenty-four hours until 400 g. has been used and electrolysis is continued until the reducing power toward Fehling's solution is virtually gone. After filtering, evaporating to one-half its volume, cooling and seeding, the solution crystallizes rapidly and must be stirred to prevent formation of a too solid cake. Filtered, washed with 50% alcohol and dried at 60°, the combined first and second crops represent 95% of the theoretical yield. The salt is readily recrystallized from water as the pentahydrate; drying as described yields the powdery anhydrous salt rotating +13.2° (0.4266 g. in 25 cc. of soln. in water; 2-dm. tube; 0.45° to the right).

Anal. Calcd. for $(C_5H_9O_6)_2Sr\cdot 5H_2O$: H_2O, 17.74. Found: H_2O, 17.72. Calcd. for $(C_5H_9O_6)_2Sr$: Sr, 20.98; C, 28.72; H, 4.34. Found: Sr, 20.79, 20.77; C, 28.77; H, 4.49.

***d*-Threose Triacetate.**—Seventy-five cubic centimeters of molar barium acetate and 50.2 cc. of half-molar ferric sulfate are added to two liters of water. Then 200 g. of anhydrous strontium xylonate is added, the solution is heated to boiling, allowed to settle, filtered through filtercel, diluted with a liter of water and cooled to 35°. One hundred twenty cubic centimeters of 30% hydrogen peroxide is added and a vigorous evolution of gas ensues. When the reaction has ended (ten minutes) the solution is cooled to 35°, and another 120 cc. of hydrogen peroxide added.

After settling the solution is filtered on filtercel, concentrated *in vacuo* to 250 cc., taken up in 1500 cc. of dry methanol, warmed and shaken, and ultimately filtered. The salts are washed with 300 cc. of warm methanol. Nine hundred cubic centimeters of ether or acetone is added to the filtrate, which is stirred and allowed time to separate a flocculent precipitate. The colorless filtrate is concentrated *in vacuo* to blubbering, taken up in dry methanol and reconcentrated. Finally it is distilled down in the presence of a little ethyl acetate to remove alcohol. Ten grams of fused sodium acetate and 100 cc. of acetic anhydride are added and the mixture is warmed on a steam-bath for an hour with frequent shaking. After acetylation is complete, the mixture is poured into ice water and neutralized with sodium bicarbonate. The solution is extracted several times with chloroform, which is separated, dried with anhydrous sodium sulfate, filtered through carbon and concentrated *in vacuo*. The thick sirup is taken up in absolute alcohol, transferred to a beaker and seeded with threose acetate, which separates on cooling; yield, to 12 g. Since the crystalline isomer represents one-third of the total, the yield represents about 15% of the theoretical.

Recrystallized from absolute alcohol as very sharp, well-formed prisms, the substance after pulverizing and drying at 60° shows m. p. 117–118° (corr.) and rotates +35.55° (0.8910 g. in 26.18 cc. of chloroform soln.; 4.83° to the right; 4-dm. tube). The acetate is somewhat soluble in hot water, sparingly so in absolute alcohol, methanol and ether, and easily in chloroform, acetone and ethyl acetate.

Anal. Calcd. for $C_{10}H_{14}O_7$: C, 48.76; H, 5.73; CH_3CO, 52.44. Found: C, 48.51; H, 5.77; CH_3CO, 52.64.

Molecular Weight of Threose Acetate.—Cottrell's ebullioscopic apparatus was used with acetone as the solvent. The sample was weighed in a calibrated 25-cc. flask, made up to the mark with acetone and reweighed. An aliquot was introduced into the apparatus by pipet. A weight of 2.6272 g. of the acetate caused a dT of 0.203° in 117.6 cc. of acetone. Molecular weight found, 240; calculated for $C_{10}H_{14}O_7$, 246. The substance is clearly a monomer.

***d*-Threose.**—Five grams of crystalline *d*-threose triacetate was dissolved in 10 cc. of dried chloroform, cooled below zero and treated with 10 cc. of approximately 2% sodium methylate in dry methanol. After twenty minutes, below 0°, 10 cc. of water was added with shaking and then an exactly equivalent volume of approximately 0.5 *N* sulfuric acid (as determined by previous titration against the sodium methylate). The whole mixture was concentrated nearly to dryness *in vacuo* at a low temperature and the sugar was taken up in 90% alcohol, leaving behind most of the sodium sulfate. Successive extractions eliminated all but a trace of salt and yielded a colorless solution of the sugar.

An accurately weighed sample, so deacetylated, concentrated to dryness and then made up to volume with water in a 50-cc. calibrated flask showed an equilibrium rotation for the free sugar of −12.3° (1.1268 g. of sugar (calcd.) in 50 cc. soln. in water; 0.277° to the left; 1-dm. tube). After elimination of practically all the sodium sulfate, the rotation was virtually unchanged.

Another sample was deacetylated with a clear aqueous solution of barium hydroxide at 30°. After complete solution of the acetate and quantitative removal of barium, the solution was levorotatory.

Barium methylate did not remove the acetyls completely.

After two successive deacetylations with sodium methylate, the same specific rotation was obtained.

***d*-Threosazone (*d*-Erythrosazone).**—An aqueous solution of *d*-threose, acidified with acetic acid and warmed for three-quarters of an hour with 5 cc. of phenylhydrazine, deposited yellow needles on cooling. Recrystallized from benzene and dried at 55°, these showed m. p. 164–165° when heated at one degree per minute. Erythrosazone has been reported about a dozen times[3] with melting point from 163 to 174°. The most frequent value is 164°.

Dibenzylidene-*d*-threitol.—The sugar from five grams of the triacetate was diluted to 100 cc. with water and well stirred at room temperature while 2% sodium amalgam was added in 50-g. portions and 20% sulfuric acid added dropwise to maintain a slight acidity to Congo red. After addition of 450 g. of amalgam, the reducing power had disappeared. The mercury was separated, the solution neutralized to phenolphthalein, concentrated to a sirup and the threitol extracted from sodium sulfate with 50 cc. of hot absolute alcohol. The extract was concentrated to a thick sirup, taken up in absolute alcohol, filtered from traces of sodium sulfate, and then reconcentrated. Finally, the sodium-free substance in 30 cc. of alcohol solution was saturated with dry hydrogen chloride and 5 cc. of benzaldehyde added whereupon fine needles promptly separated. Refrigerated, filtered, washed free of acid with absolute alcohol and dried, they weighed 7 g. After recrystallization from fifteen parts of hot benzene as clusters of fine needles, filtration, washing with cold benzene and drying *in vacuo* at 75°, they rotated $-78.2°$ (0.1860 g. in 25 cc. of chloroform soln.; 1.163° to the left; 2-dm. tube) and melted 214–216° (corr.).

After further recrystallization from a mixture of 50 cc. of chloroform with 15 cc. of absolute alcohol and drying at 90° in a high vacuum, the substance showed m. p. 218–222° (corr.) with heating at a half-degree per minute, and rotated $-78.3°$ (0.2102 g. in 25 cc. of chloroform soln.; 1.315° to the left; 2-dm. tube).

The substance dissolves in cold chloroform to about one part in one hundred; much more on warming. About seven parts per hundred dissolve in boiling benzene and less in alcohol.

Ruff[3] gives a melting point of 204–205° for dibenzylidenethreitol. Ours is the first report of its rotation.

Brucine *d*-Threonate.—The sugar from 5 g. of the triacetate was dissolved in 150 cc. of water and treated with 1.2 cc. of bromine in the presence of 12 g. of barium benzoate for forty-eight hours. The reducing power having then disappeared, the solution was worked up in the usual way[15] and the concentrated aqueous solution of threonic acid was treated with a slight excess of purified brucine. On concentrating further, the salt crystallized in the flask; free brucine was extracted with absolute alcohol and the salt purified by two recrystallizations from 85% alcohol as fine clear needles. Dried for two hours in a vacuum at 60°, they melted 197–198° (corr.) with heating at 3° per minute. The rate of heating had a strong effect upon the melting point which was only 187–190° at 1° per minute. The crystals rotated $-36.8°$ (0.4420 g. in 25 cc. of water soln.; 1.025° to the left; 2-dm. tube). Anderson[16] gives m. p. 213–214° and rotation $-32.40°$. On account of our limited amount of material, we did not attempt to set a new standard of value for these constants, but consider the agreement good evidence of identity. Wohl and Momber[13] give m. p. 204° and rotation $-29.9°$ (at 17°).

Oxidation of *d*-Threose to *l*-Tartaric Acid.—A solution of 1.5 g. of threose in 6 cc. of nitric acid (sp. gr. 1.2) was allowed to stand at room temperature until a violent reaction had occurred. The next morning the acid was distilled off *in vacuo* to a thin sirup which was several times taken up in water and reconcentrated. The sirup nearly free of nitric acid was dissolved in water and neutralized with caustic potash. Then several cubic centimeters of 10% acetic acid were added, and alcohol to a concentration of 50%, which precipitated a gum. After several days, the mother liquor was decanted and fresh 50% alcohol added to the gum whereupon it became crystalline through the separation of needles of potassium *l*-bitartrate. They were recrystallized by dissolving in a little water, filtering through carbon, and adding alcohol, were washed with dilute, then pure alcohol, and dried at 50°.

Anal. Subs. 0.1845 g. Calcd. for titration of $KH(C_4H_4O_6)$, 4.91 cc. of 0.2000 *N* NaOH. Found: 4.89 cc.

The neutralized solution of sodium potassium *l*-tartrate rotated $-29.40°$ (at 24°) (0.2061 g. in 50 cc. of water soln.; 0.242° to the left; 2-dm. tube). Landolt[17] gives $+29.7°$ for sodium potassium *d*-tartrate.

We wish to express to Dr. C. S. Hudson, Chief of the Division of Chemistry, our gratitude for the patient and sympathetic interest which made this work possible. Our thanks are also due Dr. F. H. Goldman, Dr. E. L. Jackson and Mr. C. G. Remsburg for analyses reported in this paper.

Summary

1. Ruff's method of degrading sugars has been applied in an improved form to the preparation of *d*-threose from crystalline strontium *d*-xylonate.

2. The electrolytic oxidation of xylose and preparation of the strontium salt is described.

3. The oxidation of strontium *d*-xylonate with 30% hydrogen peroxide yielded 15% of *d*-threose in an impure sirup.

4. The sugar was separated as a crystalline triacetate which is described, and from which after purification, aqueous threose sirups of known concentration can be prepared for chemical and biological study.

5. The sugar was identified by conversion into four known crystalline derivatives.

6. Its equilibrium rotation in water was found to be approximately $-12.3°$, a result in conflict with two reports by other investigators of a dextrorotation.

7. Some errors in nomenclature in the tetrose group are corrected.

The Chemistry of the Tetrose Sugars. II. The Degradation of *d*-Xylose by the Method of Wohl. The Rotation of *d*-Threose[1]

BY ROBERT C. HOCKETT

The first communication of this series[2] described the preparation of a crystalline threose triacetate by the Ruff degradation and recorded for *d*-threose prepared from the purified acetate, an equilibrium levorotation in water of −12.3°.[3] This rotation is of a sign opposite to that determined by W. Freudenberg[4] and by Deulofeu.[5] No source of error was discovered in the experiments leading to our measurement, and it was promised that further evidence would be sought in the preparation of *d*-threose by a totally different method of degradation, as one step in the complete resurvey of degradation methods which we announced in the first paper.[2] The method devised by Wohl[6] was selected as the second one to be studied, particularly because Deulofeu used this method in attempting to determine the specific rotation of *l*-threose which he reported as *to the left.*

d-Xylose, when treated with hydroxylamine, yielded a sirupy mixture of oximes of which no constituent has ever been obtained crystalline. Acetylation of this sirup gave a 48% yield of crystalline tetraacetyl-xylonic nitrile. This reaction is very exothermic so that there is great danger of the mixture becoming charred unless an inert diluent such as dioxane is used, and the acetic anhydride is added in small successive quantities.

By warming the tetraacetyl-*d*-xylonic nitrile on a steam-bath with strong aqua ammonia (28%), it is simultaneously degraded and deacetylated. The threose is obtained as a crystalline combination with two molecules of acetamide in a yield of about 78%, which is much greater than the yield obtained by using ammoniacal silver nitrate (17%).[5] Deulofeu reports the isolation of about half a gram of *l*-threose diacetamide to which he attributes a specific rotation in dilute sulfuric acid of −7.68°. The *d*-isomer, however, prepared in 50-g. batches, many times recrystallized as colorless, well-built prisms, and analyzed, has a specific rotation in water of −10.9°. Obviously the *l*-isomer should have a dextrorotation of equal numerical value and we are forced to the conclusion that Deulofeu did not have pure *l*-threose diacetamide. Moreover, acetylation of the diacetamide compound yields a crystalline triacetate, well-built prisms, m. p. 179-180°, rotation in chloroform, +74.2°, which after thorough purification and deacetylation regenerates beautifully crystalline *d*-threose diacetamide rotating −10.8°. We consider this good evidence of the purity of the latter.

To determine the equilibrium rotation of the sugar itself, Deulofeu hydrolyzed his acetamide compound to constant rotation with $N/3$ sulfuric acid. He reports a change from specific rotation −7.68° for the diacetamide compound to −24.6°, calculated for the sugar, the direct readings being unreported. In a preliminary experiment using about the same quantities, we detected a downward drift barely greater than the experimental error. We were doubtful whether an hydrolysis had occurred until tests showed that the acid-treated solution had a powerful reducing action whereas threose diacetamide fails to reduce Fehling's solution even on boiling. The necessary conclusion that the change of rotation during hydrolysis is very minute was wholly in accord with our previously determined rotations for the diacetamide compound and the sugar, respectively (−10.9 and −12.3°).

By refinements of technique, it was possible to follow the course of hydrolysis quantitatively. Control tests indicated that threose may be titrated with consistent results by Cajori's iodine oxidation method,[7] that the diacetamide compound is unaffected by the reagents employed, and that the presence of free acetamide does not interfere with the titration. It was possible, therefore, to follow the course of the hydrolysis by removing samples periodically, dropping them

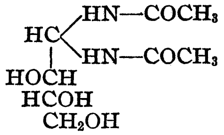
at once into dilute sodium carbonate solutions to stop action and completing the titrations within a reasonable period of time. Figure 1 shows the curve obtained. After removing the last sample for analysis, the remaining solution was immediately cooled and its rotation read. Knowing the concentration of free sugar, the concentration of diacetamide compound (by difference), the rotation of the mixture and the specific rotation of the starting substance, we calculated the equilibrium specific rotation of the sugar in dilute acid as −12.5°, a value in excellent agreement with that previously determined for *d*-threose from the acetate. (By accident, the agreement is actually closer than the experimental errors permit us to expect.)

The change in rotation during hydrolysis, though small, is measurable when a 2% soln. is read in a 4-dm. tube. Figure 2 shows the curve obtained in such an experiment. This, in contrast with Deulofeu's report, shows a downward trend, for although the specific rotation of the starting substance is less levorotatory than that of the sugar released, the molecular rotation of the former is much greater. At the end, the solution was titrated and another calculation of the specific rotation of *d*-threose was made, which gave −10.8°. This we consider to be in satisfactory agreement. The rates of reaction as determined from the two methods also agree satisfactorily.

In order to prove rigidly that the reducing substances obtained from threose acetate and from threose diacetamide are actually identical, the sugar from hydrolysis of a sample of the latter was reduced to *d*-threitol with sodium amalgam and the latter converted into dibenzylidene-*d*-threitol.[2] By rigid purification of this derivative, it was shown by rotation, melting point and mixed melting point observations to be identical with dibenzylidene-*d*-threitol from threose acetate.

Thus the equilibrium specific rotation of *d*-threose, both in water and in dilute sulfuric acid, appears well established as approximately 12° *to the left*, and sources of error are to be sought in the work of those who have found other values.

The formation by *d*-threose diacetamide of a triacetate indicates the absence of a ring in the former and establishes it as a derivative of aldehydo-*d*-threose:



The subject of ring structure among tetrose derivatives will be elucidated further in another communication.

In the search for cheaper and more efficient methods of making the tetroses, the Wohl method suffers from the disadvantage that every aldose forms several oximes so that it does not appear easy to increase the yield of the isomer necessary for this degradation.[8]

Experimental

Tetraacetyl-*d*-xylonic Nitrile.—Hydroxylamine hydrochloride (25g.) is dissolved in 15 cc. of water and a solution of sodium methylate (8.2 g. sodium in 200 cc. of dry methanol) added to the point of neutrality (phenolphthalein). After chilling the solution and filtering the precipitated sodium chloride, 45 g. of powdered *d*-xylose is added and the mixture allowed to stand overnight, then warmed on the steam-bath as long as is necessary to dissolve all the sugar. After filtering, the solution is concentrated *in vacuo* to a thick sirup, the outer bath not being allowed to rise above 75°. The sirup is dehydrated twice by adding a little dioxane and reconcentrating. Then 12 g. of fused sodium acetate and 25 cc. of dioxane are added, the mixture is warmed to 40° and 10 cc. of acetic anhydride added. The mixture is shaken vigorously until the spontaneous heating has ceased and the flask has begun to cool, then 10 cc. more of acetic anhydride is added, etc., until 120 cc. has reacted. The solution becomes homogeneous when about 20 cc. of acetic anhydride has reacted. At the end, the colorless mixture is warmed gently for an hour and poured over cracked ice. The solution is partially neutralized by stirring in solid sodium bicarbonate and the precipitated sirup soon becomes crystalline; yield, 45 g. or 48% of the theoretical. Tetraacetyl-xylonic nitrile is recrystallized from absolute alcohol as triangular plates of m. p. 81–82° (corr.) and rotation +50.3° (0.7615 g. in 25 cc. of chloroform soln., 3.06° to the right, 2-dm. tube).[9]

***d*-Threose Diacetamide.**—Thirty grams of tetraacetyl-*d*-xylonic nitrile is mixed with 300 cc. of concentrated aqua ammonia (28–29%), warmed on a water-bath until the solid is all dissolved and allowed to stand for three hours. The solution is then concentrated *in vacuo* to a thick sirup, taken up in aqua ammonia and reconcentrated. The final thick sirup is dissolved out of the flask with absolute alcohol, ether is added to turbidity and the mixture is refrigerated for forty-eight hours; yield, 16.5 g. or 78% of the theoretical. The substance is recrystallized by dissolving in two volumes of warm 75% alcohol, filtering through carbon and adding an equal volume of absolute alcohol. It crystallizes slowly, forming clear, sharp needles or prisms in rosets. When purified these show m. p.

165–167° (corr.) and rotate −10.86° (0.5979 g. in 25 cc. of aqueous soln.; 0.519° to the left; 2-dm. tube). The substance sometimes requires frequent recrystallization to get rid entirely of a gummy substance which contaminates the crude compound. A sample of the compound made by deacetylating purified triacetyl-*d*-threose diacetamide rotated −10.8° (0.9495 g. in 25 cc. of aqueous soln., 0.817° to the left; 2-dm. tube). The substance is exceedingly soluble in water, nearly insoluble in absolute alcohol, methanol, ether and chloroform.

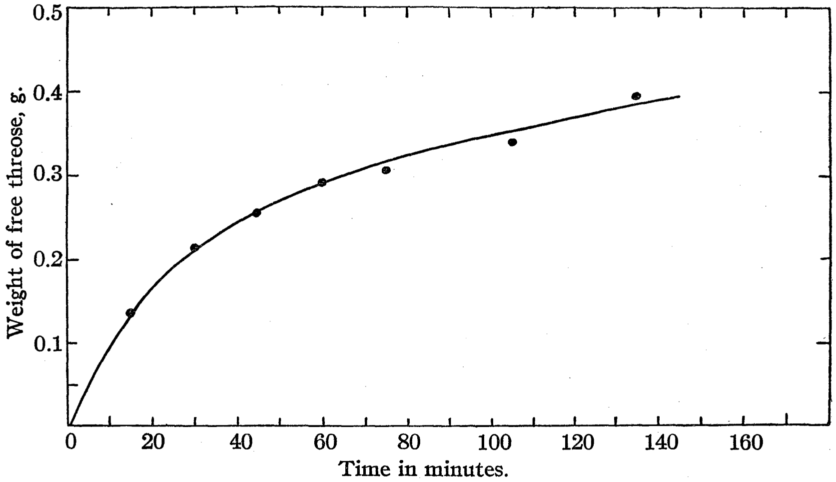

Fig. 1.—Hydrolysis of threose diacetamide by 0.100 *N* sulfuric acid (iodine titration).

Anal. Calcd. for $C_8H_{16}O_5N_2$: N, 12.72. Found: N, 12.65, 12.72.

Triacetyl-*d*-threose Diacetamide.—Two grams of purified threose diacetamide is treated with 10 cc. of acetic anhydride and 10 cc. of pyridine, warmed until the crystals dissolve and let stand overnight. The mixture is filtered through carbon, then concentrated to dryness *in vacuo*. The remaining material which crystallizes solid in the flask is dissolved in absolute alcohol and reconcentrated to dryness to remove additional pyridine; then the crystals are dissolved out of the flask with absolute alcohol, from which clear needles separate on the addition of ether. Recrystallized from the same solvents until free from pyridine, the substance shows m. p. 179–180° (corr.) and rotates +74.2° (0.3434 g. in 25 cc. of chloroform; 2.04° to the right; 2-dm. tube). The crystals are fairly soluble in water and alcohol, soluble in chloroform and practically insoluble in ether.

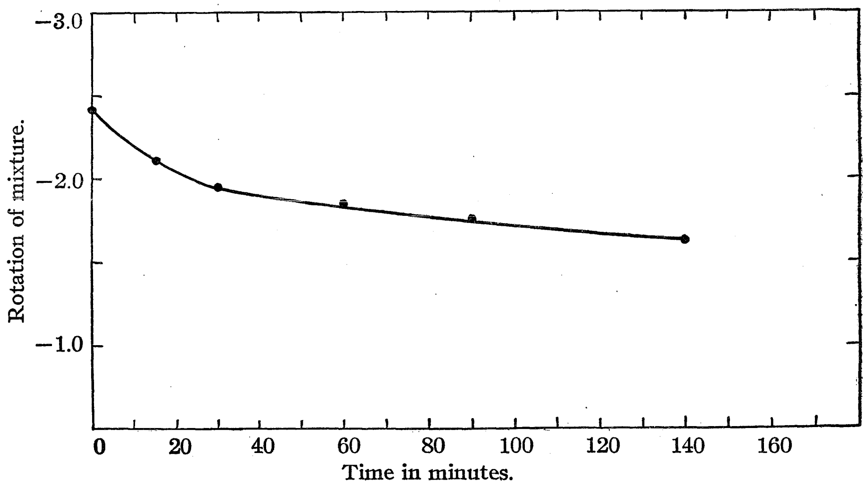

Fig. 2.—Hydrolysis of threose diacetamide by 0.100 *N* sulfuric acid (change of rotation).

Anal. Calcd. for $C_{14}H_{22}O_8N_2$: N, 8.10; acetyl, 37.29. Found: N, 8.17, 8.17; acetyl, 37.18, 37.14.

Hydrolysis of *d*-Threose Diacetamide.—After showing by control experiments that threose may be titrated quantitatively with hypoiodite, and that threose diacetamide and free acetamide are unaffected by the reagents used, the following experiment was performed. A sample of 0.9437 g. of pure threose diacetamide was made up to 50 cc. with 0.100 *N* sulfuric acid. This solution was poured by funnel into a 200-cc. flask submerged to the middle of the neck in a bath of boiling water and the time noted. At intervals 5-cc. samples were removed by pipet and run into Erlenmeyer flasks containing 5 cc. of water and 2 cc. of 15% sodium carbonate each, the time being noted and a glass stopper inserted as promptly as possible. As soon as convenient, the free sugar in these solutions was determined by adding 25 cc. of iodine–potassium iodide solution, letting stand twenty minutes in the dark, acidifying with 3 cc. of 10% sulfuric acid and titrating back with standard sodium thiosulfate using starch paste indicator. The results are shown in the curve of Fig. 1. The curve corresponds approximately to the unimolecular law; on the assumption that the reaction is unimolecular, *k* (minutes and decimal logarithms) = 0.0063 ± 0.0013.

The Equilibrium Rotation of *d*-Threose.—At withdrawal of the last sample, the whole solution was cooled and its rotation at 20° was found by two independent observers to be −0.29°. Titration showed 0.0395 g. of tetrose in 5 cc., equivalent to 0.395 g. of tetrose in a volume of 50 cc., after one hundred and thirty-five minutes of hydrolysis at 100°. At complete hydrolysis 0.515 g. of tetrose would be present. At one hundred and thirty-five minutes, therefore, 76.7% of the threose diacetamide was hydrolyzed and 23.3% or 0.220 g. unchanged. The specific rotation of threose diacetamide is −10.9°. Therefore

$$-10.9° = X \times 50/2 \times 0.220$$

and $X = -0.096°$, the rotation due to unchanged threose diacetamide. Subtracting this from −0.29°, we find −0.198° contributed by the 0.395 g. of tetrose present in 50 cc.

$$[\alpha]^{20}\text{D} = -0.198° \times 50/2 \times 0.395 = -12.5°$$

This value for the specific rotation of *d*-threose agrees well with the value −12.3° announced in the previous paper. No difference between the rotations in pure water and in dilute acid was observed.

Change in Rotation during Hydrolysis of *d*-Threose Diacetamide.—A sample of 0.9843 g. of threose diacetamide was made up to 50 cc. in a calibrated flask with 0.100 *N* sulfuric acid and poured at a noted time into a flask submerged in boiling water. At noted intervals, the whole solution was cooled and its rotation read in a 4-dm. tube. The curve of Fig. 2 shows the readings obtained. At the time of the last reading, a titration was made showing the presence of 0.4056 g. of free tetrose in 50 cc. (75.5% hydrolysis) and 0.2411 g. of diacetamide remaining. The rotation due to the latter was −0.21° and that due to the sugar −0.35°, which corresponds to a specific rotation of −10.8°. The velocity constant could not be determined with great accuracy because the range of the change is so small but the value of *k* (minutes and decimal logs) calculates to 0.0093 ± 0.0023, which is of the same order of magnitude as the constant more accurately determined by the other method.

Dibenzylidene-*d*-threitol.—The solutions remaining from the hydrolysis experiments were combined, freed from sulfuric acid with barium hydroxide and repeatedly extracted with ether to remove acetamide. Then the solution was shaken with 2% sodium amalgam under mildly acid conditions until 100 g. of amalgam had been used and all reducing action had disappeared. The dibenzylidenethreitol was prepared just as described in the previous paper.[2] After several slow recrystallizations from warm chloroform by the addition of benzene, the new sample melted from 220–222° (corr.). The old sample from threose acetate, after several recrystallizations, melted from 218–222° (corr.) and an intimate mixture of the two gave m. p. 220–223° (corr.). The new sample, after the first recrystallization, rotated −77.9° (0.1167 g. in 25 cc. of chloroform soln.; 0.727° to the left; 2-dm. tube). The value previously found was −78.2°.

***d*-Erythrosazone.**—A small volume of hydrolysate, when treated with phenylhydrazine in the usual way,[2] yielded *d*-erythrosazone of m. p. 164° (corr.).

We wish to express to Dr. C. S. Hudson, Chief of the Division of Chemistry, deep gratitude for the sympathetic and patient interest which permitted these investigations to be carried out. Our thanks are due also to Mr. C. G. Remsburg of this Laboratory for nitrogen analyses.

Summary

1. Wohl's method of degrading sugars has been applied to *d*-xylose, and *d*-threose diacetamide has been prepared in relatively large quantity.

2. This *d*-threose derivative is found to have a specific levorotation in water of −11°, which is opposite in sign to that indicated by Deulofeu, who found −7.68° for *l*-threose diacetamide.

3. Quantitative hydrolysis of *d*-threose diacetamide with 0.100 *N* sulfuric acid at 100° shows a rate corresponding to *k* (minutes and decimal logs) = 0.0063 ±0.0013 and permits determination of the equilibrium specific rotation of *d*-threose in dilute acid as −12.5°, which is in agreement with our previously determined value and contrary to the findings of W. Freudenberg and Deulofeu.

4. During hydrolysis of *d*-threose diacetamide, the rotation is found to drift toward a smaller levorotation, in opposition to the reported observation of Deulofeu, and in agreement with the rotations determined by us for *d*-threose diacetamide and for *d*-threose.

5. The formation of a *tri*acetate by threose diacetamide indicates an aldehydo structure for this compound.

6. The preparation of *d*-erythrosazone and dibenzylidene-*d*-threitol from threose diacetamide hydrolysates, shows the identity of the sugar formed with that obtained by deacetylation of *d*-threose triacetate.

The Action of Hydrogen Peroxide upon Simple Carbon Compounds. III. Glycolic Acid[1]

BY H. SHIPLEY FRY AND KENNETH L. MILSTEAD[2]

The action of hydrogen peroxide upon glycolic acid has been studied extensively and a notable variety of apparently contradictory results has been recorded. This is due to the widely different experimental conditions under which the action has been investigated and to the omission of a standardized quantitative experimental method of procedure whereby the yields of each and every product of the reaction have been checked with the quantities of hydrogen peroxide participating in the severally occurring reactions.

A brief review of the several reactions recorded by previous investigators is pertinent to the present study, the purpose of which is to *correlate quantitatively the extent of the occurrence of the most likely reactions with the amounts of the hydrogen peroxide therein participating.*

Fenton and Jones[3] reported a quantitative yield of glyoxylic acid when hydrogen peroxide reacted with glycolic acid in the presence of ferrous salts.

Heimrod and Levene,[4] with 30% hydrogen peroxide in alkaline solution, obtained formic, carbonic and glyoxylic acids.

Dakin[5] reported that glycolic acid in the presence of ferrous sulfate gave a small amount of glyoxylic acid, the main product being formaldehyde which was almost entirely oxidized to formic acid. It should here be noted that Dakin did not mention the formation of hydrogen, which would be an expected product of the reaction if formaldehyde is an intermediate product, in conformity with the established equation[1] $2HCHO + H_2O_2 \longrightarrow 2HCOOH + H_2$.

Spoehr[6] found that glycolic acid in alkaline solution was partly converted into equimolecular quantities of formic and carbonic acids, but, in the presence of ferrous sulfate, carbonic acid was much in excess. This indicated further oxidation of the intermediately formed formic acid. Spoehr made no mention of the formation of hydrogen but maintained, as did others, that glyoxylic acid was the first intermediate product of oxidation.

Wieland[7] detected glyoxylic, formic and carbonic acids and formaldehyde in the reaction mixtures. He also observed the evolution of hydrogen and naturally assumed that its formation was due to a secondary reaction between the intermediately formed formaldehyde and hydrogen peroxide.

Hatcher and Holden,[8] in attempting to clear up the conflicting opinions of previous investigators, found neither formaldehyde nor hydrogen but maintained that glycolic acid is first converted into a peracid, which, in turn, gives glyoxylic, formic and ultimately carbonic, acids.

Theoretical

From a review of the previous investigations, it follows that the present quantitative study of the action of hydrogen peroxide upon glycolic acid should not only explain the formation of the variously reported intermediate products, but also correlate quantitatively the yields of each of the recovered products of the reaction, notably hydrogen, formic and carbonic acids, with the amounts of hydrogen peroxide initially used which function in the formation of these products, both respectively and totally.

To this end, an explanatory scheme of reactions, based upon and serving further to illustrate the previously published *perhydrolysis* reaction mechanism of Fry and Payne,[1] is proposed. The equations for the involved reactions are recorded in formulas sufficiently graphic to illustrate the perhydrolysis type of reaction.

The first product of the reaction of hydrogen peroxide upon glycolic acid is generally conceded to be glyoxylic acid, which, according to Hatcher and Holden,[8] is preceded by (a) the formation and (b) the decomposition of perglycolic acid, thus

$$CH_2OHCOOH + HOOH \longrightarrow CH_2OOHCOOH + H_2O \quad (a)$$

$$CH_2OOHCOOH \longrightarrow CHOCOOH + H_2O \quad (b)$$

[7] Wieland, *Ann.*, **436**, 253 (1924).

[8] Hatcher and Holden, *Trans. Roy. Soc. Can.*, **20**, 395, 407 (1926).

$$\Sigma(a, b)\ CH_2OHCOOH + HOOH \longrightarrow CHOCOOH + 2H_2O \quad (c)$$

The glyoxylic acid thus formed undergoes perhydrolysis

$$CHOCOOH + HOOH \longrightarrow HCOOH + [HOCOOH \longrightarrow H_2O + CO_2] \quad (d)$$

$$\Sigma(c, d)\ CH_2OHCOOH + 2H_2O_2 \longrightarrow HCOOH + CO_2 + 3H_2O \quad (A)$$

Thus, glycolic acid, through the intermediate formation of glyoxylic acid, may yield not only formic and carbonic acids, but it may also undergo another concomitant reaction, namely, a direct perhydrolysis to yield formaldehyde and carbonic acid

$$CH_2OHCOOH + HOOH \longrightarrow HCHO + H_2O + [HOCOOH \longrightarrow CO_2 + H_2O] \quad (e)$$

Formaldehyde, in turn, reacts with hydrogen peroxide to give formic acid and hydrogen

$$2CH_2O + H_2O_2 \longrightarrow 2HCOOH + H_2 \quad (f)$$

The summation of equation (e), doubled, and equation (f) represents the conversion of glycolic acid to formic and carbonic acids and hydrogen.

$$\Sigma(e, f)\ 2CH_2OHCOOH + 3H_2O_2 \longrightarrow H_2 + 2HCOOH + 2CO_2 + 4H_2O \quad (B)$$

This derivation of each of the summation equations, (A) and (B), for the two principal concomitant reactions, indicates the conversion of glycolic acid to the final products, formic and carbonic acids. Equation (B) indicates the formation of hydrogen also.

The marked susceptibility of oxidation of formic acid to carbonic acid by hydrogen peroxide explains our quantitative observations, subsequently recorded, that in all experimental runs, with varied concentrations of hydrogen peroxide, the yields of carbonic acid (carbon dioxide) were greater than the yields of formic acid. This secondary reaction of intermediately formed formic acid necessitates the postulation of a third equation

$$HCOOH + HOOH \longrightarrow H_2O + [HOCOOH \longrightarrow H_2O + CO_2] \quad (C)$$

The generally reported final products of the action of hydrogen peroxide upon glycolic acid—formic and carbonic acids and hydrogen—have been identified, and their quantitative yields have been determined in the present investigation. Their formation is explained in terms of three reactions represented by the above derived equations (A), (B), and (C). The first two will be shown to be concomitant, while the third is a secondary reaction.

In order to correlate quantitatively the yields of each of the three products of the reaction with the quantities of hydrogen peroxide *active in their formation*, both respectively and collectively, it was necessary to determine how much of the hydrogen peroxide initially used did not participate in reactions (A), (B) and (C). This is the hydrogen peroxide which suffered direct decomposition into water and oxygen. The quantity of oxygen liberated in each experimental run would be equivalent to this inactive quantity of hydrogen peroxide. The difference between this and the initially used quantity is the active hydrogen peroxide. Hence, it was necessary in all experimental runs and related calculations to include a fourth equation (D) for the concomitant reaction

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \quad (D)$$

It is highly probable that the extents of the occurrence, or the rates of reactions A, B, C and D, are different in alkaline solution, in acid solution and in the presence of ferrous salts, as the observations of previous investigators apparently indicate. It should here be noted, however, that the present study is limited to the determination of the extent of the occurrence of the reactions A, B, C, and D *in acid solution*, with increasing concentrations of hydrogen peroxide, as described in the experimental part.

Experimental

The train of apparatus and the experimental method of procedure employed in this study have been previously described in detail by Fry and Payne.[1]

In five successive experimental runs (I–V), each conducted in duplicate, one-quarter mole of pure glycolic acid was added to successively increased quantities of 30% hydrogen peroxide, free from organic preservatives, specially prepared by the Roessler and Hasslacher Chemical Company, namely, (I) one-eighth, (II) one-fourth, (III) one-half, (IV) three-fourths, and (V) one mole, respectively. Each of these mixtures of hydrogen peroxide and glycolic acid was further acidified by the addition of 2.16 g. of sulfuric acid, diluted with water to a total volume of 125 cc., and heated continuously for nine hours in a 250-cc. round-bottomed Pyrex flask submerged in a water-bath at 100°.

The hydrogen formed (equation B) and the oxygen evolved (equation D) were collected in

TABLE I

MOLAR QUANTITIES OF HYDROGEN PEROXIDE AND GLYCOLIC ACID USED AND OF PRODUCTS FORMED

Run	1 Initial H_2O_2 mole	2 Initial $CH_2OHCOOH$, mole	3 HCOOH found, mole	4 H_2CO_3 found, mole	5 H_2 found, mole	6 O_2 found, mole	7 $CH_2OHCOOH$ found, mole
Ia	0.1250	0.2500	0.0142	0.0267	0.0024	0.0410	0.229
Ib	.1250	.2500	.0141	.0268	.0023	.0408	.225
IIa	.2500	.2500	.0271	.0566	.0055	.0801	.2044
IIb	.2500	.2500	.0246	.0563	.0047	.0799	.2106
IIIa	.5000	.2500	.0353	.1000	.0083	.1786	.1787
IIIb	.5000	.2500	.0339	.0979	.0087	.1726	.1781
IVa	.7500	.2500	.0374	.1530	.0134	.2605	.158
IVb	.7500	.2500	.0363	.1540	.0132	.2622	.156
Va	1.0000	.2500	.0399	.194	.0138	.3489	.1270

the gasometer at the end of the apparatus train. The total yields of each gas, determined by standard methods of gas analysis, serve to measure the extent of the occurrence of reactions represented by equations (B) and (D).

The total carbonic acid formed (equations A, B, and C) was calculated from the amounts of carbon dioxide absorbed in weighed ascarite towers.

The resultant reaction mixtures, containing practically only formic acid (equations A and B) and some unaffected glycolic acid, gave the fuchsin test for traces of aldehydes, the quantities of which, however, were too small to be determined quantitatively. Tests for the presence of glyoxylic and oxalic acids were negative.

Aliquot portions of the reaction mixture were titrated for total acidity with standard alkali. Subtracting the acidity due to the initially added sulfuric acid, gave the acidity due to the formic acid and unreacted glycolic acid. The yields of formic acid, determined gravimetrically by the standard mercuric chloride method, permitted calculations, by difference, of the quantities of glycolic acid remaining unchanged in the reaction mixtures.

In calculating the extents of the occurrence of the two principal concomitant reactions, equations (A) and (B), and the secondary reaction, equation (C), the quantity of glycolic acid which reacts to give hydrogen, as well as some of the formic and carbonic acids, is based upon the yield of hydrogen in conformity with equation (B). The remainder of the glycolic acid reacting serves as the basis for calculating the yields of formic and carbonic acids in conformity with equation (A). The difference between the sum of the yields of carbonic acid, obtained in conformity with equations (A) and (B), and the total yield of carbonic acid, measures the extent of the occurrence of the secondary reaction, equation (C).

All of the analytical data thus secured are embodied in the tables. For convenience in reference thereto, the equations for the four postulated reactions are herewith retabulated.

$$CH_2OHCOOH + 2H_2O_2 \longrightarrow HCOOH + CO_2 + 3H_2O \quad (A)$$

$$2CH_2OHCOOH + 3H_2O_2 \longrightarrow H_2 + 2HCOOH + 2CO_2 + 4H_2O \quad (B)$$

$$HCOOH + H_2O_2 \longrightarrow CO_2 + 2H_2O \quad (C)$$

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \quad (D)$$

Table I records the molar quantities of the hydrogen peroxide and glycolic acid initially present in the reaction mixtures of the five successive duplicate sets of runs, and the molar yields of the respective resultant products.

Table II records in columns 1, 2, 3 and 4, the percentages of hydrogen peroxide equivalent to the products of the reaction as calculated from the respective equations for the proposed reactions. Column 5 notes the sum total percentage of hydrogen peroxide used.

Va	46.08	14.22	39.69
Vb	44.61	15.48	39.90

A survey of the analytical data of the above tables in relation to the derived equations for the reactions assumed to occur leads to the summary and conclusions given below.

Grateful acknowledgments are extended to Mrs. Ernst Twitchell, whose renewal of the Ernst Twitchell Fellowship in Chemistry made this study possible, and to the Roessler and Hasslacher Chemical Company for kindly donating the specially prepared hydrogen peroxide used in this investigation.

Summary and Conclusions

1. Since the ratio of the yields of formic acid to those of hydrogen (Table I, columns 3 and 5) were invariably greater than 2:1, which ratio, according to the single equation (B), is 2:1, it follows that the reactions represented by equations (A) and (B) were concurrent.

2. The extents of the occurrence of the reactions represented by equations (A), (B), and (C) *with increasing concentrations of hydrogen peroxide* are shown by the data in columns 1, 2, and 3, respectively, of Table II, and likewise columns 1, 2, and 3, respectively, of Table IV, to be as follows: (A) shows a tendency to decrease; (B), small variations; and (C), a tendency to increase.

3. The sums of the percentage quantities (Table II) of the hydrogen peroxide *active* in the several reactions, equations (A), (B), and (C), and the *inactive* or directly decomposed hydrogen peroxide, equation (D), are, within the limits of experimental error, practically 100% of the initial quantities of the hydrogen peroxide employed in each experimental run.

4. In parallel with (3), the sums of the percentage quantities (Table III) of glycolic acid oxidized, equations (A) and (B), and recovered unchanged, are, within the limits of experimental error, practically 100% of the initial quantities of the glycolic acid employed in each experimental run.

5. The above results, particularly (3) and (4), serve to check quantitatively the accuracy not only of the experimental method employed, but also of the equations derived for the three reactions assumed to occur, and the extents of their occurrence, respectively, when hydrogen peroxide reacts with glycolic acid.

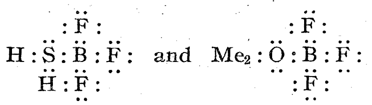
Thermal Analysis of the System Argon–Boron Trifluoride. Compounds with the Inert Gases of the Atmosphere[1,2]

BY HAROLD SIMMONS BOOTH AND KARL STUART WILLSON

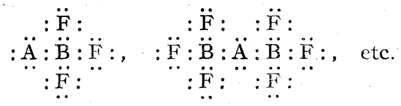
Although numerous attempts have been made to prepare compounds of the rare gases, practically all investigations have served only to show the inertness of these elements. Villard,[3] however, in 1896, reported a very unstable hydrate of argon, and since then hydrates of krypton and xenon[4] have been reported.

For some time this Laboratory has been studying compounds formed by boron trifluoride in which boron acts as acceptor for electrons from an element in another compound, usually an element with a completed octet such as oxygen in methyl ether and sulfur in hydrogen sulfide,[5] *i. e.*



$$\begin{array}{l} \phantom{\mathrm{H}:\ddot{\mathrm{S}}:}:\ddot{\mathrm{F}}: \\ \mathrm{H}:\ddot{\mathrm{S}}:\ddot{\mathrm{B}}:\ddot{\mathrm{F}}: \\ \phantom{\mathrm{H}:}\mathrm{H}:\ddot{\mathrm{F}}: \end{array} \quad \text{and} \quad \begin{array}{l} \phantom{\mathrm{Me_2}:\ddot{\mathrm{O}}:}:\ddot{\mathrm{F}}: \\ \mathrm{Me_2}:\ddot{\mathrm{O}}:\ddot{\mathrm{B}}:\ddot{\mathrm{F}}: \\ \phantom{\mathrm{Me_2}:\ddot{\mathrm{O}}:}:\ddot{\mathrm{F}}: \end{array}$$

It seemed reasonable to expect therefore that under the right conditions boron trifluoride could likewise accept electrons from elements such as argon which have self-contained octets, *i. e.*



$$\begin{array}{l} \phantom{:\ddot{\mathrm{A}}}:\ddot{\mathrm{F}}: \\ :\ddot{\mathrm{A}}:\ddot{\mathrm{B}}:\ddot{\mathrm{F}}:, \\ \phantom{:\ddot{\mathrm{A}}}:\ddot{\mathrm{F}}: \end{array} \quad \begin{array}{l} \phantom{:\ddot{\mathrm{F}}}:\ddot{\mathrm{F}}: \quad :\ddot{\mathrm{F}}: \\ :\ddot{\mathrm{F}}:\ddot{\mathrm{B}}:\ddot{\mathrm{A}}:\ddot{\mathrm{B}}:\ddot{\mathrm{F}}:, \\ \phantom{:\ddot{\mathrm{F}}}:\ddot{\mathrm{F}}: \quad :\ddot{\mathrm{F}}: \end{array} \quad \text{etc.}$$

Preliminary Study.[6]—Preliminary experiments were made with an apparatus similar to that used for thermal analysis of the systems mentioned above, save that the freezing points were measured by a two-junction copper–constantan thermocouple recorded by a special Leeds and Northrup Micromax potentiometer.

The first appearance of crystals on cooling was established in three ways: by the appearance of points of light in the field when the cell was placed between crossed Nicols, by the inflection in the cooling curves recorded on the potentiometer, and visually. It was found that the three methods of observation checked. Freezing point curves, one of which is shown in Fig. 1, revealed maxima and minima indicating compound formation corresponding to $A\cdot8BF_3$ and $A\cdot16BF_3$. However, the relatively large volume in the gas space above the liquid mixture permitted some segregation of the mixture, thus displacing the curve.

This was finally overcome by adopting the basic design of the Cailletet apparatus, using a fine capillary connecting tube and a relatively large cell similar to that used earlier in this Laboratory for determining the critical phenomena of pure gases[7] and gas mixtures.[8]

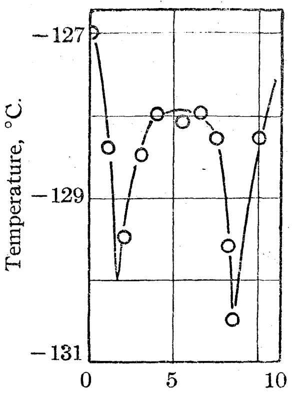


Fig. 1.—Preliminary freezing points.

Apparatus.—The all glass apparatus for preparing the samples is shown in Fig. 2. Cailletet sample tubes of Pyrex glass were joined to the system by the ground glass conical joints (J). The sample tube (L) had a volume of about 100 cc. and the cell itself where the phenomena were to be observed had a volume from 0.1 to 0.5 cc. depending on the composition of the mixture being studied. If the cells were too large, the mercury would freeze in the capillary above the cell before many points had been determined, and if the cells were too small, liquid would rise into the capillary, adequate stirring could not be obtained and erroneous results would be secured.

The mixture in the cell was stirred by the glass enclosed iron wire actuated by the electromagnets shown in Fig. 3. The lower magnet was found helpful in securing positive stirring action at the freezing point and at other points where the liquid became viscous.

Pressure was measured by a differential dead-weight gage used by Booth and Swinehart[7] which under the conditions of this investigation was observed to ±0.1 atm.

Temperature was recorded by a special high speed, high precision Leeds and Northrup Micromax potentiometer using copper–constantan thermocouples described later.

Ordinary stopcock grease is attacked by boron trifluoride but a mixture of four parts of white vaseline and one

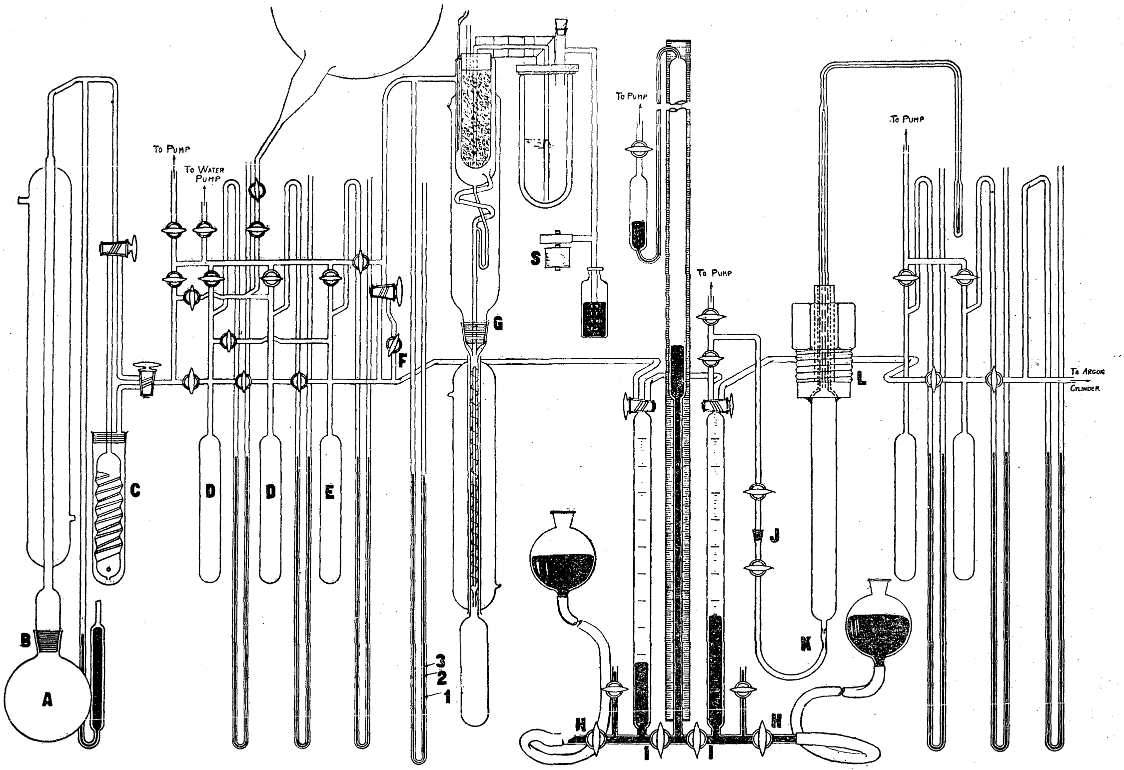

Fig. 2.

part of paraffin, saturated with boron trifluoride at 140°, then evacuated and 5% beeswax added, was found to be satisfactory.

Preparation of the Samples.—The boron trifluoride was prepared from sodium fluoborate (300 g.), boric oxide (50 g.) and sulfuric acid (300 cc.). The solid chemicals were mixed, placed in the flask (A) (Fig. 2), the acid added and the liquid mass thoroughly mixed. The flask was joined to the system by the greased conical joint (B). A rubber sleeve was placed over the joint and water circulated around it in an inverted bottle with bottom removed. The water prevented melting of the grease with subsequent sticking or leaking at the joint.

Since any silicon tetrafluoride, formed from impurities in the sodium fluoborate, was evolved at room temperature and boron trifluoride was not, the tetrafluoride was largely removed along with air, by pumping the flask with the stopcocks turned to by-pass the wash-bottle (C). After rinsing the entire system, except the generating unit and wash-bottle (C), twenty times with dry, carbon dioxide-free air, the stopcocks were reversed to include the wash-bottle, and the charged flask heated, gently at first, to avoid frothing. The boron trifluoride generated passed through the water-cooled condenser, the wash-bottle filled with sulfuric acid saturated with boric oxide to remove water and hydrogen fluoride and, after discarding the first part of the generation product through the water pump, was condensed in the ampoules (D) by means of liquid nitrogen. This method gave little silicon tetrafluoride, and by distilling to (E) and then to the still pot at a low pressure and discarding the tailings, little of the tetrafluoride was carried into the still.

The boron trifluoride was purified in the distilling column (G) described by Booth and Stillwell.[9] By distilling at about 10 cm. pressure, the temperature was such that the vapor pressure of silicon tetrafluoride, the most probable impurity, was very small and the absence of this substance in the purified gas was doubly assured. The gas, after a single distillation in the column using great care to rinse the lines with the pure gas before collecting in the ampoule, was shown to be spectroscopically pure by Mr. H. M. Strong of the Physics Department at Ohio State University.

At the beginning of series D the still head cracked and a new head of simpler design[10] was used with satisfactory results.

In operation, the boron trifluoride was permitted to reflux about fifteen minutes after any air blocks had been removed. The gas was then bled off very slowly by "cracking" the stopcock at (F), being sure that a high reflux ratio was maintained. After discarding the first few cc. of the solid distillate, about one-fifth of the gas was condensed in the nearest ampoule (D), then the middle three-fifths in the ampoule (E) where it was held until used to rinse the mixing apparatus and sample tubes, and to prepare the samples.

The argon, 99.9 + pure, was condensed from the cylinder into ampoules and then further purified by ampoule to ampoule distillation with generous discarding of first and last portions. After this treatment it was found to be spectroscopically free from nitrogen by Mr. Strong.

The purified gases were introduced into their respective

[10] To be described shortly by Booth and Bozarth.

burets of the baro-buret which had been previously dried and rinsed with the pure gases, and the pressures and volumes recorded as described by Booth and Carter.[8]

After measuring each gas, thorough mixing was assured by forcing the gases alternately from one buret to the other.

Meanwhile, the sample tubes were rinsed twenty times with dry, carbon dioxide-free, air, being flamed while pumping, and were then rinsed twenty more times with pure boron trifluoride and argon, allowing the gases to remain in the tubes some time before pumping.

The gas mixture was introduced into a sample tube to a pressure a centimeter or two less than one atmosphere. Stopcocks above and below the conical joint (J) were closed, the sample tube removed from the apparatus, and the tube broken off under dry mercury at the constriction (K). The inner seal prevented bits of glass from rising into the body of the tube. The sample tube was then placed in the steel well as shown in Fig. 3, keeping the lower end under mercury, and screwed down onto the fiber gasket. After connecting the pump line, pressure was increased to test for leaks and weakness in the glass. After releasing the pressure, the bath was raised to surround the cell.

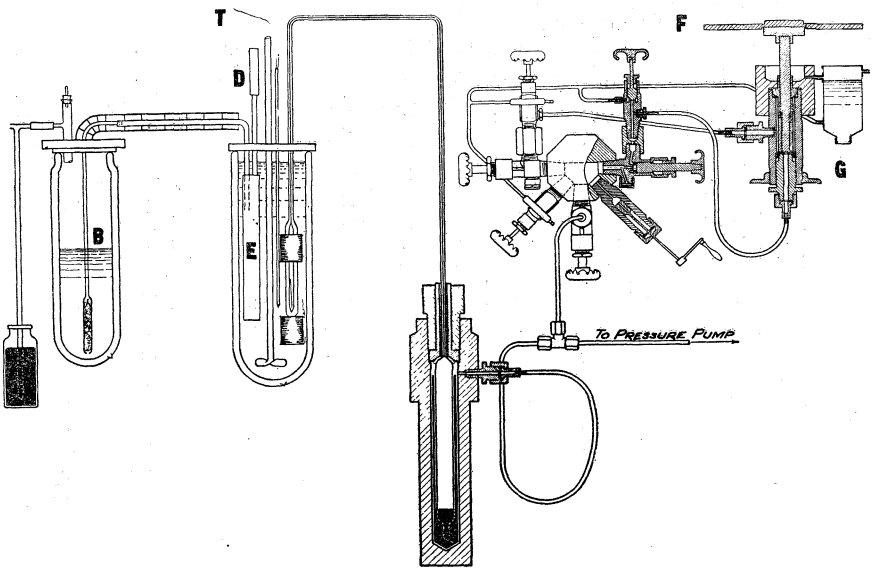

Fig. 3.

Experimental Procedure

For the freezing point determinations weights were placed on the piston of the dead weight gage and the pressure equilibrium established while the liquid butane bath was cooling. Liquid nitrogen was forced into the evaporator (E) (Fig. 3), rapidly at first, then slowly as the freezing point was approached. By adjusting a screw clamp at (D), cooling could be secured at less than 0.3° per minute, this having been found a sufficiently slow rate to prevent error due to lag in the cell, thermocouples or recorder. In the first determinations, a current was passed through a heater coil in the bath to adjust the rate of cooling, but this was later found unnecessary.

When the first crystals appeared, the temperature was noted. Since warming the sample after obtaining a freezing point would cause argon to boil off, giving rise to segregation, care was taken to raise the temperature as little above the freezing point as possible, usually not more than 3°. While the temperature was rising, more weights were placed on the piston, thus decreasing the volume of the gas and preventing segregation due to expansion. Pressure was increased and freezing points determined until the liquid rose into the capillary, preventing mixing, or until the mercury froze in the capillary.

The freezing point determinations were made in five different series.

Series A covered the preliminary work shown in Fig. 1, while series B, C, D and E were made with the Cailletet apparatus.

Series B includes all points measured by a two-junction thermocouple which had a total maximum error of ±0.4°. Ice served as the reference point. In series C, D and E greater precision was obtained by using a five-junction thermocouple with carbon dioxide snow as the reference point. The snow point was found to remain constant for long periods and was checked against an ice-bath by an identical five-junction thermocouple several times during a set of freezing point determinations. By this method a maximum error of ±0.2° in the differential temperature was secured although considerably greater accuracy was obtained since the final freezing point was the average of many values. The two and five-junction couples were also checked against each other.

The absolute temperature in the region of the freezing points was secured by comparing the couples with a platinum resistance thermometer, and by extrapolating from −123.3°, the freezing point of ether. The absolute temperature of the freezing points therefore probably shows the same order of error as the differential temperature.

After completing series C the entire purification apparatus was rebuilt to eliminate stopcock grease which had contaminated the lines. A new stopcock grease was made and new drying tubes installed. The five-junction thermocouple was recalibrated, found to check its previous value and series D and E undertaken. In series B and C, liquid nitrogen was forced into the evaporator (E) at a rapid cooling rate, adjusted by controlling the heat input of the heater. In series D and E the liquid nitrogen input was considerably slower and was adjusted to give the desired cooling rate without using the heater. The agreement between the values for the different series indicates the constancy of temperature maintained in the bath by means of the propeller, which was driven at 3600 r. p. m.

Before beginning series E every possible source of error was considered and all precautions for purity of the samples were redoubled. The cells were rinsed and flamed even more thoroughly, and the mercury used for the Cailletet well was run through a nitric acid tower and dried instead of merely washed and dried before each run.

To eliminate silicon tetrafluoride as much as possible even from the crude generation product which might contaminate the lines, fresh boron trifluoride was made using ammonium instead of sodium fluoborate. The ammonium fluoborate was recrystallized by cooling with agitation from a hot solution to give only a 50% yield, thus leaving the more soluble fluosilicates in the mother liquor.

In series D and E, before making up the samples the boron trifluoride was distilled in the column to a constant melting point measured in a cell similar to that used in the preliminary runs and stored under a mercury seal out of contact with stopcocks (not shown in Fig. 2).

Results.—The freezing points are found to increase with increase in pressure at first and then become independent of further increase in pressure within the experimental limits. This is exactly what would be expected with unstable compounds. Thus, at low pressures, the compound formed will be appreciably dissociated, shifting the equilibrium

$$A + xBF_3 \rightleftharpoons A \cdot xBF_3$$

to the left. The A and BF_3 units acting as impurities in the compound $A \cdot xBF_3$, will lower its freezing point as shown in region A, Figs. 4–6. As the pressure is increased, the equilibrium will shift to the right and less A and BF_3 units will be present, hence the freezing point will be lowered to a lesser extent.

As more and more pressure is applied, the equilibrium will shift farther and farther to the right and the freezing point will be raised until the separate A and BF_3 particles are present in too small quantities to lower the freezing point appreciably. The freezing point will then, of course, become independent of further increase in pressure as shown in region B, Figs. 4–6. The normal effect of increase in pressure tending to change the melting point in the direction of decreasing vol-

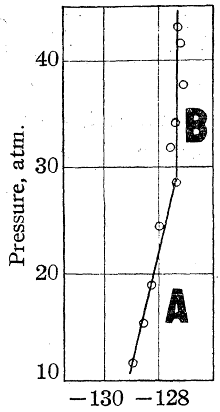
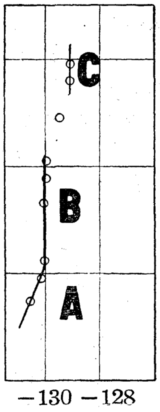
[a] At this and higher pressures a second liquid layer immiscible with the first was noted.

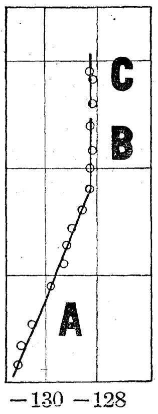
[b] This sample under-cooled considerably but the results are believed accurate to better than ±0.3° since melting points as well as freezing points could be obtained.

ume, is too slight to be measurable with the present method.

One would expect the freezing points to approach some final value asymptotically as the pressure increases. The exact curve, however, is difficult to predict and would not differ to any great extent from the straight lines shown in the figures. No significance is attached to the inflection point as drawn.







Temperature, 0°C.

Fig. 4.—33.3 Mole % argon. Fig. 5.—42.9 Mole % argon. Fig. 6.—31.4 Mole % argon.

For the samples of less than 5% argon, the liquid fills the cells after only one or two readings are taken, and hence an extended pressure range cannot be studied. However, these compositions seem to be stabilized at low pressures, and the points secured are probably for pressures above the decomposition pressure.

The freezing of the samples occurred differently depending on the composition and consequently the place on the curve. For compositions not at maxima or minima a few crystals appeared at first followed by more and more if the temperature was allowed to decrease further. However, stirring could be continued for some time before the stirrer became frozen, indicating freezing over a temperature range. At points near the maxima or minima of the curves, however, the mass tended to freeze solid immediately after the appearance of the first crystals. This phenomenon is characteristic of systems in which compounds are formed.

The possibility of under-cooling was recognized at the beginning of the work and was found to be absent or very slight for samples except those near maxima and particularly those containing 12.5, 13.5 and 15.0% argon. The 12.5, 13.5 and 15% samples showed under-cooling by as much as 2°. Fortunately, the mass did not freeze solid and by careful manipulation, *melting points* were secured although such determinations are less accurate than are the freezing points.

Since under-cooling causes the volume to decrease and subsequent warming causes expansion, fewer points could be determined if segregation was to be avoided. Furthermore, since the decomposition pressure is relatively high and mercury freezes in the capillary at a relatively low pressure, the exact decomposition pressure is less certain than in other parts of the system. However, the isobaric graphs show maxima at about 11 and 15% argon and the points plotted in Fig. 7 in this region are probably correct in relation to each other although it is possible they should be located at a slightly higher temperature.

When the isobaric freezing points are plotted *versus* composition, maxima and minima appear, indicating compound formation. Isobars cannot be plotted over the whole range since only low pressures can be measured for the low argon samples, while low pressure measurements for higher argon percentages are somewhat erratic and of little importance.

Figure 7 shows what might be termed a temperature *versus* composition plot of the "stabilized system." The pressure at which the temperatures are taken is such that it is above the decomposition pressure shown on the freezing point curves. Since the temperature was found to remain constant with increase in pressure within the experimental limits, Fig. 7 may be considered as drawn from the data by extrapolating the temperature upward to a pressure sufficiently high to be above the decomposition pressure for all of the compounds. This seems a reasonable method of drawing the diagram and should introduce only a small error due to the actual slope of the line drawn as vertical. This diagram is probably more truly representative of the system than are isobaric graphs since in the former graph, the only constituents present in appreciable quantities are $A \cdot xBF_3$ and $A \cdot x'BF_3$. In the isobaric graphs, below the inflection points, complexities are certain to be introduced due to unpredictable pressure effects on the complex equilibrium

$$A \cdot xBF_3 \rightleftharpoons A + nBF_3 \rightleftharpoons A \cdot x'BF_3$$

The stabilized diagram, together with the isobaric diagrams, shows that maxima are found corresponding to the ratios $A \cdot BF_3$, $A \cdot 2BF_3$, $A \cdot 3BF_3$, $A \cdot 6BF_3$, $A \cdot 8\ BF_3$ and $A \cdot 16BF_3$, indicating compound formation. While the range in melting points exhibited is small similar short excursions between maxima and minima are known in other systems yielding compound formation.

In the case of certain samples, as the pressure increased, a phenomenon occurred which seems best described as retrograde immiscibility. A second liquid layer, immiscible with the first, appeared as in region C, Figs. 5–6, near 35 atmospheres. Although complete miscibility would probably again be secured if the pressure were increased sufficiently, this could not be determined due to experimental difficulties. That it is not inhomogeneity of the sample, prior to the appearance of the second layer, is evidenced by the fact that while the second layer increases in volume, the first layer also increases in volume, to a comparable extent. Second liquid layers probably formed in all samples where the pressure was sufficiently high (about 35 atmospheres) although their presence was not realized since they were hidden by the electromagnet.

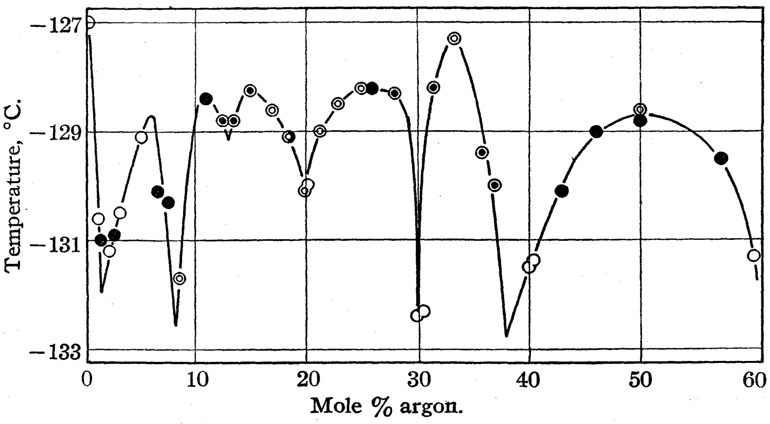


Fig. 7.—Freezing points of the stabilized system: B, ○; C, ◎; D, ●; E, ◉.

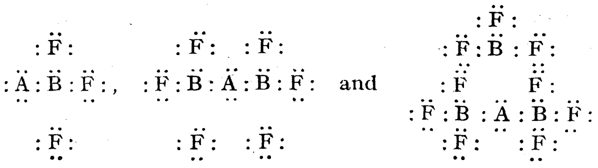
This explains the break in several of the freezing point curves. The first vertical line is the normal freezing point. The second line occurs after the second liquid layer has appeared. That the freezing point should change seems entirely reasonable since formation of a second immiscible layer might change the composition of the first liquid. Since a very slight pressure change caused all the vapor to liquefy, a close study of this region could not be made.

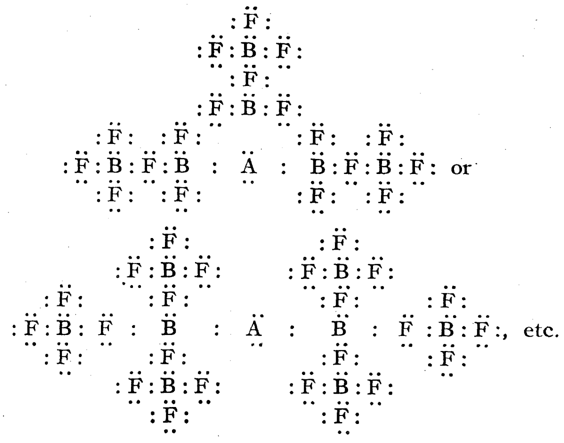
Furthermore, from about 30 to 37 atmospheres, erratic points were found in some cases indicating a metastable state in which the system was undergoing some decided change. For some samples in this pressure region, a light foam appeared on the surface of the liquid on stirring. When the second meniscus appeared the foam disappeared.

The absence of a maximum at 20% argon (Fig. 7) is surprising at first thought but may possibly be due to steric hindrance or may exist but require closer detailed study in this region to reveal it.

The compounds A·BF$_3$, A·2BF$_3$ and A·3BF$_3$ doubtless are formed by coördinate links in which the argon donates electrons to complete the boron octet



In this and other investigations in this Laboratory it has been noticed that liquid boron trifluoride at vapor pressures between five and ten atmospheres becomes viscous, indicating association. The compounds A·6BF$_3$, A·8BF$_3$ and A·16BF$_3$ doubtless contain boron trifluoride molecules linked directly to the argon atom as above and the rest of the boron trifluoride linked to these inner boron trifluoride molecules *via* their fluorine atoms,[11] *i. e.*



Another explanation of the compounds A·6BF$_3$, A·8BF$_3$, A·16BF$_3$ is that the "excess" BF$_3$ groups are merely located in the crystal lattice in more or less symmetrical arrangements.[12] The writers

[12] Sidgwick "The Electronic Theory of Valency," Oxford University Press, London, 1929, pp. 186–187 and 199.

feel, however, that the evidence points to the first explanation analogous to that of Sidgwick (*loc. cit.*, p. 199) for excessive hydration by polymerized water molecules.

Undoubtedly the system krypton–boron trifluoride will show stabler compounds and the system xenon–boron trifluoride still stabler. Investigations of these systems are already under way and will be reported as soon as possible.

Summary

Study of the system boron trifluoride–argon has shown that:

1. The freezing point of any mixture increases with increase in pressure up to a certain value and is in general little affected by any further pressure increase, indicating an equilibrium $A + xBF_3 \rightleftharpoons A{\cdot}xBF_3$ or $A{\cdot}xBF_3 + yBF_3 \rightleftharpoons A{\cdot}(x + y)BF_3$.

2. A graph of the freezing points *versus* composition exhibits maxima and minima, the maxima corresponding to the ratios $A{\cdot}BF_3$, $A{\cdot}2BF_3$, $A{\cdot}3BF_3$, $A{\cdot}6BF_3$, $A{\cdot}8BF_3$ and $A{\cdot}16BF_3$, indicating compound formation. These compounds are unstable and dissociate above their melting points. From the shape of the curve the ratio $A{\cdot}2BF_3$ appears to be the stablest.

3. The freezing points of the argon–boron trifluoride mixtures of compositions approximating that of the maxima and minima were sharp and immediately complete while intermediate compositions melted over a range of temperatures. This is typical of systems in which compounds are formed.

4. At pressures in the neighborhood of 35 atmospheres, a second liquid layer appears which is probably best explained as retrograde immiscibility.

Critical Phenomena of the System Argon–Boron Trifluoride[1]

BY HAROLD SIMMONS BOOTH AND KARL STUART WILLSON

In view of the fact that thermal analysis of the system argon–boron trifluoride[2] showed maxima indicating compound formation, it was thought interesting to see whether or not this tendency would result in abnormalities in the critical phenomena.

The gases were purified and samples prepared as previously described.[2] Temperatures were measured by the Leeds and Northrup Micromax potentiometer using a two-junction copper–constantan thermocouple with ice as reference point. The couple was calibrated at the ice and carbon dioxide snow point and the calibration curve drawn through these points guided by the theoretical curve. Temperatures are subject to a maximum error of ±0.4°.

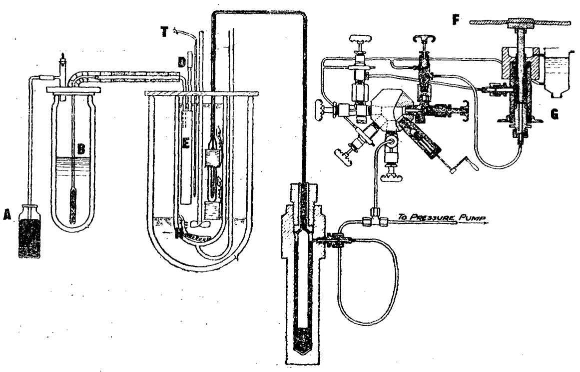

Fig. 1.—Critical apparatus.

The thermostat (Fig. 1) consisted of a pint Dewar flask set in a gallon Dewar. The temperature of the thermostat was controlled in either of two ways. For temperatures down to −85°, alcohol was used as the bath liquid and cooling was effected by placing liquid nitrogen in the outer Dewar. The rate of cooling of the bath was controlled by the depth of the liquid nitrogen in the outer bath and also by adjustment of the vacuum of the inner Dewar. The control contacts on the recording potentiometer were adjusted to close the relay heating circuit and warm the bath by means of the coil (H) when the bath cooled below the desired temperature. By adjusting the rate of cooling and the heating circuit, the bath temperature could be held within the limits of sensitivity of the recorder (±0.2°) for determination of the critical constants of the mixtures. For critical constants of pure boron trifluoride, manual control and observation of a calibrated mercury thermometer permitted an accuracy of ±0.05°.

(2) Booth and Willson, THIS JOURNAL, **57**, 2273 (1935).

To secure rapid cooling and for controlling the bath at the lower temperatures, liquid nitrogen was forced into the evaporator (E) by closing the outlet from the reservoir (B) at (A). By adjusting a screw clamp at (D) a very slow cooling rate could be secured and then the temperature maintained constant by the heater (H) operated by the relay control circuit. For these lower temperatures commercial butane served as the bath liquid.

The experimental procedure used in determining the critical constants was similar to that employed and described in detail by Booth and Carter.[3] Pressures were measured by the dead weight gage described by Booth and Swinehart.[4]

Experimental Results.—The tables and figures present the critical data. The points listed are those at which the first liquid appeared, when approached from the gaseous region.

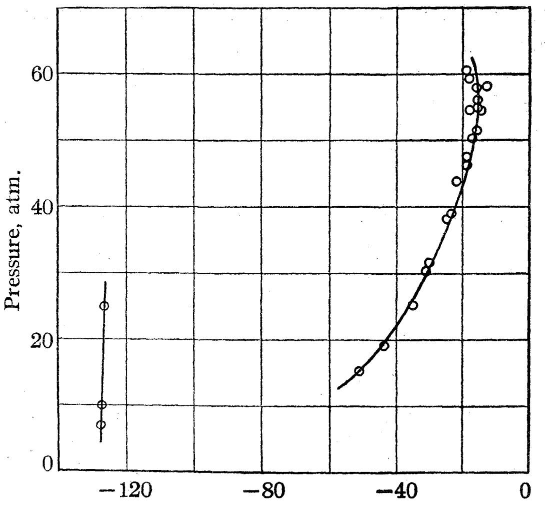

Fig. 2.—10 mole % argon.

The freezing points[2] are also plotted although the scale used does not represent adequately the experimental details found.

Discussion of Results

As commonly reported in the studies of critical phenomena of two component mixtures retrograde condensation was observed and also what may be described as a new phenomenon, retrograde immiscibility. This latter phenomenon is described in the previous paper.

In the range from 0 to 60% argon, the curve T (Fig. 9) giving the maximum temperature of liquefaction is only slightly distorted from the normal curve. On reflection this is not surprising in view of the fact that the critical region lies about 110° above the temperature at which the compounds $A \cdot xBF_3$ dissociate.

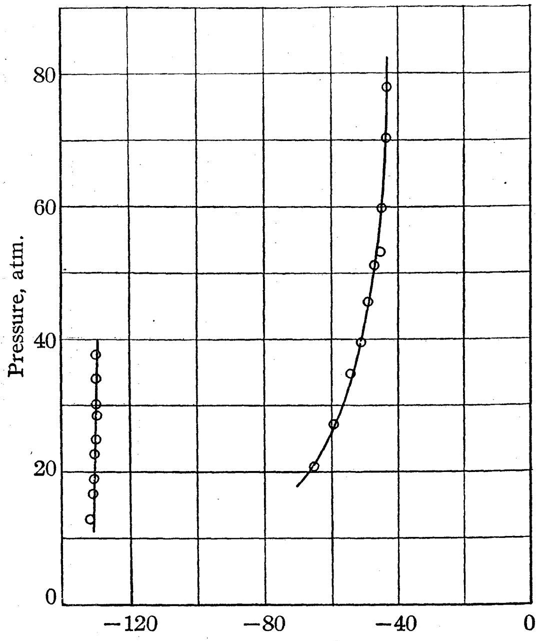

Fig. 6.—50 Mole % argon.

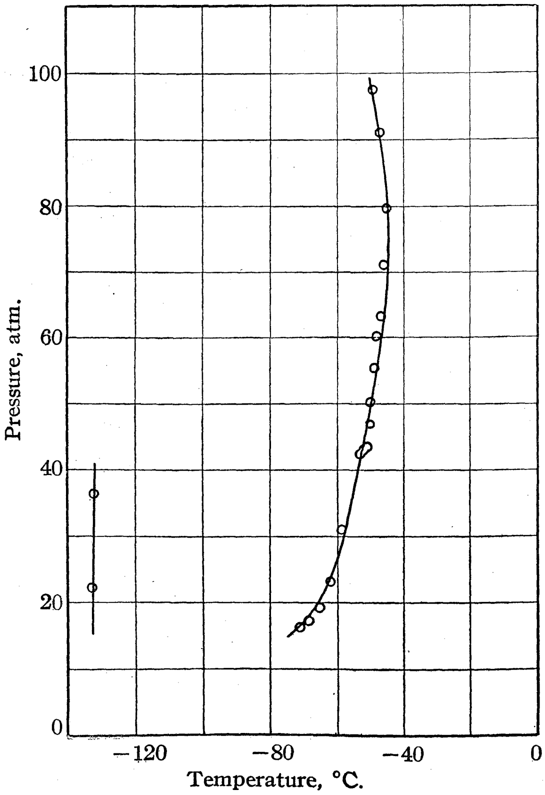

Fig. 7.—60 Mole % argon.

The maximum temperature of liquefaction T_m decreases along a smooth curve as the argon percentage is increased. The pressure P_m corresponding to T_m increases as the argon percentage increases to 50% and then decreases. The erratic points in the highest pressure regions on some of the curves are due to the liquid rising into the capillary tube and preventing adequate stirring.

The regions surrounding the critical point of a mixture have been little studied and merit an accurate investigation, but could not be studied in this work due to the low temperatures involved which caused the mercury to freeze in the capillary tubes. In the high argon samples, great difficulty in getting accurate critical data was encountered due to the small amount of liquid formed even over a wide temperature and pressure variation. Thus, the conditions under which the first trace of liquid appeared were difficult to determine, and an additional complication arose due to the liquid adhering to the walls of the cell and the stirrer, instead of falling to the bottom of the cell. The plot of the 90% argon sample shows the lack of reproducibility of the points and gives only a general idea of the critical data in that region.

Appearance of a second liquid layer in the freezing point curves for high pressures suggests pos-

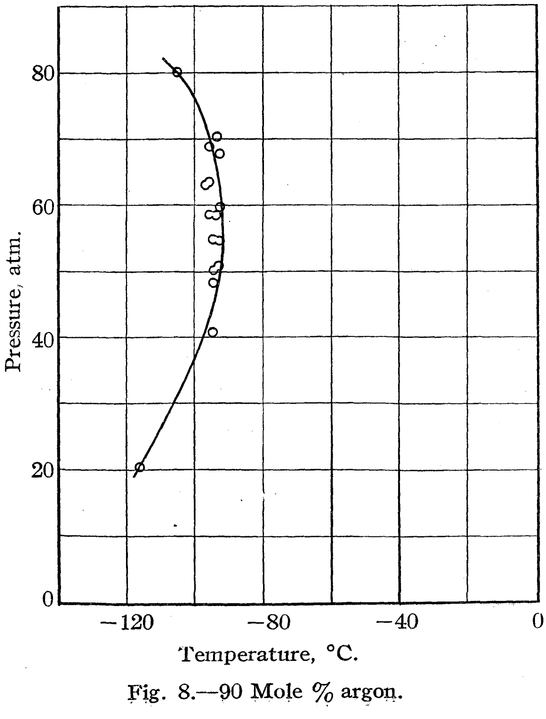

Fig. 8.—90 Mole % argon.

sible abnormalities in the high pressure, low temperature part of the critical curves but experimental difficulties precluded an investigation of this region.

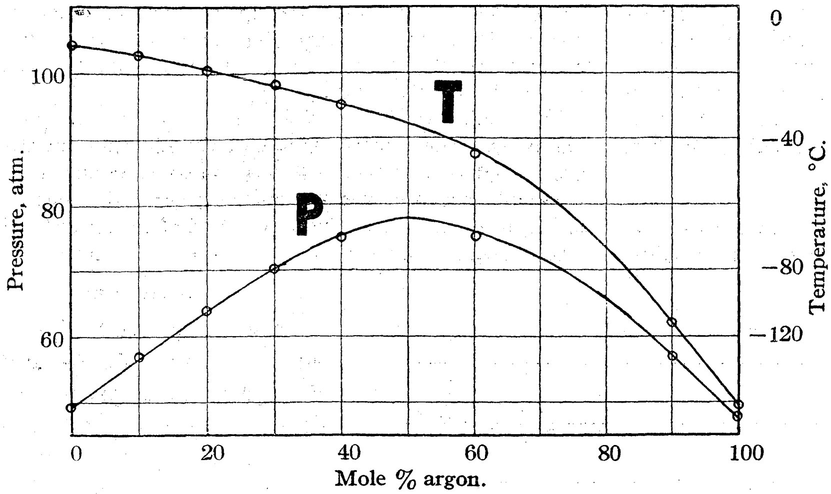

Fig. 9.—Maximum temperature of liquefaction and corresponding pressure.

Summary

The critical phenomena of the system boron trifluoride–argon exhibited the usual retrograde condensation and a new phenomenon best described as retrograde immiscibility at the low temperature, high pressure range.

The compounds formed by the gases at their melting point are practically completely dissociated at the "critical temperature region" which is about 100° higher, and so affect the curve of the maximum temperature of liquefaction only very slightly.

Temperature Coefficients in the Acid Hydration of Sodium Pyrophosphate

BY SAMUEL J. KIEHL AND EDWARD CLAUSSEN, JR.

Introduction

Normal sodium pyrophosphate in aqueous or alkaline solution on long standing at room temperature or even at the boiling point does not change to orthophosphate.[1,2] In acid solution, however, this change takes place, and its rate is dependent upon the concentration both of pyrophosphate and of the acid, used as the so-called catalyst, and the temperature.[3] The rate of change to the orthophosphate in the presence of hydrochloric acid has been measured at 45°,[3] and under very special conditions at 20 and 40° by Muus,[4] who also mentioned work at 100° although no data were presented. In general data at higher temperatures are meager.[5]

In the literature many procedures for measuring the rate of this and similar reactions are published, among which have been methods based upon gravimetric analysis, change of concentration of hydrogen ions, conductivity, colorimetry, nephelometry and volumetric analysis. For purposes of this investigation, however, a modification of the method devised earlier[2] was found to be most convenient. The unchanged pyrophosphate was determined gravimetrically in the presence of orthophosphate which was formed and the velocities at 30, 45, 60, 75 and 90° were secured. From data thus obtained temperature coefficients at fifteen-degree intervals were determined.

Preparation of Materials and Apparatus

The normal sodium pyrophosphate, the disodium orthophosphate and the hydrochloric acid were prepared as described previously.[3]

In the preparation of the zinc acetate reagent used in the analysis both the zinc acetate and the acetic acid were carefully purified to eliminate possible traces of heavy metals—especially iron and lead whose pyrophosphates would interfere in subsequent operations. The final solution of the zinc acetate reagent contained a 0.2 molar zinc acetate with sufficient acetic acid to give a *p*H value of 3.3.

A magnesia mixture without ammonia was prepared by dissolving 50 g. of $MgCl_2 \cdot 6H_2O$, 100 g. of NH_4Cl, and 5 cc. of 13 *M* HCl in one liter of water.

(3) Kiehl and Hansen, *ibid.*, **48**, 2802 (1926).

(4) Muus, *Z. physik. Chem.*, **A159**, (4) 268 (1932).

(5) Abbott, THIS JOURNAL, **31**, 763 (1909), studied the conversion of pyrophosphoric acid itself at 75 and 100°.

Water-baths at 30, 45, 60 and 75° and an oil-bath at 90° all of which were controlled by Beaver[6] regulators were used to maintain the required temperatures. The maximum deviation was $\pm 0.02°$.

Bottles of 750-cc. capacity made of acid and alkali resisting glass (trade name "No Solvit") were used to contain solutions in the baths at all temperatures except 90°. For 90° it was necessary, for the prevention of losses due to evaporation, to use a specially designed Pyrex (a borosilicate glass) glass bottle from which samples could be withdrawn through a capillary tube provided with a stopcock.

Method of Analysis

Determination of Pyrophosphates in the Presence of Orthophosphate.—The method of separation of pyrophosphate from orthophosphate and the subsequent determination of pyrophosphate was developed and conditions were established by the analysis of solutions of known mixtures whose respective phosphate content and conditions would correspond to those found in course of the actual hydration in the various solutions. The separations were made in a solution whose volume was 75 cc. and whose *p*H value of 3.3 to 3.5 was obtained by the addition of three molar acetic acid and the required amount of distilled water. The standard for *p*H value was brom phenol blue with the "Wulff" series of color standards. During the precipitation in the development of the method it was found that a slow formation of the zinc pyrophosphate was essential for the formation of a crystalline precipitate and for results of separation and analysis which would meet the required precision. This was accomplished by a dropwise addition of 10 to 30% excess of the reagent with constant and uniform stirring. The precipitate was separated from the supernatant liquid and was washed till free from the excess precipitant by repeated centrifuging and decanting through the filter and was transferred to the filter. The precipitate on the filter was ignited in platinum with the usual precautions, from gentle heating at first over a bunsen flame to constant weight finally over a meker burner. In the preliminary experimentation it was found that reprecipitations were unnecessary if manipulations were carefully and accurately done.

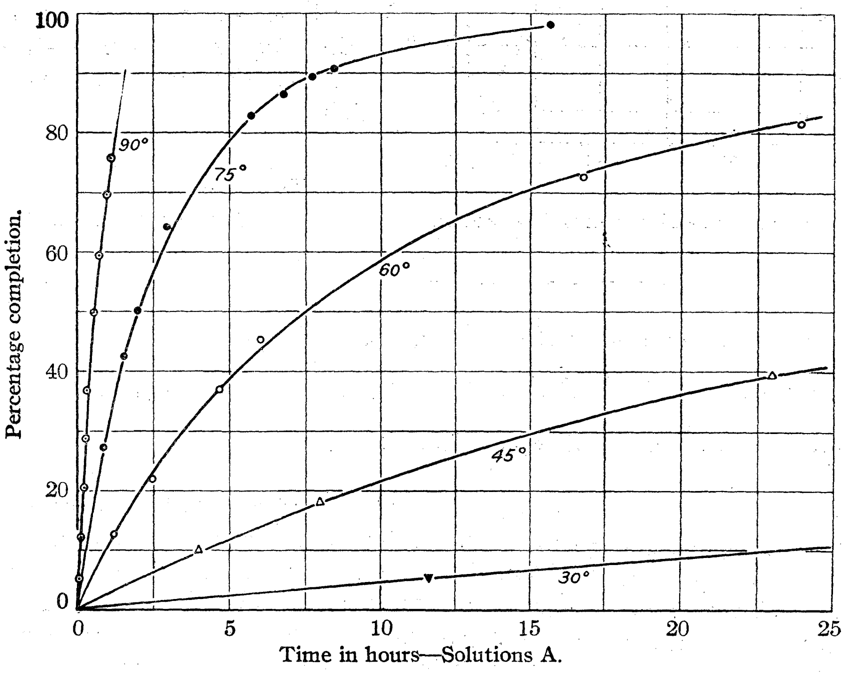

Fig. 1.—Effect of temperature on velocity.

As a further confirmation of the method of separation and analysis the orthophosphate in the filtrate from the zinc pyrophosphate was also determined in known mixtures and some examples of the subsequent hydrations by the modified magnesia mixture method of Epperson[7] the data and results for which are to be found elsewhere.[8]

Experimental

At each of five temperatures, 30, 45, 60, 75 and 90°, the velocity of conversion was measured for 0.125 *M* sodium pyrophosphate in the presence of 0.500 *M* (A), 0.425 *M* (B) and 0.350 *M* (C) hydrochloric acid, respectively.

Convenient samples were withdrawn by pipet, cooled quickly to room temperature, and weighed out in Bailey burets. The volume and hence the total weight of phosphorus was calculated from the known densities. The solution was then made just alkaline with concentrated ammonium hydroxide, and analyzed for the amount of phosphorus as pyrophosphate.

More detailed data for this work at all temperatures are available elsewhere.[8]

In Fig. 1 the effect of the five different temperatures upon the velocity of the reaction is shown for the solution designated A. The solutions styled B and C give the same type of curves.

Figure 2 shows the effect of the three different initial acid concentrations for the solutions at 45°.

In Table I a complete summary of these two effects upon the velocity is given for convenient equally spaced percentages of completion. The data were obtained from the curves for the hydrations in the respective solutions.

Discussion and Determination of Temperature Coefficients.—In order that temperature coefficients may be obtained for the reaction under the chosen experimental conditions, an equation will be necessary which will embody a factor that may be employed in establishing a unit of measure for the effect of temperature only upon the rate. This factor should remain constant under the prescribed conditions upon a definite temperature level but its value should change in going from one temperature level to another if it is to be of service for the determination of temperature coefficients. If the reaction under the conditions conformed to one of the classical orders of reaction in which the velocity constants incorporate this factor in the mathematical expression of the reaction which changes with temperature the problem would be simple. But the rate is affected greatly by a variation of the concentration of hydrogen ions[3] which on account of the difference in activity of the pyrophosphoric and orthophosphoric acids undergoes a marked decrease as the reaction proceeds. This decrease is dependent jointly upon the initial concentration of the hydrochloric acid and of the pyrophosphate.[3]

Moreover, for the proportions in which the original acid and pyrophosphate are used, the decrease of concentration of hydrogen ions during the reaction is sufficient to effect a considerable variation in the velocity. The difference in the speeds for A and B is greater at 90% completion than earlier, as reference to the slopes of the curves in Fig. 2 will show.

Therefore, due to the difference in activities of the respective phosphoric acids which causes changes in the concentration of hydrogen ions, it has been found that the reaction under discussion cannot be expressed by any of the orders of reaction unless the concentration of hydrogen ion be made to remain constant or a mathematical relation be obtained whereby it may be expressed in terms of the concentration of the phosphate.

This conclusion is supported by the work of Abbott[5] and by the work of Kiehl and Hansen.[3]

In more recent work by Muus,[4] who used radically different experimental conditions and approximately constant ionic environment at 20 and 40°, it was shown that with an extreme excess of acid (from 38 to 150 times the concentration of pyrophosphate), and in the presence of constant kinetic conditions (about 1000 times as much potassium chloride as the initial concentration of pyrophosphate), a definitely constant first order reaction velocity constant was obtained with a given concentration of hydrogen ion. These constants were directly proportional to the various concentrations of hydrogen ion under which the reaction was studied.

Consequently in this work, where the order of magnitude of the initial concentration of hydrogen ion was the same as that of the pyrophosphate, and where the inevitable consequence was that the concentration of hydrogen ion varied throughout the reaction recourse to an empirical equation to express the reaction rate seemed to be the only resort. The form of the equation was tentatively established by data from solutions at 45°[3] where concentrations of both hydrogen ion and pyrophosphate were known. Since the pyrophosphate concentration was the same in all solutions at the beginning and the initial concentration of hydrochloric acid was fixed for solution C, it was possible to express the concentration of hydrogen

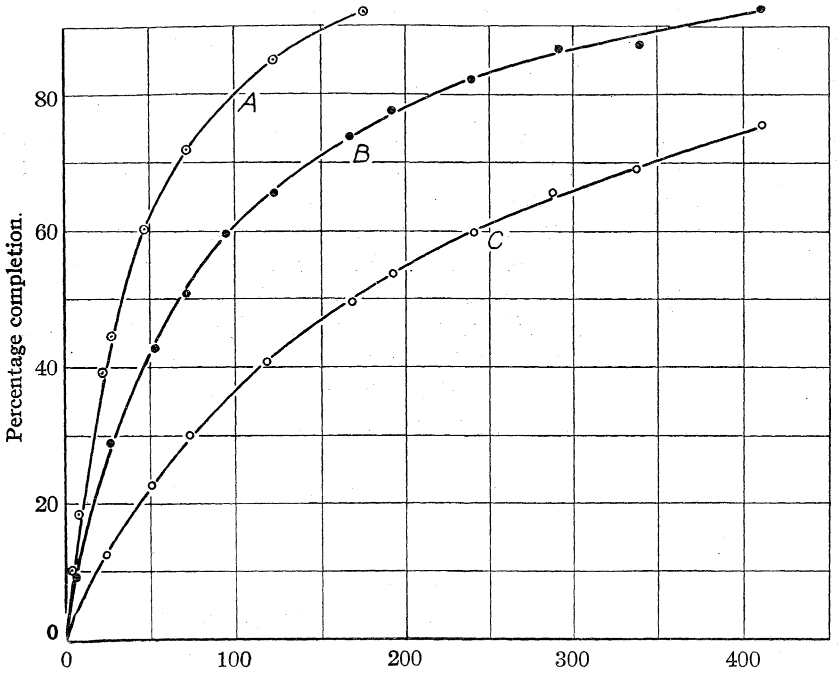

Fig. 2.—45° data—effect of initial acid concentration on velocity.

ion in terms of the pyrophosphate remaining, (x). By using such respective values from actual measurement made in synthetic solution at convenient percentage intervals, an equation of the form $(H^+) = A' + B'x + C'x^2 + D'x^3 + \ldots$, may be developed to express the relationship. The constants A', B', C', D', etc., may then be evaluated by solution of simultaneous equations. The velocity of the reaction accordingly may be expressed in the general equation $dx/dt = kf[x(H^+)]$, which by substitution of the above equation for $[H^+]$, assumes the form, $dx/dt = kx(A' + B'x + C'x^2 + D'x^3 +)$. The integration of this expression gives the final equation

$$kt = A \log x + B + Cx + Dx^2 \ldots$$

with t as time, x the fraction of the concentration of the pyrophosphate remaining, and k, A, B, C, D constants. The constants were evaluated by solving simultaneous equations representing times at 25, 35, 45, 55, 65 and 75% completion which were determined from a large smoothed-out plot of percentage against time for solution A at 60°.

Thus solved, the completed equation is

$$kt = -102.860 \log x - 68.143 + 109.690x - 42.598x^2 \ldots$$

It is noteworthy that although the equation was developed from data for solution A at 60° (0.125 M pyrophosphate and 0.500 M hydrochloric acid), it, with reasonable dependability, expresses the behavior not only of solutions A at all temperatures but also of solutions B and C throughout the entire temperature range.

By the use of this equation with all data within the limits of 25 to 75% completion, Table II was compiled. The values in Column 5 (% a. d.) were calculated from the ratio of the average deviation from the mean values of K.

The comparative constancy indicated by the average deviation of the calculated reaction velocity constants for the various solutions with the same concentration of acid at the same temperature and the consistency of change of constants for the various solutions from temperature to temperature suggest that they represent a reliable conception of the different reaction rates for the changes in initial acid concentrations and the changes in temperature. The equation holds best for the three intermediate temperatures.

TABLE II

REACTION VELOCITY CONSTANTS CALCULATED FROM THE EMPIRICAL EQUATION

Solution	$T.$, °C.	No. calculations	Mean k	Average deviation, %
A	90	4	11.60	7.4
B	90	5	8.74	5.7
C	90	3	5.75	1.0
A	75	4	3.64	2.7
B	75	4	2.17	2.3
C	75	3	1.30	2.7
A	60	3	0.966	0.3
B	60	4	.502	1.9
C	60	4	.276	2.0
A	45	4	.215	1.9
B	45	5	.102	2.3
C	45	6	.0425	3.0
A	30	4	.0393	2.6
B	30	8	.0180	6.3
C	30	7	.00626	7.5

By plotting these reaction velocity constants against temperature (Fig. 3) the customary exponential type of curve is obtained for each of the three solutions.

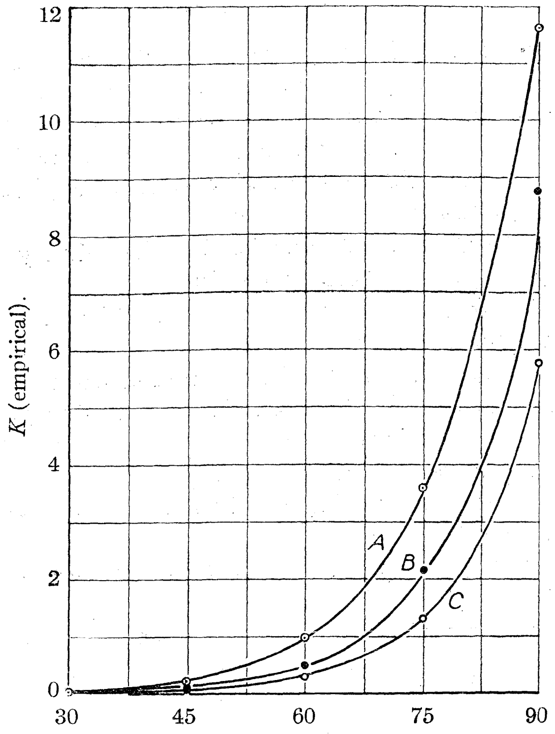

Fig. 3.—Effect of temperature on reaction velocity constant.

Temperature Coefficients

In Table III temperature coefficients calculated from the mean reaction velocity constants obtained by use of the empirical equation are compared with similar coefficients obtained by dividing the time obtained from smoothed-out curves for convenient percentages, such as 40, 50, 60, 70, at one temperature with a similar reading fifteen degrees higher.

The coefficients obtained by each of the methods described are quite comparable. Both decrease

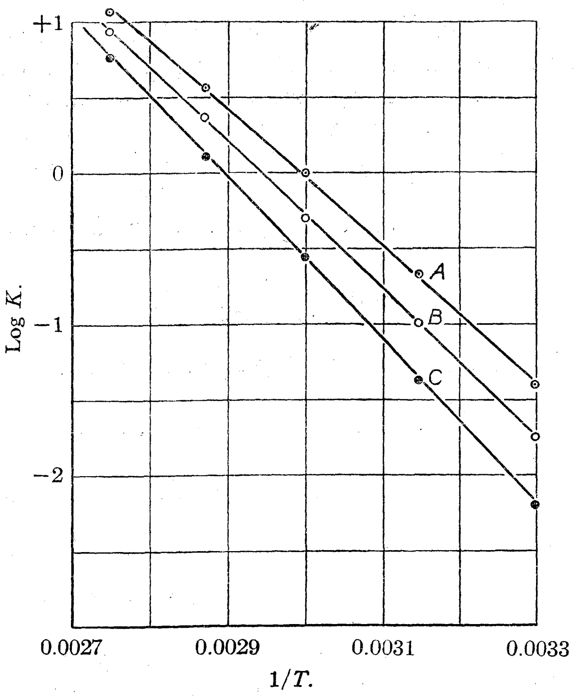

Fig. 4.—Plot of log *K* (empirical) *versus* the reciprocal of the absolute temperature.

TABLE III

TEMPERATURE COEFFICIENTS

Solution			45/30°	60/45°	75/60°	90/75°
A	From mean value of *K*		5.47	4.63	3.65	3.19
	From time data	40% completion	4.8	4.8	3.5	3.1
		50% completion	5.0	4.8	3.7	3.4
		60% completion	5.6	4.5	4.2	3.3
		70% completion	5.7	4.5	4.2	3.6
	Mean		5.3	4.7	3.9	3.4
B	From mean value of *K*		5.67	4.92	4.32	4.03
	From time data	40% completion	5.8	5.2	3.9	3.7
		50% completion	5.7	5.1	4.2	4.0
		60% completion	6.0	4.8	4.5	4.1
		70% completion	6.0	5.1	4.6	4.3
	Mean		5.9	5.1	4.3	4.0

	From time data	40% completion	6.6	6.4	4.7	4.2
		50% completion	6.9	6.5	4.9	4.3
		60% completion	7.2	6.6	5.1	4.5
		70% completion	7.3	6.6	5.4	4.7
	Mean		7.0	6.5	5.0	4.4

rather regularly with increase of initial concentration of hydrochloric acid at all temperatures, as we pass from solution C to B to A. Since the activity of the acid is greater at the beginning than at the end of the reaction the individual coefficients from the time method in any given solution tend to be greater as the reaction proceeds. Consequently the mean coefficients decrease as the temperature is raised.

If the reaction velocity constants which have been determined by use of the empirical equation be plotted, log K against $1/T$ (Fig. 4), in conformance with the differential form of the Arrhenius equation, $\mathrm{d}\ln k/\mathrm{d}T = Q/RT^2$, a straight line is obtained for each of the solutions.

Moreover, from the integral form of this same equation

$$\ln\frac{k_1}{k_2} = \frac{Q}{R}\,\frac{T_1 - T_2}{T_1T_2}$$

values for Q at fifteen degree intervals may be calculated. The values thus obtained are within the usual limits of constancy.

Summary

1. New data are presented for the velocity of conversion of pyrophosphate to orthophosphate in aqueous solution in the presence of three different concentrations of hydrochloric acid at five temperatures, 30, 45, 60, 75 and 90°. $Na_4P_2O_7\cdot 10H_2O$ was used.

2. An empirical equation for the velocity of the reaction has been developed.

3. Temperature coefficients for 15° intervals have been calculated.

4. The values for Q in the equation of Arrhenius are within the usual limits of constancy.

5. A modification of the method for the quantitative determination of pyrophosphate in presence of orthophosphate by use of zinc acetate has been made.

The Relative Strengths of Acids in *n*-Butyl Alcohol[1]

BY LELAND A. WOOTEN AND LOUIS P. HAMMETT

We have measured the relative strengths of a series of substituted carboxylic and phenolic acids in *n*-butyl alcohol, a hydroxylic solvent of relatively low dielectric constant, and have found certain relationships between the structure of the acid and the effect upon the relative strength of the transfer of the acid from water to this solvent. The solubility of lithium chloride in this solvent made it possible to work in a medium of high and constant strength, a necessary condition for the measurement of relative acid strength by the potentiometric method if specific salt effects are to be minimized or eliminated and the uncertainty due to liquid junction potentials avoided. Butylate ion was employed as the base.

Experimental

Method.—Concentration cells of the following type were set up and measured

$$\begin{array}{c|c||c||c|c}
 & \dfrac{HA_1}{NaA_1}=1 & & \dfrac{HA_2}{NaA_2}=1 & \\
\text{Au} & & \text{Satd. soln.} & & \text{Au} \\
 & \text{LiCl, 0.05 }M & \text{of LiCl} & \text{LiCl, 0.05 }M & \\
 & \text{Quinhydrone} & & \text{Quinhydrone} & \\
\multicolumn{5}{c}{\qquad\qquad\qquad a \qquad\qquad\qquad b}
\end{array}$$

The electromotive force of this cell at 25° is related to the relative strength of the two acids, HA_1 and HA_2, by the expression

$$\text{E. m. f.}/0.0591 = pK_2 - pK_1 = \Delta pK$$

where $pK = -\log K$, the negative logarithm of the ionization constant of the acid. This expression is a sufficiently precise approximation provided the acids exhibit normal weak-acid titration curves in the solvent under study. Since a fairly high neutral salt concentration (LiCl) was maintained throughout the whole system the junction potentials at a and b should be small and practically constant.

The cell used was essentially that employed by Hammett and Dietz.[2] Mixing of the solutions was minimized by ground glass plugs, which separated the buffer solutions from the salt bridge. The buffer solutions were approximately 0.0025 M and in all cases were made 0.05 M with respect

to lithium chloride. The measurements were made in an atmosphere of dry nitrogen. Rubber stoppers carried the electrodes as well as inlets and outlets for the nitrogen. A trap on the nitrogen outlet, containing *n*-butyl alcohol, sealed the system from the atmosphere. All measurements were made at room temperature, which was 25 ± 3°.

Apparatus

Potentiometer System.—The voltages were measured with a Leeds and Northrup Type K potentiometer in conjunction with a No. 2500-b Type R wall galvanometer of the same make. A newly calibrated Weston Standard cell was used in standardizing the working circuit. This system applied to butyl alcohol solutions permitted voltages to be measured to ±0.1 millivolt.

Electrodes.—In agreement with other workers, notably Hammett and Dietz[2] and Halford,[3] it was found that bright platinum is not a satisfactory electrode material for the quinhydrone reaction in non-aqueous solution. Electrodes made from new C. P. platinum wire, when first used, gave reliable results in *n*-butyl alcohol solution; after some use, however, they became erratic in behavior, disagreeing among themselves and with former measurements on the same buffer. No method of cleaning could be depended upon to restore their original good characteristics. Old platinum wire electrodes which had been used previously in inorganic oxidation–reduction systems in aqueous solution were always very erratic. These observations support the hypothesis of Hammett and Dietz[2] that platinum readily picks up surface impurities which are electromotively active, thus causing variations in the electrode potentials.

Gold-on-glass electrodes similar to those used by Hammett and Dietz[2] were prepared by the method of Newberry[4] except that the gold was deposited from a solution of gold trichloride in *n*-butyl alcohol instead of in ethyl alcohol. They were found to give satisfactory results in *n*-butyl alcohol solution provided they were subjected to a preheating treatment immediately before use. This treatment consisted in washing with ethyl alcohol, heating to dull redness in the tip of a Bunsen flame, and finally cooling in air. When treated by this method immediately before immersion in the solution to be measured, individual electrodes seldom failed to agree with each other within 1 millivolt and usually agreed within a few tenths of a millivolt.

After some use, however, gold-on-glass electrodes sometimes failed to give reproducible values when first immersed in the solution to be measured, even though they had been subjected to the usual heat treatment. In these cases the electrodes would finally attain a reproducible value, but the rate of attainment of equilibrium was very slow. This indicates that the catalytic properties of the electrode change with use. It is possible that as the electrode is used surface impurities are picked up (as in the case of platinum), which either lower the activity of the catalyst, or as a result of a lowered activity of the catalyst, become predominant in their effect on the electrode potential.

Three pairs of electrodes were used in all cells. Criteria of reliability of electrodes were: (1) agreement between several electrodes in the same buffer; (2) rapid attainment of equilibrium; and (3) in later work the reproducibility of the voltage of a given cell. The salicylate–benzoate cell was used many times for this purpose.

In addition to the electrode trouble described above there was observed at times a very slow drift in the potential of the cell being measured. That this drift was the result of a real change in the quinhydrone equilibrium was indicated by the fact that it occurred when all the electrodes were in close agreement. The rate of drift was greater as the buffer solution was made more alkaline and was generally in the direction of reduction of quinone rather than of oxidation of hydroquinone. It was found that in one or two cases the rate of drift was greatly reduced by passing the nitrogen over rather than through the solution, but this behavior could not be reproduced. As a result of these observations, however, the nitrogen was passed through the solutions only for fifteen to twenty minutes initially when the cell was set up, after which it was passed over the solution for the remainder of the period of test. This procedure seemed to give somewhat steadier potentials.

Colorimeter.—A Klett–Beaver comparator was used in the colorimetric work.

Materials

***n*-Butyl Alcohol.**—The Eastman product listed as practical (Cat. No. P-50) was used throughout this work. It was purified by extended treatment with anhydrous barium oxide, followed by distillation from barium oxide at reduced pressure (30 to 40 mm. of mercury) in an all-Pyrex glass distillation apparatus. This apparatus was fitted with a Widmer fractionating column 30 cm. in length. The presence of an excess of porous lumps of the anhydrous barium oxide permitted the distillations to be carried out at low pressure without the introduction of air or gas usually admitted to prevent bumping. The product was acid and aldehyde free. The boiling point was 117 ± 1°. The dielectric constant[5] of the purified solvent was 17.4 ± 0.1 at 24.5° when measured at frequencies of 10 and 100 k.c.

After use, the solvent was re-purified by subjecting it to two or more vacuum distillations as described above, after which it could again be used.

The Alkali Reagent.—A solution of 0.1 *N* sodium butylate was prepared by the interaction of metallic sodium and pure *n*-butyl alcohol. Before adding the sodium, the alcohol was saturated with hydrogen or nitrogen to displace carbon dioxide. After preparation, the solution was immediately stored under hydrogen in a Pyrex bottle made light-proof by painting with black lacquer. The bottle was fitted with a stopper which carried two tubes; one of these was connected through a drying tower to a tank of compressed hydrogen, and the other, which extended nearly to the bottom of the bottle, was connected to a three-way stopcock buret of 10-ml. capacity. The open end of the buret was fitted with a soda-lime tube. Before filling, the air in the buret was swept out by passing through it a stream of hydrogen. It was filled by means of a slight pressure from the compressed hydrogen tank.

[3] Halford, THIS JOURNAL **53**, 2944 (1931); *ibid.*, **55**, 2272 (1933).

[4] Newberry, *Trans. Electrochem. Soc.*, **64**, 209 (1933).

[5] The dielectric constant was measured by Dr. S. O. Morgan.

An alkali solution thus prepared and stored usually remained constant in titer against standard benzoic acid for at least one month.[6] Its purity was frequently tested by titrating potentiometrically portions of a standard picric acid in butyl alcohol solution, according to the method described by Wooten and Ruehle,[6] which provides a sensitive test for the presence of weak acid salts.

Since lithium chloride was to be added to the solutions under study, an attempt was made to employ lithium butylate as the alkali reagent, thus simplifying the system by limiting it to lithium salts. It was found, however, that lithium butylate is almost completely insoluble in butyl alcohol.

Lithium Chloride.—This salt was obtained from two sources. The fused product from Kahlbaum was found to contain 0.3% free alkali. This proved so troublesome to purify that its use was abandoned for a special anhydrous product obtained from Merck and Company which was practically free from alkali and could be used without further purification. Saturated solutions were prepared by heating in a Pyrex glass reflux apparatus a portion of the pure solvent in contact with an excess of the anhydrous salt. The solutions of lithium chloride in butyl alcohol obtained by this method were approximately 2.1 *M* when allowed to come to equilibrium at room temperature.

Quinhydrone.—The quinhydrone used in most of the work was obtained from the Eastman Kodak Co., melting point 170°. Recrystallization from butyl alcohol did not perceptibly improve its quality.

Owing to its high solubility in *n*-butyl alcohol it was not feasible to employ a saturated solution of quinhydrone. Consequently it was added in equivalent quantities to each half cell in concentration of 50 mg. per 100 ml. of solution. Variation of the concentration of quinhydrone did not influence the voltage of the cell.

Compressed Nitrogen.—Tank nitrogen was purified by passing it through towers containing soda-lime and phosphorus pentoxide and through a fritted glass wash bottle containing *n*-butyl alcohol, which served to saturate the gas with alcohol vapor. No attempt was made to remove the small amount of oxygen known to be present.

Acids.—With the exception of benzoic and trimethylbenzoic, the acids used were obtained from the Eastman Kodak Company. The benzoic acid was the Bureau of Standards Alkalimetric Standard No. 39d, and was employed both as a primary alkalimetric standard and as a standard in the measurement of relative strength. Trimethylbenzoic acid was prepared from bromomesitylene by the method of Bamford and Simonsen.[7,8]

Solid acids were dried in an oven at suitable temperature and stored over phosphorus pentoxide. In some cases they were further purified as indicated in the following table. In general they were considered of sufficient purity if they gave correct melting points within ±1°. Liquid acids were dried by treatment with anhydrous sodium sulfate followed by distillation at reduced pressure, and characterized by their boiling points. An additional check on the purity of the acids was the determination of the equivalent weight by titration in butyl alcohol with standard sodium butylate solution. The analytical results obtained on the acids are listed in Table I.

TABLE I

Acid	Physical constants, m. p., °C.	Analyses, %	Remarks

[a] Purified by Mr. H. Wadlow. These acids were treated with anhydrous sodium sulfate and triple distilled at low pressure in a special distillation apparatus.

Precision and Reliability

Logarithmic titration curves were employed to demonstrate that the acids studied behave as normal weak acids in *n*-butyl alcohol solutions of high and constant ionic strength. Some of these curves are shown in Figs. 1 and 2. Excluding picric and trichloroacetic acids, which are moderately strong acids even in *n*-butyl alcohol, the average slope of the curves obtained is 58 ± 2 millivolts per logarithmic unit, which is in close agreement with the theoretical slope given by

$$\Delta E/\Delta \log \frac{X}{1 - X} = 59 \text{ mv. at } 25°$$

where X is the fraction neutralized at voltage E.

Table II shows typical data obtained on two representative cells. Three pairs of electrodes were used in each buffer.

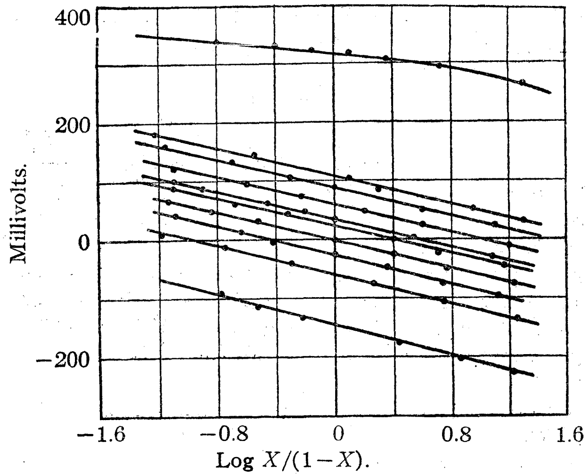

Fig. 1.—Logarithmic titration curves with quinhydrone electrode in *n*-butyl alcohol, 0.002 *M* acids titrated with 0.1 *M* sodium butoxide: in order, from the top, picric, 2,4-dinitrophenol, salicylic, *o*-chlorobenzoic, *m*-chlorobenzoic, *p*-chlorobenzoic, benzoic, *p*-methoxybenzoic, trimethylacetic, *p*-nitrophenol.

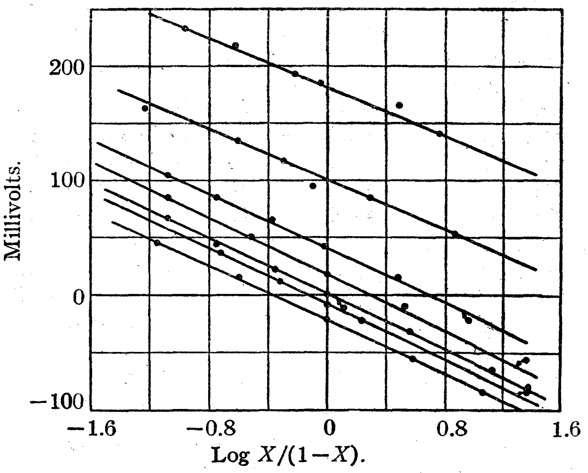

Fig. 2.—Logarithmic titration curves with quinhydrone electrode in *n*-butyl alcohol, 0.002 *M* acids titrated with 0.1 *M* sodium butoxide: in order from the top, dichloroacetic, chloroacetic, trimethylbenzoic, *o*-methoxybenzoic, *o*-toluic, *p*-toluic, *n*-caprylic.

TABLE II

(a) Salicylate–Benzoate Cell

Time	E_1, mv.	E_2, mv.	E_3, mv.
10 min.	88.9	91.3	90.8
15 min.	88.9	90.5	90.0
2 hrs.	89.0	90.6	90.5
20 hrs.	91.6	91.5	91.1

(b) Butyrate–Benzoate Cell

Time	E_1, mv.	E_2, mv.	E_3, mv.
10 min.	19.4	20.0	20.0
30 min.	21.1	20.7	20.7
45 min.	20.9	20.8	20.8
3 hrs.	21.0	20.9	21.0

Table III shows the reproducibility of the method. The values shown were obtained on salicylate–benzoate cells prepared at different times from different reagents. The measurements were made under the same conditions except for small variations in room temperature. Each value is the average of a number of measurements using three electrode pairs over a period of at least two hours.

From the results presented in Tables II and III it is seen that the precision limits of the method are easily within ±0.05 logarithmic units.

TABLE III

SALICYLATE–BENZOATE CELL

Date	E, mv.	Dev. from mean
5/19/34	88.5	−0.4
5/27/34	86.0	−2.9
6/4/34	86.3	−2.6
9/20/34	91.0	+2.1
10/6/34	90.2	+1.3
10/7/34	90.0	+1.1
11/7/34	88.5	−0.4
12/31/34	91.3	+2.4
Average	88.9	±1.6

Effect of Water.—Although precautions were taken to dry the solvent, acids and other reagents before use, the method employed did not permit the measurements to be made without some exposure of the solutions to the atmosphere. It was therefore necessary to determine the influence of water upon the electromotive force of a typical cell. In the following table the effect of water upon the salicylate–benzoate cell is shown. The same effect was observed on a number of different cells.

TABLE IV

Per cent. water added		E. m. f.	
Benzoate arm	Salicylate arm	E_1	E_2
0.0	0.0	90.1	90.1
.1	.0	91.2	91.3
.5	.0	94.5	94.6
1.0	.0	98.8	98.2
2.0	.0	101.5	101.0
3.0	.0	104.7	104.5
5.0	.0	109.5	109.0
5.0	5.0	91.3	91.0

These results show that water has definite basic properties in *n*-butyl alcohol solution and thus causes a decrease in the potential of the half-cell to which it is added. But if it is present in equivalent quantities in both half cells the effect on the voltage of the cell is apparently negligible. Traces of moisture in the solvent therefore should not alter the relative strength of the acids. The linearity of the logarithmic titration curves, however, indicates that the solvent was comparatively free of moisture.

Effect of Varying Neutral Salt.—To determine whether an 0.05 *M* concentration of lithium chloride was sufficient to produce a sensibly constant ionic environment when working with 0.0025 *M* buffer solutions the following experiment was carried out.

TABLE V

EFFECT OF VARYING NEUTRAL SALT CONCENTRATION ON THE SALICYLATE–BENZOATE CELL

Molar salt concentration		E. m. f.	
Salicylate arm	Benzoate arm	E_1	E_2
0.00	0.00	121.2	120.8
.00	.05	77.0	77.5
.05	.05	90.1	90.3
.05	.10	84.4	84.1
.10	.10	90.2	89.5
.10	.15	86.4	86.5
.15	.15	90.6	90.9

The results shown in Table V indicate that as the salt concentration is increased the voltage of the cell becomes less sensitive to changes in salt concentration. Beyond 0.05 *M*, large variations in salt concentration may occur without greatly influencing the electromotive force of the cell. The agreement of the logarithmic titration curves with the theoretical slope (Figs. 1 and 2) also indicates that an 0.05 *M* salt concentration is sufficient to produce a sensibly constant ionic environment when the concentration of the acid is 0.002 to 0.003 *M*.

Effect of Temperature.—Tests on the salicylate–benzoate and acetate–benzoate cells showed that a change in temperature of 10° caused a change in voltage of approximately 2 millivolts. It was concluded from these tests that the error caused by variations in temperature of ±3° was negligible compared to other sources of error in the method.

Results

The results on the relative strengths of acids obtained by the potentiometric method are summarized in Table VI. Variations in relative strength are expressed in logarithmic units. A negative sign indicates that an increase in acid strength relative to benzoic acid occurs when the acid is transferred from water to butyl alcohol, a positive sign that a decrease occurs.

The values for pK_{H_2O} in Table VI are at 25° and are from Landolt–Börnstein "Tabellen" unless otherwise indicated.

TABLE VI

Acid	pK_{H_2O}	ΔpK_{H_2O}	ΔpK_{BtOH}	Change in relative strength
Benzoic	4.20[9]	0	0	0
o-Chlorobenzoic	2.92[9]	−1.28	−1.00	+0.28
m-Chlorobenzoic	3.82[9]	−0.38	−0.60	− .22

Picric	0.8	−3.4	−5.4	−2.0

Colorimetric Work.—The relative strengths of 2,4-dinitrophenol and of salicylic, chloroacetic, and *o*-nitrobenzoic acids were determined colorimetrically using 2,4-dinitrophenol as indicator. The strength of the acid (pK_a) is related to the strength of the acid indicator (pK_I) and the degree of dissociation of the indicator (α) in a half-neutralized buffer of the acid in the following way.

(13) Wright, *ibid.*, **56**, 314 (1934).

$$pK_a = pK_I + \log \alpha/(1 - \alpha)$$

The buffer solutions were 0.002 molar in acid and salt, the indicator concentration was 0.00004, except for one measurement on the salicylic system, where it was one-half as great. Each item in the tables represents the mean of many colorimetric settings on an individually prepared buffer system. The reference solution for completely ionized dinitrophenol was prepared with sodium butylate in butyl alcohol. The potentiometric values were obtained by the direct comparison of the carboxylic acid with dinitrophenol. They are reasonably consistent with those obtained by comparing both carboxylic acids and dinitrophenol with benzoic acid.

Table VII contains the results obtained in solutions containing 0.05 *M* lithium chloride as in the potentiometric measurements.

TABLE VII

Acid	$pK_a - pK_I$ Colorimetric	Potentiometric
o-Nitrobenzoic	+0.12, 0.08, Av. +0.10	+0.14
Chloroacetic	+0.24	+ .24
Salicylic	+0.55, 0.33, 0.29, 0.22, Av. +0.35	+ .35

The agreement between the potentiometric and the colorimetric work is strong support for the validity of both methods of determining acid strength in this solvent.

Table VIII contains the results of some colorimetric measurements in which no lithium chloride was added.

TABLE VIII

Acid	$pK_a - pK_I$
o-Nitrobenzoic	+0.09, 0.07, 0.27, Av. 0.14
Chloroacetic	+0.21
Salicylic	+0.31, 0.34, 0.32, Av. +0.33

With these acids there does not seem to be any very important change in relative strength with salt concentration in this range.

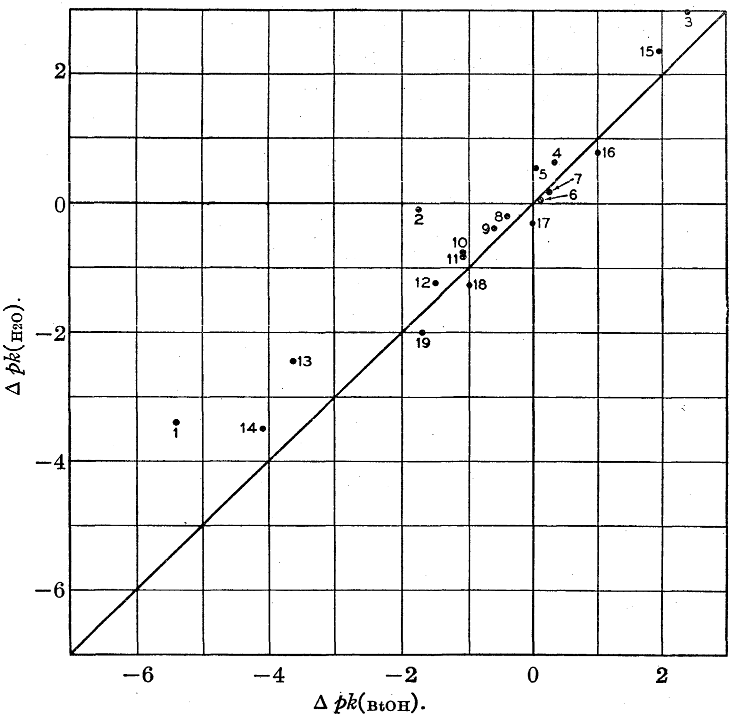

Fig. 3.—Relative strengths of acids in water and in *n*-butyl alcohol referred to benzoic acid: 1, picric; 2, 2,4-dinitrophenol; 3, *p*-nitrophenol; 4, butyric; 5, acetic; 6, *m*-toluic; 7, *p*-toluic; 8, *p*-chlorobenzoic; 9, *m*-chlorobenzoic; 10, *m*-nitrobenzoic; 11, *p*-nitrobenzoic; 12, salicylic; 13, maleic (1); 14, trichloroacetic; 15, maleic (2); 16, trimethylacetic; 17, *o*-toluic; 18, *o*-chlorobenzoic; 19, *o*-nitrobenzoic.

Discussion

Specific variations in relative strengths of acids and bases with changing solvent have been rather generally interpreted in terms of a theory[14] according to which the change in relative strength should be a function of the charge and radius of the ion and of the dielectric constant of the medium. The dependence upon ionic charge has been verified qualitatively by Brönsted,[14c] and the predicted linear dependence upon the reciprocal of the dielectric constant has been shown by Wynne-Jones[14d] to be satisfactorily fulfilled by the existing conductivity data for the solvents water, and methyl and ethyl alcohols.[15] That the variations in relative strength of closely related carboxylic acids should depend upon changes in ionic size seems, however, not very probable and the present results support a different interpretation which re-

---

(14) (a) Born, *Z. Physik*, **1**, 45 (1920); (b) Bjerrum and Larsson, *Z. physik. Chem.*, **127**, 358 (1927); (c) Brönsted, *Chem. Rev.*, **5**, 231 (1928); (d) Wynne-Jones, *Proc. Roy. Soc.* (London), **A140**, 440 (1933).

(15) The data obtained in this investigation do not agree with the relationship proposed by Wynne-Jones, but do not provide a fair test of it, since they were obtained in solutions of fairly high ionic strength. Both the theory and its previous tests apply to solutions of zero ionic strength. Our few colorimetric measurements at low ionic strengths do not indeed indicate large variations of relative strength with change in salt concentrations but are not sufficiently comprehensive to be conclusive.

cently has been discussed by Schwarzenbach and Egli.[16]

It should be noted first that there is a marked difference in behavior between acids in which the substituent is adjacent to the carboxyl group and those in which the substituent is more distantly located. Considering only the distantly substituted acids, it appears that any substitution which causes an increase in absolute strength causes an increase in relative strength, while one which causes a decrease in absolute strength causes a decrease in relative strength when the substituted and unsubstituted acids are transferred from water to *n*-butyl alcohol. This generalization is in accord with the expression which gives the additional electrical work ΔW required to ionize an acid containing a substituted polar group as compared with the unsubstituted acid in a solvent of dielectric constant D[16,17]

$$\Delta W = e\,\mu \cos \Theta / Dr^2$$

where r is the distance from the dipole to the carboxyl group, $\mu \cos \Theta$ is the component of the electric moment of the substituent along r, and e is the charge on the ion. A change in solvent resulting in a decrease in dielectric constant of the medium should therefore result in a change in relative strength, the direction of which should depend upon the influence of the substituent upon the ionization of the acid. For example, if the substitution results in an increase in ionization, ΔW is negative in sign and a change to a solvent of lower dielectric constant should result in an increase in relative strength; when substitution results in a decrease in ionization, ΔW is positive and a similar change in solvent should result in a decrease in relative strength. Thus meta and para nitro and chloro benzoic acids show an increase in strength relative to benzoic when transferred to *n*-butyl alcohol solution while meta- and para-methylbenzoic and para-methoxybenzoic acids show a decrease in strength. Similarly, beta-chloropropionic acid shows an increase in strength relative to propionic in agreement with the result expected from the fact that this acid is stronger than propionic acid in aqueous solution.

The changes in relative strength observed for ortho substituted benzoic acids and alpha substituted aliphatic acids show, however, that some quite different effect is involved when the substitution is near the carboxyl group. With the exception of *o*-hydroxy and *o*-methoxybenzoic acids, all of the ortho compounds studied decrease in strength relative to benzoic despite the fact that all substituents in this position cause an increase in the absolute strength of the acid. Likewise, chloroacetic and dichloroacetic acids decrease in strength relative to acetic. These results are similar to those obtained by Schwarzenbach[16] on the effects of substitution on the relative strengths of phenols and thiophenols in water and ethyl alcohol solutions. He concluded that while the results obtained on meta and para compounds could be explained fairly satisfactorily in terms of the electric moments of the substituents, other factors became predominant in the case of ortho substituted compounds.

It seems indeed to be a rather generally valid principle that the effects of an adjacent and of a distant substituent upon the reactions of a particular group in an organic molecule depend upon entirely different properties of the substituent. This is a familiar fact in the kinetics of reactions where an ortho substituent gives rise to a "steric hindrance."[18] With respect to equilibrium quantities it was noted by Flürscheim[19] that the introduction of any substituent into the ortho position in benzoic acid, regardless of its so-called electrochemical nature, has the effect of increasing the strength of the acid. Smallwood[17d] noted that all ortho substituted benzoic acids have especially large temperature coefficients of ionization.

Summary

1. A method for the measurement of the relatives strengths of acids in *n*-butyl alcohol has been developed.

2. The relative strengths of thirty-three representative carboxylic and phenolic acids have been measured.

3. The effect of a substituent upon the variation in relative strength with changing medium is that to be expected from the electric moment of the substituent and the dielectric constant of the medium when the substituent is introduced into the molecule at a point considerably removed from

the carboxyl group. Some other influence is however preponderant when the substitution is adjacent to the carboxyl group, that is to say when it is on the alpha carbon in an aliphatic acid, or in the ortho position in benzoic acid.

The Mechanism of the Slow Oxidation of Propane

BY ROBERT N. PEASE

In his original work[1] on the non-explosive oxidation of propane and the butanes, the writer was especially impressed with the fact that the oxidation reactions induced the dissociation of the hydrocarbons into the normal products, *e. g.*

$$\begin{aligned} C_3H_8 &\longrightarrow C_3H_6 + H_2 \\ &\longrightarrow C_2H_4 + CH_4 \end{aligned}$$

This was discussed briefly in terms of what would now be called an "energy-chain." Since this work was done, F. O. Rice has brought out his "radical-chain" theory of hydrocarbon dissociation.[2] In view of the success of this theory in accounting for such experiments as those of Frey[3] on the dissociation of *n*-butane induced by decomposing dimethyl-mercury, it appeared important to attempt to account for the reactions occurring in hydrocarbon–oxygen mixtures in terms of radical-chains. For this purpose additional information about the products of the reactions was required.

In approaching this problem—the determination of liquid as well as gaseous reaction products—we were at first "side-tracked" by the discovery that substantial quantities of organic peroxides (other than per-acids) were formed.[4] However, it was eventually found that these peroxides could be largely eliminated (by coating the reaction tube with potassium chloride) without greatly affecting the reaction rate, an observation which convinced us that peroxides took no main part in the development of reaction. Had peroxides proven of greater importance, we would have been inclined toward Egerton's energy-chain theory.[5] An exhaustive search for other liquid oxidation products was then undertaken, the result of which was to show that, in the case of propane, only methanol and formaldehyde were of any importance. However, conditions were not favorable to the production of anything like stoichiometric yields of these, and the tentative conclusion was reached that the true primary products had still to be discovered.

Further investigation of this problem now indicates that methanol and formaldehyde, in addition to carbon monoxide and water, are in fact the primary products of propane oxidation, the indicated stoichiometric equation being

$$C_3H_8 + 2O_2 \longrightarrow CH_3OH + HCHO + CO + H_2O$$

How the general result is to be expressed in terms of the radical-chain theory will be discussed following presentation of the experimental data.

Experimental

The general methods of the previous investigations were employed. The gases passed at a known rate through a heated reaction tube of Pyrex glass coated with potassium chloride. Liquid products were separated at −40°, while gaseous products were separately collected over water with the trap at 0°. Methanol was determined by reaction with acetic anhydride (forty-eight hours at room temperature); formaldehyde by the potassium cyanide method; total aldehydes by the bisulfite method; esters by saponification following the alcohol determination. Carbon dioxide was absorbed in caustic; higher olefins (designated C_nH_{2n}) in concentrated sulfuric acid; ethylene in bromine water; oxygen in "Oxsorbent." Hydrogen and carbon monoxide were oxidized over copper oxide at 350°; paraffins were oxidized at 600°.

It was desirable to eliminate the olefin-producing reactions as far as possible. For this purpose, the experiments were conducted at low temperatures (300°, with one set at 260°). This necessitated the use of rather large reaction tubes. In order to minimize secondary oxidations, only mix-

[a] "C_3H_8 used" represents the difference of two rather large numbers, and is consequently subject to a considerable error—perhaps 3 to 5 cc.

tures relatively low in oxygen (10 to 30%) were investigated.

Results are presented in Table I. The data refer to runs in which 400 cc. of reaction mixture was passed through the apparatus in ten minutes. Liquid products are calculated as cc. of vapor under standard conditions (760 ± 10 mm.; 25 ± 3°). In addition to the products listed, there were found 0 to 2 cc. of ethylene, hydrogen, acid and ester, with usually traces (<1 cc.) of peroxide. These are omitted in order to simplify the table somewhat.

Tubes of various dimensions were first investigated to determine optimum conditions. Over the range of diameters from 2 to 6.5 cm. there was little choice at 300°.[6] Sets of runs were finally made with 10, 20 and 30% oxygen at 300° with the 3-cm. tube, and at 260° with a large tube 6 cm. in diameter.

It will be noted that roughly two moles of oxygen react for every mole of propane, and one mole of carbon monoxide is formed. Next to carbon monoxide, methanol is the important product; and as the oxygen input is decreased, the amount of methanol tends to approximate the amount of propane reacting (see 10% runs). Formaldehyde behaves similarly, though the agreement is poorer. Nevertheless the *total* aldehyde ("HCHO" plus "Higher CHO") follows the methanol rather closely. Losses are clearly made up by secondary formation of carbon dioxide and methane.

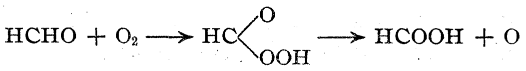
Discussion

Any consideration of the mechanism of propane oxidation must give prominence to two fundamental facts, namely, (1) the persistence of one-carbon oxidation products, particularly methanol, at low temperatures and low oxygen concentrations; (2) the induced dissociation of the hydrocarbon at higher temperatures. Bone's hydroxylation theory[7] makes no provision for lower alcohols,[8] nor for induced dissociation. Norrish's development of the latter to include radical-chains propagated via oxygen atoms and alkylidene radicals[9] comes somewhat closer to what the writer is inclined to believe is the truth, but again it is not obvious how a lower alcohol could arise as a principal product. Norrish writes for the methane-oxidation chain

$$O + CH_4 \longrightarrow CH_2 + H_2O$$
$$CH_2 + O_2 \longrightarrow HCHO + O$$

The chain is started by surface reactions

$$CH_4 + O_2 \longrightarrow HCHO + H_2O$$



$$HCHO + O_2 \longrightarrow HC\langle^{O}_{OOH} \longrightarrow HCOOH + O$$

It is ended by the reactions

$$O + CH_4 + X \longrightarrow CH_3OH + X'$$
$$O + \text{surface} \longrightarrow {}^1/_2\, O_2$$

Provision is thus made for the alcohol of the same number of carbon atoms in the process of ending a chain. This type of mechanism obviously could not account for a stoichiometric yield of alcohol, especially one of fewer carbon atoms than the original hydrocarbon contained. The

---

(6) With the 2-cm. tube, reaction had to be started at 325–350° after which it would maintain itself on cooling to 300°. With a 1-cm. tube, a temperature of 400° was required for starting; and reaction would maintain itself only above 375°.

(7) Bone and Townend, "Flame and Combustion in Gases," The Macmillan Co., 60 Fifth Ave., New York City, 1927.

(8) Methanol was identified in every experiment by preparing the 3,5-dinitrobenzoate and taking its melting point. The latter was always sharp and close to the correct value for the methyl ester (108°). The alcohol from isobutane also proved to be methanol. From *n*-butane, the derivative melted from 95–102°, indicating a mixture of methyl and ethyl (m. p. 93°) esters.

(9) Norrish, *Proc. Roy. Soc.* (London), **150A**, 36 (1935).

same objection can be brought against the similar but independently developed theories of Semenoff[10] for hydrocarbon oxidation.

The writer is inclined to go back to Rice's theory of hydrocarbon dissociation[2] as a starting point for the oxidation mechanism of propane. According to this, the dissociation of propane proceeds essentially through the reactions

Chain-starting $C_3H_8 \longrightarrow CH_3 + C_2H_5$

Chain-development $(R = CH_3, (C_2H_5), H)$

$$(1)\quad C_3H_8 + R \longrightarrow RH + C_3H_7$$

$$(2)\quad C_3H_7 \begin{matrix} \nearrow C_3H_6 + H \\ \searrow C_2H_4 + CH_3 \end{matrix}$$

Chain-ending $R + R' \longrightarrow RR'$

Quite apart from the applicability of this scheme to the normal dissociation, one may grant its usefulness in interpreting induced dissociations and allied reactions. In essence, the mechanism requires a radical, R, which is capable of removing a hydrogen atom or methyl group from the propane molecule, and which is reproduced in the subsequent reactions of the residue. Our problem is to determine what reasonable sequence of reactions of this type will yield the observed products of the oxidation reactions.

The mechanism which the writer has in mind postulates the methoxyl radical (CH_3O) and the propyl radical (C_3H_7) as chain carriers

$$CH_3O + C_3H_8 \longrightarrow CH_3OH + C_3H_7$$
$$C_3H_7 + O_2 \longrightarrow C_2H_4O + CH_3O$$

These would yield methanol and the compound C_2H_4O, which is taken to be acetaldehyde. A portion of the acetaldehyde survives (higher CHO). The remainder reacts with oxygen to give formaldehyde and carbon monoxide

$$CH_3CHO + O_2 \longrightarrow HCHO + CO + H_2O$$

The addition of oxygen to acetaldehyde is measurable at 100°. It must be extremely rapid at 300°. That the low-temperature product (peracetic acid) breaks down to yield carbon monoxide at higher temperatures appears plausible from the work of Pope, Dykstra and Edgar[11] on the oxidation of *n*-butyraldehyde and *n*-heptaldehyde. The main oxidation products (CH_3OH, HCHO, CO) are thus accounted for. Further reaction of the propyl radicals will also yield the normal products of dissociation at higher temperatures by Rice's mechanism given above. The suggested scheme thus affords a straightforward explanation of the analytical data.

The starting and stopping of chains is less clear.[12] It is to be remembered that reaction is very strongly inhibited by a packing, and is at least delayed at intermediate temperatures (375–425°) by excess of foreign gases, as well as oxygen, the reaction having a negative temperature coefficient in this range. The effect of packing rather argues against a wall reaction for starting the chains. Homogeneous dissociation of propane into radicals seems to be ruled out. Likewise a homogeneous bimolecular reaction between propane and oxygen seems doubtful since the over-all reaction depends more on the propane than on the oxygen concentration. It is accordingly suggested that the starting reactions are

$$2C_3H_8 \longrightarrow C_3H_8^* + C_3H_8$$
$$C_3H_8^* + O_2 \longrightarrow C_2H_5O + CH_3O$$

the oxidation of $C_3H_8^*$ being much faster than the deactivation of $C_3H_8^*$ by collision.

The chain-stopping reactions are taken to be association of radicals by a 3-body process occurring chiefly at the walls

$$2CH_3O + M \longrightarrow X$$
$$2C_3H_7 + M \longrightarrow Y$$
$$CH_3O + C_3H_7 + M \longrightarrow Z$$

The complete mechanism would therefore be

$$(1)\quad 2C_3H_8 \underset{\longleftarrow}{\xrightarrow{k_1,\ k_1'}} C_3H_8^* + C_3H_8$$

$$(2)\quad O_2 + C_3H_8^* \xrightarrow{k_2} C_2H_5O + CH_3O$$

$$(3)\quad CH_3O + C_3H_8 \xrightarrow{k_3} CH_3OH + C_3H_7$$

$$(4)\quad C_3H_7 + O_2 \xrightarrow{k_4} C_2H_4O + CH_3O$$

$$(5)\quad C_2H_4O + O_2 \xrightarrow{k_5} HCHO + CO + H_2O$$

$$(6)\quad 2CH_3O + M \xrightarrow{k_6} X$$

$$(7)\quad 2C_3H_7 + M \xrightarrow{k_7} Y$$

$$(8)\quad CH_3O + C_3H_7 + M \xrightarrow{k_8} Z$$

Reactions (1) and (2) together are supposed to yield CH_3O at a rate proportional to $[C_3H_8]^2$. At the steady state (point of inflection of the rate curves) we have

$$d[CH_3O]/dt = k_1[C_3H_8]^2 + k_4[C_3H_7][O_2] - k_3[CH_3O][C_3H_8] - k_6[CH_3O]^2M - k_8[CH_3O][C_3H_7]M = 0$$

$$d[C_3H_7]/dt = k_3[CH_3O][C_3H_8] - k_4[C_3H_7][O_2] - k_7[C_3H_7]^2M - k_8[CH_3O][C_3H_7]M = 0$$

Solution for the steady-state concentration of $[CH_3O]$ leads to an unwieldy expression. If we

[11] Pope, Dykstra and Edgar, THIS JOURNAL, **51**, 1875 (1929).

[12] This analysis of the starting and stopping of chains is recognized to be incomplete. In particular, the occurrence of long induction periods, the negative temperature coefficient, and the rôle played by aldehyde oxidation require further consideration.

assume chains are ended only by reaction (6), we find

$$[CH_3O] = \sqrt{k_1/k_6M}\,[C_3H_8]$$

If only reaction (7) is effective

$$[CH_3O] = \frac{1}{k_3}\left(k_1[C_3H_8] + k_4\sqrt{\frac{k_1}{k_7M}}\,[O_2]\right)$$

If only reaction (8) is effective

$$[CH_3O] \cong (k_1/2k_3)\,[C_3H_8]$$

or

$$[CH_3O] \cong \frac{k_1}{4k_3}\,[C_3H_8] \pm \sqrt{\frac{k_1k_4[C_3H_8][O_2]}{2k_3k_8M}}$$

depending upon the approximation which is made. The rate of disappearance of propane will be determined principally by the rate of reaction (3) if chains are long.

$$-d[C_3H_8]/dt \cong k_3[C_3H_8][CH_3O]$$

Substituting the above values of [CH_3O] shows that the rate will depend on a power of [C_3H_8] between 1 and 2, and will be relatively independent of oxygen concentration no matter which reaction is effective in terminating chains.

Mechanisms similar to the above may be written for methane and ethane in terms of hydroxy- instead of methoxyl radicals, yielding water in place of methanol. Such mechanisms are to be considered as an alternative to the Semenoff–Norrish mechanism.

Summary

1. Investigation of the slowoxidation of propane at lower temperatures and oxygen concentrations than heretofore employed indicates that methanol, formaldehyde, carbon monoxide and water are the primary products.

2. Results are interpreted in terms of Rice's radical-chain theory, on the assumption that methoxyl (CH_3O) and propyl (C_3H_7) are the chain carriers.

3. It is pointed out that similar mechanisms involving hydroxyl in place of methoxyl, and producing water in place of methanol, may apply to the oxidation of methane and ethane.

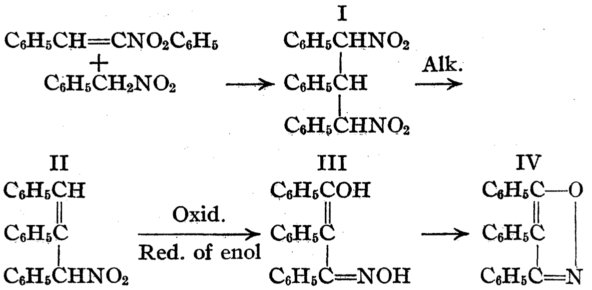
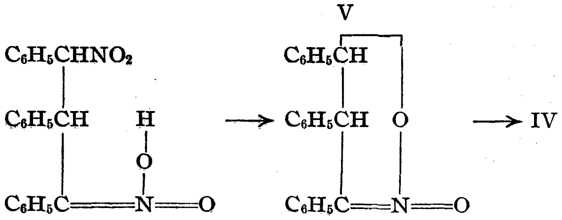
Alcoholic Ammonia as a Reagent in the Nitrostilbene Series

BY DAVID E. WORRALL

Heim[1] assumed the following transformations to account for the presence of triphenylisoxazole as a by-product in the Knoevenagel reaction



He succeeded in isolating the dinitro compound I, likewise an unsaturated nitro compound isomeric with II, but not the monoxime III. Later Kohler and Barrett[2] proved that triphenylisoxazoline oxide (V) is an intermediate between I and IV, using sodium methylate. Consequently they postulate this sequence of events.



It has now been found possible, using a milder reagent, to isolate III and while this does not necessarily mean that the oxime is the sole or even principal precursor of IV, it does fit in with the scheme of Heim.

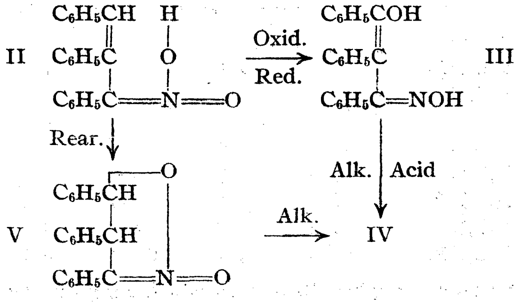
Ammonia in the absence of water does not react by addition or otherwise with nitrostilbene. A trace of water is sufficient to induce hydrolysis, the starting point of a chain that continues until sufficient phenylnitromethane is liberated to react with unchanged nitrostilbene thereby forming I. It is not improbable that this substance loses nitrous acid so as to form II, which for the most part rearranges into the isoxazoline oxide (V).

---

[1] Heim, *Ber.*, **44**, 2021 (1911).

[2] Kohler and Barrett, THIS JOURNAL, **46**, 2106 (1924).

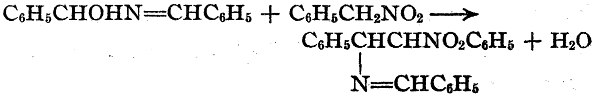
A portion, however, by an internal oxidation reaction changes into III which can be isolated.



Both compounds are rapidly changed into triphenylisoxazole by alkali. The oxime undergoes a similar transformation with acids.

The dinitro compound (I) is also formed from nitrostilbene and phenylnitromethane or even from the latter substance and benzaldehyde in the presence of alcoholic ammonia. Since derivatives of both may be used, a flexible method is available for the synthesis of substituted isoxazoline oxides and isoxazoles that are relatively uncommon. Contrary to the experience of others[3] (using sodium methylate) no difficulty was found in obtaining pure substances with satisfactory yields.

Still another reaction takes place if absolute alcohol is used in which the ammonia is directly concerned. The product probably results from the reaction of phenylnitromethane with a condensation product of ammonia and benzaldehyde. Similar to hydrobenzamide, it is easily changed back into its components by acid or alkali.



$$C_6H_5CHOHN{=}CHC_6H_5 + C_6H_5CH_2NO_2 \longrightarrow C_6H_5CH\underset{\displaystyle N{=}CHC_6H_5}{\underset{|}{C}}HNO_2C_6H_5 + H_2O$$

Experimental

Triphenylisoxazoline Oxide.—A suspension of 10 g. of nitrostilbene in 50 cc. of alcohol saturated with ammonia gas was shaken occasionally. The precipitate disappeared in a relatively short time with slight heat evolution followed by the gradual deposition of the new substance. The product, approximately 6 g. in amount, separated from alcohol in needles melting at 161–162°. An analysis revealed the isoxazoline oxide of Kohler and Barrett.[2]

Dibenzoylphenylmethane Monoxime.—The filtrate after steam distillation to remove benzaldehyde and other volatile impurities hardened to a solid; yield, 0.9 g. It was repeatedly crystallized from alcohol, separating finally as small needles melting at 152–153°.

Anal. Calcd. for $C_{21}H_{17}O_2N$: C, 80.0; H, 5.4. Found: C, 80.4; H, 5.4.

It is much more soluble in alcohol than V and is partially dissolved by sodium hydroxide solution from which it is precipitated unchanged by dilute acid. The most conspicuous property of the substance is the almost instant change into triphenylisoxazole when mixed with hot hydrochloric acid, in marked contrast to the isomeric isoxazoline oxide. A similar change takes place with hot alkali and more slowly when it is heated above the melting point. This substance has been obtained by Marshall from the corresponding diketone by the action of hydroxylamine.[4]

In another experiment 5 g. of nitrostilbene plus the equivalent amount of phenylnitromethane was mixed with alcoholic ammonia. The mixture became decidedly hot and dark red in color, while bubbles of gas doubtless from decomposition of ammonium nitrite escaped. The color faded on standing. Crystal formation took place in a few minutes; yield, 4.6 g. of isoxazoline oxide, and the equivalent of 2.5 g. of oxime estimated as isoxazole. On mixing 5 g. of phenylnitromethane with one equivalent of benzaldehyde and alcoholic ammonia crystal formation started in a few hours; yield, 3.3 g. and 0.8 g., respectively, of oxide and oxime.

Preparation and Properties of Isoxazoline Oxides.—To the nitrostilbene either alone or mixed with phenyl or *p*-bromophenylnitromethane was added a small volume of alcohol saturated with ammonia. The reaction was allowed to proceed spontaneously and the mixture kept overnight, although apparently complete in one to three hours. The product was crystallized from a moderately large volume of alcohol, separating as needles with one exception. The compound obtained from bromophenylnitromethane and anisalphenylnitromethane formed plates. All were indifferent toward hot acid or ammonia but formed yellow solutions with alcoholic potassium hydroxide that changed after heating for a few minutes into the corresponding isoxazoles. No reaction was observed between carefully dried ammonia and nitrostilbene dissolved in dry ether after forty-eight hours. Nitrotriphenylethylene was without action on alcoholic ammonia. Only the normal isoxazoline oxide was obtained on using malonic ester or nitromethane with nitrostilbene in the presence of the reagent.

Preparation of Isoxazoles.—These substances were prepared by the action of alcoholic potassium hydroxide on the isoxazoline oxide or from the crude oxime by steam distillation in the presence of hydrochloric acid. They were purified from alcohol, in which they are difficultly soluble or from acetone.

α-Nitro-α-phenyl-β-phenyl-β-benzalaminoethane.—It was observed that preparations of V melted low (about 120°) if absolute alcohol was used although the total amount of product remained about the same. This was true either with nitrostilbene or with benzaldehyde, phenylnitromethane and alcoholic ammonia. Boiling with hydrochloric acid restored the correct melting point but destroyed approximately 60% of the mixture. It was separated by hand and recrystallized. The new substance was eventually obtained in clusters of narrow pointed plates or scales melting at 137–138°.

Anal. Calcd. for $C_{21}H_{18}O_2N_2$: C, 76.4; H, 5.5; N, 8.5. Found: C, 76.1; H, 5.4; N, 8.8.

It is rapidly hydrolyzed by hot dilute hydrochloric acid

[a] Since the corresponding isoxazoline oxide was not isolated, this substance was obtained from the oxime portion; yield about 0.2 g. from 10 g. of nitrostilbene derivative.

into ammonia, benzaldehyde and phenylnitromethane. A similar change takes place with alkali except that part of the phenylnitromethane undergoes further change into triphenylisoxazole.

α-Nitro-α-phenyl-β-*o*-chlorophenyl-β-*o*-chlorobenzalaminoethane is obtained by the action of alcoholic ammonia on 5 g. of *o*-chlorobenzal phenylnitromethane even using ordinary alcohol; yield 2.1 g. Considerable hydrolysis of the nitrostilbene took place but no isoxazoline oxide was observed. It separated from alcohol in prisms melting at 144–145°.

Anal. Calcd. for $C_{21}H_{16}O_2N_2Cl_2$: C, 63.2; H, 4.0; Cl, 17.8. Found: C, 63.1; H, 3.9; Cl, 18.1.

Summary

Nitrostilbenes or their components either alone or in the presence of phenylnitromethane are converted by alcoholic ammonia into isoxazoline oxides, derivatives of the monoxime of dibenzoyl phenylmethane, and, under certain conditions, into benzalammonia condensation products. The rôle of the reagent in these transformations has been discussed.

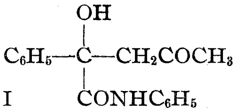
Condensations of Benzoylformanilide with Acetone, Ethyl Phenylacetate and Diethyl Malonate

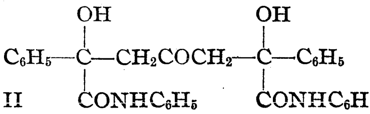
BY JOHN V. SCUDI AND H. G. LINDWALL

Acetone condenses with benzoylformanilide in the presence of diethylamine to yield 2-phenyl-2-hydroxy-4-pentanoneanilide (I), which is analogous to the product obtained with acetophenone.[1] The aldol nature of I is shown by its dissociation into the original reactants when heated with aqueous alkali; it forms a phenylhydrazone and, further, it condenses with benzoylformanilide to yield II.



$$C_6H_5\text{—}\overset{\displaystyle OH}{\underset{\displaystyle CONHC_6H_5}{C}}\text{—}CH_2COCH_3$$

I

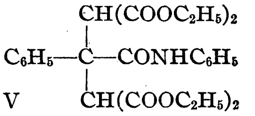


$$C_6H_5\text{—}\overset{\displaystyle OH}{\underset{\displaystyle CONHC_6H_5}{C}}\text{—}CH_2COCH_2\text{—}\overset{\displaystyle OH}{\underset{\displaystyle CONHC_6H_5}{C}}\text{—}C_6H_5$$

II

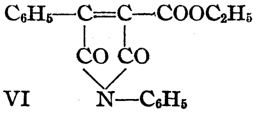
The condensation of benzoylformanilide with ethyl phenylacetate, catalyzed by diethylamine, produces α,β-diphenylmaleinanil (III); this method, while giving a good yield, is too slow to appear practical. Reduction of III gives IV, which was found to be identical with the anil of α,β-diphenylsuccinic acid, prepared by the method of Lapworth and McRae.[2]

Diethyl malonate and benzoylformanilide condense in the ratio of two moles to one, yielding V. Compound V upon being heated *in vacuo* is decomposed into α-carbethoxy-β-phenylmaleinanil (VI) which remains as a residue after diethyl malonate and a low-boiling liquid (probably ethyl alcohol) have distilled over. The corresponding α-carbethoxy-β-phenylsuccinanil (VII) results from the reduction of VI. Hydrolysis of this ester (VII) by hydrochloric acid effects also decarboxylation to yield the known phenylsuccinanil.

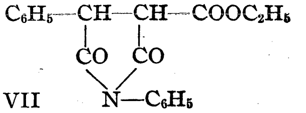


$$C_6H_5\text{—}\overset{\displaystyle CH(COOC_2H_5)_2}{\underset{\displaystyle CH(COOC_2H_5)_2}{C}}\text{—}CONHC_6H_5$$

V



VI



VII

The condensation reactions of benzoylformanilide find a parallel in the case of isatin which also condenses with acetone[3] and diethyl malonate.[4]

Experimental Part

2-Phenyl-2-hydroxy-4-pentanoneanilide (I).—A mixture of 5 g. of benzoylformanilide in 10 cc. of acetone and 5 drops of diethylamine was allowed to stand at room temperature for six hours. The white product was crystallized from toluene as hairy needles, m. p. 137–138°; slightly soluble in ether, more in benzene; yield, 80%.

Anal. Calcd. for $C_{17}H_{17}O_3N$: C, 72.08; H, 6.01. Found: C, 72.17; H, 5.90.

Phenylhydrazone of I.—A mixture of 12.5 g. of phenylhydrazine, 12.5 cc. of glacial acetic acid, 25 cc. of water and 5 g. of I, was allowed to stand for one hour at room temperature. The solid product was recrystallized from an alcohol–ethyl acetate solution (4:1 by volume); white needles, m. p. 174–175°, with decomp.; soluble in alcohol and toluene; yield, 60%.

Anal. Calcd. for $C_{23}H_{23}O_2N_3$: N, 11.26. Found: N, 11.43, 11.45.

2,6-Dihydroxy-2,6-diphenyl-4-heptanonedianilide-1,7 (II).—Compound I (2 g.) and 2.5 g. of benzoylformanilide, dissolved in a minimum amount of alcohol with 5 drops of diethylamine, were allowed to stand at room temperature for two weeks. The yield of product was 25%, but is improved by longer time; white needles after crystallization from alcohol, m. p. 171–172°.

Anal. Calcd. for $C_{31}H_{28}O_5N_2$: C, 73.23; H, 5.51. Found: C, 73.29; H, 5.57.

α-β-Diphenylmaleinanil (III).—A mixture of 1 g. of benzoylformanilide, 1 g. of ethyl phenylacetate and 3 drops of diethylamine produced a 90% yield of III after three months of standing at room temperature; yellow needles after recrystallization from alcohol, m. p. 178–179°.

Anal. Calcd. for $C_{22}H_{15}O_2N$: C, 81.23; H, 4.61. Found: C, 81.23; H, 4.73.

α-β-Diphenylsuccinanil (IV).—To a hot solution of 1 g. of III in 50 cc. of alcohol was added 1 g. of sodium hyposulfite in 30 cc. of boiling water. The yellow color disappeared at once; addition of cold water caused a white precipitation; white needles from ethyl alcohol or from glacial acetic acid; m. p. 234–235°; yield, 80%.

Anal. Calcd. for $C_{22}H_{17}O_2N$: C, 80.73; H, 5.20; N, 4.28. Found: C, 80.96; H, 5.46; N, 4.29, 4.45.

2-Phenyl-2-formanilido-1,1,3,3-tetracarbethoxypropane (V).—Five grams of benzoylformanilide, 5 g. of diethyl malonate and 5 drops of diethylamine in 10 cc. of ethyl alcohol produced a solid mass of V in three hours at

room temperature; crude yield, 95%. After washing with ether, the product was crystallized from 60% acetone; colorless crystals, m. p. 107–108°, soluble in alcohol.

Anal. Calcd. for $C_{28}H_{33}O_9N$: C, 63.74; H, 6.31. Found: C, 64.08; H, 6.50.

α-Carbethoxy-β-phenylmaleinanil (VI).—A sample of V (3 g.) was subjected to vacuum distillation; a water-white distillate was obtained, distilling at 101–102° at 25 mm. Fractional distillation of this liquid showed it to consist largely of diethyl malonate, verified by conversion to malonamide. A low-boiling fraction was evidently ethyl alcohol. The residue from the vacuum distillation was dissolved in 20 cc. of diethyl ether, and diluted with 100 cc. of petroleum ether. Hard yellow crystals separated after two hours of cooling; it recrystallized from 80% alcohol as yellow rhombic crystals, m. p. 111°, soluble in alcohol, ether, benzene; yield, 75%.

Anal. Calcd. for $C_{19}H_{15}O_4N$: C, 71.03; H, 4.67; N, 4.36. Found: C, 71.09; H, 4.79; N, 4.31, 4.56.

α-Carbethoxy-β-phenylsuccinanil (VII).—One gram of VI was dissolved in 15 cc. of boiling alcohol and to this was added 1 g. of sodium hyposulfite in 5 cc. of hot water. The mixture was heated for five minutes until it became colorless. Upon addition of 75 cc. of water and cooling, a white oil separated, which gradually solidified to white needles from 10% alcohol, m. p. 104–105°, soluble in alcohol, ether, acetone, ethyl acetate, chloroform, benzene; yield, 85%.

Anal. Calcd. for $C_{19}H_{17}O_4N$: C, 70.59; H, 5.26; N, 4.33. Found: C, 70.60; H, 5.28; N, 4.26.

Phenylsuccinanil from VII.—A solution of 1 g. of VII in 15 cc. of alcohol and 15 cc. of concd. hydrochloric acid was refluxed for one hour and then evaporated to dryness on a steam-bath. The residue was extracted with three 10-cc. portions of boiling water. Concentration of the extract to one-third its volume and cooling gave white needles, m. p. 137–138°; yield, 40%. There was no lowering of melting point when mixed with a known sample.

Summary

Benzoylformanilide condenses in the presence of diethylamine with one mole of acetone and two moles of diethyl malonate to give products analogous to those of isatin. The diethyl malonate product is decomposed by heat, losing a molecule of diethyl malonate and forming a maleinanil derivative through ring closure.

Ethyl phenylacetate reacts slowly with benzoylformanilide under similar conditions to yield symmetrical diphenylmaleinanil.

New York, N. Y. Received August 31, 1935

[Contribution from the Chemical Research Laboratories of the R. & H. Chemicals Department of E. I. du Pont de Nemours & Co., Inc.]

The Preparation of High Molecular Weight Acyloins

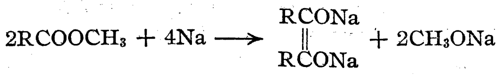
By V. L. Hansley

The simultaneous reaction and condensation of aliphatic esters by means of sodium to give α,β-keto alcohols, the so-called acyloins, has been limited in previous investigations to esters of acids of six or less carbon atoms. Previous work along this line has been summarized by Corson and his co-workers.[1]

By the use of different solvents and by making radical changes in reaction conditions, we have been able to extend this series of acyloins from 12 to 36 carbon atoms and to shorten the reaction time considerably.

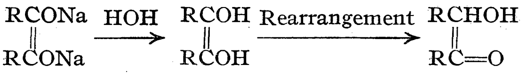
The reaction between sodium and the esters takes place essentially quantitatively according to the following equation, and neither reactant need be employed in excess.

(a)



$$2RCOOCH_3 + 4Na \longrightarrow \begin{array}{c} RCONa \\ \| \\ RCONa \end{array} + 2CH_3ONa$$

(b)



$$\begin{array}{c} RCONa \\ \| \\ RCONa \end{array} \xrightarrow{HOH} \begin{array}{c} RCOH \\ \| \\ RCOH \end{array} \xrightarrow{\text{Rearrangement}} \begin{array}{c} RCHOH \\ | \\ RC{=}O \end{array}$$

While previously recommended methods for the preparation of butyroin and other low molecular weight acyloins[2] do not suggest any difficulty in the preparation of the higher molecular weight acyloins, the work of Corson and his co-workers[1] indicates that the described methods of preparation fail when applied to these higher esters.

The failure of these investigators to obtain acyloins from acids of greater than six carbon atoms was apparently due to the insolubility of the reaction products at the temperatures employed in the particular reaction media used. Previous investigators carried out their reactions in ether or benzene at room temperature or lower, allowing even days for the reaction to take place. A few previous attempts were also made to carry

---

[1] Corson, Benson and Goodwin, This Journal, **52**, 3988 (1930); *cf.* Snell and McElvain, *ibid.*, **53**, 750 (1931).

[2] Snell and McElvain, "Organic Syntheses," J. Wiley & Sons, Inc., 440 Fourth Ave., New York City, 1933, Vol. XIII, pp. 24–26.

out the preparation of acyloins in boiling toluene[1] but the reaction products could not be worked up.

By going to reaction conditions where the sodium was kept in a molten and finely dispersed state and the reaction products kept "in solution," we have been able to obtain 80–95% yields of acyloins from aliphatic esters of 8 to 18 carbon atoms. Practically quantitative reaction was obtained between ester and sodium without employing either reactant in excess. Besides carrying out the reaction above the melting point of sodium, the rate and mode of addition of ester, molecular weight of ester and concentration and solubility of reaction products all influenced the fluidity of the reaction mixture and hence the yield. Xylene and toluene were equally good solvent media, provided impurities were absent which would react with sodium. Likewise, the esters had to be free of organic acid or hydroxyl compounds. Both of these tended to cause the reaction mixture to gel, after which the useful reaction between sodium and ester practically ceased. In such cases a large part of the sodium remained unreacted.

The amount of acyloin that could be prepared in a given amount of solvent was greater with methyl laurate than any other ester tried. Esters of higher molecular weights formed more insoluble sodium derivatives while lower molecular weight esters inherently gave a greater amount of sodium methylate which could only be held in "pseudo solution" by use of more solvent. This is probably one of the reasons why previous investigators failed to obtain satisfactory reaction in toluene. They were using acid esters of too low a molecular weight in too high concentration when employing toluene as the solvent. For similar reasons they encountered difficulty when attempting the reaction of high molecular weight esters with sodium in ether at room temperature. In the preparation of lower molecular weight acyloins, *e. g.*, from caproic or caprylic acids, the use of the *n*-butyl or secondary butyl ester permitted the preparation of a considerably larger quantity of acyloin per unit volume of solvent than was possible when the methyl esters were employed.

The reaction products obtained from the straight chain aliphatic acid esters were characterized as the corresponding α,β-keto alcohols by the analysis of their acetates and osazones. The melting points of all the acyloins prepared fall on a smooth curve which flattens out considerably at about 80° when the length of the carbon chain reaches 32–36 carbon atoms. The acyloins are all waxy, white, easily crystallizable compounds, the solubilities of which vary widely from capryloin to stearoin. The stability of the acyloins was found to increase with the molecular weight. A tendency to polymerize was noted in the case of butyroin and to some extent with capronoin. Little, if any, polymerization resulted during the isolation of acyloins from acids of eight or more carbon atoms.

Experimental Part

Preparation of the Methyl Esters.—The mixture of methyl esters obtained by the esterification of commercial coconut oil fatty acids in the usual manner was subjected to careful vacuum fractionation at 15 mm. in 5-liter batches. Pure cuts of 0.2–0.3° range were made taking the boiling points of Haller and Youssoufian[3] for the esters of even carbon atom acids from caproic to myristic esters. Methyl butyrate was obtained from the Eastman Kodak Co., their better grade being usable without further purification. Stearate and palmitate esters were obtained from a catalytically hydrogenated palm oil which was converted to the methyl esters. Methyl palmitate and stearate were fractionated from this ester mixture at 15 mm. The boiling points noted, 190.5° for the palmitate and 212.3° for the stearate, are somewhat lower than those recorded in the literature, 195–196 and 215°, respectively.[3] The nonylic acid was obtained by the ozonolysis of oleic acid and esterified in the usual manner.

Preparation of the Acyloins.—One hundred and fifteen grams of sodium (5 atoms) together with 3 liters of c. p. xylene were charged into a 5-liter 3-necked flask immersed in an oil-bath at 105°. The flask was fitted with a rather high-speed stirrer (2000–2500 r. p. m.). The air over the xylene was replaced by nitrogen or other inert gas. When the temperature of the xylene reached 105° and the sodium melted, the stirrer was started and the sodium dispersed in a finely divided state in the xylene. Methyl laurate, 535 g. or the equivalent quantity of another ester (2.5 moles) was then started into the reaction flask from a separatory funnel. The addition was at such a rate that the temperature due to heat of reaction did not rise above 110°. This required about one hour. Stirring was continued for one-half hour after the ester had been added.

Small particles of unchanged sodium were then decomposed by the addition of an excess of methanol (one to two moles). Then, after cooling to about 80° water, 0.5 to 1.0 liter, was cautiously added until the alkali was taken into an aqueous layer which was then removed by decantation. After one or two more washings with water, the remaining alkali was neutralized with a slight excess of mineral acid and the excess acid finally neutralized with sodium bicarbonate.

The xylene was removed by steam distillation from the acyloin and the resulting oily layer poured into a suitable vessel to solidify. The impure product contained 80–90% acyloin. The acyloins from methyl caproate, laurate and

---

(3) Haller and Youssoufian, *Compt. rend.*, **143**, 805 (1905).

myristate were purified by crystallization from 95% alcohol but acyloins corresponding to methyl palmitate and stearate were found to crystallize better from trichloroethylene or acetone.

Other acyloins prepared by this procedure are given in Table I.

Hydrogenation of the Acyloins to Substituted Ethylene Glycols.—All of the acyloins upon catalytic hydrogenation with a platinum catalyst at room temperature or nickel at 125–150° were converted into the corresponding symmetrically substituted dialkyl ethylene glycols. Due to the double asymmetry in the glycol molecule two forms should occur, meso and racemic. While α- and β- (low and high melting) forms of the glycols from butyroin and capronoin have been described[5] and a liquid isomeric mixture of glycols described as a by-product in the sodium reduction of methyl caprylate,[6] there is still some doubt as to whether the low melting glycols were actually obtained. We were able to obtain only the high melting form pure in each case. The four glycols prepared are shown in Table II together with the previously described glycols from butyrate and caproate esters.

TABLE II

SYMMETRICALLY SUBSTITUTED ETHYLENE GLYCOLS

Ethylene glycol RCHOHCHOHR, R =	Parent ester	M. p., °C.
$C_{17}H_{35}$	Stearate	123–124
$C_{13}H_{27}$	Myristate	124
$C_{11}H_{23}$	Laurate	125–126
C_7H_{15}	Caprylate	129–130
C_5H_{11}[5]	Caproate	135–136
C_3H_7[5]	Butyrate	123–124

Oxidation of Acyloins to the Diketones.—A 1.0202-g. quantity of lauroin was treated in dry chloroform solution with a 100% excess of Wijs solution[7] and allowed to stand overnight: 0.716 g. of iodine was consumed; calcd. for the oxidation of this amount of lauroin to the diketone, 0.695 g. of iodine. The diketone crystallized well from methanol, giving the characteristic yellow diketone which melted sharply at 71–71.5°.

The properties and further reactions of these condensation products will be taken up in a subsequent paper.

Summary

The preparation of the α,β-keto alcohols or acyloins has been carried up to and including stearoin. All acyloins from esters of acids above caproic are new. By the catalytic hydrogenation of these keto alcohols the symmetrically substituted dialkyl ethylene glycol series has been extended from 12 to 36 carbon atoms in the molecule.

The acetates and osazones of the acyloins and the diacetates of the corresponding glycols were also prepared.

One of the acyloins, lauroin, was oxidized to the corresponding *sym*-α,β-diketone.

Detosylation of 4- and 5-Tosyl[1] Monoacetone *l*-Methylrhamnosides

BY P. A. LEVENE AND JACK COMPTON

Since Ferns and Lapworth[2] have pointed out the fact that the group R–SO$_3$–O– functions as a halide atom, it is evident that the replacement of a tosyl group on an asymmetric carbon atom may be accompanied by a Walden inversion. Indeed in the sugar series such occurrences were reported first by Mathers and Robertson[3] and later by Oldham and Rutherford[4] and by Ohle and Just.[5] In all the described cases, however, opportunity existed for an ethylene oxidic ring formation as an intermediate step in the rearrangement. The question naturally arose as to whether a Walden inversion occurs in cases not permitting the oxidic ring formation. Work in this direction was initiated in this Laboratory several years ago and some of the negative results have been reported in a preliminary note.[6]

On the other hand, Muskat[7] thought he had obtained evidence in favor of the occurrence of Walden inversion on alkaline hydrolysis of 5-tosyl monoacetone *l*-methylrhamnoside. Depending upon conditions of hydrolysis, Muskat obtained either an unsaturated derivative distilling at 80° (3 mm.) or a saturated substance distilling at 100° (1 mm.). The latter product on hydrolysis was supposed to form the simple sugar, *d*-gulomethylose. The properties of the substance, its strong reducing power in the cold, mutarotation of the amorphous product and the sign of the equilibrium rotation did not agree with the found properties of *d*-gulomethylose.[8]

However, the possibility was not excluded that the higher boiling material obtained by Muskat was a mixture of several substances containing gulomethylose among the other products. The problem, therefore, required a rigorous reinvestigation.

The Nature of the Higher Boiling Material.—As a result of such an investigation, the conclusion was reached that the higher boiling material obtained by Muskat was slightly impure monoacetone *l*-methylrhamnopyranoside.

1. The tosyl derivative of this material obtained by Muskat with a melting point of 60°, $[\alpha]_D$ +22° (methanol), and the same material obtained by us, on recrystallization gave a product melting at 61–62°, $[\alpha]^{24}_D$ +22° (methanol), and the mixed melting point with 4-tosyl monoacetone *l*-methylrhamnopyranoside showed no depression.

2. The same tosyl derivative on reductive detosylation by the method of Freudenberg and Brauns[9] gave a substance with the properties of monoacetone *l*-methylrhamnopyranoside.

3. On hydrolysis with dilute acid the higher boiling fraction gave a sugar whose *p*-bromophenylhydrazone had the properties of the corresponding hydrazone of rhamnose.

The Origin of the Higher Boiling Material.—The higher boiling material was not a product of a ring shift in course of the reaction but had its origin in the contamination of the monoacetone *l*-methylrhamnofuranoside with the corresponding derivative of the pyranoside. The evidence in favor of this conclusion is as follows.

1. The tosyl derivative obtained from the monoacetone *l*-methylrhamnoside prepared in the conventional way and having a melting point of 79–80° could be separated into several fractions as shown in Table I.

2. It was shown by analysis of the various hydrolytic fractions that only the substance melting at 82–83° was the pure furanoside, and that the remaining fractions were mixtures of the furanoside with pyranoside. More precisely, the results were as follows.

(*a*) The fraction melting at 82–83° on alkaline hydrolysis yielded practically exclusively the unsaturated product (most probably of a mannal nature) together with a minimal residue of the unchanged monoacetone *l*-methylrhamnofuranoside.

The same product on reductive hydrolysis yielded exclusively monoacetone *l*-methylrhamnofuranoside.

(*b*) The other fractions gave smaller yields of low boiling material and increasing quantities of

the higher boiling fractions. From the latter fraction a tosyl derivative could be obtained melting at 61°, showing no depression of melting point when mixed with 4-tosyl monoacetone *l*-methylrhamnopyranoside. On reductive hydrolysis this tosyl derivative yielded a product identical with monoacetone *l*-methylrhamnopyranoside.

(*c*) Pure 4-tosyl monoacetone *l*-methylrhamnopyranoside, m. p. 61–62°, on alkaline hydrolysis, did not yield the unsaturated derivative, but gave exclusively the higher-boiling material which, on retosylation, yielded a tosyl derivative with the properties of the original material.

Thus, it is evident that monotosyl derivatives of rhamnose, in which the opportunity for oxide formation is excluded, behave similarly to the tosyl derivatives of other sugars, namely, they undergo alkaline detosylation without Walden inversion.[10]

It may be added that the two tosyl derivatives with melting point of 82–83° and of 61–62° were shown definitely to have the furanoside and the pyranoside ring structures, respectively.

From the experience gained during this work it is found that absolutely pure monoacetone *l*-methylrhamnofuranoside is obtained most advantageously by reductive detosylation of the tosyl derivative melting at 82–83°.

Experimental

A. Preparations

Monoacetone Methylrhamnofuranoside.—Two methods were employed in the preparation of this material, each resulting in the simultaneous formation of monoacetone methylrhamnopyranoside as an impurity.

(a) Fifty grams of anhydrous rhamnose[11] was suspended in 1000 cc. of acetone containing 5% of absolute methyl alcohol. Anhydrous copper sulfate (100 g.) was then added and sufficient concentrated sulfuric acid to make the solution 0.2%. The mixture was shaken at room temperature for twenty hours, after which it was worked up as previously described; total yield of monoacetone methylrhamnosides, 45.1 g., having the same specific rotations and refractive indices as previously recorded.[11]

(b) Fifty grams of monoacetone rhamnose[12] was dissolved in 1000 cc. of absolute methyl alcohol containing 1% of anhydrous hydrogen chloride. The mixture was allowed to stand at room temperature overnight, after which it was allowed to reflux on the steam-bath for thirty minutes. The solution was made neutral with excess silver carbonate, filtered and concentrated under diminished pressure to a thin sirup which distilled completely under diminished pressure; yield, 40 g.; b. p. 99–100° (0.8 mm.); $n^{25}\mathrm{D}$ 1.4485; $[\alpha]^{25}\mathrm{D}$ −63.0° (*c*, 3.379, methyl alcohol); $[\alpha]^{25}\mathrm{D}$ −45.5° (*c*, 2.504, water).

Anal. Calcd. for $C_{10}H_{18}O_5$: OCH_3, 14.22. Found: OCH_3, 14.22.

There remained after distillation of the monoacetone methylrhamnosides 8 g. of unchanged monoacetone rhamnose, b. p. 130–136° (0.8 mm.), and a small amount (0.5 g.) of methylrhamnopyranoside, b. p. 148–154° (0.5 mm.).

5-Tosyl[1] Monoacetone Methylrhamnofuranoside.—This compound was prepared according to the procedure of Levene and Muskat,[11] with slight modifications.

Monoacetone methylrhamnoside (20 g.) prepared as described in method (a) or (b) above, was dissolved in 30 cc. of dry pyridine and 32 g. of tosyl chloride added. Shaking was maintained until solution was complete, after which the mixture was allowed to stand overnight at room temperature. The mixture was then thoroughly cooled and 2 cc. of water added. After standing for thirty minutes the partially crystallized mass was poured with vigorous stirring into 250 cc. of ice-cold saturated sodium bicarbonate solution. The sirupy product first separating soon solidified and was removed by filtration, washed thoroughly with water and dried; yield 22 g. The product recrystallized from methyl alcohol had a melting point of 80–81°. After a second and third recrystallization, a constant melting point of 82–83° was obtained; $[\alpha]^{26}\mathrm{D}$ −13.6° (*c*, 3.168, methyl alcohol). Continued recrystallization of the mixed crystals obtained from the mother liquors gave fractions having the properties shown in Table I.

TABLE I

FRACTIONATION OF TOSYL DERIVATIVES OF MONOACETONE METHYLRHAMNOSIDE

Fraction	M. p., °C.	$[\alpha]^{26}\mathrm{D}$ in methanol
I	82–83 (max.)	−13.6° (*c*, 3.168)
II	74–75	− 5.6° (*c*, 3.046)
III	68–69	− 1.7° (*c*, 2.964)
IV	64–65	+ 5.6° (*c*, 3.030)
V	57–58	+12.1° (*c*, 2.708)

Monoacetone Methylrhamnopyranoside.—Acetonation of methylrhamnopyranoside according to the procedure of Levene and Muskat[13] led to the formation of pure monoacetone methylrhamnopyranoside, b. p. 104–105° (0.8 mm.); $n^{24}\mathrm{D}$ 1.4545; $[\alpha]^{24}\mathrm{D}$ −11.9° (*c*, 3.366, methanol).

4-Tosyl Monoacetone Methylrhamnopyranoside.—Twenty grams of monoacetone methylrhamnopyranoside was tosylated and the product isolated in the manner described for 5-tosyl monoacetone methylrhamnofuranoside; yield 25.5 g.; melting point after one recrystallization from methyl alcohol, 61–62°. Further recrystallizations from this solvent changed neither the melting point nor specific rotation; $[\alpha]^{24}\mathrm{D}$ +21.94° (*c*, 3.030 methanol).

Anal. Calcd. for $C_{17}H_{24}O_7S$: C, 54.80; H, 6.45; S, 8.60. Found: C, 54.98; H, 6.46; S, 8.69.

B. Alkaline Hydrolysis

1. Pure 5-Tosyl Monoacetone Methylrhamnofuranoside.—(Fraction I, Table I.) Forty grams of pure 5-tosyl

monoacetone methylrhamnofuranoside (m. p. 82–83°; $[\alpha]^{25}$D −13.5°) was dissolved in 1500 cc. of methyl alcohol and 120 g. (20 moles) of potassium hydroxide dissolved in 1300 cc. of water was added to the boiling solution. The reaction was 95% complete after refluxing on the steam-bath for sixty hours at 78° after which the solution was cooled and the excess of alkali exactly neutralized by means of 25% hydrochloric acid. Sufficient calcium chloride was then added to saturate the solution, after which it was exhaustively extracted with chloroform. The chloroform extract was allowed to stand over calcium chloride for twenty-four hours, filtered, and concentrated under diminished pressure. The resulting sirup distilled in two fractions: *first*, b. p. 56–60° (0.3 mm.), yield 16.0 g. n^{24}D 1.4491; *second*, b. p. 82–85° (0.3 mm.), yield 0.8 g., n^{4}D 1.4501.

Anal. First fraction. Calcd. for $C_{10}H_{16}O_4$: C, 59.97; H, 8.0; OCH_3, 15.49. Found: C, 59.64; H, 8.21; OCH_3, 15.21. *Second fraction.* Calcd. for $C_{10}H_{18}O_5$: C, 55.02; H, 8.30; OCH_3, 14.22. Found: C, 54.85; H, 8.38; OCH_3, 14.42.

A portion of the second fraction (0.6 g.) (b. p. 82–85° at 0.3 mm.), was dissolved in 1 cc. of dry pyridine and 0.8 g. of tosyl chloride added. After standing overnight at room temperature the solution was worked up as described for the tosylation of monoacetone methylrhamnofuranoside (yield 0.65 g.; m. p. 77–78°). After one recrystallization from methyl alcohol a constant melting point of 82–83° was obtained which was unchanged on admixture with an authentic specimen of 5-tosyl monoacetone methylrhamnofuranoside; specific rotation of this material $[\alpha]^{25}$D −13.05° (*c* 3.064, methanol).

The various conditions employed in attempts to obtain from pure 5-tosyl monoacetone methylrhamnofuranoside the product described by Muskat[7] are summarized in Table II.

2. Mixed 4- and 5-Tosyl Monoacetone Methylrhamnosides, m. p. 68°.—(Fraction III, Table I.) Four grams of mixed crystals of 4- and 5-tosyl monoacetone methylrhamnosides (m. p. 68°) was dissolved in 200 cc. of methyl alcohol and 12 g. of potassium hydroxide dissolved in 140 cc. of water added on the steam-bath. Refluxing was maintained for seventy-five hours, when the reaction was complete. After cooling, the hydrolysis products were isolated in the manner described above (1). Two fractions were obtained: first, b. p. 58–60° (0.3 mm.), yield 0.6 g.; second, b. p. 82–85° (0.3 mm.), yield 1.1 g.

Retosylation of the high boiling sirup (0.7 g.) with tosyl chloride (1.2 g.) in the presence of pyridine (1.0 cc.) gave a tosyl compound (0.8 g.) melting at 59–60°. After one recrystallization from methyl alcohol a constant melting point of 60–61° was obtained.; $[\alpha]^{25}$D +20.2° (*c*, 2.868, methanol). A mixed melting point of this material with pure 4-tosyl monoacetone methylrhamnofuranoside (m. p. 61–62°) showed no depression.

3. Impure 5-Tosyl Monoacetone Methylrhamnofuranoside, m. p. 79–80°.—Inasmuch as the 5-tosyl monoacetone methylrhamnofuranoside (m. p. 80°) previously reported[10] had a lower melting point than that employed in experiment 1, a sample of this compound (unfractionated) with m. p. 79–80° was used: 40 g. of 5-tosyl monoacetone methylrhamnoside (m. p. 79–80°) was dissolved in 1500 cc. of methyl alcohol and 120 g. of potassium hydroxide dissolved in 1300 cc. of water added on the steam-bath. The temperature (80°) was maintained for fifty hours when the reaction was about 95% complete. After cooling, the solution was worked up as described above; yield in three fractions: first, 17.1 g., second, 1.5 g., and third, 3.0 g. with b. p. 58–60° (0.3 mm.), 80–82° (0.3 mm.), and 83–85° (0.3 mm.), respectively.

The first fraction consisted of the unsaturated compound, whereas the second consisted of a mixture of monoacetone methylfuranoside and monoacetone methylpyranoside and the third was pure pyranoside, as shown on retosylation.

The second fraction (b. p. 80–82° at 0.3 mm.) was dissolved in 2.5 cc. of dry pyridine and 2.2 g. of tosyl chloride added. The mixture was allowed to stand overnight, after which it was worked up as described above; yield 1.4 g. Recrystallization from methyl alcohol gave a product (m. p. 58°) which after the fourth crystallization had risen to 67–68° $[\alpha]^{27}$D 0.00° (*c*, 2.976 methanol). From the mother liquors there was obtained a small amount of mixed 4- and 5-tosyl compounds, m. p. 55–58°.

The third fraction (b. p. 83–85° at 0.3 mm.) was divided into two parts. (a) A portion of this material (0.5 g.) was retosylated with tosyl chloride (0.8 g.) in the presence of dry pyridine (1.2 cc.) by allowing to stand overnight at room temperature; yield 0.6 g. After one recrystallization a substance of constant melting point of 60–61° was obtained which when mixed with pure 4-tosyl monoacetone methylrhamnofuranoside showed no depression; specific rotation of this material, $[\alpha]^{24}$D +22.1° (*c*, 3.032 methanol).

Anal. Calcd. for $C_{17}H_{24}O_7S$: C, 54.80; H, 6.45; S, 8.60. Found: C, 54.60; H, 6.30; S, 8.72.

TABLE II

EFFECT OF ALKALINE HYDROLYSIS MIXTURES ON PURE 5-TOSYL MONOACETONE METHYLRHAMNOFURANOSIDE (M. P. 82–83°)

Expt.	Wt., g.	KOH, moles	Methanol, cc.	Water, cc.	Temp., °C.	Time, hours	% Yield of unsatd. compd. of b. p. 60° (0.3 mm.)
I	4	20	200	40	74	50	95
II	2	20	100	0	100	30	90
III	4	20	160	180	80	48	95
IV	2	2	200	20	125	18	90
V	2	2	80	60	100	18	90
VI	2	20	100	40	37	2 mo.	No reaction
VII	2	20 ($NaOCH_3$)	100	30	70	50	98

(b) A second portion of this material (third fraction) (1.0 g.) was dissolved in 40 cc. of 1% sulfuric acid solution and allowed to reflux slowly for ninety minutes. The solution was rendered exactly neutral with barium hydroxide, treated with charcoal, and filtered. Upon concentrating under diminished pressure at 40° there was obtained 0.8 g. of sirupy material which on heating reduced Fehling's solution.

Four-tenths gram of this sirup was converted to the *p*-bromophenylhydrazone using one mole of *p*-bromophenylhydrazine in 5 cc. of absolute ethyl alcohol. There was thus obtained 0.35 g. of material, m. p. 168°, unchanged by further recrystallization from ethyl alcohol. A mixed melting point of this material with an authentic specimen of rhamnose *p*-bromophenylhydrazone (m. p. 167–168°) showed no depression. The mutarotation of the above *p*-bromophenylhydrazone in ethyl alcohol was in the same direction as that of rhamnose *p*-bromophenylhydrazone.

$$[\alpha]^{25}\mathrm{D}\ -11.29^\circ \xrightarrow{\text{24 hrs.}} +5.8^\circ \xrightarrow{\text{2 weeks}} -21.29^\circ \text{ the latter,}$$

$$[\alpha]^{23}\mathrm{D}\ -12.5^\circ \xrightarrow{\text{30 hrs.}} +10.2^\circ \xrightarrow{\text{2 weeks}} -23.1^\circ$$

No other *p*-bromophenylhydrazone was found in the reaction product, thus showing that rhamnose was the only sugar present in the third fraction.

Anal. Calcd. for $C_{12}H_{17}O_4N_2Br$: C, 43.24; H, 5.14; N, 8.40. Found: C, 43.35; H, 5.02; N, 8.61.

4. Pure 4-Tosyl Monoacetone Methylrhamnopyranoside.—Four grams of 4-tosyl monoacetone methylrhamnopyranoside (m. p. 61–62°) was dissolved in 150 cc. of methyl alcohol and 130 cc. of water containing 12 g. (20 moles) of potassium hydroxide added to the solution on the steam-bath. After refluxing for sixty hours, hydrolysis was complete and the excess alkali was neutralized with carbon dioxide. The solution was evaporated to dryness at 40° under diminished pressure and the resulting solid thoroughly extracted with ether. The ether extract was dried over calcium chloride, filtered, and concentrated under diminished pressure to a thick sirup which distilled completely, b. p. 84–85° (0.3 mm.); yield 2.0 g.; $[\alpha]^{25}\mathrm{D}$ −20.5° (*c*, 3.230, methanol); $n^{24}\mathrm{D}$ 1.4544.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.02; H, 8.30; OCH_3, 14.22. Found: C, 55.12; H, 8.40; OCH_3, 14.35.

Retosylation of monoacetone methylrhamnopyranoside thus obtained (0.86 g.) with tosyl chloride (1.5 g.) in the presence of dry pyridine (1.2 cc.) followed by isolation and crystallization as previously described yielded 0.90 g. of material, m. p. 61–62°. A mixed melting point of this material with 5-tosyl monoacetone methylrhamnopyranoside showed no depression. Specific rotation $[\alpha]^{25}\mathrm{D}$ +21.8° (*c*, 3.028, methanol).

C. Reductive Alkaline Hydrolysis

1. Pure 5-Tosyl Monoacetone Methylrhamnofuranoside.—(Fraction I, Table I.) Two grams of 5-tosyl monoacetone methylrhamnofuranoside (m. p. 82–83°) was dissolved in 100 cc. of 80% methyl alcohol and 25 g. of 4% sodium amalgam added under good stirring. After fourteen hours at room temperature the reaction was complete. The excess alkali was neutralized with a stream of carbon dioxide and the solution evaporated to dryness at 40° under diminished pressure. The resulting solid was thoroughly extracted with hot ether and the extract dried over calcium chloride, filtered and concentrated under diminished pressure; yield, 1.1 g. with b. p. 78–80° (0.2 mm.); $[\alpha]^{21}\mathrm{D}$ −75.45° (*c*, 2.770, methanol); $n^{24}\mathrm{D}$ 1.4466.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.02; H, 8.30; OCH_3, 14.22. Found: C, 54.99; H, 8.35; OCH_3, 14.21.

Retosylation of 0.5 g. of this pure material with 0.8 g. of tosyl chloride dissolved in 1 cc. of dry pyridine in the usual manner, gave a yield of 0.6 g. of 5-tosyl monoacetone methylrhamnofuranoside (m. p. 82–83°). The melting point was unchanged when mixed with an authentic specimen of 5-tosyl monoacetone methylrhamnofuranoside.

2. Mixed 4- and 5-Tosyl Monoacetone Methylrhamnosides, m. p. 57–58°.—Fraction V, Table I. The mixed crystals of 4- and 5-tosyl monoacetone methylrhamnosides (2.5 g.) dissolved in 250 cc. of 80% methyl alcohol were detosylated by use of 36 g. of 4% Na–Hg amalgam during fourteen hours. The product isolated as described above had a boiling point of 82–85° (0.3 mm.); yield 1.1 g.; $[\alpha]^{25}\mathrm{D}$ −38.18° (*c*, 3.156, methanol); $n^{24}\mathrm{D}$ 1.4520.

3. Pure 4-Tosyl Monoacetone Methylrhamnopyranoside.—(a) Ten grams of 4-tosyl monoacetone methylrhamnopyranoside was dissolved in 500 cc. of 80% methyl alcohol and 125 g. of 4% Na–Hg amalgam added. Good stirring was maintained for fourteen hours, after which the reaction was complete. The solution was worked up and the product isolated as previously described; yield 5.4 g.; b. p. 84–85 (0.3 mm.); $[\alpha]^{25}\mathrm{D}$ −17.76° (*c*, 3.294, methanol); $n^{24}\mathrm{D}$ 1.4541.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.02; H, 8.30; OCH_3, 14.22. Found: C, 54.94; H, 8.41; OCH_3, 14.00.

Retosylation of 0.5 g. of this material with tosyl chloride (0.8 g.) in presence of dry pyridine (1 cc.) yielded in the usual manner, 0.6 g. of material of m. p. 61–62°; $[\alpha]^{26}\mathrm{D}$ +21.88° (*c*, 3.014, methanol). A mixed melting point with original 4-tosyl monoacetone methylrhamnopyranoside showed no depression.

(b) The alkaline hydrolysis of mixed crystals of 4- and 5-tosyl methylrhamnosides (m. p. 68 or 80°) leads to the production of an unsaturated low boiling material and monoacetone methylrhamnopyranoside which in turn, upon tosylation, yields 4-tosyl monoacetone methylrhamnopyranoside (m. p. 60–61°). To prove further that this material was identical with 4-tosyl monoacetone methylrhamnopyranoside, a sample thus obtained was detosylated and the properties of the monoacetone methylrhamnopyranoside obtained were compared with those of the known derivative of this structure.

4-Tosyl monoacetone methylrhamnopyranoside (0.8 g.) with m. p. 60–61° was dissolved in 80 cc. of 80% methyl alcohol and 12 g. of 4% Na–Hg amalgam added. The time of reaction and method of isolation was carried out exactly as described previously; yield 0.4 g.; b. p. 82–85° (0.3 mm.); $[\alpha]^{25}\mathrm{D}$ −21.30° (*c*, 3.380, methanol); $n^{24}\mathrm{D}$ 1.4539.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.02; H, 8.30; OCH_3, 14.22. Found: C, 55.03; H, 8.19; OCH_3, 14.26.

D. Proof of Structure of 4- and 5-Tosyl Monoacetone Methylrhamnosides

Inasmuch as the methylglycofuranosides are hydrolyzed

at a much greater rate than the glycopyranosides,[14] the ring structure of such compounds may be determined easily. Accordingly the hydrolysis rates of the monoacetone methylrhamnosides (purified and crude) were determined in the following manner. Known weights of the monoacetone methylrhamnosides were dissolved in hydrochloric acid (0.1 or 0.03 *N*) and diluted to exactly 5 cc. with hydrochloric acid (0.1 or 0.03 *N*). The specific rotation was observed immediately and the solution then heated in a sealed tube at 100° for the time specified. The tubes were now cooled and the rotation of the solution again noted. The results obtained in this manner are given in Table III and in Fig. 1.

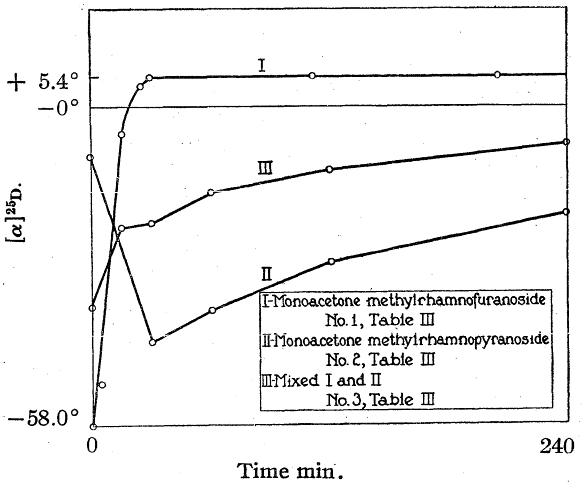

Fig. 1.—Rate of hydrolysis of monoacetone methylrhamnosides with 0.03 *N* HCl at 100°.

We wish to express our thanks and gratitude to Messrs. Geigy and Company for their generous gift of the *l*-rhamnose used in these experiments.

Summary

1. The usual methods of preparing monoacetone *l*-methylrhamnofuranoside are attended by the simultaneous formation of monoacetone *l*-methylrhamnopyranoside, at times to the extent of 30–40%.

2. Alkaline hydrolysis of pure 5-tosyl monoacetone *l*-methylrhamnofuranoside leads to the production of an unsaturated compound in 90–95% yield together with monoacetone *l*-methylrhamnofuranoside.

3. Alkaline hydrolysis of 4-tosyl monoacetone *l*-methylrhamnopyranoside yields quantitatively monoacetone methylrhamnopyranoside.

4. Tosyl monoacetone *l*-methylrhamnoside with m. p. 80° is a mixture containing, in addition to the furanoside, a small proportion of the pyranoside. Alkaline hydrolysis of this product leads to formation of the unsaturated derivative together with a small proportion of monoacetone *l*-methylrhamnopyranoside.

5. Alkaline hydrolysis of the 4- and 5-tosyl monoacetone *l*-methylrhamnosides is accomplished without Walden inversion.

The Reaction between Sulfur Dioxide and Olefins. III.[1] Higher Olefins and Some Limitations of the Reaction

BY L. L. RYDEN AND C. S. MARVEL

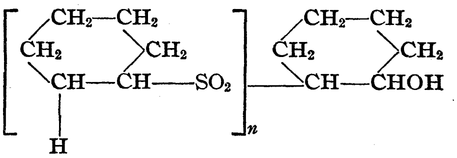
Previous investigations have shown that sulfur dioxide will combine with the simple olefins ethylene,[2] propylene,[1,2] cyclohexene[3] and methylpropene;[4] with a large number of conjugated dienes;[5] and with allyl alcohol and some of its simple ethers.[6] In order to learn more about the limitations of this addition reaction we have made this study of the formation of polysulfones from sulfur dioxide and a variety of unsaturated compounds.

Polysulfones have been obtained by the combination of sulfur dioxide and methylpropene, 1-pentene, 2-pentene, 1-nonene, 3-cyclohexylpropene and 3-methylcyclohexene. Under the same experimental conditions which were used for the production of the above polysulfones, no reaction could be obtained between sulfur dioxide and trimethylethylene, tetramethylethylene, pinene or 1,4-dihydronaphthalene. The failure of these olefins to react with sulfur dioxide indicates that increasing the number of hydrocarbon substituents on the carbon atoms which are attached by a double union will tend to block this addition reaction.

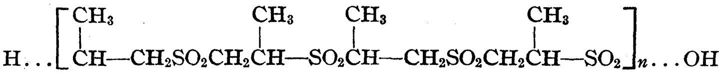
We have also treated sulfur dioxide with the following compounds which contain not only the olefin group but some other functional group as well: 1-chloropropene, trichloroethylene, allyl cyanide, 2-allyl-*p*-cresol, undecylenic acid, sodium undecylenate, ethyl undecylenate, ethyl erucate, crotonaldehyde, oleyl alcohol and undecylenyl alcohol. Of these compounds, only undecylenyl alcohol gave a polysulfone. This confirms Solonina's observation[6] that an alcoholic hydroxyl group in the olefin molecule does not interfere with the formation of a polysulfone. The failure of oleyl alcohol to combine with sulfur dioxide must be due to the fact that the double bond is in the middle of a long chain. While the negative results obtained in our other experiments must be accepted with the usual caution, they do clearly show that many simple functional groups do interfere with the addition of sulfur dioxide to an olefin group. In this connection, it may be mentioned that *d*-limonene, an unconjugated diene, also failed to combine with sulfur dioxide under the conditions of our experiments.

1-Heptyne does combine with sulfur dioxide to produce a polymeric product of the composition $(C_7H_{12}SO_2)_n$. The extension of the reaction to other acetylenes is now under investigation in this Laboratory.

In the earlier work on cyclohexene,[3] it was found that the polysulfone (I) contained an alcohol group which could be chloroacetylated.



I



$$H\cdots\left[\overset{CH_3}{\overset{|}{CH}}-CH_2SO_2CH_2\overset{CH_3}{\overset{|}{CH}}-SO_2\overset{CH_3}{\overset{|}{CH}}-CH_2SO_2CH_2\overset{CH_3}{\overset{|}{CH}}-SO_2\right]_n\cdots OH$$

II

On the other hand, it was found that propylenepolysulfone (II)[1] has a sulfonic acid group at one end of the chain. The polysulfones described in this paper are apparently of the alcohol type, as none of them are alkali soluble, and those which have been treated with an acid chloride have given acyl derivatives.

In previous work[3] an attempt was made to estimate the molecular weight of cyclohexenepolysulfone from the chlorine content of the chloroacetyl derivative. Further work on this phase of the problem has cast some doubt on the molecular weight values which are determined in this manner. It is extremely difficult to purify these compounds, and their chlorine content is

low. We have used trichloroacetyl chloride as an acylating agent in our later experiments, but even with the threefold increase in chlorine content, the experimental error is so large that the calculated molecular weight cannot be checked closer than about 50,000. Therefore, the only conclusion we have reached concerning the molecular weights of the various polysulfones is that all are in the region of 100,000 to 200,000. We have repeated some earlier work on the estimation of the molecular weight of propylenepolysulfone by determining the nitrogen content of the anilide, and have found that this polysulfone has a molecular weight of about 50,000 instead of 6000. This new value is in better agreement with the molecular weight of propylenepolysulfone which Staudinger and Ritzenthaler[2] calculated from viscosity measurements.

The alkaline degradation of these new polysulfones has not been extensively studied. 2-Pentenepolysulfone, on heating with sodium hydroxide solution, yields 2-pentene, dipentenylsulfone and sodium sulfite. Methylpropenepolysulfone gives large amounts of methylpropene and sodium sulfite under the same conditions. No other hydrolysis products were obtained. 1-Pentenepolysulfone does not regenerate the olefin when heated with alkali. Therefore, it is probable that the polysulfones derived from all olefins of the type $RCH{=}CH_2$ will be found to be closely related to propylenepolysulfone in structure.

Experimental Part

Polysulfones from Simple Olefins.—The general method developed for the preparation of cyclohexenepolysulfone[3] was followed in this work. Ten volumes of liquid olefin and ten volumes of liquid sulfur dioxide were mixed together in a pressure flask, and one volume of 3% hydrogen peroxide and one volume of paraldehyde was added. The pressure flask was sealed and the mixture allowed to stand for about twelve hours. In most cases, the reaction was then as complete as it could be made to go under these general conditions. In the case of methylpropene, 1-pentene and 1-nonene, it was observed that better results were obtained by mixing the olefin, sulfur dioxide and hydrogen peroxide, and allowing this mixture to stand for twelve hours, then introducing the paraldehyde. Within an hour, the reaction was then finished.

In all cases, the products were isolated by pouring the reaction mixture into water, and were purified by thorough washing with alcohol and ether. The yields, melting points and analyses of the new polysulfones are recorded in Table I.

Methylpropenepolysulfone is a white, amorphous powder, quite brittle and insoluble in common organic solvents. The derivatives of 1-pentene, 2-pentene and 1-nonene were soluble in acetone, and were purified by solution in this solvent and reprecipitation with water. 1-Nonenepolysulfone is a softer and more plastic material than are the polysulfones with shorter carbon chains.

Perbenzoic acid could not be satisfactorily substituted for 3% hydrogen peroxide as a catalyst for the addition reaction.

Trichloroacetyl Derivatives and Calculated Molecular Weights.—The trichloroacetyl derivatives of the polysulfones from cyclohexene, methylpropene, 1-pentene, 2-pentene, 3-cyclohexylpropene and 1-nonene were prepared by allowing a mixture of 1 g. of polysulfone and 3 cc. of trichloroacetyl chloride to stand for about twenty-four hours. Methylpropenepolysulfone was the only one which was completely insoluble in the acid chloride. At the end of twenty-four hours the reaction mixture was poured into water and filtered. Most of the trichloroacetic acid was removed by grinding the product with alcohol, filtering and repeating the process, using ether as a solvent. The trichloroacetyl derivative was then dissolved in a solvent and reprecipitated. This product was then ground up with alcohol and washed on a filter with ether at least three times. Control experiments, using the polysulfone and trichloroacetic acid, showed that all of the chlorine could be removed by this method of purification. Methylpropenepolysulfone was most difficult to purify, since it did not dissolve in any solvent which was tried. The cyclohexene derivative was purified by dissolving in benzene and precipitation with alcohol, and the other products were dissolved in acetone and precipitated with water. The products were carefully dried and analyzed for chlorine by the Parr bomb procedure. A 0.3 to 0.4-g. sample was

Table I

Properties of Some Polysulfones

Olefin used	Yield, %	M. p. (dec.), °C. Bloc Maquenne	Formula	Analyses, %					
				Calcd.		Found			
				C	H	C		H

used, and 0.05 *N* silver nitrate and ammonium thiocyanate solutions were used. Blanks were run on the reagents in each experiment. The results are summarized in Table II.

Table II

Polysulfone Trichloroacetates

Polysulfone from	Expt. no.	Chlorine, %	Calcd. mol. wt.
Cyclohexene	1	0.107	99,200
Cyclohexene	2	.075	142,000
		.075	142,000
Cyclohexene	3[a]	.109	98,000
		.065	164,000
1-Pentene	4	.077	139,000
		.045	237,000
2-Pentene	5	.045	237,000
	6	.086	124,000
Methylpropene[b]	7	.041	260,000

[a] This sample was prepared by allowing the solution of cyclohexenepolysulfone in trichloroacetyl chloride to stand for ten days.

[b] This derivative was purified by repeated washing with alcohol and ether.

The polysulfones prepared from 1-nonene and 3-cyclohexylpropene reacted with trichloroacetyl chloride to liberate hydrogen chloride. The resulting products were sticky, insoluble materials of such a nature that purification was very unsatisfactory, and hence no attempt has been made to estimate molecular weights from the chlorine content of these esters.

Propylenepolysulfonanilide. — Propylenepolysulfonanilide was prepared as described previously.[1] The product was ground up with 5% hydrochloric acid and filtered, and this process repeated four times. Sample AI was then collected. The hydrochloric acid treatment was repeated five more times, and sample AII was collected. After five more washings, sample AIII was collected. Then the remaining product was suspended in water, exactly neutralized and boiled for thirty minutes (in order to steam distill any remaining aniline). The propylenepolysulfonanilide was then washed with alcohol and ether to give sample AIV. For comparison, a mixture of propylenepolysulfone and aniline were similarly treated, and B samples I′ to IV′ were collected. Nitrogen in these samples was determined by the Kjeldahl method. The results of these experiments are given in Table III.

Table III

Nitrogen Content and Molecular Weight of Propylenepolysulfonanilide

Sample A	N, %	Sample B	N, %	N, % A − B	Calcd. mol. wt.
I	0.065	I′	0.029	0.036	38,880
II	.043	II′	.013	.030	46,600
III	.040	III′	.0076	.032	43,750
IV	.0175	IV′	.0022	.015	93,300

The fact that the nitrogen content of the polymer after correction remains fairly constant through the first three samples seems significant. The low value for nitrogen in sample IV indicates that steam distillation has caused some complex decomposition of the molecule.

Alkaline Degradation of Polysulfones

2-Pentenepolysulfone.—A mixture of 50 g. of 2-pentenepolysulfone and 160 cc. of 20% sodium hydroxide was heated under a reflux condenser for about an hour and a half. During this heating period a considerable amount of 2-pentene was formed. This was collected in a cooled trap at the upper end of the reflux condenser. The olefin was identified by its boiling point (36–37°) and by the boiling point of its dibromo derivative (176°). During the period of refluxing, an oil appeared on the alkaline solution. This product was separated and distilled under reduced pressure. It boiled at 132° at 4–5 mm., decolorized an aqueous solution of potassium permanganate, but did not take up bromine from carbon tetrachloride. It is apparently a diamylenesulfone.

Anal. Calcd. for $C_{10}H_{18}SO_2$: C, 59.04; H, 8.91; S, 15.83; mol. wt., 202. Found: C, 58.5, 58.7; H, 9.52, 9.47; S, 16.9, 16.7; mol. wt. (Rast), 206, 218.

From the alkaline solution considerable sodium sulfite was isolated. No organic sulfonic or sulfinic acid salts could be extracted from these residues.

Methylpropenepolysulfone.—A mixture of 40 g. of methylpropenepolysulfone and 150 cc. of 10% sodium hydroxide solution was heated to boiling. Within fifteen minutes over 35% of the theoretical amount of methylpropene was liberated. The olefin was identified as the dibromide, b. p. 148–149°. Sodium sulfite was produced in large quantities, but no other hydrolysis products were isolated.

1-Pentenepolysulfone.—A mixture of 35 g. of 1-pentenepolysulfone and 100 cc. of 20% sodium hydroxide solution was heated under a reflux condenser. The polysulfone dissolved in a short time producing a red-colored solution. No 1-pentene was regenerated. After about fifteen minutes a small amount of oily material separated on the surface of the solution. However, no definite products were isolated from the amount of material which was available.

Undecylenyl Alcohol Polysulfone.—Undecylenyl alcohol and sulfur dioxide combine very easily under the general conditions mentioned above, and the paraldehyde can be omitted from the reaction mixture without affecting the yield of product. The polysulfone is at first a jelly-like mass, but soon turns to a semi-transparent, crumbly substance which is insoluble in all common organic solvents, and is also insoluble in dilute aqueous alkalies. The product darkened at 330°, but did not appear to soften or liberate gas.

Anal. Calcd. for $(C_{11}H_{22}SO_3)_n$: C, 54.26; H, 9.86. Found: C, 55.91, 55.54; H, 8.99, 9.19.

The product was converted to a chloroacetyl derivative, but the properties were not changed in any noticeable fashion.

Anal. Calcd. for $(C_{11}H_{21}OCOCH_2ClSO_2)_n$: Cl, 11.4. Found: Cl, 10.8, 10.5.

1-Heptyne Polysulfone.—When 1-heptyne and sulfur dioxide were allowed to react in the presence of 3% hydrogen peroxide and paraldehyde, a 50–60% yield of a polymer was obtained after three days. The product was soluble in acetone and insoluble in alcohol, ether and cold dilute sodium hydroxide solution. It melted at 160–169°.

Anal. Calcd. for $(C_7H_{12}SO_2)_n$: C, 52.5; H, 7.50; S, 20.00. Found: C, 52.38, 52.32; H, 7.55, 7.62; S, 19.5, 19.4.

Summary

1. Methylpropene, 1-pentene, 2-pentene, 1-nonene, 3-cyclohexylpropene and 3-methylcyclohexene give polysulfones by the addition of sulfur dioxide. These polysulfones are all neutral products and the first five of them have alcohol groups at the ends of the chains. Evidence has been obtained to indicate that 1-pentenepolysulfone is degraded with alkali in a manner which is like that reported for propylenepolysulfone, whereas the methylpropene and 2-pentene derivatives are degraded more nearly after the manner of the cyclohexene derivative. The molecular weights of these polysulfones are in the range of 100,000 to 200,000.

2. Highly substituted olefins do not add sulfur dioxide under the experimental conditions used in our work.

3. Polysulfones have been obtained from 1-heptyne and from undecylenyl alcohol. No evidence of addition of sulfur dioxide to typical olefins containing chloro, cyano, phenolic hydroxyl, aldehydo, carboethoxy, carboxyl or salt of carboxyl groups could be obtained.

Arsenicals Containing the Furan Nucleus. II. Action of Chlorine. Some Substituted Furan Arsenicals

BY WESLEY G. LOWE[1] AND CLIFF S. HAMILTON

The action of chlorine on furyldichloroarsine, difurylchloroarsine and trifurylarsine in chloroform or carbon tetrachloride solution leads in every instance to the formation of 2-chlorofuran tetrachloride. This reaction can be carried out at room temperature or by introducing dry chlorine gas into a chloroform solution of the arsenical at −78° followed by evaporation of the solvent at room temperature. 2-Chlorofuran, prepared from Hill's 5-chloropyromucic acid[2] by decarboxylation in aqueous mercuric chloride,[3] adds four atoms of chlorine under the same conditions and the 2-chlorofuran tetrachloride thus obtained is identical with that prepared from the furan arsenicals.

In agreement with the observation made by Hill and Hartshorn[4] that 2,5-dibromofuran tetrabromide in alcoholic potassium hydroxide solution loses two molecules of hydrogen bromide to yield tetrabromofuran, we have found that from a similar solution of 2-chlorofuran tetrachloride 40% of the total chlorine can be precipitated with silver nitrate, indicating the loss of two molecules of hydrogen chloride and the formation of a trichlorofuran. The action of aqueous silver nitrate on an alcoholic solution of 2-chlorofuran tetrachloride is complex, varying conditions of temperature and acidity leading to a precipitation of 60, 70 and 75% of the total chlorine as silver chloride. Hydrolysis of the symmetrical molecule, 2,5-dibromofuran tetrabromide, involves a loss of five-sixths of the total bromine yielding bromomaleic acid as a final product.[4] This stepwise loss of chlorine is the same for chlorofuran tetrachloride prepared by either of the methods mentioned and is further proof of identity of structure.

Efforts to isolate a second product from the chlorination of furyldichloroarsine were unsuccessful. However, in each of six chlorinations of difurylchloroarsine it was possible to isolate a white solid which on exposure to air gave off hydrogen chloride gas. This compound was not identified as such, but on hydrolysis with cold water it yielded difurylarsinic acid which was purified by crystallization from hot water. Although it is not necessary to fractionate difurylchloroarsine to purity before chlorination in order to obtain this acid, efforts to prepare it from the mixture of arsenicals before distillation were unsuccessful. The acid, when pure, is stable to air and light, but it is more sensitive to sulfuric acid than is furoic acid and can be detected in very dilute solution by the formation of a dark ring at the water–sulfuric acid interface.

Trifurylarsine dichloride was prepared in small yields by slow evaporation of a chloroform or ether solution of chlorinated trifurylarsine. It was obtained as large diamond-shaped transparent crystals, stable in air, but readily hydrolyzed in a water–alcohol solution. Neither trifurylarsine dichloride nor difurylarsinic acid reacted with mercuric chloride in alcoholic solution to form 2-chloromercurifuran as does trifurylarsine.[5] This fact, in view of the results that have been obtained on mercuration of benzene arsenicals,[6] makes it appear that the substitution of arsenic by mercury on aromatic nuclei is a property of trivalent but not of pentavalent arsenic.

In the chlorination of furan arsenicals, three separate reactions are involved: (1) the oxidation of trivalent arsenic, (2) the saturation of the furan nucleus and (3) the scission of the carbon–arsenic bond. Since these could occur in any order, there are six possible courses for the total reaction. The isolation of difurylarsinic acid and trifurylarsine dichloride eliminates two of these since scission of the carbon–arsenic bond cannot, therefore, occur first. Against the probability of scission occurring at the second step, it has been noted that the removal of arsenic from an aromatic nucleus by means of chlorination is not accomplished at the temperature here employed,[7] and that removal of arsenic from an aliphatic radical by this means occurs only after the arsenic has been oxidized. Consequently it is most probable that scission of the carbon–arsenic bond occurs only after the nucleus has been saturated and the arsenic oxidized. Von Baeyer[8] has shown that loss of arsenic from methyltetrachloroarsine occurs at −10°. However, the results of these chlorinations are best explained by assuming that both of the reactions involving scission of the carbon–arsenic bond as the final step occur simultaneously. In other words, the oxidation of the furan nucleus and trivalent arsenic are essentially competitive in nature. Consequently it has not been found possible by means of controlled chlorination of difurylchloroarsine to preclude the formation of either 2-chlorofuran tetrachloride or difurylarsinic acid; both products always appear together. In view of these circumstances the usefulness of chlorination as a general method for preparing various furylarsonic and difurylarsinic acids is limited by the ease of chlorination of substituted furan nuclei. In addition to its failure to produce furylarsonic acid from furyldichloroarsine, repeated applications of the method to di-5-chlorofurylchloroarsine failed to lead to the synthesis of di-5-chlorofurylarsinic acid. This latter result is in accord with our observation that under similar conditions 2-chlorofuran adds chlorine more readily than does furan itself.

Tri-5-chlorofurylarsine and tri-5-bromofurylarsine were prepared by arsenation of 5-chloro-2-chloromercurifuran and 5-bromo-2-chloromercurifuran in benzene solution. The former arsenical was separated by fractional distillation and the latter by fractional crystallization. Both of these compounds are crystalline solids. An attempt was made to prepare tri-5-iodofurylarsine from 5-iodo-2-chloromercurifuran. The arsenation proceeded with great ease, but the resulting mixture of arsenicals was so unstable to the action of air that separation of its components was abandoned.

A study of the action of alcoholic mercuric chloride on these substituted trifurylarsines was made. It was found that although the arsenic can be replaced by mercury to yield the original mercurical, the action is less complete than was observed in the case of trifurylarsine itself.[5] The order of ease of substitution of arsenic by mercury in these arsenicals is: trifurylarsine, tri-5-chlorofurylarsine, tri-5-bromofurylarsine. Since this reaction is characteristic of aromatic nuclei, the aromaticity of furan is lessened by the presence of halogen in the α-position.

Experimental

2-Chlorofuran Tetrachloride.—*Method 1.*—Two grams of furyldichloroarsine, difurylchloroarsine, trifurylarsine or a mixture of these arsenicals was dissolved in 10 cc. of chloroform, the solution chilled by immersing in a bath of solid carbon dioxide and ether and chlorine passed in slowly. Chlorination was continued until on allowing a sample of the solution to warm to room temperature bubbles of chlorine gas were observed to form. The solution was then placed in an evaporating dish and allowed to stand in the open until the chloroform had evaporated. The viscous oil remaining was steam distilled until no more droplets passed over, collected with a small pipet, and dried by allowing to stand in a desiccator; yield 20%.

Method 2.—Six grams of 2-chlorofuran was dissolved in 20 cc. of chloroform, chilled and chlorinated as described above, the chloroform removed by evaporation and the product steam distilled; yield 3 g. The low yields result from the hydrolysis of the oil during steam distillation.

2-Chlorofuran tetrachloride is slightly yellow and has a pungent, penetrating odor, d^{25}_4 1.620.

Anal. Calcd. for $C_4H_3OCl_5$: Cl, 72.57. Found: Cl, 72.48, 72.06.

Reactions of 2-Chlorofuran Tetrachloride.—1. To 20 cc. of saturated alcoholic solution of potassium hydroxide was added approximately 60 mg. of 2-chlorofuran tetrachloride. A bright orange coloration appeared which faded while a precipitate of potassium chloride separated. After fifteen minutes the solution was diluted with water, made acid with nitric acid and silver nitrate added. The precipitated silver chloride was dried at 135° and weighed.

Anal. Calcd. for 40% of 72.57: Cl, 29.03. Found: Cl, 29.51, 29.40.

2. Approximately 50 mg. of 2-chlorofuran tetrachloride was placed in 15 cc. of alcohol and made slightly acid with nitric acid. Aqueous silver nitrate was added and a precipitate was observed to form gradually. The precipitation was complete at the end of twelve hours.

Anal. Calcd. for 60% of 72.57: 43.54. Found: (average of four determinations) Cl, 42.98.

3. Approximately 50 mg. of 2-chlorofuran tetrachloride was placed in 15 cc. of alcohol, made slightly acid with nitric acid and heated to boiling. When the precipitate had coagulated, it was filtered, dried and weighed.

Anal. Calcd. for 70% of 72.57: 50.80. Found: Cl, 50.75, 51.05.

4. The filtrate from the above determination was made strongly acid with nitric acid and boiled until brown fumes appeared. The coagulated precipitate was dried and weighed, the weight of this precipitate added to that found in the previous determination and per cent. of chlorine determined on the basis of this sum.

Anal. Calcd. for 75% of 72.57: 54.52. Found: Cl, 53.87, 53.87.

Difurylarsinic Acid.—Thirty-eight grams of 2-chloromercurifuran, 12 g. of arsenic trichloride, and 50 cc. of benzene was refluxed for three hours. The fraction containing difurylchloroarsine was obtained as described in a previous paper,[5] no attempt being made to purify it by further fractionation. This fraction was dissolved in 20 cc. of chloroform, the solution chilled in a bath of solid carbon dioxide and ether, and chlorine introduced slowly. From time to time a sample was removed and allowed to evaporate. When the amount of white solid formed on evaporation was a maximum, the chlorination was stopped and the entire solution evaporated by allowing to stand at room temperature in an evaporating dish. The crystals were washed three times with dry ether to remove the arsenic trichloride and 2-chlorofuran tetrachloride present and allowed to stand overnight in water. The crystals were washed with cold water, dried at room temperature and analyzed. Further purification can be effected by recrystallization from hot water. The acid is soluble in alcohol and glycol; yield, 1.1 g. or 8% of the total furan present in the mercurial; m. p. 138°.

Anal. Calcd. for $(C_4H_3O)_2AsO_2H$: As, 31.00; neut. equiv., 242. Found: As, 31.10, 31.00; neut. equiv., 228.

Trifurylarsine Dichloride.—The ether washings from the above preparation were placed in a beaker and allowed to stand overnight. A heavy oil remained in which transparent, diamond-shaped crystals were present. These were picked out and washed with ligroin, yield 0.25 g. In alcoholic solution the chlorine present in this compound was precipitable with silver nitrate; m. p. 132°.

Anal. Calcd. for $(C_4H_3O)_3AsCl_2$: As, 21.60; Cl, 20.44. Found: As, 21.47; Cl, 20.29.

5-Chloro-2-chloromercurifuran.—This compound was prepared from 5-chloropyromucic acid[2] by boiling a solution of its sodium salt with an equivalent amount of mercuric chloride, using the directions given by Gilman for the preparation of substituted 2-chloromercurifurans.[3] The mercurial was obtained in 65% yield and no other product was formed. It was purified by recrystallization from hot alcohol, m. p. 181°.

Anal. Calcd. for $C_4H_2OHgCl_2$: Hg, 59.42; Cl, 21.03. Found: Hg, 59.02; Cl, 21.13.

Tri-5-chlorofurylarsine.—Forty-three grams of 5-chloro-2-chloromercurifuran, 16 g. of arsenic trichloride and 100 cc. of benzene was refluxed for thirty minutes. The precipitated mercuric chloride was filtered off and the benzene removed from the filtrate by distillation. When the temperature of the distilling vapors reached 85° distillation was continued using a water pump until the excess arsenic trichloride was removed. The arsenicals were then twice distilled at 1 mm., the distillate being separated into two equal fractions in the second distillation. Decomposition during distillation was slight as compared with that observed in the distillation of unsubstituted arsenicals. An analysis for arsenic and chlorine indicated that the first fraction contained impure di-5-chlorofurylchloroarsine, a slightly green liquid. The second fraction on standing solidified to a white solid; total yield of arsenicals, 6 g., or 20–25%.

The trichlorofurylarsine was obtained from the second fraction by fractional crystallization from ether in the form of fine white needles, m. p. 63°.

Anal. Calcd. for $(ClC_4H_2O)_3As$: As, 19.74. Found: As, 19.54, 19.60.

No attempt was made to purify the first fraction. Chlorination failed to form di-5-chlorofuryl arsinic acid but yielded an arsenic-free highly chlorinated oil so readily decomposed during steam distillation that no analysis was attempted. Its odor, ease of hydrolysis and loss of chlorine in the presence of silver nitrate, indicated that it was probably 2,5-dichlorofuran tetrachloride.

Tri-5-bromofurylarsine.—Forty-two grams of 5-bromo-2-chloromercurifuran, 10 g. of arsenic trichloride and 100 cc. of benzene was refluxed for thirty minutes and the mercuric chloride, benzene and arsenic trichloride removed from the arsenicals as described above. After removal of the arsenic trichloride, the mixture on cooling set to a black mass in which crystals were plainly visible. On dissolving in ether and allowing to evaporate the oily constituents formed a ring at the edge of the dish and were absorbed in filter paper. By repeating this treatment four times the tri-5-bromofurylarsine was obtained as white, beautifully formed needle-shaped crystals; yield 8 g., 40%, m. p. 106°.

Anal. Calcd. for $(BrC_4H_2O)_3As$: As, 14.60; Br, 46.76. Found: As, 14.76; Br, 46.64.

Mercuration of Tri-5-chlorofurylarsine.—One-half gram of tri-5-chlorofurylarsine, 1.1 g. of mercuric chloride and 10 cc. of alcohol were heated to boiling and set aside for fifteen minutes. On the addition of water a white precipitate formed which contained 13% arsenic. Repeated crystallization from hot alcohol gave a 15% yield of 5-chloro-2-chloromercurifuran, m. p. 179–180°.

Mercuration of Tri-5-bromofurylarsine.—Mercuration of this material was attempted by the method above, the same ratio of molecular concentrations of reactants being employed. On addition of water tri-5-bromofurylarsine was precipitated almost unchanged. The experiment was repeated, water being added to the alcohol to the point where precipitation was just avoided. Boiling was continued for fifteen minutes. On cooling and adding water a precipitate was obtained which on recrystallization from water–alcohol gave a 7% yield of 5-bromo-2-chloromercurifuran, m. p. 178°.

Summary

Chlorination of furyldichloroarsine, difurylchloroarsine and trifurylarsine yields 2-chlorofuran tetrachloride in all cases. Stepwise loss of chlorine from this compound has been described. Difurylarsinic acid has been prepared by hydrolysis of a chlorination product of difurylchloroarsine and trifurylarsine dichloride has been isolated. Chlorination of furyldichloroarsine and di-5-chlorofurylchloroarsine in an effort to form furylarsonic acid and di-5-chlorofurylarsinic acid has given negative results. The chlorination of furan arsenicals is regarded as competitive oxidation of arsenic and the furan nucleus.

The preparation of some substituted furan arsenicals has been described, and a study of the action of mercuric chloride on tri-5-chlorofurylarsine and tri-5-bromofurylarsine indicates that the aromaticity of the furan nucleus is less in these compounds than in trifurylarsine itself.

The Addition of Chloroform and Bromoform to *p*-Chlorobenzaldehyde

BY JOSEPH W. HOWARD

Introduction

The fact that benzaldehyde is one of the few aldehydes to which chloroform and bromoform will add forming the corresponding trichloromethyl and tribromomethyl carbinols,[1] has led the author to undertake a study of these additions with substituted benzaldehydes.

A study of this reaction with *o*-chlorobenzaldehyde has been recently reported.[2] The present investigation was made with *p*-chlorobenzaldehyde.

Experimental Part

Preparation of Trichloromethyl-*p*-chlorophenylcarbinol.—To a mixture of 46 g. of freshly distilled *p*-chlorobenzaldehyde and 60 g. of dry chloroform was added with constant stirring 4 g. of powdered potassium hydroxide over a one-hour period. The mixture was allowed to stand for at least three hours, ether was added and the resultant mixture filtered. The ether and excess chloroform were distilled off. The residue was steam distilled to remove *p*-chlorobenzaldehyde and *p*-chlorobenzoic acid. The non-volatile portion was extracted with ether, the ether extract washed with 2% sodium hydroxide solution and dried over sodium sulfate. The ether was distilled off and the carbinol removed by distillation under diminished pressure. It came over at 187–188° at 26 mm. The yield was 20 g. of d^{20}_{20} 1.523.

Anal. Calcd. for $C_8H_6OCl_4$: Cl, 54.58. Found: Cl, 54.64.

This carbinol is insoluble in water but readily soluble in ethyl alcohol, methyl alcohol, benzene, acetone, ether, chloroform, carbon tetrachloride and carbon bisulfide.

Preparation of Tribromomethyl-*p*-chlorophenylcarbinol.—The above procedure was followed with the substitution of 130 g. of bromoform for 60 g. of chloroform. This compound boils at 198–200° at 19 mm. It solidified readily on cooling and was recrystallized from 95% ethyl alcohol. The yield was 25 g.; m. p. 90–91°.

Anal. Calcd. for $C_8H_6OClBr_3$: Cl, 9.01; Br, 60.96. Found: Cl, 9.05; Br, 60.86.

This carbinol differs in solubility from the trichloromethyl-*p*-chlorophenylcarbinol in that it is only very sparingly soluble in ethyl and methyl alcohols.

Preparation of the Esters

The esters of trichloromethyl-*p*-chlorophenylcarbinol were prepared as follows: the acetate by heating with acetic anhydride at 150–160° for three hours, the propionate with propionic anhydride at 170–180° for three hours and the butyrate with butyryl chloride at 120–130° for three hours. The usual procedure of the Schotten–Baumann reaction was used in preparing the benzoate with benzoyl chloride. The acetate was recrystallized from 75% acetic acid, the propionate and benzoate from 95% ethyl alcohol. The butyrate remained a viscous oil even after long standing.

(2) Howard and Castles, *ibid.*, **57**, 376 (1935).

The average yield of all of these esters was 85%.

ESTERS OF TRICHLOROMETHYL-*p*-CHLOROPHENYLCARBINOL

		M. p., °C.	Formula	Analyses for Cl, % Calcd.	Found
1	Acetate	120–121	$C_{10}H_8O_2Cl_4$	46.98	47.18
2	Propionate	71–72	$C_{11}H_{10}O_2Cl_4$	44.89	45.17
3	Benzoate	128–129	$C_{15}H_{10}O_2Cl_4$	38.98	38.87

The butyrate boils at 172–173° at 6 mm., d^{20}_{20} 1.331. The butyrate is insoluble in water but readily soluble in ethyl alcohol, methyl alcohol, benzene, acetone, ether, chloroform, carbon tetrachloride and carbon bisulfide. The other esters differ from this in that they are only sparingly soluble in ethyl and methyl alcohols.

A number of attempts were made to make these same esters of tribromomethyl-*p*-chlorophenylcarbinol using the same reagents and experimental conditions but the carbinol always came through unchanged. Attempts were also made to prepare the acetate by heating with acetyl chloride at 60–70° for three hours and the benzoate by heating with benzoic anhydride at 180–190° for five hours. The results here were also negative.

Summary

Trichloromethyl-*p*-chlorophenylcarbinol and its acetic, propionic, butyric and benzoic esters have been prepared and studied. The corresponding tribromo carbinol was prepared but it does not form these esters under the same experimental conditions.

Natural and Synthetic Rubber. XV. Oxygen in Rubber

BY THOMAS MIDGLEY, JR., A. L. HENNE, A. F. SHEPARD AND MARY W. RENOLL

The harmful effects of oxygen on rubber have long been known, and the formation of peroxides during milling has been qualitatively demonstrated.[1] However, quantitative measurements of the oxygen have never been made, and the nature of the oxygen compounds has not been investigated.

Rubber frequently has been analyzed by combustion and the ratio of the carbon percentage to the hydrogen percentage has invariably been found to correspond closely to a $(C_5H_8)_n$ formula. However, it does not follow that such is the formula of rubber. In every instance, the total of the carbon and the hydrogen content has fallen short of 100%. The deficiency is very small, especially in the case of pure rubber, but it invariably exists. The best analyses available, those of the Bureau of Standards,[2] done on highly purified, and on recrystallized rubber, show a deficiency of 0.3%. This cannot be accounted for entirely by contamination of the samples, nor can the combustion be assumed to be that inaccurate. It is logical to regard this deficiency as the oxygen and nitrogen content of the sample.

In the present work, the quantity of oxygen present in rubber samples has been measured by means of the combustion method described by the Bureau of Standards; an effort has been made to determine the type of oxygen present and to study the progressive oxidation of rubber. The technique of the Bureau has been altered in only two details: (1) a Jena combustion tube was substituted for the Pyrex tube, to prevent sintering at the high temperature used to burn out the last traces of carbon; (2) weighings were improved to ±0.00002 g.

Procedure

Sol rubber was prepared and purified by fractional precipitation[3] until it contained only 0.007 ± 0.0003% of nitrogen by Nessler titration. A sample of this rubber was analyzed by combustion to determine the H/C ratio and the oxygen and nitrogen content by deficiency. Another sample of the same specimen was treated with methylmagnesium iodide and the resulting methane measured to determine the amount of active hydrogen. The amount of carboxylic or ketonic groups present was investigated by treating a third sample with thionylmagnesium iodide, purifying the reaction product and analyzing it for sulfur.[4] The data are listed in Tables I and II together with the results of the same methods used on purified sodium rubber and on the degraded products of both.

Discussion of the Results

The striking fact shown by the tables is that pure synthetic rubber is oxygen free, while natu-

Degraded 31 days	.00	79.40	10.60	.1335	10.00	2.88	4300

ral rubber purified to the same extent by the same procedure contains oxygen; this oxygen is associated with an appreciable amount of active hydrogen while CO groups or oxygen of a peroxide nature are practically absent. Consequently, the experimental results may be interpreted as establishing the presence of an hydroxyl group in what has heretofore been called a hydrocarbon.

In view of the fact that oxygen is measured by deficiency, and its order of magnitude is very small, it is proper to question the significance of the experimental results.

First, may not the deficiency, as determined by the combustion, be purely an experimental error in the case of undegraded rubber?

This objection is refuted by the fact that a sample of sodium rubber has been repeatedly analyzed in the same apparatus and manner to give zero deficiency within the probable limits of experimental error.

Second, may not all of the oxygen found in undegraded rubber be attributed to an unremoved impurity?

Such an assumption is refuted by the fact that purified natural rubber gels when it is treated with a Grignard reagent; this is a test for combined oxygen in rubber, as previously shown.[5]

Third, could the combined oxygen be the result of slight degradation during fractionation? This is unlikely because synthetic rubber, which degrades quite easily, was subjected to the same method of purification, yet remained free of oxygen.

Fourth, is the combined oxygen a natural part of the rubber molecule or is it the result of slight oxidation between the time the latex left the tree and the time fractionation started?

The present results are only conclusive for the particular sample used. This sample was taken from the center of a bale of sprayed latex rubber and showed no visible signs of oxidation such as could be seen at the surface of the bale. Similar samples had been investigated previously by fractionation and no evidence of degradation had been found. It is probable, therefore, that the combined oxygen is a part of the rubber molecule occurring in nature.

Irrespective of its origin or significance, combined oxygen has been demonstrated to be present in the natural rubber investigated.

Quantitative Value of the Data

No quantitative significance is attached to any minor variation of the data except for the original undegraded sample of natural rubber and the oxygen-free synthetic; hence, this part of the discussion is confined to these two.

The values selected for the atomic weights of hydrogen and carbon are important and affect the results. The latest reported values by Aston,

---

(5) Midgley, Henne and Shepard, THIS JOURNAL, **56**, 1156 (1934).

namely, 1.0081 for hydrogen and 12.0048 for carbon, have been used in the calculations.

The deficiency of the natural rubber analysis is determined as 0.06%. This value includes the combined oxygen of the rubber and all the oxygen and nitrogen of the impurities present. The samples contained 0.007% of nitrogen. Previous experience with the fractionation of rubber has shown that the nitrogen impurities which are soluble in benzene and alcohol mixtures are easily eliminated but that an insoluble nitrogenous material collects in a gel phase. By degenerating the gel rubber this impurity may be collected. It contains two atoms of oxygen for each atom of nitrogen and behaves as an amino acid. It is almost certain that this impurity is the source of the nitrogen found, hence the total nitrogen and oxygen external from the rubber molecule itself becomes 0.023%. This leaves the combined oxygen as 0.042%.

The results of the treatment with thionyl Grignard were of no significance. The method is no more accurate than the values obtained. And even though these values were other than experimental error, they still would not represent any more oxygen than that available for this reaction in the nitrogen impurity. If there is any ketone, aldehyde or carboxyl oxygen present in the original L. S. rubber, this investigation fails to disclose it.

The hydroxyl oxygen, as disclosed by active hydrogen measurements, is more reliable. This method gives closely checking results. Blanks indicate a high accuracy for acids but a slightly low value for alcohols. If allowance is made for the active hydrogen present in the nitrogen impurity, considered as an amino acid, the final value becomes (0.028 − 0.008) = 0.02%. This value should be looked upon as possibly somewhat low, as the evidence thus developed points to the rubber molecule being an alcohol.

The value of 0.04% of oxygen as measured by combustion seems somewhat in discrepancy with the value of 0.02% as measured by active hydrogen determination, but a critical study of the possible errors involved in both methods by no means precludes the probability that the true value for the oxygen lies between these two and that hydroxylic oxygen was the only kind of oxygen present in the samples. By computing the molecular weight corresponding to the assumed presence of only one atom of oxygen in each rubber molecule, it is found that 0.04% of oxygen corresponds to a molecular weight of 40,000, while 0.02% corresponds to 80,000 (or 585 and 1170 isoprene units, respectively). This is in substantial harmony with the mol. wt. of 53,000, as determined by sulfur addition,[4] and suggests that the rubber molecule is a high molecular weight member of a pseudo homologous series occurring in nature, starting with geraniol and increasing by isoprene units to rubber.

One definite discrepancy with respect to present-day conceptions of the rubber molecule exists in the data. This is the abnormally high H/C ratio. Experience with the analysis indicates that this ratio is accurate to within ±0.0001. The theoretical H/C ratio for C_5H_8 with C as 12.0048 and H as 1.0081 is 0.13436. The indicated ratio for the original natural rubber is 0.1346. This is in perfect agreement with the value reported by the Bureau of Standards[2] and is 0.00024 too great, or 0.18% in excess, or one extra hydrogen atom for each 70 isoprene units. This is too small a number of isoprene units for it to be an end-group hydrogen. Likewise, if impurities are assumed to be responsible, a deficiency of 0.18% is required to account for it as water, 0.14% as alcohol or 0.75% of a non-volatile paraffinic hydrocarbon must be present, none of which fits the other data and/or the present accepted theories about the rubber molecule.

Oxidation Data

The data presented relative to the oxidation of rubber are to be taken as merely a preliminary study of the application of the analytical methods used to the problem of the chemistry of the oxidation of rubber. The results are, however, significant. As rubber undergoes oxidation, either by milling or exposure to oxygen and sunlight, the following events occur. The H/C ratio decreases, the combined oxygen increases, the active hydrogen increases and the molecular weight (measured by cryoscopy in benzene) decreases. The thionyl Grignard results still lack significance.

In addition to the data reported, the following experiment was performed. A fresh sample of heavily oxidized rubber was placed in a sealed tube and heated for several hours. Oxygen gas was evolved, the combined oxygen decreased to about half of its original value, the active hydrogen decreased slightly, the H/C ratio decreased and, judging by appearance, the molecular weight had greatly decreased.

These observations and data are sufficient to suggest several deductions as to the probable course of events.

1. Oxygen attaches to the rubber molecule in some peroxide linkage.
2. This linkage rearranges to an OH group with the liberation of O.
3. Some of the OH groups join with H and are eliminated as H_2O; hence the lowering of the H/C ratio.
4. The molecule is ruptured during or as the result of one of the above events.

Experimental

Combustion.—The apparatus developed by the Bureau of Standards[2] was used with the following alterations. A Jena Supremax tube was welded to a large Pyrex slip-joint at one end, and this joint was used without lubricant to connect to the purifying train. All combustions were done in air. Generally a platinum boat was used, but undegraded natural rubber was burned without a boat.

Preparation of the Samples.—Sol rubber samples were obtained by fractional precipitation, handled and stored as previously described.[3] The synthetic rubber samples were prepared from purified isoprene by polymerization over Na–K, *in vacuo*. Polymerization was so rapid that cooling was needed to prevent explosions.

Degradation.—Rubber cement (5% in benzene) was placed in an oxygen-filled round-bottom flask, and exposed to sunlight at room temperature. Dry oxygen was fed periodically to make up for the amount used.

Active Hydrogen Determination.—The apparatus was made of sealed Pyrex glass (see Fig. 1), the reaction chamber (a) being an ordinary 300-cc. Kjeldahl flask; the buret (b) was about 7 cc. in capacity and was kept at a known temperature by means of a water circulation jacket.

The reagents used were:

(1) Rubber cement in C. P. benzene. This benzene, which is also used as a wash liquid, must be run as a blank to determine its methane liberation value.

(2) Methylmagnesium iodide in butyl ether, of approximately 1.5 molecular concentration. This reagent is rid of all incidental gases by evacuation and is kept in sealed ampoules containing 7-cc. portions until it is ready to be used. One ampoule is used for each determination.

(3) C. P. triphenylcarbinol, for standardization.

Procedure.—Fill the buret completely with mercury; close the stopcock (c); evacuate the flask completely through (a); place a quantity of rubber cement in (a), such that it will generate from 1.5 to 3.5 cc. of methane; suck it into the flask, and wash (a) with C. P. benzene several times, until the total volume in the flask is about 200 cc. Heat cautiously with a small flame, while evacuating steadily through (a), and shaking vigorously, until the volume is reduced to about 50 cc.; close (b) in such a manner that a small amount of benzene distillate remains above it as a seal. Place the batch of methylmagnesium iodide in (a); reduce it to about one-half of its volume by cautious evacuation, in order to remove any possible gases; allow this reagent to be sucked into the flask, closing (b) just in time to retain a small portion above it as a seal. Heat the mixture cautiously, while shaking frequently; this causes the methane to collect in the side-arm, from where it can be drawn into the buret, together with a small amount of benzene. Close (c), and allow the flask to cool slightly; then reheat with shaking. By watching the ring of benzene condensation rising in the side arm, it is possible to ascertain whether or not more methane is being liberated. Usually two or three successive heatings are sufficient, after which pure benzene reaches the buret. The amount of gas in the buret is then measured, corrected for standard conditions, for benzene vapor and for the previously determined blank.

Summary

It has been shown that natural rubber contains oxygen, while synthetic rubber is oxygen free. This oxygen appears to be of an hydroxylic type, and its quantity corresponds to about one hydroxyl group for each one thousand isoprene units of the rubber molecule.

Rubber has been allowed to oxidize and a mechanism is proposed to interpret the quantitative data recorded.

The Action of Nitric Acid on a Bituminous Coal

BY B. JUETTNER, R. C. SMITH AND H. C. HOWARD

Bituminous coals can be converted almost completely into soluble products by treatment with nitric acid, under such conditions that great internal structural changes probably do not occur. A study of the character of the reaction and the nature of the products formed is of importance from the standpoint of our knowledge of the nature of these coals. Previous work[1] has been limited almost entirely to a study of the action of nitric acid on lignites and brown coals.

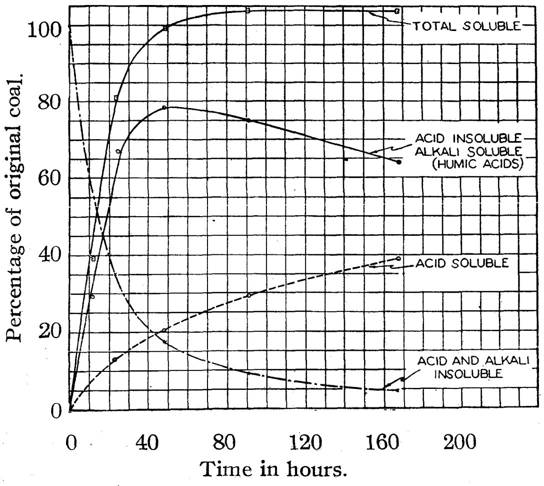

Fig. 1.—Yields of products of the reaction of 1 *N* nitric acid on coal as a function of time.

A preliminary study of the effect of acid concentration on the yield of soluble products, as a function of time showed that even with concentrations as low as one normal, five days' refluxing resulted in conversion of all but a small fraction of the original weight of the Pittsburgh seam coal used[2] into acid or alkali soluble products. At the end of an equal time with 0.1 *N* acid a residue of insoluble material of approximately 46% remained. Since a concentration of one normal appeared to be near the lower limit at which reasonably rapid reaction rates could be obtained, this concentration was chosen for detailed investigation.

Nature of the Reaction

The rates of formation of the products of the reaction, other than gaseous, are shown in Fig. 1. Acid-soluble products increase continuously with time, acid-insoluble, alkali-soluble, the so-called regenerated "humic acids," reach a maximum at about forty-eight hours and then decrease, presumably due to the fact that they are transformed to acid solubles more rapidly than they are formed from the coal. The total soluble material remains quite constant after the initial stages of the reaction are complete, since the principal reaction in the later stages is transformation of humic acids to soluble acids, with apparently little weight change, the decrease in weight due to loss of carbon dioxide during the transformation being approximately balanced by the increased oxygen content of the soluble acids formed.

The distribution of carbon and nitrogen in the oxidation products in a five- and a fifty-two-day oxidation is shown in Table I. It is evident that the reaction is chiefly an oxidation, since such a large fraction of the nitrogen in the nitric acid consumed appears as nitric oxide. The nitrogen in the organic acids decreases with time. Such behavior would be expected if a part of the nitrogen is held at first as isonitroso groups, as Fuchs[3] has suggested, which are removed by hydrolysis during the later stages of the oxidation. Transformation of the carbon of the humic acids to soluble acids with concomitant formation of carbon dioxide as the oxidation proceeds is also shown.

TABLE I

DISTRIBUTION OF CARBON AND NITROGEN IN REACTION PRODUCTS

	5-Day oxidation, %		52-Day oxidation, %	
	C	N	C	N
Humic acids	67.6	9.2	15.0	0.8
Soluble acids	9.2	4.5	33.8	3.1
Carbonic acid	14.4	..	36.2	...
Nitric oxide		82.5		102.0

The work on carbon balances was necessarily done in a closed system. In other oxidations carried out with free access of air to the system it was found that rates of formation of the various

products were approximately the same as in the absence of air, but determination of nitric acid consumed showed that only about one-fourth as much nitric acid was required. The lower oxides of nitrogen first formed in the reaction are evidently converted, in the presence of air, to nitric acid. This indicates the possibility of carrying out such an oxidation with air, using a relatively small amount of oxides of nitrogen as carrier.

Oxidations were also carried out on the residue from a 260° benzene pressure extraction of this coal[4] and on the "cokes" from its thermal decomposition in a molecular still.[5] Acid-soluble products and humic acids were obtained from the oxidation of the extraction residue as in the oxidation of the original coal. The rate of oxidation, however, was considerably greater, as can be seen by comparison with Table I, a five-day oxidation of the residue yielding 57% of the carbon as humic acids, 13.7% as soluble acids, and 22.2% as carbon dioxide. The reaction products from oxidation of the cokes were not examined in detail, but it was found that in the oxidation of cokes prepared up to about 440°, the yield of soluble products was the same as for the original coal within the limits of error in the analytical method. In Fig. 2, yields of soluble oxidation products from the cokes, determined by difference, gas evolution and tar recovered during the vacuum carbonization, have been plotted. Gas evolution is in terms of pressure in the system at a constant rate of evacuation. The strong initial gas evolution at approximately the same temperature at which the coke residue begins to show resistance to oxidation would seem to indicate some fundamental change in the "coal molecule" over this temperature interval. Tar formation, on the contrary, appears to be relatively independent of any critical range.

Nature of the Products

If the oxidation proceeds for only a few days the chief product is, of course, the dark brown, colloidal humic acids. These regenerated humic acids are similar in composition and general properties to those extracted directly from peat and brown coal. They contain carboxyl and hydroxyl groups, but the latter in definitely smaller proportions than has been reported for humic acids from other sources. For acids from typical German brown coals,[6] the ratio of hydroxyl to carboxyl is given as 1.2, 3.9 and 2.6; for acids[7] from an Italian lignite and a peat 0.87; for those[8] from an Ontario lignite, 2.0; and for acids[8] prepared from sucrose, 1.0. The corresponding figure for the acids from this coal is 0.3 to 0.4.

As in the case of humic acids from other sources,[9] only from a half to two-thirds of the oxygen in these acids can be accounted for in specific groups (see Table II); the balance probably is in ether linkages. The amount of this oxygen of unknown form corresponds approximately to the oxygen of the original coal, thus indicating the presence of a relatively stable oxygen-containing unit both in the coal and in the acids regenerated from it.

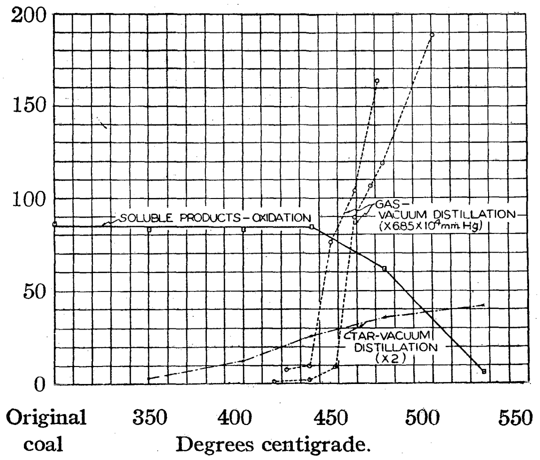

Fig. 2.—Yields of soluble oxidation products from the cokes, gas evolution and tar formation during vacuum pyrolysis as a function of temperature.

If the oxidation is carried on for several weeks, water-soluble, non-volatile acids to the extent of 35–40% of the weight of the coal can be recovered, forming a pale yellow to orange-red, amorphous, highly hygroscopic mass. These acids are lower in carbon and higher in oxygen than the humic acids, the average empirical composition for typical preparations, calculated on the basis of six carbon atoms, being $C_6H_{3.6}O_{4.8}$ for the former, and $C_6H_{3.8}O_{2.2}$ for the latter. A comparison of typical preparations of the two kinds of acids is made in Table II. The soluble acids are definitely smaller in molecular and equivalent weights, contain on the average only small amounts of

hydroxyl, and nearly all the oxygen found by ultimate analysis can be accounted for in carboxyl groups. We have observed that whether the attack on coal be made by hydrogenation or oxidation, soluble, crystallizable or distillable products are obtained only when this non-determinable oxygen is largely eliminated, thus indicating the importance of the role played by this element in the coal polymer.

The presence in the soluble acids of mellitic and benzene-pentacarboxylic acids was shown by isolation of their methyl esters. The amount of ester recovered was in each case less than 1% of the weight of the coal. German workers,[10] by oxidation of brown and bituminous coals, with oxygen under pressure and with nitric acid, obtained similar soluble acids from which they isolated various benzene carboxylic acids from benzoic to mellitic. The maximum yield of pure benzenoid acids reported was 10.4 g. per 100 g. of coal. Bone[11] and his co-workers state that alkaline permanganate oxidations of English bituminous coals yield 39–46% of the carbon as "crude benzenoid" acids, approximating the tricarboxylic in composition and corresponding to 65–81 g. of crude acids per 100 g. of coal. No figures are given on the actual quantity of pure acids isolated.

It was recognized that the isolation, in good yields, of the individual benzenoid acids from a mixture of the twelve possible, constituted a very difficult problem, hence some more general criterion of the benzenoid nature of these products was sought. Since they all contain the benzene ring as a nucleus, decarboxylation followed by recovery of the benzene formed appeared suitable.[12] Fischer's[13] method of heating the sodium salts with water to high temperatures under pressure was studied with the following known acids: benzoic, the three phthalics, and one each of the tri and tetra acids and the penta. With small samples, $^1/_{16}$ mole, recoveries ranged from 56% with iso-phthalic to 73% with benzoic. With a 1 mole sample of benzoic acid the recovery of benzene was 94%. Application of this method of decarboxylation to the soluble acids obtained in our work yielded approximately 10 cc. of steam-volatile hydrocarbons per 100 g. of acids, corresponding to 9 g. per 100 g. of coal oxidized to soluble acids. Fractionation of these hydrocarbons yielded 40% boiling in the range of benzene, 78–81°, of refractive index 1.496 at 25°. Solid hydrocarbons denser than water appeared in the higher fractions, indicating the presence of aromatic nuclei more complex than the benzene ring. This material contained diphenyl, which also appeared, in small amounts, in the decarboxylation of the known benzenoid acids, and presumably is the result of secondary reactions of the benzene. The residue in the bomb after a decarboxylation smelled strongly of cresol and of aromatic organic bases, and about 2.5% of a tarry residue was recovered by extraction with ether. If all the steam-volatile hydrocarbons are assumed to be benzenoid, approximately one-tenth of the carbon in the coal oxidized to soluble acids was recovered in the form of C_6 rings.

The gas, approximately 20 liters of which was recovered per 100 g. of acids, consisted of 25% methane, 60% hydrogen, and small amounts of ethane and unsaturates. The presence of considerable amounts of the lower aliphatic hydrocarbons and hydrogen, in the gases from decarboxylation, would indicate the presence of aliphatic acids such as oxalic, malonic and succinic, which were, however, not found; hence it appears these gaseous products must have come from the thermal decomposition of acids of more complex nucleus.

Experimental

Determination of Yields of Oxidation Products.—For determination of the rates of formation of the non-volatile oxidation products, 0.5-g. samples of 200 mesh coal[2] were refluxed with 100 cc. of 1 *N* nitric acid in 250-cc. round-bottomed Pyrex flasks connected to water condensers by ground joints. At the end of the determined period the contents of the flask were filtered through weighed Jena fritted glass crucibles with asbestos pads. The insoluble material was thoroughly washed with 1 *N* nitric acid, filtrate and washings evaporated to dryness on the water-

bath in weighed porcelain dishes and finally dried at 110° and weighed. This material constituted the yellowish-orange soluble acids. The acid-insoluble material in the Jena crucibles was dried at 110°, weighed, and then thoroughly washed with cold concentrated ammonium hydroxide. By this means the dark brown, acid-insoluble, alkali-soluble humic acids were extracted. This extraction, however, was never entirely complete; air oxidation continuously formed traces of soluble products during the extraction operation. The acid and alkali insoluble material remaining in the Jena crucibles was dried again at 110° and the weight of humic acids determined by difference. In the experiments on the oxidation of the cokes, the same method was used as for coal, except acid and alkali soluble products were removed in one step by treatment with concentrated ammonium hydroxide, followed by centrifuging and filtration, and the insolubles determined at once by drying the insoluble residue at 110°. Total soluble material was then obtained by difference. In all cases duplicate determinations were carried out, and the agreement was usually within 5 parts per 100.

In those experiments where gaseous products were recovered, to obtain carbon and nitrogen balances, oxygen was completely eliminated from the system by evacuation followed by flushing with nitrogen. The tube for collection of gas samples was sealed directly to the top of the reflux condenser and delivered through the usual U bend immersed in mercury, into mercury filled gas sampling tubes. No attack on the mercury was observed as long as oxygen was carefully excluded. Analyses of gaseous products were made in an Orsat apparatus using standard methods for carbon dioxide, unsaturates, carbon monoxide, hydrogen and methane. Nitric oxide was absorbed in freshly prepared acidified ferrous sulfate.[14] Tests were made for condensable hydrocarbons and nitrous oxide by passage of the gas through a liquid nitrogen trap before absorption in the ferrous sulfate. Negligible amounts of material condensed.

Molecular and Equivalent Weights.—Molecular weights were determined cryoscopically by a technique similar to that already described,[15] the only modification being the use of an atmosphere of dry nitrogen above the fused catechol during the measurements. Equivalent weights were determined electrometrically, using the antimony electrode,[15] and also by the method of Ubaldini and Siniramed,[7] in which the humic acid reacts with a mixture of calcium acetate and carbonate and the evolved carbon dioxide is absorbed and weighed. The latter gave somewhat higher values and the agreement between duplicate determinations was less satisfactory. For a typical regenerated humic acid, values of 233 ± 2 were obtained electrometrically, and 251 ± 4 by the Italian workers' method.

Carboxyl and Hydroxyl Groups.—Carboxyl oxygen was calculated from the equivalent weights. Hydroxyl groups were determined by exhaustive methylation followed by alkaline hydrolysis of the ester methoxyl and a volumetric microdetermination[16] of the unhydrolyzable methoxyl. Several methods of methylation were employed; diazomethane, dimethyl sulfate plus 40% alkali, and Waliaschko's[17] procedure of rubbing the potassium salt in a mortar with dimethyl sulfate. The last gave the highest results, both for total methoxyl and ether methoxyl. Hydroxyl groups in humic acids can also be estimated indirectly by the difference between the carboxyl content, calculated from equivalent weights, and the total acidity carboxyl plus phenolic hydroxyl, determined by the method of Ubaldini and Siniramed.[7] Two determinations for oxygen in hydroxyl in a typical humic acid preparation gave an average of 3.4% by this difference method, compared with an average of 2.2% determined by methylation and hydrolysis.

Examination of the Soluble Acids.—To obtain sufficient amounts of the soluble acids to attempt the isolation of individual compounds, larger quantities of coal were oxidized. In order to avoid handling large volumes the ratio of coal to acid was considerably increased, up to about 7 g. per 100 cc. of acid, and the nitric acid concentration maintained by the addition of fresh acid when required, as determined by periodic titration with standard alkali of small aliquots from the reaction mixture. After a suitable period of oxidation, thirty to sixty days, the insoluble material was separated by sedimentation and filtration and washed with water until peptization started. Filtrate and washings were concentrated to a small volume on the water bath at pressures of 10 to 20 mm. and finally freed completely of nitric and other volatile acids by prolonged evacuation at 50°, using a Megavac pump behind a liquid nitrogen trap. In two experiments of thirty-two days' duration, 33 and 34 g. of acid solubles per 100 g. of coal were recovered. The dried, ground acids were exhaustively extracted in a Soxhlet with ether, acetone and finally methyl alcohol. Approximately 40% of the material did not dissolve. Methylation of the soluble acids with an ether solution of diazomethane, in the usual manner, followed by distillation in a molecular fractioning still, up to bath temperatures of 300°, yielded 10.8 g. of distillable esters per 100 g. of coal. No pure compounds have yet been isolated from these mixed esters.

The esters of mellitic and benzene-pentacarboxylic acids were isolated as follows: 100 g. of the dried, ground acids was treated with 1 liter of concentrated ammonium hydroxide at 0° for an hour. The insoluble ammonium salts were filtered off and treated with an excess of barium hydroxide solution, at the boiling point, until all ammonia was displaced. The barium salts were filtered off, the acids liberated with dilute sulfuric acid, using brom thymol blue indicator, were separated, methylated with diazomethane and the esters fractionated as before. From the fraction evaporating at a bath temperature of 220–300°, pressure of about 1 micron, 1 g. of the methyl ester of mellitic acid, m. p. 187.4°, and 0.2 g. of the benzenepentacarboxylic methyl ester, m. p. 147.9°, were isolated. *Anal.* Hexamethyl mellitate. Calcd.: C, 50.71; H, 4.23. Found: C, 50.68; H, 4.26. Pentamethyl ester of benzenepentacarboxylic acid. Calcd.: C, 52.18; H, 4.34. Found: C, 52.34; H, 4.69. The identity of the penta compound was confirmed by a mixed melting point with the ester prepared by the action of ethereal diazomethane on a sample of Eastman benzenepentacarboxylic acid. The appearance of the penta acid along with the mellitic was

unexpected, since it is only the latter which forms an insoluble ammonium salt. It is probable that the amount of the penta acid recovered represents only a small fraction of that present.

Decarboxylation.—One hundred grams of the dried acids, 200 g. of sodium hydroxide, and 100 cc. of water were placed in a 1-liter American Instrument Company bomb furnished with a nickel liner. The temperature was raised to 450° in about four hours, maximum pressure 3800 lb. After cooling, and withdrawal of a gas sample, the pressure head of the bomb was replaced by a head carrying a delivery tube for attachment to a water condenser and an inlet for steam. The steam-volatile hydrocarbons, after passage through the water condenser, were collected over a strong calcium chloride solution acidified with hydrochloric acid, and measured in a small buret calibrated to 0.05 cc. After further drying over anhydrous calcium chloride the hydrocarbons were fractionated through a 51-cm. vacuum jacketed column.

The volume of gaseous products formed in the decarboxylation was calculated from the pressure and volume of the system and their composition determined in an Orsat apparatus by standard methods.

Acknowledgment.—The authors are indebted to F. C. Silbert and T. B. Smith for determinations of ultimate composition, and to J. M. Scott for gas analyses.

Summary

The action of dilute (1 N) nitric acid in converting bituminous coal into soluble products has been shown to be chiefly an oxidation. The yield of humic acids reaches a maximum in a few days, while that of the soluble acids increases slowly with time. If the reaction is carried out in the presence of air, only about one-fourth as much nitric acid is consumed as in its absence.

The residue from the benzene pressure extraction of this coal oxidizes more rapidly than the original coal. Oxidation of the cokes obtained by thermal decomposition of the coal in vacuum shows no difference from the original coal with cokes up to about 440°. Cokes prepared above this temperature show markedly greater resistance to oxidation. It has been pointed out that this temperature coincides with that at which gas evolution becomes rapid.

Determinations of ultimate composition and functional groups on both types of acids formed in this oxidation show the regenerated humic acids to contain markedly less hydroxyl than is reported for other humic acids, while the soluble acids contain negligible amounts. In the humic acids only approximately half the oxygen determined by ultimate analysis can be accounted for in functional groups, while in the soluble acids only small amounts of oxygen are thus unaccounted for. The presence, in the soluble acids, of benzenepentacarboxylic and mellitic acids was shown by isolation of their esters. Of the carbon of the coal which was oxidized to soluble acids, approximately one-tenth was recovered as steam-volatile, aromatic hydrocarbons, by decarboxylation. The presence of acids more complex than the benzene carboxylics is indicated.

NOTES

Decomposition of *p*-Iodoaniline

BY F. B. DAINS, R. Q. BREWSTER AND JOHN A. DAVIS

A sample of *p*-iodoaniline was prepared and carefully purified by one of us.[1]

The product stood for three years in a glass-stoppered bottle (hence a limited supply of air) in semi-diffused light, at room temperature; it had then changed to a black liquid, which was found to contain a trace of free iodine and a small amount of aniline. Further examination showed the presence of 2,4-diiodoaniline and unchanged *p*-iodoaniline. The *p*-iodoaniline was removed as its hydrochloric acid salt by extraction of the liquid with hot, dilute acid. The salt crystallized from the solution as it cooled and the free base was liberated with alkali and recrystallized from ligroin, b. p. 90–100° (m. p. 62°). The 2,4-diiodoaniline was extracted from the acid insoluble residue with hot alcohol leaving a black insoluble mass, some 80 g., which was not identified. Dark needles of the 2,4-diiodoaniline crystallized from the alcohol as it cooled. These, when recrystallized from ligroin, gave a light tan colored product (m. p. 95°). In all, 95 g. of 2,4-diiodoaniline

The Reaction of Ethylene Oxide with Acetylenic Grignard Reagents

BY JAMES P. DANEHY, RICHARD R. VOGT AND J. A. NIEUWLAND

Recently the preparation of certain acetylenic alcohols by the action of ethylene oxide on acetylenic Grignard reagents has been reported.[1,2] We can now report in a quantitative manner the products obtained from this reaction.

Two moles (192 g.) of heptyne-1 was transformed into the Grignard reagent, treated with a slight excess of ethylene oxide (90 g.) and subsequently hydrolyzed; on fractional distillation under diminished pressure 65 g. of heptyne-1, 95 g. of ethylene bromohydrin and 60 g. of 3-nonyn-1-ol were obtained. The Grignard reagents of hexyne-1 and phenylacetylene when treated with ethylene oxide give analogous products in substantially the same percentage yields.

The Fries–Rosenmund Rearrangement of N-Acetylcarbazole[1]

BY ERICH MEITZNER

3-Acetylcarbazole, in yields not stated, has been prepared by Plant and Williams[2] by heating N-acetylcarbazole with aluminum chloride. Since their method proved to be unsatisfactory, the rearrangement was carried out with nitrobenzene as solvent. With this modification in the conditions, 3-acetylcarbazole may be obtained in yields of 50 to 60%, together with tarry products, carbazole, and the hitherto unknown 1-acetylcarbazole.[3] The complexity of the process is a serious drawback to its use for large scale preparations of 3-acetylcarbazole.

The structure of 1-acetylcarbazole was demonstrated by converting the compound by potassium hydroxide fusion into the known carbazole-1-carboxylic acid.[4] The detection of 1-acetylcarbazole among the reaction products completes the parallelism of this rearrangement to that of acyl phenols to *p*- and *o*-hydroxy ketones.

Experimental

Rearrangement of N-Acetylcarbazole.—Twenty-one grams of N-acetylcarbazole was dissolved in 125 cc. of nitrobenzene, 15 g. of aluminum chloride added (water cooling) and the mixture was allowed to stand for fifteen to twenty hours. The observance of this delay is important, because immediate heating results in increased formation of tar. The mere standing at room temperature does not effect the conversion, however, as was shown by the quantitative recovery of carbazole when the mixture was worked up according to the process described below. The mixture was then heated in an oil-bath to 110–125° for thirty minutes, decomposed with ice, and the nitrobenzene distilled off with steam. The solidified residue was filtered, dried and dissolved in boiling ethyl alcohol. After filtration from an insoluble residue, the solution was evaporated to small bulk. About 12–13 g. of crude 3-acetylcarbazole (m. p. 155–160°) separated at this point. This product was purified by recrystallization from toluene, or sublimation at 170–180° and 10^{-2} mm. It forms snow white prisms, m. p. 167–168°. (3-N-Diacetylcarbazole melts at 156°; Plant and Williams, 153°.) The mother liquors were evaporated and the residue, after removal of some nitrobenzene, distilled at 170° and 10^{-2} mm. The distillate consisted of 3- and 1-acetylcarbazoles, carbazole and a yellow compound which proved to be *m*-dinitrobenzene, undoubtedly present as an impurity in the nitrobenzene used. This mixture was distilled at 130° and 10^{-2} mm.

The residue consisted chiefly of 3-acetylcarbazole, while the distillate was largely a mixture of 1-acetylcarbazole and carbazole, with a small amount of dinitrobenzene deposited farthest from the source of heat. The mixture of 1-acetylcarbazole and carbazole was sublimed at 110°, 10^{-2} mm., and the fine white sublimate of carbazole separated mechanically from the yellowish prisms of 1-acetylcarbazole. The sublimation and separation was repeated and the products recrystallized from ethyl alcohol.

1-Acetylcarbazole crystallizes in fine white needles of m. p. 136°.

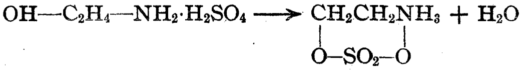
The Preparation of Ethylene Imine from Monoethanolamine

BY HENRY WENKER

In view of the readiness with which compounds containing a β-aminoethyl group can be obtained from ethylene imine, a method may be of interest by which 80 g. of this base can be prepared conveniently in the laboratory in one day from inexpensive commercial material. The process consists, firstly, in preparing β-aminoethyl sulfuric acid[1,2] by thermic dehydration of monoethanolamine acid sulfate according to the equation



$$OH{-}C_2H_4{-}NH_2\cdot H_2SO_4 \longrightarrow \begin{array}{l} CH_2CH_2NH_3 + H_2O \\ \;|\qquad\;\;| \\ O{-}SO_2{-}O \end{array}$$

secondly, in distilling this compound with alkali.

An equimolar mixture of monoethanolamine and sulfuric acid is heated rapidly over a free flame until, at a temperature of about 250°, charring begins, necessitating the end of the operation. Only 75% of the mole of water indicated by the formula can be expelled since, irrespective of the rate of heating, the product begins to turn brown rapidly when this degree of dehydration has been reached. As much as 10 moles—610 g., of monoethanolamine and 1020 g. of 96% sulfuric acid—may be used for one operation. On cooling, the thin, clear brown liquid solidifies to a hard, white crystalline cake. It is ground in a mortar with one-half its weight of 60% ethanol, filtered by suction and washed with ethanol; yield, 100 g. per mole of starting material or 71%. It is convenient to dilute both components with their own weight of water previous to mixing, and then to boil off the excess of water.

282 grams of β-aminoethyl sulfuric acid is distilled with 880 g. of 40% caustic soda solution from a 3000-cc. flask. Shortly before the boiling point is reached, a reaction occurs which keeps the mixture boiling for several minutes; during this time, heating must be discontinued. When the reaction ceases, heating is resumed and a total of 240 cc. is distilled over. One distillation requires about forty-five minutes. On addition of potassium hydroxide to the distillate, 65 cc. of base separates; this is dried repeatedly with potassium hydroxide, then with sodium, and finally fractionated. The use of an efficient distilling column is recommended since the crude base contains higher boiling by-products; yield, 23 g. of ethylene imine boiling at 55–56.5° or 26.5%.

An All-Glass Valve

BY JOHN WILLARD

An all-glass valve for use in systems where stopcocks are objectionable is illustrated in Fig. 1. It is easily constructed and may be opened and closed by merely heating a quartz tube which surrounds a fine Pyrex capillary. It is particularly useful for admitting a corrosive but thermally stable gas from a reservoir to a reaction.

The tube D is of quartz, about 6 mm. in diameter. Part C is a quartz-to-Pyrex graded seal and the portion of the device above C is of Pyrex. E is a fine Pyrex capillary. The outlet A is connected to a gas reservoir and the outlet B to an evacuated system to be filled from the reservoir.

A small flame from a hand torch applied to the quartz near the tip of the capillary, when there is only a few mm. greater pressure on the A side than on the B side, will cause the capillary to blow out without affecting the quartz. When pressure has been equalized the capillary may be sealed again by similar application of heat. Repeated openings and closings of the valve may be carried out without difficulty if the capillary is long and fairly small even though it may stick to the side of the quartz tube. During an investigation in this Laboratory this device has been in constant use for several months. As many as twenty fillings have been made with it before it was necessary to seal in a new Pyrex capillary.

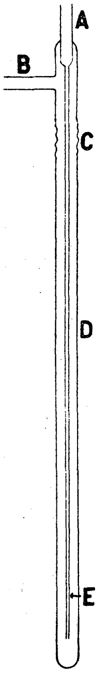

Fig. 1.

Alyea[1] has developed a valve which is similar in purpose to the one here described but which is made completely of Pyrex glass. It is opened by the use of a magnetic pellet and closed by sealing off the outer tube and the capillary together. Other types of greaseless valves are described by

Periodic Classification of the Rare Earths

BY HERMAN YAGODA

Brauner's[1] distribution of the rare earths in the periodic system, Fig. 1, has the disadvantage of placing several of the members into groups where the other elements are chiefly of an amphoteric or acidic nature. Pearce[2] has criticized the classification on the ground that the periodicities observed by Brauner are not connected with the rest of the system. The tendency of these elements to form stable trivalent compounds seems to mask the underlying fact that the properties, of their other valence states, are a periodic function of the atomic number.

Groups	I	II	III	IV	V	VI	VII
8th series	Cs 55	Ba 56	**La 57**	**Ce 58**	**Pr 59**	**Nd 60**	**Il 61**
9th series	**Sm 62**	**Eu 63**	**Gd 64**	**Tb 65**	**Dy 66**	**Ho 67**	**Er 68**
10th series	**Tm 69**	**Yb 70**	**Lu 71**	Hf 72	Ta 73	W 74	Re 75

Fig. 1.

Thus, cerium and terbium are located in the fourth group in agreement with the tetravalence exhibited in their higher oxides CeO_2 and Tb_4O_7. Praseodymium forms two higher oxides, Pr_6O_{11} and PrO_2 in which, according to Prandtl,[3] the metal has a valence of five, in harmony with the position of the element in the fifth group. Again, of all the rare earths only europium[4] and ytterbium[5] form difficultly soluble bivalent sulfates and both elements are allocated to the second group along with the alkaline earths. Evidence for the division of the metals into three series is seen in the variation of the molecular volume of the oxides, Fig. 2, the curve[5a] showing distinct maxima at both samarium and thulium, the initial members of the ninth and tenth series.

If the classification has real significance it should be possible to predict the properties of the rare earth ions in those valency states corresponding with their position in the groups. Thus, Sm^+ and Tm^+ should form difficultly soluble chloroplatinates, Ce^{++++} and Tb^{++++} phosphates, that are insoluble in mineral acids,[5b] in the same way that Eu^{++} and Yb^{++} are now known to form insoluble sulfates.

Molecular volume of the rare earth oxides (R_2O_3).

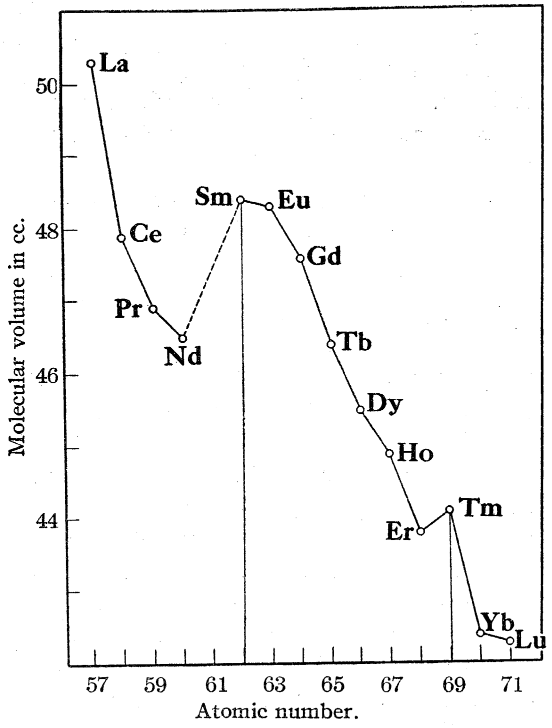

Fig. 2.

Recent investigations[6] reveal that samarium possesses radioactive properties of the same order of magnitude as potassium and rubidium the only elements which exhibit natural radioactivity outside of the members of the three radioactive series.[7] If Brauner's classification of the rare earths is correct, the radioactivity of samarium would seem to indicate that the tendency for nuclear instability in the case of atoms of low atomic weight is centered in the first periodic group. Von Hevesy examined all the members of the rare earths with

the exception of illinium and thulium and concluded that samarium was the only one of the group whose radioactivity persisted after purification.[8] As thulium is classified in the first group, it also may possess radioactive properties of a magnitude comparable with that of samarium. Hence, a study of the radioactivity of thulium preparations is well worth investigating.

COMMUNICATIONS TO THE EDITOR

ATTEMPTED PREPARATION OF VANILLOYLFORMIC ACID

Sir:

In an attempt to repeat the oxidation of apocyanin to vanilloylformic acid with nitrobenzene in alkaline solution as described by H. O. Mottern [THIS JOURNAL, 56, 2107 (1934)] no action whatever was observable under the conditions described by the author. Nitrobenzene was recovered quantitatively from the reaction mixture and neither aniline nor azobenzene was detectable by qualitative means.

Difficulty was also experienced in repeating the author's description of the preparation of apocyanin by means of the Fries reaction. The aluminum chloride double compound with guaiacol acetate is quite solid at the temperatures described (0–5°). Before a third of the required amount of aluminum chloride has been added, the mass is so hard as to be impenetrable to a stirring rod, making it impossible to incorporate the balance. The apocyanin used was prepared by the method for low temperature Fries isomerizations described by Baltzly and Bass [*ibid.*, **55**, 4293 (1933)] which differs from the authors in the use of nitrobenzene as a solvent.

FARMINGDALE, L. I. W. E. BARCH

RECEIVED MARCH 12, 1935

NOTE BY THE EDITOR

After the receipt of this Communication a repetition of the oxidation of apocyanin to vanilloylformic acid with nitrobenzene in alkaline solution as described by H. O. Mottern was attempted by a member of the Editorial Board and independently by the Director of Research of a firm manufacturing vanillin on a large scale. Both were unsuccessful; their concordant conclusion is expressed by the latter's statement: "The synthesis of vanillin cannot be carried out following the disclosures of the paper published in THIS JOURNAL, 1934, page 2107."

OCTOBER 10, 1935 ARTHUR B. LAMB, *Editor*

THERMAL DECOMPOSITION OF $CrO_4 \cdot 3NH_3$

Sir:

Some unusual observations recently made in this Laboratory, and which we hope to study in greater detail, should prove of considerable general interest. While attempting the preparation of the tetroxide of chromium, CrO_4, by deammonating $CrO_4 \cdot 3NH_3$ (I) [made according to Riesenfeld, *Ber.*, **38**, 4070 (1905)], the following was noted. (1) Compound (I) loses practically no ammonia upon standing for four months over concentrated sulfuric acid *in vacuo* and at room temperature. (2) If the pressure in a tube containing some (I) is reduced to less than 1 mm. and the tube, still attached to the vacuum line, is immersed in a bath whose temperature may be controlled, a vigorous reaction ensues at 120 ± 10°. Particles of (I) become incandescent and dart about in spectacular fashion. The action is reminiscent of the thermal decomposition of ammonium dichromate and also of certain models that have been constructed to portray molecular motion in gases. (3) The solid residue of the above mentioned decomposition of (I) is composed of microscopic, elongated square prisms of black $CrO_3 \cdot NH_3$ (II). Analysis of (II) for ammonia was made by distilling into standard acid and for chromium by forming lead chromate. The results for samples of (II) obtained from two different experiments are:

Cr found		NH_3 found	
44.50%	Run 1	14.45%	Run 1
44.39		14.47	
44.47	Run 2	14.49	Run 2
Mean 44.46		Mean 14.47	

Cr calcd., 44.44 NH_3 calcd., 14.55

This compound has not been reported previously and unlike the parent substance gives no test for the peroxide group. (4) The presence of small amounts of impurities has a marked influence upon the rate of decomposition of (I), in some cases increasing it to the point of explosive violence (danger!). In some of our experiments (I) was purposely left impure and may have contained ammonium chromate, dichromate or perchromate. (5) The reaction does not proceed under the conditions mentioned in (2) if carried out in the dark or near-dark. Radiation, in or near the visible, is apparently essential to start the reaction. (6) If the starting pressure in the tube be approximately 1 cm., (I) decomposes in the same scintillating manner as under (2) but the product gives the peroxide test and its composition is variable (37–38% Cr, 21–22% NH_3), lying between that of (I) and (II). It probably consists of a mixture of the latter two. (7) The density of (II) is 2.073 g./cc. at 23.5°. It is practically insoluble in carbon tetrachloride, stable in air under ordinary conditions, and hydrolyzed in water. It detonates in the neighborhood of 200° in the atmosphere, leaving Cr_2O_3.

It is interesting to note that (II) may be formulated as a partial dehydration product of ammonium dichromate: $(NH_4)_2Cr_2O_7 = 2CrO_3 \cdot NH_3 + H_2O$, and that neither ammonium dichromate nor chromate shows any sign of reaction under the conditions mentioned in (2).

THE PHOTOLYTIC AND THERMAL DECOMPOSITION PRODUCTS OF AZOMETHANE. THERMAL REACTION RATES IN QUARTZ, 260 TO 290°

Sir:

Pressure readings at room temperature, −78.5 and −183° at various stages of decomposition of initially pure azomethane show that (1) upon complete decomposition the pressure is approximately double the initial pressure of azomethane; (2) the ratio of the pressure increase at room temperature to the pressure of "permanent" gases formed by the reaction however, diminishes from a value of at least two, in the initial stages, to unity at complete decomposition. A plausible assumption to explain these facts is that the products include, with nitrogen, other "permanent" gases consisting largely of methane. This tentative conclusion is being tested by chemical analysis.

The above observations hold for both photochemical decomposition at 30° and for thermal decomposition at 300°. The course of the thermal reaction at 300° was unaffected by mercury vapor at a pressure of 100 mm. approximately, when this was intentionally introduced.

The thermal reaction rates in quartz fit the unimolecular formula, like Ramsperger's, but our rate constants are roughly half as great as his. The decomposition in Pyrex is being investigated.

The ten-degree temperature coefficient from the dark reaction rates at 260, 270, 280 and 290° is 2.9, in agreement with that of Ramsperger, and apparently affected but little by the presence of mercury vapor.

SEPARATION OF GUANIDINE AND METHYLGUANIDINE BY MEANS OF BETA-NAPHTHALENESULFONYL CHLORIDE

Sir:

In a study of the relation of simple and substituted guanidines to health and disease, occasion came to separate guanidine from methylguanidine. Finding the benzenesulfonyl derivatives, prepared by Ackermann [*Z. physiol. Chem.*, **47**, 366 (1906); **48**, 382 (1906)] unsuitable for the differential precipitation of these guanidines, recourse was had to beta-naphthalenesulfonyl chloride, which was found to give hitherto undescribed derivatives of guanidine and methylguanidine, suitable for the separation of these substances from each other and from other closely related compounds.

Experimental. Di-(β-naphthalenesulfonyl)-guanidine.—To one mol. of guanidine carbonate (1.5 g.) dissolved in 10 cc. of water was added 1.0

cc. of 5 *N* sodium hydroxide. Beta-naphthalenesulfonyl chloride, somewhat in excess of 2 mols. (4.5 g.), was dissolved in 10 cc. of ether, the two solutions were mixed and shaken thoroughly in a separatory funnel. After standing for five minutes, the heavy white precipitate was filtered off and washed with alcohol and ether. The yield was 4.4 g. or 93%. Upon crystallization from hot water, slightly acidified with hydrochloric acid, long, saber-shaped crystals separate rapidly. Similarly shaped but slightly shorter crystals are deposited from hot 95% alcohol. Both sets of crystals melted at 204–206° (uncorrected) apparently without decomposition. After cooling they can be melted again over a broader range, 200–206°. Hydrolysis by 20% hydrochloric acid yields beta-naphthalenesulfonic acid and free guanidine. *Analysis.* Calcd. for $C_{21}H_{17}N_3O_4S_2$: N, 9.56; S, 14.59. Found: N, 9.34; S, 14.47. The desiccator-dried sample contained two moles of water of crystallization, easily removed by heating at 105° in an oven. At 24° 100 cc. of water dissolves 9.0 mg.

Beta-naphthalenesulfonylmethylguanidine.—The procedure used for the guanidine compound yielded no insoluble complex with methylguanidine. A precipitate was obtained with higher alkalinity and a longer period of shaking. One mole of methylguanidine hydrochloride (110 mg.) was dissolved in water and added to a solution of 1 mol. of beta-naphthalenesulfonyl chloride (230 mg.) dissolved in 10 cc. of ether. The mixed solutions were shaken in a separatory funnel after the addition of 2.5 cc. of 5 *N* sodium hydroxide. Shaking was repeated at intervals of five minutes, for half an hour, and the mixture was then allowed to stand overnight. The white crystalline precipitate was removed, washed with alcohol and ether, and dried in a desiccator. The yield was 171 mg. or 65%. Upon crystallization from hot water, slightly acidified with hydrochloric acid, long, slightly curved, branching needles separated rapidly. Similarly shaped crystals are deposited from alcohol. The compound has a greater solubility in alcohol than the guanidine derivative; melting point, 101–102° (uncorrected). *Analysis.* Calcd. for $C_{12}H_{13}N_3O_2S$: N, 15.97; S, 12.18. Found: N, 15.19; S, 12.02. At 24° 100 cc. of water will dissolve 21 mg. Hydrolysis by 20% hydrochloric acid yields beta-naphthalenesulfonic acid and free methylguanidine.

Guanidine yields a di-acylated product whereas the methylguanidine derivative is mono-acylated.

Attempts to prepare insoluble beta-naphthalenesulfonyl derivatives of creatine, creatinine, glycocyamine and glycocyamidine were unsuccessful.

Fifty mg. each of the hydrochlorides of guanidine and methylguanidine were dissolved in 5 cc. of water. With use of beta-naphthalenesulfonyl chloride and a little alkali, the first precipitate was the guanidine complex, rather pure. With increase in alkali, a mixture was obtained readily fractionated and with more alkali and longer standing, the approximately pure methylguanidine complex was obtained. From the original mixture 90% of the guanidine was recovered and with no further attention to maximal yields 45% of the methylguanidine.

NEW BOOKS

Les Carotenoïdes des Animaux. (Animal Carotenoids). By EDGAR LEDERER. Hermann et Cie., Éditeurs, 6 Rue de la Sorbonne, Paris, France. 62 pp. 17 × 25.5 cm. Fr. 15.

This supplements the author's "Les Carotenoides des Plantes," which appeared last year, and resembles it in format, style, typography, etc. In the former volume, the classification of the subject matter was primarily chemical. In the present one, it is zoölogical. Its four chapters discuss (I) Carotenoids of the vertebrates, (II) Carotenoids of the invertebrates, (III) Specific animal carotenoids (asteric and salmenic acids, actinioerythryin, astacin, glycymerin and pectenoxanthin), and (IV) biochemical and biological questions.

The author pays a graceful and well-merited tribute to Palmer's classical book on "Carotinoids and Related Pigments" (Am. Chem. Soc. Monograph Series, Chemical Catalog Co., Inc., New York City, 1922), which he says that he is endeavoring to bring more nearly up to date for the animal carotenoids.

Thanks to the labors of Willstätter, Karrer, Kuhn, Von Euler, Zechmeister and their associates, the chemistry of the phytocarotenoids has been remarkably elucidated within the last year or two. Our knowledge, however, of those carotenoids which are peculiar to the animal kingdom is still meager and often but superficial. In addition to the researches of Karrer, Kuhn and von Euler, Lederer, Lönnberg and Willstaedt have made valuable contributions in this group.

The carotenoids which are peculiar to animals are found chiefly in the invertebrates. Those occurring in the vertebrates are generally only the phytocarotenoids ingested with the food. An admirable résumé is presented of the occurrence of the carotenoids in animals, how various groups of vertebrates differ in the particular carotenoids they store, where they store them and the role they play in the living organism.

The few polyene pigments peculiar to animals are described in detail, together with information as to where they are found in the invertebrates and their possible function there.

The book should be of especial value to those interested in the biological and biochemical problems of the carotenoid field.

MARSTON TAYLOR BOGERT

The Structure and Composition of Foods. Volume II. Vegetables, Legumes, Fruits. By ANDREW L. WINTON, Ph.D., and KATE BARBER WINTON, Ph.D. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1935. xiv + 904 pp. 303 figs. 15.5 × 24 cm. Price, $15.00.

This is the second volume in the series that is being written and illustrated by these authors, the first volume having appeared in 1932. The second volume is divided into two major parts, I, Vegetables, and II, Fruits. Part I is further subdivided into the sections: mushrooms; root vegetables; tuber, corm and rhizome vegetables; leaf and stem vegetables; flower vegetables; and fruit and seed vegetables. In each of these sections the material is arranged by botanical families, and under these, in turn, by genera and species. Part II, Fruits, is also arranged by families, some thirty-five being listed in the table of contents.

An introduction of twenty-four pages has been included, which contains a discussion of the chemical constitution of the principal constituents of vegetables and fruits including proteins, acids, carbohydrates, pectins, pigments and vitamins. In view of the rapid progress that is now being made in the chemistry of these substances, this portion of the book may be out of date long before the remainder has ceased to be a wholly satisfactory source of data.

The Wintons have followed much the same general plan of organization in this volume as in the earlier book. Common and botanical names head each subdivision followed by common names in several foreign languages. Usually a brief historical treatment of the origins and uses of the food in question is followed by a discussion of its macroscopic and microscopic structure. Over 300 figures have been included in this connection. These are the authors' original work, and most of them are here presented for the first time.

Then follows in each case a discussion of the chemical composition of the food. This includes not only the conventional proximate analysis, but in addition, specific constituents are often listed, described and the percentages present (when known) are recorded. In the instance of certain of the more common and important foods, the changes in composition during growth, storage and processing are also included.

The book is a veritable storehouse of useful facts, gathered by a thorough combing of the literature. Many of the latest papers, published during the present calendar year, have been consulted and mentioned in the text, which is thus up to date. The material is rendered the more useful and available by an extensive index which includes common and botanical names of the foods, foreign names and constituents.

C. H. BAILEY

Autenrieth–Rojahn, Qualitative chemische Analyse. (Autenrieth–Rojahn, Qualitative Chemical Analysis.) By DR. C. A. ROJAHN, Martin Luther University, Halle-Wittenberg. Third, revised edition. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1935. vii + 233 pp. 12 figs. 16 × 24 cm. Price, RM. 10.

This book has three parts: (I) A Systematic Scheme of Analysis; (II) Reactions of Cations and Anions, and (III) General Part (Theoretical Chemistry).

Part I (67 pages) contains a brief discussion of various types of tests useful in Qualitative Analysis. This general discussion is followed by an outline giving a scheme for the systematic separation of the cations. Mercury falls in the copper group and magnesium with the alkali metals. Superscripts refer to subsequent notes on the reactions and procedures.

Part II (90 pages) gives a selected group of reactions for each ion. The style of presentation is similar to the corresponding part of the well-known text by Treadwell and Hall.

Part III (90 pages) gives in very brief and concise form a review of the entire field of inorganic chemistry. A few of the topics included in this review are: atomic theory, Prout's theory, atomic structure, gas laws, heat of fusion, osmosis, electrolytic dissociation, hydrolysis, thermochemistry, equilibrium constants, catalysis, double salts, complex ions, Werner's theory, stereochemistry of complex compounds. Colloid chemistry, oxidation and reduction, and oxidizing and reducing agents, are put under separate headings following the general review.

C. R. CONARD

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. System-Number 53, **Molybdenum.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 9, Germany, 1935. 393 pp. 17 × 25 cm. Price, RM. 64.

This volume recounts the physical properties and the chemical behavior of elementary molybdenum and of the compounds of molybdenum with other elements of smaller "system-numbers." This includes all the non-metals, chromium and all the metals of the 0 to 5th group of the Periodic Table other than copper, silver and gold.

Molybdenum has in recent years become an important industrial metal and the up-to-date information which this volume affords particularly as regards its physical properties and the complex compounds of molybdic acid is especially welcome.

The collaborators with the Editor, R. J. Meyer, in the preparation of this volume, which appears to maintain the high standards of its predecessors, were Ellen Schön, Emma Haller, Max du Maire, Gertrud Pietsch-Wilke, Karl Becker, Ortwin von Deines. The literature has been covered through 1934.

ARTHUR B. LAMB

Toxikologische Mikroanalyse. Qualitative Mikrochemie der Gifte u. a. gerichtlich-chemisch wichtiger Stoffe. (Qualitative Microchemistry of Poisons and Other Compounds of Medico-legal Importance.) By Dr. L. ROSENTHALER, Professor at the University of Berne. Verlag von Gebrüder Borntraeger, Schöneberger Ufer 12a, Berlin W 35, Germany, 1935. viii + 368 pp. 173 figs. 16.5 × 25.5 cm. Price, RM. 25.50; bound, RM. 28.

The term poison is usually applied to substances which are injurious in comparatively small doses. The toxicologist must, therefore, often work with very small amounts of material and his results are qualitative rather than quantitative. The present volume treats of poisons only from the qualitative standpoint.

Microsublimation, microdistillation and microextraction, important procedures in detecting small amounts of poisons, are discussed in detail.

Seventy-six pages are devoted to inorganic poisons: chlorine in water, chlorates, bromine, fluorides, nitrites, phosphorus, hydrogen sulfide, selenium compounds, carbon monoxide, arsenic and antimony compounds, ammonia in the air, lead (Fairhall's methods) in blood, urine and various organs; copper, manganese, mercury, thallium, bismuth, etc.

One hundred and twenty-seven pages are devoted to non-alkaloidal organic poisons: methanol and ethanol (including Gettler's methods), aldehydes, phenols, organic acids and their esters, cyanogen compounds; halogen derivatives ("Avertin," chloral hydrate, etc.); thyroxin; barbiturates (fourteen pages), anilin derivatives, saccharin, organic arsenic derivatives (arsphenamine, etc.).

One hundred and twenty-one pages are devoted to alkaloids, glucosides and similar compounds.

Methods for the detection of blood and semen are also discussed.

There are 170 excellent figures of crystals.

REID HUNT

Neuere massanalytische Methoden. (New Methods of Volumetric Analysis.) By Dr. E. BRENNECKE, Prof. Dr. K. FAJANS, PROF. DR. N. H. FURMAN and PRIV.-Doz. Dr. R. LANG. Foreword by Prof. Dr. W. Böttger. Ferdinand Enke Verlag, Hasenbergsteige 3, Stuttgart-W, Germany, 1935. xi + 211 pp. 15 figs. 16.5 × 25 cm. Price, RM. 18; bound, RM. 19.80.

This publication is the 33rd volume in the series of monographs on Analytical Chemistry founded by B. M. Margosches. The present volume was edited by Wilhelm Böttger and contains six sections. These cover some of the more recent activities in analytical chemistry, each chapter being the work of a specialist in the field under discussion.

Chapter I (19 pages) on the Elimination of Titration Errors in Acid and Alkali Titrations, Chapter IV (21 pages) on Chromous Solutions as Reducing Agents in Volumetric Analysis, and Chapter V (44 pages) on Oxidation-Reduction Indicators were prepared by Erna Brennecke.

Chapter II (23 pages) on Ceric Sulphate as an Oxidation Agent in Volumetric Analysis is the work of N. Howell Furman.

Chapter III (52 pages) on Iodate and Bromate Methods and Bromometric Titrations According to Manchot are presented by Rudolf Lang, and Chapter VI (47 pages) on Adsorption Indicators in Precipitation Titrations was written by K. Fajans.

The monograph has been especially prepared for the purpose of inducing a wider appreciation of these methods, and of their applications in analytical chemistry. This aim has been well met, and the monograph should appeal to all analysts who desire concise summaries of the information that is available to date on the subjects that are covered, or who wish to consider possible applications of the methods in the fields of analysis in which they are working.

G. E. F. LUNDELL

Einführung in die Lehre von den Kolloiden. (**Introduction to the Study of Colloids.**) Edited by Prof. Dr. H. Bechhold, Frankfurt a. M. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1934. vii + 160 pp. 86 figs. 16 × 23.5 cm. Price, RM. 9; bound, RM. 10.

This introductory text of about 150 pages constitutes a novelty in colloid literature, because separate chapters are written by seven different authorities from three countries. It records in revised form a series of lectures given under Bechhold's auspices at the Institute of Colloid Research, Frankfurt a. M., before a general audience.

Instructors in this subject will read the book with curiosity to see what is considered worthy of mention in this brief treatment, and also to observe the attitude taken by the writers toward important questions.

The chapters include an Introduction by Bechhold, preparations by Schwarz, kinetic theory by Hock, surface phenomena by Heymann, properties other than electrical or optical by Hock, electrical properties by Heymann, separation and purification by Erbe, optical properties by Hauser and x-ray results by Brill. An author and a subject index are provided and there are a few references to journal literature. Most of the chapters end with a list of books dealing with the subject. These are mostly (and naturally), but not all, in the same language as the introductory text itself. This book is a valuable and thoroughly modern addition to any colloid library.

James W. McBain

Inorganic Colloid Chemistry. Volume II. By Harry B. Weiser, Professor of Physical Chemistry at the Rice Institute. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1935. xi + 429 pp. 70 figs. 15.15 × 23.5 cm. Price, $4.75.

The first volume of this Treatise dealing with The Colloidal Elements was reviewed last year (Vol. **56**, p. 1254). This second volume supersedes the author's well-known "The Hydrous Oxides" of ten years ago, which has been rewritten and completely revised for the purpose. Professor Weiser is not only producing a readable and authoritative treatise on inorganic colloid chemistry by making a comprehensive survey of the materials in this field, but he is furthering the advance of the subject itself by his clear and critical review of relevant theory and its applications.

The author appears justified in his hope that it will prove useful as a reference work alike to those interested in pure science and those concerned with its industrial applications, and as a text for the study of colloidal phenomena in their relation to this class of inorganic compounds.

James W. McBain

A Course in Inorganic Preparations. By William Edwards Henderson, Professor of Inorganic Chemistry, and W. Conard Fernelius, Assistant Professor of Inorganic Chemistry, The Ohio State University. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York City, 1935. xviii + 188 pp. 24 figs. 14 × 21 cm. Price, $2.50.

This book is intended as a laboratory text for advanced and graduate students of chemistry. In it is described the preparation of over a hundred inorganic compounds, which require the use of fairly simple apparatus and readily obtainable chemicals. In part I (55 pages) the preparations are classified according to the method to be employed; such as crystallization, distillation, electrolytic and others. Part II (97 pages) is concerned with the preparation of types of compounds; for example, binary, intermetallic, oxyacidic, thio salt, oxychloride, to mention only a few. Finally part III goes into the subject of colloids, and after describing preparations illustrating general methods, such things as gels, rhythmic bands and emulsions are taken up with three or more examples of each. In all cases the experimental procedures are described clearly and in some detail. At the end of each exercise are given helpful references to easily available Journals and books, especially those in English. No problems or questions are given, and the amount of theory included is small.

The exercises in part I illustrating general methods are, on the whole, well chosen. The classification of preparations in part II according to types of compounds has its advantages, and certainly the student must learn what the known types are, at some stage or other. But this classification is easily understood and would come more naturally in an elementary course. It seems to us that a classification according to types of reactions, or the rows or groups in the periodic system would be more instructive. The latter would lead to a more extensive knowledge of the chemistry of all the elements, as well as pave the way for the introduction of the elements of atomic and molecular structure. In the former it is natural to emphasize equilibria and thermodynamics. It is true that the body of chemical facts included in the book is considerable, and this is highly desirable; but the principles set forth are few and seem too elementary for advanced students.

It is probably true that freshmen and sophomores find a course in preparations helpful and even stimulating, but when they become juniors, seniors or graduates it is high time for them to realize that the unknown things in chemistry far outnumber the known. Accordingly, at this stage they could be given experimental problems which would lead to the discovery of something new, or would result in providing numerical data of interest and importance. The preparation of the substances needed for the problems would give the knowledge and technique which the experiments in the book under review aim to give. The book might well serve as a handy guide for the preparation of the required substances. But as such, and even for the purposes of a more routine course for advanced students, the number of preparations should be increased and greater variety introduced. As it now stands crystallization and precipitation methods are over-emphasized in the book.

We didn't look for errors in printing. Errors in fact and reasoning are few. The first sentence in the first new paragraph on page 5 is confusing and lacks content. In the last paragraph but one, on page 144, a roughly correct conclusion is drawn, but the thermodynamic reasoning used is wrong.

Our views on advanced courses being what they are, we can hardly recommend the book as a text for more advanced and graduate students. For a course in inorganic preparations of the conventional type, it should prove quite satisfactory. It would also serve as a very useful reference book in courses conducted along somewhat different lines.

DON M. YOST

Die organischen Katalysatoren und ihre Beziehungen zu den Fermenten. (Organic Catalysts and their Relation to Enzymes.) By DR. WOLFGANG LANGENBECK, Professor at the University of Greifswald. Verlag Julius Springer, Linkstrasse 23–24, Berlin W. 9, Germany. 112 pp. 6 figs. 16.5 × 24.5 cm. Price, RM. 7.50.

Enzymes, in the past, have been considered as "vital forces," as "active colloids," or as a new and unknown class of chemical compounds, and have only recently been shown to belong to the general class of proteins. Since the enzymes possess very marked properties not exhibited by other proteins they must possess special chemical structure. What this structure is remains to be determined. Professor Langenbeck points out that there are, in general, two methods of determining structure—degradation into known compounds, and synthesis of compounds of known structure having the same properties as other enzymes. The latter method is that chosen by Professor Langenbeck and the present volume summarizes the results of his work.

The author evidently considers enzymes as examples of homogeneous catalysis and his models thus differ from earlier ones, such as Bredig's, which were colloidal.

The guiding principle has been to start with a compound having slight catalytic activity and to form a series of substituted derivatives. These derivatives having higher activity than the original compound were then further substituted. In this way the activity has been increased in a remarkable way so that, in the case of carboxylase models, the most active substitution product was 4000 times as active as the original compound, methyl amine. The activity of this "synthetic enzyme" is of the same order of magnitude as that of crystalline pepsin. Heavy metal catalysis concerned with oxydase and catalase activity, the catalytic activity of hemin, dehydration of amino acids, and carboxylases have been studied in this way.

The group considered to be responsible for the activity is defined as that group which reacts directly with the substrate. This definition is useful and, in the case of the models, quite definite although in the case of enzymes there is, as yet, no conclusive evidence of such a direct reaction between enzyme and substrate. Substituted groups which affect the "active group" are called "activating" groups. This is also a useful term although, strictly speaking, all atoms in the molecule must affect the activity to some extent.

Theoretically, it should eventually be possible to predict in advance what the effect of any given group should be, just as it is now possible to make predictions as to the effect of substitution on the color of dyes. This will require the preparation of a very large series of derivatives, as Professor Langenbeck clearly realizes. Such a series of compounds should be of the greatest importance for the elucidation of the general theory of homogeneous catalysis as well as for the special case of enzymes.

A study of the reaction kinetics of these models has led to a very interesting equation for enzyme reactions which has the same form as the well-known Michaelis and Menten equation. It differs from the latter in that the reaction between enzyme and substrate (in hydrolytic reactions) is assumed to give rise at once to one of the products, while the enzyme remains combined with the other reaction product. This complex then breaks down, liberating the enzyme.

The book contains detailed description of laboratory technique, as well as the theoretical results, and is a decided addition to the literature of catalysis in general and enzymes in particular.

The Influence of Neutral Salts on the Optical Rotation of Gelatin. III. Effect of the Halides of Lithium, Sodium, Rubidium and Cesium[1]

BY D. C. CARPENTER AND F. E. LOVELACE

Previous communications[2] from this Laboratory have shown that in the case of the halides of potassium, the customary Hofmeister series for anions is observed in their effect on the optical rotation of gelatin held at a constant *p*H on the alkaline side of the isoelectric point. When other uni-univalent salts of potassium[3] are examined, the effect on the rotation is represented by a typical Hofmeister series arranged as follows—$KCNS > KI > KClO_3 > KNO_3 > KBr > KCl$, CH_3COOK, C_2H_5COOK and HCOOK. For uni-bivalent salts we have the series $K_2SO_4 > (COOK)_2 > K_2CrO_4$.

In the work herein reported we have examined the effect of the halides of the other alkali metals to find whether the effect of the halides is a general one and to ascertain the magnitude of the effect of the alkali metal.

Materials and Method

The halide salts used in the experiments to be described were recrystallized several times from water and were either oven dried at 104° for several days or in the case of salts crystallizing as hydrates, dried *in vacuo* over anhydrous phosphorus pentoxide for several days.

The gelatin was the same sample of calfskin gelatin that had been used in previous work. It was de-ashed by electrodialysis and further purified and dehydrated by the method described by Sheppard.[4] A 1.4% stock solution of this purified calfskin gelatin was prepared by swelling 14 g. (dry weight) in water for several hours, warming to 50° for "solution" to take place and cooling to 30°. Before making the volume up to 1000 cc. a measured quantity of 0.1 *N* lithium, sodium, rubidium or cesium hydroxide was added to adjust the *p*H of the gelatin solution to approximately 6.3. The gelatin content of this stock solution was determined by drying a known volume of solution to constant weight at 104° and correcting for the weight of alkali metal contained therein.

In preparing the various solutions for observation of the rotation, varying amounts of the pure anhydrous salts were weighed into a series of small weighed flasks and 25-cc. portions of the stock gelatin solution (*p*H 6.3) added. The total weight of solution in each flask was then brought to 50 g. by adding carbon dioxide-free distilled water. As some of the salts were extremely hygroscopic, precautions were taken in weighing and transferring and in many cases the salt concentration was determined by titrating portions of the prepared solutions with 0.1 *N* silver nitrate solution.[5] To obviate any deleterious effects on the gelatin due to the heat evolved when certain of the anhydrous salts dissolved in water, the flasks were cooled at 0° during this operation. The salt concentration was calculated to a molal basis. From each flask of a series for a given salt, a 200-mm. polarizing tube was filled. It was found advantageous to coat each end of the polarizing tube with vaseline before adjusting the cover glass and to permit a small

air bubble to remain in the tube to obviate strains within the gels, which otherwise would lead to erratic polariscope readings. The polarizing tubes were then placed in the constant-temperature bath at 0.5 ± 0.02° to come to equilibrium. A constant rotation was usually reached after five days, but the readings recorded in the tables for 0.5° were obtained after seven days so as to insure the attainment of equilibrium in all cases.

After a series of readings was completed at 0.5° the tubes were allowed to warm to room temperature and were then placed in the constant-temperature bath at 40° for half an hour for equilibrium to be established before polarizing at this higher temperature. Equilibrium is practically reached after fifteen minutes at 40°.

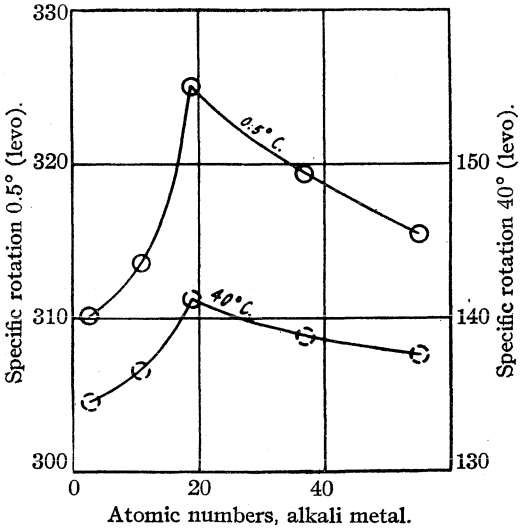

Fig. 1.—Specific rotation of alkali gelatinates.

The pH of the solutions was determined by the quinhydrone electrode, being set up as half cells against a standardized 0.1 N calomel electrode at 25° with a saturated potassium chloride solution as junction. The pH was calculated from the relation $pH = (0.3614 - E)/0.0591$ disregarding corrections for junction potential and for any effect the high salt concentrations may have had upon the quinone–hydroquinone equilibrium within the cell. The pH measurements were made primarily to show that the pH was fairly constant. We have shown before[6] that between pH 6 and 7 the change in rotation at 0.5° caused by increase in pH is not greater than 2%, and as all of our measurements fall well within this limit, pH can have no great effect on our results.

Density determinations were made of all solutions at 25° in a carefully calibrated pycnometer. For the purpose of calculation in this and subsequent articles it is assumed that the density at 0.5 and 40° is the same as that at 25°. The actual error will not be large if this assumption is made and in many cases the density at 0.5° is not experimentally attainable by pycnometer as the solutions are gels.

Specific rotation was calculated from the equation $[a] = (a \times 100)/(l \times d \times p)$ where a is the angle measured, l the length of tube in decimeters, p the grams of gelatin in 100 g. of solution and d the density of the solution. A Schmidt and Haensch triple field polarimeter was used throughout.

Discussion and Conclusions

In Table I are given the data for the specific rotation of the gelatinates of the various alkali metals without added halide salts, and in Fig. 1 these data are shown graphically. It will be seen that the effect of the alkali metal ion on the rotation of gelatin is of minor importance but that the rotation increases with increase in atomic number to a maximum value (potassium) and thereafter decreases. This decrease appears to be connected with the appearance of the shell of eighteen electrons in rubidium and the decrease becomes further augmented with cesium where an additional shell of eighteen electrons is present. Inasmuch as the ratio $[a]^{0.5}_D/[a]^{40}_D$ is practically constant for all of the alkali gelatinates, it is concluded that the effect of temperature on configuration of the gelatin molecule as shown by the rotation, is alike for all of the alkali gelatinates at pH 6–7 and that they are of analogous structure.

Table I

Specific Rotation of Alkali Gelatinates

Alkali metal	Atomic no.	pH	Levo degrees $[\alpha]^{0.5}_D$	Levo degrees $[\alpha]^{40}_D$	$\frac{[a]^{0.5}_D}{[\alpha]^{40}_D}$
Li	3	6.31	310.2	134.6	2.304
Na	11	6.30	313.6	136.6	2.295
K	19	6.36	325.0	141.2	2.301
Rb	37	6.24	319.4	138.8	2.301
Cs	55	6.38	315.1	137.6	2.290

Razukin[7] found that the specific rotation of lithium, sodium and potassium proteinates increased in magnitude with the atomic weight of the metal ion, the order of magnitude of the effect being K > Na > Li. Darmois[8] has found a similar effect on the rotation of tartrates. In the case of the alkali gelatinates we find the magnitude of the rotation to be given by the order K > Rb > Cs > Na > Li at 0.5 and 40°.

As to the effect of neutral salts on the specific rotation of gelatin, our data are recorded in Table II. To present our results clearly and at the same time with economy of space we have shown the results with the lithium halides in Fig. 2. Similar curves are obtained for the halides of each of the alkali metals. In Fig. 3 are collected to-

gether graphs for all of the salts reported in this investigation.

It is obvious from the data and graphs that the principal effect of neutral salts of the uni-univalent type is due to the anion of the added salt. The magnitude of the effect produced by iodides is greater than the effect produced by the bromides, which in turn is greater than the effect produced by chlorides. This order is the same at both temperatures for all of the alkali halides, but the effect on the rotation of gelatin is of much greater magnitude at low temperatures. We therefore conclude that, contrary to the views of Loeb,[9] there is a Hofmeister series for the anions, namely, I > Br > Cl, with all the halide salts of the alkali metals.

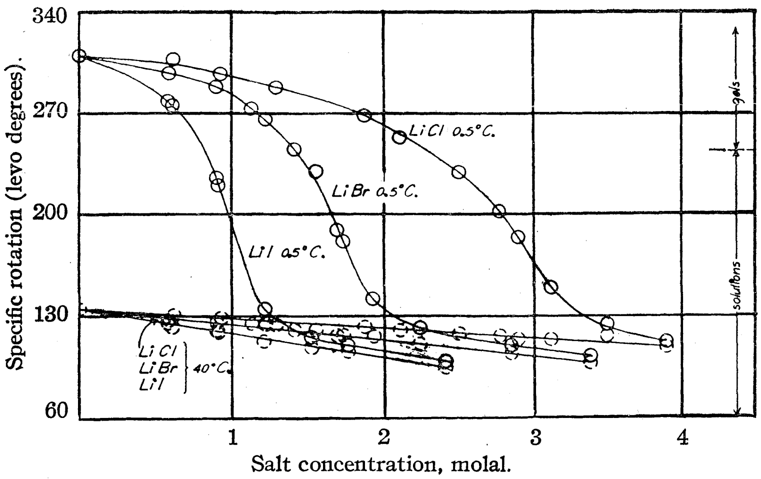

Fig. 2.—Influence of lithium halides on the specific rotation of gelatin.

The data show that there is a very minor effect on the specific rotation of gelatin due to the cation alone, when the alkali metal halides are added. This is more apparent in the case of the chlorides than with the bromides or iodides. The magnitude of this effect can be shown by the following series, Li > Cs > Rb > Na when the concentration of added salt becomes fairly high. The order of this series is practically the same, regardless of the anion in combination with the alkali metal ion, until very high concentrations of bromide and iodide are reached. At this point a slight change in the order occurs.

In experiments which largely concerned the influence of chlorides of various metals on the optical rotation of neutral asparagine, J. Liquier-Milward[10] found that among the alkali metals, the influence was greatest for the metal ion having the smallest radius (LiCl > NaCl > KCl). On account of the fact that no changes in rotation were observed on adding neutral salts to acid solutions of asparagine and none were found with dextrorotatory alanine, (which is largely in the zwitterion form), she ascribed the effect of salts on rotation to a polarization of the asparagine molecule into the zwitterion form. In short she believed the effect of added salt was to produce the zwitterion type of molecule. In acid solutions the NH_2 group is bound to acid and the presence of zwitterion is probably negligible. This fact in any case indicates that the NH_2 group is involved in whatever change in constitution occurs.

Linderstrøm-Lang and Kodama[11] found that the solubility of casein in dilute hydrochloric acid decreased with increasing salt concentration, while Sörensen and Sladek[12] found that the solubility of casein in dilute sodium hydroxide solution *increased* with increasing sodium chloride concentration until the salt concentration was about twice normal. A further increase in salt concentration reduced the solubility of the casein.

(12) Sörensen and Sladek, *ibid.*, **17**, No. 14 (1929).

These last authors concluded that compound formation had taken place between the casein and salt or one of the latter's ions.

As regards solubility of proteins in salt solutions, we have found with gelatin an effect similar to that noted by Sörensen and Sladek for casein. The gelatin–salt mixtures we have used pass from solid gels to fluids at a point where the specific rotation reaches −250°. This critical rotation value is a measure of "solubility" in our experiments. This indicates that the solubility of gelatin has been increased by the addition of salts and that the increase is largely dependent on the halide part of the salt present. The above view is understood not to exclude possible interaction between the ions and solvent and the idea of salting out coefficients.

Carpenter and Kucera[3] called attention to the fact that compounds of the zwitterion type NH_3^+–R–COO$^-$, on account of their electric charges, should suffer a diminution of activity on adding neutral salts and that their solubility should be increased. They suggested that compounds of the type NH_3I–R–COONa might be formed as the result of the operation of electrostatic forces in which the properties of the zwitterion entirely disappeared and in which the activity coefficient of the salt presumably would be considerably less. It is expected that with a linkage of nitrogen to halogen the NH_3I–R–COONa type of compound would be ionized completely into I$^-$ and NH_3–R–COONa$^+$ ions, with the protein bound to the metal as a complex.

It is pointed out that to maintain in solution a structure of the NH_3^+–R–COO$^-$ type it is necessary to assume that a large number of the fields of force associated with the two charged regions mutually form a closed field. Consequently although the zwitterion structure looks as if it were a highly reactive form, capable for instance of forming molecular chains through the operation of electrostatic forces, the fact that this is not the case can only mean that the electrified regions have been largely mutually neutralized. The effect of increase in temperature or the addition of neutral salts might easily be that of opening up the force fields around both electrified regions, so that polymerization of the molecule would be possible. If the polymer had a chain structure NH_3^+–R–COO–NH_3–R–COO$^-$ it is obvious that this would be only the first step toward the formation of a huge chain. Lewis[13] in experimenting on the possible polymerization of glycine, found that a dipolymer was formed in a measurable amount and he concluded that higher polymers were unlikely. The fact that the polymerization only goes as far as the double molecule with simple amino acids suggests that the formation of a ring structure is involved which would appear to be a more stable form on account of the relative absence of free force fields. It is assumed that this reaction would be reversible and that while polymerization due to heat or salts would proceed rapidly, the depolymerization reaction, on the other hand, would proceed much slower due to the greater stability of the ring structure. In the case of the simplest species of casein[14] we have found that heating to 40° while the protein was dissolving in buffer solution changed the molecular weight from around 96,000 to 188,000, an almost exact doubling of the molecular weight. It is possible that gelatin behaves in a similar way in which case, as a choice between the two alternate hypotheses to account for the great change in rotation of gelatin, we would favor that of polymerization to a ring structure.

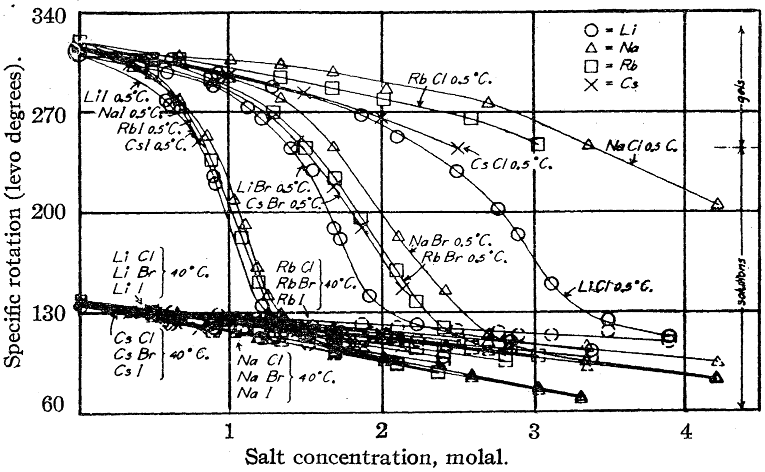

Fig. 3.—Influence of alkali halides on the specific rotation of gelatin.

Summary

The influence of the halides of lithium, sodium, rubidium and cesium on the specific rotation of gelatin at 0.5 and 40° has been examined over the

solubility range of the respective salts. The results confirm our earlier conclusions that there is a definite Hofmeister series of anions (I > Br > Cl) in their effects on the optical rotation of gelatin. There is also a definite Hofmeister series for cations (Li > Cs > Rb > Na) but the effects of cations are much less in magnitude than those of the anions.

In the absence of added salts, the optical rotation of the gelatinates of the alkali metals increases slightly with atomic number to a maximum rotation with potassium, after which the rotation slightly decreases.

The Influence of Neutral Salts on the Optical Rotation of Gelatin. IV. Rotatory Dispersion of Gelatin in Sodium Iodide Solutions[1]

BY D. C. CARPENTER AND F. E. LOVELACE

Despite the large amount of work on the rotatory dispersion of optically active substances there has been comparatively little done on the proteins. Hafner[2] discussed briefly the measurements he made at four different wave lengths in the visible on serum albumin and serum globulin. Hewitt[3] studied several proteins, making measurements at four wave lengths in the visible. Hewitt confined himself to graphing the reciprocal of the specific rotation against the square of the wave lengths and obtained straight lines which showed only that the dispersion may be expressed by a single term of Drude's equation $[\alpha]_\lambda = \sum \frac{k_n}{\lambda^2 - \lambda_0^2}$. From Hewitt's work one would conclude that absorption bands somewhere below 2700 Å. governed the rotatory dispersion of proteins.

Hansen[4] investigated the rotatory dispersion of egg albumin as influenced by protein concentration, concentration of ammonium sulfate added, *p*H and temperature. Hansen was the first investigator to calculate dispersion constants from his data. He concluded that λ_0 was largely independent of *p*H, temperature and concentration of added salt and protein, while k varied under most experimental conditions.

The rotatory dispersion of gliadin has been studied by Haugaard and Johnson[5] at three different wave lengths and by Wiles and Gortner[6] at six wave lengths. In the former paper the workers recognized that the presence of lithium chloride, as well as changes in *p*H, greatly influenced the rotations. They pointed out that the effect of lithium chloride might be due to complex salt formation or to changed conditions of dissociation of the protein or to a combination of these effects. However, their data were more or less fragmentary and evaluation of the dispersion constants was not attempted. Other alkali halides, potassium iodide, potassium bromide and sodium chloride were used by Wiles and Gortner, who confined themselves to showing that a linear relation existed between the reciprocal of the observed rotations and the square of the wave lengths used.

The purpose of the present investigation was to study the rotatory dispersion of gelatin in sodium iodide solutions, primarily to ascertain the cause of the rapid decrease in rotation experienced with iodide salts at low temperatures.

Experimental

In the present work the specific rotations of gelatin solutions at 0.5 and 40° were measured at five different wave lengths in the visible spectrum, *viz.*: red lithium line, λ = 6707.86 Å.; sodium D line, λ = 5892.617 Å. (optical mean); yellow mercury line, λ = 5780.13 Å. (optical mean); green mercury line, λ = 5460.73 Å.; and the deep blue mercury line, λ = 4358.34 Å. A quartz mercury arc lamp was used as the source for all mercury lines and an electric arc between carbons the cores of which were filled with powdered sodium glass or lithium carbonate was the source of the sodium and lithium lines, respec-

tively. To eliminate all lines but the desired wave length the light was passed through either appropriate Corning glass filters or through a glass absorption cell 1 cm. thick containing an appropriate dye solution or through both of these as required to give monochromatic light before entering the polariscope. The filters employed were as follows: Li red line, Corning Red G5 + alkaline solution containing brom thymol blue in cell; Na D line, Corning Green G701C1 + saturated alcoholic solution of Sudan IV in cell; Hg yellow line, Corning Yellow G34-O through which green and blue Hg lines do not pass; Hg green line, aqueous solution of "Light Green SF" dye, 0.1575 gm. per liter, in cell; Hg blue line, Corning Blue G585 through which yellow and green lines do not pass. To ascertain the wave lengths actually transmitted in each case, the light which reached the eyepiece of the polariscope was checked with a spectroscope.

The procedure for preparation of solutions and for measurement of rotations, density, *p*H, etc., was the same as has been described before.[7] The gelatin concentration of these solutions was 0.7704 g. per 100 g. of solution.

Discussion and Conclusions

In Tables I and II are given our data for 0.5 and 40°, respectively, for the various wave lengths employed. In Figs. 1 and 2 these data are shown graphically, plotting the reciprocal of specific rotation against the squares of the wave lengths at which these rotations were obtained. It is seen that the relationship is linear, which means that a single-term Drude equation will adequately express our results. Each straight line on these graphs represents the rotatory dispersion of a gelatin solution containing a definite quantity of sodium iodide.

It will be seen in both graphs that each straight line cuts the *x*-axis at the same point. This point represents λ^2_0 and graphically locates the absorption band of gelatin at 2200 Å. The same numerical value for λ_0 was obtained by solving our data by the method employed by Lowry and Owen.[8] So far as can be found in the visible spectrum the rotatory dispersion of gelatin dissolved in sodium iodide solutions obeys a single term of Drude's law.

That gelatin has a tremendous absorption in the neighborhood of 2200 Å. was observed in this Laboratory several years ago (D.C.C.). Although the head of the absorption band for gelatin could not be definitely determined, the graph of the extinction coefficient for gelatin (curve 2) is

---

(7) Carpenter and Lovelace, THIS JOURNAL, **57**, 2337 (1935).

(8) Lowry and Owen, *Trans. Faraday Soc.*, **26**, 371 (1930).

shown in Fig. 3. In this figure we have also plotted the absorption spectrum of sodium iodide (curve 1) recalculated from the data of Fromherz and Menschick.[9] The head of the absorption band for aqueous sodium iodide is located at 2225 Å. from these data. While the head of the absorption band for gelatin was not definitely determined it seems safe to say that the absorption is very great in the neighborhood of 2200 Å., which agrees with the position of the band calculated from our dispersion data.

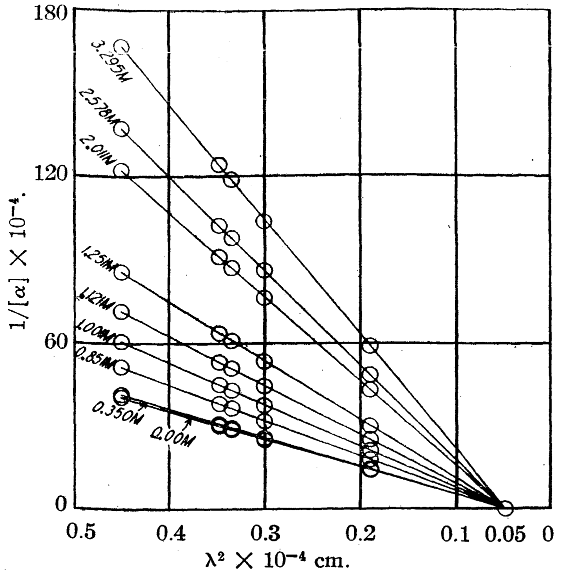

Fig. 1.—Graph of reciprocal of specific rotation *versus* wave length squared at (0.5°).

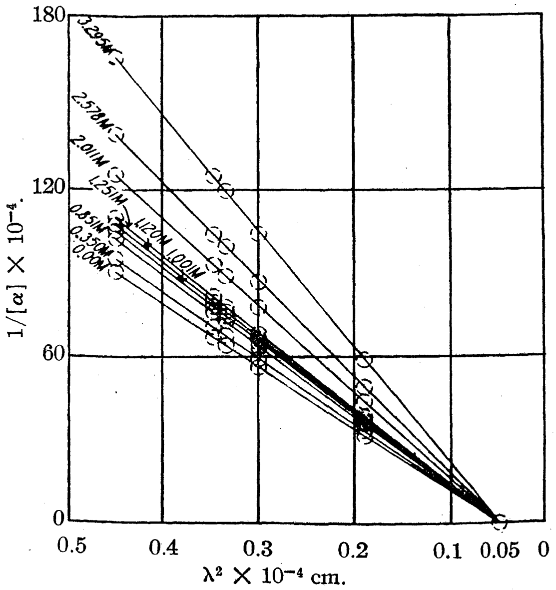

Fig. 2.—Graph of reciprocal of specific rotation *versus* wave length squared at (40°).

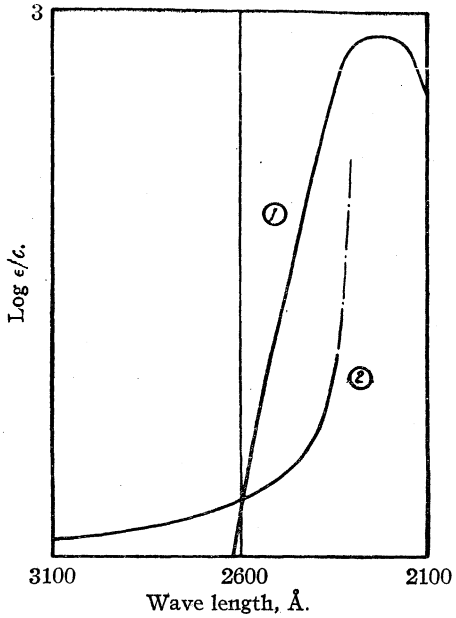

Fig. 3.—Extinction coefficient of aqueous gelatin (2) and sodium iodide solutions (1).

The values of k, numerator in the Drude equation, were calculated for each concentration of sodium iodide and appear in Table III and are graphed in Fig. 4. At 40° the k values bear a linear relation to the concentration of sodium iodide as given by the equation

$$k_{40^\circ} = 44.5170 - 6.220C_{\mathrm{NaI}} \qquad (1)$$

At 0.5° the curve for the k values is made up of two parallel straight lines at the extreme ends as salt concentration is varied, united by a curve which resembles the general type of curve representing a dissociation or association process. In the straight line portion of the curve the k values bear the relation to salt concentration given by the equation

$$k_{0.5^\circ} = 46.3300 - 6.7605C_{\mathrm{NaI}} \qquad (2)$$

and in the rapidly changing part of the curve

$$C_{\mathrm{NaI}} = \frac{1}{2.66} \log \left(\frac{a}{1-a}\right) - \log (1/K) \qquad (3)$$

where a represents the fraction dissociated as shown by the change in magnitude of the dispersion constants $k_{0.5^\circ}$. In Table III are given the a values for the dissociated fraction and the calculated values obtained for log $(1/K)$. The latter agree very well with one another and indicate a mean value of 0.9983.

It is obvious that there will be a log $(1/K)$ value that will be characteristic for iodide and which

---

(9) Fromherz and Menschick, *Z. physik. Chem.*, **B7**, 439 (1930).

will be different in magnitude but equally characteristic for bromides, etc. It is seen from the graphs in the previous paper[7] that the log $(1/K)$ values are approximately 1.0 for iodides, 1.8 for bromides and 3.7 for chlorides (LiCl). The factor $^1/_{2.66}$ preceding the dissociation term regulates how rapidly the dissociation takes place. The numerical value of this factor increases in going from iodides to chlorides, approaching unity in the latter case.

Inasmuch as the rotatory dispersion constants for gelatin at 0.5° in the presence of salts follow a dissociation equation, it is concluded that the transformation from what we have hitherto designated as the "gel" form of gelatin to the "sol" form, is a process of dissociation or association of the gelatin molecule.

TABLE III

ROTATORY DISPERSION CONSTANTS AT 0.5 AND 40°

Soln.	Concn. NaI (molal)	$k_{0.5°}$	a	Log $(1/K)$	$k_{40°}$

$k_{0.5°} = 46.3300 - xC_{\text{NaI}}$ where $x = 6.7605$
$k_{40°} = 44.5170 - xC_{\text{NaI}}$ where $x = 6.220$
mean log $(1/K) = 0.9983$

By the method of determinants, Lucas[10] has developed a formulation from which the number of optically active species in a system may be determined. Lucas' relation is based on the assumption that the active species have different dispersion constants and, of course, would only apply to systems satisfying this requirement. In the case of two active components the equation takes the form

$$k = \left[\frac{[a]_1 - [a]_2}{[a]_1 - [a]_n}\right]_{\lambda_a} = \left[\frac{[a]_1 - [a]_2}{[a]_1 - [a]_n}\right] = \left[\frac{[a]_1 - [a]_2}{[a]_1 - [a]_n}\right]_{\lambda_c} \text{etc.} \quad (4)$$

where $[a]_1$, $[a]_2$ and $[a]_n$ represent the specific rotations of the active material in a related series (with a given salt) at wave lengths λ_a, λ_b, λ_c, etc. In applying Lucas' equation a series of any two pairs may be selected for comparison. If a constant is obtained for different wave lengths λ_a, λ_b, λ_c, etc., it is good evidence that two optically active components and only two are present.

TABLE IV

CALCULATION OF THE LUCAS CONSTANT FOR GELATIN–SODIUM IODIDE SYSTEM CONTAINING TWO OPTICALLY ACTIVE COMPONENTS (0.5°)

Combination[a]	λ6708 Å.	λ5892 Å.	λ5780 Å.	λ5461 Å.	λ4358 Å.

1–7/1–9	.883	.883	.883	.883	.884
1–8/1–9	.931	.931	.931	.934	.932

[a] The numbers in this column refer to corresponding soln. no. in Table I.

We have applied Lucas' method of analysis to our data for the rotation of gelatin at 0.5° and the results are given in Table IV. In the column headed "Combination" is given the combination of specific rotations employed in the various calculations of k, the numbers 1, 2, 3, 4, etc., referring to the same gelatin solutions as given in Table I. It is obvious from the calculated values of the Lucas constant for the five wave lengths, for the systematic series of combinations employed, that a constant is actually obtained for any combination (within the probable error of polariscope readings) as is required for a mixture of two optically active substances. Any other combination that might be chosen would give a similar constancy for the Lucas constant. We therefore conclude that at 0.5° gelatin is converted from one optically active form to another by the action of neutral salt. There appear to be only two optically active species present. This is entirely in harmony with our foregoing conclusion that the two forms are closely related

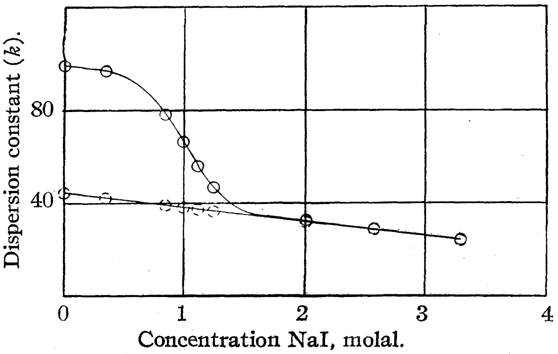

Fig. 4.—Rotatory dispersion constant of gelatin in sodium iodide solutions at 0.5 and 40°.

---

(10) Lucas, *Ann. phys.*, [10] **9**, 381 (1928); *Trans. Faraday Soc.*, **26**, 418 (1930).

to each other, one being a dissociated (or associated) form of the other and also that the associated form is likely a polymer of a ring type resulting from the mutual electrostatic neutralization of zwitterion structures.

Summary

The rotatory dispersion of gelatin has been examined in various concentrations of sodium iodide at 0.5 and 40°, at five different wave lengths in the visible spectrum.

A single term Drude equation was shown to express the experimental results. From calculations it was shown that an absorption band at 2200 Å. governed the dispersion. Absorption spectrum data showed that gelatin has a high absorption in this region.

The rotatory dispersion constants of gelatin at 40° follow the linear equation $k_{40°} = 44.5170 - 6.220C_{\mathrm{NaI}}$.

The rotatory dispersion constants at 0.5° were found to be expressed by the sum of two equations

$$C_{\mathrm{NaI}} = \frac{1}{2.66}\log\left(\frac{a}{1-a}\right) - \log\left(\frac{1}{K}\right)$$

and the linear equation

$$K_{0.5°} = 46.3300 - 6.7605C_{\mathrm{NaI}}$$

It was concluded that the linear effect of salt concentration on the dispersion constant was due probably to a shift in the association of the solvent (hydrol–polyhydrol equilibrium) or an association between solvent and salt, and that the much greater effect of added salt at 0.5° was due to a dissociation or association of the gelatin molecule.

Based on the formulation of Lucas, it was shown that two and only two optically active species exist in gelatin solutions or gels.

The Catalytic Chlorination of Dioxane[1]

BY J. J. KUCERA AND D. C. CARPENTER

According to recent investigations,[2] 1,4-dioxane and 2,3-dichlorodioxane on chlorination without catalysts give poor yields of the tetrachlorodioxanes and particularly of the symmetrical isomers  $O\langle{}^{\mathrm{CHCl-CHCl}}_{\mathrm{CHCl-CHCl}}\rangle O$, which are valuable because of their quantitative yield of glyoxal on hydrolysis. Since preliminary experiments with copper, iron, manganese, nickel, tin and iodine chlorides showed that the two latter substances catalyzed the chlorination most vigorously, we have carried out carefully chlorinations using them.

Technical dioxane was purified by distillation, crystallization and a final distillation over sodium. The purified dioxane boiled at 101.5–101.7° and melted at 11°. The usual method of chlorination was employed, the amount of chlorine absorbed being calculated from the increase in weight of the reaction vessel.

Starting with 78.5 g. of dioxane and chlorinating at a temperature of 90°, a yield of 96.6% of the 2,3-dichlorodioxane was obtained, both with stannic chloride (added as 1 g. of $SnCl_2$) and with iodine chloride (added as 1 g. of I) catalyst. The amount of decomposition was negligible. This yield is considerably greater than that (69%) previously reported in the absence of a catalyst.[3]

In the chlorination of 47 g. of the 2,3-dichlorodioxane at 145° using stannic chloride as a catalyst (added as 0.5 g. of $SnCl_2$), the following unsymmetrical tetrachlorodioxanes were obtained: 37 g., b. p. 96° at 14 mm., and 1 g., m. p. 57–58°, together with symmetrical tetrachlorodioxanes: 12 g., m. p. 70° and 6 g., m. p. 143°. This corresponds to a total yield of 83% and a 32% yield of the symmetrical tetrachlorodioxanes. In the run with iodine chloride (added as 1 g. of I) as a catalyst at 145°, and starting with 81.8 g. of 2,3-dichlorodioxane, 68 g. of the unsymmetrical tetrachlorodioxane b. p. 96° at 14 mm., and 2 g., 21 g. and 10 g. of the symmetrical isomers melting respectively at 60, 70 and 143° were obtained. This corresponds to a total yield of 85% and a 33% yield of the symmetrical isomers. In

(2) Butler and Cretcher, THIS JOURNAL, **54**, 2987 (1932); Christ and Summerbell, *ibid.*, **55**, 4547 (1933); Baker, *J. Chem. Soc.*, 2666 (1932).

(3) Böeseken, Tellegen and Henriquez, *Rec. trav. chim.*, **50**, 909 (1931).

corresponding runs without catalysts total yields of 83 and 33% of the symmetrical isomers were obtained. These experiments show that these catalysts have no influence on either the total yield or the total yields of the symmetrical isomers. This is presumably due to the fact that because of the more elevated temperature required for this reaction, the stannic chloride and the iodine monochloride are volatilized and lost from the reaction mixtures despite the presence of a condenser.

Summary

Iodine and tin chlorides are suitable catalysts for the chlorination of dioxane to 2,3-dichlorodioxane, the yield being almost quantitative. Their use is not adapted to the further chlorination of 2,3-dichlorodioxane to tetrachlorodioxane on account of the high temperatures required for the latter reaction at ordinary pressures. The yields of the various tetrachlorodioxanes produced have been recorded.

The Sourness of Acids

By R. M. Beatty[1] and L. H. Cragg

Many attempts have been made in the past to relate the sourness of acids to various other properties such as their hydrogen-ion concentration, normality, vapor pressure, surface tension, etc., but with little success. A fairly complete survey of the literature up to the year 1926 was made by Dietzel.[2] Several important papers were missed in that discussion and further work has been done on the subject since 1926.[3]

In a preliminary paper, F. B. Kenrick[4] showed that the proportion of a phosphate buffer required to bring the *p*H of various acids of the same molar concentration to a fixed value of about 5 is roughly proportional to the sourness of the various acids alone, the sourness being defined as the normality of the hydrochloric acid solution of equal sourness. From this work it appeared that the sourness of an acid might be determined roughly by titration with a phosphate buffer to the shade of bromcresol green indicator corresponding to *p*H 5. To obtain the relative sourness of the acids Kenrick made use of the table of threshold values given by Paul and Bohnen (see Dietzel[2]) and assumed on the basis of a few experiments that the relative sourness of equimolar solutions was roughly independent of the concentration.

The present research was undertaken to test (a) the validity of this assumption, and (b) the accuracy of the conclusion drawn from the preliminary experiments. The *p*H's and total phosphate concentrations of the buffers used were within the ranges of the values possessed by most physiological fluids, such as saliva and blood serum.

Procedure

Equally sour solutions of various acids were prepared and the *p*H's of these solutions with addition of varying proportions of buffer were determined.

In all experiments (with the exception of those in section 2) hydrochloric acid was used as the standard and each of the other acids was altered in concentration until it had the same sourness as the hydrochloric acid.

The following precautions were taken in tasting the solutions in order to make the comparisons as accurate as possible.

(a) The nose was closed by a pair of balance forceps to prevent the interference of odors.

(b) For the more dilute acids 20 cc. of solution was taken into the mouth for each test and between each the mouth was rinsed with distilled water; in the case of acids which were sour enough to "set the teeth on edge" the tongue was dipped into a crucible of the liquid.

(c) In the final comparisons the effect of personal equation was reduced by placing the solutions in two tubes indistinguishable except for a hidden marking, and recording the decisions before re-identifying the tubes. These comparisons were continued until after seven tests there was no definite preponderance of choice of one as the sourer.[5]

[4] F. B. Kenrick, *Trans. Roy. Soc. Can., III*, [3] **25**, 227 (1931).

[5] Opinions as to the sourness of an acid vary slightly but definitely from one taster to another; consequently, although with accumulated experience (Cragg) small differences such as that between values for acetic acid equisour to 0.0025 *M* HCl (0.0070 in 3b and 0.0065 in 1) can now be reduced, it has been thought advisable to confine the data to the observations of one individual (Beatty in 1931).

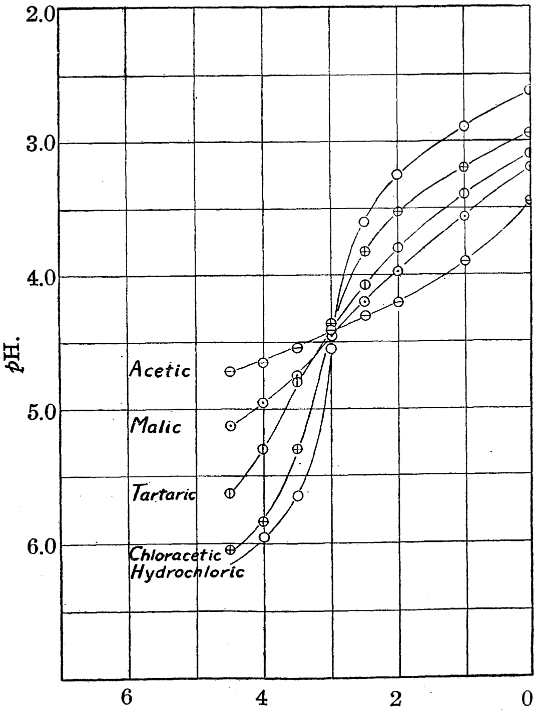
The pH's of the various solutions were determined electrometrically with a Leeds and Northrup potentiometer and a cell of the type

Hg/HgCl, KCl (satd.)/acid solution + quinhydrone/Pt

In some of the experiments a gold electrode was used; it was found that platinum and gold gave the same results, but the platinum required cleaning less frequently.

Experimental Results

1. Various Acids.—Solutions of chloroacetic, tartaric, acetic and malic acids were adjusted by dilution to a sourness equal to that of 0.0025 *M* hydrochloric acid (*M* = moles per liter). These solutions were titrated with a phosphate buffer of pH 6.9, made up as follows: 3.240 g. of sodium dihydrogen phosphate $NaH_2PO_4 \cdot H_2O$, 0.480 g. of disodium hydrogen phosphate $Na_2HPO_4 \cdot 12H_2O$, 10 cc. of approximately normal sodium hydroxide solution, made up to one liter with distilled water. The results are given in Fig. 1.

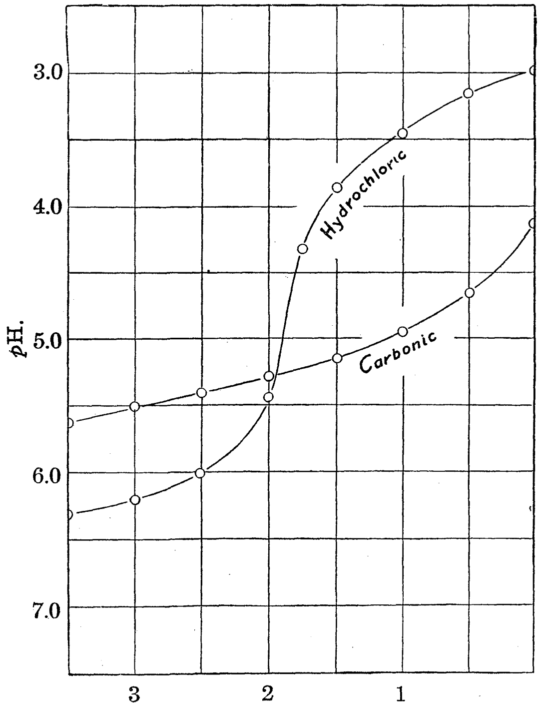


Cc. of buffer (pH 6.9) added to 15.0 cc. of acid.

Fig. 1.—Concentration *M*: hydrochloric, 0.0025; chloroacetic, 0.0028; tartaric, 0.0016; malic, 0.0021; acetic, 0.0065.

2. Saturated Carbon Dioxide Solution.—When comparing hydrochloric acid and carbon dioxide solutions it was found advantageous to adjust the concentration of the hydrochloric acid solution. As the very peculiar taste of carbon dioxide solutions made comparison difficult, attempts were made to imitate the prickling sensation by adding thymol, chloroform, capsicum, oil of cloves, etc., to the hydrochloric acid. Although the prickling could be duplicated to a certain extent in this way, it was found that the sensation gradually increased in intensity so that when enough of the substance in question was added to imitate the immediate sensation characteristic of carbon dioxide solution, the liquid in a few seconds became too painful to retain in the mouth; when less was added the effect was too slow in coming. Attempts to imitate this sensation by supersaturating the hydrochloric acid with nitrous oxide were also unsuccessful. Finally, however, 0.0013 *M* hydrochloric acid was chosen as having about the same sourness as a saturated solution of carbon dioxide (0.0361 *M* from solubility data). The buffer used was the same as in section 1.

The results are shown in Fig. 2. Each point on the curve for carbonic acid was determined with a freshly made solution.



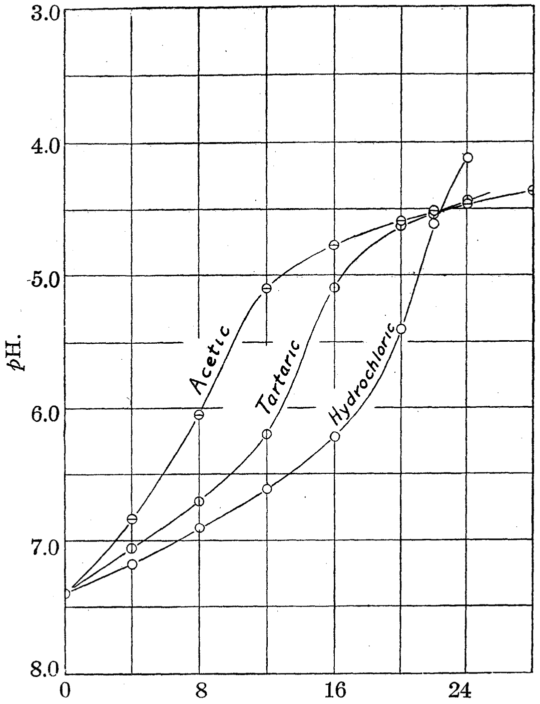
Cc. of buffer (pH 6.9) added to 15.0 cc. of acid.

Fig. 2.—Concentration *M*: hydrochloric, 0.0013; carbonic, 0.0361.

3. Equisour Acid Solutions at Various Concentrations.—In these experiments equisour hydrochloric, acetic and tartaric acid solutions (representative of strong and weak monobasic acids and dibasic acids, respectively) were used with a buffer of pH 7.4, ten times as dilute as that of section 1.[6]

In each set of experiments the concentrations of acetic and tartaric acids were chosen so that the acids were equisour to the hydrochloric acid used in that set. The acids were added to a measured volume of buffer.

The results are summarized in Figs. 3a, b, c, d and e.

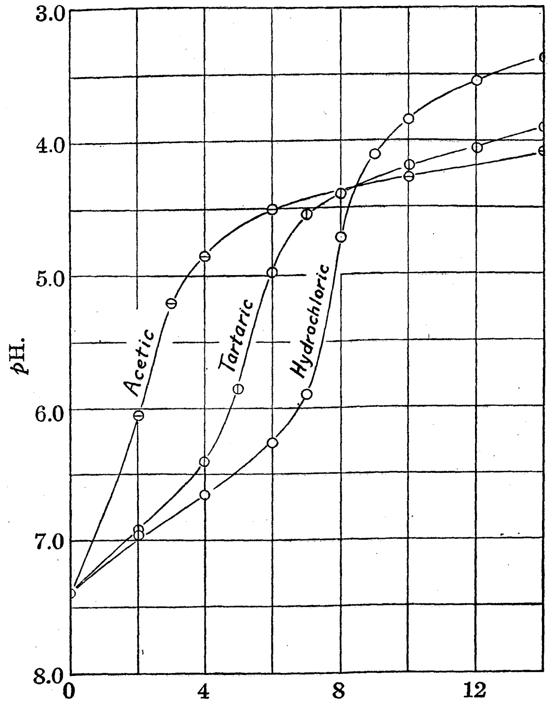


Cc. of acid added to 10.0 cc. of buffer.

Fig. 3(a).—Concentration M: hydrochloric, 0.0010; tartaric, 0.0006; acetic, 0.0022.

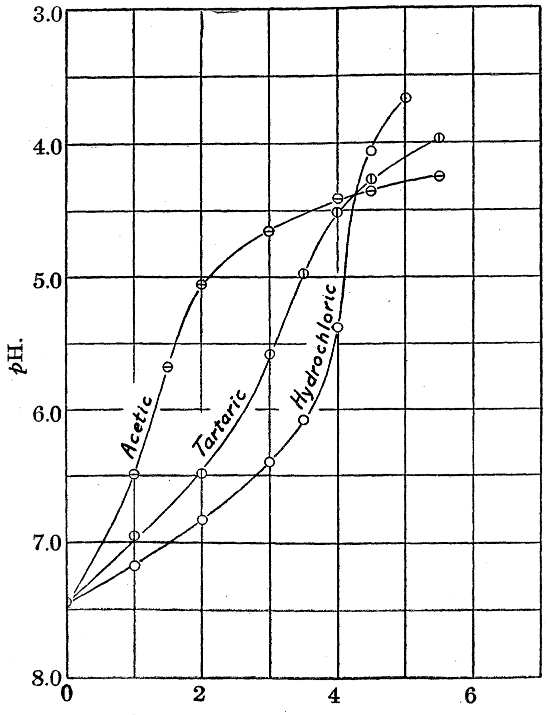
Discussion

When 0.0025 M hydrochloric acid and the various equisour acid solutions are titrated with buffer of pH 6.9, the titration curves cross at a pH of 4.40 to 4.45 (see Fig. 1), *i. e.*, it requires the same amount of buffer to bring the pH of the different acids to pH 4.4. The position of this point is not affected by moderate changes in the pH and concentration of the buffer, for from Fig. 3b the curves still cross at pH 4.4 when acids of the same concentration as were used in section 1 are titrated with a buffer ten times as dilute and with a pH of 7.4. Furthermore, its position is constant even when the concentrations



Cc. of acid added to 10.0 cc. of buffer.

Fig. 3(b).—Concentration M: hydrochloric, 0.0025; tartaric, 0.0016; acetic, 0.0070.



Cc. of acid added to 10.0 cc. of buffer.

Fig. 3(c).—Concentration M: hydrochloric, 0.0050; tartaric, 0.0030; acetic, 0.0140.

---

[6] 0.3240 g. of $NaH_2PO_4 \cdot H_2O$, 0.0480 g. of $Na_2HPO_4 \cdot 12H_2O$, and 2.0 cc. of approximately normal NaOH solution, all made up to one liter with distilled water.

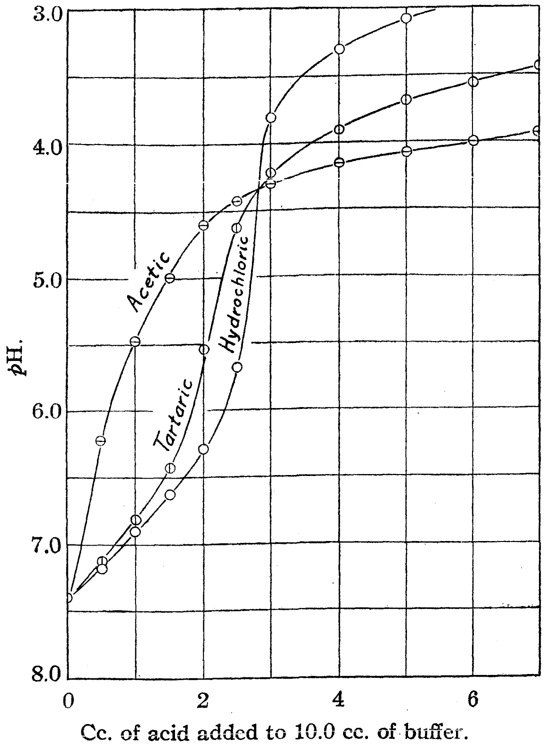


Fig. 3(d).—Concentration *M:* hydrochloric, 0.0075; tartaric, 0.0043; acetic, 0.024.

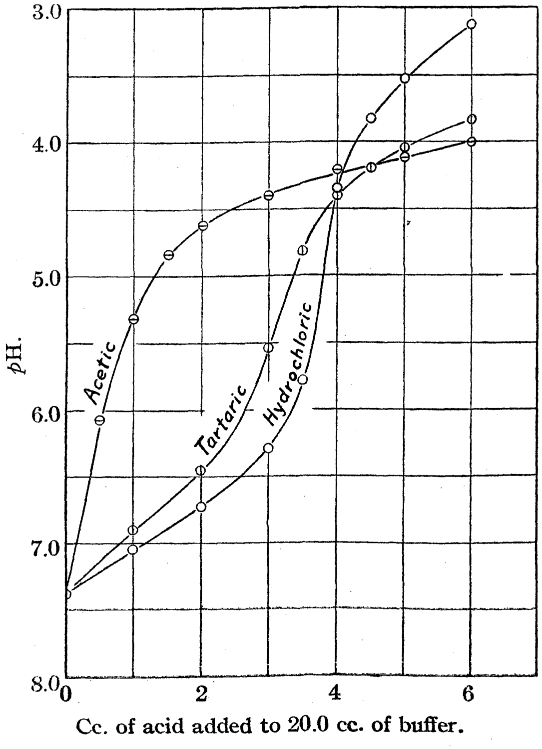

Fig. 3(e).—Concentration *M:* hydrochloric, 0.0100; tartaric, 0.0055; acetic, 0.045.

of the acids used are varied over almost the whole range of taste perception (see Table I).

TABLE I

Fig. no.	Concn. of HCl (standard), *M*	*p*H at intersection
3a	0.0010	4.5
3b	.0025	4.4
3c	.0050	4.4
3d	.0075	4.4
3e	.0100	4.2–4.4[a]

[a] The unpleasant sensation caused by acids of this concentration in the mouth makes judgment uncertain and it is very difficult to make an accurate comparison with the tongue dipping into the liquid.

It will be noted that the titration curves for hydrochloric acid and equisour carbon dioxide solution do not cross at *p*H 4.4, but at 5.3. We do not know whether this deviation indicates an exception to the rule or is due to the difficulty in tasting carbon dioxide solutions referred to in Section 2.

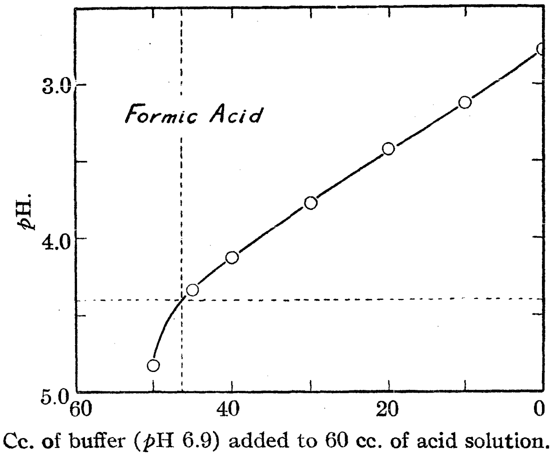

Fig. 4.

These results show the very considerable degree of accuracy of the statement that the volume of buffer required to bring a given volume of an acid to a *p*H of 4.4 (Kenrick said "about 5") is proportional to its sourness. This is illustrated for acetic, tartaric and hydrochloric acids in Table II.

Acids more sour than 0.0100 *M* hydrochloric and less sour than 0.0010 *M* hydrochloric[7] cannot be compared by taste measurements, so that these results cover the whole range of measurable sour taste. They may be summed up by the formula $S = x/470$, where S is the sourness of the acid and x is the volume in cc. of the buffer required to bring 1 cc. of the acid to *p*H 4.4.

(7) Paul and Bohnen (see Dietzel[2]) consider this the threshold value for hydrochloric acid.

TABLE II

Fig. no.	Concentration, M Acetic	Concentration, M Tartaric	Sourness = normality of equisour HCl, M	Vol. buffer to bring 1 cc. acid to pH 4.4 Calcd. from figs.	Vol. buffer / Sourness
	M = moles per liter				
3a	0.0022	0.0006	0.0010	0.463	46 × 10
3b	.0070	.0016	.0025	1.18	47
3c	.0140	.0030	.0050	2.35	47
3d	.024	.0043	.0075	3.54	47
3e	.045	.0055	.0100	5.0 approx.	50[a]

[a] When checking the pH curves of 3e it was found that it required 4.15 cc. of buffer to bring 20 cc. of 0.0100 M hydrochloric acid to pH 4.4 rather than 4.0 cc., thus making the constant 480 approximately. The curves however still did not cross at a common point. This was attributed to the difficulty of making taste comparisons at this concentration. After trying acetic acid solutions of various concentrations, it was estimated that a solution 0.0038 M would give a titration curve crossing at pH 4.4, approximately. It is interesting to note that when plotted on Fig. 5, this point gives a continuation of the curve for acetic acid more similar in shape to that for tartaric acid.

Since it has been shown that changing the concentration and pH of the buffer within certain limits does not affect the validity of this relation the formula can be extended to take account of small variations in the buffer used; thus $S = x/K$ where K is a constant characteristic of the buffer.

Example: To Measure a Sourness by Titration.—Formic acid was chosen because it had not been used in the preceding experiments. The constant K for the buffer of pH 6.9 used in Sec. 1 can be calculated from the results in Fig. 1: $S = 0.0025$, $x = 3/15$ and therefore $K = x/S = 80$.

A formic acid solution (0.0090 M) was titrated with the buffer of pH 6.9 with the results shown in Fig. 4. From this curve it is seen that 60 cc. of acid required 46.5 cc. of buffer, and $S = 46.5/(60 \times 80) = 0.0097$.

The actual sourness of this formic acid solution was measured by Beatty in 1931 and found to be 0.0100. Thus even for a sourness as high as 0.0100, the two values agree to within 3%.

These results also enable us to verify the assumption that the relative sourness of equimolar solutions is independent of concentration. Fig. 5 is plotted from the data of 3a, b, c, d and e. The curves give the sourness of acetic and tartaric acids at various molar concentrations. It is obvious that if these curves were straight lines the assumption would be exactly true. As it is the curves differ very little from straight lines up to a sourness of 0.0075, beyond which tasting becomes difficult. The assumption is therefore approximately true over the whole range of accurate tasting.

This research was carried out at the suggestion and under the direction of Dr. F. B. Kenrick.

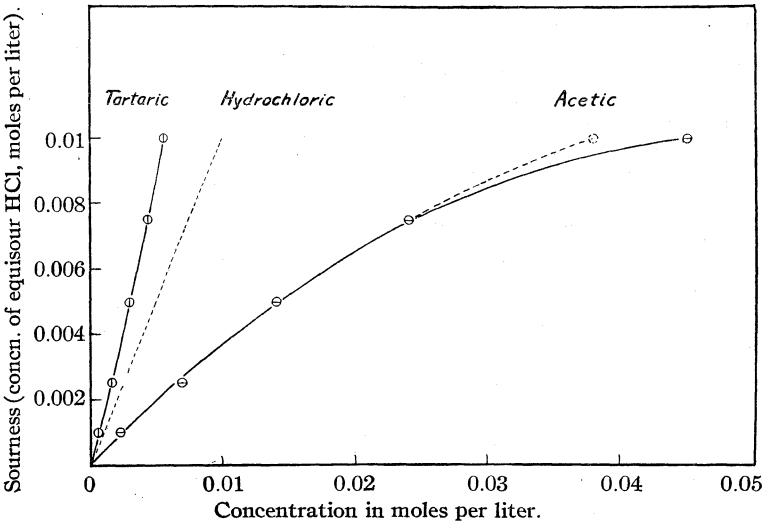

Fig. 5.—Sourness of acetic and tartaric acid solutions (Beatty).

Summary

The sourness of a solution being defined as the normality of an equally sour hydrochloric acid, it has been established for several typical acids that the sourness of an unbuffered acid solution is expressed by x/K, where x is the volume of a phosphate buffer required to bring a unit volume of the acid to a pH of 4.4 and K is a constant characteristic of the buffer used.

This relation has been verified for buffers of pH from 6.9 to 7.4 and of total concentration of anhydrous sodium phosphates from 0.04 to 0.35% by weight—within which ranges most physiological liquids lie.

The Sensitized Decomposition of Hydrogen with Electrons of Controlled Energy

BY GEORGE GLOCKLER AND LLOYD B. THOMAS[1]

I. Introduction

The use of electrons of known energy as activating agents for chemical reactions has been studied by one of us[2,3] in the case of hydrogen and oxygen. In this paper we wish to report further experiments on the decomposition of hydrogen in the presence of mercury using electrons of controlled speed as activating agents. This reaction is the analog of the Cario and Franck[4] experiment substituting for the incident radiation (λ = 2537 Å.) electrons of definite voltage. The general basis of studying such electron activated reactions is to elucidate mechanisms for such reactions as are produced in electric fields (ozonizers) and by alpha particles[5] and to compare reactions activated by various agents.

The photosensitized decomposition of hydrogen can be described best by the steps

$$h\nu\ (2537\ \text{Å.}) + \mathrm{Hg}(6^1\mathrm{S}_0) \longrightarrow \mathrm{Hg}(6^3\mathrm{P}_1)$$
$$\mathrm{Hg}(6^3\mathrm{P}_1) + \mathrm{H}_2(^1\Sigma_g^+) \longrightarrow 2\mathrm{H(atoms)} + \mathrm{Hg}(6^1\mathrm{S}_0)$$
$$2\mathrm{H(atoms)} + \mathrm{CuO(solid)} \longrightarrow \mathrm{H_2O(liq.)} + \mathrm{Cu(solid)}$$

The last reaction simply serves as a means of removing hydrogen atoms so that the whole process may be followed by a pressure decrease. From this photochemical reaction one would predict that the corresponding electron-activated reaction should be

$$\mathrm{E}^-(4.9\ \text{e.v.}) + \mathrm{Hg}(6^1\mathrm{S}_0) \longrightarrow \mathrm{Hg}(6^3\mathrm{P}_1)$$
$$\mathrm{Hg}(6^3\mathrm{P}_1) + \mathrm{H}_2(^1\Sigma_g^+) \longrightarrow 2\mathrm{H(atoms)} + \mathrm{Hg}(6^1\mathrm{S}_0)$$
$$2\mathrm{H(atoms)} + \mathrm{CuO(solid)} \longrightarrow \mathrm{H_2O(liq.)} + \mathrm{Cu(solid)}$$

Electrons of 4.9 e. v. energy should dissociate hydrogen molecules in the presence of mercury vapor. Since it is known that electrons in the absence of mercury atoms must have 11.7 e. v. energy[2,6] before they can dissociate molecular hydrogen, it should be easy to detect the effect of mercury atoms on the decomposition of hydrogen when induced by electrons. The pressure decrease should happen at 4.9 instead of 11.4 volts.

The results of the experiments described in this paper are not in accordance with this prediction. We find that *at low pressures (H_2 at 0.02 mm. and Hg at 0.002 mm.) decomposition starts at 7.7 volts.* The reasons for this difference will be given below.

II. Experimental Procedure and Results

The apparatus used is shown in Fig. 1. The experimental tube used is the sixth one developed in this work. The earlier ones were discarded for various reasons. They are described in detail elsewhere.[1] It is important in this work to produce a copious stream of electrons from a filament of as low a temperature as can be attained. The filament must not heat up the copper oxide surface. A hot copper oxide surface would readily be reduced by molecular hydrogen, entailing a large background of pressure drop, which would be very undesirable. The filament was made of nickel, oxide covered (9 mm. long, 0.5 mm. wide and about 0.1 mm. thick) and required only 1.5 amperes heating current. The filament drop was less than 0.4 volt so that less than 0.6 watt was consumed. Since only the central portion of the filament was hot enough to emit electrons, it delivered electrons of nearly uniform velocity. The electron current to the plate was of the order of 50 microamperes depending on the accelerating voltage. Since very little heat is evolved by a filament of this kind no large background of pressure drop was observed and the Pirani gage showed very little zero drift, *i. e.*, pressure drop at "zero" accelerating voltage. The wire of the Pirani gage was a tungsten filament 5 cm. long and 0.025 mm. thick. The glass tube carrying this wire concentrically was of 8 mm. inside diameter. A six-volt storage battery connected in series with a milliammeter and a dial resistance box (10,000 ohms) heated the gage to a dull red heat. The fall of potential over the Pirani wire is balanced by the potentiometer using a moderately sensitive galvanometer (5.68×10^4 cm. divisions per volt) with telescope and scale. The rate of pressure change is measured by the rate of drift of the galvanometer. The potentiometer is not read but is used as a convenient means of bringing the galvanometer to the desired position on the scale. If the tungsten wire is allowed to cool or to run a long time without heating strongly its resistance drops markedly so that it cools below red temperature. As adsorbed gases are driven from the filament the wire will assume its original condition. After baking the tube out and setting the apparatus in operation, it required at least two days to reach steady conditions. Even during the calibration measurements some adsorption of gas is noted for the ascending and descending portions of the curves for hydrogen (Fig. 1) do not coincide, but the difference is noted to be very small. A mixture of krypton and hydrogen was also studied and it is seen that the slope of the curve is the same in pure hydrogen or in mixtures containing various amounts of krypton. Kryp-

ton was more convenient to use than mercury as foreign gas. Dividing the slope of the pressure *versus* voltage curve by that of the deflection *vs.* voltage curve gives the pressure change per scale division. The former value for hydrogen is 0.480 mm. Hg/volt and the latter is 5.68×10^4 cm./volt so that the sensitivity of the Pirani gage is 8.45×10^{-6} mm. pressure change per cm. scale deflection. In order to determine the validity of this calibration it was checked by an entirely different method. A certain pressure of krypton was led into the apparatus and its volume was reduced by allowing a mercury column to rise in one of the cut-off tubes. The galvanometer deflection was observed for the two positions of the mercury column. The agreement was very good with the deflection predicted from the compression, the slope of the curve (Kr) and the galvanometer sensitivity.

It was found that a well baked out tube would adsorb the water formed during the reaction so that liquid air was not necessary for the removal of the reaction product, although it was used in some of the runs. Hydrogen was introduced through a palladium tube in the usual manner. The applied voltage was read on a "Jewel" precision voltmeter. The volume of the reaction tube to the mercury cut-off was 77.9 cc. The plate galvanometer had a current sensitivity of 3.81×10^{-8} amp./cm. on shunt 1.0 and one-tenth and one-hundredth of this value on shunts 0.1 and 0.01.

It is desired to determine the number of hydrogen molecules decomposed per electron passing between the filament and plate as a function of the energy of the electrons. This relationship may be calculated from the following four readings taken at a series of accelerating potentials: the accelerating voltage as registered by the precision voltmeter, the drift of the galvanometer in the Pirani circuit, the time over which the drift is measured and the current which reaches the plate. From the pressure decrease, the volume of the tube (77.9 cc.) and the temperature (298°), the number of hydrogen molecules disappearing per minute may be calculated.

The detailed calculations and data can be found in another place.[1] The results are shown in Fig. 3 and Table I. The experimental values of the electron energies needed to cause the decomposition of hydrogen with and without mercury atoms as sensitizers are found to be 7.77 and 11.86 e. volts. These values must be corrected for the initial velocity of the electrons.

Initial Velocity Correction.—A variety of methods was tried to determine the initial velocity of the electrons as they leave the filament. The most satisfactory results are obtained by the use of the excitation potential or term value of the ${}^3\Sigma_g^+$ state of hydrogen. This value is known from spectroscopic studies[7–9] to be 11.72 e. volts. On this basis then the correction is 0.14 e. v. and the non-sensitized decomposition happens at 11.72 ± 0.22 e. v. This value is higher than the earlier results[2,6] by 0.28 e. v. Since the spectroscopic term is more accurate than the values based on any current-potential experiment, the present figure is greatly to be preferred. It is well known that the matter of obtaining velocity corrections in an unambiguous manner is difficult. We have studied five different methods of obtaining the initial velocity correction. They gave values which would lower the result (11.86 e. v.) by 0.4 to 1.0 e. volt. However, every method has its drawbacks. Either a foreign gas or a gas mixture (H_2 and He or H_2 and Hg) has to be employed or the method depends on some complicated use of current-potential relations. After an extended and time-consuming study of the situation, we came to the conslusion that the use of the spectroscopic term value of ${}^3\Sigma_g^+$ of hydrogen was the most satisfactory way of eliminating the initial velocity correction of the electrons.

III. Discussion of Results

The Non-Sensitized Reaction.—The higher energy states of hydrogen molecules which need to be considered in the interpretation of these experiments are given in Table II and Fig. 2.

TABLE II

ENERGY STATES OF HYDROGEN MOLECULE

State	Term-values (zero vibration)	Excitation potential (Franck–Condon)	Possible transition
$(1s^2)\ {}^1\Sigma_g^+$	Zero		
$(2p)\ {}^3\Sigma_u^+$	Repulsive	8.5–10.4	Two H atoms
$(2p)\ {}^1\Sigma_u^+$	11.12 e. v.	11.4–12.6	Radiation
$(2p)\ {}^3\Pi_u$	11.72 e. v.	11.7–13.0	Metastable H_2
$(2s)\ {}^3\Sigma_g^+$	11.73 e. v.	11.6–12.4	Continuum + 2H
$(2p)\ {}^1\Pi_u$	12.22 e. v.	12.2–13.6	Radiation
$(2s)\ {}^1\Sigma_g^+$	12.25 e. v.	12.0–13.4	Metastable H_2

Electrons can transfer normal hydrogen molecules into the various excited states shown above.[10] If the excited state is an odd singlet state then the excited molecule can return to normal with emission of radiation. Such transitions will lead to chemical action with only low probability for it would mean that the excited molecule during its short life will either have to make an impact with another normal molecule or the wall in order that decomposition occurs. The chance for reactions of the type

$$H_2({}^1\Sigma_u^+) + H_2({}^1\Sigma_g^+) \longrightarrow \text{H atoms etc.}$$
$$H_2({}^1\Pi_u) + H_2({}^1\Sigma_g^+) \longrightarrow \text{H atoms etc.}$$

most likely is much smaller than the return to the normal state with radiation

$$H_2({}^1\Sigma_u^+) \longrightarrow H_2({}^1\Sigma_g^+) + h\nu\ (1109.3\ \text{Å.})$$
$$H_2({}^1\Pi_u) \longrightarrow H_2({}^1\Sigma_g^+) + h\nu\ (1009.5\ \text{Å.})$$

If the life of an excited hydrogen molecule is of the order of 10^{-7} seconds it can readily be calculated that it will make only very few collisions (0.01) during its life. At 0.01 mm. pressure, its collision diameter would have to be many times the kinetic theory diameter of the normal molecule in order that these states would be involved in the reaction. It can also readily be shown that the average excited molecule cannot reach the wall of the reaction tube during its life. It would appear then that the excited states ${}^1\Sigma_u^+$ and ${}^1\Pi_u$ do not contribute to the chemical reaction.

The repulsive state ${}^3\Sigma_u^+$ could be reached by impact with electrons having 8.5 or 10.5 e. v. energy or any value between these limits (Franck–Condon principle). However no such transfer is observed and we conclude that this step is of very low probability

$$H_2({}^1\Sigma_g^+) + E^-(8.5 - 10.5\ \text{e. v.}) \longrightarrow \text{No reaction}$$

The last excited state mentioned in **Table II**, $(2s)\,{}^1\Sigma_g^+$ with a term value and excitation potential of 12.25 e. v. is higher than two other states which appear to contribute to reaction. The state appears to have the desired property of a long life, for it cannot combine with any lower triplet nor singlet state and hence is metastable. It should contribute to reaction when the impinging electrons reach the appropriate energy.

The most likely states which are responsible for the initial pressure decrease in our reaction are the states $(2p)^3\Pi_u$ and $(2s)^3\Sigma_g^+$. Being triplet states they cannot combine with the normal state which is a singlet state and hence they cannot radiate and return to normal. Nor can the state ${}^3\Pi_u$ interact with the repulsive triplet state ${}^3\Sigma_u^+$ on account of the "odd-even" selection rule. Hence this state ($(2p)^3\Pi_u$) is metastable. Hydrogen molecules in this state should readily reach the wall and there react with the copper oxide, reducing it. But the ${}^3\Sigma_g^+$ state also should be involved in the chemical reaction. While it can radiate the continuum[11,12] when the molecule goes to the repulsive state it also produces two hydrogen atoms of high kinetic energy which should readily reduce copper oxide producing a

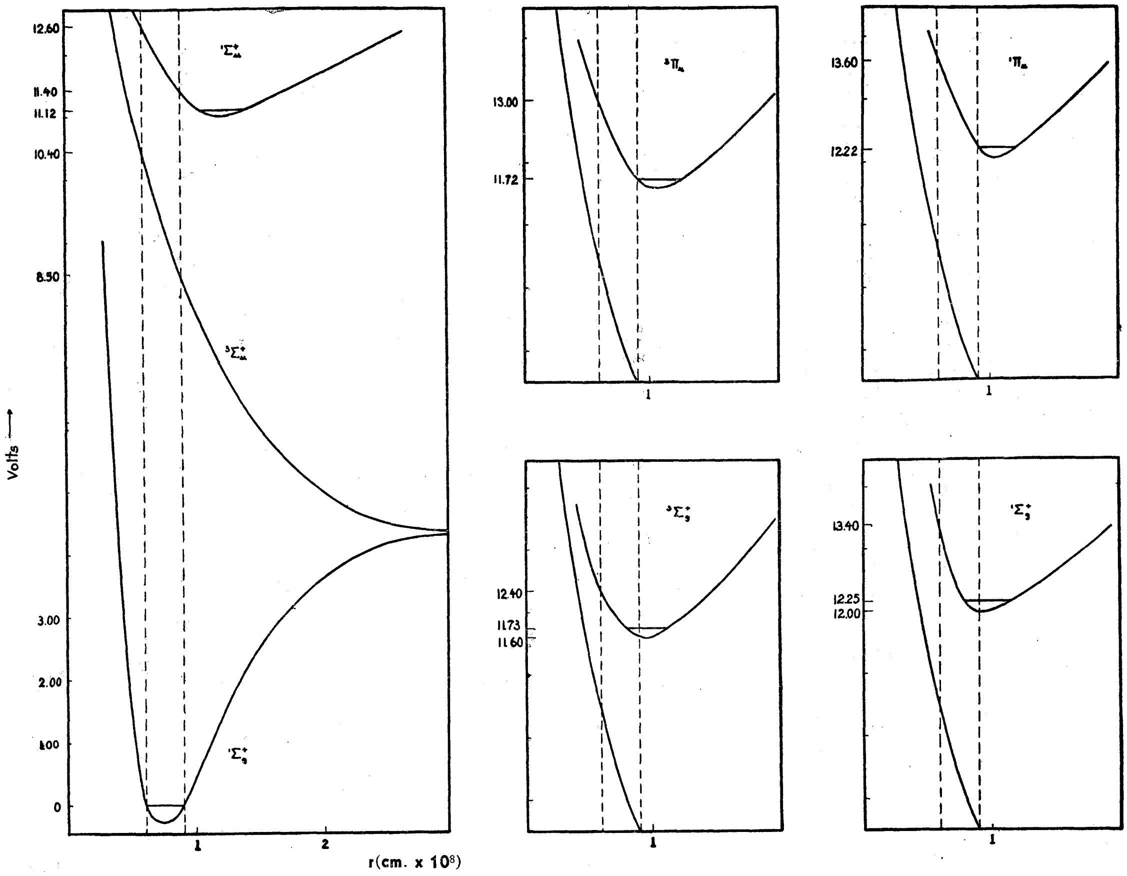

Fig. 2.—The one and two quantum states of hydrogen molecule.

pressure drop under our experimental conditions. The reactions taking place are

$$H_2(^1\Sigma_g^+) + E^-(11.72 \text{ e. v.}) \longrightarrow H_2(^3\Pi_u) + E^-(\text{zero e. v.})$$
$$H_2(^3\Pi_u) + CuO(\text{solid}) \longrightarrow H_2O(\text{liq.}) + Cu(\text{solid})$$

and

$$H_2(^1\Sigma_g^+) + E^-(11.73 \text{ e. v.}) \longrightarrow H_2(^3\Sigma_g^+) + E^-(\text{zero e. v.})$$
$$H_2(^3\Sigma_g^+) \longrightarrow H_2(^3\Sigma_u^+) \longrightarrow 2H \text{ atoms} + \text{Kin. Energy} + \text{continuum}$$
$$2H \text{ atoms} + CuO(\text{solid}) \longrightarrow H_2O(\text{liq.}) + Cu(\text{solid})$$

No choice is possible between these two reaction mechanisms. Both should happen. They have nearly the same electron energy and their excitation potentials are nearly the same. Hence it appears reasonable to consider 11.72 e. v. to be the voltage for onset of pressure drop. We calculate the initial velocity correction to be 11.86 − 11.72 = 0.14 e. v. as was noted above.

A change in slope in the curves (*M/E vs.* electron speed) is noticeable at about 15.5 e. v. Ionization is known to set in at this voltage. The slope decreases, showing lessened probability for reaction. When ions are produced their recombination is necessarily involved in the reaction mechanism. At the low pressures used such recombination between hydrogen mole ions and electrons would be very infrequent and reaction of the cluster type[5] would not happen readily. The reaction observed is most likely due to excited states which are still produced with some probability even at voltages somewhat higher than their term values. Hydrogen mole ions might be thought of as ionic catalysts. However, they would not be expected to attract greatly hydrogen molecules of small polarizability nor would these molecules be greatly distorted in the field of the ion. Hence at low pressures of hydrogen ionization does not produce increased chemical action.

The Mercury Sensitized Reaction.—From Table I it is seen that the presence of mercury lowers the voltage at which reaction sets in from 11.86 to 7.77 e. v. (uncorr.). Applying the correction just determined we find that the mercury-sensitized reaction occurs at 7.77 − 0.14 = 7.63 e. v. and not at 4.86 e. v. as might be predicted from the photosensitized reaction. It must mean that at low pressures the 6^3P (4.9 e. v.) state of mercury is inefficient in producing reaction. The energy states of the mercury atom which must be considered in the interpretation of the experimental results are the following: $6^3P_0(4.64)$, 6^3P_1 (4.86), $6^3P_2(5.43)$, $6^1P_1(6.67)$, $7^3S_1(7.69)$ and 7^1S_0 (7.86) e. v.

Since the metastable states of mercury 6^3P_0 and 6^3P_2 do not assist the reaction, we must suppose that the efficiency of their direct production by electron impact is small. If they are produced then mercury atoms in these metastable states should be able to transfer energy to hydrogen molecules by collisions of the second kind with consequent dissociation. That these two metastable states are indeed much less readily produced by electron impact can be seen from current-potential curves obtained by Franck and Einsporn[13] and Foard.[14] The 6^3P_1(4.9 e. v.) state, however, is not metastable and hence can return to normal with emission of 2537 Å. Hence this state will only be efficient if the excited mercury atoms during their short life can make a sufficient number of impacts with hydrogen molecules. At low enough hydrogen and mercury pressures an insufficient number of mercury atoms may be created and not enough impacts may happen to produce a measurable pressure change. We believe that these conditions are maintained in our experiments. Similarly therefore the states 6^1P_1(6.67 e. v.) and 7^1S_0(7.86 e. v.) are inefficient. The only remaining state is the term 7^3S_1(7.69 e. v.). While it also will radiate to the three ^3P states, only two of these are metastable and will have a sufficiently long life to interact with hydrogen molecules in accordance with the following reaction mechanism.

$$E^-(7.7\text{ e. v.}) + \text{Hg}(6^1S_0) \longrightarrow \text{Hg}(7^3S_1) + E^-(0\text{ e. v.})$$
$$\text{Hg}(7^3S_1) \longrightarrow \text{Hg}(6^3P_{0,2}) + h\nu\ (5461\text{ or }4047\text{ Å.})$$
$$\text{Hg}(6^3P_0) + H_2(^1\Sigma_g^+) \longrightarrow 2\text{H(atoms)} + \text{Hg}(6^1S_0) + 0.3\text{ e. v. K. E.}$$
$$\text{Hg}(6^3P_2) + H_2(^1\Sigma_g^+) \longrightarrow 2\text{H(atoms)} + \text{Hg}(6^1S_0) + 1.1\text{ e. v. K. E.}$$
$$2\text{H(atoms)} + \text{CuO(solid)} \longrightarrow H_2\text{O(liq.)} + \text{Cu(solid)}$$

It is seen that the term value (7.69 e. v.) of the 7^3S_1 state of mercury is closer to our experimental onset voltage (7.63 e. v.) than any other possible term value and the above mechanism affords a reasonable picture of the steps leading to reaction.

There have been mentioned in the literature[13,15] some energy states of the mercury atom which do not fit into the spectroscopic set of term values. These states were found by critical potential methods. The values of interest here are 7.1 and 7.45 e. v. We have not involved these states in our considerations of a reaction mechanism for the sensitized reaction because we feel that they are not close enough to our experimental value for the beginning of the reaction. Similarly we have excluded the possible formation of mercury hydride in a triple collision which might happen at 7.05 e. v.[9]

$$E^-(7.05\text{ e. v.}) + \text{Hg}(6^1S_0) + H_2(^1\Sigma_g^+) \longrightarrow \text{HgH}(^2\Pi) + \text{H atom} + E^-(0)$$

However the formation of mercury hydride may be involved in the reaction

$$\text{Hg}(6^3P_0) + H_2(^1\Sigma_g^+) \longrightarrow \text{HgH}(^2\Sigma^+) + \text{H atom} + 0.67\text{ e. v. K. E.}$$
$$\text{Hg}(6^3P_2) + H_2(^1\Sigma_g^+) \longrightarrow \text{HgH}(^2\Sigma^+) + \text{H atom} + 1.43\text{ e. v. K. E.}$$

We see that greater amounts of kinetic energy are liberated when mercury hydride molecules are involved. On the well-known principle that collisions of the second kind happen with greatest probability when the amount of energy going to kinetic energy is smallest, it is seen that the $^3P_0$ state is more likely to lead to reaction.

The 7^3P States of Mercury.—From Fig. 3 we can see that there is a change in slope at about 8.5 e. v. in the curve (*M/E vs.* voltage). This kink would indicate a new process becoming of importance. Indeed we notice that the 7^3P states of mercury atom have the term values 8.57, 8.61 and 8.78 e. v. We therefore interpret the reaction in the following way.

$$E^-(8.57\text{ e. v.}) + \text{Hg}(6^1S_0) \longrightarrow \text{Hg}(7^3P_0) + E^-(0\text{ e. v.})$$
$$\text{Hg}(7^3P_0) \longrightarrow \text{Hg}(7^3S_1) + h\nu\ (13951\text{ Å.})$$
$$\text{Hg}(7^3S_1) \longrightarrow \text{Hg}(6^3P_{0,2}) + h\nu\ (5461\text{ or }4047\text{ Å.})$$
$$\text{Hg}(6^3P_0) + H_2(^1\Sigma_g^+) \longrightarrow 2\text{H(atoms)} + \text{Hg}(6^1S_0) + 0.3\text{ e. v. K. E.}$$
$$\text{Hg}(6^3P_2) + H_2(^1\Sigma_g^+) \longrightarrow 2\text{H(atoms)} + \text{Hg}(6^1S_0) + 1.1\text{ e. v. K. E.}$$
$$2\text{H(atoms)} + \text{CuO(solid)} \longrightarrow H_2\text{O(liq.)} + \text{Cu(solid)}$$

The mercury atoms reach the metastable states by two radiative transitions. We have not looked for the radiations involved for the presence of the filament makes the discovery of a faint radiation a matter of great difficulty.

However, we have been able to explain the reactions studied on the basis of the energy level

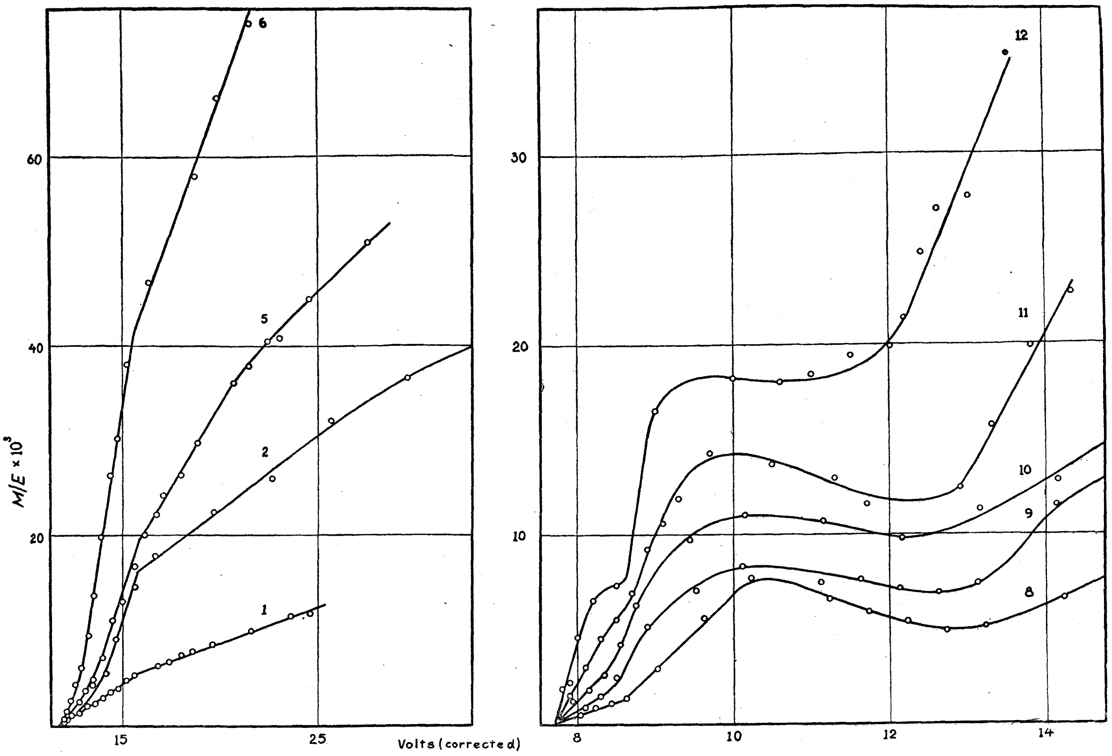

Fig. 3.—Molecules of hydrogen reacting per electron as a function of electron speed; non-sensitized and sensitized by mercury atoms.

diagrams of the substances involved. While we hope to deal with more complicated cases later, we expect to study next the effects of increasing pressure for the case reported here. At higher mercury and hydrogen pressures onset of reaction should appear at 4.9 e. v., corresponding to the original Cario–Franck experiment.

Abstract

Hydrogen molecules have been dissociated by electrons of known speed using mercury atoms as a sensitizing agent. These reactions are analogous to the photochemical decomposition of hydrogen using $\lambda = 2537$ Å. and mercury (Cario and Franck experiment). From the photochemical case one would predict that 4.9 e. v. electrons should initiate the mercury-sensitized reaction; while without a sensitizer electrons must possess 11.7 e. v. energy. In the present experiment it is found that at low pressures (H_2 at 0.02 mm. and Hg at 0.002 mm.) the short-lived radiative states of mercury (4.9 and 6.7 e. v.) and the well-known metastable states ($6^3P_{0,2}$) are not efficient or are too short-lived to cause reaction. However, electrons of 7.7 e. v. energy can cause dissociation of hydrogen in the presence of mercury. The sequence of reaction is

$$E^-(7.7\text{ e. v.}) + Hg(6^1S_0) \longrightarrow Hg(7^3S_1) + E^-(\text{zero e. v.})$$

$$Hg(7^3S_1) \longrightarrow Hg(6^3P_{0,2}) + h\nu \text{ (5461 or 4047 Å.)}$$

$$Hg(6^3P_{0,2}) + H_2(^1\Sigma_g^+) \longrightarrow 2H(\text{atoms}) + Hg(6^1S_0)$$

$$2H(\text{atoms}) + CuO(\text{solid}) \longrightarrow H_2O(\text{liq.}) + Cu(\text{solid})$$

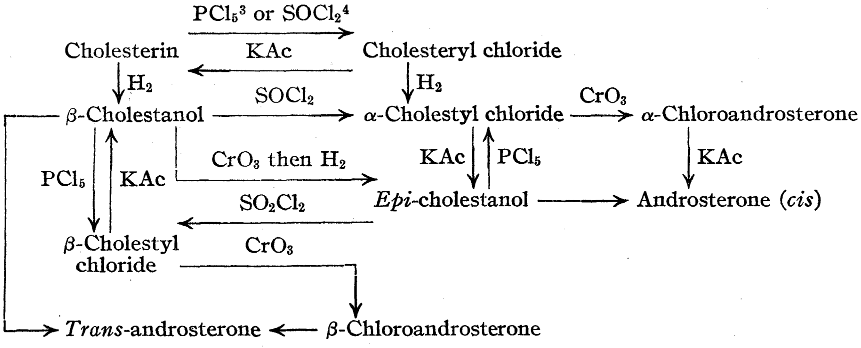
Androsterone and Related Sterols

BY RUSSELL E. MARKER, FRANK C. WHITMORE AND OLIVER KAMM

In the preparation of androsterone and other physiologically active compounds it is often necessary to change the —OH in the sterols from the *trans-* into the *cis*-form. This was shown by Ruzicka[1] and co-workers in the preparation of *trans* and *cis* androsterone in which they showed that the *cis*-form which is the natural androsterone (*epi*-OH) had about seven times the activity of the *trans* derivative. This conversion into the *epi*-form was brought about by first reducing cholesterin to beta-cholestanol. This was oxidized to beta-cholestanone which was then reduced by hydrogen in butyl ether at 70° according to the method of Vavon and Jakubowicz.[2] This reaction requires two catalytic reductions and an oxidation, which due to the small solubility of the compounds and the large amount of platinum oxide catalyst necessary, is very expensive and time-consuming. To overcome this, advantage is taken of the following scheme to produce the *epi*-form of the sterols in quantity. Also conversion of the *cis*-form back into the *trans*-form can be brought about by these reactions.



When cholesterol is treated with either phosphorus pentachloride or thionyl chloride cholesteryl chloride is formed. This on hydrolysis gives cholesterol with the —OH unchanged. However, if cholesteryl chloride is reduced with platinum oxide and hydrogen, α-cholestyl chloride is formed which on hydrolysis then gives the —OH in the *cis*-form. In the first case there was no Walden inversion in the final product, whereas in the reduced product a Walden inversion occurred in one of the steps.

Whereas when cholesterol is treated with either phosphorus pentachloride or thionyl chloride the same chloride is formed, if beta-cholestanol is treated with thionyl chloride it gives beta-cholestyl chloride and when treated with thionyl chloride alpha-cholestyl chloride. A Walden inversion occurs in one of the halogenations and not in the other. The same is true for *epi*-cholestanol. When this is treated with phosphorus pentachloride it gives alpha-cholestyl chloride but when treated with thionyl chloride it gives beta-cholestyl chloride.

In the hydrolysis of the various chlorides, alpha-cholestyl chloride gives *epi*-cholestanol while beta-cholestyl chloride gives beta-cholestanol.

When alpha-cholestyl chloride is oxidized it gives alpha-chloroandrosterone which apparently is identical to the chloride produced by Butenandt and Dannenbaum[5] by the reduction of an unsaturated chloro ketone isolated from urine. This chloro ketone on hydrolysis gives androsterone. α-Chlorocholanic acid is isolated as a by-product of this oxidation. Since this work was completed Ruzicka and co-workers[6] have prepared α-chloroandrosterone from *epi*-cholestanol.

The authors wish to express their thanks to The Parke, Davis Laboratories, Detroit, Mich., for a grant making this work possible.

Experimental

Cholesteryl Chloride.—This was prepared both by the method of Mauthner[3] by the use of phosphorus pentachloride on cholesterol and by the method of Diels and Blumberg[4] by the action of thionyl chloride on cholesterol. Mixed melting points showed the two products to be identical, m. p. 95° (uncorr.).

α-Cholestyl Chloride.—(1) By reduction of cholesteryl chloride. Fifty grams of cholesteryl chloride was dissolved in 500 cc. of ether and 2 g. of platinum oxide and 10 cc. of glacial acetic acid added. The product was shaken for one hour with hydrogen at 45 pounds pressure. Although reduction was complete in fifteen minutes it was shaken for one hour. The product was crystallized from acetone; m. p. 112° (uncorr.).

(2) By the action of phosphorus pentachloride on *epi*-cholestanol. Five grams of *epi*-cholestanol, m. p. 185°, was added to 2.5 g. of phosphorus pentachloride and ground in a mortar until a paste was obtained. This was added to water and boiled for thirty minutes. The product was extracted with ether and crystallized twice from alcohol–ether, then three times from acetone; m. p. 112° (uncorr.). Mixing with α-cholestyl chloride prepared by the first method gave no depression in the melting point.

(3) By the action of thionyl chloride on beta-cholestanol. Five grams of beta-cholestanol was added to 5 g. of thionyl chloride. The product was let stand overnight, then poured into a 2% sodium hydroxide solution. It was extracted with ether, then crystallized twice from alcohol–ether and three times from acetone; m. p. 112° (uncorr.). Mixed with α-cholestyl chloride prepared by the two previous methods it showed no depression in the melting point, whereas when mixed with pure beta-cholestyl chloride it gave a depressed melting point of 75–80°; yield, 4 g.

Anal. Calcd. for $C_{27}H_{47}Cl$: C, 79.7; H, 11.7. Found: C, 79.9; H, 11.8.

Beta-Cholestyl Chloride.—(1) By the action of phosphorus pentachloride on beta-cholestanol. This was prepared according to the method described by Ruzicka and co-workers[1] giving a product melting at 102–103° (uncorr.) after crystallizing from acetone. Mixture with α-cholestyl chloride gave a depression to 78–83°.

2. By the action of thionyl chloride on *epi*-cholestanol. Three grams of *epi*-cholestanol was treated with 5 cc. of thionyl chloride and let stand at 40° overnight. This was shaken with 2% sodium hydroxide, extracted with ether, crystallized first from alcohol–ether, then from acetone; m. p. 102–103° (uncorr.). Mixture with beta-cholestyl chloride showed no depression, whereas mixture with α-cholestyl chloride gave a depression to 78–80°.

Anal. Calcd. for $C_{27}H_{47}Cl$: C, 79.7; H, 11.7. Found: C, 79.5; H, 11.9.

Hydrolysis of α-Cholestyl Chloride.—One gram of α-cholestyl chloride was added to 10 g. of potassium acetate in 20 cc. of valeric acid. The product was refluxed for thirty hours, then alkali added. The neutral product was extracted with ether, then boiled with alcoholic potassium hydroxide for two hours. The alcohol was distilled off and the product extracted with ether. This was treated with norit and the product crystallized from alcohol; m. p. 185–186°. Mixed with *epi*-cholestanol prepared by the method of Vavon and Jakubowicz,[2] it showed no depression in melting point. Mixture with beta-cholestanol gave a depression of the melting point to 131°.

Anal. Calcd. for $C_{27}H_{48}O$: C, 83.4; H, 12.5. Found: C, 83.6; H, 12.5.

Hydrolysis of Beta-Cholestyl Chloride.—Three grams of beta-cholestyl chloride was hydrolyzed as described for α-cholestyl chloride. The product was crystallized from alcohol four times; m. p. 139°. Mixture with beta-cholestanol showed no depression in melting point, whereas mixture with *epi*-cholestanol gave a melting point of 116°.

Anal. Calcd. for $C_{27}H_{48}O$: C, 83.4; H, 12.5. Found: C, 83.3; H, 12.7.

α-Chloroandrosterone.—A total of 700 g. of α-cholestyl chloride was oxidized in 100-g. quantities; one hundred grams of the chloride was added to 3.5 liters of glacial acetic acid and heated to 95°. A solution of 250 g. of chromic oxide in 175 cc. of water and 400 cc. of glacial acetic acid was slowly run in over a period of four hours. It was then heated an additional ten hours on a steam-bath with stirring. The acetic acid from the seven oxidations was evaporated *in vacuo* and the residue dissolved in water and ether. The ether extract was washed with water and then treated with a 10% sodium hydroxide solution by shaking. An insoluble sodium salt of α-chlorocholanic acid precipitated. This was extracted with ether and the ether distilled to one liter. Two liters of alcohol was added and the remainder of the ether distilled off. On cooling the unoxidized chloride precipitated out. This was filtered off, washed with cold alcohol and dried at 100°; 310 g. of unchanged chloride was obtained. This was again oxidized in 100-g. quantities, and the total alcoholic filtrates evaporated to dryness on a steam-bath. The residue was then steam distilled to remove volatile ketones. The neutral oil was dissolved in 400 cc. of alcohol, filtered and 44 g. of semicarbazide hydrochloride and 53 g. of sodium acetate added. The product was heated for thirty minutes then put in a refrigerator for two days. The crystalline material was filtered, washed with ether and boiled with water. It was filtered again and washed with cold alcohol then ether; m. p. of crude material 272–273° (dec.). This was crystallized several times from alcohol–chloroform; m. p. 279–281° (dec.); yield, 9.2 g. and 4 g. additional with a slightly lower decomposition point recovered from the alcohol.

Four grams of the semicarbazone was added to 200 cc. of 75% alcoholic solution of hydrochloric acid. This was refluxed for three hours, neutralized and evaporated to one-third. The product was extracted with ether, treated with norit and recrystallized from methyl alcohol and finally from hexane, m. p. 170–171° (uncorr.).

Anal. Calcd. for $C_{19}H_{29}OCl$: C, 73.9; H, 9.5. Found: C, 74.0; H, 9.7.

α-Chlorocholanic Acid.—The insoluble sodium salt from the oxidation of α-cholestyl chloride was filtered, washed with dilute alkali, extracted with ether, then treated with hydrochloric acid. The oily material was extracted with ether and crystallized from acetone; m. p. 174–175°.

Anal. Calcd. for $C_{24}H_{39}O_2Cl$: C, 73.0; H, 10.0. Found: C, 73.2; H, 10.1.

We wish to thank Dr. F. W. Breuer for the micro-analyses on the compounds reported in this paper.

Summary

A method of converting *cis*-OH sterols into the *trans*-OH form, and the *trans* back into the *cis*

has been established. α-Chlorocholestane has been oxidized to produce α-chloroandrosterone and α-chlorocholanic acid.

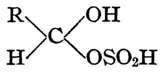
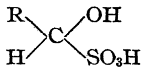
The Constitution of the Bisulfite Addition Compounds of Aldehydes and Ketones

BY WALTER M. LAUER AND CARL M. LANGKAMMERER

Since the discovery of the first aldehyde and ketone bisulfite addition compounds[1] many difficulties have been encountered in attempting to decide between the α-hydroxysulfite ester formula (I) and the α-hydroxysulfonic acid formula (II) for these compounds.



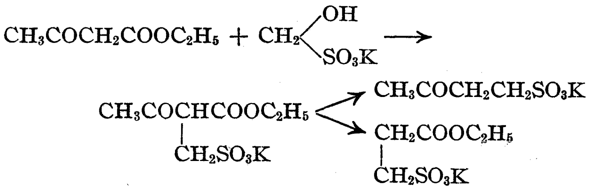
I



II

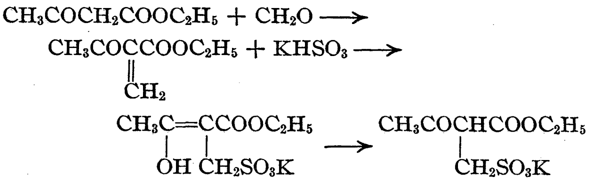
Each structure had its proponents[2] and the problem apparently was solved many years ago with the preparation of a "hydroxymethane sulfonic acid" which was not identical with formaldehyde bisulfite.[3] Since then additional "α-hydroxysulfonic acids" have been prepared;[4] they too differed from the corresponding bisulfite addition products. It is natural, therefore, that formation of the α-hydroxynitriles upon treatment of the bisulfite addition compounds with potassium cyanide came to be regarded as characteristic of the –O–SO_2H group.[5] These views were current until the time of the exemplary investigations of Raschig and Prahl.[6] These investigators were able to show that the "hydroxymethane sulfonic acid" obtained by Müller on sulfonating methyl alcohol was actually symmetrical acetone disulfonic acid, formed by the sulfonation of acetone present in the methyl alcohol of that early date. The "hydroxymethane sulfonic acid" described by Glimm and by Reinking, Dehnel and Labhardt as the product of the action of sulfuric acid on methyl alcohol was demonstrated to be an isomer, methyl hydrogen sulfate. Likewise, the "α-hydroxyisopropyl sulfonic acid," $(CH_3)_2C(OH)SO_3H$, which Schroeter prepared by the hydrolysis of the diphenyl ester of dimethylmethionic acid, $(CH_3)_2C(SO_2OC_6H_5)_2$, and which was not identical with the acetone bisulfite addition compound, was shown to be the methyl ether of this sulfonic acid.

After thus removing much of the evidence which was damaging to the α-hydroxysulfonic acid structure (II), Raschig and Prahl submitted the reaction



$$CH_3COCH_2COOC_2H_5 + CH_2{<}^{OH}_{SO_3K} \longrightarrow$$
$$\underset{CH_2SO_3K}{CH_3COCHCOOC_2H_5} \begin{matrix} \nearrow CH_3COCH_2CH_2SO_3K \\ \searrow \underset{CH_2SO_3K}{CH_2COOC_2H_5} \end{matrix}$$

as indicative of structure II, since the cleavage products were definitely sulfonic acids. However, these investigators[7] were not unmindful of the possibility of intermediate formation of methylene-acetoacetic ester with subsequent 1,4-addition of potassium bisulfite but their evidence led them to regard this as unlikely.



$$CH_3COCH_2COOC_2H_5 + CH_2O \longrightarrow$$
$$\underset{CH_2}{\underset{\|}{CH_3COCCOOC_2H_5}} + KHSO_3 \longrightarrow$$
$$\underset{OH\ CH_2SO_3K}{CH_3C{=}CCOOC_2H_5} \longrightarrow \underset{CH_2SO_3K}{CH_3COCHCOOC_2H_5}$$

Backer and Mulder[8] a short time ago have introduced independent evidence for the hydroxysulfonic acid structure, for the compound $NH_2CH_2SO_3H$ (or $NH_3^+CH_2SO_3^-$) obtained by treating formaldehyde bisulfite with ammonia contains a carbon–sulfur linkage since treatment with nitrosyl chloride yields chloromethane sulfonic

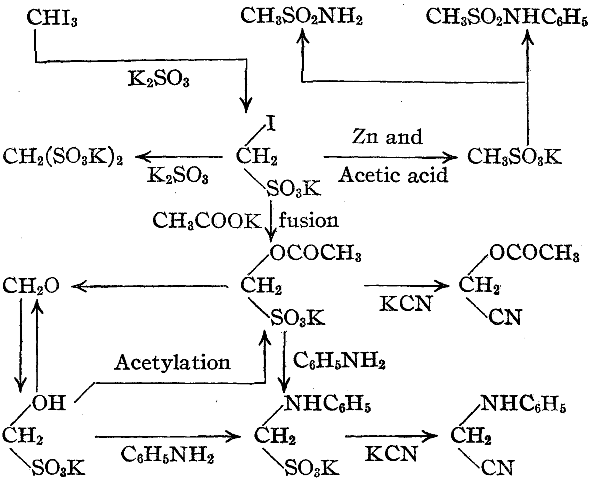
acid. In spite of this excellent evidence for structure II, it was thought desirable[9] to add still further and, if possible, equally conclusive proof.

The following series of reactions, which needs but little explanation, has been carried out.



Iodomethane sulfonic acid is definitely a sulfonic acid since it can be transformed into methionic acid and methane sulfonic acid. Fusion (*ca.* 200°) of this compound with potassium acetate and acetylation of the formaldehyde bisulfite addition compound each yields acetoxymethane sulfonic acid. The identity of these two preparations has been demonstrated. This evidence, in conjunction with that submitted by other investigators, supplies ample proof of the hydroxymethane sulfonic acid structure for formaldehyde bisulfite and makes it unnecessary to resort to a "polymolecule formula," (R_2CO), (SO_2), (HOH), of the type suggested by Schroeter.

Experimental

Potassium Iodomethane Sulfonate.—Since the preparations of the salts of iodomethane sulfonic acid are described only in patent literature[10] the details of procedure are included here.

Ninety-five grams (0.6 mole) of potassium sulfite was dissolved in 450 cc. of water in a 1-liter round-bottomed flask and 78.8 g. (0.2 mole) of freshly recrystallized iodoform added so that the iodoform formed a layer above the water. The reaction mixture was refluxed for a period of three to four hours until practically all of the iodoform and methylene iodide had disappeared. After filtering the solution it was evaporated to dryness on a steam-cone. (Blowing a stream of compressed air over the beaker shortens considerably the length of time required for this operation.) The dry solid was extracted with methyl alcohol at room temperature. One extraction with 300 cc. followed by two extractions with 200 cc. of methyl alcohol is sufficient to remove almost all of the inorganic iodide. The residue was then treated with 800 cc. of boiling 80% ethyl alcohol and filtered. The cooled filtrate yielded 38.0 g. (73%) of shiny, white plates which were washed with absolute alcohol and ether and then air dried.

Anal. Calcd. for CH_2ISO_3K: K, 15.03. Found: K, 14.95, 15.05.

The sodium salt was prepared in a similar way; however, in this case it is not necessary to remove the sodium iodide. The evaporated reaction mixture is extracted directly with 300 cc. of 90% ethyl alcohol; yield, 68%.

Anal. Calcd. for $CH_2ISO_3Na \cdot H_2O$: K, 8.78; H_2O, 6.68. Found: K, 8.78; H_2O, 7.16.

Potassium Acetoxymethane Sulfonate (a) from Potassium Iodomethane Sulfonate.—After refluxing potassium acetate and potassium iodomethane sulfonate in aqueous solution for fifteen hours no iodide ion had formed. However, when 10.4 g. (0.04 mole) of potassium iodomethane sulfonate and 5 g. (0.05 mole) of potassium acetate were ground in a mortar and heated to 200–205° in a Wood's metal-bath and held there for an hour with stirring the mass liquefied. The reaction was maintained at this temperature for two and one-half hours. After cooling to room temperature the mass was chipped out of the flask and ground. The solid was extracted with two 200-cc. portions of methyl alcohol and then with one 100-cc. portion, all at room temperature. The methyl alcohol extracts were evaporated to dryness and then dissolved in 100 cc. of water. Titration of a 10-cc. portion with silver nitrate showed that 92% of the iodine in the original compound had been changed to iodide ion.

The solid remaining after the methyl alcohol extraction was treated with 400 cc. of boiling 95% ethyl alcohol. The cooled filtrate produced 1.03 g. of solid. A second extraction yielded 0.55 g. of the same material, yield 20.5%.

Anal. Calcd. for $C_3H_5O_5SK$: K, 20.35. Found: (for 1.03-g. fraction) K, 20.07, 20.11; (for 0.55-g. fraction) K, 20.09.

Potassium Acetoxymethane Sulfonate (b) from the Potassium Bisulfite Addition Compound of Formaldehyde.—Treatment of the potassium bisulfite addition compound of formaldehyde with acetic anhydride according to the procedure of Raschig and Prahl[11] yielded a product the potassium content of which was somewhat too high for potassium acetoxymethane sulfonate. Recrystallization lowered the percentage of potassium but it was still higher than theory. The substance was prepared in the following way.

Twenty grams of the potassium bisulfite addition compound of formaldehyde (K, 26.15; calcd., 26.04) was added to a 200-cc. round-bottomed flask containing 100 cc. of acetic anhydride and 10 cc. of glacial acetic acid. After twenty minutes of refluxing *with constant shaking* the flask was filled with a mass of crystals. Filtered, washed with

[11] Raschig and Prahl, *Ann.*, **448**, 305 (1926).

absolute alcohol, followed by ether and then dried, the solid weighed 20.0 g. (75%). The potassium content of the crude product was 20.77%. The solid was recrystallized from 95% alcohol; approximate solubility hot, 0.55 g. per 100 cc. of 95% ethyl alcohol; cold, 0.07 g. per 100 cc. of 95% ethyl alcohol. In larger amounts the substance can be recrystallized satisfactorily from 80% alcohol.

Anal. Calcd. for $C_3H_5O_5SK$: K, 20.35. Found: (for various fractions) K, 20.34, 20.38, 20.17, 20.33.

Comparison of the Potassium Acetoxymethane Sulfonate Prepared by the Two Methods.—The decomposition temperature of the first preparation is 239–245°; that of the second 243–246°. A mixture of the two substances decomposes at 240–246°.

Dr. E. B. Sandell of the division of analytical chemistry of the University of Minnesota kindly submits the following crystallographic comparison. Both substances recrystallized from 95% alcohol form plates and flattened prisms which are anisotropic and exhibit parallel extinction. The index of refraction corresponding to light vibrating parallel to the long direction of the prisms is 1.491 ± 0.002, whereas the index most often exhibited crosswise is 1.521 ± 0.003 *in both samples.*

Potassium Methionate from Potassium Iodomethane Sulfonate.—Twenty-six grams (0.1 mole) of potassium iodomethane sulfonate and 47.5 g. (0.3 mole) of potassium sulfite were dissolved in water and diluted to 500 cc. Placed in a 1-liter round-bottomed flask under a reflux condenser the reaction mixture was heated on a steam-bath. At approximately twenty-four hour intervals 10-cc. portions were removed and extracted with methyl alcohol. The alcoholic extract was evaporated and the resulting solid titrated with silver nitrate solution using eosin as an indicator. At the end of twenty-four hours, 34.3% reaction; forty-eight hours, 49.3%; seventy-two hours, 65.0%; ninety-six hours, 68.8%; one hundred and twenty hours, 76.8%; one hundred and forty-four hours, 87.3%; one hundred and sixty-eight hours, 87.0%. The solution was then evaporated to 150 cc., cooled and the solid filtered off. Recrystallized from 125 cc. of hot water this yielded 15.50 g. of air-dried potassium methionate.

Anal. Calcd. for $CH_2O_6S_2K_2$: K, 30.99. Found: K, 30.91.

A further crop of 3.7 g. potassium methionate was obtained by working up the filtrates; total yield, 19.2 g. (84.6%).

Potassium Methane Sulfonate from Potassium Iodomethane Sulfonate.—Twenty-six grams (0.1 mole) of potassium iodomethane sulfonate, 20 g. of glacial acetic acid and 25 g. of zinc dust were placed in 380 cc. of 50% alcohol and refluxed for two and one-half hours. The excess zinc dust was filtered off and the solution evaporated to 200 cc. The zinc sulfide formed on saturating the solution with hydrogen sulfide was filtered off and the filtrate evaporated to dryness. An extract with 150 cc. of methyl alcohol was discarded. The remaining solid was recrystallized from 150 cc. of 80% ethyl alcohol; total yield (3 crops), 9.8 g. (73%).

Anal. Calcd. for CH_3SO_3K: K, 29.14. Found: K, 28.90.

The amide prepared in the customary manner melted at 89–90°.[12] The sulfonanilide melts at 102–103°.[13]

Acetoxyacetonitrile from Potassium Acetoxymethanesulfonate.—19.2 g. of potassium acetoxymethanesulfonate (0.1 mole) and 6.5 g. (0.1 mole) of potassium cyanide were dissolved in 50 cc. of water and allowed to stand at room temperature for thirty minutes. An oil formed on the surface and was extracted with ether (200 cc.) and the ether extract dried over anhydrous sodium sulfate. The ether was removed on a water-bath and the oil remaining distilled: 105–178°, 1.65 g.; 178–179°, 1.70 g.; total yield 33.9%; after redistillation $n^{20}{}_D$ 1.4040°. Henry[14] reports a boiling point of 179–180° and $n^{20}{}_D$ 1.4107 for acetoxyacetonitrile prepared by the action of potassium acetate on chloracetonitrile.

Potassium Anilinomethane Sulfonate from Potassium Acetoxymethane Sulfonate.—3.84 g. (0.02 mole) of potassium acetoxymethane sulfonate and 40 cc. of aniline were refluxed until the reaction mixture set almost to a solid mass. The flask was cooled to room temperature and an equal volume of absolute alcohol added. The solid after filtration weighed 3.88 g. (85%). Recrystallized from methyl alcohol it analyzed for potassium anilinomethane sulfonate.

Anal. Calcd. for $C_7H_8O_3NSK \cdot H_2O$: H_2O, 7.41; K, 16.07. Found: H_2O, 6.79; K, 16.31.

Treatment with potassium cyanide yielded an oil which was presumably anilinoacetonitrile. Since difficulty was experienced in crystallizing this oil a small part of it was converted to phenylglycine the melting point (124–126°) of which was not depressed on adding authentic phenyl glycine.

Hydrolysis of Potassium Acetoxymethane Sulfonate.—One gram of potassium acetoxymethane sulfonate was dissolved in 25 cc. of water in a 50-cc. distilling flask, 1 cc. of concentrated sulfuric acid was added and the solution distilled slowly into 1 g. of dimethyl dihydroresorcinol dissolved in 75 cc. of water. A precipitate was formed which melted below the melting point of dimethyl dihydroresorcinol. After filtering off this solid the filtrate was treated with potassium bicarbonate and the precipitate recrystallized from a small amount of acetone. The melting point and mixed melting point with a sample of formaldehyde dimethone melting at 191–192°, was 191–192°.

The authors gratefully acknowledge a grant from the Graduate School Fund of the University of Minnesota, which made this work possible.

Summary

It has been shown that the bisulfite addition compound of formaldehyde and presumably all aldehyde and ketone bisulfites are salts of α-hydroxysulfonic acids, $R_2C(OH)SO_3Me$.

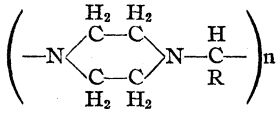
Derivatives of Piperazine. VIII. Condensation with Aldehydes

BY W. T. FORSEE, JR., AND C. B. POLLARD

The literature reveals very few data on reactions between piperazine and aldehydes and this small amount of published work is somewhat contradictory. Experimental evidence has failed to establish a basis for predicting the type of compound expected when an aldehyde is condensed with piperazine.

In this investigation piperazine was condensed with formaldehyde, acetaldehyde, butyraldehyde, benzaldehyde, salicylaldehyde, *p*-tolylaldehyde and *o*-chlorobenzaldehyde. With two exceptions, data indicate compounds of the structure



The structure of the products from acetaldehyde and butyraldehyde have not yet been determined. Formaldehyde and piperazine[1] gave the same product as was obtained from methylene iodide and piperazine. Benzaldehyde and piperazine[2] gave the same product as was obtained from benzal chloride and piperazine. These reactions and the analyses show these condensation products to be a N,N′-bis-piperazylalkylmethane type of compound. However, the molecular structure might be one of any number of polymers. Since these compounds are practically insoluble in all solvents and are unstable at temperatures near the melting points, a molecular weight determination by ordinary methods was impossible. Purification was accomplished by using highly purified reagents and washing the products repeatedly with several solvents.

In order to block the possibility of polymerization, N-monophenylpiperazine was condensed with various aldehydes. Compounds of the N-bis-(N′-phenylpiperazyl)-alkylmethane type were obtained from formaldehyde, acetaldehyde, benzaldehyde, *p*-tolylaldehyde and anisaldehyde. N-Monophenylpiperazine with formaldehyde[3] gave the same compound as was obtained from N-monophenylpiperazine and methylene iodide.

Properties of the compounds obtained from piperazine are shown in Table I. Table II gives

the data for those obtained from N-monophenylpiperazine.

All of the condensation products are readily decomposed by acids. In contrast to the products from piperazine those from N-monophenylpiperazine were readily crystallized from appropriate solvents.

All of the condensation products were prepared by reacting the amine with the aldehyde either in the absence or presence of a solvent. The method recommended by Cummings, Hopper and Wheeler[4] was used in all reactions which involved alkyl halides.

Summary

It has been shown that when aldehydes react with piperazine or N-mono-substituted piperazines, one molecule of the aldehyde reacts with two amino groups and a molecule of water is eliminated.

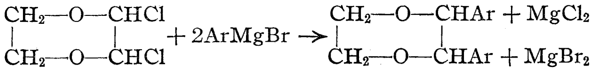
Studies in the Dioxane Series. II. Aryl Substituted Dioxanes Synthesis of *p*-Dioxene[1]

BY R. K. SUMMERBELL AND L. N. BAUER

The preparation of 2,3-diphenyl-1,4-dioxane by the reaction of 2,3-dichloro-1,4-dioxane with phenylmagnesium bromide was described by Christ and Summerbell.[2]



$$\begin{array}{l} CH_2—O—CHCl \\ | \qquad\quad | \\ CH_2—O—CHCl \end{array} + 2ArMgBr \rightarrow \begin{array}{l} CH_2—O—CHAr + MgCl_2 \\ | \qquad\quad | \\ CH_2—O—CHAr + MgBr_2 \end{array}$$

The same method of synthesis has been satisfactorily applied to a number of aryl substituted dioxanes.

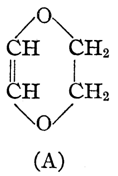
Although two 2,3-disubstituted dioxanes may be predicted from theory, only one was obtained in each case. In a repetition of the 2,3-diphenyl-1,4-dioxane synthesis, a yield of 80% of the previously described material was obtained, and attempts to isolate a second disubstituted dioxane were unsuccessful. The high yield of a single product in this case, and the failure to obtain two isomers in any of the experiments described in this paper, may be taken to indicate that the 2,3-dichloro-1,4-dioxane used was a pure compound, rather than a mixture of *cis* and *trans* isomers.

The reaction of benzylmagnesium chloride with dichlorodioxane might give an *o*-tolyl derivative.[3] As only a small amount of phthalic acid was obtained on permanganate oxidation of the reaction product, there is very little, if any, of this type of rearrangement. Further work on high molecular weight residues must be carried out to explain all that takes place in this reaction.

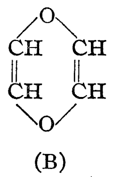
In an attempt to extend this method of synthesis to alkyl substituted dioxanes, only small yields of dimethyl, diethyl and dibutyl-1,4-dioxanes were obtained. The yields were so small that a discussion of their properties will be withheld, pending the outcome of experiments now under way on modifications of procedure designed to increase the yield and hence the material available for investigation.

---

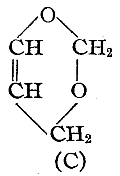
[1] The name 1,4-(or *p*-)dioxene for a new compound (A) described in this paper requires explanation. It follows logically from 1,4-dioxane, the preferred name [Patterson, THIS JOURNAL, **55**, 3911 (1933)] of the fully hydrogenated analog. It might be called 2,3-dihydro-1,4-dioxin since dioxin has been proposed [Widman, *Ber.*, **42**, 3269 (1909)] to represent the least hydrogenated member. Unfortunately for the logic involved, dioxin turns out to be either $C_4H_4O_2$ or $C_4H_6O_2$ depending on whether 1,4-dioxin (B) or 1,3-dioxin (C) is being considered.



(A)



(B)



(C)

(See *Chem. Abs.*, **28**, 8219 (1934) for both structures.) It is incredible that two related non-isomeric substances of known structures should needlessly be assigned the same name.

The logical name for (C) is 1,3-dioxene. Instead of 1,4-dioxin, the name dioxadiene is proposed for (B). The name is simple, informative, and free from an ambiguous past.

This plan applies equally well for the sulfur analogs: dithiane, dithiene, oxathiane and oxathiene. The last two names are preferable to thioxane and thioxene since, according to the rules of numbering ring systems, the oxygen should be numbered one; thus 1,4-oxathiane, etc. We acknowledge assistance in this formulation from E. J. Crane and A. M. Patterson, members of the A. C. S. committee on nomenclature.—C. D. HURD, C. M. SUTER AND R. K. SUMMERBELL.

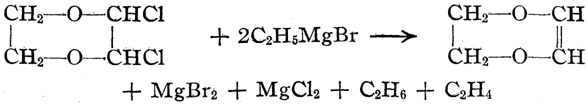
[3] Gilman and Kirby, *ibid.*, **54**, 345 (1932); John R. Johnson, *ibid.*, **55**, 3029 (1933); and earlier work to which these articles contain references.

The chief product in the reaction of methyl, ethyl, and butylmagnesium bromides with 2,3-dichlorodioxane was *p*-dioxene.



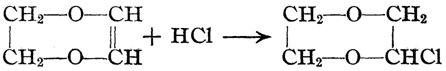
$$\begin{array}{l}CH_2\text{—}O\text{—}CHCl\\ |\qquad\quad |\\ CH_2\text{—}O\text{—}CHCl\end{array} + 2C_2H_5MgBr \longrightarrow \begin{array}{l}CH_2\text{—}O\text{—}CH\\ |\qquad\quad \|\\ CH_2\text{—}O\text{—}CH\end{array}$$
$$+ MgBr_2 + MgCl_2 + C_2H_6 + C_2H_4$$

The identity of this compound was proved by: (a) analysis and molecular weight determinations; (b) ozonization and identification of the expected products, formic acid and ethylene glycol; and (c) addition of chlorine to form the known 2,3-dichloro-1,4-dioxane.

The chief hydrocarbon products of the reaction are as represented in the equation above, although there was produced also a small amount of a saturated hydrocarbon of higher molecular weight, probably butane.

Dioxene adds bromine very readily to form 2,3-dibromo-1,4-dioxane. This compound had previously been described in a very impure liquid state by Tellegen.[4] As we obtained it, it is an unstable solid, constantly evolving hydrogen bromide. It reacts with phenylmagnesium bromide to yield 2,3-diphenyl-1,4-dioxane, thus indicating its structure.

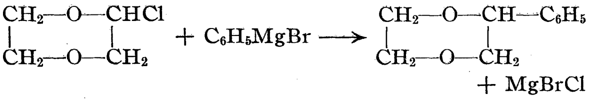
Hydrogen chloride also adds to the double bond of *p*-dioxene to give monochloro-*p*-dioxane. The chlorine atom of the latter compound, being alpha to an oxygen atom, should be reactive, and



$$\begin{array}{l}CH_2\text{—}O\text{—}CH\\ |\qquad\quad \|\\ CH_2\text{—}O\text{—}CH\end{array} + HCl \longrightarrow \begin{array}{l}CH_2\text{—}O\text{—}CH_2\\ |\qquad\quad |\\ CH_2\text{—}O\text{—}CHCl\end{array}$$

thus the compound should be a valuable intermediate for the sythesis of monosubstituted *p*-dioxanes.

Monochloro-*p*-dioxane does react with phenylmagnesium bromide to give phenyl-*p*-dioxane.



$$\begin{array}{l}CH_2\text{—}O\text{—}CHCl\\ |\qquad\quad |\\ CH_2\text{—}O\text{—}CH_2\end{array} + C_6H_5MgBr \longrightarrow \begin{array}{l}CH_2\text{—}O\text{—}CH\text{—}C_6H_5\\ |\qquad\quad |\\ CH_2\text{—}O\text{—}CH_2\end{array}$$
$$+ MgBrCl$$

The isolation of monochloro-*p*-dioxane is of peculiar interest, in that it has never been isolated in the direct chlorination[5] of *p*-dioxane. The failure to isolate monochloro-*p*-dioxane is easy to understand from its properties, for it is unstable at room temperature, and would be much less stable at the usual temperature of chlorination. If one assumes that the addition of hydrogen chloride to *p*-dioxene is reversible, one has a satisfactory picture of a mechanism for the chlorination of 1,4-dioxane to give 2,3-dichloro-1,4-dioxane. Probably monochloro-*p*-dioxane is first formed. It readily loses hydrogen chloride to give *p*-dioxene, which, in turn, adds a molecule of chlorine to give 2,3-dichloro-1,4-dioxane. The addition of chlorine to a double bond would probably give chiefly one isomer, whereas chlorination of the two carbon atoms independently would give a mixture of isomers. The 2,3-dichloro-1,4-dioxane obtained by us seems to be a pure compound and not a mixture of isomers.

Further work on the role of this compound in the chlorination of dioxane and its use in synthesis is contemplated and under way at the present time.

Experimental

A. General.—As the procedure was in all cases similar to that previously described,[6] only notes on important details, analysis, etc., will be given here. Grignard reagents were prepared with at least five moles of ether for each mole of freshly distilled halide. They were titrated[7] by the method of Gilman.

The 2,3-dichloro-1,4-dioxane was prepared by chlorinating[8] 632 g. of purified 1,4-dioxane which melted at 11–12.5° for sixteen hours at 90° with mechanical stirring. The product was obtained in 61% yield, m. p. 28–30°; b. p. 85° (15 mm.).

Molecular weights were determined by the lowering of the melting point of camphor.[9,10]

B. 2,3-Diphenyl-1,4-dioxane.[11]—The synthesis of this compound was repeated in order to determine accurately the yield on a run of moderate scale, and to furnish material for a more intensive search for an isomeric 2,3-diphenyldioxane.

Phenylmagnesium bromide was prepared in the usual manner, using the following quantities of materials: 701 g. of bromobenzene, 108 g. of magnesium, and 2300 cc. of anhydrous ether; yield of Grignard reagent, 4.27 moles or 95.7%. The entire preparation, a large excess, was treated with 167.6 g. (1.067 mole) of 2,3-dichloro-1,4-dioxane. Hydrolysis of the reaction product was carried out with dilute sulfuric acid. The ether layer was fractionally distilled, the major part of high boiling material distilling at 185–187° (13 mm.). After recrystallizing seven times from ligroin in an effort to separate any foreign

material, 205 g. of 2,3-diphenyl-1,4-dioxane melting at 49–50° was obtained. The yield is 80%. No isomeric substance was found in the mother liquors.

C. **New Symmetrical 2,3-Diaryl-1,4-dioxanes.**—Other new symmetrical 2,3-diaryl-1,4-dioxanes were prepared and analyzed as shown in Tables I and II.

The smaller yields are due partially to smaller scale experiments.

TABLE I

SYMMETRICAL 2,3-DIARYL-1,4-DIOXANES

Substituents	Yields, RMgX	in % Dioxane	M. p., °C. (corr.)	Mol. wt. Found	Calcd.

[a] Observed b. p. 255–258° (3–4 mm. (uncorr.)).

[b] Part of product lost in purification.

[c] A viscous, sirup-like mass remaining in the distilling flask which would not distil below a bath temperature of 300° at a pressure less than 1 mm. has not been investigated. Permanganate oxidation [Gilman and Kirby, THIS JOURNAL, 54, 345 (1932)] of the 2,3-dibenzyldioxane gave a large quantity of benzoic acid and only traces of phthalic acid, indicating very little rearrangement to the *o*-tolyl derivative. The small yield is doubtless connected with the low yields of aliphatic dioxanes prepared by this method. They are being investigated.

TABLE II

Several of the aryl disubstituted dioxanes form picrates. Use was made of this fact in obtaining solid 2,3-*p*-ditolyl-1,4-dioxane. The reaction product was a very viscous liquid which, however, formed a solid picrate. On treatment of this picrate with alkali, a solid was obtained which was used to seed the main mass of material, which then solidified; m. p. of picrates: *m*-ditolyldioxane, 91–92°; *p*-ditolydioxane 96.5°; *p*-dianisyldioxane, 107–108°; α-dinaphthyldioxane, 166–167°.

D. **Preparation of *p*-Dioxene.**—2,3-Dichloro-1,4-dioxane (2.43 moles) dissolved in 500 cc. of anhydrous ethyl ether was added over a period of four hours to 4.85 moles of ethylmagnesium bromide. The heat evolved resulted in gentle refluxing. After standing for twenty hours, the reaction product was hydrolyzed with an excess of water at 0°. The ether layer was separated, dried over anhydrous sodium sulfate, and fractionated by distillation in a 50-cm. vacuum-jacketed column containing a nichrome wire coil. Two chief products were obtained: (a) 140.5 g. of a liquid which was light greenish-yellow in color immediately after distillation, but which turned colorless on standing, b. p. 94.5° (754.3 mm.); (b) 22.3 g. of a colorless liquid having the odor of green willow bark, b. p. 164–175° (747.9 mm.). This compound is evidently an impure sample of 2,3-diethyldioxane. It is being investigated.

During the addition of 2,3-dichloro-1,4-dioxane to ethylmagnesium bromide, copious quantities of gas were evolved. The small yield of the expected product made the identification of this gas of interest. A similar run was made, and a sample of the evolving gas collected. This gas was analyzed by absorption and combustion.[12,13] Of 91.8 cc. of gas, 44.5 cc. was absorbed by 96% sulfuric acid. Combustion of the saturated remainder showed *n*, the number of carbon atoms, to be 2.13, 2.14. The analysis then corresponds to 48.5% unsaturated hydrocarbon, probably ethylene, 48.2% ethane, and 3.4% butane. The butane may have been the result of a side reaction of the original Grignard reagent synthesis. The principal course of the reaction must have followed the equation given in the theoretical part.

E. Properties and Structure of *p*-Dioxene

(a) **Properties.**—Fraction (a) of the above was again distilled; b. p. 94.2° (749.9 mm.); $d^{20}{}_4$ 1.083; $n^{22.5}{}_D$ 1.4375; $n^{25}{}_D$ 1.4362.

Anal. Calcd. for $C_4H_6O_2$: R_L[14] 21.38; mol. wt., 86; C, 55.81; H, 6.98. Found: R_L, 20.99; mol. wt., 89.9[15] 90.6;[16] C, 55.94; H, 7.11.

(b) **Ozonization.**—Pure dioxene (4.55 g.) was dissolved in 80 cc. of carbon tetrachloride and placed in a flask surrounded by ice. Over a period of eight and one-half hours, 0.03 cu. meter of pure dry oxygen was run through an ozonizer and bubbled through the solution. The ozonide thus formed was hydrolyzed with water at the temperature of a steam-bath for two hours. Titration with 0.4554 *N* potassium hydroxide required 194.6 cc., indicating a yield of 83.7% of formic acid. The solution of the potassium salt was evaporated, and the presence of the formate ion proved by reaction of a portion of the neutral potassium salt with 0.005 mole of *p*-bromophenacyl bromide.[17] The *p*-bromophenacyl ester of formic acid, m. p. 140°, mixed m. p. 140°, was obtained.

To prove that ethylene glycol was also a product of ozonization and hydrolysis, the solution obtained by neutralization was treated with benzoyl chloride in the presence of an excess of potassium hydroxide. An excellent yield of the dibenzoate of ethylene glycol resulted, m. p. 70°, mixed m. p. 70°.

F. Reaction of 2,3-Dichlorodioxane with other Alkylmagnesium Halides

(a) **Methylmagnesium Bromide.**—The reaction of 2,3-dichlorodioxane with methylmagnesium bromide was

[15] Method of Dumas.

[16] Method of Victor Meyer.

[17] Hurd and Christ, THIS JOURNAL, **57**, 2007 (1935).

carried out as described for the reaction with ethylmagnesium bromide. The chief product isolated was *p*-dioxene.

(b) **Butylmagnesium Bromide.**—The reaction of 0.573 mole of 2,3-dichlorodioxane with 1.146 mole of *n*-butylmagnesium bromide was carried out as described for ethylmagnesium bromide. A yield of 38.8 g. (78.7%) of crude *p*-dioxene was obtained. A small fraction, 2.5 cc. boiling at 122.5–125° (746.7 mm.), n^{20}_D 1.3985, was probably *n*-octane. Another fraction, 2.5 g., b. p. 120–122° (16–17 mm.), is probably 2,3-dibutyl-1,4-dioxane and will be investigated when more material is available.

The gases evolved during the reaction were condensed in a solid carbon dioxide trap. A portion was allowed to distil and analyzed. The sample analyzed 46.3% saturated, butane, and 53.7% soluble in 82% sulfuric acid, butylene.

G. Addition of Chlorine to *p*-Dioxene.—*p*-Dioxene (23.27 g. or 0.271 mole) was dissolved in pure carbon tetrachloride. Fifteen and three-tenth grams of chlorine gas mixed with dry nitrogen was dried over anhydrous magnesium perchlorate, and passed into the vigorously stirred solution at 0° during a period of four hours. The reaction product was fractionated, and 22.7 g. of a liquid boiling at 85° (15 mm.) (2,3-dichloro-1,4-dioxane) was obtained; yield, 53.4%. The product was positively identified by reaction of a portion with *o*-tolylmagnesium bromide to form 2,3-*o*-ditolyl-1,4-dioxane, m. p. 106–107°.

H. The Addition of Bromine to *p*-Dioxene.—To 4.29 g. (0.05 mole) of *p*-dioxene dissolved in 15 cc. of dry carbon tetrachloride was added 7.97 g. (0.05 mole) of bromine dissolved in 25 cc. of dry carbon tetrachloride. During the dropwise addition of the latter, which took one hour, the reaction mixture was stirred vigorously and the temperature maintained at 0°. The carbon tetrachloride was evaporated by decreasing the pressure (26–15 mm.) and white crystals formed. Recrystallization from dry ether gave 11.3 g. of a product that softened at 64° and melted at 69–70°; yield 92.2%. The crystals were soluble in ether, carbon tetrachloride, dioxane, and water, but not readily so in petroleum ether. They may be kept in an evacuated (approx. 15 mm.) desiccator for several days, but on exposure to the atmosphere, hydrogen bromide is continuously evolved and a dark brown oil eventually results.

Anal. Calcd. for $C_4H_6O_2Br_2$: Br, 65.00. Found: Br, 63.60, 63.22.

A sample which had stood for two days in a vacuum desiccator showed a slight lowering of melting point and gave 63.06% of bromine. The continually decreasing bromine content serves to explain why all of the analyses are below theoretical.

Since these analyses were only moderately satisfactory, it seemed desirable to prepare a derivative that would prove whether or not the above crystals were 2,3-dibromodioxane; 22.6 g. of the compound was prepared as described above, dissolved in 50 cc. of anhydrous ether, and added over a period of an hour to an ether solution of phenylmagnesium bromide (0.20 mole). The reaction mixture was cooled to 0°, hydrolyzed with water and dilute sulfuric acid, and the ether layer separated. On distillation, 13 g. of a colorless oil, b. p. 185–189° (11–12 mm.), resulted. On crystallization of this oil from petroleum ether, 12.4 g. of 2,3-diphenyldioxane, m. p. 49°, mixed m. p. 49°, was obtained; yield, 56.2%.

I. Addition of Hydrogen Chloride to *p*-Dioxene. (Monochloro-*p*-dioxane.)—It was observed that much heat is evolved when dry hydrogen chloride is passed into *p*-dioxene. As one of the reactions that may be postulated would indicate the unknown monochloro-*p*-dioxane, the following experiment was carried out in an attempt to isolate this compound.

p-Dioxene (6.5 g. or 0.076 mole) was cooled to 0°. Hydrogen chloride was slowly bubbled through the *p*-dioxene with stirring at 0°. Immediate fractionation yielded 6.6 g. of a product, b. p. 59° (17 mm.). Approximately 1 g. of a tarry residue remained. Redistillation gave a b. p. of 62–63° (14 mm.); d^{20}_{20} 1.276.

Anal. Calcd. for $C_4H_7O_2Cl$: Cl, 28.94. Found: Cl, 26.84.

An experiment using ether as a solvent failed to give as good a yield as the above procedure.

In yet another experiment, bismuth trichloride was used as a catalyst, with rather surprising results. To 12.04 g. (0.14 mole) of *p*-dioxene was added 0.0135 g. (0.0001 mole) of bismuth trichloride. Dry hydrogen chloride was passed in for thirty minutes as the liquid was agitated, the temperature being maintained at 0°. The reaction product became light brown to orange in color. Less than 1 cc. distilled at 12–13 mm. when the temperature of the bath surrounding the distilling flask was raised to 275°. The material remaining in the distilling flask became a dark colored tarry residue. It is probably a polymer of *p*-dioxene, and is being further investigated.

Monochloro-1,4-dioxane is a colorless liquid. It constantly loses hydrogen chloride, and on standing for a few minutes becomes yellow. Within a week it changes to a black, viscous tar. Analyses other than those given above on freshly distilled material gave 25.66% Cl and 27.62% Cl compared with the calculated value of 28.94% Cl. Evidently the compound decomposes to such an extent that a satisfactory analysis is impossible; however, the identity of the compound was proved by the following experiment.

J. Monophenyl-*p*-dioxane.—A Grignard reagent was prepared by reaction of 19.28 g. (0.126 mole) of bromobenzene with 3.064 g. (0.126 mole) of magnesium, using 75 cc. of dry ether.

Freshly prepared monochloro-*p*-dioxane (7.31 g. or 0.06 mole) was dissolved in 10 cc. of dry ether and added to the agitated Grignard reagent at such a rate that the vigorous reaction resulted in a gentle refluxing of the solvent. Hydrolysis was carried out with water and dilute sulfuric acid at 0°. The ether layer upon evaporation yielded 4.8 g. of crystals, m. p. 45–46°. Recrystallization of the product from either alcohol or petroleum ether gave a melting point of 46°; yield, 49%.

Alkaline permanganate oxidation of the monophenyl-*p*-dioxane prepared above gave benzoic acid, proving a phenyl radical attached to carbon. The identity of the benzoic acid was ascertained by the formation of the *p*-toluidide, m. p. 156.5–157°.

Anal. Calcd. for $C_{10}H_{12}O_2$: mol. wt., 164.1; C, 73.13; H, 7.37. Found: mol. wt., 175;[18] C, 73.43; H, 7.36.

---

[18] Mol. wt. by Rast camphor method.

Conclusions

1. A number of 2,3-diaryl-1,4-dioxanes have been synthesized for the first time.
2. The reaction of alkylmagnesium halides with 2,3-dichloro-1,4-dioxane produces *p*-dioxene, a new compound, of which the structure has been proved.
3. The reactions of *p*-dioxene have been studied.
4. Monochloro-*p*-dioxane has been obtained for the first time, and a mechanism for the chlorination of dioxane proposed.
5. Monophenyl-*p*-dioxane has been prepared.
6. The work is being continued.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF NORTH CAROLINA]

The Identification of Phenols with 2,4-Dinitrochlorobenzene

BY R. W. BOST AND FRANK NICHOLSON

Although numerous reagents have been proposed for the identification of phenols,[1-5] nevertheless serious objections may be raised against most of them. The method of Koelsch[5] is perhaps the best but many of his derivatives melt so close together that identification is difficult, whereas the *o*- and *p*-nitrophenols were not obtained.

The value of 2,4-dinitrochlorobenzene as a reagent for the identification of mercaptans has been shown in previous communications.[6,7] Since the reactions of mercaptans and phenols are similar in many respects, it seemed desirable to study the usefulness of 2,4-dinitrochlorobenzene as a reagent for phenols. In a few cases 2,4-dinitrophenyl ethers occur in the literature and in such cases the melting points and literature references are given in the table. In cases where discrepancies occur between the melting points of those reported in the literature and of those obtained in our study, analyses were made and herein recorded.

Procedure

0.01 Mole of the phenol is added to 0.01 mole of sodium hydroxide dissolved in 5 cc. of water. The resulting solution of sodium phenolate is added to 0.01 mole of 2,4-dinitrochlorobenzene dissolved in 30 cc. of ethyl alcohol (95%). In some cases with difficultly soluble compounds more alcohol must be added to keep the substance in solution. The solution at this point is always highly colored. In most cases it turns dark red in color; however in some cases it is almost black. The solution is then heated under reflux on a steam-bath until the red color is discharged and a copious precipitate of salt appears. (Usually one-half hour is sufficient.) The reaction mixture is diluted with an equal part of water whereupon the 2,4-dinitrophenyl ether is precipitated, then filtered, washed with water and finally recrystallized from alcohol. As a rule one recrystallization is sufficient.

Discussion of Results

There are times when a precipitate occurs at the point when the aqueous solution of the phenolate is added to the alcoholic solution of the reagent. This precipitate is not to be confused with the precipitate of salt which appears after heating for some time. It has been shown[8] that 2,4-dinitrochlorobenzene forms addition products with certain phenols, and apparently the precipitate first formed in our work is of such a nature, since it contains both nitrogen and chlorine. Upon heating, it loses chlorine as well as its color, and sodium chloride is precipitated.

The 2,4-dinitrophenyl ethers which were obtained are easily purified, highly crystalline, and possess sharp melting points widely enough separated to ensure identification. An exception is noted only in the case of derivatives of 2,4-dibromophenol and 2,4,6-tribromophenol, which have the same melting point. However, in this case, the original phenols melt 56° apart. With the exception of the derivatives of thymol, carvacrol and hexylresorcinol, all are precipitated from the reaction mixture as solids. The reagent is superior to the isocyanates in that the presence of water in the phenol does not interfere with the formation of the derivative. The melting points are high enough so that very few are obtained as oils, again indicating the superiority of the reagent. 2,4-Dinitrochlorobenzene is more stable than both

the isocyanates and the nitroacyl halides and possesses an advantage in this respect. The procedure is simple and requires no special degree of skill. Good results may be obtained in the hands of a beginner.

Summary

1. 2,4-Dinitrochlorobenzene reacts with phenols forming highly crystalline stable solids, easily purified, and possessing sharp melting points.

2. The procedure is simple and requires no unusual of technique.

3. Derivatives of twenty-eight phenols are given.

Studies on the Polymethylbenzenes. XIII.[1] Mercuration

BY LEE IRVIN SMITH AND F. LOWELL TAYLOR[2]

Direct mercuration is a characteristic substitution reaction of aromatic hydrocarbons which has not been studied previously in the series of the polymethylbenzenes. In the study reported in this paper, six polymethylbenzenes, namely, mesitylene, pseudocumene, durene, isodurene, prehnitene, and penta-methylbenzene were mercurated and the acetoxymercuri-, halogenomercuri-, and bis-arylmercury derivatives were prepared and characterized.

Michaelis[3] treated bromomesitylene and 5-bromopseudocumene with sodium amalgam in xylene, and obtained the corresponding bis-arylmercury compounds; from the latter he prepared arylmercuric halides by the action of mercuric halides. Whitmore[4] and his students mercurated mesitylene directly with mercuric acetate, but they did not report the properties of acetoxymercurimesitylene. Jacobsen[5] obtained bis-(pentamethylphenyl)-mercury when he attempted to prepare pentamethylbenzoic ester from bromopentamethylbenzene, chloroformic ester and sodium amalgam.

The polymethylbenzenes were mercurated by mercuric acetate in methanol solution. Pentamethylbenzene, durene, and mesitylene gave good yields of monoacetoxymercuri derivatives; pseudocumene and prehnitene formed considerable amounts of diacetoxymercuri derivatives. Pseudocumene mercurated first in the 5-position; the position of the second mercury atom in the diacetoxymercuri compound was not determined. Acetoxymercuriisodurene was most conveniently prepared from the fraction of b. p. 79–91° (15 mm.) obtained by direct methylation of xylene. Most of the durene was removed from this fraction by filtration at −10°, and the filtrate then contained about 90% of isodurene.[6] Since acetoxymercuriisodurene was more soluble than acetoxymercuridurene in alcohol, the two compounds were separated by crystallization. This procedure avoided the time consuming preparation of pure isodurene. Samples of acetoxymercuriisodurene prepared from the mixture of hydrocarbons and from pure isodurene had the same melting point; the melting point of the substance was depressed by acetoxymercuridurene.

Chloro-, bromo- and iodomercuri derivatives of the hydrocarbons were prepared from the acetoxymercuri compounds by metathesis, since the halides were less soluble than the acetates. Likewise, since the bis-(polymethylphenyl)-mercury compounds were less soluble than the iodomercuri compounds, they were prepared from the iodo compounds by the action of sodium iodide.[4] Iodomercuripentamethylbenzene could not be prepared from the acetate because even less than one mole of sodium caused the formation of bis-(pentamethylphenyl)-mercury.

The mercury compounds which were previously unknown are listed in the tables, with melting points and analytical data.

Experimental Part

Mercuration.—The hydrocarbons were dissolved in five volumes of methanol, and a mole of mercuric acetate was introduced. Enough acetic acid was added to prevent hydrolysis of the mercury salt[7,8] and the solutions were refluxed. Mercuration of durene, mesitylene and pentamethylbenzene required five to seven days for completion. Isodurene, prehnitene and pseudocumene were allowed to react for only twenty to forty hours because of the formation of large amounts of diacetoxymercuri derivatives. The procedures for isolation of the products were determined by the solubilities. The following specific conditions were used in the preparation of the individual compounds.

Acetoxymercuripentamethylbenzene was insoluble in the hot reaction mixture; the product was filtered and crystallized from chloroform; m. p. 180°; yield 80%.

Acetoxymercuridurene was soluble in the hot reaction mixture; the solution was filtered from the insoluble diacetoxymercuridurene and cooled. The crude product (m. p. 152–156°, yield 60%) was crystallized from methanol (solubility, 12 g. per 100 cc. at the b. p.; 3 g. per 100 cc. at 0°). The melting point of the pure substance was 158–159°.

Acetoxymercurimesitylene was soluble in the cold reaction mixture. The solution was filtered from diacetoxymercurimesitylene and then diluted with water. The oil[9]

[a] Jacobsen, *loc. cit.* reported the m. p. as 266°.

which separated did not crystallize until unchanged mesitylene had been removed by steam distillation. Crystallization from methanol gave the pure substance; m. p. 102–103°; yield 30%.

Acetoxymercuriisodurene also separated as an oil[9] when the reaction mixture was diluted with water, but the substance solidified after it was washed by decantation and cooled. It was crystallized from 75% alcohol (warmed only to 60°). The yield of the product, m. p. 108°, was 30%, when prepared from either pure isodurene or the mixture of tetramethylbenzenes ("durene filtrate").

Acetoxymercuriprehnitene was soluble in the hot reaction mixture. The solution was filtered from insoluble diacetoxymercuriprehnitene, cooled, and diluted with water. The substance crystallized from methanol in radial needles, m. p. 147°; yield 15%.

5-Acetoxymercuripseudocumene was isolated in the same manner as the prehnitene derivative; the substance was crystallized from 95% ethanol; m. p. 145–147°; yield 30%.

Crude acetoxymercuri derivatives were recovered by dilution of the alcoholic filtrates with water. The filtrates were then treated with salt or hydrochloric acid to remove the remainder of the organomercury compounds by precipitation as chloromercuri derivatives. The final filtrates from the reaction mixtures were treated with sulfide to recover mercury.

Halogenmercuri Compounds.—The halides were prepared as follows: the acetoxymercuri compounds were dissolved in chloroform, alcohol or a mixture of the two solvents. Hydrochloric acid, sodium bromide or sodium iodide, respectively, was dissolved in aqueous alcohol and added to the solutions of the mercury compounds. The precipitates were filtered, washed and crystallized. The solvents which were used for the individual substances are listed in Table II.

It was necessary to use less than one equivalent of sodium iodide in the preparation of iodomercuripolymethylbenzenes in order to prevent formation of bis-arylmercury compounds. Despite that precaution, the product from acetoxymercuripentamethylbenzene was a mixture of iodomercuripentamethylbenzene and bis-(pentamethylphenyl)-mercury. Separation of the two substances by crystallization was impossible. Mercuric iodide was formed, which indicated that the iodomercuric compound in solution was converted to the bis-aryl compound by heat alone.

Bis-arylmercury Compounds.—The iodomercuri derivatives were precipitated from alcoholic solutions of the acetates and, without purification, were digested for several hours in alcohol with four moles of sodium iodide.[10] The substances were crystallized from chloroform. Diduryl mercury was prepared also by reduction of the acetate with sodium stannite.[7,11] The method was unsatisfactory because separation of the product from finely divided mercury was difficult.

Analyses.—Furter[12] demonstrated that mercury causes low analytical values for carbon. However, satisfactory carbon and hydrogen analyses of most of the mercury compounds were obtained by the semi-micro method with a Pregl universal filling in the combustion tube when precautions were taken. The substances were covered with cupric oxide and burned in an oxygen stream which had half the usual velocity. Silver foil was used in the tip of the combustion tube to collect free mercury. Silver was not very satisfactory for the purpose, but gold was not available.

Mercury analyses, in the absence of halogens, were made by titration with potassium thiocyanate after the organic material had been destroyed by hot concentrated nitric acid and permanganate.[13]

Summary

1. The mercuration of six polymethylbenzenes (mesitylene, pseudocumene, durene, isodurene, prehnitene and pentamethylbenzene) has been studied.

2. A number of related mercury derivatives have been prepared from each of the primary products of mercuration.

3. Twenty new organomercury compounds have been described.

Organic Flocculating Agents in the Quantitative Precipitation of Zinc Sulfide[1]

BY JOHN R. CALDWELL AND HARVEY V. MOYER

Comprehensive reviews of proposed methods for the precipitation of zinc sulfide are to be found in the comparatively recent publications of Jeffreys and Swift,[2] J. N. Frers,[3] and Mayr.[4]

Practically all of the efforts made to obtain the precipitate in a suitable physical form are based on three general procedures: (a) precipitation from hot solution; (b) salting-out with a large excess of some neutral salt; (c) maintenance of a low *p*H value by means of buffers. It is a well-recognized fact that in the early stages of precipitation most sulfides exist as hydrosols, and the formation of an insoluble precipitate depends to a large extent on the rate of transformation from sol to flocculent state. This transformation may be promoted by the presence of finely divided solid matter as demonstrated by Kolthoff[5] and by Frers.[3]

Recently we have found that certain organic substances may be used to alter the nature of analytical precipitates.[6,7] It seemed quite probable that flocculation of colloidal zinc sulfide could be induced by a somewhat similar procedure. The coagulation of precipitates by means of small concentrations of organic substances has been reported frequently by colloid chemists. Contrary to the ordinary behavior, certain hydrophilic colloids such as agar-agar, gelatin, gum arabic, etc., will not stabilize suspensoid sols if present in minute traces, but will bring about complete and rapid flocculation. This phenomenon, called sensitization, has been known for many years, but apparently never before has been applied to analytical chemistry. A brief review of recent colloid literature furnished ample indication that this field offers attractive possibilities for further investigation.

Rossi and Scandallari[8] showed that minute quantities of gelatin brought about rapid coagulation of sulfur sols. Chaudhury[9] reported that sols of ferric hydroxide and arsenic trisulfide were sensitized and flocculated by methyl alcohol,

ethyl alcohol, pyridine, urea and glycerol. Gelatin was used to flocculate sols of antimony trisulfide[10] while gum arabic had a similar effect on arsenic trisulfide and manganese dioxide sols.[11] Ghosh and Dhar[12] demonstrated that gelatin and tannin rapidly flocculated sols of ferric hydroxide and arsenic trisulfide. Weiser showed that certain organic compounds not only brought about rapid flocculation of arsenic trisulfide and ferric hydroxide sols, but also reduced the amount of adsorbed ions carried down by the precipitate.[13]

A review of the literature revealed that at least two attempts have been made to flocculate zinc sulfide precipitates by a mechanism similar to those just described. K. Bornemann[14] passed hydrogen sulfide into a zinc solution containing soldium bisulfite and buffered with ammonium acetate. He claimed that the colloidal sulfur formed in the reaction helped to coagulate the zinc sulfide. More recently, Hibbard,[15] in a procedure for the microdetermination of zinc as the sulfide, added talc to the solution in order to promote flocculation.

With the object of developing an improved method for precipitation of zinc sulfide, a systematic study was made of the effect of various hydrophilic colloids on the coagulation of the freshly formed precipitate.

Materials

Standard Zinc Solution.—Zinc ammonium sulfate was prepared by mixing concentrated solutions of C. P. ammonium sulfate and C. P. zinc sulfate. The zinc ammonium sulfate crystals which separated from solution were recrystallized twice. A solution was prepared containing approximately 5 mg. of zinc per ml. and was standardized by precipitating the zinc in 50 ml. as sulfide from a sulfate buffered solution according to the directions of Jeffreys and Swift[2] and also from chloroacetic acid–sodium acetate buffered solutions according to the procedure of Mayr.[4] In all cases the zinc sulfide was ignited to the oxide in an electric muffle at a temperature of 1000° as recommended by Hillebrand and Lundell.[16] The temperature of ignition was measured with a thermocouple. Of eight determinations, the extreme values were 0.3163 and 0.3155 g. of zinc oxide, the average being 0.3160 g.

Sulfates of Other Metals.—Reagent grade sulfates of nickel, cobalt and manganese were dissolved and filtered before use. Chromium, aluminum and iron were used in the form of their potassium alums.

Organic Materials, Gums, Soaps, etc.—No attempt was made to determine the purity of these materials and they were used without further treatment. Low-ash gelatin (0.03%) was purchased from the Eastman Kodak Co.

Experimental Work

Three hundred milliliters of a solution containing 0.25 g. of zinc as the sulfate and 6–8 g. of ammonium sulfate was used as the starting point for the tests. Two general plans were followed: (a) the substance to be tested was added to this solution and hydrogen sulfide passed in for fifteen to twenty minutes; (b) hydrogen sulfide was passed in for fifteen to twenty minutes and the test material was added slowly with stirring in the form of a dilute aqueous or alcoholic solution. Both methods were carried out at room temperature. Among the agents used were gelatin, agar-agar, gum ghatti, gum tragacanth, gum arabic, casein, egg albumin, sucrose, saponin, various soaps, and mixtures of these.

It was found that gelatin (0.5 to 2.0 mg.) and agar-agar (2 to 5 mg.) produced the desired effect. When added to the solution either before or after precipitation with hydrogen sulfide, these two agents caused instantaneous and complete flocculation of the zinc sulfide. Gelatin was chosen as the more suitable flocculating agent, because it can readily be obtained practically ash-free.

Further experimental work was carried out at higher dilutions and it was found that 0.05 mg. of gelatin would give a pronounced flocculation in volumes up to 500 ml. This is a dilution of one to ten million and the sensitivity is comparable to that of precipitin reactions with immune sera used in bacteriological work. If several milligrams of egg albumin was added to the solution before precipitation, the sensitivity of the gelatin was increased until it gave flocculation in dilutions of one:one hundred million.

Procedure for Quantitative Precipitation of Zinc Sulfide.—The procedure finally adopted for quantitative precipitation of zinc is based essentially on conventional methods. A solution free of chlorides, containing approximately 0.25 g. of zinc and 6 to 8 g. of ammonium sulfate is diluted to 250 to 300 ml. and made just acid to methyl orange. A rapid stream of hydrogen sulfide is passed through the solution for thirty minutes at room temperature. Five to 10 ml. of a 0.02% solution of gelatin is added with rapid stirring and the precipitate is allowed to settle. The most satisfactory gelatin for the purpose is a low-ash product containing less than 0.1% ash. A few drops of oil of wintergreen will preserve a dilute solution for several months. An instantaneous and complete flocculation of the colloidal precipitate takes place upon the addition of the gelatin, and if 10 to 20 mg. of gelatin is added, the flakes of precipitate are so large that they cling together and tend to slow up filtration. After fifteen minutes' standing, the supernatant liquid is practically clear, and may be decanted from the precipitate. The precipitate is easily washed by decantation and distilled water may be used as there is no peptizing action. In about 100 precipitations, a clear filtrate was always obtained when Schleicher and Schull blue-band filter paper was used.

The gelatin is adsorbed completely on the precipitate as shown by negative protein color tests on the filtrate,

It was found that this quantity of gelatin (1 to 2 mg.) does not interfere with the ferrocyanide volumetric determination of zinc.

If iron is present, it is better to wash with hydrogen sulfide water to keep the iron in a reduced state.

Quantitative Experiments.—Fifty milliliters of standard zinc solution, equivalent to 0.3160 g. of zinc oxide, precipitated according to the procedure outlined above, gave this weight of zinc oxide after ignition at 1000° with deviations of +0.6, −0.3, −0.4, +0.1, +0.3 mg.

Separation of Zinc from Iron, Nickel, Cobalt, Manganese, Aluminum, Chromium.—Table I summarizes the results obtained when zinc sulfide was precipitated in the presence of other metals. In each case, the precipitate was ignited to the oxide and analyzed for the contaminating metal. The iron was reduced with sulfur dioxide and the sulfur dioxide removed with carbon dioxide before saturation with hydrogen sulfide. This step was necessary, as the *p*H of the solution allows the formation of a small amount of ferric hydroxide before reduction of iron by hydrogen sulfide is complete. Iron in the ignited precipitate was determined colorimetrically as ferric thiocyanate. Manganese was determined colorimetrically as permanganate after oxidation with potassium periodate. Nickel was determined with dimethylglyoxime. Cobalt was determined colorimetrically by dissolving the precipitate in concentrated hydrochloric acid and comparing with standards prepared in the same way. For aluminum and chromium, the precipitate was dissolved in hydrochloric acid and the solution made just basic to methyl red with ammonia. No precipitate appeared with aluminum, and a trace of precipitate was formed with chromium.

Table I

Precipitation in Presence of Other Metals

Volume 250 to 300 ml. containing 6 to 8 g. of $(NH_4)_2SO_4$. Zinc equivalent to 0.3160 g. of ZnO, and 0.25 g. of other metal present.

Other metal	Other metal in ZnO ppt., mg.	Ignited ppt., g.	Dev. from std., g.

	7.0	.3258	+ .0098
Cr	0.1	.3162	+ .0002
	.1	.3159	− .0001
Fe	.3	.3166	+ .0006
	.2	.3164	+ .0004

If zinc sulfide is precipitated in the presence of small concentrations of certain aldehydes, practically no cobalt is carried down. A new separation of zinc and cobalt based on this principle will be described in a later paper.

As a final test of the method, zinc ore No. 2a from the Bureau of Standards was analyzed according to the procedure outlined by Lord and Demorest.[17] The only departures from the original procedure were a reprecipitation of cadmium sulfide, and the use of 2 mg. of gelatin as a flocculating agent. The average of four determinations was 30.45% of zinc, while the value given by the Bureau was 30.53%.

Precipitation in Solution Buffered with Chloroacetic Acid–Sodium Acetate.—When it is necessary to precipitate zinc in the presence of alkaline earth metals, it is not permissible to use a sulfate buffer. Mayr[4] has proposed a chloroacetic acid–sodium acetate buffer for this purpose. It is also possible to make a separation from iron without preliminary reduction, as the *p*H is sufficiently low (2.8) to hold ferric iron in solution. Excellent results were obtained when this method was used together with flocculation by gelatin. Mayr recommends a wash solution consisting of the diluted buffer saturated with hydrogen sulfide, but when the precipitate has been flocculated by 1–2 mg. of gelatin, distilled water may be used and no peptization occurs. Satisfactory separations from all metals but cobalt were obtained.

Other Applications.—Further applications of this principle are now being investigated, and preliminary experiments on the precipitation of other sulfides, ammonium phosphomolybdate, certain fluorides, and the hydrous oxides indicate a promising field for future research.

Summary

A new method for flocculating certain colloidal precipitates is proposed. It has been found that gelatin (0.5 to 2 mg.) and agar-agar (2 to 5 mg.) will produce instantaneous and complete flocculation of 0.3 g. zinc sulfide in 300 ml. of solution. Precipitations are made at room temperature, and the solution may be filtered within fifteen minutes after precipitation. Satisfactory separations from all metals but cobalt are obtained, and the precipitate may be washed with cold distilled water.

A Separation of Zinc from Cobalt Based on a New Method for Reducing Post-Precipitation[1]

BY JOHN R. CALDWELL AND HARVEY V. MOYER

At the present time there is no method described in the literature that will give a quantitative separation of zinc sulfide from cobalt in one precipitation. The zinc sulfide always carries down an appreciable quantity of cobalt, and several reprecipitations must be made. Our observations, as well as those of Jeffreys and Swift,[2] indicate that this contamination has a mechanism similar to that described by Kolthoff for the post-precipitation of zinc on copper sulfide.[3]

Recent work published by us has shown that the presence of certain hydrophilic colloids and of some organic compounds exerts a profound influence upon the physical nature of precipitates.[4,5,6] It seemed probable that this principle could be used to reduce post-precipitation and co-precipitation in standard sulfide precipitations.

When zinc sulfide is contaminated with cobalt it is colored green, and the depth of color indicates approximately the relative amount of cobalt carried down.

Two general classes of material were investigated: (a) protective colloids such as agar-agar, gum arabic, egg albumin, etc., were used with the possibility that they might be preferentially adsorbed in place of the hydrogen sulfide and thus reduce the concentration of hydrogen sulfide at the surface of the zinc sulfide particles; (b) organic compounds capable of reacting with hydrogen sulfide were investigated with the expectation that if they were absorbed on the precipitate they might reduce the concentration of hydrogen sulfide below the precipitation value. Among the compounds used for this purpose were alcohols, ketones, aldehydes, nitro compounds, amines, aromatic nitro acids, unsaturated compounds and others.

Materials

Standard Zinc Sulfate Solution.—The preparation of this solution was described in an earlier paper.[6] It was equivalent to 0.3160 g. of zinc oxide per 50 ml.

Cobalt Sulfate.—A C. P. grade was dissolved and filtered before use. It contained no zinc.

Organic Compounds, Gums, Colloids, etc.—A large number of organic compounds and hydrophilic colloids were used in the investigation. No attempt was made to secure these in a purified condition except in those cases discussed in detail below.

Experimental Work

The substance to be tested was added to 300 ml. of solution containing 0.25 g. of zinc, 0.50 g. of cobalt and 6 to 8 g. of ammonium sulfate. Hydrogen sulfide was passed in for thirty minutes at room temperature, the precipitate flocculated by gelatin,[6] and filtered off. The cobalt content was then determined by comparison with known standards. The amount of cobalt in the standards had been determined colorimetrically by dissolving a precipitate of the same color in hydrochloric acid, and comparing with known amounts of cobalt chloride dissolved under the same conditions. This method was suitable for quantities of cobalt ranging from 0.1 to about 20 mg.

It was found that certain aldehydes would greatly reduce the amount of cobalt carried down. The aldehydes tested were benzaldehyde, cinnamic aldehyde, propionaldehyde, paraldehyde, acetaldehyde, furfural, heptaldehyde, isoamyl aldehyde, *m*-nitrobenzaldehyde, anisaldehyde, crotonaldehyde, chloral, piperonal, paraformaldehyde, glucose, butyraldehyde, formaldehyde and acrolein. Some of the aldehydes were very effective in preventing post-precipitation of cobalt, but they formed troublesome resins which interfered with filtration, or in some cases they prevented complete precipitation of the zinc. It was found that acrolein was best suited for the purpose. It was very effective in small concentrations, did not form a resin readily, and allowed complete precipitation of the zinc.

Freshly distilled acrolein was used for some of the quantitative determinations, but it was found that the liquid part of an old, partly polymerized product was just as effective. For convenience in handling, an aqueous solution containing 4 ml. of acrolein per 100 ml. of water was prepared. About 10 mg. of hydroquinone and 1 drop of concentrated hydrochloric acid were added per 100 ml. of solution to inhibit polymerization. This solution retained its activity for several weeks.

Quantitative Procedure.—The quantitative procedure adopted for precipitation of zinc sulfide in the presence of cobalt is but slightly different from conventional methods. The *p*H of a chloride-free solution containing 0.25 g. of zinc and cobalt up to 0.5 g. is adjusted until the hydroxides just remain in solution, then 6 to 8 g. of ammonium sulfate is added. The total volume is brought to 250 to 300 ml., and 0.2 ml. of acrolein is added. A rapid stream of hydrogen sulfide is passed in at room temperature for thirty minutes. Five to 10 ml. of a 0.02% gelatin solution is added[6] and the precipitate is filtered off after fifteen to

[6] Caldwell and Moyer, *ibid.*, **57**, 2372 (1935).

twenty minutes' standing. Cold distilled water is used to transfer and wash the precipitate. In some cases, the filtrate develops a faint white turbidity after standing. This is due to the formation of a small quantity of resinous acrolein–hydrogen sulfide reaction product. If the filtrate is to be used for further analysis, it is strongly acidified and boiled down to about one-third of its original volume. This treatment will drive out most of the acrolein, and if any still remains, it will appear as small yellow flakes which are readily filtered off.

Quantitative Experiments.—Solutions containing 50 ml. of standard zinc solution, 0.5 g. of cobalt and 6 to 8 g. of ammonium sulfate were precipitated according to the procedure outlined above. When no acrolein was present, 6 to 10 mg. of cobalt was carried down. When 0.2 ml. of acrolein was added before precipitation, the precipitate contained from 0.2 to 0.4 mg. of cobalt. Four determinations using acrolein yielded weights of zinc oxide that deviated by +0.6, ±0.0, +0.1 and +0.3 mg. from the standard value of 0.3160 g. If more than 0.3 ml. of acrolein was used for 0.25 g. of zinc, there was some resin formation and filtration was retarded.

Kolthoff[3] showed that an increase in temperature caused an increase in the amount of zinc post-precipitated with copper sulfide. We found the same general rule to hold with cobalt and zinc. Acrolein proved to be very effective in preventing post-precipitation in hot solution. Solutions having the composition described above were heated for thirty minutes on a boiling water-bath after precipitation. When 0.20 ml. of acrolein was present, the precipitates contained 0.4 to 0.5 mg. of cobalt. In controls containing no acrolein, more than 30 mg. of cobalt was carried down.

If the solution containing zinc and cobalt is first heated to boiling, and hydrogen sulfide then passed in, the effect of acrolein is not so pronounced, and several milligrams of cobalt is carried down. This may be due to the possibility that acrolein is not so readily adsorbed from hot solution.

Precipitation in Chloroacetic Acid–Sodium Acetate Buffer.—For procedures where it is undesirable to have sulfates in the solution, Mayr[7] has proposed the use of a chloroacetic acid–sodium acetate buffer. He reported satisfactory separations from all metals but cobalt. Good separations were obtained with the use of acrolein, when precipitation was carried out at room temperature. The results are summarized in Table I.

TABLE I

PRECIPITATION IN SOLUTION BUFFERED WITH CHLOROACETIC ACID–SODIUM ACETATE

Total volume 250 ml. containing 15 ml. 2 *N* monochloroacetic acid, 15 ml. of 1 *N* sodium acetate, and 0.2 ml. of acrolein. Zinc equivalent to 0.3160 g. of ZnO. Precipitate flocculated by gelatin.

Other metal present in solution, g.	Wt. other metal found in ppt., mg.	Ignited ppt., g.	Dev. from std. soln. value, g.
0.25 Fe .25 Co	[a] [a]	0.3159	−0.0001
.25 Fe .25 Co	[a] [a]	.3158	− .0002
.50 Co	0.3	.3162	+ .0002
.50 Co	.3	.3161	+ .0001

[a] Not determined.

From the table, it is evident that this procedure gives satisfactory separations from cobalt, and from mixtures of iron and cobalt.

Theoretical Discussion.—Although a number of aldehydes were effective in reducting post-precipitation, there seemed to be a high degree of specificity in the case of acrolein that made it far superior to all others tried. A probable explanation of the effect may be based on Kolthoff's theory of post-precipitation. He showed that certain organic compounds containing sulfur were adsorbed by cupric sulfide precipitates and reduced the concentration of hydrogen sulfide at the surface. The action of aldehydes in general, and of acrolein in particular, apparently goes one step farther. They not only are readily adsorbed by the sulfide precipitate, but they also react rapidly with the hydrogen sulfide on the surface and reduce its concentration below the precipitation value. A survey of the organic literature shows that in general aldehydes will react with hydrogen sulfide under the above conditions to give various types of polymerized thioaldehydes.[8,9,10]

Microscopic examination of the precipitate shows that a distinct alteration in the nature of the surface has taken place. The reaction is apparently confined mainly to the surface of the particles, because there is very little decrease in hydrogen sulfide concentration in the solution itself.

It is planned to continue this study as applied to the post-precipitation of zinc on copper sulfide.

Acknowledgment

We wish to take this opportunity to express our appreciation to Professors C. E. Boord and W. R. Brode for their generosity in supplying us with a large number of aldehydes and other organic compounds used in this research. We also wish to acknowledge the kind assistance of Mr. G. R. Owens who furnished the acrolein, and of Mr. C. M. Hull who supplied a quantity of propionaldehyde.

Summary

If zinc sulfide is precipitated in the presence of small concentrations of certain aldehydes, particularly acrolein, the amount of cobalt carried down

is greatly reduced. This makes it possible to separate zinc and cobalt by one precipitation. Experimental evidence indicates that acrolein reacts with hydrogen sulfide on the surface of the zinc sulfide particles, thereby reducing post-precipitation.

The Accuracy of the Titration of Thiocyanate with Mercuric Mercury

BY I. M. KOLTHOFF AND J. J. LINGANE

In a previous paper[1] it was shown that in the direct and the reverse titration of silver with thiocyanate nearly theoretical results are obtained, slight deviations being found as a result of side reactions occurring during the reaction of the silver and thiocyanate ions. It was thought of interest to test the accuracy of the titration of mercuric mercury with thiocyanate and the reverse titration, especially since it had been shown that the end-point could be determined with great precision. The titrations were made potentiometrically and also with ferric iron as indicator.

Materials and Apparatus

Pure potassium thiocyanate prepared as described in a previous paper[1] was used.

Mercury.—The metal was purified in the usual manner by bubbling hot air through it for several hours, followed by washing with dilute nitric acid and distillation in vacuum.

Mercuric Thiocyanate.—The salt was precipitated from a dilute potassium thiocyanate solution by adding a slight excess of mercuric nitrate solution. The crystalline precipitate was washed thoroughly with water, and was then recrystallized from a large volume of hot water.

Mercury Electrode.—The electrode shown in Fig. 1 was specially designed for this work, the electrode mercury being contained in the conical cup. Electrical connection between the mercury cup and the mercury column in the stem was made by means of a platinum wire, sealed solidly in the neck connecting the cup and stem. The cup had a diameter of 1 cm. at the top and was filled with pure mercury so that the level of the latter was slightly above the rim of the cup. The stem was filled with ordinary mercury, into which the copper wire potentiometer lead dipped.

This electrode was much more convenient than the conventional type, prepared by electrodeposition of mercury on a platinum electrode, and it eliminates the trouble of frequent replating necessary with the latter type.

Standard Solutions.—Standard stock solutions of potassium thiocyanate were prepared by weight according to the technique already described.[1] Standard mercuric nitrate solutions were prepared by dissolving carefully weighed samples (corrected to vacuum) of the pure metal in a moderate excess of 6 *N* nitric acid, boiling to remove oxides of nitrogen, and diluting to a known weight. This solution was *ca.* 0.4 *N* (0.2 molar) by weight, and was *ca.* 0.02 *N* in free nitric acid. An exactly 0.05 *N* solution, for the finish of the titrations, was prepared by dilution of a weighed portion of the stock mercuric nitrate solution in a calibrated flask.

The total operative error involved in the preparation of the standard stock solutions (weighing materials and solutions) was probably less than 0.005%. The solutions were stored in the all-glass storage flasks previously described.[1]

Procedure and Results of the Titrations

The general procedure of the titrations was as follows. A suitable portion of one of the stock solutions (*ca.* 50 g. of the potassium thiocyanate solution or 25 g. of the mercuric nitrate solution) was weighed into a 250-cc. beaker from a weight buret and diluted to 100-125 cc., with addition of sufficient nitric acid to make its concentration 0.1 *N* at the end of the titration. The mercury electrode, stirrer and salt bridge were then placed in the solution and the titrating solution was added from a weight buret with thorough stirring, until the measured e. m. f. indicated that either a slight excess or a slight deficiency had been added. The titration was then finished with the appropriate dilute solution from a calibrated 5-cc. microburet. The end-point was located in the usual way from the maximum in $\Delta E/\Delta V$. The final volume at the end of the titration was about 200 cc.

Titrations were made both at room temperature (*ca.* 23°) and at 0°, the titration beaker being placed in a jar of cracked ice for the latter titrations. Titration at 0° is preferable to titration at room temperature because the maximum in $\Delta E/\Delta V$ at the end-point is much more pronounced (change in solubility and dissociation with temperature). This is illustrated in Fig. 2, in which the data, in the region of the equivalence point, have been plotted for two typical titrations at 23 and at 0°.

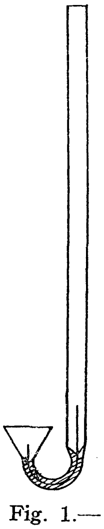

Fig. 1.—Mercury electrode for potentiometric titrations.

Steady e. m. f. readings are obtained very quickly throughout the entire course of the titration, which is a marked advantage of the thiocyanate–mercury titration over the thiocyanate–silver titration.

The results obtained in ten titrations, given in Table I, have been expressed in terms of the ef-

fective strength of the potassium thiocyanate. In view of the careful technique employed in the comparisons, the total operative errors, including preparation of stock solutions, weighing portions of the solutions for titration and location of the exact equivalence point, were probably less than 0.01%.

In the first four titrations the standard mercuric nitrate solution was added to the potassium thiocyanate solution and the titrations were made at room temperature. In the first three titrations a slight deficiency of the mercuric nitrate was added and the titration was finished with the dilute mercury solution; in the fourth trial a slight excess of the mercuric nitrate solution was added and the excess was titrated back with the dilute thiocyanate solution. The remaining six titrations were all made at 0°. In experiments 5–7, the mercuric nitrate solution was added to the potassium thiocyanate solution, but in the last three trials the reverse order of precipitation was employed.

The visual Volhard method for locating the end-point was compared with the potentiometric method as follows. The suspension remaining from a potentiometric titration, which contained a slight known excess of mercuric nitrate, was transferred to a glass-stoppered flask and after adding 2 cc. of saturated ferric alum as indicator, the solution was cooled to 12°[2] and titrated with the dilute thiocyanate solution to the appearance of the first reddish-brown coloration.

A comparison flask was prepared which contained the same quantity of recrystallized mercuric thiocyanate and the same concentration of nitric acid, potassium nitrate and ferric alum at 12° as the solution titrated. In this way the end-point could be determined to within about 0.07 cc. of 0.01 *N* thiocyanate solution in a volume of 200 cc. corresponding to a titration error of 0.01%.

[2] I. M. Kolthoff and L. H. van Berk, *Z. anal. Chem.*, **71**, 339 (1927).

In these titrations it was found that the Volhard end-point came 0.02% later than the potentiometric end-point, with respect to thiocyanate, or in other words, the effective strength of the potassium thiocyanate by the Volhard method was 0.02% less than the effective strength by the potentiometric method.

Discussion of Results

The data in Table I show that the reaction between mercuric mercury and thiocyanate is not exactly stoichiometric. When the mercury solution was added to the thiocyanate the effective strength of the potassium thiocyanate was found to be 99.94% at 25° and 99.96% at 0°. However, when the titration was carried out in the reverse way an effective strength of 100.03% was found at 0°. Although the deviation from the theoretical value is within the limits of an accurate analytical determination, it is greater than corresponds to the experimental error. The deviation found indicates that in the reaction between mercuric mercury and thiocyanate slight side reactions occur similar to those in the thiocyanate–silver titration.[1]

By using the same technique described in the latter case we were able to detect small, but definite, quantities of fixed ammonia in the supernatant solutions after precipitation, whereas no trace of ammonia could be detected in the original mercuric nitrate and potassium thiocyanate solutions, or in any of the reagents and water used.

The presence of ammonia in the final solutions is definite proof that side reactions, probably involving the intermediate formation of cyanic acid and its subsequent decomposition to ammonium ion and carbon dioxide, take place during the precipitation of mercuric thiocyanate.

The occurrence of these side reactions is a serious objection to the use of potassium thiocyanate as a primary standard substance in mercurimetry, in extremely precise work. However, the errors caused by the side reactions are small (−0.05 to +0.05%, depending on the order of precipitation), so that the salt should be a useful standard substance in work not requiring an accuracy better than ±0.05%.

Acknowledgment.—We wish to express our appreciation to the Graduate School of the University of Minnesota for financial assistance during the course of the work described in this paper.

Summary

1. The effective strength of potassium thiocyanate as found by titration with mercuric mercury solution depends upon the order of precipitation, being an average of 99.95% when the mercury is added to the thiocyanate solution and 100.03% when the reverse order of precipitation is used. The effective strength is 0.02% lower by the visual Volhard method than by the potentiometric method when the solution at the end-point has a temperature of 12°.

2. The slight deviations from the theoretical value are attributed to the occurrence of side reactions; the presence of ammonium ion was detected in the solution at the end of the reaction.

3. In the potentiometric titration a much sharper break is found at 0° than at room temperature.

4. Potassium thiocyanate can be recommended as a standard substance in mercurimetry for work not requiring an accuracy greater than ±0.05%.

Oxidation in the Benzene Series by Gaseous Oxygen. V. The Oxidation of Tertiary Hydrocarbons

BY H. N. STEPHENS AND FELICIANO L. RODUTA[1]

It has been shown by one of us[2] that alkyl benzenes are slowly oxidized at the α-carbon atom at 100°. If at least two hydrogen atoms are attached to this carbon atom an aldehyde or ketone is formed and the oxidation is completely inhibited by excess water. If two alkyl groups and only one hydrogen atom are attached to the α-carbon atom a ketone is formed, through the loss of one of the alkyl groups, and the oxidation is not inhibited by water. The absence of inhibition by water in the latter type of hydrocarbon was previously established only in the cases of cumene and cymene but in the present paper a similar behavior is shown for methylethylphenyl-, methylpropylphenyl-, methylbutylphenyl-, methyldiphenyl-, and triphenylmethane. One further example of a secondary hydrocarbon, diphenylmethane, was included as a control and in conformity with previous experience its oxidation was completely inhibited by water.

Inhibition by water has been ascribed to a reversible elimination of water in the decomposition of a primary oxidation product. The failure of water to inhibit the oxidation of tertiary hydrocarbons therefore implies that in this case there is no such reversible decomposition. This may find explanation in the fact that the formation of a molecule of water from one of a primary addition product of oxygen and tertiary hydrocarbon would require the contribution of one of the hydrogen atoms from an alkyl group. The resulting alkylene residue then must drop off if a ketone, which is always the observed product, is formed. The loss of a carbon atom attendant upon the elimination of water may so reduce the probability of reversal of this step by excess water that no observable inhibition results.

It has been found that hydrocarbons of the type  $C_6H_5\overset{CH_3}{\underset{R}{C}}H$, in which R is ethyl, *n*-propyl, or *n*-butyl, lose the larger group, and acetophenone was the only ketone that could be identified. The absence of the alternative ketone was checked very carefully in the case of methylethylphenylmethane by oxidizing 100 g. of the hydrocarbon at a temperature higher than usual (140°). In 7.5 g. of crude ketone obtained from the oxidation no propiophenone could be detected and it appears quite safe to say at least that acetophenone constitutes well over 90% of the total ketone formed. On the basis of the above mechanism this would indicate that the larger alkyl group is involved in the elimination of water from the primary oxidation product. Such behavior is strongly reminiscent of the dehydration of the phenyldialkylcarbinols, which apparently involves the larger alkyl group exclusively.[3] Triphenylmethane distinguishes itself from all other examples studied by having no alkyl group to participate in the elimination of water. The only products identified in this case were benzophenone and phenol.

Experimental Part

Materials and Apparatus.—The hydrocarbons listed below were oxidized in 15 to 25-g. samples for periods varying between fourteen and twenty-nine days in the absence of water and between thirty-one and thirty-four days in the presence of an equal weight of water. Oxidation was carried out in a specially constructed flask, by bubbling oxygen slowly through the hydrocarbon. The flask was sealed to a tall reflux condenser and enclosed in a vapor-bath for maintaining constant temperature. Boiling pentanol-2 (b. p. 119°) was used in this bath for oxidations in the absence of water and boiling water for oxidations in the presence of water. The following is a description of the hydrocarbons employed.

1. Methylethylphenylmethane, from Friedel and Crafts reaction; b. p. 173–174°, n^{25}_D 1.4863.
2. Methyl-*n*-propylphenylmethane, from Friedel and Crafts reaction; b. p. 191–192°, n^{25}_D 1.4902.
3. Methyl-*n*-butylphenylmethane, from Friedel and Crafts reaction; b. p. 206–207°, n^{25}_D 1.4902.
4. Methyldiphenylmethane, from paraldehyde and concd. H_2SO_4; b. p. 267–269°, n^{25}_D 1.5702.
5. Triphenylmethane, from Kahlbaum; m. p. 90°.
6. Diphenylmethane, from Friedel and Crafts reaction; b. p. 258–259°, n^{25}_D 1.5649.

It has been emphasized in previous papers that oxidations of the alkyl benzenes proceed very slowly at temperatures of the order of 100°. It is desirable, however, to keep

---

[1] This paper is based largely on the Master's Thesis of Roduta, Minnesota, 1931.

[2] Stephens, THIS JOURNAL, **48**, 1824, 2920 (1926); **50**, 2523 (1928).

the temperature as low as possible in order to avoid excessive secondary reactions. Therefore, it follows that, within a reasonable time, only small amounts of oxidation products will be obtained. In the present investigation, as in previous ones, no attempt was made (except in one case) to carry the oxidation any further than was necessary to yield readily identifiable amounts of products. When the dry hydrocarbons were used the yields of ketones were approximately 0.5 to 1.5 g. In the presence of water the amounts were smaller, due to the lower temperature. Although the yields of ketone are of no particular significance it was considered very important to establish the presence or absence of other early oxidation products. To this end we made a careful search in each case for alcohols, but with consistently negative results.

The ketone was identified in each case as the dinitrophenylhydrazone and the identity of these derivatives with specimens prepared from pure ketones was established by mixed melting points. In addition to ketone there was always formed an appreciable amount of soft reddish-brown or dark brown resin with no simple empirical composition. These obviously arise essentially from further oxidation of the ketones, as the oxidation of acetophenone itself yields a product similar to those from hydrocarbons which give acetophenone.

The ketones obtained from the respective hydrocarbons were

Methylethylphenylmethane—acetophenone
Methyl-*n*-propylphenylmethane—acetophenone
Methyl-*n*-butylphenylmethane—acetophenone
Methyldiphenylmethane—benzophenone
Triphenylmethane—benzophenone
Diphenylmethane—benzophenone (no oxidation in the presence of water).

In order to make sure that we had not missed the alternative ketones, propio-, butyro- and valerophenone which might have been formed from the first three hydrocarbons, we oxidized 100 g. of methylethylphenylmethane for ninety days at 140°. On fractional distillation we obtained 7.5 g. of crude ketone which was cut into 4 fractions of 1.7, 4.1, 0.6 and 0.8 g. (residue). The dinitrophenylhydrazones of fractions 1, 2 and 3, without recrystallization, melted at 230–238, 235–238 and 234–238°, respectively. The derivative from acetophenone melts at 237.5–238.5°. The whole of the last fraction was treated with dinitrophenylhydrazine and yielded 0.2 g. of derivative which, after extracting with boiling ligroin and recrystallizing from a mixture of alcohol and chloroform, melted at 174–180°. A mixture of this material with the dinitrophenylhydrazone of propiophenone (m. p. 190–191.5°) melted at 169–172°. From these facts it is obvious that propiophenone was present, if at all, in only very small amount. It might be mentioned that 4.2 g. of benzoic acid was obtained in this particular experiment. This arises from further oxidation of acetophenone, as it was found that 198 g. of the latter, oxidized at the same temperature (140°) for six days, yelded 1.9 g. of benzoic acid. Benzoic acid had not previously been detected in the oxidations at lower temperatures.

Accompanying the ketone there ought to appear in each case some product corresponding to the alkyl radical which has been eliminated. It has been shown that cumene and cymene yield formic acid if oxidation is carried out at 80°. Similarly 12 g. of methyldiphenylmethane, oxidized at 80–85° in the presence of water for thirty days, gave a strongly acid water layer in which formic acid was recognized by the mercuric oxide test. In oxidations involving elimination of alkyl radical with two or more carbon atoms we have had great difficulty in obtaining a satisfactory identification of the corresponding acids. In the oxidation of methyl-*n*-butylphenylmethane, for example, the presence of butyric acid was indicated by the odor but we were unable to obtain a pure derivative. The second oxidation product of triphenylmethane, however, was readily identified as phenol. The crude product from 15 g. of hydrocarbon, oxidized at 119° for twenty-one days, was extracted with 80% alcohol, and on distilling the residue from this solution under reduced pressure a mass of colorless crystals collected in the condenser. On dissolving a few of these crystals in dilute acetic acid and adding bromine water a copious precipitate of tribromophenol (m. p. 92°) was obtained. Triphenylcarbinol was searched for with negative results.

The writers wish to acknowledge assistance from Messrs. D. Tenenbaum and J. R. Vincent in part of this work, the assistance being made available through a grant from the Graduate School.

Summary

Results obtained from a study of the oxidation of several tertiary hydrocarbons show that oxidation always takes place at the α-carbon atom and that the reactions are not inhibited by water.

The Effect of Wave Length on the Iodine-Sensitized Decomposition of Ethylene Iodide in Carbon Tetrachloride Solution

BY ROSCOE G. DICKINSON AND NELSON P. NIES

The present work was undertaken primarily in order to obtain a partial answer to the question as to what extent iodine atoms are produced by the absorption of radiation by iodine in carbon tetrachloride solution when the radiation is of longer wave length than that of the band convergence of gaseous iodine. The absorption spectrum of gaseous iodine in the visible is continuous for wave lengths below 4989 Å. and shows many fine lines at longer wave lengths. In a well-known paper, Franck[1] has considered absorption in the continuous region to produce dissociation into a normal ($^2P_{3/2}$) and metastable ($^2P_{1/2}$) iodine atom, and absorption in the discontinuous to produce electronically excited molecules. These views, aside from their agreement with the dissociation energy of iodine, have received support from experiments[2] showing the disappearance of fluorescence when the wave length of the exciting light is decreased into the continuous; and further support from experiments[3] showing the presence of atomic absorption lines in strongly illuminated iodine vapor. Atomic absorption experiments in the presence of argon[4] showed iodine-atom formation even when the gas was illuminated with wave lengths longer than 5100 Å.; apparently the excited iodine molecules were dissociated by collisions with argon. For iodine in carbon tetrachloride solution, similar information does not exist, but use has been made of photochemical methods.

The decomposition of ethylene iodide in carbon tetrachloride solution has been found to be sensitized to visible radiation by iodine[5] and a chain mechanism has been proposed which is essentially a catalysis of the decomposition by iodine atoms. For this solution reaction, relative values of quantum yields have been measured[6] using both radiation corresponding to the continuum of the gas and radiation corresponding to the region of discontinuous absorption. For the wave length 4358 Å. the quantum yields measured were five to six times as great as those for the wave length 5461 or for the lines at 5770 and 5790. From these facts it was concluded that the excited iodine molecules produced by the absorption of the green or yellow lines, under the conditions of the experiments usually gave up their energy without dissociating.

This conclusion, however, has seemed to us not justified. The reaction in question is one whose rate is proportional to the square root of the intensity of illumination.[5] With a reaction of this type if two experiments were to be made with different wave lengths but with the same concentrations, the same intensities (using einsteins), and substantially complete absorption in each case, then even though the two wave lengths were equally effective in dissociating the absorber, the rates of reaction could be different in the two experiments if the absorption coefficients for the two wave lengths were different; indeed, with properly stirred solutions, the rates should be inversely proportional to the square roots of the absorption coefficients.[7]

The available measurements[8] of the absorption coefficient of iodine in carbon tetrachloride solution show much higher values in the green than in the blue so that, qualitatively, smaller quantum yields in the green than in the blue are to be expected. Unfortunately, however, the published data concerning the quantum yields are insufficiently detailed to permit satisfactory recalculation. We have accordingly attempted to measure the dependence of this reaction rate on the wave length under appropriate conditions, and have measured the absorption coefficients at the temperatures of interest.

Materials.—The carbon tetrachloride was purified by the treatment described by Polissar.[9] The ethylene iodide was prepared as described by Mooney and Ludlam,[10] and contained a small amount of free iodine. A weighed amount was dissolved in a weighed amount of the purified carbon tetrachloride. In most of the experiments the iodine concentration was increased by adding iodine which

had been resublimed from potassium iodide. The free iodine was determined by titration with thiosulfate freshly diluted to 0.00544 *N* and the ethylene iodide concentration calculated.

Apparatus.—A diagram of the experimental arrangements is shown in Fig. 1. The reaction vessel was a Pyrex cylinder 4.0 cm. in diameter and 2.1 cm. in internal length between the plane ends; an accessory bulb provided a free gas space of 25 cc. Since uniformity of concentration of the reactants throughout the solution was desired, the cell was provided with a magnetically operated glass spiral plunger which kept in operation throughout the illumination. The volume of stirrer glass in the light beam was 0.15 cc.; the error in rate caused by its presence is estimated to be 0.8% at most and usually much less. In each experiment the cell was filled with 28.0 cc. of solution (measured at room temperature) and sealed off. It was found imperative to avoid decomposition of carbon tetrachloride during the sealing-off process; this was accomplished, as shown by blank experiments, by sweeping any liquid as well as vapor from the side tube with a stream of air and sealing quickly before more vapor could diffuse into the side tube.

The thermostat was so constructed that the reaction cell could be placed in a small closed air space which was provided with double windows and surrounded by the vapor of boiling liquid except at the ends and top. The reaction cell was heated in the dark to approximately the right temperature; it was then transferred to the thermostat (a dim red room light was used) and was left for twenty minutes before illumination. During illumination stray light was avoided by the use of a cylindrical shield at the window near A and by closing with a black shutter the window near B. After illumination the cell was rapidly cooled to room temperature in the dark. The titration occurred in light; but since the temperature coefficient of the reaction is fairly large (1.6 for 10°) little reaction resulted here.

The light source was a quartz mercury arc; the source was defined by a hole 1.1 cm. in diameter. The light was filtered through 1 cm. of 10% $CuCl_2 \cdot 2H_2O$ solution to remove infra-red and red, and through suitable Corning glass filters to isolate the desired mercury lines. All filter combinations were examined spectroscopically. With the filter for 4358, only this line and its immediate weak neighbors were appreciably transmitted; in particular, the line 4916 and the lines near 4050 and shorter were absent from a plate showing reversal of 4358. The filter for 5461 gave a radiation contaminated by less than 1% of the yellow lines. That for 5770 and 5790 gave a radiation contaminated by less than 0.5% of the green line.

With the aid of the lenses and the 3.5-cm. diaphragm at A, the beam was adjusted so that all of it passed through the reaction solution and remained substantially constant in diameter in so doing. The lens at B threw on the face of a Moll microthermopile an image of the diaphragm A. The thermopile elements were situated at the center of this image whose diameter was 31 mm. The thermostat was mounted on tracks and could be removed entirely from the light beam.

The reaction was followed by measuring the iodine concentration. Before and after illumination, 5 cc. of the reaction mixture at room temperature was pipetted into slightly acidified potassium iodide solution and titrated with thiosulfate.

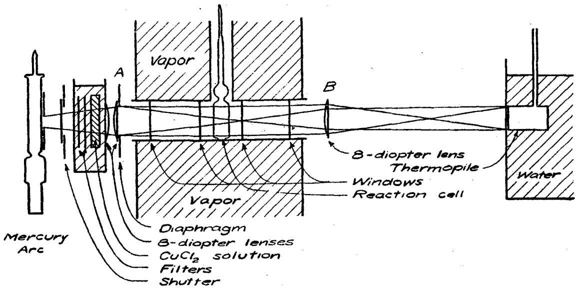

Fig. 1.—Vapor-thermostat and optical arrangements. The thermostat was removable from the light beam for measurement of incident intensity. The window near B was closed by a shutter (not shown) during reaction.

Absorption Coefficients.—The absorption coefficients of iodine solutions at various wave lengths were determined by measuring: (1) the transmission τ_0 of the thermostat with the reaction cell in place and containing only carbon tetrachloride; (2) the transmission τ of the thermostat with a known iodine solution in the cell. The coefficients α' were then calculated from the equation

$$\alpha' = \frac{1}{(I_2)l} \log_e \frac{\tau_0}{\tau}$$

where (I_2) is the concentration of iodine in moles per kilogram of solution, and l is the inside thickness of the cell (2.1 cm.). These and the coefficients α, calculated with concentrations in moles per cc., are given in Table I.[11] Although these absorption coefficients were determined in pure carbon tetrachloride solution, the small effect of non-polar solvents on the molal absorption coefficients of the halogens makes it unlikely that the values are unsuitable for use in solutions containing mol fractions of ethylene iodide of 0.01 or less.

Treatment of Reaction Rate Data.—From the work of Schumacher and Wiig,[5] we have taken the local rate of photochemical reaction in any illuminated element of the solution to be given by

$$d(I_2)/dt = k(I_{abs.})^{1/2}\,(C_2H_4I_2) \qquad (1)$$

where $(I_{abs.})$ is the local rate of absorption of radiation in einsteins × cc.$^{-1}$ × sec.$^{-1}$. This assumption receives *a posteriori* justification in the present work. The average rate in a solution of

---

[11] The thermal expansion of the solution was assumed equal to that for pure carbon tetrachloride. The density of carbon tetrachloride was taken as 1.59 g./cc. at 22°; 1.48 at 76.6°; and 1.45 at 99°.

volume v and thickness l illuminated by a parallel beam of cross-section a, is then given by

$$\frac{d(I_2)}{dt} = \frac{2kI_0^{1/2}(C_2H_4I_2)\,a}{\alpha^{1/2}(I_2)^{1/2}\,v}\,(1 - \sqrt{\tau}) \qquad (2)$$

Here I_0 is the intensity of radiation incident on the solution in einsteins × cm.$^{-2}$ × sec.$^{-1}$; and τ is the transmission $e^{-\alpha(I_2)l}$ of the solution. In obtaining (2) it is assumed that: (a) the concentrations of the reactants are maintained uniform throughout the solution; (b) Beer's law applies; (c) the rate in one element of solution is unaffected by the intensity prevailing in neighboring elements.

With constant incident intensity, values of the specific rate constant k may be obtained from equation (2)

$$k = \frac{\alpha^{1/2}\,v}{2I_0^{1/2}\,a\,\Delta t}\int_{c_1}^{c_2}\frac{(I_2)^{1/2}\,d(I_2)}{(1-\sqrt{\tau})\,(C_2H_4I_2)} \qquad (3)$$

where Δt is the time of illumination and c_1 and c_2 are the values of (I_2) just before and after illumination. We have calculated the specific rate constant in arbitrary units k_a using the equation

$$k_a = \frac{1}{\lambda^{1/2}\,G^{1/2}\alpha'\,\Delta t}\int_{y_1}^{y_2}\frac{y^{1/2}\,dy}{(1-e^{-y/2})\left(S - \dfrac{y}{\alpha' l}\right)} \qquad (4)$$

In equation (4), $G^{1/2}$ is the mean of the square roots of the corrected galvanometer deflections, λ is the wave length (used to obtain proportionality to einsteins), y is equal to $\alpha'(I_2)l$ and S is the total concentration of iodine (free and combined). Since the value of the integrand may be calculated for any stated value of y, we have approximated the integral using Simpson's rule;[12] this is convenient since the integrand often remains fairly constant over a considerable range of values of y.

---

(12) See, for example, E. B. Wilson, "Advanced Calculus," 1912, Ginn and Co., Boston, p. 77.

The results of the measurements and calculations of k_a are given in Table II. The measurements at 76.6° are more extensive than those at 99° and are more reliable because of smaller uncertainty arising from thermal reaction. Since the mechanisms of the thermal and photochemical reactions are probably not independent, it is doubtful whether the results would be improved by subtraction of the thermal from the combined rates; at 76.6° thermal reaction would amount to 0.5 to 3% of the combined reaction in the present experiments, and at 99° from 3 to 10%. No correction for thermal contribution to the reaction during illumination has been applied; but for the experiments at 99° the initial iodine concentrations have been corrected (by separate blank experiments) for thermal reaction previous to the beginning of illumination. At the close of illumination the solution was quickly cooled. The results show that at either temperature there is only a small decrease of k_a with increasing wave length.

Discussion.—It is possible to draw conclusions from the comparative constancy of k_a with wave length without making detailed representations as to the complete mechanism of the reaction. This may be especially important since the possible effect of oxygen has not been investigated, and air was present in these experiments. Since it is probable that blue light dissociates iodine molecules, and since the empirical rate expression is of the same form for all visible wave lengths investigated, we may assume simply that light brings about reaction through dissociation of iodine molecules, either directly or on collision subsequent to absorption; and, further, that at a point in a solution of given composition the local rate of reaction is dependent only on the rate at which iodine atoms are produced by light regardless of the wave length that produces them. This rate of production of iodine atoms by light is $2\beta(I_{\text{abs.}})$ where β is the fraction of the absorbed quanta which result in dissociation (and may depend on λ). From the empirical result $\mathrm{d}(\mathrm{I}_2)/\mathrm{d}t = k(I_{\text{abs.}})^{1/2} f(c\ldots)$, where $f(c\ldots)$ depends only on the composition but where k may depend on the wave length, it may readily be shown that $\mathrm{d}(I_2)/\mathrm{d}t = \beta^{1/2}(I_{\text{abs.}})^{1/2}k' f(c\ldots)$ where k' is independent of the wave length.

For two different wave lengths it is evident that $\beta_1/\beta_2 = k_1^2/k_2^2$. The data of Table II give the result that at 76.6°, $\beta_{5461}/\beta_{4358} = 0.87$ and $\beta_{5780}/\beta_{4358} = 0.75$. On the assumptions made it appears, then, that wave lengths corresponding to discontinuous absorption in gaseous iodine are little less effective than those corresponding to continuous absorption in producing dissociation in carbon tetrachloride solution.

Absolute Values of the Rate Constants.—Although not essential to the examination of wave length effect, we have made an approximate determination of the absolute value of the k of equation 1 using equation 3. For this purpose, the units employed throughout were moles, einsteins, centimeters and seconds. The determination involved: (a) calibration of the thermopile against a Bureau of Standards carbon filament lamp; (b) corrections for reflection at various windows (multiple reflections were ignored); (c) examination, with the aid of the thermopile, of the distribution of intensity across the beam at the position of the cell and at the diaphragm A; (d) determination of the relative galvanometer deflections with the thermopile in the position shown and with it at the center of A. From this calibration it was found that the effective value of $aI_0^{1/2}$ in ergs$^{1/2}$ × cm. × sec.$^{-1/2}$ was given by 87.1 $G^{1/2}$. These values of k, expressed in einsteins$^{-1/2}$ × cm.$^{3/2}$ × sec.$^{-1/2}$ are: at 76.6°, 0.42 for 4358, 0.39 for 5461, 0.37 for 5780; and at 99°, 1.4 for 4358, and 1.2 for 5461 Å. The radiation measurements and corrections should be good to 20% or better.

Quantum yields, calculated as moles of iodine formed per quantum absorbed in the whole experiment, are, of course, quite variable. The first two experiments of Table II, for example, give the values 2.9 and 8.8, respectively, while the twelfth gives 0.96.

Summary

The dependence on wave length of the rate of iodine-sensitized decomposition of ethylene iodide in carbon tetrachloride solution has been reexamined. In view of the lack of proportionality between rate and intensity, absorption coefficients have been measured and special attention has been given to the distribution of intensity through the solutions. The wave lengths used were 4358, 5461, and 5770 and 5790 Å.; for these three radiations the relative values of the rate-constant at 76.6° have been found to be 1:0.931:0.867. The results indicate that light corresponding to continuous absorption in gaseous iodine is slightly

more effective in bringing about dissociation of iodine in the solution than light corresponding to the discontinuous absorption, but that the difference is not large. Absolute values of the empirical specific rate constant have been measured.

Determination of the Zirconium–Hafnium Ratio[1]

BY GRANT WERNIMONT[2] AND THOMAS DE VRIES

The optical rotation of solutions containing potassium tartrate along with various amounts of zirconium or hafnium oxychloride has been studied by de Boer and Emmens.[3] They found that the effect of zirconium was somewhat less than that of hafnium and suggested that the polariscope might be used for determining zirconium–hafnium ratios. This paper describes such a procedure in which the fluorides were used.

Experimental

The rotation measurements were made with a Schmidt and Haensch No. 52b, Lippich type polarimeter using sodium D light from a monochromator.

Three samples of zirconium oxide were prepared (one by the method of Drophy and Davy[4] to remove completely small amounts of hafnium) from C. P. zirconium salts which were shown to contain no iron or titanium.

Measurement of Rotation Change.—To measure the rotation change, zirconium oxide samples were weighed into platinum crucibles, dissolved in 5 ml. of 50% hydrofluoric acid, evaporated to dryness on the steam-bath and the residues taken up with a little water. The solutions were transferred to volumetric flasks, 10 ml. of approximately 20% tartaric acid solution (about 14 millimoles) and 10 ml. of six normal potassium hydroxide were added along with sufficient water to make 50 ml. of solution. Blank solutions containing no zirconium were also prepared.

The rotations of the solutions and blank were determined in 2-dm. tubes, the differences being taken as the rotation change. When the weight of zirconium oxide was plotted against rotation change, a straight line resulted (Fig. 1). The equation for this is $\Delta\alpha_{Zr} = 5.37W_{Zr}$ where W_{Zr} is the grams of ZrO_2 and $\Delta\alpha_{Zr}$ is the corresponding rotation change in degrees. Twenty-six points ranging from 0.1017 to 1.002 g. of oxide were used to fit the equation. The maximum deviation of calculated rotation change from the observed value was 0.09° and the average of all deviations was 0.04°.

When less than 0.3 g. of ZrO_2 was present in solution, these results are in good agreement with those of de Boer and Emmens but when more than this amount of zirconium was present, the values found by de Boer and Emmens were less than those found in this investigation.

As the molecular ratio of tartrate to zirconium approached or became greater than two to one, the observed values were less than the calculated values. Therefore care must be taken that the ratio of tartrate to zirconium (and hafnium) is greater than two to one in the final solutions.

Hafnium salts, free from zirconium, were not available in this Laboratory; hence it was necessary to use the values of de Boer and Emmens for the rotation of hafnium tartrate solutions. Their results give a straight line (Fig. 1) and were fitted to the equation $\Delta\alpha_{Hf} = 1.16W_{Hf}$.

Calculation of Zirconium–Hafnium Ratios.—A convenient method of evaluating the ratio of hafnium to zirconium was devised by using the linear equations to derive a general expression for the relation between mole ratio, rotation change and weight of zirconium–hafnium oxide present in solution. The following equation was obtained

$$\frac{N_{Hf}}{N_{Zr}} = 0.5851 \times \frac{5.37W - \Delta\alpha}{\Delta\alpha - 1.16W}$$

where W is the grams of mixed oxides present in 50 ml. of test solution and $\Delta\alpha$ is the corresponding rotation change measured in a 2-dm. tube using sodium D light.

Preparation of Zirconium–Hafnium Oxide Samples for Analysis.—Two oxide samples were prepared from two fractions of a series of

[4] Drophy and Davy, *Phys. Rev.*, **25**, 882 (1925).

fractional precipitations as follows. Five grams of the zirconium–hafnium phosphate mixture was dissolved in 50% hydrofluoric acid. The solution was filtered into cold 5% potassium hydroxide and the hydroxides were washed by decantation until free from phosphate.

The supernatant liquid was decanted and enough cold 10% sulfuric acid added to double the volume of the remaining mixture, which was then stirred and allowed to stand until the hydroxides had dissolved. Eight grams of tartaric acid was added, the solution was made alkaline with ammonia, saturated with hydrogen sulfide and the sulfide precipitate was filtered off. The filtrate was acidified, boiled and the zirconium and hafnium precipitated in the cold with a 6% cupferron solution. The precipitate was washed, dried and ignited to the oxide.

This procedure can be used quite generally to prepare samples of the mixed oxides for analysis with the polariscope. Titanium is not removed by the procedure but it was known to be absent from our samples. It should be noted that the incomplete removal of substances which have an effect on the rotation of the reference tartrate solution, makes the ratio of hafnium to zirconium appear to be less than it actually is.

Table I summarizes the results of the analysis of the two samples of mixed oxides. Three different weights of Sample No. 1 gave almost a straight line when plotted (Fig. 1). The ratios found by this method are in reasonable agreement with ratios found by the other methods indicated.

TABLE I

MOLE RATIO OF UNKNOWN MIXTURES OF ZIRCONIUM AND HAFNIUM

Sample	Expt.	Grams of oxide	Rotation change	Mole ratio Hf/Zr This method	Mole ratio Hf/Zr Other methods
1	a	0.207	0.74°	0.43	0.45 (density of mixed oxides)
	b	.408	1.46	.43	
	c	.607	2.22	.40	
2	a	.635	2.79	.18	0.15 (spectroscopic method)

Millimoles of $H_6C_4O_6$ = 14.8; millimoles of KOH = 63.3; total volume of solutions = 50.0 ml.

The method is not thought to be more accurate than other methods which have been used for determining the zirconium–hafnium ratio. Of course it is not to be compared with a careful atomic weight determination. It is rapid and therefore convenient for following fractional separations of hafnium from zirconium.

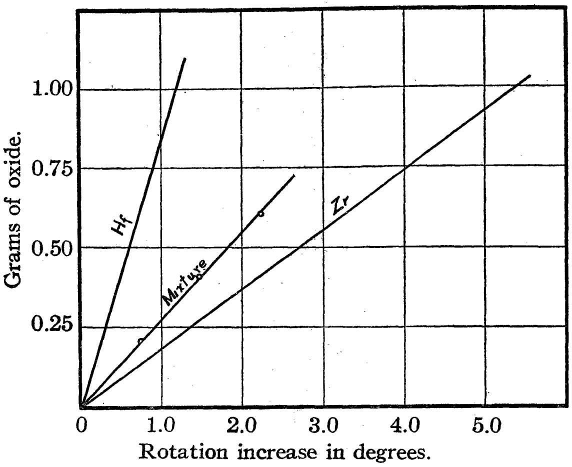

Fig. 1.

Summary

The optical rotation of basic tartrate solutions containing various amounts of zirconium have been measured and compared with the values obtained by de Boer and Emmens.

A procedure has been described for the rapid preparation of samples of zirconium–hafnium oxide suitable for analysis with the polariscope.

An equation has been given which may be used to calculate the mole ratio of hafnium to zirconium in mixtures of the two when the effect of a known weight of the mixed oxides on the rotation of certain reference tartrate solutions has been measured.

The mole ratios of two samples of zirconium–hafnium oxide have been determined and compared with the mole ratios found by other methods.

The Kinetics of the Auto-oxidation of Catechol in the Presence of Several Foreign Substances

BY G. E. K. BRANCH AND M. A. JOSLYN

It is well recognized that many auto-oxidations are inhibited by small quantities of foreign substances.[1-5] As a rule this process destroys the inhibitor and its action is temporary. This phenomenon is readily explained only on the assumption of a chain mechanism for the auto-oxidation, and the existence of a typical temporary inhibition is one of the best indications for a chain mechanism for a thermal auto-oxidation.

Since we had studied the kinetics of the absorption of oxygen by moderately alkaline solutions of catechol[6] it seemed desirable to find out whether or not the reaction involved a chain mechanism. With this in view we measured the rate of auto-oxidation of catechol in the presence of a number of foreign substances. During these investigations we observed certain peculiarities in the behavior of catechol in the presence of small quantities of pyrogallol, hydroquinone, or resorcinol, which led us to investigate the auto-oxidation when a large proportion of catechol was replaced by one of these phenols.

Experimental

The experimental procedure was essentially that used for pure catechol.[6] The rates of absorption of oxygen were measured by changes in pressure at constant volume; the solutions were buffered by the mixture of KH_2PO_4 and K_2HPO_4 obtained on addition of catechol to 0.8 *M* K_2HPO_4; and the *p*H values of the solutions were obtained with a glass electrode. The solution was shaken sufficiently vigorously to maintain it saturated with oxygen. During each individual experiment the concentration of catechol and the pressure of oxygen were practically constant as the total amount of oxygen absorbed was small with respect to both the oxygen and the catechol in the reaction vessel. The only variation from our previous procedure was that the foreign substances were added to the catechol solutions, or to the phosphate buffer when some reaction in the catechol solution was expected. In our search for inhibitors the foreign substances were all 0.001 *M* and the catechol 0.1 *M*. In experiments with large quantities of foreign phenols, the total phenol concentration was maintained at 0.1 *M* but the proportion of catechol was varied.

The rates are expressed in cc. of oxygen at 25° and 1 atmosphere absorbed by 125 cc. of solution. The average error in the measurements is 7%, most of which is due to error in *p*H measurement. An effect of less than 10% is not considered as significant.

Data and Discussion

Effects of Small Quantities of Foreign Substances.—Under the conditions of our experiments, when pure catechol solutions are used, about 20 cc. of oxygen can be absorbed without the rate decreasing by more than 10%. This approximately constant rate is that of the first measurable step in the reaction between oxygen and catechol.

When the foreign substance is not oxidized specifically faster than catechol, the rate of absorption is also practically constant, and may be faster, slower or equal to that characteristic of pure catechol, according as the foreign substance acts as a catalyst, or an inhibitor or is without action on the absorption of oxygen by catechol.

When the foreign substance is oxidized specifically much faster than catechol, its concentration is reduced to practically zero before that of catechol has been affected greatly, for the foreign substances were always added in quantities very small with respect to catechol. The foreign substances were added in quantities equivalent to about 3 cc. of oxygen in a reaction in which one molecule of oxygen reacts with one of the foreign substance. The result is that the absorption rate changes at the beginning of the experiment but becomes approximately constant before the end. When the products of the oxidation of the foreign substance are without action on the absorption of oxygen by catechol, the approximately constant final rate is that of pure catechol, and may be recognized as such. In these cases the initial rate is slower or faster than the final rate according as the foreign substance is an inhibitor or accelerator of the auto-oxidation of catechol. A foreign substance that absorbs oxygen independ-

ently of catechol, and at a specific rate ten times as fast as that of the auto-oxidation of catechol, would behave like an accelerator that is oxidized specifically much faster than catechol.

When the foreign substance is itself without action on the absorption of oxygen by catechol but is readily oxidized to a catalyst or inhibitor, the absorption starts at the rate characteristic of catechol but changes to that of a catalyzed or inhibited reaction. This final rate may be approximately constant if the product reaches a steady state concentration before the discontinuation of the experiment. This phenomenon is not restricted to substances that are rapidly auto-oxidized, for its oxidation may be induced by that of catechol. Resorcinol is an example of such a case. Catalytic or inhibitory actions of less than 10%, and independent absorptions of oxygen by the foreign substances less than ten times the specific rate of that by catechol are not observable in our experiments as they are indistinguishable from experimental fluctuations.

The data obtained are summarized in Table I, which shows the initial and final rates, the *p*H values, and the rate in pure catechol at the same *p*H values. This table shows examples of all the cases discussed above, excepting that of an inhibitor that is formed during the reaction.

TABLE I

OXYGEN ABSORPTION BY CATECHOL IN THE PRESENCE OF FOREIGN SUBSTANCE

Foreign substance	*p*H	Initial rate	Final rate	Rate in pure catechol
Ammonium chloride	8.3	3.4	3.4	3.3
Arsenious acid	8.3	2.8	2.8	3.3
Benzidine HCl	8.35	3.5	3.5	3.7
Cysteine HCl	8.3	0.1	3.2	3.3
Cystine	8.3	3.3	3.3	3.3
Gallic acid	8.3	3.8	3.8	3.3
Glycine	8.3	3.3	3.3	3.3
Hydroquinone	8.2	2.6	3.5	2.6
Indigo carmine	8.3	3.2	3.2	3.3
Maleic acid	8.3	3.1	3.1	3.3
Methylene blue	8.3	3.3	3.3	3.3
o-Aminophenol·HCl	8.3	0.8	3.2	3.3
p-Aminophenol·HCl	8.3	4.1	4.1	3.3
p-Hydroxybenzoic acid	8.3	3.3	3.3	3.3
Phenol	8.2	2.3	2.3	2.6
Picric acid	8.3	2.4	2.4	3.3
Potassium cyanide	8.3	3.3	3.3	3.3
Potassium iodide	8.2	2.4	2.4	2.6
Potassium sulfite	8.3	0.2	3.1	3.3
Potassium thiocyanate	8.3	3.2	3.2	3.3
Pyrogallol	8.2	4.8[a]	2.4	2.6
Resorcinol	8.2	2.7	3.6	2.6
Salicylic acid	8.3	3.2	3.2	3.3
Sodium phosphate	8.3	3.3	3.3	3.3
Tyrosine	8.3	3.2	3.2	3.3
Urea	8.3	3.3	3.3	3.3

[a] This is strictly a maximum rate, as in the first few seconds the rate is sensibly that for pure catechol.

It is evident that most of the substances tested had practically no effect on the rate of oxygen absorption. Of the substances which maintained a steady rate, three, namely, arsenious acid, phenol and picric acid, exhibited a slight inhibition and two, gallic acid and *p*-aminophenol, showed slight catalytic action.

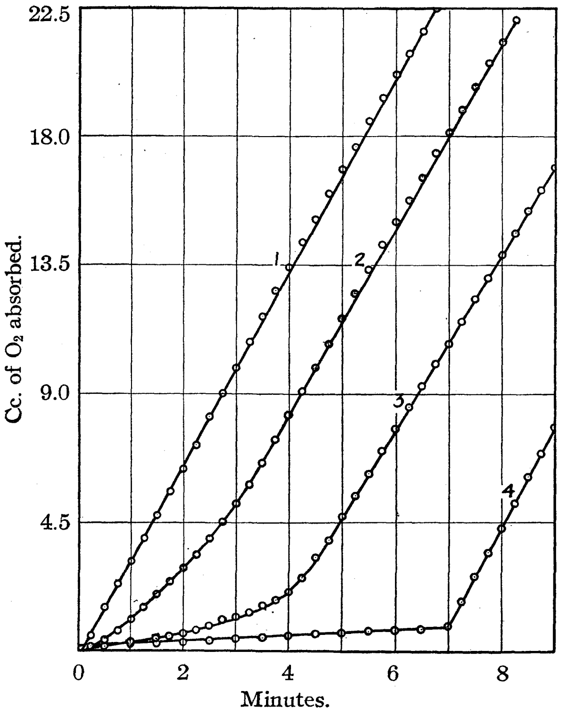

Fig. 1.—Rate of oxygen absorption by catechol at *p*H 8.3 in presence of: 1, no added substance; 2, *o*-aminophenol; 3, potassium sulfite and 4, cysteine hydrochloride.

It is evident from the data summarized in Table I and presented in more detail in Fig. 1 that *o*-aminophenol, cysteine and potassium sulfite are definite inhibitors for the reaction. The curves show reactions that are slow at first, but after a period rapidly change to the normal rates. This phenomenon is characteristic of an inhibited reaction in which the inhibitor is destroyed either in the act of inhibition or by the products of oxidation or both. This indicates that the absorption of oxygen by moderately alkaline solutions of catechol has a chain mechanism.

We have shown previously that the rate law for the oxidation of catechol in the range of *p*H value 6.5 to 10 is given by

$$V \propto (\text{cat}^-)(O_2)\ C/(C + A)$$

where C is the total concentration of catechol—being the sum of the concentration of dissociated and undissociated molecules—and A some constant. The kinetics can be accounted for on the assumption that "catechol," oxygen and the monovalent ion function in chain initiating and chain continuing processes and that "catechol" and solvent function in chain breaking processes.

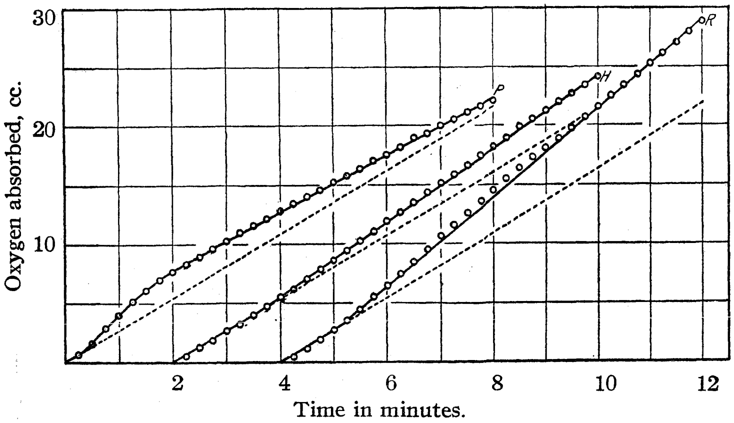

Fig. 2.—Rate of oxygen absorption by catechol in presence of small quantities of pyrogallol (P), hydroquinone (H) and resorcinol (R) at *p*H 8.3. The abscissas of the curves for H and R are displaced 2 and 4 minutes, respectively, to the right. The dotted lines show the rate in pure catechol.

The term "catechol" as used above refers to both the undissociated molecule and its ions. The constant A is the ratio of the specific rate of the chain breaking process of the solvent to that of catechol.

This mechanism also explains why so few of the chosen substances acted as inhibitors. For catechol is its own inhibitor, and the foreign molecule must compete in the chain breaking process with a hundred molecules of catechol.

The inhibition of cysteine is of special interest. Assuming that one molecule of oxygen can destroy four molecules of cysteine, about 0.75 cc. is sufficient to remove the cysteine added. After the absorption of 1 cc. of oxygen the cysteine is removed, as is shown by the appearance of the normal rate. This leads to the conclusion that cysteine is an extremely effective inhibitor and must almost completely *remove the chain character of the reaction.* This conclusion is further confirmed by the extremely sharp break in the cysteine curve between the inhibited and the normal absorption. The inhibited reaction is about 0.03 times the normal rate, and the length of the normal chain may be estimated as between 30 to 60 links.

Small amounts of pyrogallol, hydroquinone and resorcinol after an initial period in which they exerted practically no effect (which extends for about fifteen seconds for pyrogallol, one minute for resorcinol and one and three-fourths minutes for hydroquinone) appreciably increased the rate of oxidation of catechol (see Fig. 2). This increase in rate is maintained over more than five minutes by hydroquinone and resorcinol but the maximum rate reached in thirty seconds in pyrogallol is reduced in about two minutes to that of catechol alone.

Effect of Pyrogallol, Hydroquinone and Resorcinol in Large Quantities.—The rates of oxygen absorption by mixtures of catechol and pyrogallol, hydroquinone or resorcinol in which the mole fraction of the foreign phenol varied from 0 to 1.0 but at constant concentration of total phenol (0.1 *M*) are shown in Figs. 3 and 4.

It is seen from the data presented in Fig. 3, that pyrogallol and hydroquinone act as catalysts for the oxidation of catechol. But the type of catalysis is peculiar. Pyrogallol–catechol and hydroquinone–catechol mixtures oxidize at much faster rates than would be possible if the components of the mixture oxidized at rates independent of each other. In both mixtures a molal fraction of 0.2 of the more reactive phenol produces an oxygen absorption almost as fast as that of the more reactive phenol by itself. One way of explaining this phenomenon is to assume that either phenol can continue or break the chain initiated by either activated phenol. Then neglecting the chain breaking effect of the solvent

$$V = k_1C\,\frac{a_{11}C + a_{12}P}{b_{11}C + b_{12}P} + k_2P\,\frac{a_{12}C + a_{22}P}{b_{12}C + b_{22}P}$$

where V is rate; C and P the respective concentrations of catechol and pyrogallol or hydroquinone; a the rate constant for the chain continuing process, the subscript 11 referring to the chain initiated by C and continued by C, and 12 to the chain initiated by C and continued by P, etc.; b the rate constant for the chain breaking process; and k_1 and k_2 the rate constants for the chain initiating processes for catechol and pyrogallol or hydroquinone, respectively. If the more reactive phenol is specifically much more efficient in both continuing and breaking the chains begun by either phenol, *i. e.*, $a_{12} > a_{11}$, $b_{12} > b_{11}$, $a_{22} > a_{21}$ and $b_{22} > b_{21}$, then

$$V = k_1 \frac{a_{12}}{b_{12}} C + k_2 \frac{a_{22}}{b_{22}} P \text{ (approx.)}$$

even when P is small with respect to C. If $k_1(a_{12}/b_{12})$ is approximately equal to $k_2(a_{22}/b_{22})$, the rate of oxidation of the mixtures of pyrogallol or hydroquinone and catechol is approximately that of the more reactive phenol of the same total concentration

$$V = k_2(a_{22}/b_{22})(P + C) \text{(approx.)}$$

The above explanation necessitates that the more reactive phenol be used up at a faster specific rate than catechol, so that when the concentration of the more reactive phenol is very small, its concentration would decrease appreciably while but little oxygen is absorbed. This would result in an observable decrease of the rate to that of pure catechol. This is true for molal fractions of 0.01 pyrogallol but is not true for hydroquinone at this concentration.

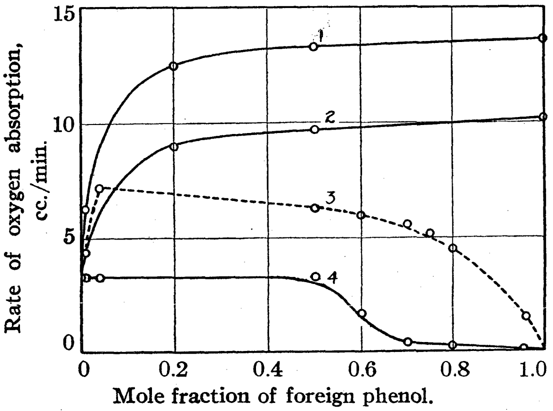

Fig. 3.—Rate of oxygen absorption at pH 8.3 by mixtures of catechol and the following phenols: 1, pyrogallol; 2, hydroquinone; 3, 4, resorcinol. Curve 3 is for first constant rates and curve 4 for initial rates. The pH values of the solutions were between 8.2 and 8.3. The rates are corrected to pH 8.3 on the assumption that the rates change with pH in the same way for the mixtures as for pure catechol. The error introduced cannot be significant.

Another possible explanation is as follows. Let us assume that chains of activated pyrogallol are longer than those of activated catechol; that any chain may be continued or broken by either phenol; that the length of the chain depends chiefly on the nature of the activated phenol and less on the nature of the phenol acted upon; and that a chain begun as an activated catechol chain may be converted into an activated pyrogallol chain, or *vice versa*. If chains are initiated at approximately equal rates by catechol or pyrogallol, the rate of oxygen absorption in a mixture depends chiefly on the relative proportions of catechol and pyrogallol chains, but owing to the chain exchanging process this proportion is not that of the phenols in the mixture. Should the change of activated catechol to activated pyrogallol be specifically faster than the reverse process, then the pyrogallol chains would predominate and the rate approximate that of pure pyrogallol even when catechol is in excess.

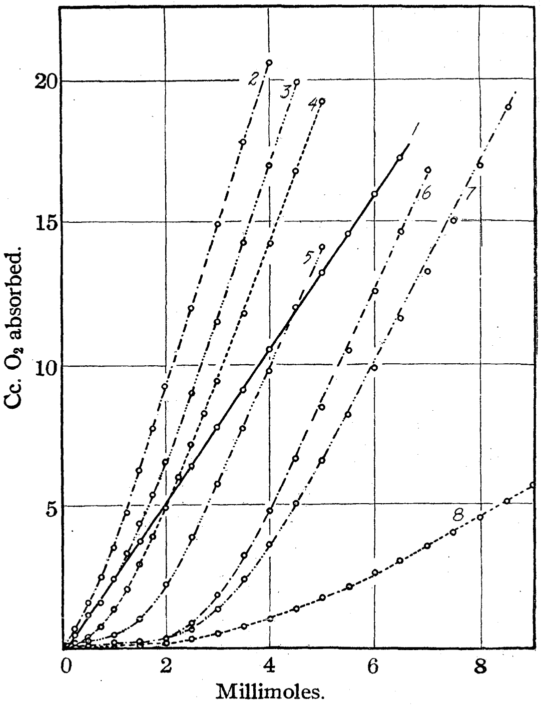

Fig. 4.—Rate of oxygen absorption at pH 8.2 by mixtures of catechol and resorcinol having the following mole fractions of resorcinol: 1, 0.0; 2, 0.04; 3, 0.5; 4, 0.6; 5, 0.7; 6, 0.75; 7, 0.8; 8, 0.96. The rate for pure resorcinol was measured as 0.0038 cc. of oxygen per minute at pH 8.3.

In this explanation of the phenomenon, the rate of oxidation of the more reactive phenol may, but need not, be specifically faster than that of catechol in mixtures of the two. It is therefore applicable to both pyrogallol and hydroquinone and is to be preferred.

When small quantities of pyrogallol or hydroquinone are used the initial rate is that of pure catechol and the catalysis does not show itself until a certain lapse of time (see Fig. 2). This would suggest that the chain exchanging process on which the catalysis depends occurs with an intermediate product of the oxidation of pyrogallol or hydroquinone, such as a deactivated peroxide. When larger quantities of pyrogallol or hydroquinone are used, the necessary intermediate is formed so quickly that the induction period is not noticeable.

The ideas presented may be clarified by the following mechanism for the delayed and limited catalysis of the oxidation of catechol by hydroquinone or pyrogallol provided the reader realizes that the formulation is schematic. In this formulation A refers to catechol, B to the more active phenol and activated molecules are starred. Initiation, continuation and termination of chains by B and termination of chains by the solvent have been omitted for the sake of brevity.

1. $A + O_2 + OH^- \longrightarrow AO_2^{-*}$ (chain initiating)
2. $AO_2^{-*} + A \longrightarrow AO_2 + A^{-*}$ (chain continuing)
3. $A^{-*} + O_2 \longrightarrow A^*O_2^-$
4. $AO_2^{-*} + A \longrightarrow AO_2 + A^-$ (chain breaking)
5. $AO_2^{-*} + B \longrightarrow BO_2 + A^{-*}$ (reaction upon which 6 must wait)
6. $BO_2 + A^{-*} \longrightarrow B^{-*} + AO_2$ (chain exchanging)
7. $B^{-*} + O_2 \longrightarrow BO_2^{-*}$
8. $BO_2^{-*} + A \longrightarrow B^{-*} + AO_2$ (continuing new chain)
9. $BO_2^{-*} + A \longrightarrow B^- + AO_2$ (breaking new chain)

Now if the specific rate of 6, k_6, is greater than that of 4, k_4, the chains in solution tend to become B chains as reaction progresses. Furthermore if $k_8/k_9 > k_2/k_4$ the new chains will be longer than the old.

In mixtures of catechol with small quantities of pyrogallol, the pyrogallol is used up specifically faster than is catechol and the rate soon becomes that for pure catechol; whereas, in mixtures of catechol and small quantities of hydroquinone, the maximum rate is maintained for a long time, showing that the composition of the mixture does not change much, the catechol and hydroquinone being oxidized at rates approximately proportional to their concentrations. Apparently, then, the essential difference between the behavior of pyrogallol–catechol and hydroquinone–catechol mixtures lies in the fact that pyrogallol is acted upon by the activated chains specifically faster than is hydroquinone. This is borne out by the longer induction period with hydroquinone.

The resorcinol–catechol mixtures, as seen in Fig. 3, differ from those of pyrogallol–catechol or hydroquinone-catechol in two important respects. In the first place, the induction periods, observable only when small concentrations of pyrogallol or hydroquinone are used, exist in all proportions of resorcinol to catechol and may last for a considerable duration of time. Secondly, the steady rates that are obtained eventually are higher than those obtained with either phenol alone. We have included, therefore, in Fig. 4 two curves for resorcinol, one for that of the steady rates and the other that for initial rates. But as the initial rates are often very slow the points on that curve are somewhat dubious.

The curves for the catechol–resorcinol mixtures are similar to those given by an inhibitor which is used up during the reaction, except that the final rate obtained is faster than that for catechol. It, therefore, is possible that we may be dealing with an auto-catalyst, resorcinol and small quantities of an inhibitor introduced with the resorcinol. The curve for the steady rates would not be affected by the introduced impurity but the curve of the initial rates would be that for reactions inhibited by an impurity. To test this we subjected the resorcinol to prolonged oxidation (about six hours) but the increase in the rate of absorption of oxygen which would be expected after the destruction of the inhibitor was not observed. The amount of oxygen absorbed in this test (over 1 cc.) was sufficient to have produced a marked increase in the rate of oxygen absorption by a catechol–resorcinol mixture. The experiment is not absolutely conclusive because it is possible that the oxidation of the inhibitor could be induced by that of catechol but not by that of resorcinol. However, we shall discuss the behavior of the catechol–resorcinol mixtures on the assumption that no inhibiting impurity was introduced with resorcinol.

The simplest explanation of the curve for the steady rates is that a rapidly oxidized intermediate is formed in the induced oxidation of resorcinol. This intermediate (probably a polyhydroxybenzene) acts like pyrogallol or hydroquinone in producing longer chains than those characteristic of either catechol or resorcinol. The curve is more complex than that for either pyrogallol–catechol or hydroquinone–catechol mixture because it is the result of the action of three components instead of two.

In the initial stages of the reaction we are dealing with the oxidation of mixtures of catechol and resorcinol before the resorcinol has been oxidized to the more active intermediate. The initial rates may be compared to those obtained in mixtures of pyrogallol or hydroquinone with catechol except that in catechol–resorcinol mixtures, catechol is the more instead of less active phenol. When mixtures of hydroquinone and catechol are oxidized there is a lag in the reaction during which the rate approximates that of the less reactive phenol followed by a steady rate approximating that of the more reactive phenol. This lag can be observed only when the time necessary for the formation of an intermediate in an amount sufficient to produce the steady rate is appreciable. This time varies inversely with the product of the concentration of the more reactive phenol by the true initial rate. Because of the fast initial rate in hydroquinone–catechol mixtures, this lag is observable only when small quantities of hydroquinone are present. The plot of observed initial rates against composition shows a double inflection as we pass from compositions in which the lag is observable to those in which it is not. The inflections for the hydroquinone–catechol mixtures occur very near to the axis representing 100% catechol. In the more inactive mixtures of catechol and resorcinol the inflections occur at about 50 mole per cent. of catechol.

The curve of the initial rates of oxygen absorption by catechol–resorcinol mixtures is therefore a combination of two phenomena. With high concentrations of catechol the measured initial rate is that characteristic of the mixture which has absorbed sufficient oxygen to give the maximum rate obtainable in absence of the formation of the more reactive intermediate from resorcinol. With smaller quantities of catechol the measured initial rate is approximately that of a mixture which has not absorbed sufficient oxygen to permit the change from the shorter resorcinol chains into the longer catechol chains.

Although it is thus apparent that the behavior of resorcinol–catechol mixtures can be explained in accordance with the general theory for pyrogallol or hydroquinone and catechol mixtures, the measurements seem to indicate an additional inhibitory action of resorcinol. This inhibition is shown in both the initial and steady-state rates obtained. The initial rates with small quantities of catechol are decidedly lower than those that would be expected for the same concentration of catechol in the absence of resorcinol, using the equation $V \propto [C^2/(C + A)]$. The steady-state rates obtained with large quantities of resorcinol are definitely lower than those with small quantities. This could be due either to inhibition by resorcinol or to the active intermediate being produced only in the induced oxidation of resorcinol. Inhibition by resorcinol would result if chains are shorter when they oxidize resorcinol than when they oxidize catechol, pyrogallol or hydroquinone.

At *p*H 8.3 the rate of absorption of oxygen by resorcinol (0.0038 cc./min.) is much slower than the rate of absorption by catechol inhibited by cysteine (0.1 cc./min.). If we accept the conclusion that in the cysteine inhibited reaction the chain is very short, the chain initiating reaction must be much slower for resorcinol than for catechol.

Acknowledgment.—We take this opportunity to thank Mr. Leo A. Joslyn for his aid in making the rate measurements.

Summary and Conclusions

1. The effect of a large number of foreign substances on the rate of oxygen absorption by catechol was studied. Most of these had little effect but cysteine, potassium sulfite and *o*-aminophenol behaved as genuine inhibitors destroyed during the reaction. Hydroquinone, resorcinol, pyrogallol, gallic acid and *p*-aminophenol appreciably increased the rate of oxygen absorption.

2. The oxidation of mixtures of catechol with pyrogallol or hydroquinone was studied at constant concentration of total phenol but varying proportions of the two phenols. The chief effect of pyrogallol or hydroquinone was to increase the rate of the reaction to almost that of pure pyrogallol or hydroquinone, respectively, over wide ranges of concentration of the latter. This is explained on a chain mechanism by the introduction of a chain exchanging process wherein a chain initiated by one phenol is convertible into a chain characteristic of the other.

3. In the presence of resorcinol, the initial rates are smaller than those of catechol alone, but these rates then increase until they are considerably greater than the rate for pure catechol.

This has been explained on the assumption that resorcinol is an inhibitor whose oxidation is induced by that of catechol to form poly-hydroxylbenzenes whose effects are similar to those of pyrogallol or hydroquinone.

The Reaction between Diphenylchloromethane and Ethyl Alcohol

BY F. G. KNY-JONES AND A. M. WARD

The results of a study of the rate of displacement of chlorine from diphenylchloromethane in ethyl alcoholic solution, obtained by Norris and Morton[1] differ in a number of respects from those obtained by one of us.[2]

Norris and Morton determined the velocity of the displacement from measurements of changes in the conductance of ethyl alcoholic solutions of the chloro compound, and concluded that the reaction is reversible, $CHPh_2Cl + EtOH$ (excess) $\rightleftharpoons CHPh_2OEt + HCl$, the direct reaction proceeding, under their experimental conditions, from 84.3 to 94.6% toward completion (Norris and Morton, Table IV, p. 1801); the factors which influenced this variation were not discussed, and the values of k for the postulated reverse reaction varied from 0.0015 to 0.0230. Ward[2] did not detect the reverse reaction in his kinetic study, which was based upon titration with alcoholic alkali of the hydrogen chloride formed. We did not obtain evidence of the reverse reaction by titrating alcoholic hydrogen chloride solutions of the final products.

Norris and Morton[1] (p. 1802) were unable to verify experimentally the calculated value for the reverse reaction and recorded but one experiment to show that the reaction was reversible; in this they passed hydrogen chloride into a solution of diphenylmethyl ethyl ether, dissolved in a mixture of dry benzene and petroleum ether, to which calcium chloride was added to remove the ethyl alcohol formed. The fact that they obtained diphenylchloromethane under these conditions does not afford any proof, however, of reversibility under the conditions of the kinetic experiments.

The velocity coefficients obtained by Ward (*e. g.*, $k = 0.00341$, 0.00349) are considerably higher than those of Norris and Morton ($k = 0.00281$ to 0.00310), which are higher also than those of Norris and Banta ($k = 0.00266$).[3] The values of k for the forward reaction were found to increase rapidly with increase in the water content of the alcohol, and the differences in the three sets of results may well be due to varying small amounts of water in the alcohol. According to Norris and Morton[1] (Table V, p. 1801) the extent of the reverse reaction diminished with increasing concentrations of water present. The equilibrium constant (K) for the reactions

$$CHPh_2Cl + EtOH \text{ (excess)} \rightleftharpoons CHPh_2OEt + HCl$$

is given by

$$K = \frac{k_1}{k_2} = \frac{[CHPh_2OEt][HCl]}{[CHPh_2Cl]}$$

where k_1 is the velocity coefficient of the forward reaction, k_2 that of the reverse reaction, and equilibrium concentrations are shown in square brackets. If the initial and equilibrium concentrations in g./mole/liter of diphenylchloromethane are C and $(1 - \alpha)C$, under the conditions of Norris and Morton's experiments $k_1/k_2 = \alpha^2C/(1-\alpha)$. The percentage conversions, calculated from their data (Table V), are shown.

Water, % by weight	0.15	0.58	1.07
Formality of $CHPh_2Cl$	.0990	.1191	0.1065
$k_1 \times 10^5$	316	358	407
$k_2 \times 10^4$	26	12	9
Conversion, %	93.0	96.3	97.8

Even if some 0.5% of water were present, about 4% of chloro compound should therefore be unchanged.

The failure to detect the reverse reaction in Ward's experiment might be due (1) to continued hydrolysis during the titrations, which were carried out by addition of alcoholic sodium hydroxide to a sample of the reaction mixture. Norris and Morton[1] (p. 1802), in checking results obtained by their conductivity method, added the reaction mixture to ice-cold water, removed cloudiness by means of carbon bisulfide, and then

titrated; (2) to water present in the alcohol, which was dried over lime, but the densities of the solvents used were not measured.

Further experiments, therefore, were carried out in which the alcohol used was purified by heating with quicklime and calcium, and fractionated (d^{20}_4 0.78940; Osborne, McKelvy and Bearce[4] give d^{20}_4 0.78934; the latter corresponds with Norris and Morton's value, d^{25}_4 0.78506). Diphenylchloromethane was prepared as previously,[5] and chlorine was determined by dissolving a sample in alcohol and titrating with sodium hydroxide, with warming, until displacement was complete.

Experiments were carried out by dissolving a known weight of chloro compound in the purified alcohol at 25.0°, adjusting the total volume to 250 ml., and leaving in the thermostat for two days; 50-ml. samples were then (1) titrated directly with standard alcoholic sodium hydroxide (approx. $N/20$); (2) added to about 200 ml. of ice-cooled water, free from carbon dioxide, and titrated with standard aqueous sodium hydroxide (approx. $N/20$); (3) added to 200 ml. of ice-cooled water, containing some 50 ml. of carbon bisulfide; the acidity of the mixture was previously removed by means of dilute sodium hydroxide. The mixture was well shaken, and then titrated as in (2). Phenolphthalein was used throughout as indicator.

RESULTS OF EXPERIMENTS

Chloro compound, g.		5.0014	4.7940	5.3020	8.1916

Calcd. titer, x% displ.	$x = 100$	98.2	94.2	104.6	161.5
	$x = 94.6$	92.9	89.1	98.9	152.8
	$x = 84.3$	82.8	79.4	88.1	136.1

The end-points in procedures (1) and (2) were generally discharged by boiling; the further additions of $N/20$ alkali, necessary to produce permanent end-points after boiling, in the four series of experiments were

(1)	0.21	0.13	0.34	nil.	ml.
(2)	0.32	0.50	0.04	0.33	ml.

These results confirm that displacement was complete in the two processes.

The foregoing experiments, standing alone, do not disprove the findings of Norris and Morton concerning reversibility for the equilibrium position may be so rapidly displaced under the conditions of titration that any remaining chloro compound is completely hydrolyzed. It must be borne in mind, however, that hydroxyl ions are not effective in this hydrolysis, which depends upon a slow ionization of the diphenylchloromethane. To obtain evidence on this, three experiments were carried out.

(1) Diphenylchloromethane (about 0.5 g.) was dissolved in dry ethyl alcohol (about 50 ml.) at 17° and at once titrated with alcoholic sodium hydroxide ($N/20$) in presence of phenolphthalein. Good end-points were obtained.

Time after mixing, min.	1/2	2	3	6	13
Titer (total), ml.	0.10	0.26	0.34	0.78	1.49

The temperatures at which the solutions were titrated can be considered to approximate to room temperature, and as the time of titration did not exceed three to five minutes, any displacement error would not have exceeded about 0.5 ml. This is very much smaller than the differences required from Norris and Morton's equilibrium values.

(2) Diphenylchloromethane (about 0.5 g.) was dissolved in ethyl alcohol (50 ml.), at once added to about 200 ml. of ice-cold water, and titrated at the times shown, against $N/20$ aqueous sodium hydroxide.

Time, min.	1	2	5	12
Titer, ml.	4.40	5.57	6.27	7.63

The rapidity of reaction of the aqueous alcoholic emulsion was much too great to allow any deduction to be drawn concerning the possible equilibrium, the difference between the titers for complete and 94.6% displacement being of the same order as the above titration values, after two minutes.

(3) The experiment was as in (2), but the alcoholic solution was added to ice-cold water containing carbon bisulfide, previously neutralized.

Time, min.	1/2	2	9	15
Titer, ml.	1.45	1.55	1.95	2.20

These results, showing an initial rapid reaction, followed by a slow change, indicate that rapid displacement of halogen takes place before the compound is extracted by the carbon bisulfide, but that afterward the reaction is slow.

The foregoing results show that titration with alcoholic alkali is the most satisfactory titration

[5] Ward, *J. Chem. Soc.*, 2288 (1927).

technique for arriving at the displacement figure and no evidence is obtained by titration methods for reversibility.

Summary

1. Norris and Morton, from conductance measurements, considered the reaction between diphenylchloromethane and ethyl alcohol to be reversible. Ward, by a titration method, found the reaction to be irreversible.

2. The titration method has now been examined in greater detail. No evidence is obtained for reversibility.

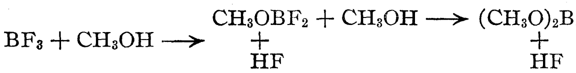
A New Method for the Preparation of Alkoxyboron Halides and their Reaction with Metals

BY CORLISS R. KINNEY, H. THERON THOMPSON AND LEE C. CHENEY

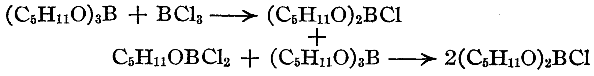
Alkoxyboron halides were first prepared by Gasselin[1] in 1894 by the action of methyl alcohol on boron trifluoride.



$$\mathrm{BF_3 + CH_3OH \longrightarrow \underset{HF}{\underset{+}{CH_3OBF_2}} + CH_3OH \longrightarrow \underset{HF}{\underset{+}{(CH_3O)_2BF}}}$$

In 1932 Bowlus and Nieuwland[2] observed that alcohols higher than methyl or ethyl did not produce fluoro esters, but a complex hydrocarbon mixture. The chloro esters were first investigated by Ramser and Wiberg[3] and later by Wiberg and Sütterlin[4] who prepared the methyl and ethyl derivatives from the corresponding alcohols or ethers and boron trichloride.

Preliminary experiments on the action of metals on diethoxyboron chloride indicated that larger groups would be desirable; consequently diisoamyloxyboron chloride was prepared and studied. The substance was prepared first using Wiberg and Sütterlin's method, but the yield was not satisfactory. Several attempts were made to prepare the substance from triisoamyl borate and dry hydrogen chloride, thionyl chloride, and phosphorus pentachloride[5] but the desired product was not obtained. With boron trichloride, however, the chloro ester was obtained and in much increased yields.



$$\mathrm{(C_5H_{11}O)_3B + BCl_3 \longrightarrow \underset{C_5H_{11}OBCl_2}{\underset{+}{(C_5H_{11}O)_2BCl}} + (C_5H_{11}O)_3B \longrightarrow 2(C_5H_{11}O)_2BCl}$$

Diisoamyloxyboron chloride did not react with "molecular silver" at room temperature, but did react readily with sodium or zinc when warmed. The reaction was exothermic and became violent unless cooled. Unexpected gaseous products were observed even at 70° in a benzene solution. The gas contained hydrogen chloride and probably isoamylene and hydrogen. The liquid product did not react with water to form hydrogen, indicating that $(C_5H_{11}O)_2BNa$ or possibly $(C_5H_{11}O)_2BB(OC_5H_{11})_2$ was absent. On distillation only triisoamyl borate and boric anhydride were obtained.

The reaction was obviously complex and involved secondary reactions. Without doubt the sodium removed the chlorine atom and the resulting radical, instead of combining with another of its kind, decomposed into an isoamyl radical and isoamyl metaborate.

$$\mathrm{(C_5H_{11}O)_2BCl + Na \longrightarrow (C_5H_{11}O)_2B\text{—} + NaCl}$$
$$\mathrm{(C_5H_{11}O)_2B\text{—} \longrightarrow C_5H_{11}OBO + C_5H_{11}\text{—}}$$

The unsaturated hydrocarbon gas and the hydrogen are accounted for by the decomposition of the isoamyl radical into isoamylene and nascent hydrogen, and the hydrogen chloride by the action of the hydrogen on another molecule of the chloro ester.

$$\mathrm{C_5H_{11}\text{—} \longrightarrow C_5H_{10} + H}$$
$$\mathrm{(C_5H_{11}O)_2BCl + H \longrightarrow (C_5H_{11}O)_2B\text{—} + HCl}$$

Finally, the isolation of triisoamyl borate and boric anhydride are to be expected because the attempt to isolate a metaborate by fractional distillation always results in the orthoborate and boric anhydride.

Experimental Part

The Reaction of Diethoxyboron Chloride with Metals.—Diethoxyboron chloride reacted readily with sodium or dry zinc dust when warmed slightly. Gases were evolved and a liquid product distilling between 110 and 150° was

obtained. The yield amounted to practically one-third the weight of chloro ester taken. Assuming that one molecule of the ester yields one third of a molecule of triethyl borate, the crude yield was 93%. Upon redistillation more than 75% of the product distilled between 112 and 114°, the boiling point of triethyl borate at 640 mm. The residue was boric anhydride.

The Preparation of Diisoamyloxyboron Chloride.—Upon adding dry isoamyl alcohol to boron trichloride dissolved in dry chloroform and cooled to −20°, a yield of only 15% of diisoamyloxyboron chloride was obtained. On the other hand, by mixing triisoamyl borate with boron trichloride in the ratio of two moles to one, allowing the mixture to stand for twenty-four hours and then fractionating, a yield of 45% was obtained. The yield was not increased by allowing the mixture to stand for a longer time or by heating it in a sealed tube to 100° for eleven hours. The compound distilled at 110 to 115° at 14 mm. pressure. The substance was analyzed by decomposing a weighed sample with water and titrating the hydrochloric and boric acids produced, using methyl orange and phenolphthalein as indicators.

Anal. Calcd. for $(C_5H_{11}O)_2BCl$: Cl, 16.1; B, 4.9. Found: Cl, 15.9; B, 4.9.

The Reaction of Diisoamyloxyboron Chloride with Metals.—Diisoamyloxyboron chloride reacted vigorously with sodium or zinc dust when warmed. In order to avoid excessive decomposition the reaction was carried out in a dry benzene solution. Twenty-two grams (0.1 mole) of the chloride was dissolved in 75 cc. of benzene dried over sodium and 4.5 g. of sodium shavings added. The flask was equipped with a reflux condenser to which a tube was attached to carry the evolved gases through a wash bottle containing water and then through another bottle containing a carbon tetrachloride solution of bromine. Upon heating the flask to 70° the sodium reacted slowly and bubbles of gas were evolved. The gas turned the water acidic in the first bottle and a test for chloride ion with silver nitrate was positive. On the other hand, a test for borate ion with turmeric paper was negative. After passing through the water the gas had an odor similar to that of gasoline, burned with a sooty flame and when passed into the bromine solution rapidly decolorized it. The residual gas was odorless and burned with a pale blue flame similar to that of hydrogen.

The reaction mixture was heated until no chlorine could be detected in the benzene solution, a period of seven hours being required. The dark red solution was filtered from the solid residue which dissolved completely in water leaving no residue of amorphous boron. Thirty grams of the total of seventy-five grams of the solution was treated with water in an apparatus designed to detect the liberation of gas, but none was evolved. The remainder of the solution was fractionated twice and 6.6 g. of pure triisoamyl borate boiling at 245 to 250° at 640 mm. pressure and 2.0 g. of boric anhydride were obtained.

Summary

1. Diisoamyloxyboron chloride has been prepared.

2. Dialkoxyboron halides react with metals forming extensive decomposition products.

The Thermal Equilibrium of the Cis–Trans Isomers of Dichloroethylene at High Temperatures

BY WILLIAM MARONEY

In the investigation of the thermal and photochemical equilibria of the *cis–trans* isomers of dichloroethylene, Olson and Maroney[1] were limited by decomposition reactions to temperatures below 350°. In the present study, the temperature range has been extended to 975° by using a flow method and low pressures.

The method of preparing the materials and the method of analysis are the same as those described in the previous paper.

The experimental method consisted in passing mixtures of known composition of the gaseous isomers through a heated reaction tube, and finding the change in composition due to the thermal isomerization. The reaction tube used at 825° was a section of quartz tubing, 4.5 mm. inside diameter and the portion heated, 17 cm. long. The heating element was wound in five sections. The current through each section could be regulated separately. The temperature was measured by five thermocouples, one for each section. The reaction tube used at 975° was made in a similar manner. The inside diameter of the tubing was 2.5 mm., the heated portion, 12 cm. long. Three heating units and three thermocouples were used. It was found that the length and bore of the tubes employed could be changed without altering the values found for the equilibrium composition.

The pressure at each end of the reaction tube was measured by sulfuric acid manometers. Since the manometers were about 20 cm. from the

---

[1] A. R. Olson and William Maroney, THIS JOURNAL, **56**, 1320 (1934).

ends of the reaction tube, the pressure which they recorded was only approximately that at the ends of the tube.

In making a run, the vapor from a mixture of the isomers in the liquid state contained in a glass storage bulb was allowed to flow through the reaction tube at a definite rate, controlled by a Fowler[2] gas leak and a streaming manometer. The reaction products were frozen out in a liquid air trap, from which they could be removed for analysis. The composition of the samples used in the runs was varied sufficiently so that the equilibrium was approached from both sides.

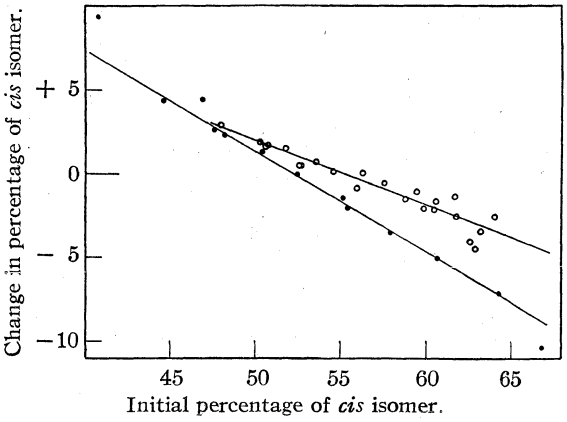

Fig. 1.—●, 975°; ○, 825°.

The two lines in Fig. 1 were obtained by plotting the change in the percentage of the *cis* isomer during a run against the initial percentage of that isomer. The composition corresponding to the point of zero change is the composition of the equilibrium mixture. The second and third columns of Table I give the average values of the pressures at the ends of the reaction tube as measured by the manometers. The values for the composition of the thermal equilibrium mixtures given in the next column are from Fig. 1.

TABLE I

Temp., °C.	Pressure, mm. Hg Input	Output	% *cis* at equil.
975	7.5	0.30	52.3
825	11.2	.34	55.1

In calculating ΔH, the heat of transition, Olson and Maroney[1] used the approximate equation $N_{trans}/N_{cis} = e^{-\Delta H/RT}$ because the possible errors in the equilibrium constants were so large compared to the change in the equilibrium constant for the fifty-degree change in temperature. If we now combine the present equilibrium constants with those given by Olson and Maroney and use the exact equation

$$\Delta H = \log \frac{K_1}{K_2} \times 4.58 \frac{T_1T_2}{\Delta T}, \text{ we get}$$

$$\Delta H_{300-975°} = 725 \text{ cal.}, \quad \Delta H_{350-875°} = 510 \text{ cal.}$$

the average of which agrees almost exactly with the value $\Delta H_{300°} = 600$ cal. given by Ebert and Büll.[3]

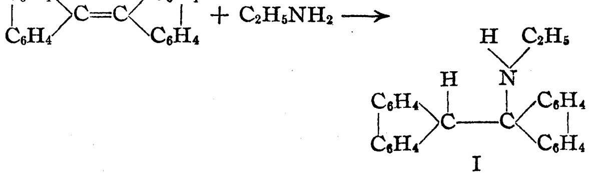
Interaction of Amines and Ammonia with Dibiphenyleneethylene

BY L. A. PINCK AND GUIDO E. HILBERT

With the aim of obtaining more information that might aid in elucidating the mechanism of the interaction between 9-fluorylamine and dibiphenyleneethylene in liquid ammonia which gives as end-products 9-iminofluorene and dibiphenyleneethane,[1] and in order to test the suspected similarity of the double bond in dibiphenyleneethylene to an ethylenic linkage adjacent to an activating group, as carbonyl or cyano,[2] we have been led to investigate the action of amines on dibiphenyleneethylene.

It has now been found that dibiphenyleneethylene combines easily at room temperature with ethylamine, methylamine or dimethylamine to give 1-ethylamino (I), 1-methylamino (II) and 1-dimethylaminodibiphenyleneethane, respectively.



$$(C_6H_4)_2C{=}C(C_6H_4)_2 + C_2H_5NH_2 \longrightarrow (C_6H_4)_2CH{-}C(NHC_2H_5)(C_6H_4)_2$$

I

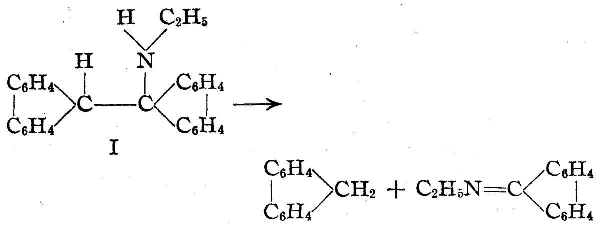
---

(1) Pinck and Hilbert, THIS JOURNAL, **54**, 710 (1932).

(2) Lapworth and McRae, *J. Chem. Soc.*, **121**, 2741 (1922), and Kolker and Lapworth, *ibid.*, **127**, 307 (1925), have suggested that the properties of an ethylenic linkage, which is in the α,β-position with respect to a carbonyl group, are intermediate to those of a normal ethylenic linkage and those of the carbonyl group.

As the rate of addition of these amines to the double bond is relatively rapid, the slow side reactions which occur subsequent to the formation of the amine, are of minor significance and depress the yield of the primary product only slightly below that required by theory. However, in the interaction of benzylamine or ammonia with dibiphenyleneethylene the rate of addition of the base to the unsaturated grouping is so slow that the secondary reactions assume a major role. These reactions are favored by elevated temperatures and 1-benzylaminodibiphenyleneethane (III) can be prepared in fair yield only by carrying out the reaction (several months for completion) at room temperature. When ammonia is used as the basic reactant, only secondary products can be isolated from the reaction mixture. In contrast to the behavior of the above amines, diethylamine, triphenylmethylamine or aniline do not react under conditions which are generally more favorable than those used for the other amines. The comparative data obtained indicate that the rate of addition of amines to dibiphenyleneethylene is in the order $CH_3NH_2 > C_2H_5NH_2 > (CH_3)_2NH > C_6H_5CH_2NH_2 > NH_3 > (C_2H_5)_2NH$ or $C_6H_5NH_2$. Such data as are available in the literature point to the same order of addition of amines to α,β-unsaturated acids. It is interesting to note that although II readily forms an acetyl derivative, I and III fail to react when subjected to the usual acetylation procedures. All three amines however interact with nitrous acid to give nitroso derivatives. Additional evidence indicating the presence of the –NH– grouping in I, II and III was secured by Dr. Wulf and Mr. Liddel of the spectroscopic section of this Laboratory by a study of the infra-red absorption spectra in the region 1.65–1.45 μ; the molal absorption area ($cm.^{-1}$) was found to be 7, 9 and 8, respectively. The –NH– absorption per molecule is thus somewhat lower than has yet been experienced with the rather large and varied group of organic –NH– compounds which they have investigated.[3]

These amines are quite sensitive to thermal conditions and the nature of the decomposition is influenced by the character of the medium in which they are dissolved. In alcohol at 100° the dismutation of I yields fluorene and 9-ethyliminofluorene exclusively. But in ethylamine a different type of scission leading to the formation of dibiphenyleneethane and ethylideneimide also occurs. Because of the high temperature and the length of time required to effect a reaction between ammonia and dibiphenyleneethylene, the primary product formed, 1-aminodibiphenylenethane, does not survive and only the secondary products, fluorene and 9-iminofluorene are found in the reaction mixture.



Although there are numerous examples of the facile combination of ammonia or amines with unsaturated acids or related compounds in which the double bond is in the α,β-position to form the respective β-amino or β-substituted amino acids,[4] the only investigation other than the work reported here on the combination of amines with the ethylenic linkage of unsaturated hydrocarbons appears to be that of Hickinbottom.[5,6] The employment of a promoter (amine hydrochloride) in the examples studied by Hickinbottom obscures the mechanism of the reaction and it is by no means certain, in view of the type of catalyst used, that the reaction product was not formed indirectly.[7] On the other hand, the combination of amines with dibiphenyleneethylene is effected in the absence of any promoter and would thus seem to allow of no other interpretation than that of direct addition of the amine to the ethylenic linkage.

Although general experience in the past[8] would have seemed to indicate that there is an abrupt change in the reactivity of ethylenic linkages in unsaturated hydrocarbons as compared to those in unsaturated α-carbonyl compounds toward

[5] Hickinbottom, *J. Chem. Soc.*, 2646 (1932); 319 and 1981 (1934).

[6] It is interesting to note that calculations assuming the validity of the Nernst approximation formula indicate that the reaction of ethylene and ammonia to give ethylamine is thermodynamically possible.

[7] A discussion of the nature of the reaction was postponed by Hickinbottom in order to test experimentally the various hypotheses that might be proposed to account for the reaction. As the aromatic amine hydrochlorides, which were used as catalysts, are appreciably dissociated at the temperatures at which these reactions were carried out, it seems to us quite possible that the formation of the amines was dependent on the prior addition of hydrogen chloride to the double bond.

[8] Lapworth and McRae *J. Chem. Soc.*, **121**, 2741 (1922); Kolker and Lapworth, *ibid.*, **127**, 307 (1925).

certain reagents as amines, hydrogen cyanide, diethyl malonate, etc., our work shows that the properties of the double bonds, even in unsaturated hydrocarbons, when the appropriate groups are attached, can approach in similarity those of the unsaturated linkage in the grouping —CH=CHCO—. The natural inference is that the electronic configuration of the double bond in dibiphenyleneethylene is more like that of the ethylenic linkage with an adjacent carbonyl group than that of the normal type in ethylene. This suggests the possible interaction of dibiphenyleneethylene with other reagents that are generally considered to be specific for compounds containing the group —CH=CHCO—. Moreover, in view of the activating influence of the biphenylene group upon a double bond, one might expect a like effect upon the methylene group in fluorene and its derivatives and this seems to be substantiated by the remarkable parallelism of many of its reactions, although the rates are much slower, with those of the methylene group in a compound such as diethyl malonate.

We wish to express our appreciation to Dr. R. T. Milner and Mrs. M. S. Sherman for the recorded microanalyses.

Experimental

Interaction of Dibiphenyleneethylene with Ammonia.—A mixture of 1 g. of dibiphenyleneethylene and 15 cc. of liquid ammonia was heated in a sealed tube at 65° for three weeks. At the end of this time it was apparent that the red ethylene compound was completely altered. After opening the tube, the ammonia was removed and the residue triturated with dry ether. The fraction insoluble in ether weighed 0.5 g. and melted at 295°; it was crystallized from acetone and separated as colorless prisms; m. p. 300°.[9] Treatment of the ether extract with dry hydrogen chloride precipitated the orange colored hydrochloride of 9-iminofluorene, yield 0.40 g.; m. p. 303° (dec.).[10] The hydrochloride was converted into the free base which was crystallized from hexane; yellow needles; m. p. 123°; m. p. when mixed with 9-iminofluorene unchanged.

Anal. Calcd. for $C_{13}H_9N$: C, 87.11; H, 5.06; N, 7.82. Found: C, 87.22; H, 5.25; N, 7.81.

The ether filtrate from 9-iminofluorene hydrochloride was concentrated to dryness; 0.07 g. of fluorene was removed by sublimation; m. p. 114°; the m. p. when mixed with fluorene was unchanged.

1-Ethylaminodiphenyleneethane (I).—Two grams of dibiphenyleneethylene in 10 cc. of ethylamine reacted completely in two days when heated at 65°. Excess ethylamine was removed by distillation, the residue dissolved in dry benzene and 1-ethylaminodibiphenyleneethane precipitated as the hydrochloride; m. p. 210–215° (dec.). This was converted to the free base, which was crystallized from a benzene–alcohol solution; it separated as colorless prisms melting at 165°; yield 65% of the theoretical. It is soluble in benzene, hot hexane and slightly soluble in alcohol.

Anal. Calcd. for $C_{28}H_{23}N$: C, 90.04; H, 6.21; N, 3.75; mol. wt., 373. Found: C, 89.86; H, 6.39; N, 3.73; mol. wt., 369.

From the benzene–hydrogen chloride filtrate there were isolated small amounts of the secondary products fluorene (sublimation) and dibiphenyleneethane. As is shown below these products originated from a relatively slow degradation of I in ethylamine and obviously for the preparation of it in good yield excessive heating and a delay in working up the reaction mixture is to be avoided.

The picrate crystallized from an alcoholic acetone solution; yellow diamond-shaped prisms; m. p. 228° (dec.).

Anal. Calcd. for $C_{34}H_{26}N_4O_7$: C, 67.76; H, 4.35; N, 9.30. Found: C, 67.86; H, 4.50; N, 9.19.

The nitroso derivative was prepared by treating a solution of the amine in acetic acid with an aqueous solution of sodium nitrite. It separated from an acetone–alcohol solution as pale yellow rhombic crystals melting at 217°; very soluble in acetone and slightly soluble in alcohol and ether; the yield was practically quantitative.

Anal. Calcd. for $C_{28}H_{22}N_2O$: C, 83.55; H, 5.51; N, 6.96. Found: C, 83.98; H, 5.47; N, 6.98.

This, as well as the other nitroso derivatives, did not respond to the Liebermann nitrosoamine test, which is based on the nitrous acid formed in the scission of the —N—N— linkage. The negative test in these particular compounds may be accounted for by the preferential rupture of the —C—N— linkage[11] to form methyldiazonium hydroxide, which would decompose and liberate nitrogen. It is noteworthy that the nitrosoamine when treated with concentrated sulfuric acid immediately generated considerable gas. When warmed, the brown colored acid mixture turned to a red solution and this on dilution with water deposited red flocks suggestive of dibiphenyleneethylene. An oxdiazolidine structure has also been considered for the nitroso compound but this possibility was definitely excluded since a carbon tetrachloride solution showed no —NH— absorption in the region 1.65–145 μ.

Dismutation of 1-Ethylaminodibiphenyleneethane.—A solution of 2 g. of 1-ethylaminodibiphenyleneethane in 20 cc. of absolute ethyl alcohol was heated at 100° for ten days. After concentrating the alcoholic solution, the yellow sirupy residue was dissolved in hexane and treated with dry hydrogen chloride, yielding 0.90 g. of a pale peach-colored precipitate. The residue obtained by concentrating the filtrate was sublimed *in vacuo;* yield 0.81 g. of a yellow colored sublimate, that consisted mainly of fluorene contaminated with some fluorenone, which was probably formed by the hydrolysis of a portion of the imide. The fluorenone was separated from fluorene by converting it to the difficultly soluble fluorenone ketazine (0.10 g.; m. p. 267°).[12] Fluorene was recovered from the

---

(9) Evidence concerning the structure and the mechanism of the formation of this compound is the subject of a further investigation.

(10) All melting points are corrected.

(11) Kharasch and Howard [This Journal, **56**, 1370 (1934)] showed that triphenylmethylamine is hydrolyzed by acid.

(12) Taipale, *Ber.*, **63**, 243 (1930).

filtrate and identified; yield, 0.67 g. The hydrochlorides representing the basic fraction were treated with liquid ammonia and the mixture concentrated. The residue was extracted with hexane and the extract concentrated to a yellow sirup (9-ethyliminofluorene). This was hydrolyzed to fluorenone; yield 0.31 g. In another experiment the amine (0.5 g.) was degraded and the 9-ethyliminofluorene isolated as the picrate by adding an alcoholic solution of picric acid to the reaction mixture; yield 0.20 g.; m. p. 204° (dec.), m. p. 205° (dec.) when mixed with the specimen obtained below.

Anal. Calcd. for $C_{21}H_{16}N_4O_7$: C, 57.79; H, 3.70; N, 12.86. Found: C, 58.03; H, 3.81; N, 12.94.

The decomposition of 1-ethylaminodibiphenyleneethane was also studied in ethylamine in order to gain information concerning the origin of the fluorene and dibiphenyleneethane that were isolated as by-products in the interaction of ethylamine with dibiphenyleneethylene. 1-Ethylaminodibiphenyleneethane (1 g.) was heated in ethylamine (15 cc.) in a sealed tube at 85° for several days. The ethylamine was removed from the reaction mixture, the residue dissolved in benzene and the bases separated by means of hydrogen chloride. From the filtrate there was isolated 0.18 g. of dibiphenyleneethane and 0.15 g. of fluorene. Attempts to ascertain the nature of the basic fragment resulting simultaneously with dibiphenyleneethane were not successful and this is not surprising, since the initial product to be expected, ethylideneimine[13] would subsequently either suffer polymerization or react with the medium to yield ethylideneethylamine.

9-Ethyliminofluorene was prepared for purposes of comparison with the product obtained above. A solution of 1.3 g. of 9-iminofluorene[14] and 20 cc. of ethylamine was heated at 55° for eighteen hours and gradually assumed a pale green color. The ethylamine was removed and the yellow sirup was placed in an evacuated desiccator containing sulfuric acid; it did not crystallize and slowly developed a greenish color. It was converted to the *picrate* which separated from a solution of nitrobenzene and alcohol as orange needles; m. p. 206° (dec.).

Anal. Calcd. for $C_{21}H_{16}N_4O_7$: C, 57.79; H, 3.70; N, 12.86. Found: C, 58.00; H, 3.90; N, 12.86.

The low yield, 0.57 g., of the imide picrate is significant and may be accounted for by isomerization of the imide during its preparation as it is a prototropic system.[15]

1-Methylaminodibiphenyleneethane.—The reaction between dibiphenyleneethylene (2 g.) and methylamine at room temperature was complete in one day. The reaction product was crystallized from hexane; yield 1.55 g.; m. p. 151°.

Anal. Calcd. for $C_{27}H_{21}N$: C, 90.22; H, 5.89; N, 3.90. Found: C, 90.41; H, 5.92; N, 3.98.

The acetyl derivative separated as colorless plates from alcohol; m. p. 232°.

Anal. Calcd. for $C_{29}H_{23}NO$: C, 86.75; H, 5.78; N, 3.49. Found: C, 86.66; H, 5.80; N, 3.40.

The nitroso derivative crystallized from alcohol as long prisms melting at 203°. It was soluble in hot carbon tetrachloride and separated with one molecule of solvent of crystallization.

Anal. Calcd. for $C_{27}H_{20}N_2O \cdot CCl_4$: CCl_4, 28.38. Found: CCl_4 (loss *in vacuo*), 28.65. Calcd. for $C_{27}H_{20}N_2O$: C, 83.47; H, 5.19; N, 7.22. Found: C, 83.48; H, 5.20; N, 7.39.

1-Dimethylaminodibiphenyleneethane crystallized from a solution of alcohol containing 20% benzene as colorless distorted hexahedra; m. p. 215° (dec., red liquid).

Anal. Calcd. for $C_{28}H_{23}N$: C, 90.04; H, 6.21; N, 3.75. Found: C, 89.88; H, 6.44; N, 3.85.

Reaction of Dibiphenyleneethylene with Benzylamine.—A mixture of 5 g. of dibiphenyleneethylene and 20 cc. of benzylamine was kept in a sealed tube for about six months, when it was evident that no more of the unsaturated hydrocarbon was present. The supernatant liquid was decanted from the precipitated dibiphenyleneethane (0.80 g.) and transferred into one leg of a two-legged tube. The benzylamine was distilled under diminished pressure from one portion of the tube which was immersed in boiling water, to the other which was cooled by an acetone–carbon dioxide mixture. The residue was triturated with a small quantity of cold alcohol and dried; yield 4.62 g. 1-Benzylaminodibiphenyleneethane was purified by crystallizing first from a solution of 1 part benzene and 4 parts alcohol and then from propyl alcohol; short stout prisms; m. p. 168°.

Anal. Calcd. for $C_{33}H_{25}N$: C, 91.04; H, 5.79; N, 3.17. Found: C, 91.00; H, 5.84; N, 3.27.

The hydrochloride could be recrystallized from benzene; m. p. 215–218°.

Anal. Calcd. for $C_{33}H_{26}NCl$: N, 2.97; Cl, 7.51. Found: N, 3.04; Cl, 7.40.

The nitroso derivative separated from a solution of acetone and alcohol as stubby prisms melting at 217–218°.

Anal. Calcd. for $C_{33}H_{24}N_2O$: C, 85.31; H, 5.21; N, 6.03. Found: C, 85.68; H, 5.42; N, 6.28.

An attempt to prepare the methiodide was unsuccessful.

When a solution of dibiphenyleneethylene (5 g.) in benzylamine (10 cc.) was heated at 100° the reaction was completed in six days. From the reaction mixture there were isolated dibiphenyleneethane (2.2 g.), fluorene (0.05 g.), an unidentified hydrocarbon (1.0 g., small colorless plates from xylene; m. p. 318° (decomp. to red melt). *Anal.* Found: C, 94.43; H, 5.49), 1-benzylaminodibiphenyleneethane and an unidentified base[16] crystallized from alcohol; m. p. 90°.

Anal. Calcd. for $C_{21}H_{22}N_2$: C, 83.43; H, 7.33; N, 9.24. Found: C, 83.67; H, 7.24; N, 9.19. Hydrochloride, m. p. 212°. *Anal.* Calcd. for $C_{21}H_{24}N_2Cl_2$: C, 67.19; H, 6.45; N, 7.47. Found: C, 67.23; H, 6.42; N, 7.27.

Dismutation of 1-benzylaminodibiphenyleneethane was effected by heating 1 g. in 20 cc. of absolute ethyl alcohol in a sealed tube at 100° for ten days. Fluorene (0.25 g.), small quantities of fluorenone and benzaldehyde[17] and a few milligrams of an unidentified product, which separated

from benzene–alcohol as colorless prisms melting at 202°, were isolated.

Anal. Found: C, 88.40; H, 5.64.

Summary

Dibiphenyleneethylene combines with ethylamine, methylamine and dimethylamine with facility at room temperature to give the corresponding substituted 1-aminodibiphenyleneethane derivatives. These products are quite labile and readily suffer dismutation to give fluorene and the substituted 9-iminofluorenes. The addition of benzylamine and ammonia to the ethylenic linkage was relatively sluggish, and in the reaction involving the latter only the secondary products fluorene and 9-iminofluorene were obtained. With the possible exception of the recent work of Hickinbottom this appears to be the first case reported of the addition of amines to an unsaturated hydrocarbon containing an olefin double bond.

The Direct Carboxylation of Carbon Compounds. III. The Free Energy of Benzoic Acid at 522°K.

BY W. D. BONNER AND C. R. KINNEY

Two papers dealing with the direct carboxylation of carbon compounds have been published from this Laboratory.[1] The theme of these two papers was that carboxylic acids may be produced directly from carbon compounds and carbon dioxide through the formation of an equilibrium gas mixture at high temperature and pressure. A catalyst always was present to facilitate the establishment of this equilibrium. The yields, except for one or two instances, were small. Furthermore, as stated in the first paper, an approximate calculation of the free energy showed that equilibrium probably lay well to the left in the reaction $C_6H_6 + CO_2 \longrightarrow C_6H_5COOH$. Since, however, it did not seem possible to make a more precise free energy calculation, and as carboxylic acids certainly were obtained, albeit in small amounts, there seemed no reason for withholding the data from publication. Recently we have been able to calculate a more acceptable free energy value, and to arrive at a plausible reason for the observed formation of carboxylic acids.

Free Energy Calculations

For the reaction $C_6H_6(g) + CO_2(g) \longrightarrow C_6H_5CO_2H(l)$ we find that $\Delta F^0_{298} = 4300$ cal.[2] However, we wish to know ΔF^0 at 522°K.

The free energy of formation of benzene at any temperature T is given by the relation[3]

$$\Delta F^0_T = 24{,}400 + 19.6T \ln T - 0.013T^2 - 87.0T$$

Therefore, $\Delta F^0_{522} = 39{,}600$ cal. In a similar manner the free energy of formation of carbon dioxide at 522° is[4] $\Delta F^0_{522} = -94{,}263$. For benzoic acid a corresponding equation does not appear in the literature. Parks and Huffman[5] give for the reaction

$$7C + 3H_2 + O_2 \longrightarrow C_6H_5CO_2H(l);\quad \Delta F^0_{298} = -59{,}160$$

ΔH_{298} (benzoic acid solid) as $-93{,}210$ cal. and the heat of fusion of benzoic acid at the melting point as 4140. Putting the general free energy equation into the form

$$\Delta F^0_T = \Delta H^0 - \Delta C_P\, T \ln T + IT$$

we can evaluate these quantities one by one, and finally arrive at a value of ΔF^0_{522} for benzoic acid. $\Delta C_P = C_P$ (products) $- C_P$ (reactants) $= C_P$ (benzoic acid) $- C_P(7C, 3H_2, O_2)$. Using available heat capacity data[6] we find ΔC_P between 25 and 249.2° to have an average value of 17.9 cal. per mole.

Using the value of ΔH_{298} (benzoic acid solid) already referred to, and assuming C_P (benzoic acid liquid) to be the same below as above the melting point, we calculate ΔH_{298} (benzoic acid liquid) $= -90{,}927$ calories. Then, since $\Delta H_T = \Delta H_0 + T\Delta C_P$, it follows that $\Delta H_0 = -90{,}927 - 17.9(298) = -96{,}261$ cal. The integration constant I, then is

$$I = \frac{\Delta F^0{}_{98} - \Delta H_0 + \Delta C_P T \ln T}{T} = \frac{-59{,}160 + 96{,}261 + 17.9(298)\ (5.697)}{298} = 226.5$$

(6) Parks and Huffman, *loc. cit.*, pp. 45, 46; "International Critical Tables," Vol. V, pp. 104, 110.

Substituting these and the value of ΔF^0_{298} into the free energy equation we get ΔF^0_{522} (benzoic acid) $= -36{,}491$ cal. From this it follows that the free energy of formation of benzoic acid from benzene and carbon dioxide at 522°K. is 18,172 cal. The equilibrium constant for this reaction is calculated, from the relationship $-\Delta F^0 = RT \ln K$, to be $K = 10^{-7.63}$.

It can be shown readily that this value will not be much affected by an increase of pressure of the order of 35 atmospheres. It is evident that in the reactions studied by Kinney and his students, the equilibrium amounts of carboxylic acids cannot account for the quantities actually found. The most plausible explanation, it seems to us, is that the zinc oxide of their oxide catalyst was slowly converted into the zinc salt of a carboxylic acid, and in this way appreciable amounts were built up in their apparatus. This would account also for the observation that fresh catalysts were always most effective and that the catalyst became almost inactive by the third usage.

This emphasizes the fact that catalysts may not always be purely catalysts, but that small amounts of products may result from direct chemical action with the catalyst or with one of its constituents. In such cases free energy data if available are of great value.

We acknowledge indebtedness to Professor George S. Parks for criticizing the preliminary calculations, and to Dr. Lyman G. Bonner for rechecking the final ones. The latter also has made a precise calculation of the free energy of benzoic acid at the boiling point, using complete heat capacity equations. This calculation, however, differs from ours by less than 0.5%.

Binary Systems of p-Dichlorobenzene with Diphenyl, Naphthalene and Triphenylmethane

BY ROSS E. MORRIS AND WALTER A. COOK

Schröder[1] some years ago showed that p-dibromobenzene forms an almost perfect solution with benzene. The purpose of this investigation was to find the nature of solutions of p-dichlorobenzene with various aromatic hydrocarbons. Those chosen were diphenyl, naphthalene and triphenylmethane. These solutions have not been previously investigated.

In the following report the solubilities, eutectic temperatures and eutectic compositions are compared with values calculated for perfect solutions from the equation given by Washburn[2]

$$\mathrm{d}T_f = \frac{RT_f^2}{\Delta H_f}\frac{\mathrm{d}N}{N}$$

where T_f is the freezing point of the solution, ΔH_f is the heat of fusion of the crystals separating from the solution at the freezing point, R is the gas constant and N is the mole fraction of the component which crystallizes at the freezing point. The values for ΔH_f are given in Table I.

Materials.—Commercial naphthalene and p-dichlorobenzene were purified by distillation until no further changes in melting points were observed. Eastman C. P. grade of diphenyl and triphenylmethane were purified by recrystallization, the former from alcohol and the latter from acetone, and dried *in vacuo*. The melting points of the purified materials are compared with the "International Critical Tables" values in Table II.

TABLE I

HEAT OF FUSION ΔH_f

	G. cal./mole	Ref.
p-Dichlorobenzene	$-10{,}250 + 94.07T - 0.1511T^2$	3
Diphenyl	$-11{,}240 + 112.8T - 0.2835T^2 + 0.0002568T^3$	4
Naphthalene	$+4265 - 26.31T + 0.1525T^2 - 0.0002140T^3$	4
Triphenylmethane	$-9230 + 66.35T - 0.07324T^2$	4

The agreement in melting points is good except in the case of triphenylmethane. The "I. C. T." value is undoubtedly too low for this compound.

Triphenylmethane	93.2	92.5

Smith and Andrews[5] in their careful work on the heat capacity and melting point of triphenylmethane found 93.1° by thermometer, which is in good agreement with our value.

Experimental.—Temperatures were measured with short stem Anschütz precision thermometers. Two thermometers were used, covering the ranges −13 to 60° and 38 to 110°, respectively. Each was 155 mm. over-all length and contained an enclosed white glass scale which was divided in 0.2° unit. With the aid of a magnifying glass the thermometers could be read accurately to 0.05°. Both were compared with a thermometer standardized by the Bureau of Standards. With these thermometers there was no correction for emergent stem because the entire thermometer was enclosed with the melt.

Weighed samples in test-tubes (22 mm. in diameter) were placed in larger test-tubes which were immersed in a water-bath. The melt was allowed to cool with the bath, the difference in temperature between the melt and bath never amounting to more than three degrees. The melt was well stirred with a glass stirrer having a ring at the bottom encircling the thermometer. When supercooling occurred the highest temperature attained after crystallization started was taken as the melting point. This temperature could be checked to within 0.2°. Supercooling never amounted to more than 0.5°.

The procedure of projecting back the cooling curve of the two-phase system to intersect with the liquid cooling curve and taking the point of intersection as the melting point has been used frequently in work of this type.[6] However, in this investigation we found that this procedure was inapplicable, especially at low temperatures and high concentrations of one of the constituents. The ring stirrer became caked with crystals so that uniform stirring could not be obtained and therefore the heat transfer was affected. Taylor and Rinkenbach[7] experienced the same difficulty

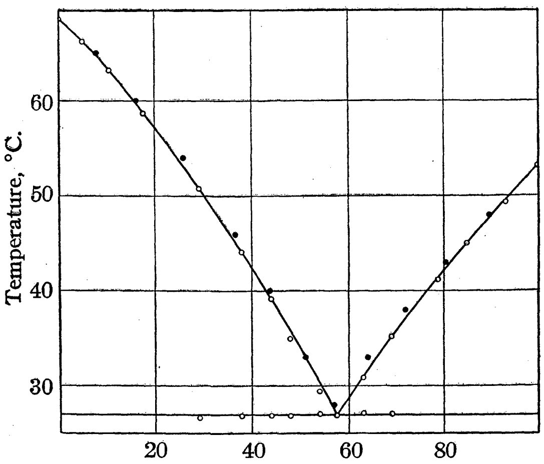
in their work on the solubility of trinitrotoluene in carbon tetrachloride.

Results and Discussion.—The data obtained are given in Tables III, IV and V, and the freezing point–composition diagrams are shown in Figs. 1, 2 and 3. The ideal solubilities calculated from the above equation are shown by the filled circles in the figures. A comparison of the ideal eutectic compositions and temperatures is presented in Table VI.



Mole per cent. of *p*-dichlorobenzene.

Fig. 1.—*p*-Dichlorobenzene–diphenyl.

One may conclude that these three binary systems show a fairly close approach to ideal properties.

Although *p*-dichlorobenzene is non-polar, the presence of the chlorine atoms in the molecule evidently influences the properties of the latter sufficiently to make its solution with hydrocarbons somewhat less perfect than mixtures of hydrocarbons. For example, Lee and Warner[8] have shown that diphenyl, dibenzyl and naphthalene form practically perfect solutions among themselves.

Equilibrium in the System, Lithium Phthalate–Phthalic Acid–Water

BY STERLING B. SMITH, WILLIAM A. STURM AND EDWARD C. ELY

Introduction

The use of acid phthalates as standards in volumetric analysis has become widespread during the past twenty years. Both the potassium and the sodium acid salts are used. Their use was first suggested by Dodge[1] and by Hendrixson.[2] A phase rule study of the system potassium phthalate, phthalic acid and water has been made by Smith,[3] and the system sodium phthalate, phthalic acid and water by Smith and Sturm.[4] It is possible that the acid phthalates of other alkali metals could be used for similar purposes and it is with this point in mind that an investigation of the solubility relations in the system lithium phthalate, phthalic acid and water has been undertaken.

Experimental Part

Materials and Methods.—Phthalic acid was prepared by crystallizing from aqueous solution sublimed phthalic anhydride obtained from the Eastman Kodak Co.

Lithium phthalate was prepared by neutralizing in aqueous solution an equivalent weight of phthalic acid with C. P. lithium carbonate. The resulting solution was boiled to drive off carbon dioxide, evaporated to a small volume and allowed to crystallize. The resultant crystals of lithium phthalate were filtered on a Büchner funnel and dried in the air. The composition of this salt was found by analysis to be $2Li_2C_8H_4O_4{\cdot}3H_2O$.

Lithium acid phthalate, while not a component of this system, appears as one of the important solid phases and is used in the preparation of mixtures for analysis. This salt as will be apparent later cannot be crystallized from aqueous solution at room temperature and was prepared by adding less than the equivalent weight of phthalic acid to each equivalent of lithium phthalate prepared as above, and allowing the acid salt to crystallize from a solution of lithium phthalate.

Solubilities were determined by analyzing solutions obtained by rotating for a minimum of twenty-four hours mixtures of the three components in an electrically controlled thermostat. At zero degrees the temperature was maintained constant by the use of ice and a small amount of salt. Temperature variations were within ±0.1°. When equilibrium was attained, the mixtures were allowed to settle and samples for analysis removed from the clear supernatant liquid by means of a pipet. At elevated temperatures the pipet was previously warmed to prevent crystallization during the sampling. When necessary, to prevent entrance of solid phase into the pipet, a small plug of cotton was placed in a short length of rubber tubing slipped over the end of the pipet.

Phthalic acid was determined by titration with alkali using phenolphthalein as the indicator. Lithium phthalate was determined by conversion into lithium sulfate with sulfuric acid and evaporating to dryness. The excess sulfuric acid was removed by ignition in a stream of ammonia. Water was determined by difference.

In making up the original mixtures, wherever possible the salts were used which exist as solid phases after equilibrium has been reached. The composition of the solid phases was determined by the analysis of wet residues according to Schreinemakers.[5] Because of the viscosity of many of the solutions, no attempt was made to determine their density.

Experimental Results.—Isotherms at 0, 25 and 50° have been completed. Compound formation takes place at all these temperatures. The solubility isotherms at these temperatures consist of three intersecting curves, representing isothermally univariant equilibrium between the solutions and one solid phase, and two isothermally invariant points where two solid phases are in equilibrium with the solutions. Inasmuch as no new solid phases appeared and the same solid phases remained at these three temperatures, no further isotherms were completed.

Experimental results are given in Table I. The symbol "P" is used here as in previous work to designate the phthalate radical, $C_8H_4O_4$. The figures representing the composition of the solutions at the isothermally invariant points are the average of several closely agreeing results.

The Acid Salt.—The composition of the acid salt, $LiHP{\cdot}2H_2O$, is most important as it is this material that has possibilities as a standard in volumetric analysis. The composition of this salt has been determined both graphically and by analysis. The extrapolated tie lines at each

A sample of the acid salt was carefully prepared by adding solid lithium phthalate and phthalic acid to a solution of lithium phthalate, the proportions being arbitrarily selected, as will be apparent. The mixture was rotated in the thermostat at 25° for sixty hours and then allowed to settle. The composition of the liquid phase was found by analysis to be H_2P = 7.32% and Li_2P = 35.27%, represented by a point in approximately the middle of the line representing the composition of all solutions in equilibrium with the acid salt as solid phase. The residue was quickly centrifuged and analyzed, giving the data: H_2P = 39.22%, Li_2P = 43.80%, H_2O by difference = 16.98%. The percentage composition

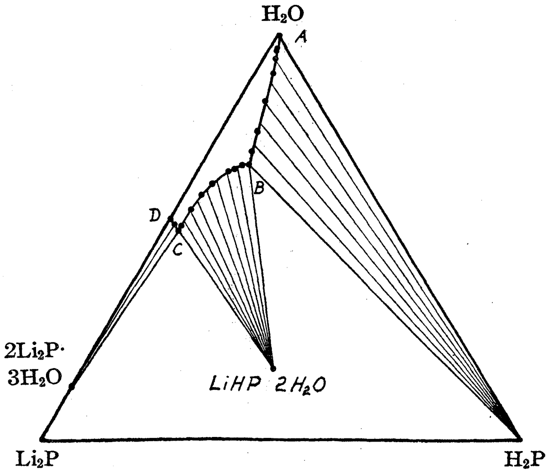

Fig. 1.—Temperature, 0°.

---

corresponding to the formula $LiHP \cdot 2H_2O$ is $H_2P = 39.91\%$, $Li_2P = 42.77\%$, $H_2O = 17.32\%$.

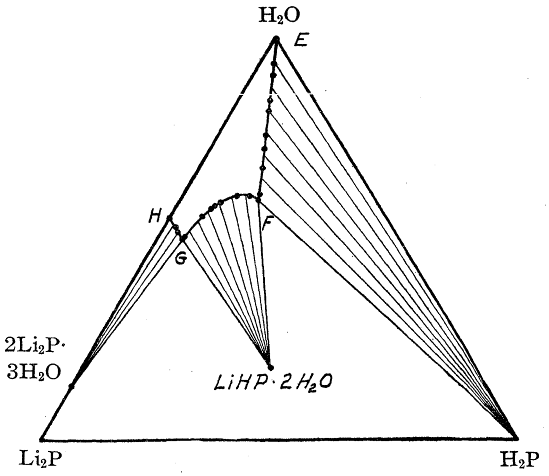

Fig. 2.—Temperature, 25°.

Discussion of Results

In order that a salt shall be crystallizable from aqueous solution at a given temperature, it is necessary that a straight line on the triangular diagram for that temperature, drawn from the apex, representing pure water, to that point on the diagram representing the composition of the salt in question, shall pass through the line representing the composition of all solutions in stable equilibrium with that salt as the solid phase.

Inspection of Fig. 3 shows that such a line would pass directly through the isothermally invariant point, "J." This means that at 50° lithium acid phthalate cannot be purified by crystallization from aqueous solution if the impurity is phthalic acid. Such procedure would result in the deposition of both salts. If the impurity were lithium phthalate, purification would result from recrystallization. At temperatures below 50°, Figs. 1 and 2, this reference line crosses the line representing the composition of all solutions in stable equilibrium with phthalic acid as the solid phase. Purification by recrystallization from aqueous solution at temperatures below 50° is obviously impossible.

It is apparent that the isothermally invariant point representing the composition of solutions in stable equilibrium with the two solid phases, phthalic acid and lithium acid phthalate, is working toward the right side of the diagram and approaches the above mentioned reference line as the temperature increases. In order to determine whether or not it has moved sufficiently so that our reference line crosses the line representing the composition of all solutions in stable equilibrium with lithium acid phthalate as the solid phase, a few experiments were carried out at 60°.

The composition of the solution in equilibrium with solid phthalic acid and solid lithium acid phthalate at this temperature was found to be $H_2P = 27.31\%$ and $Li_2P = 28.05\%$. This point has now moved across our reference line, showing the acid salt, $LiHP \cdot 2H_2O$, to be crystallizable from aqueous solution at 60°.

Lithium acid phthalate might therefore be purified by recrystallization from aqueous solution for use as a volumetric standard provided the crystallization were carried out at a temperature not less than 60°. Owing to the high cost of lithium salts as well as to the fact that recrystallization must be carried out at a high temperature resulting in large losses, it is doubtful that lithium acid phthalate will be added to our list of volumetric standards.

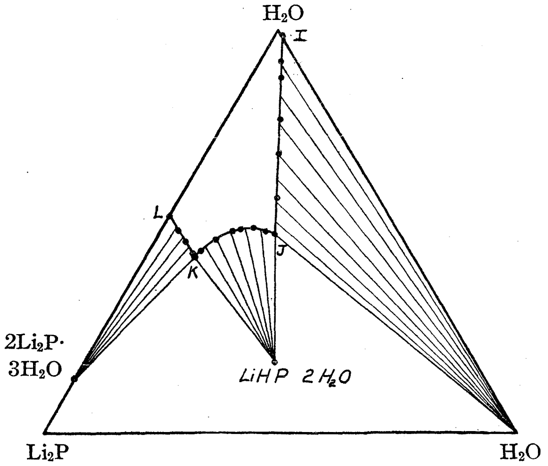

Fig. 3.—Temperature, 50°.

Summary

1. The solubility relations in the ternary system, lithium phthalate, phthalic acid and water at 0, 25 and 50° have been determined.

2. Compound formation has been found to take place at all of these temperatures.

3. The composition of this compound has been shown to be $LiHC_8H_4O_4 \cdot 2H_2O$.

4. It has been shown that this acid salt is crystallizable from aqueous solution at temperatures not lower than 60°.

Volumetric Determinations in Strongly Alkaline Solutions. III. The Titration of Thallium and Cerium with Hypobromite

BY O. TOMÍČEK AND M. JAŠEK

In the preceding communications of this series,[1,2] the results of titrations with ferricyanide were given. In the present paper new titrations with hypobromite are described. This reagent has already been used for the determination of ammonia, ammonium salts and urea,[3] for the determination of arsenites,[4] iodides,[5] thiocyanates,[6] and thiosulfates.[5,7]

Applying the potentiometric control, we have repeated the mentioned determinations[8] and also tried the possibility of the titration of yet other reduction–oxidation systems. Efforts to bring about a direct oxidation of plumbous, ferrous and chromic salts were without success. However, cerous salts could be titrated in a way analogous to that which has been described for the use of ferricyanide.[9] Such a titration with hypobromite proceeds very slowly and is not very satisfactory, while that of thallous salts (in the form of sulfate, carbonate, chloride or nitrate) is quick and complete. As thallous salts, especially the carbonate and sulfate, are easily prepared in a pure and well-defined state, they can be recommended as starting substances for the standardization of hypobromite solutions; thallous carbonate has already been employed as an acidimetric standard.[10]

A second reason for the advisability of thallous salts as starting substances for the direct standardization of solutions of alkali hypobromites is the fact that the accuracy of the determination is not so much dependent upon the basicity of the solution as in the case of arsenite solutions, which would otherwise be most suitable.

Materials and Apparatus

Solution of Sodium Hypobromite (in Some Cases the Potassium Salt).—About 0.05 *M* sodium hypobromite [potassium hypobromite] was prepared as follows. To an aqueous solution of *ca.* 0.5 *M* sodium [potassium] hydroxide of usual purity, which is cooled by freezing mixture of salt and ice to −4°, is added chemically pure bromine (8 g. per liter). The solution is well mixed and then left in the freezing mixture for two hours in the dark. After twelve more hours its titer was determined. The solution which has a yellow to greenish-yellow color was always stored in a bottle of dark hard glass in a cool place. Even hypobromite solutions, which were prepared with the utmost care, contain bromide and bromate ions (and sometimes perhaps also traces of bromite). For the direct titration in alkaline solutions only the hypobromite content is of significance. The standardization is made with arsenite or thallous salt as described below. The total oxidizing capacity of the solution (equal content of $BrO^- + BrO_3^-$) is determined, if desired, best by introducing the hypobromite solution in a solution of potassium iodide, which has been acidified with sulfuric acid; the titration then is carried out with thiosulfate. The solutions of hypobromite are not very stable; it is therefore advisable to check their titer before and after each series of experiments. For instance, the titer of a solution *ca.* 0.05 *M* sodium hypobromite and *ca.* 0.5 *M* sodium hydroxide was unchanged for a month; after three months it fell 16.7% and after six months 30.2%.

Solution of Arsenite (0.05 *M*).—It was prepared from chemically pure arsenic trioxide by the usual method.[11]

Thallous Salts and their Solutions.—For their preparation were used anhydrous, chemically pure thallous salts, which had been dried at 100° to constant weight, *viz.*, thallous sulfate (Tl_2SO_4) and thallous carbonate (Tl_2CO_3). To prepare a 0.025 *M* standard solution, 5.860 g. of thallous carbonate or 6.311 g. of thallous sulfate was weighed out exactly, then dissolved by warming and after cooling made up to 500 cc. Such a solution is very stable and does not change its titer even after many months. The other solutions were furthermore controlled by titrating with exactly standardized potassium ferricyanide.[1]

For the determination of cerium, a solution of cerous chloride, free from other earths, had been prepared; its titer was determined with 0.1 *M* ferricyanide solution.[9]

All other salts and reagents used were of average purity.

The apparatus and the calibrated vessels were the same as described in the previous communication.[1] In cases where oxidation by atmospheric oxygen did not interfere, the solution was stirred by an electrical stirrer without passing any carbon dioxide. The titration vessels were of hard glass throughout.

Titration of Thallium

The titrations were carried out as follows. To 25 cc. of the 0.025 *M* solution of thallous sulfate were first added

various quantities of sodium or potassium hydroxide. Then the solution was titrated sometimes in an atmosphere of carbon dioxide and sometimes open to the air with *ca.* 0.05 *M* sodium hypobromite solution, which had been standardized with arsenite simultaneously under the same conditions.

It was found unnecessary to work in an atmosphere of carbon dioxide. The liquid, which at the beginning remained clear even after the addition of sodium hydroxide, became turbid at once after the first drops of the hypobromite were added, forming a precipitate of thallium hydroxide. If the solution is stirred vigorously, this precipitate does not at all delay the quick attainment of a stable potential, and thus does not interfere with the exact course of the titration. A few results of many experiments are compiled in the following tables. It may be seen that the most suitable alkalinity is that when the reaction liquid at the end of titration is 1.5 to 2 *M* sodium hydroxide. Under these conditions, the inflection potential lies at +0.05 volt against the saturated calomel electrode. The drop in potential is considerable and well recognizable, and a stable potential is quickly attained also in the neighborhood of the equivalent point. With increasing concentration of hydroxide, this jump in potential is somewhat smaller. It is advisable to clean the indicating platinum electrode before each titration by washing with hydrochloric acid and burning in the flame. The course of a titration may be seen from Fig. 1.

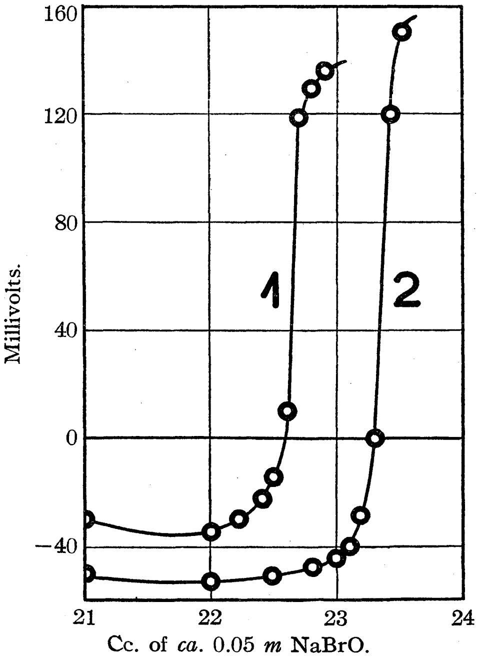

Fig. 1.—The titration curves of thallous salts by hypobromite: Curve 1, the titration of thallous carbonate in 3 *M* NaOH. Curve 2, the titration of thallous sulfate in 2.5 *M* NaOH.

The following experiments show that thallous nitrate also may be titrated in the same way: 0.2358 and 0.4510 g. of thallous carbonate were treated with a few drops of dilute nitric acid until the evolution of carbon dioxide ceased; the resulting solution was diluted with water and then treated as in the preceding experiments. It was found that the presence of nitrate ions did not interfere at all. The amount of *ca.* 0.05 *M* sodium hypobromite spent was as follows: 14.95 cc. (calcd. 15.00 cc.) and 28.75 cc. (calcd. 28.70 cc.).

TABLE I

TITRATION OF 25.00 CC. 0.025 *M* Tl_2CO_3 AND 0.025 *M* Tl_2SO_4

Beginning	End	0.05 *M* Na_3AsO_3	0.025 *M* Tl_2CO_3	
0.5	0.5	30.15	29.73	29.73
1.0	0.8	30.20	29.90	29.90
2.0	1.5	30.05	30.07	30.07
3.0	2.5	29.95	30.07	30.07
4.0	3.5	29.80	30.07	30.07
			0.025 *M* Tl_2SO_4	
0.5	0.5	23.15	22.95	22.95
1.0	0.8	23.25	22.95	22.93
2.0	1.5	23.05	22.95	22.95
3.0	2.5	22.95	22.95	22.95
4.0	3.5	22.75	22.95	23.00

TABLE II

TITRATION OF VARIOUS QUANTITIES OF 0.025 *M* Tl_2SO_4

0.025 *M* Tl_2SO_4, cc.	Basicity of titration, *M*		*Ca.* 0.05 *M* NaBrO, cc.		
	Beginning	End	Calcd.	Used	
5.00	2.0	1.9	3.73	3.75	3.73
10.00	2.0	1.8	7.45	7.43	7.45
20.00	2.0	1.65	14.90	14.85	14.90
50.00	2.0	1.5	37.25	37.20	37.30

Also the reverse titration of hypobromite with a solution of thallous salts is possible, but is of less importance due to the readiness with which it is oxidized by air. It is of no particular interest to study the interference of easily oxidizable cations as the main purpose of these investigations was to prove that thallous salts are very suitable for the standardization of hypobromite solutions.

For the standardization of *ca.* 0.025 *M* hypobromite solution a thallium salt is therefore quite suitable, in accordance with the equations

$$Tl_2CO_3 + 2NaBrO + 2NaOH + 2H_2O = 2Tl(OH)_3 + 2NaBr + Na_2CO_3$$

$$Tl^+ + BrO^- + OH^- + H_2O = Tl(OH)_3 + Br^-$$

Either 0.025 *M* solution of thallous sulfate or carbonate may be used in the standardization, or 0.25-g. portion of salt may be weighed out, dissolved in about 20 cc. of water, with warming if necessary. The cool solution is then diluted with concd. sodium or potassium hydroxide in such amount that the final solution (50–75 cc.) is 2–3 *M* in base. This solution is titrated with the unknown hypobromite to the maximum of inflection, according to the procedure already described.

Determination of Cerium

Preliminary experiments to titrate cerous salts with hypobromite in a solution which had been made alkaline with sodium or potassium hydroxide gave no satisfactory results. However, a cerous salt solution (either the chloride or sulfate) to which so much potassium carbonate had been added that it contained 20 to 30% of potassium carbonate at the end of the titration could be titrated with hypobromite, if the atmospheric oxygen was removed from the solution by passing carbon dioxide or nitrogen (free from oxygen) through it. The reaction liquid remains clear and becomes yellow in color after the addition of hypobromite. Yet the attainment of stable potentials is extremely slow and could not be accelerated by changes of temperature or any addition of catalyzers. It is, therefore, of advantage to obtain an idea as to the position of the maximum by a preliminary titration. For the proper titration almost the whole amount of necessary hypobromite is added at once and only the remaining few tenths cc. are used to accomplish the titration. On the whole the procedure is the same as has been described[9] for the much quicker and thereby much more satisfactory titration of cerous salts with ferricyanide. The inflection potential under the given conditions is 0.10 volt against the saturated calomel electrode.

Experiments.—20.00 cc. of *ca.* 0.1 *M* cerous chloride solution required for a titration 19.13 and 19.13 cc. of 0.1 *M* ferricyanide. The same quantity of cerous chloride required 19.20, 19.13, 19.04 and 19.09 cc. of the 0.05 *M* solution of hypobromite.

Summary

1. A new and simple titration of thallous salts with hypobromite has been described. It is very suitable for the standardization of hypobromite solutions by using thallous carbonate or sulfate as standard.

2. Also cerous salts can be titrated with hypobromite in 20 to 30% solution of potassium carbonate from which the atmospheric oxygen has been removed. However, the titration with ferricyanide is to be preferred.

Photochemical Investigations. II. The Photochemical Decomposition of Ethylene Iodide in Solutions of Carbon Tetrachloride[1]

BY ROBERT E. DERIGHT AND EDWIN O. WIIG

The thermal decomposition of ethylene iodide in solutions of carbon tetrachloride was found by Polissar[2] to consist of two parts, the ordinary and that catalyzed by iodine. Arnold and Kistiakowsky[3] found similar reactions to occur in the gas phase. The iodine photosensitized decomposition in solutions of carbon tetrachloride was found by Schumacher and Wiig[4] to be a chain reaction propagated by iodine atoms. It was thought that an investigation of the decomposition brought about by light absorbed by the ethylene iodide itself might give some insight into the mechanism of the decomposition and the manner in which the iodine is split off the ethylene iodide.

Experimental Details

Preparation and Purification of Materials.—The carbon tetrachloride was purified by the method used by Polissar.[2] Only the middle fraction from the last distillation was retained. The ethylene iodide was prepared from pure ethylene and iodine[5] and purified by recrystallization from dry ether. Attempts to prepare ethylene iodide by bubbling ethylene into concentrated solutions of iodine in carbon tetrachloride gave negligible yields. Uranyl sulfate and oxalic acid were purified in the manner described by Leighton and Forbes.[6]

The decomposition of ethylene iodide was followed by titrating the liberated iodine with *N*/200 solutions of sodium thiosulfate and of iodine. The relative strength of these solutions was checked frequently, the normality of the iodine being determined by titration against potassium permanganate solutions, the titer of which against sodium oxalate remained constant over long periods.

Apparatus and Procedure.—The reaction cell was cylindrically shaped with optically plane windows. The cell, made from fused quartz with fused seams, was 40 mm. in diameter and 35 mm. in length and was filled with 37 cc. of solution by means of a 12-mm. tube located near the rear window. In the experiments with the uranyl sulfate–oxalic acid solutions a stirrer was inserted through this tube. This cell was immersed in a thermostat, provided with a fused quartz window, in which the temperature of the water was regulated to ±0.03°.

The light source was a vertical Uviarc quartz mercury vapor lamp operated on 120 volt d. c. The lamp was rigidly mounted and the voltage carefully controlled so that the intensity was constant over long periods. A large crystalline quartz monochromator (f:1.9) with collimator and exit slits of 1.50 and 1.05 mm., respectively, was adjusted with the aid of a Beck fluorescent spectroscope to give the maximum intensity of light of the wave length desired. In all experiments, except those used to evaluate

the photosensitized reaction, light of λλ303 and 313 mμ was used. Photographs of this light overexposed thirty times showed only traces of longer wave lengths. The light intensity was measured by means of a linear thermopile of the Coblentz type. The thermopile was calibrated after each experiment against a standard lamp which had been compared with Radiation Standard C-67 calibrated by the Bureau of Standards. A resistance pattern of the type described by Leighton and Leighton[7] was used to decrease the deflections of the galvanometer. The solutions of ethylene iodide were prepared by adding weighed amounts to carbon tetrachloride contained in a volumetric flask. These solutions were prepared in artificial light to prevent decomposition and could be stored indefinitely in the dark. The cell was filled, allowed to come to the temperature of the thermostat, and then exposed to the light when the lamp had reached a steady state. At the end of an experiment the cell was cooled to room temperature and two 15-cc. samples pipetted into 100-cc. portions of distilled water. Enough sodium thiosulfate was added to give *ca.* 10 cc. excess. The flask was then shaken thoroughly and slowly back titrated with iodine solution.

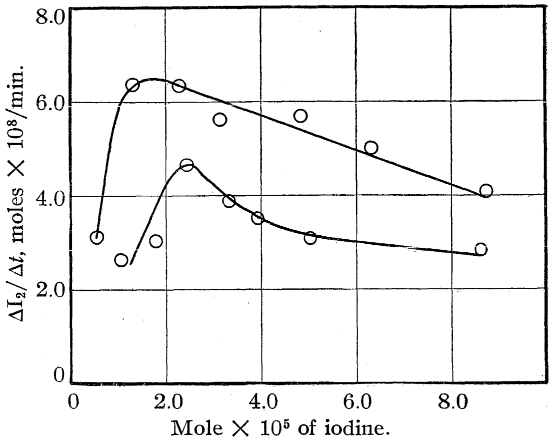

Fig. 1.—The rate of decomposition of ethylene iodide: upper curve, Table I; lower curve, Table II.

Results

Absorption Spectrum.—The absorption spectra of solutions of ethylene iodide in carbon tetrachloride were obtained by photographing the light from impregnated carbon arcs which had passed through the reaction cell filled with solutions containing 0.5, 1.0 and 2.0 g. (1.79, 3.57 and 7.14 × 10^{-3} mole) of ethylene iodide per 50 cc. of carbon tetrachloride. The photographs were made with a large Hilger spectrograph, employing a method described by O'Brien.[8] Absorption was found to begin at a wave length of 360 mμ. The 303 and 313 mμ Hg lines were strongly absorbed. The intensity of this light transmitted by various solutions of ethylene iodide and of iodine was measured with the thermopile. The iodine absorbed weakly in this region. These data were then used to obtain absorption coefficients which could be used to calculate the partition of the light at any time in an experiment.

Rate of Reaction.—A series of experiments was carried out for various lengths of time. The temperature of the thermostat in these experiments was 25°. The data are shown in Table I.

TABLE I

THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE FOR VARIOUS LENGTHS OF TIME

Molarity of ethylene iodide 0.0357

Time, min.	Total I_2 mole × 10^5	ΔI_2 mole × 10^5	$\frac{\Delta I_2 \times 10^3}{\Delta t}$	$\frac{\Sigma \Delta I_2 \times 10^3}{\Sigma \Delta t}$
180	0.57	0.57	3.15	3.15
300	1.33	.76	6.35	4.43
450	2.28	.95	6.33	5.07
600	3.12	.84	5.60	5.20
900	4.82	1.70	5.67	5.36
1200	6.32	1.50	5.00	5.27
1800	8.76	2.44	4.07	4.87

Two similar series of experiments were performed outside the thermostat. The light was first passed through 1 cm. of 0.0055 and 0.0147 molar solutions of iodine in carbon tetrachloride contained in a filter cell. These data are shown in Table II.

	720	1.66	0.49	2.72
	1380	3.91	2.25	3.41

The data from Tables I and II are shown graphically in Fig. 1.

It is apparent that in every case, despite changes in intensity and passage of the light beam through solutions of iodine, the rate increased to a maximum and then fell slowly. These facts preclude the possibility that the increase was due to absorption by the iodine of light of longer wave

(8) O'Brien, *Bull. Am. Phys. Soc.*, Feb. 10 (1932).

length. The increase was much larger than the experimental error.

Effect of Concentration.—The effect of varying the initial concentrations of ethylene iodide, iodine and ethylene in experiments performed outside the thermostat is shown in the following tables.

TABLE III

THE EFFECT OF THE INITIAL CONCENTRATION OF ETHYLENE IODIDE ON THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE

$C_2H_4I_2$ molar	Time, min.	Total I_2 moles $\times 10^5$	ΔI_2 moles $\times 10^5$	$\frac{\Delta I_2 \times 10^3}{\Delta t}$
	300	1.24	1.24	4.13
0.0357	600	2.89	1.65	5.50
	945	5.50	2.61	7.57
	300	1.28	1.28	4.27
0.0714	603	2.86	1.58	5.21
	936	5.47	2.61	7.84
	300	1.23	1.23	4.10
0.143	660	3.14	1.91	5.31
	960	6.03	2.89	9.63

TABLE IV

THE EFFECT OF THE INITIAL CONCENTRATION OF IODINE ON THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE

Molarity of ethylene iodide, 0.0357

Time, min.	Mole $\times 10^5$ iodine added initially	Total mole $\times 10^5$ dec.	Mole $\times 10^7$ dec. per min.
600	0	3.12	0.520
620	0.87	3.09	.498
600	2.72	2.75	.458
603	3.26	2.62	.436
600	4.17	2.56	.427
607	7.52	2.46	.405
600	10.78	2.40	.400

TABLE V

THE EFFECT OF ETHYLENE ON THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE

Molarity of ethylene iodide, 0.0357

Ethylene added	Time, min.	Total mole $\times 10^5$ dec.	Mole $\times 10^7$ dec. per min.
Yes	615	2.94	0.478
Yes	660	3.30	.500
No	600	2.89	.482

These data show that increasing the concentration of the ethylene iodide appears to increase the rate of decomposition slightly. Small initial concentrations of ethylene had no measurable effect on the rate while increasing amounts of iodine caused successively larger decreases in the rate of decomposition.

Effect of Intensity.—The light absorbed was varied thirty fold. These results are shown in Table VI. The rate of decomposition was approximately proportional to the energy absorbed throughout the range investigated.

TABLE VI

THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE FOR VARIOUS LIGHT INTENSITIES ABSORBED

Molarity of ethylene iodide, 0.0357

Reaction ratio	1.71	1.74	2.01	1.91	1.93
Intensity	1.83	1.83	1.91	1.91	1.91
Moles decompd.	1.03	1.87	1.35	2.23	2.36
Reaction ratio	2.32	2.50	2.10	28.7	28.5
Intensity ratio	2.38	2.38	2.38	28.4	28.4
Moles decompd.	1.17	1.66	3.91	0.44	0.43

Effect of Temperature.—Measurements of the rates of decomposition at 20 and 30° showed only very slight effects of temperature so that some of the preceding experiments, as already indicated, were not carried out in the thermostat. Raising the temperature to 50°, however, resulted in a measurable increase in the rate as shown in the following table.

TABLE VII

THE EFFECT OF TEMPERATURE ON THE RATE OF DECOMPOSITION OF ETHYLENE IODIDE

Molarity of ethylene iodide, 0.0357

Temp., °C.	Time, min.	Total mole $\times 10^5$ dec.	Mole $\times 10^7$ dec. per min.
25	720	3.64	0.506
50	615	3.75	.610
50	618	3.71	.601

Using these data and additional data at 25° from Table I, the ratios of the times necessary for equal amounts of decomposition were determined. The decomposition which occurred in 615 minutes at 50° required 694 minutes at 25° or a ratio of 1.13. The corresponding temperature coefficient for 10° is 1.05. It is to be noted that the thermal reaction which is responsible for this temperature coefficient accounts for only a part of the total reaction.

Evaluation of the Photosensitized Reaction.—Since Schumacher and Wiig[4] found the iodine photosensitized decomposition of ethylene iodide to be a chain reaction and since iodine, a product of the photodecomposition, absorbs slightly light of the wave lengths used here, experiments were carried out to determine whether the acceleration observed could be accounted for by a sensitized reaction. The yield at λλ436 and 465 mμ, where ethylene iodide does not absorb and iodine absorbs strongly, was determined under our experimental conditions. Assuming the same quantum efficiency at the shorter wave lengths and calculating the partition of light of these wave lengths between iodine and ethylene iodide, the maximum possible effect of the photosensitized reaction was found to be less than 2–3% of the observed increase in rate at any time.

Determination of the Quantum Yield.—The quantum measurements were made outside the thermostat but the variation of room temperature was less than ±1°. The lamp voltage was carefully controlled and the intensity measured frequently as described previously. The experiments with the uranyl sulfate–oxalic acid actinometer were carried out under identical conditions. Assuming a quantum yield[6] of 0.561 at λ313 mμ the following transmission factors for the rear window of the cell and optical system were obtained: 1.480, 1.481, 1.490 and 1.511, or an average of 1.490. The results of the quantum measurements are given in Table VIII.

TABLE VIII

THE DETERMINATION OF THE QUANTUM YIELD FOR THE DECOMPOSITION OF ETHYLENE IODIDE

Molarity of ethylene iodide, 0.0357

Time, min.	Mole × 10^5 dec.	Molecules × 10^{19} dec.	Quanta × 10^{19} absorbed	Quantum yield
600	1.29	0.78	1.10	0.71
600	1.35	.82	1.11	.74
900	2.00	1.21	1.62	.75
900	2.23	1.35	1.67	.81
960	2.36	1.43	1.77	.81

Discussion

The mechanism of the photochemical decomposition of ethylene iodide is probably given by the equations

$$C_2H_4I_2 + h\nu \longrightarrow C_2H_4I + I \qquad (1)$$
$$C_2H_4I_2 + I \rightleftharpoons C_2H_4I + I_2 \qquad (2) \text{ and } (3)$$
$$C_2H_4I \rightleftharpoons C_2H_4 + I \qquad (4) \text{ and } (5)$$
$$I + I \longrightarrow I_2 \qquad (6)$$

Light of the wave lengths used supplies more than enough energy to break the carbon–iodine bond so that reaction (1) is possible. The remaining equations have been suggested previously in connection with the formation,[9] thermal decomposition[3,9] and the photosensitized decomposition[4] of ethylene iodide. Some calculations by Narayanmurti[10] based on the mechanism for the last-mentioned reaction indicate that the theoretical and observed rates are in excellent agreement. Reactions analogous to (2) through (5) have been suggested in connection with the photosensitized decomposition of dibromotetrachloroethane.[11] With reasonable simplifying assumptions these reactions lead to the rate equation

$$-d(C_2H_4I_2)/dt = I_{\text{abs.}}/[1 + (k_3/k_4)\,(I_2)]$$

This is in agreement with the experimental results except that it does not account for the increase in the decomposition rate observed when only small amounts of iodine have been formed. The initial increase in rate might be due either to a decrease in the concentration of an inhibitor or to some unknown reaction involving perhaps C_2H_4I or I_3. The carbon tetrachloride was carefully purified but air was not removed or excluded from the reaction mixture. That oxygen may have an inhibiting effect has been found in somewhat similar reactions.[12] The amount of iodine formed at the maximum (Fig. 1) is less than the solubility of oxygen in carbon tetrachloride, so that inhibition by oxygen is a possibility. Unfortunately no experiments were performed to test this.

In the early stages of an experiment reaction (3) would be of no importance because of the low iodine molecule concentration. As the concentration of iodine builds up, however, reaction (3) will predominate over (2), since their energies of activation are 1.8 and 11.8 cal., respectively.[13] This explains the retarding effect of iodine.

The quantum yield experiments give an average value of 0.76 but the measurements include the period in which the reaction rate is rising. If the yield is calculated for the period of six-hundred to nine-hundred minutes in Table VIII, a value of 0.86 is obtained. The light intensities employed in the experiments in Table I may be estimated quite readily. The quantum yields corresponding to those energies are 0.54 at the beginning, 1.10 at the maximum and 0.70 at the end of the measurements. The value to be assigned to the quantum efficiency of the primary process depends upon the interpretation of the initial increase in reaction rate.

The value of the quantum yield for the primary photo-process is of interest in connection with theories of photochemical reactions in solution. In a recent paper, Franck and Rabinowitsch[14] discuss the photochemistry of reactions in solution. They compare reactions in solution with the bet-

ter known gas reactions and point out three effects which are of importance in the former. (1) There is a certain time lag between the absorption of light and the decomposition of the molecule. The large number of collisions with solvent molecules makes deactivation possible during this interval. (2) Similarly, since all collisions of reaction products would be triple collisions, secondary recombination would be enhanced. (3) If the decomposition yields atoms or radicals these would lose their excess kinetic energy by collision before going much more than the length of a molecular diameter and if they were still close together they would undergo primary recombination. All of these effects would decrease the quantum yield but the third would be of greatest importance. Hence, they conclude that for all reactions involving atoms or radicals the primary quantum yield should be definitely less than one. Furthermore, light of shorter wave length should cause the decomposition products to leave with greater kinetic energy; they should travel further before losing their kinetic energy and primary recombination would be decreased. Thus light of shorter wave length should produce a greater quantum yield. The photodecomposition of ethylene iodide would seem to proceed by atoms and radicals. If the low yield at the beginning of an experiment is not due to inhibition, then the present results would tend to substantiate the theory of Franck and Rabinowitsch.

Without citing any evidence, Emschwiller[15] states that when solutions of ethylene iodide are exposed to polychromatic ultraviolet light the primary decomposition products are ethylene and iodine. Such a simple mechanism cannot account for the retardation of the reaction rate observed in our experiments, since union of ethylene and iodine proceeds too slowly at room temperatures. The mechanism suggested here follows from related studies on the decomposition of ethylene iodide. With polychromatic light the ethylene iodide photodecomposition is quite likely complicated by the iodine photosensitized decomposition, which would increase the difficulty of interpreting the results.

The study of the photodecomposition of the halogen addition products of ethylene is being continued in this Laboratory. It is also planned to extend the investigations to the gaseous reactions.

Summary

The apparent quantum yield for the photodecomposition of ethylene iodide in carbon tetrachloride solutions by light of wave lengths 303 and 313 mμ was found to be 0.76. This includes both the photo- and any subsequent thermal reactions. A mechanism involving a primary dissociation into C_2H_4I and atomic iodine has been suggested. The rate equation based on this mechanism is in agreement with the data obtained. A further study of this reaction should be of interest in connection with the Franck and Rabinowitsch theory of photochemical reactions in solution.

Reaction of Paraffins with Aromatic Hydrocarbons (Destructive Alkylation)[1]

BY ARISTID V. GROSSE AND V. N. IPATIEFF

We have recently described the catalytic reaction of saturated hydrocarbons with olefins.[2] We have also found that paraffins can react with aromatic hydrocarbons in the presence of catalysts under mild conditions. The reaction consists in the splitting of the paraffin into a lower molecular weight paraffin and an olefin "in statu nascendi," which immediately alkylates the aromatic hydrocarbon. The general reaction proceeds according to the equation

$$\underset{\text{Paraffin}}{C_{(m+n)}H_{2(m+n)+2}} + \underset{\text{Aromatic hydrocarbon}}{C_xH_{2x-6}} \xrightarrow{\text{Catalyst}} \underset{\text{Lower molecular paraffin}}{C_nH_{2n+2}} + \underset{\text{Alkyl-aromatic hydrocarbon}}{C_xH_{2x-5}\cdot C_mH_{2m+}}$$

---

[1] Presented before the Organic Division of the 90th meeting of the American Chemical Society at San Francisco on August 21, 1935.

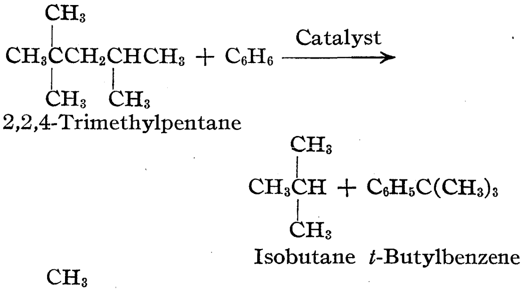
[2] V. N. Ipatieff and A. V. Grosse, THIS JOURNAL, **57**, 1616 (1935).

This reaction may be appropriately termed destructive alkylation.

The reaction was first discovered in the case of an octane (2,2,4-trimethylpentane) and benzene, and will be described in detail here. The same reaction takes place with *other aromatic* hydrocarbons, for instance, with toluene and the xylenes, and with *other paraffins*, for instance, *n*-heptane, hexanes and pentanes.

The reaction between 2,2,4-trimethylpentane and benzene was studied in the presence of aluminum chloride, zirconium chloride, boron fluoride and magnesium chloride. In the last two cases there is no reaction, and both hydrocarbons remain unchanged.

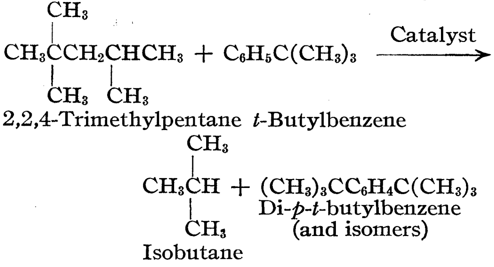
In the presence of aluminum chloride and zirconium chloride, the following reactions take place



$$CH_3C(CH_3)_2CH_2CH(CH_3)CH_3 + C_6H_6 \xrightarrow{\text{Catalyst}} CH_3CH(CH_3)CH_3 + C_6H_5C(CH_3)_3 \quad (1)$$

2,2,4-Trimethylpentane

Isobutane *t*-Butylbenzene



$$CH_3C(CH_3)_2CH_2CH(CH_3)CH_3 + C_6H_5C(CH_3)_3 \xrightarrow{\text{Catalyst}} CH_3CH(CH_3)CH_3 + (CH_3)_3CC_6H_4C(CH_3)_3 \quad (2)$$

2,2,4-Trimethylpentane *t*-Butylbenzene

Isobutane Di-*p*-*t*-butylbenzene (and isomers)

The octane can be *practically completely* converted into isobutane and the *t*-butylbenzenes. With aluminum chloride, the reaction takes place at 25–50° and ordinary pressure during about four hours; with zirconium chloride, at a temperature of 50–75° during about four hours. These chlorides act as real catalysts, since one molecule of each of them can convert at least twenty molecules of the octane. Hydrogen chloride is added in each case to promote the action of the chlorides. The aluminum chloride and also zirconium chloride partly combine with the aromatic hydrocarbons forming the well-known pasty or liquid brown-red addition compounds of Gustavson.[3]

Experimental Part

(1) Reaction of 2,2,4-Trimethylpentane with Benzene in the Presence of Aluminum Chloride

The reaction was carried out at atmospheric pressure in a three-necked glass flask fitted with (a) a stirrer, (b) a separatory funnel, (c) a reflux condenser with an outlet tube and (d) a gas inlet tube for nitrogen and dry hydrogen chloride from a cylinder.

The gas from the outlet tube of the condenser passed through two dry ice receivers, Nos. 1 and 2, at −78°, a mercury manometer, a safety bottle and a graduated gas holder. A known quantity of the aluminum chloride was placed in the flask. Before starting the reaction, the whole apparatus was flushed out with oxygen-free nitrogen and then the benzene and octane were poured in through the separatory funnel.

From the start of the experiment, dry hydrogen chloride gas was bubbled through the liquid reagents until saturation, a few bubbles being added from time to time during the course of the reaction. The reaction proceeded at room temperature (20°) with evolution of condensable gas and the formation of a dark brown lower layer which quite rapidly increased in quantity. After about one hour the temperature of the reaction vessel was slowly increased to 50° by placing it in a water-bath. After a total reaction time of four and one-half hours, the reaction was stopped.

The Products of the Reaction and their Identification.—The reaction products consisted of (a) gases (condensable and uncondensable at −78°), (b) a clear, water-white upper layer and (c) a dark brown lower layer.

In one typical experiment, the amounts of reagents used and the products obtained after the completion of the reaction, were as follows:

BEFORE REACTION		Grams
Aluminum chloride (9.4 g. or 0.0705 mole reacted, 8.8 g. recovered unchanged)		18.2
Hydrogen chloride		≃ 0.3
2,2,4-Trimethylpentane (very pure, n^{20}_D 1.3922), 1.40 moles		160.1
Benzene (very pure), 1.63 moles		127.3
Total		305.9
AFTER REACTION		
Uncondensable gas (at −78°) = 800 cc.

[a] The paraffins remained after the aromatics were absorbed by shaking (in a volume ratio of 1:1) first with 100% sulfuric acid, second with 7% or 15% free SO_3–H_2SO_4, until the residual hydrocarbon gave no reaction with nitrating mixture.

isobutane was very pure; it had a constant boiling point of −10.2° at 760 mm. pressure and the theoretical molecular weight when determined by Stock's gas balance.

The uncondensable gas (800 cc.) was nitrogen, displaced by isobutane from the reaction flask.

(b) **Upper Layer.**—After washing with water and drying, the upper layer was subjected to a high temperature Podbielniak distillation. The distillation curve is shown on Diagram 1; the properties of the fractions are given in Table I. All fractions were water-white and stable to potassium permanganate solution and therefore free from olefins; all reacted with nitrating mixture and therefore contained aromatic hydrocarbons. The principal products of the reaction are present in fractions 4 and 6, since fractions 1, 2 and 3 contain pure unreacted benzene and isooctane.

From the data of Table I it can be seen that fraction 4 consists of a very pure aromatic hydrocarbon (or mixture of closely boiling isomers), and fraction 6 is also practically free from paraffins.

TABLE II

	Bromide from fraction 4	Bromo-*t*-butylbenzene[4]
Boiling point at 740 mm., °C.	230–231	230
Melting point, °C.	+19	+14
Bromine, %	36.8 (Parr bomb)	37.5

Density, d^{15}_4	1.2519	1.2572
Appearance	White needles	White needles

Investigation of Fraction 4.—The composition of this fraction corresponds to an alkyl-benzene of the formula $C_{10}H_{14}$. *Anal.* Calcd.: C, 89.48; H, 10.52. Found: C, 89.39, 89.49; H, 10.60, 10.59.

By bromination in the presence of iron powder, it was practically quantitatively converted into a monobromine derivative which proved to be identical with bromo-*t*-butylbenzene described by Schramm[4] as seen from the data of Table II.

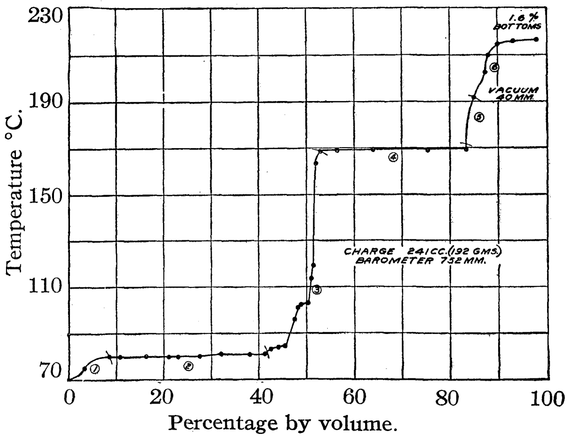

Fig. 1.—High temperature Podbielniak distillation.

For further identification this hydrocarbon was sulfonated and the sulfonic acid, obtained quantitatively, converted into a phenol. The barium salt of the acid (proved later to be *p*-*t*-butylbenzene sulfonic acid) was fractionally crystallized; all fractions were identical proving the homogeneity of our hydrocarbon.

The potassium salt (obtained through double decomposition with potassium sulfate) was melted with potassium hydroxide at 280–350° in a copper dish. The phenol, ob-

---

(4) Schramm, *Monatsh.*, 9, 846 (1888).

tained in nearly quantitative yields, proved to be identical with *p*-*t*-butylphenol by comparing the data of Table III.

TABLE III

	Phenol from fraction 4	*p*-*t*-Butylbenzene[5]
Melting point, °C.	98.5 (sharp)	98.5

% C	89.49	89.48
% H	10.59	10.52
Monobromide from	Identical (see Table II)	
Phenol from	Identical (see Table III)	

Investigation of Fraction 6.—On cooling well-developed spears or needles appeared, which when recrystallized from methanol melted at 76°, and on mixing with pure di-*p*-*t*-butylbenzene (1:1) showed no depression and can be therefore identified with it. Its quantity corresponded to ≃40% of the fraction, the remainder being composed in all probability of the *o*- and *m*-isomers.

(c) **Investigation of the Lower Layer.**—This layer represents a deep red liquid which is much more mobile than the lower layer in ethylene polymerization.[6] It contained, besides unreacted aluminum chloride, addition compounds of aluminum chloride with hydrocarbons and hydrogen chloride. Water easily decomposed these compounds into a water-white hydrocarbon layer and an acid solution of aluminum chloride.

The hydrocarbons were fractionated; fractions below 200° (about 60% of the layer) contained only benzene and mono-*t*-butylbenzene. Fractions from 200–300° (E. P.) decolorized permanganate solution rapidly and contained unsaturated hydrocarbons, which in all probability retarded the continued activity of aluminum chloride.

(2) Reaction of 2,2,4-Trimethylpentane with Benzene in the Presence of Zirconium Chloride

This reaction was carried out in a rotating autoclave (volume, 750 cc.), the chemicals being placed in a glass liner, at a temperature of 50° for one and one-half hours and at 75° for two hours, the maximum pressure increasing to 7 kg./sq. cm. The balance of reagents used and the products obtained are given below.

BALANCE OF PRODUCTS

Bomb evacuated to 4 mm. before HCl addition; reaction products collected in same apparatus as with $AlCl_3$.

BEFORE REACTION

		Grams
Benzene (c. p., Na dry)		63.01
2,2,4-Trimethylpentane (purest, n^{20}_D 1.3922)		78.52
$ZrCl_4$		16.73
HCl		≃ 8.00
Total		166.0

AFTER REACTION

Uncondensable gas = 0.0 cc.		0.00
HCl (in NaOH scrubbers)		4.00
Condensable gas at −78°		41.63
Upper layer		82.50
Lower layer	hydrocarbon part and HCl	21.28
	$ZrCl_4$	16.73
Total		166.0

The liquefied gas contained 40.4 g. of isobutane and 1.2 g. of benzene. The isobutane was absolutely pure.

The water-white upper layer was fractionated with a high temperature Podbielniak column, the results obtained being given in Table IV.

There was obtained, just as in the case of aluminum chloride, mono-*t*-butylbenzene and di-*t*-butylbenzenes (only the para compound was isolated in the pure state), and some unreacted benzene and octane.

TABLE IV

Charge = 89 cc. = 72.5 g.

hydrochloric acid decomposes it rapidly, giving liquid hydrocarbons and a zirconium oxychloride solution. These hydrocarbons consisted of benzene, *t*-butylbenzene and some partly unsaturated, in all probability polynuclear, hydrocarbons.

(3) Reaction of 2,2,4-Trimethylpentane with Benzene in the Presence of (a) Magnesium Chloride ($MgCl_2$) and (b) Boron Fluoride (BF_3)

There was no reaction in the presence of magnesium chloride and hydrogen chloride at 200° and a pressure of 20 atmospheres during twenty hours. Boron fluoride, promoted by nickel and water, effected no reaction at 55° during four hours in a nickel-lined autoclave.

Summary

A new reaction between paraffins and aromatic hydrocarbons in the presence of catalysts has been described. It consists in the formation of a lower molecular weight paraffin and an alkylated aromatic hydrocarbon, for instance, 2,2,4-trimethylpentane reacts with benzene, giving isobutane and mono- and di-*t*-butylbenzenes.

The Constitution of Osazones[1]

BY LEWIS L. ENGEL[2]

The first suggestion that the Fischer formula for the osazones[3] does not give an adequate explanation of their behavior was made by Zerner and Waltuch,[4] who observed a small but unmistakable mutarotation of the phenylosazones of *l*-arabinose and *l*-xylose in alcoholic pyridine solution. Later, Levene and LaForge[5] confirmed these findings and extended them to the phenylosazones of *d*-glucose, *d*-altrose, *d*-galactose and *d*-gulose. The first observation of the mutarotation of an osazone formed from a secondary hydrazine was made by Votoček and Valentin,[6] who reported that the methylphenylosazone of fructose shows a large mutarotation in methyl alcoholic solution. As an explanation for mutarotation, Zerner and Waltuch suggested that the classical osazone structure (I) was present in equilibrium with the isomeric azo-form (II). The finding of Votoček and Valentin, however, seems to exclude this explanation, since fructose methylphenylosazone possesses no hydrogen capable of migrating in this manner. The present author has been unable to confirm this result of Votoček and Valentin, but has found other evidence which conflicts with the hypothesis of Zerner and Waltuch.

(III)

Haworth[7] has suggested that if one of the phenylhydrazine groups in an osazone be assumed to exist as a phenylhydrazino group attached to a cyclic sugar (III), mutarotation could be explained as being due to a shift from the α-form to the β-form. It is also possible that the mutarotation of osazones may be due to partial hydrolysis in solution. In order to test these views it is necessary to ascertain, first, whether the osazones are cyclic compounds; second, whether the nature of the attachment of the sugar to phenylhydrazine is such that hydrolysis will take place under the conditions of the mutarotation experiments; and third, whether the mutarotation is affected by factors which should affect the equilibrium.

It was hoped that the question of the ring could be settled by a study of the methylation products of glucose phenylosazone, but unexpected difficulties were encountered. Methylation by a number of methods was attempted but in no case was it possible to obtain homogeneous crystalline products. Methylation in dioxane with dimethyl sulfate and alkali yielded sirupy products with methoxyl contents ranging from 16.3

to 22.6% and crystalline mixtures having methoxyl contents ranging from 14.1 to 20.7%. Basic products, comprising N-methylated osazones and methylphenylhydrazine, were always formed. Methylation of partially methylated material with methyl iodide and silver oxide or carbonate led to slight increase in methoxyl content, but considerable decomposition occurred. Neither methylation of partially acetylated glucose phenylosazone with dimethyl sulfate and alkali, nor treatment of a partially methylated sirup with sodium–potassium alloy followed by treatment with dimethyl sulfate, led to satisfactory results. Methylation of fructose methylphenylosazone by the liquid ammonia technique of Muskat[8] led to cleavage of the N–N linkages instead of methylation of the hydroxyl groups. The only crystalline product isolated was trimethylphenylammonium iodide. The question of ring structure could thus not be solved by methylation experiments. However, light has recently been thrown on it by the observation of Bergmann and Grafe[9] that the compound IV displays a large and rapid mutarotation in pyridine, the rotation changing from +226 to +311° in three hours. The possibility that this change may be due to deacetylation is excluded by the fact that the deacetylated compound has a lower initial rotation and mutarotates downward.

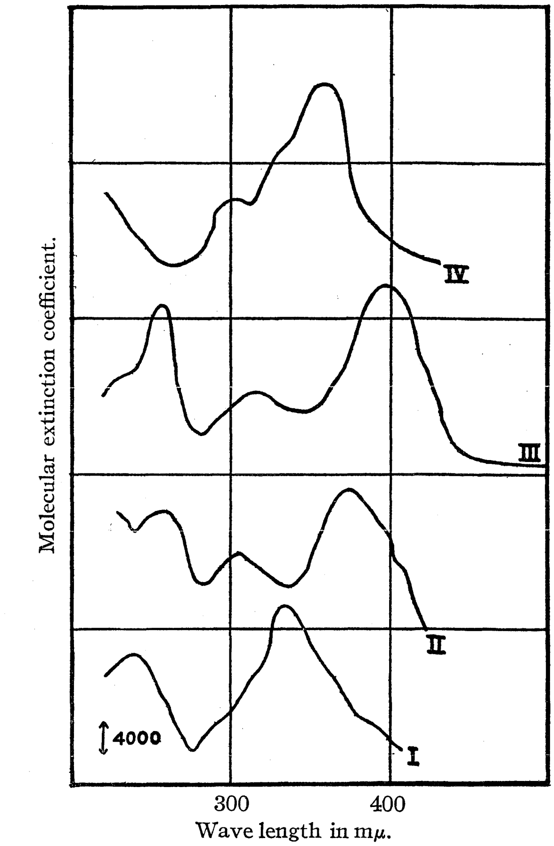

Fig. 1.—Absorption spectra of osazones. Curve I. Fructose methylphenylosazone. Curve II. Glucose phenylmethylphenylosazone. Curve III. 3, 4, 6-Trimethylglucose phenylosazone. Curve IV. Dimethylglyoxal phenylosazone. Each curve is displaced vertically by 20,000 units to avoid confusion of lines.

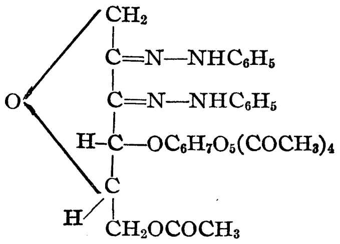

(IV)

Attention was turned to the study of the absorption spectra of osazones and their derivatives. The earliest measurements on this class of compounds were made by Baly, Tuck, Marsden and Gazdar.[10] The results (Table I, Fig. 1) obtained by the present author, which are in fairly good agreement with some of the findings of these investigators, indicate that the absorption spectra of the osazones studied can be divided very sharply into two classes: one class consisting of the sugar osazones and their derivatives, and the other, the osazones of simple α-keto-aldehydes and α-diketones. The compounds of the second class studied in the present investigation were the phenylosa-

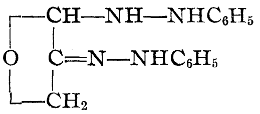
zones of methylglyoxal and dimethylglyoxal (diacetyl), which have almost identical absorption spectra. Sugar osazones show among themselves an equally marked resemblance in absorption characteristics. In the case of tetrabenzoylglucose phenylosazone the four benzoyl groups are undoubtedly responsible for the intense absorption in the region of shorter wave length.

The substantial coincidence of the absorption spectra of all the sugar osazones, including glycerose phenylosazone, indicates their structural similarity. In the cyclic formula of Haworth the conjugated system $—N=\overset{|}{C}—\overset{|}{C}=N—$, presumably strongly chromophoric, is replaced by the grouping $—\overset{|}{N}—\overset{|}{C}—\overset{|}{C}=\overset{|}{N}$, which would be expected to absorb far less strongly. Application of the Haworth formula to glycerosazone would lead to the inherently improbable structure



This four-membered ring cannot exist in 3,4,6-trimethylglucose phenylosazone, the absorption characteristics of which coincide with those of the phenylosazones of glucose and glycerose.

The grouping responsible for the specific absorption of the sugar osazones may therefore be represented by V, in which R may be hydrogen,

(V) 
$$\begin{array}{l} CH=N—NHC_6H_5 \\ | \\ C=N—NHC_6H_5 \\ | \\ CH—O—R \\ | \end{array}$$

alkyl or acyl. The difference between the absorption spectra of sugar osazones on the one hand, and the osazones of simple α-diketones on the other, is ascribable to the presence on carbon atom 3 of the oxygen atom which functions as an auxochrome.

It is interesting to note the coincidence of the absorption spectrum of one of the crystalline methylation products of glucose phenylosazone (m.p. 130° (corr.), OCH_3, 20.4%) with that of the mixed osazone, glucose phenylmethylphenylosazone (Fig. 1). The absorption characteristics of these compounds differ quite markedly from those of fructose methylphenylosazone (Fig. 1). Acetylation of the latter compound leads to a tetraacetate, the absorption spectrum of which is closely similar to that of the parent compound.

Evidence that the attachment of the hydrazine group in osazones is of such a nature that it may be split off under the conditions which obtain during mutarotation has been accumulating for some time. In an extended study, Votoček and Vondracek[11] found that the phenylhydrazine group in the sugar phenylhydrazones and osazones readily could be replaced by another hydrazine group. In the case of the osazones, they found that either one or both of the hydrazine groups could be replaced by the entering hydrazine. In the case of the condensation products of glucose with phenylhydrazine and methylphenylhydrazine, they prepared both isomeric mixed osazones in pure form. They carried out the reactions at water-bath temperature; the present author has found that certain of them can be conducted at room temperature. If fructose methylphenylosazone is allowed to stand in methyl alcoholic solution for two weeks with two moles of *p*-nitrophenylhydrazine, the mixed osazone, glucose *p*-nitrophenyl-methylphenylosazone crystallizes out. Similarly, fructose methylphenylosazone in contact with phenylhydrazine yields glucose phenylmethylphenylosazone.

This type of reaction is characteristic of the condensation products of carbonyl compounds with nitrogenous bases in general. Phenylhydrazones can be reversibly converted to oximes,[12,13,14] semicarbazones[15] and azines.[16]

The carbohydrate residue in an osazone or hydrazone may similarly be replaced by another carbonyl compound, as in the most commonly employed method of preparing a free sugar from a hydrazone, or an osone from an osazone.

All of these reactions suggest that hydrolysis may occur in solution even when the compound is not subjected to the influence of a competing hydrazine or carbonyl compound.

If mutarotation is partly or wholly ascribable to the establishment of an equilibrium between the osazone and its hydrolysis products, it should be possible to influence its course by the addition of one of the components of the system. Experimentally, it is easiest to measure the effect of phenylhydrazine since it is optically inactive and readily obtainable in the pure state. The rota-

tion of 3,4,6-trimethylglucose phenylosazone in alcoholic pyridine was found to change from −48.8 to +61.5° in one hundred and eight hours. In the presence of phenylhydrazine (16.3 moles of phenylhydrazine per mole of osazone) the rotation changed from −50.6 to +30.0° in one hundred and fifty-five hours (Fig. 2). The addition of phenylhydrazine, therefore, has the effect which it would be expected to have if it were one of the components of a system approaching equilibrium.

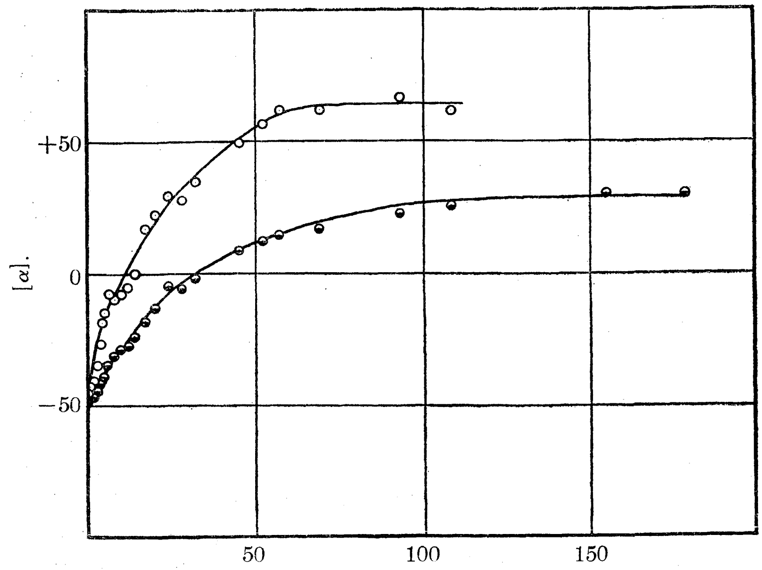

Fig. 2.—Mutarotation of 3,4,6-trimethylglucose phenylosazone. ○—3,4,6-Trimethylglucose phenylosazone in 1 : 1 95% alcohol-pyridine. ◐—3,4,6-Trimethylglucose phenylosazone and phenylhydrazine in 1 : 1 95% alcohol-pyridine (16.3 moles of phenylhydrazine per mole of osazone).

Experimental

Methylation of Glucose Phenylosazone.—Of many experiments, only one will be described in detail. To a suspension of 50 g. of the osazone in 250 cc. of dioxane were added, in twenty portions of each, 500 cc. of methyl sulfate and 1500 cc. of 30% sodium hydroxide at 50–55°. Stirring was continuous throughout the addition, which occupied five hours. The temperature was then raised to 65° for half an hour. The dioxane layer, in which all of the methylated osazone had dissolved, was evaporated to dryness under reduced pressure; the residue dissolved in 50% alcohol was held at 0° for a week. The solid which separated was fractionally crystallized from mixtures of ethyl acetate and petroleum ether and from aqueous alcohol of various concentrations. Four crystalline but apparently inhomogeneous, fractions were obtained:

(1) M. p. 102–105° (corr.); CH_3O, 14.24%
(2) M. p. 110° (corr.); CH_8O, 15.3%
(3) M. p. 106–108° (corr.); CH_3O, 18.66%
(4) M. p. 110–116° (corr.); CH_3O, 20.67%

In another similar experiment, the crude product was dissolved in ether and shaken repeatedly with 0.1 *N* hydrochloric acid. The neutral fraction, which formed the principal product, contained 16.3% of methoxyl. The basic fraction was separated into two fractions by shaking an ethereal solution with 5% acetic acid. That extracted by acetic acid consisted mainly of methylphenylhydrazine; the *p*-nitrobenzal derivative had a m. p. 135.5° (corr.), unaltered on admixture of an authentic sample. The fraction soluble in hydrochloric acid but insoluble in acetic acid was a yellow sirup which possessed an absorption spectrum identical with that of fructose methylphenylosazone. An authentic sample of the latter was also found to be soluble in 0.1 *N* hydrochloric acid.

Replacement of Methylphenylhydrazine by Phenylhydrazine in Fructose Methylphenylosazone.—Two-tenth gram (0.52 millimole) of fructose methylphenylosazone and 0.2 cc. (1.95 millimoles) of phenylhydrazine were dissolved in methyl alcohol and the solution made up to 25 cc. After standing at room temperature for a week, pale yellow needles separated out. After recrystallization from 50% alcohol they melted at 192–193° (corr.). Glucose methylphenyl-phenylosazone is reported to melt at 192°.[11]

Anal. Calcd. for $C_{19}H_{24}N_4O_4$: C, 61.3; H, 6.45. Found: C, 60.82; H, 6.50.

Replacement of Methylphenylhydrazine by *p*-Nitrophenylhydrazine in Fructose Methylphenylosazone.—A mixture of 0.5 g. (1.3 millimoles) of fructose methylphenylosazone and 0.4 g. (2.6 millimoles) of *p*-nitrophenylhydrazine was dissolved in methyl alcohol and diluted to 25 cc. After standing for two weeks, the orange needles were filtered off, washed with methyl alcohol and recrystallized from dilute ethyl alcohol. The product was glucose methylphenyl-*p*-nitrophenylosazone, m. p. 223.5–224.5° (corr.).

Anal. Calcd. for $C_{19}H_{25}N_5O_6$: N, 16.79. Found: N, 16.86.

Monoacetone Galactose Phenylosazone.—To a suspension of 5 g. of galactose phenylosazone in 200 cc. of acetone 10 g. of phosphorus pentoxide[17] was added in small portions with stirring over a period of one hour, keeping the temperature at 0°. Stirring was continued for two hours more and the solution was filtered and washed with saturated potassium carbonate. The acetone was evaporated under reduced pressure and the residue taken up in warm ethyl acetate. The product crystallized on the addition of ligroin to the dried solution. After recrystallization, once from 95% alcohol and once from ether and petroleum ether, monoacetone galactose phenylosazone was obtained as yellow needles, m. p. 183.5–184.5° (corr.).

Anal. Calcd. for $C_{21}H_{26}N_4O_4$: N, 14.08. Found: N, 14.14.

3,4,6-Trimethylglucose Phenylosazone Hydrate.—Trimethyl inulin was prepared by the method of Haworth

---

(17) Smith and Lindberg, *Ber.*, **64**, 505 (1931).

and Streight.[18] Acid hydrolysis[19] yielded 3,4,6-trimethylfructofuranose which was converted to the osazone.[20] For the mutarotation and absorption spectrum measurements, the osazone was recrystallized three times from petroleum ether containing a trace of ether and three times from dilute alcohol; m. p. 81–82° (corr.).

Glycerose Phenylosazone.—To a mixture of 264 g. of diacetin, 149.4 g. of $Na_2Cr_2O_7 \cdot 2H_2O$ and 450 cc. of glacial acetic acid, a solution of 227.4 g. of sulfuric acid in 375 cc. of acetic acid was added with stirring over a period of eight hours at 20–25°. Then 55.5 g. of hydrated sodium acetate was added and the solution stirred for two hours. The precipitate was filtered off and washed with acetic acid. The filtrate and washings were evaporated to dryness under reduced pressure, the residue was taken up in ether, washed thoroughly with saturated sodium chloride, dried over sodium sulfate and distilled under reduced pressure. The fraction boiling at 130–150° (8 mm.) was redistilled, yielding 111.3 g. (b. p. 134–136° at 8 mm.) of a liquid.

That dihydroxyacetone diacetate was the principal constituent was demonstrated by the preparation of the 2,4-dinitrophenylosazone of monoacetylglyceraldehyde by warming 0.5 g. with 0.6 g. of 2,4-dinitrophenylhydrazine in 25 cc. of hot glacial acetic acid on the steam-bath for a half hour. The product, crystallized once from absolute alcohol and once from glacial acetic acid, formed yellow needles, m. p. 196–197° (corr.).

Anal. Calcd. for $C_{17}H_{14}N_8O_{10}$: N, 22.86. Found: N, 22.93.

Three and one-half grams of crude dihydroxyacetone diacetate was dissolved in 15 cc. of water and 5 cc. of 28% ammonia by warming on the steam-bath. The solution was cooled, treated with 6 cc. of glacial acetic acid and 6.5 g. of phenylhydrazine, and then warmed on the steam-bath for fifteen minutes, after which it was diluted with water and chilled. The product was filtered off and recrystallized once from 50% alcohol and once from benzene; m. p. 130° (corr.).

Tetrabenzoylglucose Phenylosazone.—This compound was prepared by the method of Fischer and Freudenberg[21] and was obtained as an amorphous solid, m. p. 100–110°, which decomposed at 125° (corr.).

Anal. Calcd. for $C_{46}H_{38}N_4O_8$: N, 7.24. Found: N, 7.20. $[\alpha]^{24}_D$ $-16.5°$, for $c = 0.606$ in *s*-tetrachloroethane.

$[\alpha]^{24}_D$ $+20.7°$, for $c = 0.435$ in a mixture of 1.5 parts 95% ethyl alcohol and 1 part pyridine. After forty-eight hours this value fell to +17.2°. Fischer and Freudenberg found $[\alpha]^{20}$ $-12.16°$ in *s*-tetrachloroethane (Welsbach light).

Acetylation of Glucose Phenylosazone.—Two grams of glucose phenylosazone was suspended in a mixture of 8 cc. of acetic anhydride and 20 cc. of pyridine. On heating to 50° for one hour the osazone dissolved, giving a dark orange solution which was poured into ice-water and allowed to stand overnight. The brown gum crystallized partly after standing for several weeks. It was washed repeatedly with 50% alcohol on a centrifugal filter until microscopic examination showed it to consist entirely of yellow needles. The product was dried *in vacuo;* m. p. 102–104° (corr.); $[\alpha]^{25}_D$ $-58.5°$, for $c = 0.431$ in 95% alcohol.

Anal. Calcd. for tetraacetylglucose phenylosazone, $C_{26}H_{30}N_4O_8$: C, 59.25; H, 5.86; N, 10.64. Found: C, 59.33; H, 5.60; N, 10.73.

Acetylation of Fructose Methylphenylosazone.—Fructose methylphenylosazone was acetylated as in the preceding description. The product, after one recrystallization from 95% alcohol, was obtained in orange-yellow needles, m. p. 126–127° (corr.); $[\alpha]^{27}_D$ $-184.8°$, for $c = 0.403$ in 95% alcohol.

Anal. Calcd. for tetraacetylfructose methylphenylosazone, $C_{28}H_{34}N_4O_8$: C, 60.62; H, 6.18; N, 10.11. Found: C, 60.62; H, 7.24; N, 10.09.

The author wishes to express his gratitude to Professor Hans T. Clarke for the guidance and encouragement he has given throughout the course of this research.

Conclusions

1. The spectral absorption characteristics of the sugar osazones are practically identical and in concord with the structure originally suggested by Fischer.

2. The bis-phenylhydrazones of methylglyoxal and dimethylglyoxal have practically coincident absorption curves; the differences from those of the sugar osazones are ascribable to the presence in the latter of an oxygen atom on the neighboring carbon atom.

3. Osazones are readily susceptible to hydrolysis under mild conditions; the mutarotation of sugar osazones appears to depend upon the establishment of an equilibrium between them and their hydrolysis products.

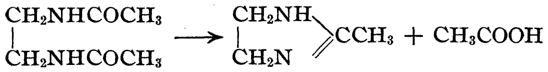
Some Alkyl-glyoxalidines[1]

BY HENRY C. CHITWOOD AND E. EMMET REID

In 1875 Ladenburg[2] distilled *o*-phenylenediamine with acetic acid and obtained ethenylphenylenediamine. Hofmann[3] distilled diacetylethylenediamine in a current of hydrogen chloride and got μ-methyl-glyoxalidine.



$$\begin{array}{l} CH_2NHCOCH_3 \\ | \\ CH_2NHCOCH_3 \end{array} \longrightarrow \begin{array}{l} CH_2NH \\ | \\ CH_2N \end{array} \!\!> CCH_3 + CH_3COOH$$

Ladenburg[4] prepared the same compound by distilling a mixture of ethylenediamine hydrochloride with two moles of sodium acetate. The ethyl and propyl derivatives have also been made.[3,4,5]

The present investigation was undertaken to improve the method of preparation, to prepare some of the higher members of the series, and to obtain more knowledge of the physical and pharmacological properties of the alkyl-glyoxalidines.

We were unable to obtain glyoxalidine itself from diformylethylenediamine but have greatly improved the method of preparing its methyl derivative, obtaining a 68% yield as compared with 11 and 8% by following Hofmann and Ladenburg. It is a curious fact that the above reaction can be carried out by heating the diacetylethylenediamine alone or with such diverse reagents as hydrogen chloride, caustic soda, magnesia, magnesium, zinc and sodium. As acetic acid is one of the products of the reaction, the use of acid-binding materials seemed desirable. Such materials did improve the yields, magnesium giving the best.

Methyl-glyoxalidine is a strong base, melting at 105° and boiling at 198–200°. It is very soluble in water, alcohol and chloroform, less so in benzene, carbon tetrachloride and petroleum ether. It is readily brominated in cold chloroform solution, forming the hydrobromide of the monobrominated base. The bromine is probably attached to a nitrogen, since it is readily eliminated by boiling with water with the regeneration of the original base. It was hoped that it could be split off as hydrobromic acid leaving methylglyoxaline but this could not be effected. Methylglyoxalidine when heated with an aqueous alkali is hydrolyzed back to ethylenediamine. Attempts to hydrogenate or dehydrogenate it were unsuccessful. It readily forms complexes with salts of silver, copper and cobalt. When it is added to a solution of a cupric salt, copper hydroxide is precipitated and then redissolved, giving a dark blue solution. A solution of the base dissolves cobalt carbonate. It dissolves freshly precipitated silver chloride but the solution is not stable.

The alkyl-glyoxalidines, methyl to undecyl, have been prepared by heating the corresponding diacylethylenediamines with sodium or magnesium, the lower ones distilling out while the higher ones were extracted from the mass after heating. The octyl, decyl and undecyl were prepared in a molecular still. The bases were taken up in hydrochloric acid, liberated with alkali, extracted with benzene, dried over solid caustic potash and distilled *in vacuo*. The lower members of the series are hygroscopic and very soluble in water, giving strongly basic solutions. This solubility decreases with the lengthening of the alkyl side chain; the undecyl is practically insoluble in water. All dissolve in hydrochloric acid to give well-defined salts. The hydrochlorides of the three highest give soapy solutions in water. All are very soluble in alcohol and moderately so in benzene but only slightly soluble in ether or petroleum ether. The lower ones are best purified by distillation, the higher ones by recrystallization from benzene with the addition of petroleum ether. They are best identified by their picrates, which are readily formed by adding a saturated aqueous picric acid solution to solutions of the bases or of their salts. Their gold or platinum double salts are formed when the hydrochlorides of the bases are added to solutions of the metal chlorides. The gold salts were analyzed by simple ignition as recommended by Hofmann and by Klingenstein.

The necessary diacyl derivatives of ethylenediamine were prepared by heating the acids or their ethyl esters with ethylenediamine. Their solubility in water decreases rapidly as we go up

the series, the diheptoyl and higher being quite insoluble. With increasing size of the alkyls they become less soluble in alcohol and more so in ethyl acetate. They are best recrystallized from mixtures of these three solvents.

The melting points of the bases, their picrates and the diacylethylenediamines from which they were prepared are given in Table I.

Amyl	178.5	33.8	128.4	41.07	41.04
Hexyl	173.0	46.2	...	39.90	39.95
Heptyl	171.0	60.0	104.8	38.80	38.66
Octyl	167.0	52.1	...	37.76	38.65
Nonyl	164.6	71.4	122	36.77	36.76
Decyl	160.8	79.5	82.0	35.84	35.83
Undecyl	158.8	79.8	61.5	34.95	35.08

The picrates of the hexyl and octyl derivatives could not be made to crystallize. The melting points of the diamine derivatives show slight alteration from 5 to 11 while those of the alkyl-glyoxalidines alternate from 2 to 9 but show a reversal of the alternation at the hexyl.

Pharmacological. — Methyl-glyoxalidine, known also as lysidine, has been considered as a solvent for uric acid.[4] In friendly coöperation, the pharmacological properties of it and of the next four members of the series have been studied by Dr. David I. Macht who reports as follows.

Aqueous solutions of the compounds were tested on seedlings of *Lupinus albus*, goldfish, tadpoles, mice, rabbits and cats. Contrary to the usual pharmacological experience, the toxicity of the five compounds decreased with the increase in length of the alkyl radical. Goldfish and tadpoles survived in solutions of 1:5000 but succumbed in the order named when placed in solutions of 1:1000. Ten milligrams of the methyl compound, administered intraperitoneally, killed mice, but the higher members of the series were not so toxic. Phytotoxic indices also showed that the latter were less poisonous for plants. Half a gram per kilo of any one of these compounds, given by stomach, was not toxic for rabbits and did not impair their kidney function. The methyl compound, however, increased the acidity of the urine. Ten milligrams injected intravenously in cats under ether, produced a transient fall in blood pressure but little effect on the respiration.

Experimental

The best method of preparing methyl-glyoxalidine so far found is to heat 30 g. of diacetylethylenediamine with 5 g. of magnesium powder in a flask in a solder-bath at 270° for seventy-five minutes. The hydrogen that is evolved helps carry over the product. Some acetone was noticed. Solid potassium hydroxide is added to the distillate with boiling benzene. The reaction flask is rinsed with hot benzene. The benzene solutions are united and dried over solid caustic potash, decolorized with active charcoal, filtered and evaporated to 30 cc. On cooling the methyl-glyoxalidine crystallizes out. A second crop of crystals may be obtained by concentrating the mother liquor and adding petroleum ether; yield 12.7 g. or 68%.

In comparative experiments the yields obtained were:

Ladenburg's method	8.0%
Hofmann's method	11.4
Simple dry distillation	24.6
Distillation with sodium hydroxide	22.3
Heating with sodium	39.3
Heating with zinc	43.4
Heating with magnesium	68.0
Heating with magnesium oxide	44.0
Ethylenediamine and acetic acid	19.1
Monoacetylethylenediamine hydrochloride with sodium hydroxide	26.2

Various other methods were tried, such as distilling diacetylethylenediamine under reduced pressure or dropping it in small portions into a heated flask, but without any improvement.

The higher homologs were all prepared from the diacylethylenediamines by distilling with sodium or magnesium, or by refluxing the diamides with the metal and extracting the bases with benzene. In most cases the product was dissolved in benzene, decolorized by activated carbon, dried over potassium hydroxide and purified by vacuum distillation. When very small amounts of materials were used, as in making the octyl, decyl and undecyl glyoxalidines, the reactions were effected in a molecular still. The bases were extracted from the distillate by dilute hydrochloric acid, precipitated by addition of alkali, extracted with hot benzene and redistilled. Table II gives a summary of experiments on the production of the glyoxalidine homologs.

The diacyl derivatives of ethylenediamine as intermediates in the preparation of the bases can be made by heating ethylenediamine with the ethyl esters, although the lower members are conveniently obtained on refluxing ethylenediamine with the free acids. The solubility in water decreases abruptly in going up the series, the diheptoyl and higher derivatives being quite insoluble. They are increasingly soluble in ethyl acetate and decreasingly soluble in alcohol, and may be recrystallized from solutions in appropriate mixtures of ethyl acetate and alcohol, on cooling the solutions and on addition of one or the other of these liquids. Diformylethylenediamine closely resembles granular sugar in appearance. The diacetyl derivative crystallizes in beautiful large white prisms, while the others, due to their abrupt change in solubility on cooling, usually come down as fine light crystals.

TABLE II

PREPARATION OF ALKYL-GLYOXALIDINES

	Ethylenediamine deriv.	Wt. used	Metal	Wt.	T., °C.	Press., mm.	Time, hours	Wt. of product, g.	Yield
I	Diacetyl	30	Mg	5	270	at.	1.25	12.7	68
II	Dipropionyl	20	Mg	1.5	300	at.	5	5.2	46
III	Dibutyryl	20	Mg	1.2	330	at.	1.25	5.5	49

VI	Diheptoyl	12	Mg	.5	300	at.	7	.1	1.7
VII	Dicaprylyl	1.7	Na	.1	270	at.	1	.4	47
VIII	Dipelargonyl	0.7	Na	.2	250	2	..	.08	21
IX	Dicapryl	5.5	Mg	.5	300	at.	6	.015	5.6
X	Diundecylyl	0.9	Na	..	300	10	..	.10	22
XI	Dilauroyl	1.6	Na	..	300	2	0.5	.20	24

Reactions of Methyl-glyoxalidine.—To 5 g. of the base dissolved in chloroform was added a solution of bromine in the same solvent, with shaking and cooling, until the color remained. The heavy yellow precipitate was filtered off, washed with chloroform and dried in a vacuum desiccator. The yield was 11.9 g. or 82%. Analysis gave 65.23% of bromine; calculated for $C_4H_7N_2Br \cdot HBr$, 65.53. The product appears to be the hydrobromide of the brominated base.

Summary

The method of preparing methyl-glyoxalidine has been improved. Its homologs with normal alkyls have been made up to the undecyl. Their pharmacological properties have been determined.

The Omega-Benzyl Derivatives of Acetophenone and their Reduction Products

BY G. ALBERT HILL AND A. J. COFRANCESCO

Although Haller and Bauer were not the first to prepare omega benzylated acetophenones, no earlier investigator produced these substances by the use of sodamide.[1,2] They did not, however, make tribenzylacetophenone. From our experience[3] with omega benzylated pinacolones, it was believed that tribenzylacetophenone could be synthesized by the sodamide method. As a consequence, it was decided that the preparation of the series of omega, mono-, di- and tri-benzyl acetophenones should be undertaken. Furthermore, it was decided to parallel our earlier investigation of the benzylpinacolone derivatives and to prepare, in addition to the ketones, their oximes, the corresponding carbinols and their phenylurethans, and also the hydrocarbons resulting from the replacement of each of the ketone oxygen atoms by two atoms of hydrogen.

Some trouble was experienced because the solvents employed in the ketone syntheses, ether, benzene, and toluene, seemed to form additive compounds with the first products of the reactions, the sodium derivatives of acetophenone, of monobenzylacetophenone, and of dibenzylacetophenone, respectively. This effect increased the viscosity of the systems to an extraordinary degree, making thorough mixing and temperature control difficult. These factors markedly affect the success of a given synthesis and may lead to the decomposition of the desired product when that has been formed.

Monobenzylacetophenone was prepared from sodamide, acetophenone, and benzyl chloride, in toluene, since the above-mentioned difficulties were minimized in this medium. Though odorless at first, the ketone developed fragrance on standing. This was probably caused by oxidation and splitting, an effect which is known to occur with dibenzyl ketone.[4] No attempt was made to isolate or to identify the odorous substances. With hydroxylamine, the ketone yielded a crystalline oxime.[5]

The secondary alcohol derived from monobenzylacetophenone had already been prepared

by reduction with sodium and alcohol,[6] and also catalytically.[7] The ketone was reduced in this Laboratory by the older methods and by Hartung's[8] which had not been reported previously. Contrary to expectations, this method did not yield the hydrocarbon, for reduction stopped at the alcohol stage. The phenylurethan obtained from this product melted at 86°. Straus and Grindel reported a melting point of 83—84°.

Monobenzylacetophenone, previously reduced to 1,3-diphenylpropane, only by catalytic means,[7] in this investigation was reduced by the action of red phosphorus and hydriodic acid in a heated sealed tube.[9] It is significant that neither Clemmensen's[10] nor Hartung's method accomplished the desired result.

Dibenzylacetophenone was formed simultaneously with the monobenzyl compound. Its purification was complicated by a tendency to yield intractable condensation products if the temperature were too high or if the vacuum were not sufficiently low. Although the earlier investigators were unable to prepare its oxime, this compound was finally obtained.

The corresponding alcohol, 1,3-diphenyl-2-benzylpropanol-1,[11] had not been prepared before by the reduction of this ketone. Sodium and alcohol sufficed to bring about the desired transformation. This alcohol readily yielded a phenylurethan.

Dibenzylacetophenone was reduced to a hydrocarbon by the method involving hydriodic acid and red phosphorus. The product, so synthesized, has already been reported.[12] In the reduction of dibenzylacetophenone, as in the case of the monobenzyl ketone, Clemmensen's method failed completely; Hartung's gave only the secondary alcohol.

Tribenzylacetophenone was prepared from dibenzylacetophenone. Despite strenuous efforts, all attempts to isolate its oxime were uniformly unsuccessful. It is believed that steric hindrance is the cause of these negative results.

The corresponding carbinol, 1,3-diphenyl-2,2-dibenzylpropanol-1, was easily formed from the ketone by the use of sodium and absolute alcohol. Attempts to purify the product, a gummy mass, by vacuum distillation, always failed because of resinification. The carbinol was separated from the unchanged ketone by taking advantage of its greater solubility in ethyl alcohol. All efforts to prepare a phenylurethan invariably came to nought.

Tribenzylacetophenone was not affected when subjected to the reducing action of Hartung's or of Clemmensen's method. Heating in a sealed tube with red phosphorus and hydriodic acid brought about the desired result, the formation of 1,3-diphenyl-2,2-dibenzylpropane, tetrabenzylmethane. This hydrocarbon had previously been prepared by treating appropriate Grignard reagents with certain organic halides.[13,14] However, the yields never approached those obtained in this investigation.

The consistent failure of the Clemmensen method to reduce the ketones of this series, and the analogous derivatives of pinacolone, previously reported, seems sufficiently interesting to merit further study.

In the experimental part only the reactions leading to new products or to considerably improved yields of known compounds will be reported.

It is a pleasure to acknowledge the assistance given us by W. F. Bruce and R. W. Ehlers in certain preliminary work in the synthesis of tribenzylacetophenone. Without the financial aid afforded by the Atwater Fund this investigation could not have been undertaken.

Experimental

Dibenzylacetophenone Oxime.—Five grams of ketone was dissolved in 75 cc. of 95% ethyl alcohol. An excess (3 g.) of hydroxylamine hydrochloride and 2 g. of potassium hydroxide in 3 cc. of water were added. The system was refluxed vigorously for ninety-six hours. Water, sufficient to dissolve the potassium salt, was added and the solution extracted with ether. After drying with anhydrous sodium sulfate, the ether solution was distilled. The white crystalline residue was recrystallized from 95% ethyl alcohol, in which any unchanged ketone dissolved readily. The oxime melted at 157°.

Anal. Calcd. for $C_{22}H_{21}ON$: N, 4.45. Found: N, 4.50.

Phenylurethan of 1,3-Diphenyl-2-benzylpropanol-1.—Three grams of the alcohol was dissolved in 3 cc. of dry toluene; 2 g. of phenyl isocyanate was added and the solution kept at 40° for fourteen hours. The white, crystalline solid which settled out was recrystallized from 95% ethyl alcohol. The melting point was 185°.

Tribenzylacetophenone.—160 g. of dibenzylacetophenone was dissolved in twice its volume of toluene, 400 cc. Cooling occurred as solution progressed. Twenty-three grams of sodamide of the necessary high quality was finely pulverized and placed in a three-necked flask equipped with a condenser, a mercury-seal stirrer, and a dropping funnel. The ketone solution was introduced dropwise during two hours while the mixture was stirred and refluxed. At the end of the two-hour period, the system became purple and ammonia was evolved very rapidly. The reaction was continued for eighteen hours. Seventy-four grams of benzyl chloride, b. p. 176–178°, was then introduced at a rate of three or four drops a second. Heating and stirring were continued for twenty-four hours more. By the end of this period the purple color had given place to yellowish-brown. The flask was cooled, 250 cc. of water was added and the toluene layer separated. It was washed with water, dilute hydrochloric acid, and again with water, dried with calcium chloride and distilled on a steam-bath under slightly reduced pressure. The crude ketone which crystallized was filtered and washed with 50 cc. of methyl alcohol in which tribenzylacetophenone is but very slightly soluble, whereas the dibenzyl compound is soluble. The product, recrystallized from toluene, melted at 127–128°. The average yield of crude crystals was 135–140 g., about 68%. The unused dibenzylacetophenone was recovered. Neither the use of a larger proportion of sodamide nor longer heating had a material effect in increasing the output.

Anal. Calcd. for $C_{29}H_{26}O$: C, 89.23; H, 6.67; mol. wt., 390. Found: C, 89.24, 89.17; H, 6.74, 6.77; mol. wt. (ebullioscopic method with benzene), 383, 380.

1,3-Diphenyl-2,2-dibenzylpropanol-1.—Five grams of tribenzylacetophenone was dissolved in 400 cc. of absolute alcohol. As rapidly as possible, 50 g. of sodium was added to the solution. When the vigor of the reaction had abated, the system was heated and refluxed for half an hour, then 200 cc. of water was added to the cooled contents of the flask. The gummy organic product was heated repeatedly with portions of hot ethyl alcohol which removed the carbinol, but had little effect on any unchanged ketone. Evaporation of the alcohol yielded 2 g. of a very viscous, light yellow liquid which decomposed when heated even under a low pressure. Two grams of ketone was recovered.

When a similar experiment was conducted with isoamyl alcohol as the medium, there resulted in addition to the oil, mentioned above, a solid which, after treatment with acetone and finally with toluene, was found to be tetrabenzylmethane.

Anal. Calcd. for $C_{29}H_{28}O$: C, 88.77; H, 7.14; mol. wt., 392. Found: C, 88.73, 88.75; H, 7.06, 7.08; mol. wt. (Rast method), 383, 384.

Tetrabenzylmethane.—Four grams of tribenzylacetophenone was heated for twenty-four hours at 200° in a sealed tube with 4 g. of red phosphorus and 80 cc. of 47% hydriodic acid. The cooled tube was opened and the contents extracted with toluene. This solution was washed with aqueous potassium hydroxide and with water, and then dried with calcium chloride. Removal of the toluene left a gummy white mass which upon repeated crystallization from ethyl alcohol gave 0.5 g. of large diamond-shaped crystals melting at 164°. The yield is 13%.

Anal. Calcd. for $C_{29}H_{28}$: C, 92.55; H, 7.45; mol. wt., 376. Found: C, 92.50; H, 7.38; mol. wt. (Rast method), 374.

Summary

1. Tribenzylacetophenone has been produced by a sodamide synthesis.
2. Certain derivatives of the omega-benzylacetophenones, analogous to a series of omega-benzylpinacolone derivatives, have also been prepared.

A Useful Integrated Form of the Equation for Calculating Change of Equilibrium with Temperature

BY J. B. AUSTIN

There are a number of thermodynamic equations expressing the change of equilibrium with temperature which have the general form

$$\mathrm{d} \ln f/\mathrm{d}T = \Delta H/RT^2 \qquad \text{I}$$

where f is the equilibrium constant, vapor pressure, solubility, or some other similar quantity which characterizes a state of equilibrium, ΔH is the molar heat effect for the reaction in question at the absolute temperature T, and R is the gas constant. If ΔH is assumed constant with T, this equation integrated between T' and T gives

$$\ln f'/f = \frac{\Delta H}{R}\left(\frac{T'-T}{T'T}\right) \qquad \text{II}$$

This relation, according to which $\ln f'/f$ is a linear function of $1/T$, has proved very useful as an aid in the critical examination of experimental observations, and even as a basis for estimating values of f'/f from ΔH (or conversely) when no direct measurement is available. The ease with which it can be applied, however, can be considerably increased in a number of cases, particularly in condensed systems, by a simple transformation into an approximate form which holds over a restricted temperature range. Thus, the approximate equation shows: (1) that experimental values of f, whatever it may be, when plotted against T on double logarithmic coördinates should fall on a straight line; (2) that if we plot on double logarithmic coördinates, not T directly but a "reduced" temperature—that is, if the actual absolute temperature is divided by a suitable reference temperature, such as the melting point of the solvent in considering solubility the data for all substances which have the same entropy change in the given reaction (in the case of solubility, the same entropy of melting) fall on the same straight line; and (3) that these relations hold in many cases even if ΔH varies with T, so long as this variation is effectively linear over the temperature range considered. The transformed equation also leads directly to the useful empirical rules of Ramsay and Young and of Dühring.

The Generalized Transformation

The transformation employed can be applied directly to many forms of equation I integrated on the assumption that ΔH is constant, but since the results are identical with those obtained on the basis of the general postulate that ΔH varies linearly with T, the discussion is confined to the latter case. If in equation I we put $\Delta H = \Delta H_0 + AT$ and integrate, we have

$$\ln f'/f = \frac{\Delta H_0}{RT'}\left(\frac{T'-T}{T}\right) + \frac{A}{R}\ln\frac{T'}{T} \qquad \text{III}$$

Now if we set $T'/T = X$, the quantity $(T' - T)/T$ in III is equal to $(X - 1)$ which is the first term in a well-known series expansion of $\ln X$[1] which is convergent for values of X between 0 and 2. For values of X not much different from unity, which covers nearly all the practical applications of such an equation, the higher terms of the series are negligible compared to the first one, *i. e.*, $(X - 1)$; hence for $(X - 1)$ we may substitute $\ln X$, on which basis we get the equivalent equations

$$\left.\begin{aligned} \ln f'/f &= \frac{\Delta H_0 + AT'}{RT'}\ln\frac{T'}{T} = \frac{\Delta H'}{RT'}\ln\frac{T'}{T} && \text{(a)} \\ \ln f'/f &= \frac{\Delta H'}{RT'}\ln T' - \frac{\Delta H'}{RT'}\ln T && \text{(b)} \\ f'/f &= \left(\frac{T'}{T}\right)^{\Delta H'/RT'} && \text{(c)} \end{aligned}\right\} \quad \text{IV}$$

where $\Delta H'$ is the heat effect at T'.

The magnitude of the error introduced by the substitution of $\ln T'/T$ for $(T' - T)/T$ is indicated by a comparison of some typical values as given in Table I. The first two columns contain values of $(T' - T)/T$ and $\ln T'/T$, respectively; the third and fourth give values of f'/f calculated from the first two columns on the basis that $\Delta H'/RT' = 10$, which is a fair average of values likely to be used in applying the equation. It is apparent that the error in this case is relatively small for values of $(T' - T)/T$ less than 0.100. If $\Delta H'/RT'$ is smaller, the error is less; if greater, the error is larger. It should be noted that since the approximation is valid for small values of $(T' - T)$—that is, when $(X - 1)$ is not far from unity—the condition for convergence of the series is fulfilled.

Applications

I. Solubility Relations in Ideal Solutions

A Complete Immiscibility in Solid Phase.—Since there are a number of advantages deriving from the use of the approximate equation in specific applications, a number of examples will be considered. The first is that of the lowering of the freezing point of an ideal solution from which one component separates as a pure phase on cooling; that is the components are completely miscible in the liquid but completely immiscible in the solid. Under these conditions $\Delta H' = \Delta H_m$ the heat of fusion of the solvent, T' is the melting temperature of the pure solvent, and $f = N_2$, the mole fraction of solvent in the liquid at T. Obviously $f' = N'_2 = 1$, hence equation IV may be written in the equivalent forms

$$\left.\begin{aligned} \ln N_2 &= \frac{\Delta H_m}{RT_m}\ln T/T_m && \text{(a)} \\ \log N_2 &= \frac{\Delta H_m}{RT_m}\log T - \frac{\Delta H_m}{RT_m}\log T_m = \\ &\qquad \frac{\Delta H_m}{RT_m}\log T + \text{const.} && \text{(b)} \\ N_2 &= (T/T_m)^{\Delta H_m/RT_m} = (T_m/T)^{-\Delta H_m/RT_m} = \\ &\qquad \text{const. } T^{\Delta H_m/RT_m} && \text{(c)} \end{aligned}\right\} \quad \text{V}$$

Table I

Comparison of Values of f'/f Calculated from $\dfrac{T'-T}{T}$ and from $\ln T'/T$

$\dfrac{T'-T}{T}$	$\ln T'/T$	f'/f calcd. from $\Delta H'/RT' = 10$ $(T'-T)/T$	$\ln T'/T$	Difference, %
0.010	0.0100	0.904	0.904	0

---

[1] See, for example, Hudson, "The Engineers Manual," John Wiley and Sons, Inc., New York, 1917, p. 35.

Equation V shows that if we plot N_2 against T/T_m on double log paper, the data for all ideal solutions in the same solvent should fall on the same straight line; moreover, that these straight lines all radiate from a single point ($N_2 = 0$, $T/T_m = 1$) and that for any solvent the angle between its characteistic line and the temperature axis depends only on the magnitude on $\Delta H_m/RT_m$. Consequently, by plotting a few guiding lines for integral values of $\Delta H_m/RT_m$ or $\Delta H_m/T_m$, the line for any given solvent can be quickly and easily drawn, provided, of course that ΔH_m and T_m are known. On the other hand ΔH_m, if not known, can be rapidly estimated by plotting the available data for appropriate solutions and drawing the best straight line through them. It should be noted that $\Delta H_m/RT_m$ is $1/R$ times the entropy of melting of the pure solvent, which is approximately the same for many chemically related substances; hence, when plotted in this way, the straight lines for many related substances as solvents coincide, a fact which is useful in estimating solubility in the absence of any direct measurement of N_2 or ΔH_m.

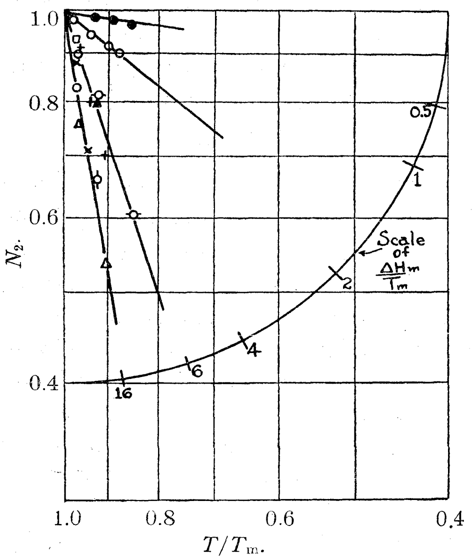

Fig. 1.—Solubility relations in systems with immiscibility in the solid phase plotted on double log coördinates using a reduced temperature according to eq. Va. Solid lines are calculated from heat of melting of solvent (component *italicized*): △, *anorthite*-diopside; □, *NaCl*-$Na_2Cr_2O_7$; ⦶, *diopside*-anorthite; ▲, *NaCl*-CsCl; ×, *diopside*-albite; -○-, *NaCl*-Na_2SO_4; ○, *magnesium*-nickel; +, *NaF*-NaCl; ●, *iron*-iron carbide.

In order to illustrate the usefulness of these relations a few typical data have been plotted in this manner in Fig. 1. The solutions selected are all high temperature systems—metals, fused salts and silicates—because they cover a relatively wide range of values of $\Delta H_m/T_m$; but the method applies equally well to any substantially ideal solution. It should be noted that the condition for proper application of the equation is met in that the value of T/T_m is never far from unity, even though a relatively wide range of temperature is included.

The points on the lowest line are for three silicate solutions taken from Bowen's study of the system diopside ($CaO\cdot MgO\cdot 2SiO_2$)–anorthite[2] ($CaO\cdot Al_2O_3\cdot 2SiO_2$)–albite ($Na_2O\cdot Al_2O_3\cdot 6SiO_2$). Following Bowen the molecular weights are taken as 217, 278 and 263, respectively. The full line is the calculated curve based on the directly determined heat of fusion of anorthite (105 cal. per gram).[3] It is evident that the solubility data are in excellent accord with the values calculated from ΔH_m for anorthite. Since anorthite and diopside are very similar, this agreement indicates that the entropy of melting of silicates of this type is very nearly the same and is close to 16 e. u.

The next curve compares the experimental data for four fused salt solutions, as given in "International Critical Tables" (Vol. IV), with the line calculated from the entropy of fusion of sodium chloride. Not only do the points for three solutions in sodium chloride as solvent fall on the line but those for a solution of sodium chloride in sodium fluoride come very close to it, indicating again that the behavior of solutions in related solvents can be represented by a single line with ample accuracy for many practical purposes.

The third line represents the solubility of nickel in magnesium as determined by Hanson and Payne,[4] compared with the solubility calculated from the entropy of fusion of magnesium. In this case it was demonstrated by direct measurement that the maximum solid solubility of nickel in magnesium is of the order of 0.1% so that the system closely approaches the ideal case of zero solid solubility. It should be noted that the entropy of fusion of magnesium is practically 2, which is a good average for that of most elements; hence $\Delta H_m/RT_m$ is close to one, which greatly simplifies the calculations.

(3) Vogt, "Das Silikatschmelzlösungen," Vol. II Videnskabs.-Selskabets Skrifter, I Math. naturv. Klasse, 1904, No. I.

(4) Hanson and Payne, *J. Inst. Metals*, **54**, advance copy (1934).

The uppermost curve in Fig. 1 gives the effect of carbon (Fe_3C) on the $\alpha \longrightarrow \gamma$ transformation temperature of iron, as taken from Sato[5] and is included, first because it shows that the equation applies to solid solutions and solid transformations as well as to liquid solutions and melting; and second because it is a good example of a transformation which has a very small entropy change (0.2 e. u.).

In Fig. 2, the data for the silicates have been plotted directly on double-log paper. The heat of fusion calculated from the slope of these curves is: for anorthite, 39,900 cal. per mole (107.5 cal. per gram) in good agreement with the directly determined value (105 cal. per gram); for diopside 20,000 cal. per mole or 93 cal. per g. in satisfactory agreement with the experimental value (approximately 100 cal./g.).[3]

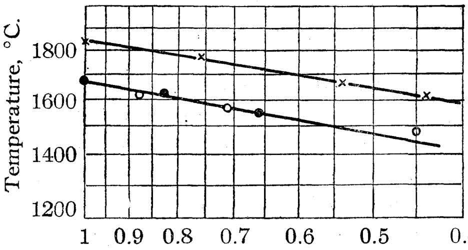

Fig. 2.—Solubility relations in some silicate systems plotted on double logarithmic coördinates according to eq. Vb. The solvent is the component *italicized.* ○, *Diopside*-anorthite; ●, *diopside*-albite; ×, *anorthite*-diopside.

Equation Vc is especially interesting because it shows that *the addition of a given mole fraction of solute lowers the (absolute) melting point of all solvents of related composition, i. e., those for which* $\Delta H_m/T_m$ *is the same, by the same percentage;* or *the solubility of a given solute at an absolute temperature which is a given fraction of the melting temperature is the same for all such solvents.* In other words, if N_2, the mole fraction of solvent, is plotted against T/T_m on rectangular coördinates, a single solubility curve is obtained for all ideal solutions in a given solvent, or for all ideal solutions in which the solvents have the same entropy of melting, thus providing a convenient way of representing a large number of data on a single curve or family of curves. An illustration of this method of plotting is given in Fig. 3.

It should be noted that the conclusion given in italics in the preceding paragraph is a rule for solutions exactly analogous to the rule of Ramsay and Young for vapor pressures which, as will be shown later, can be derived in the same way as equation Vc. It also leads to a rule for solutions analogous to the Dühring rule for vapor pressure. Thus if we plot the temperature at which a given substance has a given solubility in one solvent as ordinate and the temperature at which it has the same solubility in a "related" solvent (one whose entropy of melting is the same, or nearly the same) as abscissa, the experimental points should fall on a straight line whose slope is the ratio of the melting temperatures of the solvents.

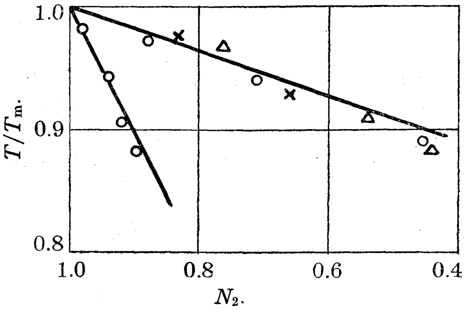

Fig. 3.—Solubility relations plotted on Cartesian coördinates using a reduced temperature according to eq. Vc. The solid lines are calculated from the heat of fusion of the solvent which is the component *italicized:* ×, *Diopside*-anorthite; ○, *diopside*-albite; △, *anorthite*-diopside; ●, *magnesium*-nickel.

It is also obvious that equation Vc in the form N_2 = const. $T^{\Delta H_m/RT_m}$ where the constant is $(T_m)^{-\Delta H_m/RT_m}$, enables one to draw in the actual solubility curve on linear coördinates with very little effort. Furthermore, the equation in this form demonstrates the factors which govern the shape of the solubility curve when plotted as N_2 against T. Clearly, when $\Delta H_m/RT_m = 1$ the solubility curve is a straight line between ($N_2 = 1$, $T = T_m$) and ($N_2 = 0$, $T = 0$); when $\Delta H_m/RT_m > 1$ the curve lies above this straight line and is concave to the N_2 axis, and when $\Delta H_m/RT_m < 1$ the curve is below the straight line and is convex to the composition axis. These relations, illustrated schematically by the curves in Fig. 4, are easily checked by considering a specific example. If $\Delta H_m/RT_m = 2$ equation Vc is a parabola passing through the origin ($N_2 = 0$, $T = 0$) and the melting point ($N_2 = 1$, $T = T_m$) and is symmetrical about the N_2 axis; whereas if $\Delta H_m/RT_m = 0.5$,

---

(5) Sato, *Tech. Repts. Tohôku Imperial Univ.*, **8**, 27 (1928).

the curve passes through the same two points but is symmetrical about the T axis at the $N_2 = 0$ side. Actually the equation would not hold over this range, but it does hold as N_2 approaches unity and in this region has the same form as if it were valid to $N_2 = 0$. It is concluded, therefore, that if the entropy of melting is close to 2, as it is for most of the elements, the solubility curve is substantially a straight line; if it is greater than 2, the curve is concave to the composition axis; if it is less than 2, the curve is convex to this axis, and in each of the last two cases the curvature becomes less as N_2 approaches unity. From this reasoning it is clear that if the curvature of the solubility line changes sign, then ΔH has changed in such a way that $\Delta H_m/RT_m$ has passed from its initial value through unity. These points are illustrated by Fig. 5, which shows data for three types of solution plotted as N_2 against T.

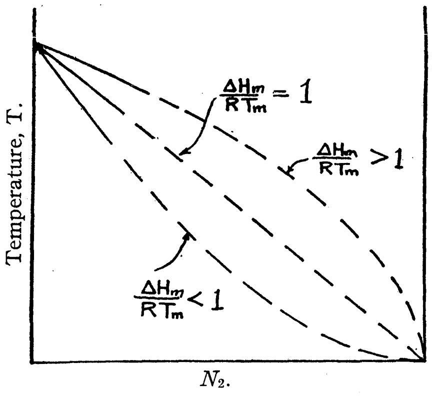

Fig. 4.—Schematic chart showing the relation between the entropy of melting and the curvature of the solubility line in a system in which there is no solid solubility.

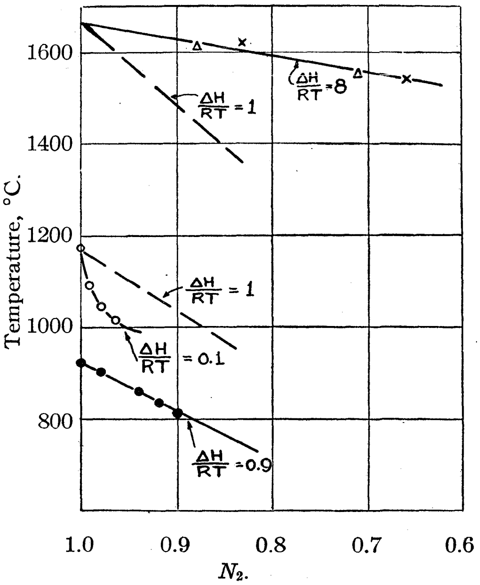

Fig. 5.—Chart illustrating the relation between the entropy of melting and curvature of the solubility line. △, *Diopside*–albite; ×, *diopside*–anorthite; ○, *iron*–iron carbide; ●, *magnesium*–nickel.

There is another interesting transformation which can be applied to equation V. It is a well-known fact that the value of $-\ln X$ approaches $(1 - X)$ as X approaches unity; hence, as N_2 approaches unity, that is, in a dilute solution, $-\ln N_2$ can be replaced by $(1 - N_2)$ or N_1, the mole fraction of solute in the liquid at T. On this basis we have

$$dN_1/dT = -\Delta H_m/RT^2 \qquad \text{VI}$$

which is the van't Hoff freezing point equation for dilute solutions. By the methods already indicated this becomes

$$\left.\begin{aligned} N_1 &= \frac{\Delta H_m}{RT_m}\ln\frac{T_m}{T} = -\frac{\Delta H_m}{RT_m}\ln T/T_m && \text{(a)}\\ N_1 &= -\frac{2.3\,\Delta H_m}{RT_m}\log T + \text{const.} && \text{(b)}\\ T &= T_m\,e^{-N_1T_mR/\Delta H_m} = T_m\,e^{-aN_1} && \text{(c)}\end{aligned}\right\}\ \text{VII}$$

In this case plotting on semi-logarithmic coördinates gives a straight line. The advantages of these equations for dilute solutions are in general those mentioned for equation V and need not be discussed in detail again. Data for the silicates and for magnesium which have been plotted on this basis are shown in Fig. 6.

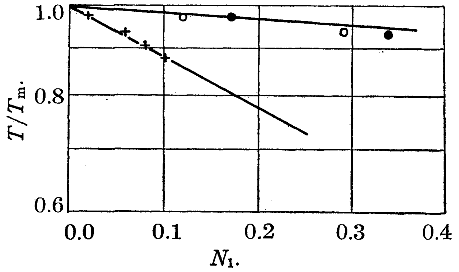

Fig. 6.—Solubility relations in some high temperature systems plotted on semi-logarithmic coördinates using a reduced temperature according to eq. VIIa. ×, *Magnesium*–nickel; ○, *diopside*–albite; ●, *diopside*–anorthite.

Case 2. Miscibility in the Solid Phase.—The second general case to be considered is that of a system showing solubility of the components in the solid phase (or in the low temperature form in the case of a solid transformation). In this case $\ln N_2$ is replaced by $\ln N_l/N_s$ where N_l and N_s are the mole fractions of solvent in the liquid and solid, respectively,[6] and we have

---

[6] The solvent is taken as the component whose heat of melting and melting temperature are used, usually the component present in the largest concentration.

$$\left.\begin{aligned}
\ln N_l/N_s &= \frac{\Delta H_m}{RT_m}\ln T_m/T = \\
&\qquad -\frac{\Delta H_m}{RT_m}\ln T/T_m && \text{(a)}\\
\log N_l/N_s &= -\frac{\Delta H_m}{RT_m}\log T + \text{const.} && \text{(b)}\\
N_l/N_s &= \left(\frac{T}{T_m}\right)^{-\Delta H_m/RT_m} = \\
&\qquad \text{const. } T^{-\Delta H_m/RT_m} && \text{(c)}
\end{aligned}\right|\ \text{VIII}$$

These equations are entirely analogous to equations V, and show that by plotting N_l/N_s against T/T_m or against T directly on double log paper, a straight line having the slope $\Delta H_m/RT_m$ should be obtained. Equation VIIIa shows that the lines again radiate from a common point, as is evident from Fig. 7 which shows a few typical data plotted in this manner. The lowest curve is for anorthite-rich solutions of albite and anorthite,[2] and the middle one is for the albite-rich end of this system plotted so as to fall on the graph instead of above it as it normally would. The uppermost curve shows the ratio N_l/N_s at the eutectic temperature of each of a series of aluminum alloys.[7] The full lines are those calculated from the directly-measured heat of fusion while the dashed line (for albite) is the best straight line through the data. The entropy of fusion of albite is considerably lower than that of anorthite, indicating that $\Delta H_m/RT_m$ does not have the same value for all silicates; nevertheless, the agreement demonstrated previously between the entropy of fusion of diopside and anorthite, which are closely related chemically, suggests that the silicates can be classified into a small number of groups, the members of each group having the same entropy. The comparison of silicates emphasizes that Fig. 1 is nothing more than a special case of Fig. 7—the value of N_s being unity in the former. The data of Fig. 1 can therefore be plotted on Fig. 7, and the lines for anorthite and diopside would coincide. The uses of equation VIIIb are apparent and need no further discussion.

While the equations as given are derived for melting phenomena, it is obvious that they apply equally well to the boiling point of solutions of a volatile solute in a volatile solvent. Thus by making ΔH_m the heat of vaporization, T_m the boiling point and changing N_l and N_s to N_v and N_l, the mole fractions of solvent in vapor and liquid, respectively, we get

$$\left.\begin{aligned}
\ln N_v/N_l &= \frac{\Delta H_v}{RT_v}\ln\frac{T_v}{T} = -\frac{\Delta H_v}{RT_v}\ln T/T_v && \text{(a)}\\
\log N_v/N_l &= -\frac{\Delta H_v}{RT_v}\log T + \text{const.} && \text{(b)}\\
N_v/N_l &= (T/T_v)^{-\Delta H_v/RT_v} = \\
&\qquad \text{const. } T^{-\Delta H_v/RT_v} && \text{(c)}
\end{aligned}\right\}\ \text{IX}$$

Since these equations are precisely analogous to equations VIII whose application has been considered, no further discussion is needed, except to state that for a non-volatile solvent, $N_v = 1$ and the equations simplify to the form analogous to equation V.

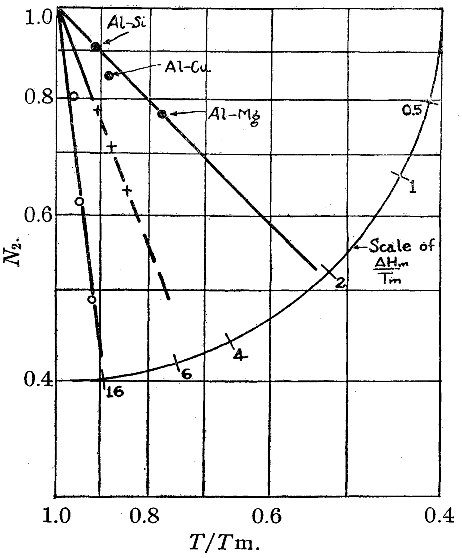

Fig. 7.—Solubility relations on systems having solid solubility, plotted on double logarithmic coördinates using a reduced temperature according to VIIIa. The solid lines are calculated from the heat of melting of the solvent which is the component *italicized:* ○, *Anorthite–albite*; +, *albite*–anorthite; ●, *aluminum* alloys at eutectic temp.

Other Applications.—In a purely formal way the approximate equations are valid for any quantity whose variation with temperature is given by equation I, and apply therefore to the equilibrium constant of a reaction, vapor pressure, dissociation pressure or electron emission. Actually, the change in these quantities with temperature is such that the restriction of keeping T'/T less than 1.2 imposes a serious limitation so that the equations are useful in only a few special cases.

There are, however, certain interesting aspects of the equations for some of these quantities, particularly the one for vapor pressure. Thus, if f' in IVc is the vapor pressure at T' of a liquid

---

(7) Fink and Freche, *Trans. A. I. M. M. E.*, **111**, 304 (1934).

whose normal boiling point is T, it follows that for "related liquids," *i. e.*, those whose entropy of vaporization is the same, at the same vapor pressure

$$T_1/T_2 = T_1'/T_2' = \text{constant}$$

which is the empirical rule of Ramsay and Young.

Dühring's rule also follows from IVc, for considering a given pressure we write

$$\left(\frac{T_1'}{T_1}\right)^{\Delta H_1'/RT_1'} = \left(\frac{T_2'}{T_2}\right)^{\Delta H_1'/RT_2'}$$

and for "related liquids"

$$T_1' = T_1/T_2T_2' = \Delta H_1'/\Delta H_2' \times T_2'$$

which is the equation for the Dühring line. It also indicates that the slope of the Dühring line is the ratio of the absolute boiling temperatures or the heat of vaporization of the liquids chosen.

It is also possible to give some basis to Guldberg's empirical rule that for many liquids the normal boiling point is two-thirds of the absolute critical temperature. Thus, denoting the values of the quantities at the boiling point and critical point by the subscripts b and c, it can be shown on the basis of IVc that $T_b/T_c = (^1/P_c)^{-\Delta H_b/RT_b}$. Since P_c for most liquids is of the order of magnitude of 60 atmospheres, and by Trouton's rule, $-\Delta H_b/RT_b = -11$, the ratio T_b/T_c is roughly 0.7.

Summary

By a simple transformation the equations relating the change of solubility with temperature can be changed into an approximate form which is in many cases more convenient for interpolation or extrapolation than the original equations. Thus it is shown that experimental values of these quantities fall on a straight line when plotted against the temperature, or the reduced temperature, on double logarithmic coördinates. The approximate equation for vapor pressure leads directly to the rules of Ramsay and Young and of Dühring.

The Formation and Composition of Lithium Aluminate

BY HAROLD A. HORAN AND JOHN B. DAMIANO

Introduction

According to Allen and Rogers,[1] an insoluble aluminate of lithium is formed when aluminum is dissolved in a solution of lithium hydroxide. Analysis of the air-dried substance for alumina and water led them to assign the formula, $LiH(AlO_2)_2 \cdot 5H_2O$. As a result of conductometric measurements on the saturated solution of the substance, similarly prepared, Prociv[2] concluded lithium and aluminum were present in the ratio of 0.8Li:2Al, which, he says, is an atomic ratio of approximately 1Li:2Al. According to him lithium aluminate may also be precipitated by the addition of a solution of lithium hydroxide to a solution of an aluminum salt or by adding a solution of a lithium salt to a solution of an alkali aluminate. On ignition, he claims, the compound is converted into $Li_2O \cdot 2Al_2O_3$. Dobbins and Sanders[3] describe the formation of lithium aluminate by the addition of dilute ammonia to a solution containing a lithium and an aluminum salt, in the presence of phenolphthalein as an indicator. However, they claim the compound contains lithium and aluminum in atomic ratio of 2Li:5Al and, as a result of a series of ignitions assign the formula, $2Li_2O \cdot 5Al_2O_3$, for the ignited product.

Thus there is disagreement as to the composition of lithium aluminate prepared by different methods. This might be attributed to a variation of conditions, *i. e.*, alkalinity, relative ionic concentrations or temperature, in the different methods used. Concerning temperature, Allen and Rogers[1] and Heyrovsky[4] suggest precipitation at low temperatures, (near 0°), to prevent decomposition of the aluminate.

Since the compound has not been extensively studied, this investigation was undertaken in order, (1) to determine conditions for the precipitation of lithium aluminate from a solution of an aluminum salt, (2) to determine, by analytical means, the atomic proportions of lithium to aluminum in the substance precipitated, (3) to

determine the behavior of the substance on ignition.

Materials

Aluminum Ammonium Sulfate.—The C. P. substance was recrystallized twice from water. Solutions were made up and standardized by the oxine method.[5]

Acetic Acid.—A good grade, practically free of nonvolatile matter, was used.

Ammonia.—This was freshly distilled and made up to approximately 0.5 molar concentration.

Ammonium Acetate.—An approximately 2 molar solution was prepared by mixing the proper amounts of acetic acid, ammonia and water.

8-Hydroxyquinoline.—This was the Eastman Kodak Co. product.

Lithium Chloride.—This was purified by the usual method of precipitating the carbonate and evaporation with hydrochloric acid. An approximately 5% solution was made up and standardized by evaporating a known volume to dryness, in the presence of a little sulfuric acid, gently igniting and weighing the residue.

Experimental

To solutions containing known amounts of aluminum and having volumes of 100 cc., lithium chloride solution was added in amounts to provide an excess (approx. 10%), over the calculated amount, assuming for calculations 1Li:2Al. The solutions were cooled to approximately 5° and maintained at that temperature until after filtration. Dilute ammonia was added, with stirring, to effect precipitation. The amounts added varied in several cases. In some, just enough was added to give the solution a faint yellow color in the presence of neutral red as an indicator. In others, phenolphthalein was used as an indicator and a faint pink color established, while still in others a deep pink color was established by the addition of larger amounts of ammonia. The precipitates which formed were allowed to settle, filtered and washed with cold water (approx. 5°), until washings showed no test for chlorides with silver nitrate solution. To ensure proper washing and prevent "channeling" the precipitates were stirred while washing. The precipitates were analyzed as outlined below.

Another series of precipitations was carried out in solutions where the amounts of aluminum were held constant and the lithium chloride added was varied over a considerable range. Dilute ammonia was added to these solutions, in the presence of phenolphthalein, until the solutions had a definite pink color. The solutions and precipitates were handled as described above.

For the analyses of the freshly precipitated aluminates, most of the precipitate was washed from the paper, with water, into a clean beaker. The filter paper was then boiled up with sulfuric acid (1:6) to dissolve the remaining aluminate, and extracted several times with small portions of boiling water. The sulfuric acid solution and water extractions were filtered into the beaker containing the bulk of the precipitate, which dissolved upon heating. The solution was diluted to 100 cc. with water and almost neutralized with ammonia. The aluminum was then determined by the oxine[5] method. To recover the lithium sulfate, the filtrate and washings were carefully evaporated in platinum to approximately 10 cc. Concentrated nitric acid was added, in small increments, while the evaporation was continued. After destruction of most of the ammonium salt, acetic acid and organic matter, the solution was evaporated to incipient dryness. The residue was transferred with hot water to a platinum crucible. The crucible and contents were heated in an air-bath until dry. The excess sulfuric acid was carefully expelled and the crucible heated to constant weight at about 600°. Several blanks were run on solutions containing the same amounts of aluminum but no lithium. The lithium sulfate weights were then corrected. These corrections never amounted to more than 0.6 mg. The residues from the blank determinations revealed a trace of aluminum, probably due to the solubility of the quinolate.

The results of the two series of analyses are given in Tables I and II. The lithium–aluminum ratios are also given.

TABLE I

[5] Kolthoff and Sandell, THIS JOURNAL, **50**, 1900 (1928).

Several samples were precipitated using various amounts of lithium chloride solution and varying the alkalinity over the range indicated above. They were filtered, washed and transferred to silica crucibles. The precipitates were dried and the paper burned off at a low temperature. The temperature was gradually increased, the final ignitions to constant weight being made in a muffle at about 1050°. Some of the results are given in Table III. The calculated values, using formulas $Li_2O \cdot 2Al_2O_3$ and $2Li_2O \cdot 5Al_2O_3$ are also given.

TABLE III

Expt.	Al_2O_3 (taken), g.	Ignited residue, g.	$Li_2O \cdot 2Al_2O_3$ (calcd.), g.	$2Li_2O \cdot 5Al_2O_3$ (calcd.), g.

27	.0987	.1127	.1132	.1103
28	.0554	.0631	.0636	.0619
29	.0554	.0632	.0636	.0619

Expts. 25, 29 were done using neutral red as an indicator. Expts. 23, 24, 27 were done using phenolphthalein as an indicator until a faint pink color resulted. Expts. 26, 28 were done using phenolphthalein as an indicator until a very deep pink color resulted.

Discussion

The results in Table I show that within limits of experimental error the same results are obtained whether the solution is made faintly or definitely alkaline (*p*H 7.5–10.5). Thus there is no need for careful adjustment of alkalinity as suggested by Dobbins and Sanders.[3] Large excess of hydroxide should be avoided, as this causes slow solution of the precipitate.

As shown in Table II, the lithium chloride concentration has been varied over a considerable range without effect on the composition of the precipitate. It is not desirable to have too large a concentration of lithium chloride present, since this would entail prolonged washing of the precipitates to render them free of the excess, with consequent losses due to solubility and hydrolysis.

The lithium sulfate values given in Tables I and II are slightly lower than predicated by a 1Li:2Al ratio. This is undoubtedly due to loss of lithium in the solution and washings, for we have found more than traces removed if the washing is prolonged. The values are higher by some 25% than demanded by a 2Li:5Al ratio, making certain that the components are not present in that ratio.

In Table III the weights of the ignited residues, though slightly lower than expected, indicate that the ignition product is better represented by the formula $Li_2O \cdot 2Al_2O_3$ than by $2Li_2O \cdot 5Al_2O_3$. The percentage differences are only some 2.5% and, were it not for the large differences in lithium sulfate values mentioned above, one might not be justified in assigning a ratio of 1Li:2Al.

In assigning a 2Li:5Al ratio, Dobbins and Sanders[3] were led to this conclusion by (1), a series of ignitions of precipitates formed in solutions containing known amounts of aluminum and (2), Prociv's 0.8Li:2Al ratio, determined conductometrically. Concerning the first, it should be pointed out that precipitations and washings were made at room temperature where losses due to decomposition and solubility probably amount to at least 1%. In addition, no analysis of un-ignited precipitates was made prior to assignment of the formula. These points are important since the percentage difference in the weight of an ignited residue as calculated by one formula and the other is only 2.5%. Concerning Prociv's value, it is according to himself only approximate. It is an isolated value and not the result of a series of measurements. Other values obtained by Prociv[2] were quite close to a 1Li:2Al ratio.

Conclusions

1. An insoluble aluminate of lithium is precipitated, practically quantitatively, when a solution of an aluminum salt containing sufficient lithium salt, is made alkaline with ammonia.

2. Analysis shows that the substance contains lithium and aluminum in atomic ratio of 1Li:2Al.

3. Upon ignition at a high temperature the substance becomes constant in weight. The weight of the residue, obtained from a precipitate containing a known amount of aluminum, suggests the formula $Li_2O \cdot 2Al_2O_3$ for the residue.

BROOKLYN, N. Y. RECEIVED APRIL 26, 1935

Purification and Physical Properties of Organic Compounds. X. The Freezing Point Diagram for the System Acetanilide–Propionanilide[1]

BY EVALD L. SKAU AND LOUIS F. ROWE

In 1923 Hurd[2] isolated a white crystalline substance composed of propionanilide and acetanilide and concluded that in spite of the sharp melting point and apparent homogeneity of its long needle-like crystals it was not a compound but a mixture. Gilbert and Clarke[3] constructed the freezing point diagram of this binary system by a slightly modified Beckmann method and concluded that a compound crystallized from mixtures containing between 43 and 58 mole per cent. of propionanilide. Due to the unreliability of the Beckmann method for determining binary freezing points[4] it was thought desirable to reconstruct the diagram using a static method.

Materials.—Eastman Kodak Co. products were purified by repeated recrystallization from acetone. Their freezing points were determined by means of heating curves in an apparatus described elsewhere.[5] The curves showed that each still contained a trace of impurity.

Method.—The sample weighing from 1 to 3 g. was sealed in a glass tube (12 mm. diameter and 1 mm. wall thickness) extreme precautions being taken to avoid any overheating. The sample tube was fastened to the arm of an electric bell and vigorously agitated in a 2-liter water or glycerol bath. A 17-ohm nichrome filament wound around a Pyrex U-tube and connected to a lighting circuit through an 80-ohm Vitrohm rheostat controlled the temperature of the bath. A stream of bubbles released below the heater wires circulated the liquid. The temperature of the bath was measured by means of a carefully calibrated thermometer with 0.1° graduations. This type of thermostat was very easy to manipulate from one constant temperature to another and the temperatures in various parts of the bath differed by less than 0.1°.

The freezing point was determined by finding two temperatures, 0.2° or less apart, such that at the lower temperature a few crystals[6] persisted during thirty minutes of agitation and at the higher temperature the sample became completely liquid. The average of these two temperatures was taken as the freezing point of the sample after stem-emersion and calibration corrections had been made.

Results and Discussion

The results are given in Table I and are compared graphically in Fig. 1 with those previously obtained by the Beckmann method. Table I gives the equilibrium temperatures between the melt and the stable crystalline phases. For compositions up to and including 46.00% the crystalline phase is acetanilide (flakes), between 49.95

[6] Formed by bringing the very tip of the sample tube containing the liquid at that temperature above the surface and touching it with a cold object.

and 54.86% it is compound (needles), and between 56.57 and 100% it is propionanilide (granules).

The results bear out the fact that the Beckmann method, giving values as it does from 0.5 to 5° too low, is not suitable for determining binary freezing points. It is found that the needle-shaped crystals of the compound are in stable equilibrium with liquid mixtures between about 49.5 and 55 mole per cent. of propionanilide instead of between about 43 and 58 mole per cent. as previously accepted. The 49.5 per cent. composition, freezing at 79.4°, is a eutectic between the compound and acetanilide; and the 55 per cent. point, at 80.1°, is an incongruent melting point for the compound.

An interesting fact was noted in regard to the behavior of mixtures between about 42 and 57 mole per cent. propionanilide but outside the compound region. When the tip of the sample tube containing the supercooled liquid was brought above the surface of the bath and touched with a cool object, needle-shaped crystals were formed. These seemed always to melt rapidly when agitated in the bath unless the temperature was below about 79.5° on the acetanilide side and about 80.2 to 80.5° on the propionanilide side. If the temperature was so regulated that the needles persisted, the liquid became turbid in a few minutes and very soon the characteristic flake-like crystals of acetanilide (or the granular crystals of propionanilide in the case of compositions above 55 per cent.) formed as the needles disappeared. These flakes (or granules) did not then disappear until the melting point represented for this composition in the diagram was reached. It was never found possible to cause the flakes of acetanilide to crystallize out spontaneously even by continued agitation at temperatures between the full line and the dotted line in the figure. This behavior makes it seem probable that Gilbert and Clarke were dealing with the unstable solid phase at either end of the compound region and illustrates an additional source of error involved in the Beckmann method.

The determination of the exact composition of the compound was hindered by the great difficulty of isolating it in a pure state but our results indicate that it is perhaps composed of two moles of propionanilide and one mole of acetanilide. A small crop of the needle-shaped crystals was crystallized from a mixture containing 55 mole per cent. of propionanilide and separated by means of a centrifugal filtration tube.[7] Due to the fact that the temperature range over which the compound forms is so small (0.7°) these crystals were undoubtedly contaminated with a very considerable amount of the eutectic mixture of about 49.5 per cent. composition. Their melting point was 80.2° and after being kept just below this temperature for a few minutes, granular propionanilide crystals formed which did not dissolve until 81.3° had been reached, corresponding to a composition of 56.5 mole per cent. of propionanilide. This also corroborates the fact that the compound has an incongruent melting point.

Grateful acknowledgment is made for grants from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences and from Curtis H. Veeder, of Hartford, which have made this investigation possible.

Summary

The binary freezing point diagram for the acetanilide–propionanilide system has been reconstructed by means of an accurate static method; the Beckmann method for binary freezing point determinations has again been shown to be unreliable. The system shows compound formation with incongruent melting. The compound tends to crystallize out in unstable equilibrium from liquid mixtures near the compound region.

Purification and Physical Properties of Organic Compounds. XII. The Lower Aliphatic Bromides[1]

BY EVALD L. SKAU AND ROGERS MCCULLOUGH

In the course of some rate of reaction work it became necessary to know the densities of certain bromides of the aliphatic series. The data in the literature showed considerable disagreement. Accordingly a number of these bromides were prepared in as pure a form as practicable and their boiling points, densities and freezing points were determined.

Preparation and Purification of the Bromides.—The bromides were all prepared by the action of constant boiling hydrobromic acid of high purity on the corresponding pure alcohols by the method of Norris[2] as modified by McCullough and Cortese.[3] The alcohols were carefully fractionated pure materials boiling over a range of not more than 0.1°. Their purity was checked by density determinations. For the sample of *n*-amyl bromide we are indebted to Dr. Richard H. F. Manske of the Canadian National Research Laboratories, Ottawa.

Each of the bromides was washed repeatedly with constant boiling hydrobromic acid and then dried over anhydrous sodium sulfate or calcium chloride and subjected to systematic fractional distillation through a 180-cm. spiral fractionating column electrically heated and supplied with a still-head for controlling the reflux. The boiling ranges and boiling points recorded in the accompanying table are the values obtained for the best fraction in this distillation. In the case of isopropyl bromide this sample was then fractionally crystallized from its own melt by means of an apparatus to be described in a later communication.

The final step in the purification always consisted of distilling the material in a high vacuum at low temperatures by immersing the receiver in liquid air. One portion of the middle fraction was collected in a freezing point tube and another, for use in the density determination, was collected in a special sample tube. Both were sealed off without admitting air.

Measurement of Physical Constants.—The boiling points except as noted were read by means of Anschütz thermometers totally immersed in the vapors. They were calibrated under the same conditions against standards of the same design certified by the U. S. Bureau of Standards and the Deutsches Reichsanstalt. In the cases of *n*-butyl, *s*-butyl and *n*-amyl bromide, a carefully calibrated copper–constantan thermocouple was used. Correction to 760 mm. was made by use of the temperature–pressure coefficients given in the "International Critical Tables."

The densities were determined by means of a 5-cc. Pyrex Sprengel pycnometer having the arms bent up at an angle of about 20° and provided with tightly fitting ground glass caps. The pycnometer after being rapidly filled from a freshly opened vacuum-sealed ampoule was capped and allowed to remain immersed in the thermostat for at least twenty minutes before the adjustment was made between two scratch marks. The temperature of the thermostat, which was maintained at 25.00 ± 0.01°, was checked by a standard certified Reichsanstalt thermometer which was in turn carefully checked against a platinum resistance thermometer at the ice-point and in a thermostat maintained at 30.000 ± 0.002°. The pycnometer was always allowed to stand inside the balance case for thirty minutes before being weighed with calibrated weights, making correction to vacuum.

The freezing points were determined from both cooling and heating curves,[4] an average being taken of the values obtained by the two methods.

Results and Discussion.—The results obtained are listed in Table I. For comparison with previous values in the literature only those of Timmermans, who with his co-workers has done the most extensive accurate work in this field, have been cited except where more recent accurate determinations have been made.

[d] Simon, *Bull. soc. chim. Belg.*, **38**, 47 (1929). [e] Timmermans, *ibid.*, **30**, 62 (1921). Deese, THIS JOURNAL, **53**, 3673 (1931). [g] Bridgman, *Proc. Am. Acad. Arts Sci.*, **68**, 1 (1933). [h] Calculated from the values given for 0, 15 and 30° values except for ref. (*f*).

The boiling point values agree very closely with those of Timmermans and others except in the case of isobutyl bromide which differed by 0.3 to 0.6°.

The density values are slightly higher than those previously reported except in the case of isobutyl and secondary butyl bromides. It was found that the final high vacuum distillation to which all the samples were subjected always raised the density. It should also be pointed out that the method of preparation and purification used avoided the formation of traces of unsaturated compounds and ethers[3] which might be difficult to remove and which would tend to lower the density. The largest discrepancy in density is in the case of isobutyl bromide. This was probably due to the presence of impurities as mentioned below.

The shape of the heating curves indicates that all of the compounds studied were of a high degree of purity[4] with the exception of the secondary butyl bromide, which contained a slight trace of impurity, and the isobutyl bromide. The latter gave very unsatisfactory cooling curves due to sluggish crystallization, and the heating curves indicated the presence of considerable impurity. The actual freezing point obtained was −118.1°, showing acceptable agreement with the best value previously reported, −118.05°, but it is probable that it would be at least 0.5° higher for the pure compound. It seems probable, on the other hand, that the other freezing points do not differ by more than a few tenths of a degree from the correct values for the pure bromides.

There are two solid forms of *n*-amyl bromide, an unstable form, melting at −94.6, and a stable form, melting at −87.9°. The unstable form always appeared when cooling curves were run in the usual way. When kept for some time at a temperature 10 to 20° below its melting point or when suddenly cooled in liquid air the unstable form transformed in the solid state to the stable form with an evolution of heat. It was found possible to get a heating curve on the unstable form immediately after a cooling curve even though the temperature of the sample fell to −102° meanwhile and remained there some twenty minutes. A cooling curve on the stable form was finally obtained on a sample which had been completely transformed in the solid state and then partially melted. This behavior proves that *n*-amyl bromide is dimorphous and further that it is monotropic. It also explains why Simon obtained a freezing point of −95.25° for this compound while Deese[5] obtained −88.0° (see Table I). The former obtained his value by freezing point measurements and the latter by heat content measurements which involved preliminary cooling to much lower temperatures.

An inspection of Table I shows that our freezing points agree acceptably with previous values except in the case of isopropyl bromide and the unstable form of *n*-amyl bromide.

The Estimation of Transference Numbers in Dilute Solutions from Limiting Ionic Conductances

BY BENTON BROOKS OWEN

While the known transference data of simple strong electrolytes can be reproduced with high precision by the empirical evaluation of a single parameter in the Longsworth[1] equation, or by the adjustment of two parameters in the equation of Jones and Dole,[2] the semi-empirical relation

$$T_+ = T_+^0 + \frac{(2T_+^0 - 1)\beta\sqrt{C}}{\Lambda^0 - (\alpha\Lambda^0 + 2\beta)\sqrt{C}}\left[1 - (1 - \alpha\sqrt{C})\sqrt{2C}\right] \quad (1)$$

permits the estimation of certain transference numbers from limiting conductances alone.[3] This equation is formally equivalent to that of Longsworth, but a comparison of coefficients shows that the parameter, A, which Longsworth evaluated from the transference data for each individual electrolyte, may be replaced by the quantity $-\beta\sqrt{2}(2T_+^0 - 1)/\Lambda^0$, characteristic of the whole group of electrolytes conforming to the Longsworth equation. Although this replacement is accompanied by a loss in precision, there are obvious practical advantages afforded by the gain in generality.

TABLE I

TEST OF EQUATION (1) AT 25°

Electrolyte	Λ^0	$T_+^{0\,a}$	$(T_+(\text{Eq. (1)}) - T_+(\text{Obs.}))10^4$		
HCl	426.17	0.8209	−6	−11	−24
$NaC_2H_3O_2$	90.99	.5507	−1	1	4
NH_4Cl*	149.94	.4909	−3	− 6	−12
KCl	149.86	.4906	0	− 1	2
KI*	150.29	.4892	2	− 1	− 7
KBr*	151.63	.4849	7	2	− 8
NaCl	126.43	.3963	−2	− 8	4
LiCl	115.03	.3364	−6	− 9	5
Concentration (moles per liter), $C =$			0.05	0.1	0.2

[a] $\lambda^0_{Cl^-} = 76.34$.

In Table I are recorded the differences between T_+ calculated by Equation (1) and the smoothed experimental values recently tabulated by Longsworth.[4] The average differences are (with increasing concentration) three, five and eight units in the fourth decimal place of the transference numbers. The maximum individual difference amounts to nearly 0.3%. The necessary values of $\Lambda^0(=\lambda_+^0 + \lambda_-^0)$ and $T_+^0(=\lambda_+^0/\Lambda^0)$ are all computed from the table of limiting ionic conductances given by MacInnes, Shedlovsky and Longsworth,[5] except those indicated with an asterisk. Of these latter, $\Lambda^0(KBr)$ is due to Jones and Bickford,[6] $\Lambda^0(KI)$ to Lasselle and Aston,[7] and $\Lambda^0(NH_4Cl)$ is given by Longsworth.[8] All values have been adjusted to conform to the primary conductance standard of Jones and Bradshaw.[9]

Equation (1) is not in accord with the known transference data for silver and potassium nitrates,[4] for calcium[4] and barium[2] chlorides, and for sodium sulfate.[4] Its failure in this respect is parallelled by that of the Longsworth[1] equation, but the results in Table I indicate that we might confidently expect an accuracy of better than one unit in the third decimal place of the transference number when it is applied to *dilute solutions* ($C < 0.15$ normal) *of uni-univalent electrolytes in which ionic association is negligible.* Precise limiting conductances are already available for a number of electrolytes in this category, including the chlorides, bromides, iodides, acetates, propionates, chloro substituted acetates, etc., of lithium, sodium and potassium. The accuracy to be expected in such calculations for the halides of hydrogen and ammonia, and possibly the hydroxides of the alkali metals, would hardly be better than two or three in the third decimal place of the transference numbers at 0.2 normal, but should improve with dilution, because the equation reduces, in the limit, to the theoretical tangent derivable from the Onsager[10] conductance equation. With proper attention to the above limitations, however, it appears that this equation might have considerable application in problems involving diffusion and liquid junction potentials, and in the determination[11] of the activity coefficients of salts (the bromides and iodides of lithium and sodium, for example) at high dilution.

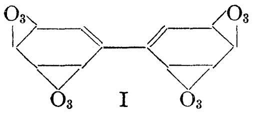
The Ozonation of Certain Hydrogenated Diphenyls

BY C. R. NOLLER AND G. K. KANEKO

During the course of his exhaustive work on the ozonation of organic compounds, Harries found that[1] whereas benzene forms a triozonide in accordance with the Kekulé formula, diphenyl forms only a tetraozonide. He suggested that the tetraozonide had Formula I and that the non-addition of ozone to the double bonds in the 1 and 1′ positions was due to steric hindrance.

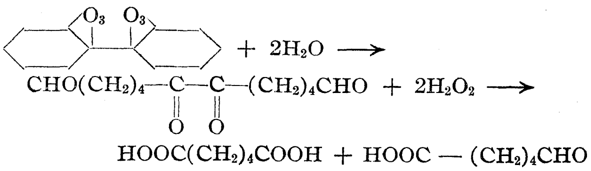


I

II

Because of the difficulty of preparing the tetraozonide, the products formed on decomposition with water have not been identified, but it should be possible to determine whether steric hindrance plays a role by studying compounds such as 1-phenylcyclohexene-1 and dicyclohexenyl-1,1′ (II) in which non-benzenoid double bonds occur in positions similar to those which are supposed to be sterically hindered in benzene.

A review of the literature showed that Brus and Peyresblanques[2] had ozonized 1-phenylcyclohexene-1 and they state that one mole of ozone adds rapidly and quantitatively while benzene adds ozone only slowly. One might be led to believe, however, from the curves given, that the addition was more like that to benzene rather than to an aliphatic double bond. They did not report the decomposition products of the ozonide and it is conceivable as in the case of diphenyl that the ozone is not added to the double bond in the 1- or 1′-position. This work was therefore repeated on 1-phenylcyclohexene-1 and extended to include dicyclohexenyl-1,1′. It was found that phenylcyclohexene adds one mole of ozone as readily as does a simple unsaturated compound such as methyl oleate, and that the ozonide on decomposition with water gives δ-benzoyl-*n*-valeric acid proving that the ozone added to the double bond in the cyclohexene ring. Moreover, dicyclohexenyl-1,1′ was found to add one mole of ozone rapidly while the second double bond added ozone slowly but at a faster rate than benzene. Decomposition of the ozonide did not yield the expected diketo-dibasic acid but adipic acid instead. The reaction may be formulated



$$+ 2H_2O \longrightarrow$$

$$CHO(CH_2)_4—\underset{\underset{O}{\|}}{C}—\underset{\underset{O}{\|}}{C}—(CH_2)_4CHO + 2H_2O_2 \longrightarrow$$

$$HOOC(CH_2)_4COOH + HOOC — (CH_2)_4CHO$$

The aldehyde acid was probably oxidized also to the dibasic acid, due to the exposure to air during the boiling and isolation. Adipic acid could hardly arise from an ozonide other than the diozonide shown and it therefore seems unlikely that steric hindrance, in the sense that there is no room for two ozonide groups to occupy the 1,1′ positions, can account for the non-formation of a diphenylhexaozonide.

During the course of this work the structure of tetrahydrodiphenyl obtained by the reduction of diphenyl with sodium in amyl alcohol[3] also was determined. When diphenyl is reduced by hydrogen in the presence of a nickel catalyst,[4] the products are phenylcyclohexane and dicyclohexyl. This fact led Turner[5] to predict that the tetrahydrodiphenyl of Bamberger and Lodter was a phenylcyclohexene rather than a dicyclohexadiene. Tetrahydrodiphenyl prepared according to the procedure of Bamberger and Lodter was ozonized and found to absorb about 68% of the calculated amount of ozone. Decomposition of the ozonide gave δ-benzoyl-*n*-valeric acid, identical with that obtained from 1-phenylcyclohexene-1. Hence tetrahydrodiphenyl is 1-phenylcyclohexene-1, contaminated with diphenyl or with phenylcyclohexane.

Experimental

Reagents.—1-Phenylcyclohexene-1[6] was prepared by the dehydration of 1-phenylcyclohexanol-1 in 75% yields by distilling 49 g. of the alcohol with 1 g. of potassium bisulfate and 50 cc. of bromobenzene through a 30-cm. Vigreux column as long as water came over (about two hours). The bromobenzene was separated from the distillate and returned to the flask from time to time. Finally all of the bromobenzene was distilled and the product fractionated under a vacuum; b. p. 136–138° (25 mm.).

---

(1) Harries and Weiss, *Ann.*, **343**, 337, 374 (1905).

(2) Brus and Peyresblanques, *Compt. rend.*, **190**, 685 (1930).

(3) Bamberger and Lodter, *Ber.*, **20**, 3077 (1887).

(4) Sabatier and Murat, *Compt. rend.*, **154**, 1390 (1912).

(5) Turner, *Rec. trav. chim.*, **48**, 821 (1929).

(6) Sabatier and Mailhe, *Compt. rend.*, **138**, 1321 (1904).

Dicyclohexenyl-1,1′, b. p. 133–135° (23 mm.) was prepared in 68% yields by dehydrating dicyclohexanediol-1,1′[7] using an analogous procedure. The latter compound was prepared in poor yields by following the procedure given in "Organic Syntheses," Coll. Vol. I, p. 448, for pinacol hydrate. This was found to be superior to the sodium reduction method of Zelinsky.[8]

Tetrahydrodiphenyl was prepared by the procedure of Bamberger and Lodter.[3]

Ozonation and Decomposition of the Ozonides.—Oxygen containing 4–5% ozone was passed into a solution of the compound in glacial acetic acid until a sample no longer decolorized a solution of bromine in carbon tetrachloride. To the acetic acid solution of the ozonide was added 25 cc. of water and the solution refluxed for one hour. The acetic acid and water were distilled under reduced pressure and the residue poured into an evaporating dish to solidify. In the cases of phenylcyclohexene and tetrahydrodiphenyl the products were crystallized from ether and melted at 77–78°; the semicarbazones melted at 191–192° and mixed melting points showed no depression. Auwers and Treppmann[9] report the melting point of δ-benzoyl-*n*-valeric acid as 77–78° and the semicarbazone as 187°.

The crude product of the decomposition of the ozonide of dicyclohexenyl-1,1′ was crystallized from ethyl acetate, when it melted at 152–153° and had a neutralization equivalent of 74.6. Adipic acid melts at 153–153.5° and has a neutralization equivalent of 73. A mixed melting point showed no depression.

Summary

1. 1-Phenylcyclohexene-1 adds one mole of ozone to the double bond in the cyclohexene ring and dicyclohexenyl-1,1′ adds ozone to both double bonds. This indicates that steric hindrance in the 1 and 1′ positions is not the factor involved in the failure of diphenyl to form a hexaozonide.

2. Tetrahydrodiphenyl prepared by reducing diphenyl with sodium and amyl alcohol is chiefly 1-phenylcyclohexene-1.

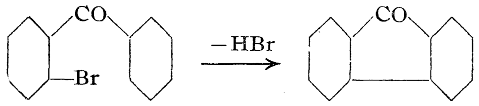
The Higher Benzenoid Hydrocarbons. II. The Isomeric Bromofluorenones[1]

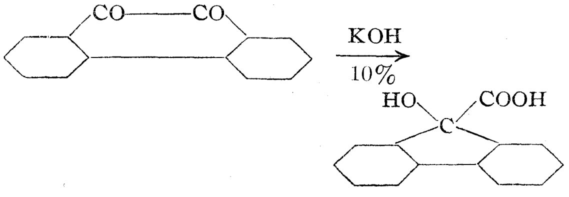
BY HARRY F. MILLER AND G. BRYANT BACHMAN

Of the four possible monobromofluorenones, 2-bromofluorenone is the only one readily available. The preparation of the 4-isomer has never been recorded and the 1- and 3-isomers have been prepared in small quantities only and by way of difficultly accessible intermediates.[2] As a part of our program to elucidate the fundamental chemistry of some of the polycyclic coal tar hydrocarbons it was decided to devise nuclear syntheses for the 3- and 4-bromofluorenones which would make them more readily available and which would serve to establish definitely their structure.

There are five general methods which have been used for the preparation of substituted fluorenones. (1) *Direct substitution.* This serves very well for the preparation of 2-bromo and 2,7-dibromofluorenones. Apparently, however, no other isomers arise in the bromination of either fluorenone or fluorene.[3] (2) *Elimination of hydrogen bromide from substituted o-bromobenzophenones.*



Although this method was used by Montagne to prepare 1- and 3-bromofluorenones, the yields are small and the intermediates difficult to prepare. Furthermore, in view of the high temperatures employed to effect condensation, there is always to be considered the danger of an intramolecular rearrangement. (3) *The rearrangement of phenanthraquinone derivatives.* This is an application of the benzil–benzilic acid rearrangement.



The diphenyleneglycolic acid formed decomposes in the presence of boiling water liberating fluorenone. The method has been used successfully in the preparation of certain nitrofluorenes[4] and of a

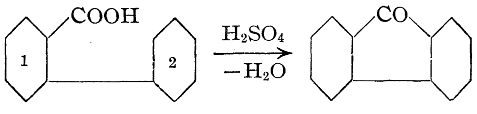
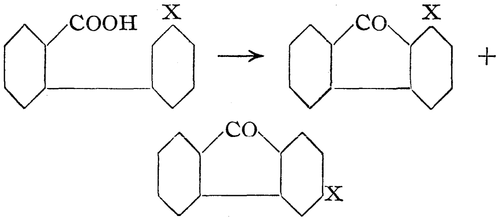
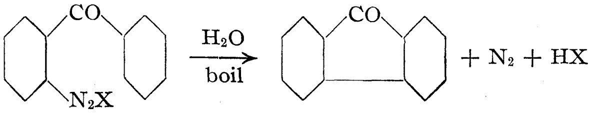
few other fluorene derivatives, but its broader application awaits the further development of phenanthrene chemistry, since in many cases the necessary phenanthraquinones are unknown. The isomeric bromophenanthraquinones have not yet been thoroughly studied. (4) *The dehydration of o-carboxydiphenyl derivatives.* This method is



of particular value in that it gives very high yields as a rule. Applied to the synthesis of substituted fluorenones however it will be noted that the method suffers certain disadvantages if the substituent group is located in the meta position of ring 2. In such cases either one or both of two different isomers may result upon ring closure



Where establishment of structure is being attempted such a mixture might lead to confusion and should be avoided. Furthermore, it has been our experience that mixtures of bromofluorenones are not easily separable. Substituents in ring 1 and in the ortho or para position of ring 2 lead to but one product, however, and since this method is otherwise quite general in its application and relatively simple to apply, it is to be recommended. The above arguments apply to all nuclear fluorenone syntheses in which ring closure of this type occurs. These include methods (2), (4) and (5). *Method* (5) consists in the coupling of diazotized *o*-aminobenzophenone derivatives.[5]



For the present work methods (4) and (5) have been used since they seemed to be most satisfactory from the standpoints of yield, cost, and generality of application. The flow diagram shown in Table I indicates the various steps used for the synthesis of 3- and 4-bromofluorenones. For 3-bromofluorenone the over-all yield from phthalic anhydride (5 steps) was 55%, from anthranilic acid (4 steps) 21%. The 4-bromofluorenone was obtained from bromophthalic anhydride (5 steps) in 25% yield, from *o*-iodobromobenzene and methyl *o*-iodobenzoate (2 steps) in 14% yield. The difficulty of preparing the last two intermediates makes this last synthesis of little practical value. Fortunately 4-bromofluorenone may be obtained more readily by the oxidation of the easily prepared 4-bromofluorene whose synthesis will be described in the succeeding paper.

It should be pointed out that by combinations of the two general methods here used some of the heteronuclear dibromofluorenones could also be prepared. The conversion of the bromofluorenones into the corresponding bromofluorenols and bromofluorenes is described in the succeeding paper.

The Synthesis of 3-Bromofluorenone

2-(4-Bromobenzoyl)-benzoyl Chloride.—The condensation of phthalic anhydride with bromobenzene in the presence of aluminum chloride according to Ullmann and Sone[6] yielded 2-(4-bromobenzoyl)-benzoic acid, m. p. 171–172°, in 83% yields (above authors report 86%). Fifty-three grams of this product, 37 g. of phosphorus pentachloride and 200 cc. of benzene were refluxed until no more hydrogen chloride was evolved. On cooling, the acid chloride separated as white opaque needles; yield 92% theoretical, m. p. 162–163°.

Anal. Calcd. for $C_{14}H_8O_2BrCl$: Br and Cl, 35.66. Found: Br and Cl, 35.48.

2-(4-Bromobenzoyl)-benzamide.—Twenty-five grams of finely powdered acid chloride was added in small portions to 200 cc. of liquid ammonia in a Dewar tube. The mixture was stirred by a stream of air bubbles from a capillary at the bottom of the tube. After the ammonia had evaporated water was added and the residue separated and recrystallized from a mixture of 500 cc. of xylene and 50 cc. of acetone. The amide formed feathery white needles, m. p. 184.5–185.0°, and was obtained in 95% yields.

Anal. Calcd. for $C_{14}H_{10}O_2NBr$: Br, 26.20. Found: Br, 26.05.

2-(4-Toluenesulfonamido)-benzoyl Chloride.—Anthranilic acid was converted into its *p*-toluenesulfonanilide (yield 86%, m. p. 217–218°)[5b] and then into the corresponding acid chloride[7] with phosphorus pentachloride (yield 96%, m. p. 129°). In this latter reaction it was found simplest to use no solvent since the acid is but slightly soluble in benzene and other inert solvents.

2-(4-Bromobenzoyl)-aniline. First Procedure.—Ten grams of 2-(4-bromobenzoyl)-benzamide and 30 cc. of 10% sodium hydroxide solution were made into a thin paste in a mortar. A sodium hypobromite solution was prepared from 15 g. of sodium hydroxide, 13 g. of bromine

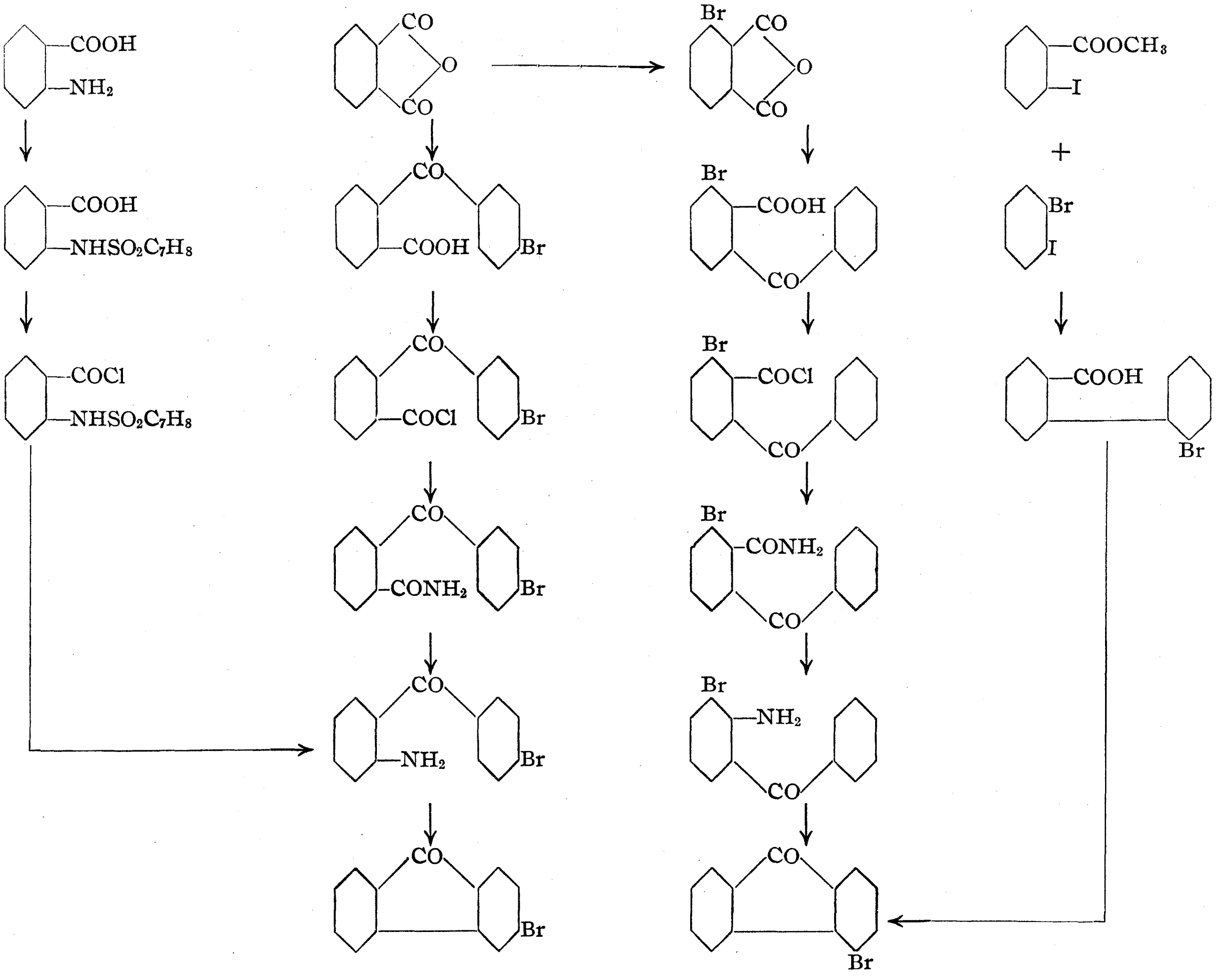
TABLE I

SYNTHESIS OF 3- AND 4-BROMOFLUORENONES



and 100 cc. of water. The mixture was cooled in an ice-bath and the amide paste added in small portions with vigorous stirring. Most of it dissolved. After standing for one hour in the cold, the solution was filtered, 5 cc. of ethanol added, and the mixture then boiled for one-half hour and allowed to stand for one day. The yellow amine crystallized in a cake and was filtered and dried. It melted at 107–108° and was pure enough for further synthesis. The filtrate was boiled with 20 cc. of saturated sodium bisulfite solution and on cooling deposited 1.5 g. of unchanged amide. On acidification, the second filtrate precipitated 3.9 g. of 2-(4-bromobenzoyl)-benzoic acid. The total yield of amine was 3.8 g. (82.5%, based on the amide used).

Second Procedure.—Fifty-three grams of 2-(4-toluenesulfonamido)-benzoyl chloride was refluxed with 100 g. of bromobenzene until solution took place. One hundred grams of anhydrous aluminum chloride was added to the cooled solution and the mixture warmed on the water-bath, gently at first, and then at the boiling point for eight hours. The mass was cooled, decomposed with ice, water and hydrochloric acid, the water layer decanted, and the pitch-like solid steam distilled to remove excess bromobenzene. The remaining dark solid sulfonamide was too insoluble to be purified by solution in alkali, therefore it was converted directly to the amine. This was done by dissolving the crude product in a mixture of 300 cc. of 90% sulfuric acid and 150 cc. of glacial acetic acid, heating for three hours on the water-bath, and then allowing to stand overnight. The solution was poured into 3 liters of water and filtered. The clear filtrate was neutralized cautiously with concentrated sodium hydroxide. On cooling, bright yellow needles of the amine, melting at 108°, formed. By treating the residue once more with sulfuric acid, as above, a further quantity of amine was obtained; total yield 12.9 g. (28% of theoretical).

Third Procedure. The Oesterlin Reaction.—Oesterlin[8] has proposed a general method for the conversion of carboxy acids into amines directly. In applying this reaction to 2-(4-bromobenzoyl)-benzoic acid the expected synthesis occurred to a very small extent only and the dimorph of the original acid was obtained as the principal product. Eight and seven-tenths grams of acid dissolved in 50 cc. of chloroform was treated with 50 cc. of concd. sulfuric acid, the temperature being maintained at 40–45°. To the mixture was then added in small portions 1.8 g. of

---

[8] Oesterlin, *Z. angew. Chem.*, **45**, 536 (1932).

sodium azide. There was a vigorous gas evolution after each addition. The mixture was held at 40° for one hour and then poured into 600 cc. of cold water. The white solid which precipitated was filtered and dried. It weighed 7.3 g., melted at 158°, and proved to be the dimorph of the original acid. After resolidification it melted at 173° and was identical with the original acid. The yellow-colored filtrate was made alkaline with 10% sodium hydroxide. On standing 0.15 g. of 2-(4-bromobenzoyl)-aniline precipitated; yield 1.9%, m. p. 106–107°.

Anal. Calcd. for $C_{13}H_{10}OBrN$: Br, 28.95. Found: Br, 28.77.

3-Bromofluorenone.—To 5 g. of 2-amino-4-bromobenzophenone suspended in 50 cc. of water was added 4 cc. of concentrated sulfuric acid. The amine dissolved in the hot solution, but the amine sulfate quickly precipitated as a fine suspension. This suspension was cooled to 10° and diazotized with 1.3 g. of sodium nitrite in 3 cc. of water. The sulfate first dissolved and the solid diazo compound on warming gradually took on the yellow color characteristic of fluorenones, and, after standing for three hours, was filtered by suction, washed with water and then warmed with 5% sodium hydroxide solution in a beaker, with stirring. The solid was again filtered, washed well with water and air dried. Recrystallization from benzene gave light yellow needles, melting at 162°; total yield 4.3 g. (92% of theoretical).

Anal. Calcd. for $C_{13}H_7OBr$: Br, 30.73. Found: Br, 30.67.

The Synthesis of 4-Bromofluorenone

2-Benzoyl-6-bromobenzoyl Chloride.—To 7.8 g. of 2-benzoyl-6-bromobenzoic acid, prepared from bromophthalic anhydride, benzene and aluminum chloride according to the directions of Stephens,[9] were added 5.5 g. of phosphorus pentachloride and 25 cc. of benzene. The mixture was refluxed for forty-five minutes, then cooled, and 25 cc. of ligroin added. Light brown prisms of the acid chloride, m. p. 119–120°, separated; yield 7.1 g., 85.9%.

Anal. Calcd. for $C_{14}H_8O_2ClBr$: Br and Cl, 35.66. Found: Br and Cl, 35.70.

2-Bromo-6-benzoylbenzamide.—A mixture of 5 g. of 2-benzoyl-6-bromobenzoyl chloride and 15 g. of finely powdered ammonium carbonate was heated until gas evolution began. It was maintained at this temperature with stirring for ten minutes and then cooled. Water was added and the insoluble residue separated, dried and recrystallized from 150 cc. of xylene. The amide formed white matted needles, m. p. 135–140°; yield 4.2 g., 87%.

Anal. Calcd. for $C_{14}H_{10}O_2BrN$: Br, 26.20. Found: Br, 26.09.

2-Bromo-6-benzoylaniline.—Three grams of 2-bromo-6-benzoylbenzamide was subjected to the Hofmann degradation in a manner similar to that used in the preparation of 2-(4-bromobenzoyl)-anilines. On heating to boiling an oily yellow liquid separated which solidified on cooling. Recrystallization from alcohol gave 1.6 g. of the amine, m. p. 128–130°, a 57% yield. Acidification of the filtrate gave 0.8 g. of 2-bromo-6-benzoylbenzoic acid, formed by the hydrolysis of part of the amide.

Anal. Calcd. for $C_{13}H_{10}OBrN$: Br, 28.95. Found: Br, 28.76.

2-Bromo-2′-carboxydiphenyl.—A 500-cc., three-necked flask was fitted with a stirrer, an air condenser, and a 400° thermometer. Fifty-three grams of methyl-*o*-iodobenzoate and 56 g. of *o*-bromoiodobenzene were placed in the flask and the mixture heated to 260° in a Woods metal bath. Sixty grams of copper powder which had been treated as recommended by Kleiderer and Adams[10] was then added over a one-hour period to the vigorously stirred mixture, after which the temperature was raised to 290°, kept there for a further half hour, and then allowed to cool. The voluminous precipitate of copper iodide was extracted with two 150-cc. portions of boiling ethanol, which were combined and evaporated to 100 cc. This solution then was refluxed for eight hours with 500 cc. of 10% sodium hydroxide solution, and cooled. The water layer was filtered and acidified slowly with dilute acetic acid. A precipitate formed on standing which was filtered, redissolved in sodium hydroxide solution, and again precipitated as above with acetic acid. The product so obtained was recrystallized from 80% acetic acid to give 5.7 g. (14% yield) of 2-bromo-2′-carboxydiphenyl, white clumps, which darkened on standing, and melted at 186–187°.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.84. Found: Br, 28.61.

The combined filtrates, on acidification with dilute hydrochloric acid, gave 15.6 g. of diphenic acid, m. p. 227°.

4-Bromofluorenone. First Procedure.—Two grams of 2-bromo-6-benzoylaniline was added with stirring to 20 cc. of 25% sulfuric acid. The amine sulfate immediately precipitated in a finely divided form. After cooling to 10° diazotization was effected with 1 g. of sodium nitrite dissolved in 3 cc. of water. The precipitate slowly changed to a lighter shade of color. The solution was allowed to warm up to room temperature, and after five hours' standing was heated to boiling. As soon as the precipitate clumped together and turned yellow, the mixture was cooled and the yellow solid filtered, and stirred into 50 cc. of 10% sodium hydroxide solution. The undissolved solid was filtered, washed with water several times, and dried. When recrystallized from benzene, 1.3 g. of 4-bromofluorenone, m. p. 185–187°, was obtained in the form of light yellow clumps. This corresponded to a 70% yield.

Second Procedure.—One gram of 2-bromo-2′-carboxydiphenyl was heated on a steam-bath with 40 cc. of concentrated sulfuric acid for one-half hour. The hot mixture was poured onto 500 cc. of ice and allowed to stand an hour with occasional stirring, after which the yellow solid was filtered with suction and air-dried. Recrystallization from benzene gave light yellow needles, melting at 190–191°; yield quantitative.

Anal. Calcd. for $C_{13}H_7OBr$: Br, 30.73. Found: Br, 30.61.

Summary

1. 3- and 4-bromofluorenones have been prepared by nuclear syntheses and their properties described.

The Higher Benzenoid Hydrocarbons. III. The Isomeric Monobromo-9-fluorenols and Monobromofluorenes

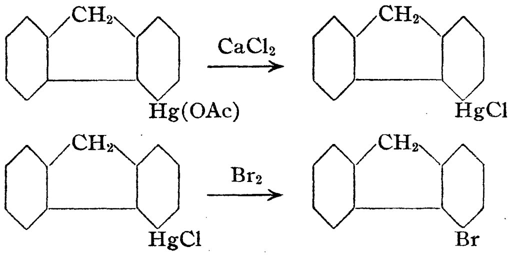
BY HARRY F. MILLER AND G. BRYANT BACHMAN

The reduction of the bromofluorenones with zinc dust and alcoholic ammonia leads to the formation of the corresponding bromo-9-fluorenols in excellent yields. However, the subsequent reduction of these bromofluorenols to bromofluorenes is not always readily accomplished because of the lability of the bromine atoms particularly in the 3-position. We found that with hydriodic acid and phosphorus 3-bromo-9-fluorenol yields fluorene only. Montagne and Moll[1] have also called attention to the ease with which the bromine in this position is removed on reduction with sodium amalgam in boiling alcohol. This lability is rather remarkable in view of the equally great stability of the bromine atom in the 2-position. It was shown previously[2] that 2-bromofluorene either does not yield a Grignard reagent or does so with unusual difficulty. Loevenich, Becker and Schröder[3] have shown that toward potassium phenolate and sodium acetate 2-bromofluorene is only about 50–75% as reactive as bromobenzene and is similar to meso-bromoanthracene in stability. The contrast between 2- and 3-bromofluorenes is reminiscent of the similar contrast in stability offered by 1- and 2-bromonaphthalenes.

Preparation of the bromofluorenes by direct reduction of the bromofluorenones by Clemmensen's method is highly satisfactory even in the case of 3-bromofluorene. Of the five possible monobromofluorenes only two, 2-bromofluorene[4] and 9-bromofluorene[5] have been prepared previously. In the present work 3- and 4-bromofluorenes have been obtained for the first time by reduction methods from the bromofluorenones described in the preceding paper.

Mercuration of Fluorene

Having once established the structure of the isomeric bromofluorenes by nuclear synthesis, it was decided to determine the position or positions in which fluorene mercurates, by heating the hydrocarbon with mercuric acetate and converting the product into one or more bromofluorenes as the case might be. As is well known, the entering mercuric group often attaches itself to a different position than that attacked by other reagents such as the halogens, nitric acid, sulfuric acid, etc. In the case of fluorene all of these latter reagents enter the 2-position first and the 7-position next, so that with bromine for example, the 2- and the 2,7-derivatives only are obtained by direct substitution. Goswami and Das-Gupta[6] report that fluorene reacts with mercuric acetate, but the structure of the product was not elucidated. We find that in the presence of acetic acid fluorene mercurates predominantly in the 4-position. In the absence of solvents some of the 3-isomer is also formed. By treatment of the product with alcoholic calcium chloride and subsequent bromination of the fluorene mercurichloride, good yields of 4-bromofluorene were obtained.



3-Bromofluorene was also prepared by this method.

An interesting point may be raised in view of the above results. Conant and Wheland[7] and others have offered the idea that in the reaction

$$RH + R'Na \longrightarrow RNa + R'H$$

the hydrocarbon RH may be regarded as a very weak acid, which is, however, relatively stronger than R'H for it is able to abstract Na from the salt R'Na. For instance, fluorene is a stronger acid than triphenylmethane, for it abstracts sodium from triphenylmethyl–sodium to form fluoryl-9-sodium. A whole series of compounds in the order of their acidities may be formed by

such competitive reactions. Gilman[8] suggests further that if metalation is a function of relative acidities, then the most acid hydrogen atom in an aromatic compound is that replaced in the metalation reaction. Accordingly, he calls the hydrogen atom in the 4-position in dibenzofuran more acidic than those in the 2- or 3-positions. Such a statement is inapplicable to fluorene, for, if it were true, fluorene should mercurate in the 9-position. It is recognized that the hydrogen atoms in the methylene bridge are very active, as shown by many condensation reactions, by the fact that ethane is liberated from ethylmagnesium bromide to form fluoryl-9-magnesium bromide and by the fact that fluorene will form fluoryl-9-sodium by reaction with sodium triphenylmethyl. Gilman's hypothesis might be modified to state that mercuration may only determine the most acidic hydrogen atom on a truly aromatic hydrocarbon ring.

The Dibromo and Chlorobromofluorenes

By saturating alcoholic solutions of the bromo-9-fluorenols with hydrogen bromide or hydrogen chloride the corresponding *x*-9-dibromo- and *x*-bromo-9-chlorofluorenes were obtained. The properties of these and the other fluorene derivatives prepared are indicated in Table I. Further work on the preparation and reactions of the Grignard reagents of the isomeric bromofluorenes is now under way.

TABLE I

BROMO DERIVATIVES OF FLUORENE

Substance	Cryst. form	Yield, %	M.p., °C.	Anal. for halogen Calcd.	Anal. for halogen Found
2-Bromofluorenol[a]	Fluffy needles	97	130		
3-Bromofluorenol	White plates	85	142–145	30.62	30.45
4-Bromofluorenol	Feathery needles	92	149–150	30.62	30.57
2-Bromofluorene[a]	White plates	82	110		
3-Bromofluorene	Short needles	Quant.	90–91	32.61	32.51
4-Bromofluorene	Needles	80	165	32.61	32.49

3-Bromo-9-chlorofluorene	Fluffy needles	87	116–117	41.28	41.08
4-Bromo-9-chlorofluorene	Matted needles	86	141–142	41.28	41.11

[a] Previously recorded in the literature.

Experimental

Reduction of Bromofluorenones to Bromofluorenols with Zinc and Alcoholic Ammonia.—The reduction of one isomer only will be described since the procedure in all other cases was similar.

Three and five-tenths grams of 4-bromofluorenone, 14 g. of zinc dust, 110 cc. of ethanol and 20 cc. of concentrated ammonium hydroxide were refluxed for one hour and filtered hot. Water was added to precipitate a gelatinous mass of 4-bromofluorenol. This was filtered by suction, pressed down well, and washed with 40% ethanol. After drying and recrystallizing from benzene, 3.2 g. of feathery white needles, m. p. 149–150°, was obtained, a 91.5% yield.

Reduction of Bromofluorenols to Bromofluorenes.—Although 2-bromofluorene is known, its preparation from the corresponding fluorenol has never been recorded.

One gram of 2-bromofluorenol, 1 g. of red phosphorus and 1 g. of iodine were refluxed for two hours in a solution of 20 cc. of glacial acetic acid and 2 cc. of water. The hot solution was filtered and added to 200 cc. of cold water containing 4 cc. of saturated sodium bisulfite solution. The white precipitate which formed was filtered after standing for one hour. Recrystallization from alcohol yielded a pure product melting at 110° alone or when mixed with an authentic sample of 2-bromofluorene. The material weighed 0.75 g., corresponding to an 82% yield.

Reduction of Bromofluorenones to Bromofluorenes.—One gram of 3-bromofluorenone and 20 cc. of ethanol were added portionwise over a three-hour period to a refluxing mixture of 7 cc. of concentrated hydrochloric acid, 3 cc. of water and 25 g. of amalgamated zinc. During this period 10 cc. of concentrated hydrochloric acid also was added portionwise. The mixture was refluxed three more hours, and the liquid portion decanted hot. The zinc was washed with two 5-cc. portions of hot ethanol, and the washings added to the main solution. On cooling short white needles formed, which were recrystallized from hot ethanol. Long white needles formed, melting at 90–91°. The yield was practically quantitative.

Preparation of *x*-9-Dibromofluorenes.—A solution of 3 g. of 3-bromofluorenol in 15 cc. of ethanol was saturated in the cold with dry hydrogen bromide. The mixture was stoppered tightly and left in the ice-bath, which was allowed to warm up overnight. Short stubby needles of 3,9-dibromofluorene formed which, after two days of standing, were filtered at the pump, washed with 50% alcohol, and dried. They melted at 124–125°. A second small crop was obtained by diluting the filtrate with water. The total yield was 3.1 g. (92%).

---

[8] Gilman and Young, THIS JOURNAL, **56**, 1415 (1934).

Preparation of *x*-Bromo-9-chlorofluorenes.—Two grams of 4-bromofluorenol was dissolved in 10 cc. of ethanol and saturated in the cold with dry hydrogen chloride. The container was well stoppered and left in the ice-bath, which was allowed to come to room temperature. Unlike the other chlorides, this one precipitated first as an oil, and it was necessary to add a few drops of water to the mixture and place it in an ice-chest to induce it to crystallize. The white matty needles were filtered by suction, washed with 50% ethanol and recrystallized from benzene to give 1.94 g. of white needles melting at 141–142°, an 86% yield.

Mercuration of Fluorene in the Absence of a Solvent.—Eighty-three grams of fluorene was melted in a 2-liter round-bottomed flask and 159 g. of mercuric acetate added as soon as the temperature of the melt reached 125°. By means of an oil-bath the temperature of the melt was raised to 145°, at which point acetic acid began to distil (hood). The melt was held at this temperature for twenty-five minutes, at the end of which time the reaction had ceased, as indicated by the cessation of acetic acid fumes. The mixture was cooled to 110° and 500 cc. of glacial acetic acid added. The fluorene mercuriacetate went into solution easily. The solution was immediately treated with 2500 cc. of a saturated alcoholic calcium chloride solution. The mixed fluorene monomercurichlorides immediately precipitated in a voluminous mass, which was filtered hot and washed with glacial acetic acid, hot benzene, more glacial acetic acid, and finally with water. The air-dried white powder weighed 136 g., a 66% yield. However, 16 g. of pure fluorene was recovered from the filtrate, which raised the yield by difference to 81.4%. The product did not melt below 225°, and was shown to be a mixture of the 3- and 4-isomers in the ratio of approximately 3:1 by conversion of the mixture into the corresponding bromofluorenes and separating by recrystallization. The separation of the mixed mercurichlorides was not attempted due to their insolubility in all solvents tried.

The product obtained did not correspond with that of Goswami and Das-Gupta. These authors describe their unknown fluorene mercurichloride as a light pink solid melting at 130–132° with decomposition.

Bromination of the Mercurated Fluorene Mixture.—Eighty grams of the mixed mercurichlorides, obtained by mercuration of fluorene in the absence of a solvent, was suspended in 150 cc. of glacial acetic acid in a 500-cc. round-bottomed flask. Thirty-two grams of bromine in 25 cc. of glacial acetic acid was added with efficient stirring over a seven-hour period. The mixture was heated to boiling and filtered hot. Hydrogen sulfide was passed into the hot filtrate to remove dissolved mercury compounds, and the mixture was filtered again. As the filtrate cooled, a white crystalline precipitate slowly formed. This was removed by filtration and several more crops obtained by successive evaporation of the solvent. Each crop melted over a wide temperature range. The combined product totalling 35.4 g. (72.2% yield) was added to a mixture of 500 cc. of ligroin and 25 cc. of benzene. This mixture was boiled for five minutes and filtered hot, approximately two-thirds of the solid dissolving. On evaporation of the solvent a white waxy solid was obtained which was recrystallized from 75 cc. of glacial acetic acid. The 22.1 g. (45% yield) of white flaky material so obtained melted at 148–149°, and proved to be 4-bromofluorene. The ligroin insoluble portion was recrystallized twice from glacial acetic acid to give 7.2 g. (14% yield) of 3-bromofluorene, m. p. 88–94°.

Mercuration of Fluorene in Acetic Acid.—Eighty-three grams of fluorene, 159 g. of mercuric acetate and 250 cc. of glacial acetic acid were refluxed for twelve hours. A pink-colored solid settled out during the last six hours. The solution was filtered hot and 250 cc. of a saturated alcoholic calcium chloride solution added with stirring. A pink-colored precipitate formed immediately. This was filtered and washed with glacial acetic acid, hot benzene, glacial acetic acid and finally water. The color was not removed by this treatment. The solid after being air-dried weighed 40 g. (63% yield based on the fluorene used). The product melted at 235–240° with darkening at 165°. It was shown by bromination to be practically pure fluorene-4-mercurichloride.

Bromination of Fluorene-4-mercurichloride.—Forty grams of fluorene-4-mercurichloride suspended in 200 cc. of glacial acetic acid was brominated with 14.5 g. of bromine in 25 cc. of glacial acetic acid during an eight-hour period. The product was isolated as before. All of it melted from 145–148° and recrystallization from acetic acid gave white needles; m. p. 165°; yield 16.1 g. (66%). 4-Bromofluorene also crystallizes occasionally in white plates.

Oxidation of 3- and 4-Bromofluorenes.—In order to establish further the structure of the 3- and 4-bromofluorenes obtained through mercuration, they were converted into the corresponding bromofluorenones by oxidation with sodium dichromate and acetic acid. The products so obtained were identical with the bromofluorenones obtained in the preceding paper by ring closure methods.

Five and six-tenths grams of 4-bromofluorene and 16 cc. of glacial acetic acid were placed in a 120-cc. round-bottomed flask fitted for reflux. The mixture was brought to a vigorous boil and a hot mixture of 20 g. of technical sodium dichromate, 10 cc. of water and 28 cc. of glacial acetic acid was added by means of a dropping funnel over a one-half hour period, in such a manner that no lumps of unreacted material separated. After refluxing vigorously for three hours, the hot material was poured into 200 cc. of ice and water, allowed to stand for two hours, filtered by suction and washed, first with 4% sulfuric acid, and then several times with water. The air-dried material was dissolved in 15 cc. of benzene and left to crystallize. Five and nine-tenths grams (96%) of yellow needles of the ketone was obtained, melting at 185–187°.

Summary

1. The 2-, 3- and 4-monobromo-9-fluorenols and monobromofluorenes have been prepared by the reduction of the corresponding monobromofluorenones.

2. The monobromo-9-fluorenols have been converted into the corresponding *x*,9-dibromofluorenes and *x*-bromo-9-chlorofluorenes.

3. The mercuration of fluorene with mercuric acetate in the presence and in the absence of

a solvent has been studied. The preparation of 3- and 4-bromofluorenes from the resulting fluorene mercury derivatives has been described.

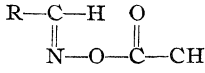
The Removal of Hydrogen and Acid Radicals from Organic Compounds by Means of Bases. II. The Removal of Acetic Acid from Acetyl-aldoximes by Alkalies

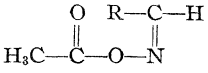
BY CHARLES R. HAUSER AND EARL JORDAN

As part of a general program on the removal of the elements of acids from organic compounds by means of bases it was of interest to study the removal of acetic acid from geometrically isomeric acetyl-aldoximes, (I) and (II).



$$\begin{array}{ccccc} R-C-H & & O & & \\ \| & & \| & & \\ N & -O- & C & - & CH_3 \end{array}$$

(I) *syn* (α)



$$\begin{array}{cccc} & O & & R-C-H \\ & \| & & \| \\ H_3C- & C & -O- & N \end{array}$$

(II) *anti* (β)

It is well known that in the presence of alkali one of these isomers eliminates acetic acid more readily than the other. Indeed, this reaction is used to distinguish a pair of geometrically isomeric aldoximes; the isomer whose acetyl derivative more readily forms nitrile is designated the β-, whereas the other is designated the α-isomer. Formerly, it was assumed that the unstable (β-) acetate had the *syn* configuration simply because the hydrogen atom and acetate group are in closer proximity in (I) than in (II); this view was based presumably on the assumption that the elements of acetic acid were removed simultaneously. At the present time, however, the unstable (β-) acetate is assigned the *anti* configuration (II), whereas the more stable (α-) isomer is assigned the *syn* (I). This view is based on a good deal of experimental evidence[1] accumulated during the past ten years. It is supported also on theoretical grounds on the basis of the hypothesis that, in the formation of nitrile, a proton is removed first by the action of alkali followed by the release of the acetate ion. According to Mills,[2] after the removal of a proton, the movement of the nitrogen nucleus to form the triple bond of the nitrile favors the release of the acetate ion, only in the case of the isomer with configuration (II). It should be pointed out also that the proximity of the acetate group to the hydrogen atom in (I) might offer some steric hindrance to the removal of the proton, thereby hindering the release of the acetate ion and formation of nitrile.

Although the reactions of acetyl aldoximes with alkalies have been studied extensively in connection with the determination of configurations of aldoximes there appears to have been relatively little quantitative work carried out under controlled conditions. In this investigation we have studied these reactions at definite temperatures and in most cases have isolated almost quantitative yields of products. The results are given in the following tables. The melting points of the crude products and those recorded in the literature are listed consecutively following the yields. In most cases the melting points of the crude products were either practically the same as those reported in the literature or were raised to these values after one recrystallization.

Discussion

It is often stated or implied in the literature that acetyl-α-, and acetyl-β-aldoximes react entirely differently toward alkali, that the α- give only oxime, and the β- only nitrile. Recently, however, it has been shown[3] that with sodium hydroxide certain acetyl-β-aldoximes give both nitrile and oxime, the yields of these products being dependent on the temperature, and now it has been found that at the temperature of the boiling water-bath at least certain acetyl-α-aldoximes with alkali give some nitrile in addition to the corresponding oxime.

It can be seen from Table I that, in general, acetyl-β-benzaldoximes with 2 *N* sodium hydroxide gave higher yields of oxime than nitrile at 0°, but greater yields of nitrile at 30°. These results confirm and extend those previously reported.[3]

In Table II are given the yields of products obtained from the reactions of certain acetyl-α-benzaldoximes with 2 *N* sodium hydroxide. It can be seen that at 61–64° the 2-nitro derivative

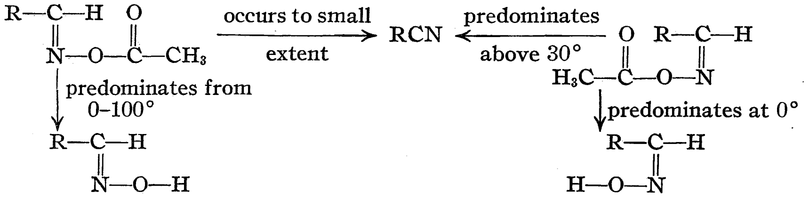
[a] The corresponding amide was obtained in this case.

gave some nitrile and acid in addition to the corresponding oxime, and at the temperature of the boiling water-bath several of the other acetyl-α-derivatives also gave appreciable yields of the acid. Even at 30° it has been possible to isolate small quantities of acid from the nitro derivatives. Although most of the yield of the carboxylic acid reported in each case in Table II was probably produced by the hydrolysis of the corresponding nitrile formed from the acetyl derivative by elimination of acetic acid, a small percentage of it was apparently produced, directly or indirectly, by a reaction of alkali with the α-oxime which was formed by the hydrolysis of the acetate. The yields of acid obtained from blanks determined with α-oximes are given in brackets in Table II. The actual yields of acid obtained from the acetyl derivatives through the intermediate formation of nitrile may be calculated by subtracting the blanks from the yields reported in this table. The small quantities of acid obtained from the oximes were probably also produced through the intermediate formation of nitrile formed from the oxime by elimination of water.

Since it is unlikely that these acetyl-α-derivatives rearranged[4] to the corresponding β-isomers previous to elimination of acetic acid, these results indicate that acetyl-α- and acetyl-β-benzaldoximes undergo fundamentally the same types of reaction with sodium hydroxide; they form oxime by hydrolysis and nitrile by elimination of acetic acid as represented by the scheme.



The yields of products in each case depend on the relative rates of the two competing reactions. It is obvious that with acetyl-β-aldoximes at 0° the hydrolysis proceeds more rapidly than the elimination of acetic acid, but at 30° or above, the elimination process is more rapid; whereas with the α-isomers,[5] the hydrolysis is more rapid than the elimination reaction even at 100°. At 30°, most acetyl-α-derivatives form an almost negligible yield of nitrile.[6] It is noteworthy that the elimination reaction apparently has a higher temperature coefficient than the hydrolysis.

The fact that at a given temperature the acetyl-β-aldoximes give much higher yields of nitrile, and correspondingly lower yields of oxime than

---

(4) It should be pointed out that aldoximes tend to undergo the reverse change in alkaline solution. At 30° β-oximes are relatively stable but at the temperature of the boiling water-bath they are converted within a few hours to the α-isomers and corresponding carboxylic acids.

(5) There is a possibility that at 100° certain α-aldoxime acetates might give more nitrile than oxime.

(6) This is not the case, however, with certain carbethoxy-α-benzaldoximes; at 30°, the 2-nitro derivative gives a higher yield of nitrile than oxime (see following paper).

the α-isomers indicates, that the β-isomers eliminate acetic acid much more rapidly than the α-, or that the latter are hydrolyzed much more readily. Actually, β-3,4-methylenedioxybenzaldoxime acetate undergoes hydrolysis somewhat more rapidly than the corresponding α-isomer; therefore the β-derivative must eliminate the elements of acetic acid much more readily than the α-isomer in order to account for the much higher yield of nitrile produced. From Table III it can be seen that with aqueous[7] or alcoholic sodium hydroxide the β-acetate is hydrolyzed more rapidly than the α-isomer. The 64 and 70% yields of oxime obtained from the β-acetate after three minutes at -8 and 0°, respectively, correspond to practically complete decomposition of this derivative (see Table I). On the other hand, the α-acetate was only 53 and 69% decomposed under the same conditions.[8]

On the basis of the hypothesis proposed for the formation of nitrile it should be expected that the rate of removal of acetic acid from an acetyl aldoxime would be dependent on the activity of the aldehydic hydrogen atom and on the strength of the base used. The activity of the hydrogen atom is apparently dependent on at least two factors, (a) on polarity, as influenced by the presence of so-called negative atoms or groups, and (b) on a steric factor.

Since the acetate group and the aldehydic hydrogen atom are closer in a *syn* acetate (I) than in the *anti* isomer (II), it would appear that the relative unreactivity of the hydrogen atom in the former is at least in part due to a steric factor.

Of the *syn* (α-) acetates studied in this investigation, only the *o*-nitro derivative gave nitrile fairly readily (36% at 61–64°). It is probable that the greater yield of nitrile obtained in this case is due primarily to an increased rate of elimination of acetic acid rather than to a retarded hydrolysis, since the presence of the nitro group in *o*-nitrobenzalchlorimine ($RCH{=}NCl$) greatly facilitates the removal of hydrogen chloride by alkali.[9] Apparently the nitro group in the ortho position in both the aldchlorimine and the acetyl aldoxime greatly enhances the reactivity of the aldehydic hydrogen atom.

It was of interest to study the reactions of acetyl aldoximes with certain other alkaline reagents. Sodium carbonate has often been used instead of sodium hydroxide to distinguish α- and β-isomers;[10] the β- gives mostly nitrile, whereas the α- is either unattacked or is hydrolyzed to the corresponding oxime. Contrary to the results recently reported[11] it has now been found possible to isolate low yields of oxime in addition to high yields of nitrile from the reaction products of certain acetyl-β-benzaldoximes and sodium carbonate. These results are given in Tables III and IV. From Table III it can be seen that, similar to the results obtained with sodium hydroxide, β-3,4-methylenedioxybenzaldoxime acetate is hydrolyzed by excess sodium carbonate in aqueous acetone solution more rapidly than the corresponding α-isomer. After six minutes at 0°, approximately the same yields (12–15%) of oxime were obtained from both isomers. Since a 30% yield of oxime was obtained from the β-acetate on complete decomposition, the 12–15% yield of oxime obtained after six minutes corresponds to approximately 50% decomposition of the β-acetate. On the other hand, the α-acetate was only 12–15% decomposed under the same conditions.

It is to be observed that the yields of oxime obtained with sodium carbonate are much lower, and the yields of nitrile correspondingly higher, than those obtained with sodium hydroxide (see Table I). This rather striking fact suggests that the carbonate ion is capable of removing the elements of acetic acid from β-acetates to form nitrile, but has relatively little if any effect on the hydrolysis, whereas the hydroxyl ion brings about both reactions. The high concentration of carbonate ion and low concentration of hydroxyl ion in the carbonate solution would then cause the elimination reaction to proceed at a relatively rapid rate, and the hydrolysis at a relatively slow rate.

It seemed possible that acetyl-α-aldoximes might form considerable nitrile when treated with

---

[7] A part of the difference in rate with aqueous sodium hydroxide might be due to a difference in solubility. Although the α-aldoxime acetate is more soluble in ether or benzene, the β-isomer appears to be more soluble in water. This is being studied.

[8] It is possible that certain α-aldoxime acetates might be hydrolyzed more rapidly than the corresponding β-isomers, but it is not likely that there would be any great difference in their rates.

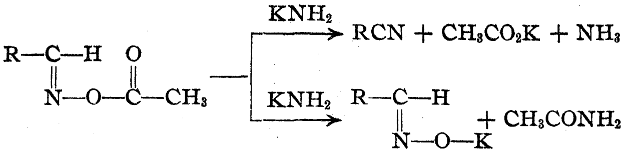
[9] The rates of removal of hydrogen chloride from $RCH{=}NCl$ by alkali in alcoholic solution are in general in the same relative order as the ionization constants of the corresponding acids (RCOOH). In this reaction nitrile is formed almost quantitatively. Hauser, LeMaistre and Rainsford, THIS JOURNAL, **57**, 1056 (1935).

[10] Brady has found that certain acetyl-β-aldoximes are relatively stable in sodium carbonate. See *J. Chem. Soc.*, **117**, 1045 (1920); **123**, 1800 (1923); **125**, 1419 (1924).

[11] It has usually been considered that acetyl-β-aldoximes with sodium carbonate give only nitrile. Also in a recent paper[3] it was reported that it was not possible to isolate oxime from the reaction products of certain acetyl-β-aldoximes and sodium carbonate.

sodium ethylate or potassium amide, which are stronger bases than sodium hydroxide. However, when certain acetyl-α-aldoximes were added to sodium ethylate[12] in absolute alcohol at the refluxing temperature, the sodium salt of the corresponding oxime precipitated almost immediately, very little acid being produced (see Table V). Apparently the rate of the reaction leading to the formation of the oxime (alcoholysis) was more rapid than the elimination reaction.

As was expected the reaction of potassium amide in liquid ammonia with acetyl-α-aldoximes formed considerable nitrile, in addition to the corresponding oxime. The yields of products are given in Table VI. It is probable that the reaction took place as represented by the equations



$$R{-}\underset{\displaystyle N{-}O{-}\underset{}{C}{-}CH_3}{\overset{}{C}}{-}H \quad (\overset{O}{\|}) \longrightarrow \begin{cases} \xrightarrow{KNH_2} RCN + CH_3CO_2K + NH_3 \\ \xrightarrow{KNH_2} R{-}C{-}H\ (=N{-}O{-}K) + CH_3CONH_2 \end{cases}$$

Evidently, the rate of removal of acetic acid from the α-acetate was more rapid than the reaction leading to the formation of oxime (ammonolysis).

Finally, it should be mentioned that the products of reaction of acetyl aldoximes with alkalies at 100° often had the isocyanide odor. However, it has not been possible to isolate an isocyanide; even attempts to obtain a positive test for an isocyanide failed. It is evident, therefore, that the reactions of an acetyl aldoxime with alkali yield not more than a trace if any of an isocyanide (which would be a rearrangement product), but form almost quantitative yields of the non-rearrangement products, nitrile, acid and oxime. According to the mechanism proposed for the formation of nitrile from an acetyl aldoxime, it should not be expected that the elimination of acetic acid would be accompanied by rearrangement of the molecule, since the negative fragment that is formed by the removal of a proton should be stabilized most readily by the release of acetate ion and shift of an electron pair, thus

$$\left(R:\ddot{C}::N:\underset{\cdot\cdot}{\ddot{O}}:Ac\right)^{-} \longrightarrow R:C:::\underset{\cdot\cdot}{N} + :\overset{-}{\underset{\cdot\cdot}{\ddot{O}}}:Ac$$

it should be expected that an electron pair would shift more readily than the group (R).

The Configuration of Aldoximes and their Acyl Derivatives.—In the determination of the configurations of aldoximes no difficulty should be encountered. However, both geometrical isomers should be isolated and their acetyl derivatives treated with alkali under the same conditions, preferably at about 30°. If only one isomer is known its configuration might be determined at least in some cases by comparing the alkaline decomposition products of its acetyl derivative with those of similarly constituted acetyl derivatives which are known in two isomeric forms. Although most acetyl α-benzaldoximes with sodium hydroxide even at the temperature of the water-bath give high yields of oxime and relatively little nitrile or acid, certain other acyl-α-derivatives produce considerable nitrile under the same conditions, and accordingly have been erroneously assigned the β-configuration. Certain of these are discussed in the following paper.

Experimental

Preparation of Acetyl Benzaldoximes.—The acetyl-α-benzaldoximes were prepared by a modification of the method of Brady and Dunn.[13] The pure α-oxime was dissolved in about equal weight of acetic anhydride and the solution allowed to stand at room temperature for five to ten minutes. Sufficient ice and sodium carbonate solution was then added to decompose the excess acetic anhydride and precipitate the α-acetate. The mixture was filtered through a Büchner funnel and the solid washed with cold water until free from the odor of acetic anhydride. After sucking the precipitate practically dry, the α-acetate was dissolved by pouring through the funnel small portions of acetone or alcohol. To this solution was added about 3 volumes of finely crushed ice and the mixture vigorously shaken. The α-acetate separated as small white crystals which were filtered off and dried. In most cases a pure product was obtained by this procedure in 70–80% yields. If the melting points were low, the compound was recrystallized.

The acetyl-β-benzaldoximes were prepared by the method recently described.[3]

Reaction of Acetyl Benzaldoximes with 2 *N* Sodium Hydroxide.—The reactions of acetyl-α-benzaldoximes were carried out usually at 30 ± 0.1° in a thermostat, and at 97–100° in a boiling water-bath; the reactions of the β-derivatives at 0° in an ice-bath and at 30°. The products were filtered through sintered glass crucibles of the Gooch type.

In general, a 1.0-g. sample of acetate was added to 15 cc. of 2 *N* sodium hydroxide which had previously been brought to the desired temperature. For the reactions at 97–100°, the samples were made into pellets and introduced into the hot solution through a short reflux condenser. After the reactions were complete (forty-five to ninety minutes at 97–100°, one to four days at 30° and two to

---

[12] In this connection it is of interest to note that Segaller [*J. Chem. Soc.*, **103**, 1430 (1913)] found that more isobutylene was formed from tertiary butyl iodide in the presence of potassium hydroxide than in the presence of sodium ethylate under the same conditions.

[13] Brady and Dunn, *J. Chem. Soc.*, **103**, 1619 (1913).

seven days at 0°), the mixture was filtered and the solution extracted with ether. This procedure removed nitrile. The alkaline solution was then saturated with carbon dioxide to precipitate oxime. After filtering off the oxime and extracting the filtrate with ether, the aqueous solution was acidified with hydrochloric acid to precipitate carboxylic acid. This was filtered off and the solution extracted again with ether. These ether extracts were dried with sodium sulfate and evaporated in tared beakers. Even in cases where no precipitate formed, the solution was extracted with ether. The residue from the first ether extract contained small amounts of oxime and nitrile. These were separated by dissolving the oxime in a small amount of cold alkali. All products were dried, weighed, and their melting points taken. After recrystallization mixed melting points with authentic specimens were determined.

Relative Rates of Hydrolysis of the Acetyl Derivatives of α- and β-3,4-Methylenedioxybenzaldoximes

With Aqueous Sodium Hydroxide.—After a given time the reaction mixture of 15 cc. of 2 *N* sodium hydroxide and 1 g. of the acetate was filtered rapidly with suction and the filtrate saturated with carbon dioxide. The extent of hydrolysis was then calculated from the amount of oxime obtained.

With Alcoholic Sodium Hydroxide.—A 1-g. sample of the acetate was dissolved in 60 cc. of 80% alcohol at 0°, and the solution added to an equal volume of 1.3 *N* sodium hydroxide in the same solvent, also at 0°. After a certain time the solution was poured into an excess of acetic acid containing ice. Most of the alcohol was then quickly evaporated in an air draft and the mixture extracted with benzene, which in turn was extracted with 100 cc. of ice cold 1 *N* alkali to remove the oxime. The oxime was precipitated with carbon dioxide in the usual way. During the extraction of the benzene solution with alkali, a small amount of the unchanged acetate was hydrolyzed. Therefore the extraction process was standardized, each extraction being shaken ten times, using 100 cc. of 1 *N* sodium hydroxide at 0°. Under these conditions 80–90% of the free oxime in the benzene solution was extracted as the sodium salt, whereas when a 0.6-g. sample of either the α- or β-acetate in benzene solution was extracted with alkali under the same conditions only 3–5% of oxime was obtained. The yields of oximes reported in Table III are those obtained as described above minus this blank (3–5%).

In the experiments carried out at −0.8°, 1 g. of the acetate in 80 cc. of 95% alcohol was mixed with an equal volume of 0.6 *N* sodium hydroxide in 95% alcohol.

With Sodium Carbonate.—The sodium carbonate used in this work was prepared from pure sodium bicarbonate. A 1-g. sample of the acetate was dissolved in 60 cc. of acetone at 0°, and added with stirring to 250 cc. of a 2% aqueous sodium carbonate solution also at 0°. A slight turbidity was produced, but no precipitate was formed. After standing at 0° for a certain time the solution was poured into an excess of cold acetic acid and then extracted with benzene. The benzene solution was extracted with ice cold alkali. The oxime was precipitated from the alkaline solution in the usual manner. In cases where some unchanged acetate was present, blanks of 3–5% have been subtracted from the yields of oxime obtained. These are given in Table III.

Reaction of Acetyl-β-benzaldoximes with 10% Sodium Carbonate.—A 1-g. sample of the acetate was added to 15 cc. of a 10% aqueous sodium carbonate solution at 0 or 30°. After three to six days the solid was filtered off. When the filtrate was saturated with carbon dioxide and extracted with ether a very small amount of oxime was obtained. It was shown that the solid consisted mostly of nitrile mixed with a small amount of oxime. When cold sodium hydroxide was poured over the solid the oxime dissolved, leaving the nitrile in the funnel. The oxime was isolated by saturating the alkaline solution with carbon dioxide and extracting with ether.

In order to show that the oxime obtained in this manner had not been produced by the action of the sodium hydroxide on some unchanged acetate, the following experiment was carried out. The solid, obtained after filtering off the carbonate, was dissolved in benzene and the solution extracted with cold alkali. The yield of oxime obtained by saturating the alkaline solution with carbon dioxide was approximately the same as that obtained in the manner described above. It has been shown that even if as much as 0.6 g. of acetate in benzene solution is extracted with alkali in the manner employed yields of oxime of only 3–5% are obtained.

Reaction of Acetyl-α-benzaldoximes with Alkali in Alcoholic Solution.—A 1-g. sample of an acetate was introduced through a reflux condenser into 15 cc. of 2 *N* sodium ethylate in absolute alcohol at the refluxing temperature of the solution. The acetate reacted immediately, forming a precipitate of the sodium salt of the oxime. After refluxing for forty-five minutes the mixture was cooled and an equal volume of water added. After evaporating most of the alcohol in an air draft the products were isolated from the alkaline solution in the usual manner.

The experiment was repeated with 2 *N* sodium hydroxide in 50% alcohol.

Reaction of Acetyl-α-benzaldoximes with Potassium Amide in Liquid Ammonia.—The potassium amide in liquid ammonia was prepared[14] by suspending a rusty nail in a 2 *N* potassium solution in liquid ammonia until the blue color disappeared.

A 1-g. sample of an acetate was dissolved in a minimum of dry ether (20–50 cc.). To this solution was added with rapid shaking, about 50 cc. of the potassium amide solution of liquid ammonia. After the ammonia had evaporated cold water was added and the mixture extracted with ether. The nitrile was obtained by evaporation of the ether solution. The oxime and acid were isolated in the usual manner.

Summary

1. The products of the reactions of certain acetyl-β-benzaldoximes with 2 *N* sodium hydroxide have been determined at 0 and 30°. Both nitrile and oxime were formed at these temperatures, the yields of oxime in most cases predominating at 0°, and those of the nitrile at 30°.

---

[14] See Bergstrom and Fernelius, *Chem. Rev.*, **12**, 59 (1933); and Coleman and Maxwell, THIS JOURNAL, **56**, 133 (1934).

2. The products of the reactions of certain acetyl-α-benzaldoximes with 2 N sodium hydroxide have been determined at 30 and 100°. Both nitrile (or the corresponding acid) and oxime were formed at 100°, and in certain cases, even at 30°. With the exception of the o-nitro derivative, the yields of oxime were much greater than those of the acid; at 30°, the yields of acid were extremely small.

3. It has been shown that β-3,4-methylenedioxybenzaldoxime acetate is hydrolyzed somewhat more rapidly than the corresponding α-isomer, but it is probable that there is no very great difference in these rates.

4. It has been concluded that α- and β-aldoxime acetates undergo fundamentally the same types of reaction with alkali; they form oxime by hydrolysis, and nitrile by elimination of acetic acid. They differ primarily in the ease with which they eliminate acetic acid, the β-isomers undergoing this reaction much more readily than the corresponding α-isomers.

5. These results are discussed on the basis of the hypothesis that the formation of nitrile from acetyl aldoximes consists of the removal of a proton by alkali, followed by the release of acetate ion.

6. It has been shown that in the presence of sodium carbonate certain acetyl-β-benzaldoximes give high yields of nitrile and low yields of the corresponding oxime.

7. It has been found that certain acetyl-α-benzaldoximes with potassium amide in liquid ammonia form both nitriles and oxime, the yields of nitrile being greater.

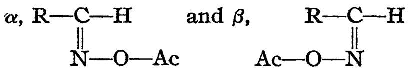
The Reactions of Aldoxime Derivatives with Bases. II. The Reactions of Carbethoxy-α-benzaldoximes with Sodium Hydroxide

BY CHARLES R. HAUSER, EARL JORDAN AND RUTH O'CONNOR

In the previous paper[1] it has been shown that the acetyl derivatives of a pair of geometrically isomeric aldoximes



$$\alpha,\ \begin{matrix}\mathrm{R{-}C{-}H}\\ \|\\ \mathrm{N{-}O{-}Ac}\end{matrix}\qquad \text{and } \beta,\ \begin{matrix}\mathrm{R{-}C{-}H}\\ \|\\ \mathrm{Ac{-}O{-}N}\end{matrix}$$

undergo fundamentally the same types of reaction with sodium hydroxide; they form oxime by hydrolysis, and nitrile by elimination of acetic acid. They differ primarily in the ease with which they eliminate the elements of acetic acid, and therefore can be readily distinguished. At 30° the β-isomer gives a high yield of nitrile, whereas the α-isomer gives a high yield of oxime, with only a trace or a very small yield of nitrile. At the temperature of the boiling water-bath, however, certain acetyl-α-benzaldoximes[2] give considerable nitrile or corresponding acid, in addition to the α-oxime. Since the yields of products are dependent upon the relative rates of the two competing reactions it appeared not improbable that certain other acyl-α-derivatives might eliminate the elements of acid sufficiently rapidly, relative to their rates of hydrolysis, to give high yields of nitrile at ordinary temperatures, and if the acyl derivative is known in only one isomeric form it might readily be mistaken for the β-isomer. It seemed worth while therefore to reinvestigate the reactions of alkali with various acyl derivatives prepared from α-aldoximes, especially those that have been assigned the β-configuration. In this paper are reported the results obtained with carbethoxy derivatives, certain of which have been previously assigned the β-configuration.[3]

Experimental

Preparation of the Carbethoxy-α-benzaldoximes.—These compounds were prepared from the α-oxime in cold alkaline solution and ethyl chlorocarbonate (ethyl chloroformate), and recrystallized from acetone, alcohol and water according to the method of Brady and McHugh.[3] The yields were about 70%. The melting points of our

---

[2] Acetyl-α-o-nitrobenzaldoxime gives 36% nitrile and acid even at 61–64°.

[3] Brady and McHugh [*J. Chem. Soc.*, **123**, 1190 (1923)] have reported that of fourteen carbethoxy derivatives prepared from α-aldoximes and ethyl chlorocarbonate, ten had the α-configuration, but, contrary to what was expected, four of them (2-nitro-, 4-nitro-, 4-methoxy- and 3,4-methylenedioxybenzaldoxime derivatives), appeared to have the β-configuration since nitrile (or acid) was obtained when they were heated with alkali on the water-bath. They point out that an explanation is required for the formation of β-derivatives from α-oximes in the presence of alkali, especially since, under the same conditions, β-oximes yield nitriles.

4-Methoxy-	70	53– 55	60	12	58– 60	64	82

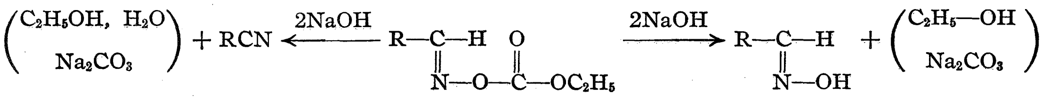
products were the same as those reported by Brady and McHugh. We were not able, however, to isolate the *p*-nitro derivative in two forms. Our product melted 108–109°, agreeing with that of the higher melting α-product reported by these earlier workers.

Reactions of Carbethoxy-α-benzaldoximes with 2 *N* Sodium Hydroxide.—A 1-g. sample of the carbethoxy-α-benzaldoxime was added to 15 cc. of 2 *N* sodium hydroxide at a definite temperature, and after the reaction was complete (usually two to seven days at 30° and one to two hours at 97–100°) the products were isolated according to the method previously used in the study of the reactions of acetyl-α-benzaldoximes with alkali.[1] The results are given in Table I. The melting points of the crude products and those recorded in the literature are listed consecutively following the yields. In most cases the melting points of the crude products obtained were either practically the same as those reported in the literature or were raised to these values after one recrystallization.

Reaction of Carbethoxy-α-benzaldoximes with Potassium Amide in Liquid Ammonia.—The reactions with potassium amide were carried out in a manner similar to that used in the study of the reactions of the acetyl-α-benzaldoximes with this reagent.[1]

Discussion

It can be seen from Table I that nitriles (or the corresponding acids) and α-oximes have been obtained from all of the carbethoxy derivatives. The fact that α-oximes[4] and not their β-isomers,[5] have been obtained by the hydrolysis of the carbethoxy derivatives, shows that these derivatives had also the α- or *syn*[6] configuration. Hence the reactions of carbethoxy-α-derivatives with alkali might be represented as follows



$$\left(\begin{matrix}C_2H_5OH,\ H_2O\\ Na_2CO_3\end{matrix}\right) + RCN \xleftarrow{2NaOH} \begin{matrix}R-C-H\quad O\\ \|\qquad\ \|\\ N-O-C-OC_2H_5\end{matrix} \xrightarrow{2NaOH} \begin{matrix}R-C-H\\ \|\\ N-OH\end{matrix} + \left(\begin{matrix}C_2H_5-OH\\ Na_2CO_3\end{matrix}\right)$$

It can be seen from Table I that at 30° the yields of oxime were much greater than those of

---

(4) The configurations of these oximes have previously been established from a study of the reactions of alkali with their acetyl derivatives and with the acetyl derivatives of the corresponding β-isomers. See previous paper.[1]

(5) The hydrolysis of acetyl-β-aldoximes at 30° gives the corresponding β-oximes. The latter in alkaline solution are relatively stable at 30°. Therefore if the carbethoxy derivatives listed in Table I had had the β-configuration, the corresponding β-oximes should have been formed on hydrolysis.

(6) See previous paper[1] for references to the evidence supporting the view that the α-oximes and their derivatives have the *syn* configuration.

nitrile with the exception of the *o*-nitro derivative, which gave considerable nitrile even at 0°. At 97–100°, the yields of nitrile were higher than those obtained at 30°, and in several cases even greater than those of oxime. As with the acetyl derivatives, the elimination reaction appears to have a higher temperature coefficient than the hydrolysis.

It should be pointed out that the yields of nitrile obtained from these carbethoxy derivatives are higher, and those of oxime correspondingly lower, than those obtained from the analogous acetyl-α-aldoximes under the same conditions.[1] Evidently, a carbethoxy-α-aldoxime eliminates the elements of acid to form nitrile more readily, and/or undergoes hydrolysis less rapidly, than the corresponding acetyl-α-derivatives.

In Table II are given the yields of products obtained from the reactions of potassium amide in liquid ammonia with certain carbethoxy-α-derivatives. It can be seen that high yields of nitrile and low yields of oxime were produced.

Summary

1. The relative yields of nitriles and oximes formed in the reactions of carbethoxy-α-benzaldoximes with sodium hydroxide are a function of the temperature.

2. Contrary to the previously accepted view, that certain carbethoxy derivatives of α-benzaldoximes have β-configurations, it has been shown that they are all of the α-type.

3. The carbethoxy-α-benzaldoximes with sodium hydroxide give higher yields of nitrile, and lower yields of oxime, than the corresponding acetyl-α-benzaldoximes.

Dehalogenation of β-Bromo Acids. IV. β-Bromophenylpyruvic Acid

BY BEN SOBIN AND G. BRYANT BACHMAN

In the present work an effort has been made to extend the β-bromo acid synthesis of olefin derivatives to the preparation of ketenes. It seemed probable from previous studies[1] that α-keto-β-bromo acids ought to dehalogenate predominantly as follows

$$\mathrm{RCHBrCOCOOH} \longrightarrow \mathrm{RCH{=}C{=}O} + \mathrm{HBr} + \mathrm{CO_2} \qquad (1)$$

in view of the strongly electronegative character of the α-carbonyl group. In order to test this hypothesis, β-bromophenylpyruvic acid was prepared and its dehalogenation studied under a variety of conditions.

The difficulty of selecting a suitable solvent and a suitable dehalogenating agent for the proposed study was immediately apparent, for no substance could be present at any time which would react with the ketene formed. This of course eliminated a good many common solvents and bases from consideration. At first sight, tertiary amines seemed ideally suited for the purpose both as solvents and as dehalogenating agents. When the reaction was tried, however, with pyridine and dimethylaniline the results were unsatisfactory. Carbon dioxide was evolved as expected but the products were tars which were apparently complex in nature and which contained no ketene.

An endeavor was next made to adapt the method to the synthesis of ketene derivatives. It was hoped that primary or secondary amines either in the presence or absence of other solvents would react to form substituted amides of phenylacetic acid. Here again, however, in addition to carbon dioxide only tars were obtained, and no evidence was found of the presence of simple ketene derivatives. Fortunately, we were able to secure decomposition in the desired manner by simply boiling the bromo acid with water. Carbon dioxide was evolved and phenylacetic acid in 77% yield was recovered from the solution. Furthermore, when an aqueous solution of the acid was shaken with silver oxide the same product was obtained in 94% yields. It is difficult to account for the product formed other than by assuming the intermediate formation of phenylketene which then reacted further with water to form phenylacetic acid.

$$\mathrm{C_6H_5CHBrCOCOOH} \longrightarrow \mathrm{C_6H_5CH{=}C{=}O} + \mathrm{HBr} + \mathrm{CO_2} \qquad (2)$$

$$\mathrm{C_6H_5CH{=}C{=}O} + \mathrm{H_2O} \longrightarrow \mathrm{C_6H_5CH_2COOH} \qquad (3)$$

---

[1] Bachman, THIS JOURNAL, **55**, 4279 (1933); Farrell and Bachman, *ibid.*, **57**, 1281 (1935); Alberts and Bachman, *ibid.*, **57**, 1284 (1935).

The above reactions are remarkably sensitive to increases in the hydroxyl-ion content of the solution. With sodium carbonate solution no phenylacetic acid was formed and the principal product consisted of benzoylcarbinol.

$$C_6H_5CHBrCOCOOH \xrightarrow{Na_2CO_3} C_6H_5CHOHCHO + CO_2 + HBr \quad (4)$$

$$C_6H_5CHOHCHO \longrightarrow C_6H_5COCH_2OH \quad (5)$$

The spontaneous rearrangement of mandelic aldehyde to benzoylcarbinol (5) has been previously pointed out by Nef[2] and by others. Evans[3] has shown that benzoylcarbinol undergoes further decomposition in the presence of alkalies to form benzoic acid. This substance was also identified in the reaction product and increased in amount at the expense of the benzoylcarbinol upon prolonged boiling of the reaction mixture.

With sodium bicarbonate which is intermediate in basicity between water and sodium carbonate a 40% yield each of phenylacetic acid and benzoylcarbinol was obtained and a new product as yet unidentified made its appearance in small amounts. It was a bright yellow solid, m. p. 218–219°, which qualitative tests showed to be an alpha hydroxy acid of high molecular weight. It was but slightly soluble in most organic solvents.

In view of the reaction of bromophenylpyruvic acid with water it was decided to attempt the preparation of the ethyl ester of phenylacetic acid by reaction with alcohol. Accordingly a solution of the bromo acid in ethyl alcohol was boiled until no more carbon dioxide was evolved. The product after distillation and saponification yielded a little benzoic acid but no phenylacetic acid. Better success was obtained when an alcoholic solution of the bromo acid was treated with a half molal portion of silver oxide. From the filtrate a 36% yield of ethyl phenylacetate was obtained by distillation.

Further efforts to adapt the dehalogenation of α-keto-β-bromoacids to the synthesis of ketenes and their derivatives are being made.

Experimental

Preparation of β-Bromophenylpyruvic Acid.—To 55 g. of phenylpyruvic acid[4] suspended in 750 cc. of carbon tetrachloride was added slowly with stirring 54 g. of bromine. The solid product was filtered and allowed to stand for two days at the end of which time no more hydrogen bromide was being evolved. The yield was practically quantitative and the product melted at 103–104°. Recrystallization from benzene gave fine yellow needles with the same melting point.

Anal. Calcd. for $C_9H_7O_3Br$: Br, 32.84. Found: Br, 32.84, 32.86.

Conversion of β-Bromophenylpyruvic Acid to Phenylacetic Acid.—Four grams ($^1/_{60}$ mole) of the bromo acid in 50 cc. of water was refluxed one-half hour and the filtered solution extracted with ether several times. The extract yielded 1.3 g. of a product which, after recrystallization from petroleum ether, melted at 76° and was confirmed as phenylacetic acid by a mixed melting point with an authentic sample; yield 77%.

In a similar experiment 2.0 g. of bromo acid dissolved in 50 cc. of water was shaken with 0.9 g. of silver oxide and finally warmed on the steam-bath. After removal of the silver bromide a 94% yield of phenylacetic acid was recovered from the filtrate.

Conversion of β-Bromophenylpyruvic Acid to Ethyl Phenylacetate.—To 24 g. of the bromo acid in 200 cc. of absolute alcohol was added portionwise 11.5 g. of silver oxide. At the end of the initial reaction the mixture was filtered and the filtrate distilled. There was obtained 6 g. (36% yield) of a product (b. p. 120–130° at 20 mm.) which upon saponification yielded phenylacetic acid.

Reaction of β-Bromophenylpyruvic Acid with Other Reagents.—With Aqueous Sodium Carbonate.—A solution of 24 g. of the bromo acid in 40 cc. of 25% sodium carbonate was refluxed for one-half hour. Upon cooling and extracting with ether 5.0 g. of benzoylcarbinol, m. p. 85°, was obtained. The identity of this substance was confirmed by oxidizing it to mandelic acid, m. p. 118°, with cupric acetate by the method of Evans.[3]

The alkaline solution from which the benzoylcarbinol had been extracted was then acidified with dilute hydrochloric acid, extracted with ether, and the ether evaporated. The thick oil which remained was extracted with petroleum ether. Evaporation of the petroleum ether left 3 g. of benzoic acid, m. p. 121°. The amide was also prepared for confirmation and melted at 128°.

With Aqueous Sodium Bicarbonate.—Four grams of the bromo acid was gradually added to 3.5 g. of sodium bicarbonate dissolved in 41 cc. of water, and allowed to stand overnight. Extraction of the alkaline solution with ether, and subsequent evaporation of the ether left 0.5 g. (40% theoretical) of benzoylcarbinol. The solution was then acidified with dilute hydrochloric acid and extracted with ether. Evaporation of the ether left a yellow gummy solid. The solid was extracted with boiling petroleum ether for an hour, and yielded in this way 0.9 g. (40% theoretical) of phenylacetic acid. The yellow residue from the extraction was difficultly soluble in hot benzene, from which on cooling it crystallized as very fine yellow needles. When dry, the powder was found to be highly electrophoric, and to have a melting point of 218–219°. Qualitative tests showed it to be an acid. It gave a yellow color with ferric chloride indicating the presence of an hydroxyl group alpha to a carbonyl. An alcoholic solution decolorized bromine water and potassium permanganate solution. It did not give a phenylhydrazine test. However, it reacted with acetyl chloride to give a derivative melting at 162–163°. The neutralization equivalent was

---

[2] Nef, *Ann.*, **355**, 247 (1907).

[3] Evans, THIS JOURNAL, **35**, 125 (1906).

[4] Hemmerlé, *Ann. chim.*, [9] **7**, 229 (1917).

found to be 181 and the molecular weight as determined by the melting point depression of naphthalene as 373. Evidently there were two carboxyl groups in the molecule. The compound was analyzed for carbon and hydrogen. *Anal.* C, 73.1, 73.3; H, 4.4, 4.4. From the carbon and hydrogen analysis and the molecular weight determination the molecular formula of the yellow compound was calculated to be most probably $C_{23}H_{16}O_5$.

With Nitrogen Bases.—Portions of the bromo acid were treated in turn with anhydrous pyridine, aniline, dimethylaniline and diethylamine. In all cases an evolution of carbon dioxide resulted, and considerable heat was evolved. All three amines gave tarry and gummy masses from which the reaction products could not be isolated. With aqueous ammonium hydroxide a dark brown solution was obtained which yielded a little benzoylcarbinol by extraction with ether. Upon acidification a tar precipitated which was almost insoluble in most organic solvents.

Summary

1. The dehalogenation of β-bromophenylpyruvic acid has been studied under a variety of conditions. Evidence has been obtained for the intermediate formation of phenylketene under certain of the above conditions.

2. The possibilities and some of the difficulties of utilizing the dehalogenation of α-keto-β-bromo acids as a new method of synthesis of ketene derivatives have been pointed out.

Reactions between Organomercury Compounds and Nitrosyl Compounds[1,2]

BY LEE IRVIN SMITH AND F. LOWELL TAYLOR

The reactions between nitrosyl compounds and organomercury compounds were discovered by Baeyer,[3] who first prepared nitrosobenzene by the action of nitrosyl bromide upon diphenylmercury.[4]

Bamberger[5] studied the reactions between nitrogen oxides and bis-arylmercury compounds. Apparently, he concluded that the action of nitrogen sesquioxide upon organomercury compounds was entirely different from that of nitrogen dioxide. He represented the reaction between nitrogen dioxide and diphenylmercury by equation (1).

$$(C_6H_5)_2Hg + N_2O_4 \longrightarrow C_6H_5HgNO_3 + C_6H_5NO \quad (1)$$

Despite the fact that he also obtained a small quantity of nitrosobenzene by the action of nitrogen sesquioxide, Bamberger represented the reaction between the sesquioxide and diphenylmercury by equation (2).

$$(C_6H_5)_2Hg + 2N_2O_3 \longrightarrow C_6H_5HgNO_3 + C_6H_5N_2NO_3 \quad (2)$$

He ascribed the formation of the nitrosobenzene to the action of nitrogen dioxide formed by dissociation of the sesquioxide. Moreover, nitric oxide did not act upon diphenylmercury, but did act upon nitrosobenzene, *o*-nitrosotoluene, and *p*-bromonitrosobenzene. The corresponding diazonium nitrates were formed (equation 3).

$$C_6H_5NO + 2(NO) \longrightarrow C_6H_5N_2NO_3 \quad (3)$$

In the present work it was found that nitrogen sesquioxide, nitrogen dioxide, and nitrosyl chloride formed nitroso compounds by their action upon organomercury derivatives of polymethylbenzenes. The nitroso group replaced the mercury, which was removed as an inorganic salt. Equations (4) and (5) express the reactions in general forms, where NOX denotes the nitrosyl compounds.[6]

$$R_2Hg + NOX \longrightarrow RHgX + RNO \quad (4)$$
$$RHgX + NOX \longrightarrow HgX_2 + RNO \quad (5)$$

A diazonium nitrate was formed only when a mixture of nitrogen sesquioxide and excess nitric oxide was allowed to act upon a mercury compound. It seemed, then, that the primary reaction (5) between nitrogen sesquioxide and the arylmercury compound was accompanied by a

secondary reaction (3) between nitric oxide and the nitroso compound.[7]

The yields which were obtained in preparation of the mercury compounds described in the previous paper and in preparation of the nitroso compounds were sufficient to make the reactions satisfactory for synthesis of the compounds in quantity. The most convenient procedure made use of the reaction between organomercury compounds and nitrosyl chloride. Nitrosyl chloride was prepared in the reaction mixture from ethyl nitrite.[8] Nitrosopolymethylbenzenes are valuable intermediates for preparation of the amino methylbenzenes because the mono-nitro compounds cannot be prepared by direct nitration of the hydrocarbons.[9] The nitroso compounds were characterized by conversion to the known amines and acetamines. Nitrosomesitylene[10] and 5-nitrosopseudocumene[11] were known previously. Both forms of 5-nitrosopseudocumene, the green, labile form, m. p. 45–46°, and the white form, m. p. 65°, were isolated. Nitrosoprehnitene, which has a structure very similar to that of nitrosopseudocumene, was isolated only in a green, stable form, m. p. 72°. The other nitroso compounds resembled nitrosomesitylene in that their melting points were high and their solutions were colorless, or yellow, in the cold but green when dilute or warm. The new nitroso compounds are listed in the table with their melting points and analytical data.

The action of nitric acid upon arylmercury compounds usually causes replacement of the mercury by a nitro group, although the replacement is probably not direct.[4,12] Under certain conditions, nitration of the aryl group in arylmercury compounds may occur without destruction of the carbon–mercury bond.[13]

Nitric acid of specific gravity 1.26 formed nitrodurene and nitroisodurene by action upon the corresponding acetoxymercurimethylbenzenes. Probably the nitroso compounds were formed as intermediates. Nitrodurene and nitroisodurene were prepared also by oxidation of the nitroso compounds with nitric acid (sp. gr. 1.26). The substances are listed in the table.

TABLE I

NITROSO- AND NITRO-POLYMETHYLBENZENES

				Analyses, %			
				Carbon		Hydrogen	
Substance	Yield, %	M. p., °C.	Formula	Calcd.	Found	Calcd.	Found
Nitrosopentamethylbenzene	80	160[a]	$C_{11}H_{15}NO$	74.52	74.2	8.54	8.42
Nitrosodurene	81	160[a]	$C_{10}H_{13}NO$	73.57	73.3	8.03	8.16
Nitrosoisodurene	61	134	$C_{10}H_{13}NO$	73.57	71.5[b]	8.03	7.9[b]
Nitrosoprehnitene	70	72	$C_{10}H_{13}NO$	73.57	73.3[b]	8.03	8.0[b]
Nitrodurene	40	112–113	$C_{10}H_{13}NO_2$	67.00	67.1	7.32	7.49
Nitroisodurene		39	$C_{10}H_{13}NO_2$	67.00	66.7	7.32	7.41

[a] Decomposition, rapid heating; slow heating, m. p. 152–155°. [b] Average of several concordant analyses.

Experimental Part

A. Preparation of Nitrosopolymethylbenzenes

1. **General Method.**—The acetoxymercuri polymethylbenzene (20 g.) was dissolved in chloroform (100 cc.); the solution was cooled in an ice-bath and stirred mechanically. Ethyl nitrite (5 cc.; 1 + mole)[14] was added; this was followed by addition, in one portion, of a mixture of hydrochloric acid (15 cc. concd.; 3 moles) and acetic acid (20 cc.). The fresh precipitates of arylmercuric halides reacted quickly with nitrosyl chloride. The reaction mixtures were stirred for fifteen minutes to one hour. The procedures for isolation of the products are described separately.

2. **Nitrosopentamethylbenzene.**—The reaction mixture was washed with water (mercury salt recovered) and filtered. The precipitate was crude nitroso compound (4.5 g.). The green filtrate, evaporated to 40 cc. and cooled, deposited an additional 4 g. of nitroso compound. The substance was crystallized from chloroform; needles, m. p. 160°; yield, 80%. The melting (decomposition) point depended upon the rate of heating.

---

(7) Since nitrosopolymethylbenzenes were formed by the action of either nitrogen sesquioxide or dioxide, it was concluded that the nitrosobenzene found by Bamberger was probably the primary product, and that the diazonium nitrate was formed from nitrosobenzene by the action of nitric oxide (equation 3) which resulted from dissociation of the sesquioxide. If the reaction between nitric oxide and nitrosobenzene were much faster than the reaction between nitrogen sesquioxide and diphenylmercury (equation 4), then most of the nitroso compound would be converted to the diazonium nitrate which Bamberger found. Apparently, the reactivity of mercury derivatives of benzene hydrocarbons toward nitrogen sesquioxide increases with the number of methyl groups attached to the ring; the reverse is true of the nitroso derivatives.

(14) Prepared by the method of Wallach, ref. 8.

Reduction of the nitroso compound by stannous chloride in alcohol and hydrochloric acid gave 6-aminopentamethylbenzene, m. p. 151°; reported m. p. 151–152°[15] and 151°.[16] The amine was acetylated by acetic anhydride. The melting point of acetaminopentamethylbenzene was 211°; reported, m. p., 213°[15] and 212–213°.[16]

3. Nitrosodurene.—The chloroform solution was extracted with water, warmed to dissolve all the product, extracted three more times, treated with 10 cc. of methanol, filtered, concentrated to 50 cc. by distillation, and cooled. The pure white, crystalline product changed to a powder when it was dried in air; m. p. 160° (decomposition, rapid heating); yield, 73%.

The melting point of crude aminodurene obtained by reduction of nitrosodurene was 74–75°. The reported melting points are 75°;[16] after sublimation, 72–73°.[17] The amine was crystallized from 60% methanol; the product, m. p. 71°, was analyzed.

Anal. Calcd. for $C_{10}H_{15}N$: C, 75.40; H, 10.13. Found: C, 75.23, 76.20; H, 9.48, 9.24.

The melting point of acetaminodurene was 207–208°; reported m. p. 207°.[16]

4. Nitrosoisodurene.—After the chloroform solution was washed, it was concentrated to 40 cc., treated with 40 cc. of methanol, distilled until a precipitate formed, cooled and filtered. The melting point of the product was 132°; yield, 61%.

For analysis, 1 g. of nitrosoisodurene was crystallized from 15 cc. of methanol and 5 cc. of benzene. The crystalline product, m. p. 137°, was dried in vacuum for five hours at 55°. It changed to a powder, m. p. 134°. Analyses gave values for carbon which were 2% low. However, when reduced, a liquid amine was formed; reported melting point of aminoisodurene, 14°[18a] and 23–24°.[18b] The melting point of acetaminoisodurene was 215°; reported m. p. 215°,[18b] 210–211°,[19a] 216°,[19b] and 214–215°.[15]

When 1 g. of nitrosoisodurene, m. p. 132°, was crystallized from methanol (10 cc.) and chloroform (3 cc.) the melting point of the product (dried over sulfuric acid) was 138°.

Anal. Found: C, 67.42, 67.35; H, 7.51, 7.54. Calcd. for $C_{10}H_{13}N + CH_3OH$: C, 67.64; H, 8.78.

The compound was not characterized; it was probably an addition product. In solution it behaved as nitrosoisodurene.

5. Nitrosoprehnitene.—The chloroform solution was washed, excess methanol was added, and the solution evaporated nearly to dryness to remove all of the chloroform. The methanol solution was cooled and filtered; the melting point of the product was 72°, yield 35%. Crude material (35%) was obtained from the filtrate. Nitrosoprehnitene (0.7 g.) was crystallized from 3 cc. of methanol and dried over sulfuric acid, m. p. 72°; when dried in vacuum for six hours at 55°, the melting point was 72°. The green solid did not change color during several months.

Reduction formed aminoprehnitene, m. p. 64–65°; reported m. p. 64–66°,[18b] and 70°.[20] The melting point of acetaminoprehnitene was 170–171°; reported m. p. 169.5°[18b] and 172°.[20]

6. Nitrosomesitylene.—The solvent was washed, excess methanol added, and the solution evaporated until the chloroform was removed. The final mixture (75 cc.) was cooled and filtered. The melting point of nitrosomesitylene was 121–122°; yield, 90%; reported m. p. 122°[10b] and 129°.[10a]

7. Nitrosopseudocumene.—The crude substance was obtained by evaporation of the solvent; yield, 68%. The melting point of the green form was 44°; of the white form, 64–65°; recorded m. p., green, 45–46°; white, 65°.[11]

B. Reactions between Nitrogen Oxides and Mercury Compounds

1. Preparation of the Nitrogen Oxides.—The red oxides of nitrogen were prepared by the reaction between nitric acid and copper, in an all-glass apparatus which was connected directly to a reaction flask through the hollow mechanical stirrer.

(a) **Nitrogen Sesquioxide.**—The red oxides were treated with dry nitric oxide until the condensate was converted to blue sesquioxide; the oxide was dried by phosphorus pentoxide.

(b) **Nitrogen Dioxide.**—Dry oxygen was used to oxidize the red oxides to the light yellow dioxide; the dioxide was dried by phosphorus pentoxide.

(c) **Nitric oxide** was prepared from sodium nitrite by the method of Noyes,[21] and dried by passing it through a train of concentrated sulfuric acid and phosphorus pentoxide.

2. Nitrogen Sesquioxide and Acetoxymercuriisodurene.—Acetoxymercuriisodurene (15 g.) was dissolved in 125 cc. of absolute chloroform and the solution was kept at −10°. Nitrogen sesquioxide was distilled into the solution. A voluminous white precipitate (I) formed and then dissolved and left a brown precipitate (II). The precipitate was removed by filtration (filtrate III), washed with absolute chloroform, and dried at 60°; weight 7 g. The material was almost completely soluble in water. The solution contained mercuric and nitrite ions. Values for mercury content of the solid varied from 59 to 70%; calcd. for mercuric nitrite, 68.5% mercury. The substance was evidently impure mercuric nitrite.

The filtrate (III) was treated as described in part A 4. The product was nitrosoisodurene, m. p. 125°; weight, 4 g. (64%).

The white precipitate (I) was removed (in a separate experiment), washed with absolute chloroform, and dried in a desiccator. Values for mercury content were 54 and 58%; calculated for $C_{10}H_{13}HgNO_2$, 52.8%. The substance was probably nitritomercuriisodurene contaminated with mercuric nitrite.

3. Nitrogen Dioxide and Acetoxymercuriisodurene.—The experiment was performed as described in part 2;

dioxide was used instead of sesquioxide. Crude nitrosoisodurene was obtained, m. p. 123°; yield, 4.5 g. (72%).

C. Preparation of Nitrodurene and Nitroisodurene

Oxidation of Nitrosodurene.—A mixture of 2 g. of nitrosodurene and 40 cc. of nitric acid (sp. gr. 1.26) was heated to 70° and shaken for ten minutes. The material was dissolved and nitrogen oxides were evolved. The solution was cooled immediately, poured into 100 cc. of ice and water, and filtered. The product was crystallized from 14 cc. of alcohol; pale yellow prisms, m. p. 112–113°; yield, 0.87 g. (40%). Reduction of nitrodurene formed aminodurene, m. p. 71°.

Acetoxymercuridurene and Nitric Acid.—The mercury compound (11.8 g.) was heated and shaken with 120 cc. of nitric acid (sp. gr. 1.26); the substance was changed to material which floated (probably nitrosodurene). Nitrogen oxides were evolved. At 70°, the material was dissolved within five minutes; the solution was kept warm two minutes longer, then it was poured into ice and water, and filtered. The precipitate was triturated and washed with water, and dried for one day over sulfuric acid. The crude nitrodurene weighed 4.8 g. (89%); m. p. 100–105°.

Oxidation of Nitrosoisodurene.—The substance was oxidized with nitric acid at 70–80°; the oxidation was stopped by dilution with ice and water as soon as the material had dissolved. The diluted mixture was extracted with ether; the ether was washed and evaporated. The residual oil was steam distilled; the yellow oil was removed from the distillate by extraction with ether; the residue from evaporation of the ether was crystallized from methanol at the temperature of liquid air. The product was dried for three days in a desiccator. The melting point of nitroisodurene was 38–39°.

Nitrosoisodurene was oxidized also by nitrogen dioxide. The solvent, absolute chloroform, was heated nearly to the boiling point by the heat of reaction. After action had subsided the chloroform was washed with water and evaporated. The residual oil was steam distilled; the distillate was extracted with ether, the ether was evaporated and the residue crystallized from low boiling petroleum ether. The melting point of nitroisodurene was 39°.

Acetoxymercuriisodurene and Nitric Acid.—The procedure was the same as for the reaction between nitric acid and acetoxymercuridurene. From 4 g. of the mercury compound, there was obtained 1.5 g. (82%) of crude (liquid) nitroisodurene. Further oxidation of nitroisodurene occurred when the reactions were continued too long, or were allowed to proceed at higher temperatures.

Reduction of nitroisodurene formed a liquid amine. The melting point of acetaminoisodurene was 215°.

Summary

1. A method was developed for synthesis of nitroso compounds by the action of nitrosyl chloride upon organomercury derivatives of polymethylbenzenes. Four new nitroso and two new nitro compounds were prepared.

2. The action of nitrogen sesquioxide upon arylmercury compounds, like that of the dioxide, formed nitroso compounds as the primary products.

The Peroxide Effect in the Addition of Reagents to Unsaturated Compounds. X. The Addition of Hydrogen Bromide to Methylacetylene (Allylene)

BY M. S. KHARASCH, J. G. MCNAB[1] AND M. C. MCNAB

Introduction

In previous communications from this Laboratory Kharasch and his collaborators[2] have demonstrated the importance of peroxides in directing the addition of hydrogen bromide to olefinic hydrocarbons, in which the double bond is at the end of the chain. It seemed desirable to extend the investigation to the acetylene series, and so the addition of hydrogen bromide to methylacetylene was studied in some detail.

The experiments of Réboul[3] have previously shown that hydrogen bromide in aqueous solution adds to methylacetylene to yield 2,2-dibromopropane.

Addition of Hydrogen Bromide to Methylacetylene.—We found it expedient, after a few preliminary experiments, to limit our investigation to a study of the final product formed by the addition of two moles of hydrogen bromide to methylacetylene. These experiments were carried out in the presence of peroxides and also *in vacuo* under peroxide-free conditions.

The structure of the molecule first formed, under peroxide-free conditions, by the addition of one mole of hydrogen bromide to methylacetylene, can be inferred readily from a consideration of the products isolated in this investigation, together

---

[1] The authors wish to express here their appreciation to the Eli Lilly Company of Indianapolis for support which made this work possible.

TABLE I

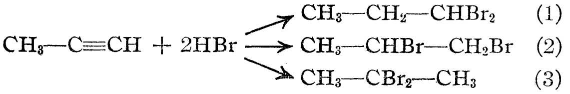
ADDITION OF HYDROGEN BROMIDE TO METHYLACETYLENE

In all experiments 15 g. of methylacetylene and 91 g. of hydrogen bromide were used. The reaction mixture was allowed to stand for four days. The experiments recorded were checked many times. The yields were quantitative (95–100%).

Conditions	B. p., °C.	n^{20}_D	% 1,2-dibromopropane	% 2,2-dibromopropane
No agent added. Vacuum technique	112–115	1.4977	0	100
0.4 g. diphenylamine added to the methylacetylene. Vacuum technique	112–115	1.4977	0	100
0.2 g. thiocresol added to methylacetylene. Vacuum technique	112–115	1.4977	0	100
0.8 g. ascaridole added to methylacetylene, HBr passed in at −33°	139–142	1.5192	100	0
Same as above except vacuum technique used	139–142	1.5193	100	0

with the work on the addition of hydrogen bromide to various bromopropylenes under way in this Laboratory.

From structural considerations, it is obvious that methylacetylene can add two moles of hydrogen bromide to yield three dibromopropanes.



$$CH_3—C≡CH + 2HBr \rightarrow \begin{cases} CH_3—CH_2—CHBr_2 & (1) \\ CH_3—CHBr—CH_2Br & (2) \\ CH_3—CBr_2—CH_3 & (3) \end{cases}$$

In all of our experiments, however, the reaction product proved to be the 2,2-dibromopropane, the 1,2-dibromopropane or a mixture of these two compounds. The possibility of obtaining the 1,1-dibromopropane was not disregarded, but careful analysis of the reaction products (experimental part) revealed none of this compound.

Some of our experimental results are given in Table I. A consideration of these data leaves little doubt regarding the striking effect peroxides exert in governing the direction of the addition. The 2,2-dibromopropane is formed when the reaction is allowed to take place *in vacuo*, and in the absence of any appreciable amounts of peroxides; on the other hand, 1,2-dibromopropane is formed exclusively in the presence of peroxides.

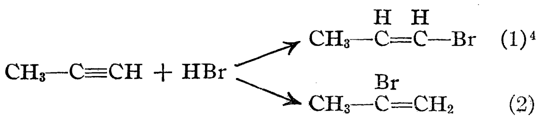
It should be mentioned here that although it is possible to obtain the "abnormal" product (1,2-) in the presence of added peroxides, the system as a whole is not particularly sensitive to traces of peroxides. This of course readily can be predicted from the fact that freshly prepared methylacetylene, or even material three to four days old, does not give a peroxide test, even though no precautions are used to exclude oxygen. Further corroboration of the low susceptibility of the system to the "peroxide effect" is found in the fact that the same product (2,2-dibromopropane) was formed whether the addition was carried out in air, or *in vacuo* or with antioxidants *in vacuo*. In this respect methylacetylene is similar to propylene,[2] and markedly different from halogen ethylenes, which are extremely sensitive even to traces of oxygen and (or) peroxides.

A critical consideration of this addition, in the light of our knowledge of the effect of peroxides on the direction of addition, points to the conclusion that the product of the non-catalyzed first addition of hydrogen bromide to methylacetylene should be 2-bromopropylene.

$$CH_3—C≡CH + HBr \longrightarrow CH_3—CBr=CH_2$$

If the probability of a rearrangement is ignored (and there is not the slightest reason to assume it) then only 2-bromopropylene can yield the 2,2-dibromopropane under peroxide-free conditions. It is to be noted that from the standpoint of the theory developed in our earlier papers,[2] the methyl group and the bromine atom in 2-bromopropylene reinforce each other in their directive effect, an interpretation in strict agreement with the exclusive formation of 2,2-dibromopropane under peroxide-free conditions.

The structure of the bromopropylene formed in the addition of hydrogen bromide to methylacetylene under peroxide conditions, is not deducible from a consideration of our data.



$$CH_3—C≡CH + HBr \rightarrow \begin{cases} CH_3—\overset{H}{C}=\overset{H}{C}—Br & (1)^4 \\ CH_3—\overset{Br}{C}=CH_2 & (2) \end{cases}$$

In the light of our experience, the 1,2-dibromopropane should be the product formed by addition of hydrogen bromide to either (1) or (2) in the presence of peroxides. To check this prediction, the addition of hydrogen bromide to the isomeric bromopropylenes is now under way in our laboratory. However, it is clear that the information thus obtained may not give an unequivocal

---

(4) We have purposely omitted in this discussion the probability of formation of the *cis–trans* isomers of 1-bromopropylene, and the possibility of formation of different products due to a difference in the addition to the two stereoisomers. The justification for this omission rests upon our demonstration of the identity of the products formed in the addition of hydrogen bromide to many *cis-trans* isomers [McNab, Doctorate Dissertation, University of Chicago, 1935].

answer regarding the nature of the product when methylacetylene reacts with one mole of hydrogen bromide under peroxide conditions.

An experimental solution of the problem, namely, the actual isolation of the bromopropylene formed under peroxide-catalyzed conditions, is not very easy, because of the number of possible isomers, and particularly because of the greater sensitivity of the bromopropylenes to peroxides, which leads to the formation of large amounts of the 1,2-dibromopropane. A few preliminary experiments have convinced us that both the theoretical and experimental objections to this approach are well justified.

Typical examples of experimental runs are recorded in Table I. It was necessary to depart slightly from the standard Kharasch–Mayo technique in order to effect complete reversal of hydrogen bromide addition through the agency of peroxides. As a rule a tube containing the unsaturated compound was immersed in a bath of carbon dioxide and acetone, ascaridole added and hydrogen bromide bubbled into the mixture. When the required amount of hydrogen bromide had been introduced, the tube was sealed and allowed to stand at room temperature until the addition was complete. However, in the case of methylacetylene, in order to reverse the addition of the halogen acid completely by peroxides, it has been found necessary to pass in the hydrogen bromide at a temperature between −33 and −40°. This is undoubtedly due to the fact that ascaridole is but very slightly soluble in methylacetylene at the temperature of the carbon dioxide–acetone mixture.

Experimental Work

I. Technique of Addition.—The usual Kharasch–Mayo[2] vacuum technique was employed in experiments involving the addition of hydrogen bromide under peroxide-free conditions. Quantitative yields of 2,2-dibromopropane were obtained in each case. In a few experiments using peroxides (ascaridole), the hydrogen bromide was bubbled into the mixture at −78°. Only a partial reversal in the addition was produced. However, it was observed that the ascaridole dissolved but slightly in the unsaturated hydrocarbon at the low temperature. In other experiments the ascaridole–methylacetylene mixture was allowed to stand for one hour in a bath of liquid ammonia (at which temperature the peroxide is appreciably dissolved) and hydrogen bromide introduced at a slow rate. In this case complete reversal was effected, the addition product being exclusively 1,2-dibromopropane.

II. Preparation of Methylacetylene.—Methylacetylene was prepared in 200-g. lots by the action of dimethyl sulfate on a solution of sodium in liquid ammonia according to the method of Meinert and Hurd.[5] From our standpoint this was the best method, since the only impurity, acetylene, is readily removed by careful fractionation in a Davis column. Working with such relatively large quantities of materials, the experimental difficulties in this preparation (which is hard to carry out even on a small scale) were numerous. After some practice, however, we were able to obtain pure methylacetylene in yields of 70–80%. A sample of the product gave no test for peroxides.

III. Analysis and Identification of Products.—The reaction tubes were opened, allowed to stand for one hour to remove excess hydrogen bromide, the product weighed for yield and fractionally distilled three times *in vacuo*. This treatment was followed by washing with sodium bicarbonate solution and water, drying over calcium chloride and careful fractionation. The 1,2- and 2,2-dibromopropanes are distinguishable by their boiling points and can be separated to a large extent by repeated fractionations. Kharasch and Mayo[6] have reported the refractive index, $n^{20}\text{D}$ of 1,2-dibromopropane as 1.5194. We have found the refractive index of 2,2-dibromopropane (not previously reported) to be 1.4977.[7] Under peroxide-free conditions, a yield of 75 g. of product was obtained, all of which boiled in a range of 3° (112–115°). This product is the 2,2-dibromopropane. In the presence of peroxides we obtained 75 g. of product (100% yield) all of which distilled within the range 139–142° (1,2-dibromopropane). The 2,2-dibromopropane was further identified by conversion to acetone. Ten grams of the dibromide and 100 g. of water were heated at 160° for sixteen hours in a sealed tube. The acetone was distilled from the water solution and treated with 2,4-dinitrophenylhydrazine. The melting point of the product thus obtained was that given for the 2,4-dinitrophenylhydrazone of acetone (m. p. 128°). The melting of a sample was not depressed when mixed with a known synthetic sample.

Summary

1. It has been shown that the "normal" addition of hydrogen bromide to methylacetylene produces exclusively 2,2-dibromopropane.

2. Under the influence of added peroxides, hydrogen bromide adds to methylacetylene to give 1,2-dibromopropane.

3. It has been found that the hydrogen bromide must be passed into the methylacetylene, containing the added peroxide at a temperature of −33 to −40° in order to effect a complete reversal of the "normal" addition.

[7] This substance was also prepared by us by direct bromination of isopropyl bromide. There was a perfect agreement of physical constants in the products obtained.

The Decomposition of Propane and *n*-Butane at Carbon Filaments

BY LEONARD BELCHETZ[1] AND ERIC K. RIDEAL

In a previous communication[2] it was shown that methylene and ethylene, respectively, were the primary products of the decomposition of methane and ethane at hot carbon surfaces. The methods employed in this work have now been extended to an investigation of the reactions of propane and *n*-butane.

Propane was found by Hague and Wheeler[3] to decompose at 700° mainly to methane and ethylene and to a less extent to hydrogen and propylene, a view supported by the work of Pease.[4]

$$C_3H_8 \longrightarrow CH_4 + C_2H_4 \qquad (1)$$
$$C_3H_8 \longrightarrow H_2 + C_3H_6 \qquad (2)$$

Attempts to distinguish between the primary and secondary reactions by progressively varying the rate of flow of the gas at a given temperature and extrapolating the data obtained were made by Schneider and Frolich,[5] who were able to show that at 725° and one atmosphere pressure, 48% of the reaction proceeded according to (1) and 42%, according to (2). The order of importance of these processes was however reversed at 600°.

In the case of *n*-butane, Hague and Wheeler[3] determined the main reactions at 750° to be

$$C_4H_{10} \longrightarrow C_2H_6 + C_2H_4 \qquad (1)$$
$$C_4H_{10} \longrightarrow CH_4 + C_3H_6 \qquad (2)$$
$$C_4H_{10} \longrightarrow \text{Butylenes} + H_2 \qquad (3)$$

occurring, respectively, to the extent of 40, 35 and 20%. The reaction at 700°, according to Hurd and Spence,[6] occurred in a similar manner, but propylene and methane proved to be the principal products at 600°. Essentially the same conclusions were arrived at by Neauhaus and Marek,[7] who applied the method of Schneider and Frolich[5] for propane to the investigation of the primary decomposition of *n*-butane.

Rice and his co-workers have[8,10] obtained radicals on passing propane and *n*-butane through a hot silica tube at 800°, and on the assumption that methyl and ethyl radicals are produced in the primary rupture of the hydrocarbon chain, have developed a chain mechanism to account for the olefinic products of decomposition.

Experimental.—To avoid as far as possible the occurrence of secondary reactions, the hydrocarbon vapors were passed at a high streaming velocity and low pressure (0.1 mm.) across a heated carbon filament situated 2–3 mm. from a tellurium mirror maintained at 100°, with which any radicals formed could react. These conditions are most favorable for the detection of methylene radicals as the polymer of telluroformaldehyde[9,2] and of methyl radicals as dimethyl ditelluride.[10] Separate experiments under corresponding conditions of temperature and pressure, but in the absence of tellurium, were also performed for the purpose of identifying the olefin products of reaction, these being condensed out together with excess hydrocarbon in a liquid air trap and distilled into a side tube containing bromine. Bromination was allowed to proceed at about −10°, excess of the reagent being avoided.

The Decomposition of Propane on a Carbon Filament.—In experiments performed at 1650°, 1,2-dibromopropane (b. p. 141°) was the only liquid product which could be isolated, while experiments with tellurium indicated that no radicals were being simultaneously produced. These, however, were detected at 1750° at which temperature also it was possible to separate ethylene dibromide (b. p. 132°) from the brominated olefin products.

The action of the products of decomposition at 1750° on hot tellurium gave rise to a small quantity of a yellow solid, finally identified as the polymer of telluroformaldehyde, as well as an orange liquid resembling dimethyl ditelluride. When, however, a boiling point determination of the latter was attempted by the micro method, decomposition of some constituent of the oil to metallic tellurium occurred between 140–160°. The addition of ether to the oil precipitated a yellow solid, which, since it decomposed at about 150° to metallic tellurium, proved to be the methylene–tellurium complex $(TeCH_2)_n$, of Rice

and Glasebrook.[9] With cold tellurium mirrors, dimethyl ditelluride and dimethyl telluride only were obtained.

Previous work[2] has shown that unless the accumulation of the non-volatile polymer of telluroformaldehyde on the tellurium acceptor is entirely prevented—this being partially achieved by maintaining the mirror at 100°—reduction of this substance by atomic or hot molecular hydrogen to the methyl tellurides readily ensues. It is believed that the dimethyl ditelluride and dimethyl telluride obtained in these experiments were produced in an analogous manner.

Experiments with Mercury.—If the dimethyl ditelluride isolated in the above experiments was in fact due to methyl radicals produced by the scission of the propane chain, ethyl radicals in quantities equivalent to those of methyl should be capable of detection among the reaction products. Experiments with mercury similar to those devised by Rice, Johnston and Evering[8] and Rice and Rodowskas[11] for the identification of alkyl radicals were therefore performed. As a result of ternary collisions between methylene, atomic hydrogen and mercury, it was expected that mercury dimethyl, at any rate, would be obtained in appreciable amounts.

In these experiments a filament temperature of 1800° was employed. The products of decomposition were allowed to react with mercury continuously condensing on a water cooled bulb, and the mercury alkyls frozen out in a liquid-air trap from which they were extracted with ether. On filtering this solution into an alcoholic solution of mercuric bromide, a copious precipitate of mercurous bromide (in some cases a mixture of mercury and mercurous bromide) was obtained. This was filtered off, the filtrate evaporated to dryness *in vacuo*, and the residue steam distilled. The white solid so separated after being washed with a little alcohol and dried *in vacuo*, melted at 160° (m. p. of CH_3HgBr, 160°).

In other experiments, the mercury alkyls were diffused into a liquid-air cooled side tube where they condensed as a white solid. After the liquid propane had evaporated, part of the mercury compound was observed to decompose to mercury, leaving a clear colorless liquid which boiled at 95° (b. p. $Hg(CH_3)_2$, 95°).

The product obtained in these experiments behaved as if it were a compound of the formula $HgCH_3$, decomposing at room temperatures in contact with, and in the absence of, air as follows

$$2HgCH_3 \longrightarrow Hg + Hg(CH_3)_2$$

It was, however, stable in a cold ether solution, reacting with mercuric bromide in the following manner

$$2HgCH_3 + HgBr_2 \longrightarrow Hg + 2CH_3HgBr$$

No evidence was thus obtained for the formation of ethyl radicals.

The Decomposition of Normal Butane on Carbon Filaments.—These experiments were performed in exactly the same manner as those for propane. At 1650°, about two-thirds of the olefin product proved to be propylene, 1,2- and 2,3-butylene constituting the remaining third. It is significant that radical formation at this temperature was appreciable.

The products at 1750° contained butadiene, identified as the solid tetrabromide, propylene also being present in relatively increased proportions. No ethylene could be isolated.

The radicals produced here also appeared to be methylene, while experiments with mercury again failed to reveal the presence of ethyl radicals.

The Decomposition of Propylene on Carbon Filaments.—Since these experiments suggest that methylene radicals are produced in the secondary decomposition of the olefin products, probably before they are desorbed from the filament, the reactions of propylene were investigated from the point of view of free radicals. Here also hot tellurium was employed as the radical acceptor. The products obtained were essentially those reported for the decomposition of propane and butane at high temperatures, telluroformaldehyde and dimethyl ditelluride being produced. The presence of hydrogen telluride indicated that dehydrogenation of propylene also occurred. As propadiene and methylacetylene do not appear as products of the decomposition of propane, it is probable that their formation cannot take place when hydrogen is present in appreciable quantities.

In this connection, it is significant that Schneider and Frolich[4] obtained principally ethylene and butylene as decomposition products of propylene. This reaction clearly proceeds in the following stages:

$$CH_3CH{=}CH_2 \longrightarrow CH_2{=}CH_2 + CH_2$$
$$CH_2 + CH_3CH{=}CH_2 \longrightarrow CH_3CH_2CH{=}CH_2$$

---

[11] Rice and Rodowskas, THIS JOURNAL, **57**, 350 (1935).

Certain discrepancies in the experimental work of Rice and his co-workers give rise to some doubt as to whether ethyl radicals are formed at all in the reactions of propane and butane. Thus when the decomposition products of butane were allowed to react with mercury and the mercury alkyls converted to mercury alkyl bromides and fractionally sublimed, Rice, Johnston and Evering[8] obtained a product corresponding in melting point to a mixture of CH_3HgBr and C_2H_5HgBr in the ratio of 2.3 to 1. The corresponding experiments of Rice and Glasebrook[10] with tellurium as an acceptor, however, resulted in the formation of pure dimethyl ditelluride only. One must conclude, therefore, that the mercury alkyl bromides of Rice, Johnston and Evering were imperfectly separated from mercuric bromide, and that only methyl radicals were produced in these experiments. In view of the experience of Rice and Glasebrook[9] with the decomposition of diazomethane in the presence of butane or ether at temperatures above 650°, when only methyl and no methylene radicals could be detected, it is not unlikely that all the methyl radicals formed in hot tube decompositions of the hydrocarbons, are in reality only secondary products of methylene.

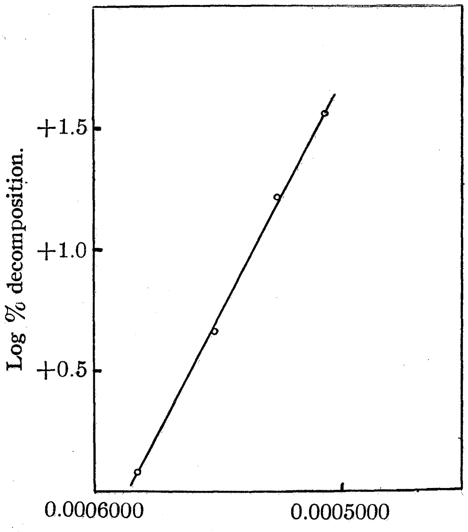

Fig. 1.—Decomposition of *n*-butane on carbon: $E = 93{,}200$ cal.

The Energy of Activation for the Decomposition of Propane and *n*-Butane on Carbon Filaments.—Except for the fact that the products of decomposition were made to pass through a liquid-air trap placed between the Gaede pump and the 2-liter bulb in the forevacuum side of the apparatus instead of being adsorbed on charcoal, the experimental procedure was identical with that employed in the corresponding work with methane and ethane.[2] Here also the rate of reaction was followed with respect to hydrogen, hydrocarbons being frozen out of the sample with liquid nitrogen boiling under reduced pressure. The results for propane are given in Table I, the percentage of the gas decomposing to propylene and hydrogen being calculated on the assumption that this was the only reaction occurring at the temperature of the investigation.

TABLE I

Temp., °K.	H_2 in product, %	Decomposition, %
1723	1.03	1.04
1843	4.75	4.99
1948	17.4	21.4
2023	34.0	51.5

The energy of activation for the decomposition of propane on carbon works out to be 94.2 kcal. (Fig. 1) a value very close to that obtained for methane and ethane.

TABLE II

Temp., °K.	Hydrogen in product, %	Decomposition, %
1713	1.17	1.19
1813	4.31	4.50
1903	14.0	16.3
1973	26.6	36.2

The corresponding data for the decomposition of *n*-butane are shown in Table II, from which an energy of activation of 93.2 kcal. is obtained (Fig. 2).

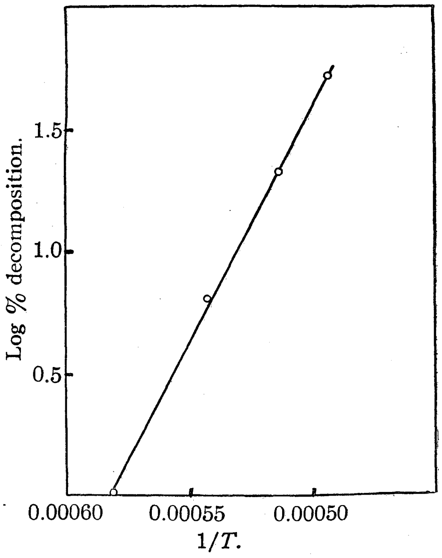

Fig. 2.—Decomposition of propane on carbon: $E = 94{,}200$ cal.

It will be observed that although high percentages of propane and butane passed through the reaction vessel decompose in the region of 1700°, the linearity of the energy of activation curve is very closely preserved. This must mean that secondary processes involving the production of methylene radicals do not appreciably alter the total volume of gaseous products, and that interaction between methylene and the parent hydrocarbon molecules must occur readily. Methane can only have constituted a small percentage of the products (not exceeding 5% at the highest temperatures) as evidenced by the negligible diminution in partial pressure of the residual gas when condensable hydrocarbons were first frozen out with liquid nitrogen boiling under atmospheric pressure, and later with liquid nitrogen boiling under reduced pressure.

Discussion

It would appear from these results that the primary reaction at a carbon surface involves the dissociation of hydrogen from the parent hydrocarbon.

$$CH_3CH_2CH_3 \longrightarrow CH_3CH{=}CH_2 + H_2$$

$$CH_3CH_2CH_2CH_3 \begin{array}{l} \nearrow CH_3CH{=}CHCH_3 + H_2 \\ \searrow CH_3CH_2CH{=}CH_2 + H_2 \end{array}$$

The next stage consists in the further decomposition of the olefin with the production, in the case of propane, of ethylene and methylene.

$$CH_3CH{=}CH_2 \longrightarrow CH_2{=}CH_2 + CH_2$$

Whereas 2,3-butylene dissociates to propylene and methylene

$$CH_3CH{=}CHCH_3 \longrightarrow CH_3CH{=}CH_2 + CH_2$$

1,2-butylene is capable of undergoing further dehydrogenation to butadiene

$$CH_3CH_2CH{=}CH_2 \longrightarrow CH_2{=}CHCH{=}CH_2 + H_2$$

The propylene formed from 2,3-butylene can of course decompose still further to ethylene and methylene, although this step was never realized in our experiments.

It is interesting to note that the energy of activation for the decomposition at a carbon surface is constant, and has the relatively high value of *ca.* 94 kcal. for the four hydrocarbons investigated. Separate experiments indicated that the rate of reaction was approximately proportional to the pressure. We must thus conclude that the reaction velocity is not governed by the desorption of hydrogen but rather by some reaction taking place at collision. The energy of activation may well represent a complex mechanism involving the transformation of a relatively inert carbon surface into a reactive carbon pair similar to that found in dehydrogenation of hydrocarbons. We should thus obtain conditions permitting of a quantum mechanical transfer of two hydrogen atoms from one to another carbon pair at the moment of collision.

In conclusion, one of us (L. B.) would like to express his thanks to the governing bodies of Emmanuel College, Cambridge, and to the University of South Africa, for scholarships, and to the Philgas Co., Bartlesville, Oklahoma, for their gift of C. P. propane and *n*-butane.

Summary

The decomposition of propane and *n*-butane on carbon filaments has been investigated from the point of view of radicals and olefin products.

The experiments indicate that the initial act is the production of hydrogen and the complementary olefin. The latter can then dissociate to methylene and the next lower olefin, except in the case of 1,2-butylene which is capable of further dehydrogenation to butadiene. Methylene subsequently undergoes reaction with the surrounding molecules.

The energies of activation for the two reactions have been determined at 94.2 and 93.2 kcal.

The Changes of the Magnetic and Catalytic Properties during the Transformation of a Mixture of Calcium Oxide and Ferric Oxide into Calcium Ferrite[1]

BY GUSTAV F. HÜTTIG, JOSEF FUNKE AND HERBERT KITTEL

1. Purpose of the Investigation

If a stoichiometrical mixture of the oxides of a bivalent metal and of a trivalent metal is brought to higher temperatures, in many cases a crystalline compound will be formed according to the scheme $MeO + R_2O_3 \longrightarrow MeR_2O_4$. In several former communications it was shown[2] by us that *before* the formation of the crystallized addition compound very active intermediate substances are formed, *e. g.*, some with a very high catalytic effect, as high magnetic susceptibility and similar enhanced properties. From the magnetic, optic, x-ray spectroscopic, catalytic, and other properties, it could be concluded without doubt that these active intermediates are by no means mixtures of the starting materials ($MeO + R_2O_3$) with the crystallized end-products (MeR_2O_4) but that the reaction mixture or parts of it are present in specifically characterized compositions. In agreement with the theory of W. Jander,[3] the experimental results pointed to the conclusion that these active intermediates consist of comparatively thin films which envelop the starting material, thus leaving the kernel entirely unaffected. It was possible to obtain about 30% in the system CaO/Fe_2O_3, about 15% in the system SrO/Fe_2O_3, and about 10% in the system BaO/Fe_2O_3 of the total mixture in the form of this film. If the heating is continued further, crystals of the compound MeR_2O_4 begin to form in increasing quantities while the amount of starting material ($CaO + Fe_2O_3$) diminishes. With the onset of this crystallization, the activity of the substance decreases and the film has but little more to do with the building up of the system.

In view of the generality of this phenomenon and of the great significance of oxidic mix-catalyzers in industry, it seemed necessary to find an explanation of the nature of these carriers of the active properties and their changes with time by systematic investigations. For this purpose parts of a stoichiometrical mixture of calcium oxide (as calcium carbonate) and ferric oxide were brought to various temperatures (t_1); each substance thus prepared was tested for its magnetic properties, its catalytic effect at different temperatures (t_2) and other properties which might help to explain its nature. The results of the investigations and the conclusions reached are described in the following sections.

2. Experimental Arrangement and Nomenclature

The substances, after being prepared as described in the following section, were tested for their catalytic activity in the decomposition of nitrous oxide ($2N_2O \longrightarrow 2N_2 + O_2$) at different temperatures (t_2). Further their magnetic susceptibility, their "powder-density" (weight of 1 cc. of the finely ground powder after being shaken to a fairly compact mass), their color, and (in the experimental series II) their carbon dioxide content was determined. The catalytic activity in the formation of carbon dioxide ($2CO + O_2 \longrightarrow 2CO_2$) as well as x-ray data, which had been obtained by us in former similar experiments, were sometimes used for comparison.

The *catalytic activity* in the decomposition of nitrous oxide was measured with the same arrangement as has been described before.[4] In all the experiments mentioned here 577 cc. (*c*, measured at 20°) of nitrous oxide, always purified and dried in the same way, were led past the catalyzer per hour. The cross section of the catalysis tube was 1.54 sq. cm. In experiments with pure, unmixed calcium oxide, the sample weighed 0.208 g. (0.00371 mol calcium oxide) in those with pure, unmixed ferric oxide 0.59 g. (0.00371 mol ferric oxide), and in the mixed catalyzer, consisting of calcium oxide *and* ferric oxide 0.800 g. (0.00371 mol $CaO \cdot Fe_2O_3$). In substances containing the calcium oxide partially or wholly bound to carbon dioxide, 0.800 g. was also weighed out each time; in these cases the number of moles is somewhat smaller (depending on the carbon

dioxide content) than when carbon dioxide-free samples are used, and the measured catalytic activity is therefore not at once comparable with that of the carbon dioxide-free substances. The percentage of nitrous oxide which was decomposed by the catalyzer is represented by α, while t_2 is the temperature at which the catalysis was observed.

The *magnetic susceptibility* was measured *before* the substance had been used as catalyzer, employing two different field strengths (480 and 950 gauss) and an arrangement which has been applied and described in former investigations.[5] χ represents the "magnetic mass-susceptibility" (susceptibility referred to 1 g. of the substance) and ρ the "powder-density" (defined above).

The *color* of the samples (Ow) is designated according to the color chart (with 24 divisions) of Wilhelm Ostwald (Grosser Farbatlas; editor Unesma G. m. b. H., Leipzig). In our case the following were important:

4	5	6	7	8
reddish	reddish with brown tint	reddish-brown	reddish-purple	purple

The two added letters indicate the content of gray.

In samples where calcium carbonate was used as starting material, the *carbon dioxide content of the catalyzer* is given by the number of moles of carbon dioxide (n) which exist per 1 mole of calcium oxide; *e. g.*, $n = 0.33$ signifies that one-third of the total calcium is present as calcium carbonate.

3. Preparation of the Samples

Series I.—Starting materials: *calcium oxide* (Kahlbaum "pro analysi") was heated for two hours to 1050°; it then showed a $\rho = 0.957$ and $\chi = -0.58.10^{-6}$. The *ferric oxide* (Fe_2O_3) was prepared from an aqueous solution of ferric chloride by precipitation with ammonia[6] and ignition for two hours over the Bunsen burner of the ferric hydroxide formed. *Preparation of the parts of the system CaO/Fe_2O_3:* the calcium oxide and the ferric oxide were mixed in molar proportions ($1CaO:1Fe_2O_3$), pulverized in an agate mortar for one-half hour and pressed through a 10,000-mesh sieve; then they were mixed for two hours in a machine and afterward kept for six hours in a crucible at a temperature t_1 (see Table I). Every sample has been subjected to the complete temperature treatment of the substances prepared at lower temperatures. The samples were cooled from temperature t_1 to room temperature in a vacuum desiccator. After this, they were once more pressed through the same sieve and mixed for one hour; then they were ready for the investigation. Great care was taken to keep moisture and carbon dioxide away from the sample.

Series II.—Calcium carbonate (Schering and Kahlbaum, Berlin, D. A. B. 5; analysis 99.57% $CaCO_3$, 0.43% H_2O) was mixed with the same ferric oxide as in series I in molar proportions ($1CaCO_3:1Fe_2O_3$), then pulverized for one-half hour in an agate mortar and finally mixed for twelve hours with a machine. The further treatment was as in series I, only that instead of pressing it through a sieve, the mixture was pulverized in an agate mortar.

Series III.—These samples were prepared exactly as those of series II with the only difference that after preparing the stoichiometrical mixture ($1CaCO_3:1Fe_2O_3$) a further 3% of crystalline calcium ferrite ($CaFe_2O_4$) was admixed. The latter was identical with the product of series I after the sample had been heated to $t_1 = 1000°$.

Series IV.—In preparing the samples of this series, special care was taken that the heating, and therefore also the changes caused thereby, were the same in all layers of the sample. The preparation was the same as in series II; however, the heating was not done in a crucible but the mixture was made into a paste with purest methanol (puriss. free from acetone) and with that the middle portion of a porcelain tube, which fitted exactly in the center of an Heraeus furnace, was covered evenly with a layer 0.25 mm. thick. Within two hours the furnace was brought to a temperature of 120° while a stream of dry air was passed through it. After leaving it at that temperature for two hours, the passage of air was stopped, the oven heat-insulated and the temperature gradually brought to t_1 in five hours where it was held for $\tau = 6$ hours. Here the various samples do *not* have the same temperature treatment as the substances prepared at lower temperatures.

A number of preliminary experiments have shown that the treatment with methanol is without influence upon the products formed. A crucible was divided into 2 symmetrical parts by an exactly fitting plate of eternite. One-half was filled with the mixture without methanol, while the other half contained the paste prepared with methanol. The whole was then heated as has been described above. By repeating the experiments at different temperatures, t_1, a series of samples were prepared. In all cases the contents of both halves of the crucible showed identical magnetic properties, in particular also the temperature t_1, at which ferromagnetism at first becomes apparent, is the same.

The samples of series V were prepared exactly as those of series IV, with the only difference that the time of heating (τ) to temperature t_1 was not the same in the various samples, as is stated in Table I, column 1.

4. The Results Obtained

The observed catalytic activity in the decomposition of nitrous oxide is given for all samples in Fig. 1. In the lower left corner of each graph the number of the experimental series corresponding to one of the above described modes of preparation is given. The temperature (t_1) of prepara-

(6) Hüttig and Garside, *ibid.*, **179**, 49 (1929).

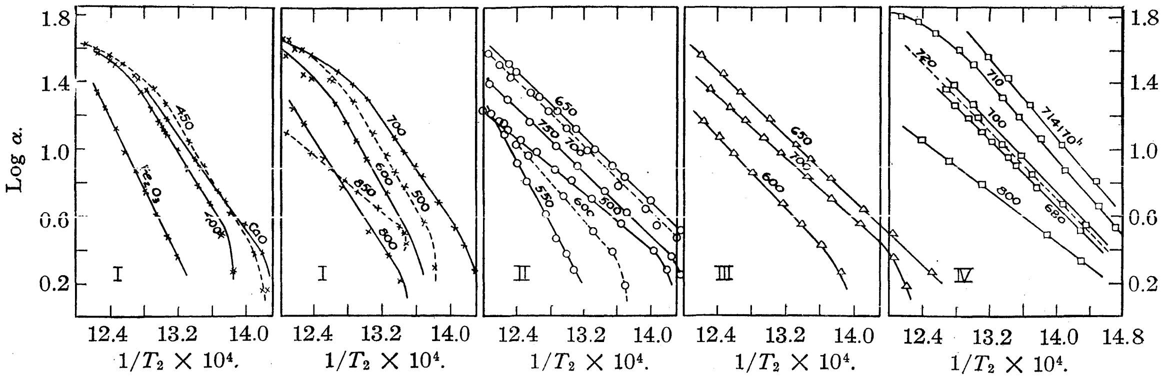

Fig. 1.

tion is given with each curve and identifies the various substances within a given series. The value $1/(t_2 + 273) = 1/T_2$ is plotted as abscissa, while the ordinates represent the corresponding value for $\log_{10} \alpha$. In the interval $\alpha = 2$ to 30%, the experimental results form a straight line on the graph. It is therefore possible to represent these results by the equation $\log_{10} \alpha = -(q'/T_2) + \log n'$, where q' and $\log n'$ are individual constants for each sample. If q (cal.) is set equal to $1.986 \times 2.303\ q'$, then q represents in the usual notation the "heat of activation," *i. e.*, a number which for a given sample must be the smaller, the more catalytically active any single active place, while n' represents a number which is proportional to the number of catalytically active places.

In Table I, columns 2 and 3, the values q and log n' for the various samples are given; the identity of the samples may be seen in columns 1. As the decomposition products of nitrous oxide have an influence upon the catalytic activity[7] and also other complications are possible, these figures may only be used for qualitative comparisons. In columns 4 to 6 are given the mass susceptibilities (χ) measured with field strengths of 480 and 950 gauss; in column 7 the powder densities (ρ), in column 8 the color. The amount of carbon dioxide given off by the sample during its preparation ($1-n$) is given as a footnote to series II and III. The significance of the figures given in column 9 (γ) is explained in section 5.

Series III (Table I) below the observed χ-values those susceptibilities appear in brackets which are found if the known magnetic effect of the added calcium ferrite is eliminated by calculation from the observed values.

In Figs. 2 and 3 the temperature of preparation (t_1) is always plotted as abscissa and perpendicularly to it some of the properties characterizing the substance. Points referring to samples of series I are always marked with x, those of series II with o, those of series III with Δ and those of series IV with $\Box$. In Fig. 2a the α-values of samples of series I for temperatures of catalysis (t_2) of 500°, 515 and 530° are drawn. For comparison also the catalytic activities, observed previously[8] with a similar set of experiments and measured by the reaction $2CO + O_2 \longrightarrow 2CO_2$ are here drawn as a dotted curve (the divisions of the ordinates are, however, not valid for this curve). Figure 3b gives curves for the α-values of series I (. . . curve), III (--- curve) and IV (-·- curve) for t_2 = 530° and of series II (drawn out curve) for t_2 = 500°, 515 and 530°. In Fig. 2a, the ($1-n$) values are given for series IIa. For the first 4 experimental series, the q-values are given in Figs. 2b and 3c, while the values for log n' of the same series are plotted in Figs. 2c and 3d. Figures 2d and 3e show the magnetic susceptibilities (χ); here in the case of series IV the calculated figures (in brackets in Table I) have been used. Figures 2e and 3f refer to the powder densities (ρ) and Figs. 2f and 3g give a graphical presentation of

the differences in color, the ordinates representing the number of the color chart. Figure 2g is based on previously obtained x-ray data[4a] (p. 311) curve A representing the estimated intensity of a line of the Debye photograph (characteristic of the oxide mixture) and curve B referring similarly to a line of the crystallized calcium ferrite.

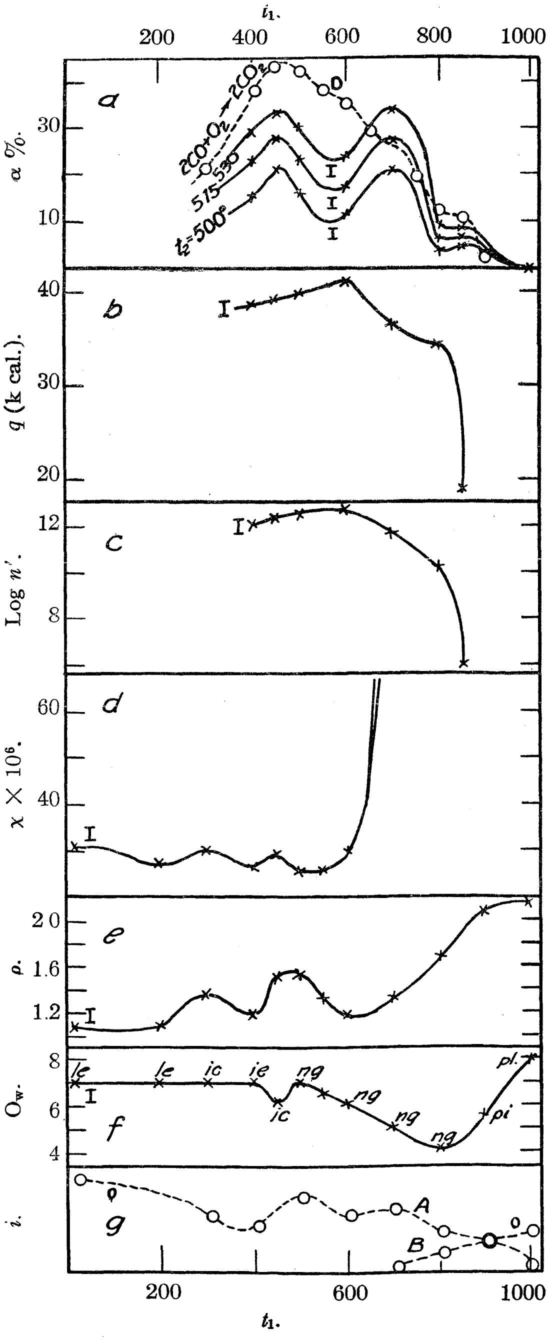

Fig. 2.

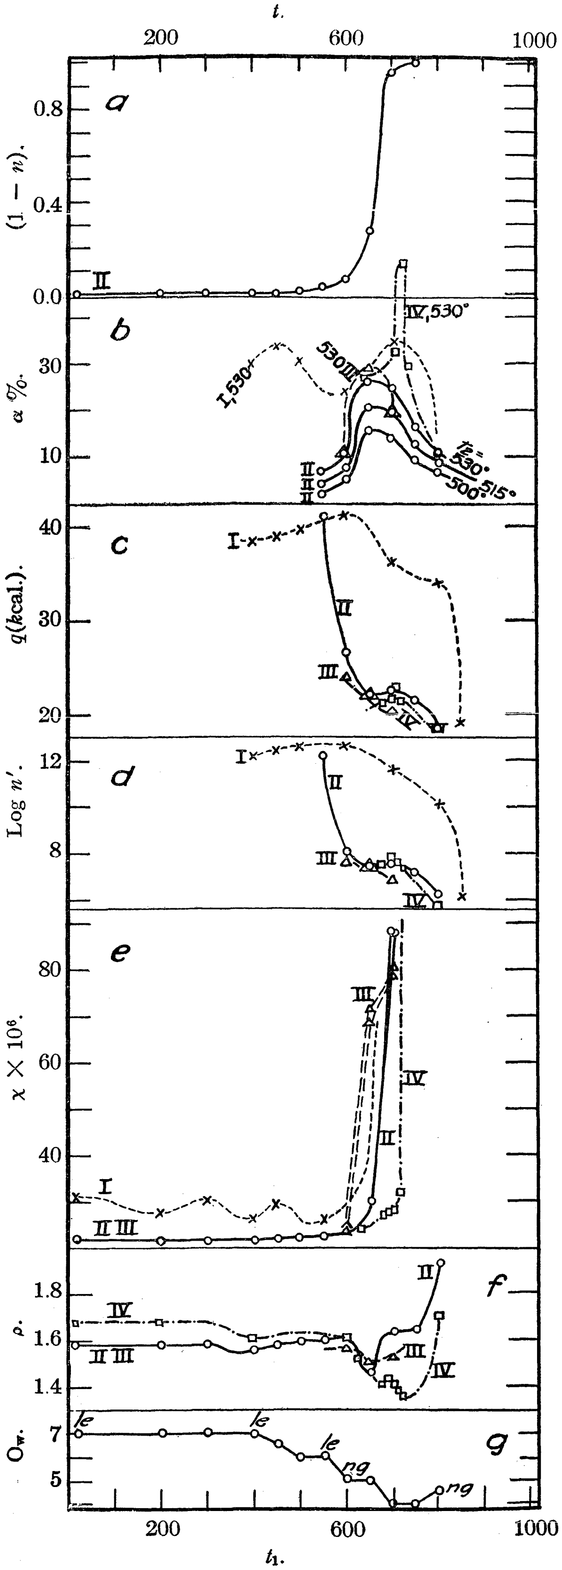

Fig. 3.

For an evaluation of the above catalytic data, the following results from *preliminary experiments* may also be mentioned.

No.	Sample	Amount used for catalysis, g.	Streaming velocity (c) cc./hr.	q, cal.	Log n'
1	CaO	0.800	577	31640	10.67
2	CaO	.208	577	31640	10.23
3	CaO (previously 12h at 1000°)	.800	577	31690	10.56
4	Fe_2O_3	.8000	577	46280	13.81
5	Fe_2O_3	.592	577	46280	13.75
6	Fe_2O_3	.592	200	49780	14.01

The starting substances were the same as described for experimental series I in Section 3.

5. Evaluation of Results

Let us consider first the series II, Table I. The mixture of calcium carbonate and ferric oxide, prepared at room temperature, does not change its properties if it is heated to $t_1 = 400°$. On heating further, a slight loss of carbon dioxide commences in the region from 400 to 450°; the original color 7 le changes toward 6 le and the paramagnetism here shows its first increase.[9]

All these changes take place in the temperature interval from 450 to 650°. At 650° the magnetic susceptibility which is independent of the field strength reaches a maximum with $\chi \times 10^6 = 29.9$; here also the catalytic activity in the decomposition of nitrous oxide reaches maximal values (Fig. 3b). About 28% of the total carbon dioxide content of the sample has been given off by that time and the color has changed to 5 ng. In the region from 650 to 700° ferromagnetism suddenly appears which becomes rapidly larger with increasing temperature of preparation, while simultaneously a decrease of the catalytic activity toward minimum values is observed.[10]

The carrier of the increased activity, as is observed to a greater degree with samples prepared between 400 and 650°, *cannot be the crystallized calcium ferrite,* because even the smallest quantities of calcium ferrite (cryst.) would induce strong ferromagnetic properties in the sample, and no paramagnetism could be observed with substances containing calcium ferrite; besides, no calcium ferrite in this region is determinable even by x-ray spectra (*cf.* Fig. 2g). The carrier of the increased activity must therefore be an intermediate between the original oxide mixture and the crystallized calcium ferrite; it must be a specifically characterized composition which *no longer* possesses the properties of the original mixture *nor yet* the properties of the crystallized calcium ferrite. With regard to the *quantity* of this "*active intermediate*" it could further be determined that it cannot, in general, be limited simply to a covering of the surface in a layer with a thickness of a few molecules. Such a thin covering by the active intermediate, though it would be sufficient to explain the changes of those properties which only depend upon the condition of the surface (*e. g.*, catalysis[11] or color), would never be able to explain the fundamental changes of those observed properties which represent a mean value of the condition of *all* molecules (*e. g.*, the magnetic susceptibility or the pycnometrically determined density).[12]

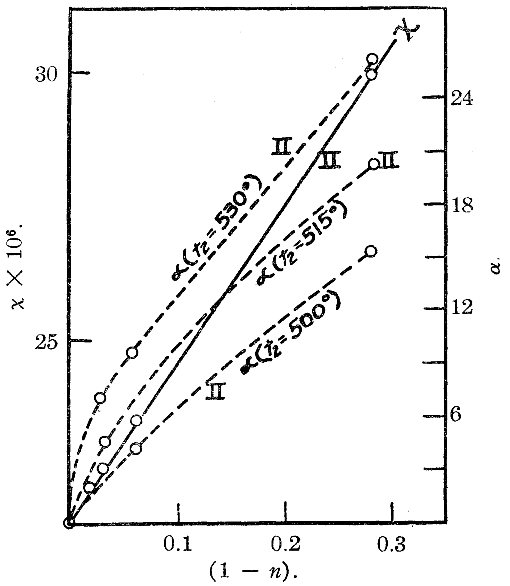

Fig. 4.

In the following way a numerical idea may be obtained from our experiments as to the percentage of the total sample (γ, *cf.* Table I) which is present in the "active intermediate" form. If the number of moles of carbon dioxide $(1 - n)$ which have been given off by the sample per 1 mole of calcium carbonate during its preparation is plotted as abscissa, and the ordinates represent the magnetic susceptibility (χ), the relationships between χ and $(1-n)$ as shown in Fig. 4 (drawn out curve) are obtained. It can be seen that a strict proportionality exists between the increase of susceptibility and the amount of carbon dioxide

given off by the sample.[13] Because calcium oxide as well as calcium carbonate can only be diamagnetic, this probably means only[14] that each mole of calcium oxide, formed by the decomposition of calcium carbonate, at once forms the "active intermediate" with the ferric oxide and remains as such for some time. By extrapolating the straight line (Fig. 4) to the value $(1-n) = 1.0$ a value is obtained for $\chi \times 10^6 = 51.5$; *i. e.*, this susceptibility (*independent* of the field strength) should be observed if 100% of the sample were to exist in the "active intermediate" form; the increase in susceptibility $\chi \times 10^6$ of such a sample compared to that of the original mixture ($\chi \times 10^6 = 21.5$) amounts therefore to $51.5 - 21.5 = 30.0$.[15] By comparison of the actual increase obtained with different samples of this value, which corresponds to a 100% product, the percentage of "active intermediate" present in the different samples is obtained. This is given as γ% in column 9 of Table I. In series II, the sample which was prepared at 650° contains the largest quantity of the "active intermediate" (27.7%).

The "active intermediate," at least in a first approximation, represents a uniform substance. If this substance soon after its formation should undergo slow changes, perhaps by aging, the measurements should show a continuity of states, and such a proportionality as is evident from Fig. 4 would be unthinkable. Aside from the magnetic mass susceptibility $\chi = 51.5 \times 10^{-6}$, this intermediate form may also be characterized by the heat of activation in the nitrous oxide decomposition, which in our experimental arrangement is measured as $q = 20{,}000$ to 25,000 cal. (*cf.* column 4 of the series II, III, and IV). Corresponding to the fact that the magnetic susceptibility of the ferric oxide, which is used as starting material, may have very different values depending upon the preparation, the magnetic susceptibility obtained for the pure active intermediate varies greatly with different starting substances. In the present case, the starting mixture $CaCO_3 + Fe_2O_3$ had $\chi = 21.5 \times 10^{-6}$, the active intermediate $\chi = 51.5 \times 10^{-6}$. In another series[13] the starting mixture had $\chi = 16.3 \times 10^{-6}$ and the active intermediate $\chi = 45.3 \times 10^{-6}$. In both cases, however, the *increase* is practically the same, *viz.*, about 30×10^{-6}.

If, as is demonstrated in Fig. 4 by the interrupted curves, $(1-n)$ is plotted as abscissa and the catalytic activity as ordinate (α), the α becomes larger with increasing $(1-n)$ and accordingly also with increasing χ, however, without having a direct proportionality. Compared to direct proportionality, the α-values slow up in their increase, and that to a greater degree the more "active intermediate" is formed. This means that a smaller portion of the active molecules formed (*cf.* also the log n'-values of column 5, Table I) is available for catalysis, if a more active intermediate is formed. This seems to us a proof that the active intermediates are formed primarily on the surface of the particles, from where further formation proceeds toward the interior of the particles, whereby the molecules are the less accessible for the molecules to be catalyzed the further away they are from the surface.

That in the series II the formation of a 100% "active intermediate" is not reached is due to the fact that the formation of the crystallized calcium ferrite from the active intermediate commences before the whole starting mixture has been transferred into the "active intermediate." If therefore a high content of the "active intermediate" is desired, it is necessary to prevent the premature formation of calcium ferrite, *i. e.*, to let the whole sample in all parts be transformed as uniformly as possible and to interrupt the process at the proper moment. Such conditions are fulfilled in the working method according to which the samples of series IV (see section 3) have been prepared. By this method it was possible to obtain products with a content of active intermediate (γ) as high as 35%. On the basis of experience gained from series IV, samples with even 60% of the active intermediate have been obtained in series V (*cf.* Table I). In the case of these products which contain practically no more carbon dioxide, one has to imagine that the proportionality between the carbon dioxide given off and the increase of susceptibility ceases if the last remaining portions of calcium carbonate have no ferric oxide sufficiently near them to combine to form the active intermediate; in this case the decomposition of calcium carbonate into calcium oxide and carbon dioxide could take place free from complications.

---

[13] Kittel and Hüttig, *Z. anorg. allgem. Chem.*, **219**, 256 (1934).

[14] The absolute applicability of this reasoning is probably only then guaranteed, when experiments with mixtures in various proportions $CaCO_3$:Fe_2O_3 have also been made.

[15] See footnote 13, p. 262, where these "increases" for the system CaO/Fe_2O_3, SrO/Fe_2O_3 and BaO/Fe_2O_3 have been calculated, but erroneously have not been stated as increases but as total susceptibilities.

On the other hand, it seemed probable that a little addition of crystalline calcium ferrite (as was the case in series III) would hasten the formation of calcium ferrite. Our respective observations (Fig. 3e, curve III) make it probable that in such a case the "active intermediate" is formed already at a lower temperature, while this statement could not be made for the crystallized calcium ferrite. As the magnetic values which form the basis here are obtained by a complicated correction by calculation, the reliability of these statements is less than in the other observations.

If instead of a mixture of calcium carbonate and ferric oxide a stoichiometric mixture of calcium oxide and ferric oxide is used, as has been done in series I, an excess of calcium oxide is always present, and every calcium oxide molecule necessary for the reaction with ferric oxide does not have to be furnished by the primary decomposition of calcium carbonate. Accordingly portions of the starting material can *at first* proceed toward the formation of a more basic product.[16] Thus the fluctuations of the magnetic susceptibilities (Fig. 2d), as they appear with samples prepared at temperatures up to 600°, can be explained. The double maximum of the catalytic activity (Fig. 2a) could also have the same cause[4a] (pp. 308–309). The q and $\log n'$ values do not show similar double turning points (Figs. 2b and 2c).

Summary

1. Mixtures in stoichiometrical proportions $1CaO{:}1Fe_2O_3$ and $1CaCO_3{:}1Fe_2O_3$ were heated to various high temperatures under varying conditions.

2. Samples thus obtained were tested for their catalytic activity in the decomposition of nitrous oxide at various temperatures; further their magnetic susceptibility, their powder density, color, and carbon dioxide content were determined.

3. A detailed description of the preparation of the samples is given.

4. The results of the experiments are presented in figures and tables. For each sample the heat of activation (q) in cal. and a number n' is given which is proportional to the number of active centers in cases free from complications. Previously obtained results for the catalytic activity in the formation of carbon dioxide and x-ray data are used for comparison.

5. The following conclusions are drawn from the observations. The carrier of the increased activity is a specifically characterized "active intermediate" which no longer possesses the properties of the original mixture nor yet those of the crystallized calcium ferrite. A way to calculate the percentage of the "active intermediate" is given; the most active samples contain up to 60% of it. The "active intermediate" is a uniform substance with a susceptibility which is independent of the field strength and equal to $\chi = 51.5 \times 10^{-6}$, and with a heat of activation (in the decomposition of nitrous oxide from 20,000 to 25,000 cal. Its formation starts on the surface of the particles and proceeds toward their interior.

Reduction of Nitroguanidine. II. Preparation and Properties of Nitrosoguanidine[1]

BY V. J. SABETTA, DAVID HIMMELFARB AND G. B. L. SMITH

Introduction

Nitrosoguanidine and aminoguanidine are formed by the reduction of nitroguanidine.[2] Nitrosoguanidine is a mixed ammonocarbonic–aquonitrous acid anammonide or anhydride, or a mixed ammonohydroxylamic carbonic acid and it is related to nitroguanidine as nitrous acid is to nitric acid.[1a] Thiele[2] has prepared nitrosoguanidine by reducing nitroguanidine in a solution of sulfuric acid with zinc. Reduction with zinc employing a solution of ammonium chloride has been used in this Laboratory for the preparation of nitrosoguanidine and has been found to be convenient and to give satisfactory yields. This paper describes the preparation and some of the general properties of this interesting substance.

Preparation

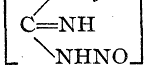
The reduction of nitroguanidine to nitrosoguanidine must be carried out so as to provide the following environmental conditions: (a) the reaction must be controlled so as to prevent the reduction proceeding beyond the nitroso stage; (b) dearrangement and hydrolysis must be minimized by controlling both the temperature and acidity of the solution; (c) nitrosoguanidine formed must be readily isolated without contamination with the reducing agent or with other substances formed by the reaction or present in the reaction system. With these conditions in mind the following method has been developed and has been used repeatedly by many workers.

Nitroguanidine[1b] (60 g.) is dissolved in 1 liter of boiling water and the nitroguanidine is precipitated in a finely divided form by violently agitating the solution while it is being rapidly chilled in an ice bath. Ammonium chloride (15 g. thus giving a concentration of 1.5%) is added to the solution and zinc powder (generally about 60 g.) is introduced at such a rate that the temperature of the reaction mixture is maintained below 50°. Samples of zinc dust vary widely in reducing activity so that the time of reduction and amount of zinc dust required must be established for each new sample of zinc. From twenty to forty minutes is usually sufficient for the reduction and when all the white nitroguanidine has been replaced by the yellow precipitate of nitrosoguanidine (nitroguanidine may be detected also by filtering 10 ml. of the mixture, treating the solid material with 5 ml. of hot ethanol, evaporating to half volume and cooling—white needles indicate the presence of nitroguanidine) ice is added to the reaction mixture and after cooling the solids are separated by filtration. Nitrosoguanidine is extracted from the mixture on the filter with 3–4 liters of water at 70° and recovered from the filtrate by chilling to 5° for half an hour. The product so obtained (98% nitrosoguanidine) is recrystallized from water (60–70°), washed with ethanol, ether and dried *in vacuo;* yield 40 to 60%.

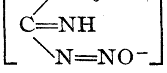
Properties

Nitrosoguanidine is a yellow crystalline solid, individual crystals having a greenish cast by transmitted light and slightly pinkish by reflected light. Aqueous solutions are colored yellow and the intensity of this color is proportional to the concentration at constant temperature and *p*H between 6 and 10. At 10° the color intensity is 70% of that at 40° and at *p*H of 2 and 12 it is 80% of that at *p*H 7.[3] The solid detonates rather sharply at 161° and leaves only a slight amount of solid residue. It may be detonated on the open palm of the hand without any injury resulting. The following are the solubilities of nitrosoguanidine in grams per 100 g. of water at the several temperatures: 5°, 0.093; 15°, 0.118; 20°, 0.154; 25°, 0.185; 30°, 0.246; 40°, 0.365; 50°, 0.527; 72°, 1.22; 73°, 1.31. It is practically insoluble in diethyl ether and sparingly soluble in ethanol. In a slightly acidic solution a large excess of permanganate ion oxidizes nitrosoguanidine to nitroguanidine but in strongly acidic solutions nitric acid and guanidine are formed. In a solution of sodium hydroxide, permanganate ion is reduced to manganate ion and a gas is formed; further reduction yields acid permanganite ion while cyanamide and nitrate ion were identified.

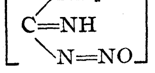
Nitrosoguanidine is an ampholyte. It is dissolved to a greater extent in acidic and basic solution than in neutral solution and the isoelectric point is near *p*H 7.[3] The three forms present in aqueous solutions may be represented as follows



I



II



III

This amphoteric character of nitrosoguanidine is of importance in connection with hydrolytic and

dearrangement reactions of the substance in aqueous solutions. Guanidine and nitrous acid are formed in acidic aqueous solutions, nitrous acid having been recovered quantitatively and guanidine nitrate and picrate being isolated from the reaction solution. In neutral solution cyanamide and nitrogen are formed as Thiele[2] observed. In alkaline solutions carbon dioxide, ammonia, cyanamide and nitrogen have been detected.[4]

Measurements of velocity constants of the decomposition in acidic, neutral and basic solutions show that the reactions are all monomolecular or rather pseudo-monomolecular. The constants vary with the hydrogen-ion concentration in acid solution and with the hydroxyl-ion concentration in basic solution. The energy of activation in acidic and basic solutions is about 19,000 calories per mole and is probably somewhat higher in neutral solutions.[5]

Analytical Methods

Five methods for the determination of nitrosoguanidine are indicated from the studies of its properties and have been developed: (1) colorimetric; (2) estimation of nitrous acid formed by hydrolysis of nitrosoguanidine in a dilute solution of nitric acid; (3) titration with a standard solution of potassium permanganate; (4) weighing as silver nitrosoguanidine; (5) weighing silver chloride from the conversion of silver nitrosoguanidine. These methods have all been found to be of moderate precision and (3) which has been used in the routine establishment of the purity of nitrosoguanidine will be described in more detail.

A sample of nitrosoguanidine (approx. 0.2 g.) is dissolved in 100 ml. of 3 *M* sulfuric acid to which has been added about 2 g. of manganous sulfate. A standard solution of potassium permanganate (0.1 *N*) is added only as rapidly as the solution is decolorized and when about three-fourths of the nitrosoguanidine has been decomposed the reaction proceeds slowly. The end-point is taken when the pink color of permanganate ion persists for two minutes during which period the solution is violently agitated.

Analytical Results.—Method 2: Nitrosoguanidine taken: 0.1246, 0.1578, 0.1703, 0.1728 g. Found: 0.1250, 0.1576, 0.1708, 0.1735 g. Method 3: Nitrosoguanidine taken: 0.2000 g. (5 samples). Found: 0.2016, 0.1996, 0.2006, 0.2003, 0.1993 g. Method 4: Nitrosoguanidine taken: 0.1440, 0.2042, 0.1654 g. Found: 0.1447, 0.2046, 0.1653 g. Method 5: Nitrosoguanidine taken: 0.2332, 0.2449, 0.2830 g. Found: 0.2332, 0.2440, 0.2836 g.

Summary

A method for the preparation of nitrosoguanidine by reduction of nitroguanidine with zinc in a solution of ammonium chloride is proposed. Some of the characteristic physical and chemical properties of nitrosoguanidine are described. Five methods for the determination of nitrosoguanidine are suggested.

Reduction of Nitroguanidine. IV. Preparation of Nitrosoguanidine by Catalytic Hydrogenation

BY EUGENE LIEBER AND G. B. L. SMITH

Introduction

In this extended investigation of the reduction of nitroguanidine[1] catalytic hydrogenation to nitrosoguanidine has been accomplished over both the Adams platinum[2] and the Raney nickel catalysts.[3] These reactions may be used for the preparation of nitrosoguanidine, which is obtained in excellent yield and relatively high purity.

Method

Nitroguanidine[1a] (10.4 g.) is suspended in 150 ml. of water and 0.5 g. of Adams or 5 g. of Raney nickel catalyst is added. The reduction is carried out either at four atmospheres pressure using the Burgess–Parr apparatus[2] (p. 452) or at one atmosphere, in which case the hydrogen is introduced from a 100-ml. buret and the Burgess–Parr shaking equipment is employed. The reaction is discontinued when slightly more than one mole of hydrogen (2300 ml.) has been adsorbed. The contents of the reduction bottle are transferred to an Erlenmeyer flask and decolorizing charcoal is added. The solution is diluted to 700–800 ml., heated to 65° and then rapidly filtered. The filtrate is again treated

with decolorizing charcoal at 65° and refiltered. The filtrate is cooled to 5°, the nitrosoguanidine is separated on a Büchner funnel and dried *in vacuo*. The yield varies from 36 to 62% (3.2–5.5 g.). Typical preparations are summarized in Table I.

TABLE I

TYPICAL DATA REGARDING THE CATALYTIC HYDROGENATION OF NITROGUANIDINE[1c]

H_2 press. atm.	Time of redn.	Rate ml. H_2/min.	Nitroso-guanidine yield, %	Purity of nitroso-guanidine, %
Adams Platinum Oxide Catalyst				
1	108	20.6	55.7	93.5
1	109	20.6	59.2	94.3
4	45	45.2	58.5	98.3
Raney Nickel Catalyst				
1	139	16.6	43.4	96.3
1	137	16.8	39.8	99.5
4	110	18.5	44.3	100.3
4	99	20.5	36.6	100.0

Discussion

Water, methanol, ethanol, dioxane and benzene were used as reaction media and water was found to be the most suitable for the Adams catalyst and satisfactory for the Raney catalyst. Methanol gave somewhat higher adsorption rates with Raney nickel (23 ml. of hydrogen per minute) and yields of 45% were obtained consistently. Higher pressures gave increased adsorption rates for the Adams catalyst but were without much effect for the Raney catalyst. The yields of nitrosoguanidine were not affected markedly. The optimum temperature is 25–35° and a decrease or increase of 10° resulted in a lowering of the rate of hydrogen adsorption of 40–70%. The yields of nitrosoguanidine were not affected with the Adams catalyst but with the Raney nickel the yields were materially decreased.

With the Raney nickel catalyst it was found that the optimum ratio of catalyst mass to nitroguanidine was 0.5 g. of catalyst per gram of nitroguanidine. A smaller ratio decreases the rate of adsorption of hydrogen while a ratio of 1 gives a maximum rate but at the same time the yields of nitrosoguanidine are very greatly lowered.

A more comprehensive study of the catalytic hydrogenation of nitroguanidine, now in progress, will include the further reduction to aminoguanidine, the effect of other catalysts and the reduction of nitroaminoguanidine, alkylnitroguanidines and nitrourea.

Summary

Nitroguanidine can be reduced by catalytic hydrogenation using either the Adams platinum oxide catalyst or the Raney nickel catalyst to give a satisfactory yield of nitrosoguanidine.

BROOKLYN, NEW YORK RECEIVED OCTOBER 4, 1935

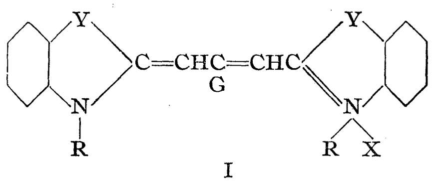
[COMMUNICATION NO. 562 FROM THE KODAK RESEARCH LABORATORIES]

Studies in the Cyanine Dye Series. II.
Carbocyanines with Substituents in the Three-Carbon Chain

BY L. G. S. BROOKER AND FRANK L. WHITE

Ethyl orthoformate was employed for the preparation of dyes of the thiacarbocyanine series by König and Meier[1] and by Hamer.[2] The latter, using ethyl orthoacetate, prepared thiacarbocyanines containing an 8-methyl group.[3]

It is now found that ortho esters of higher aliphatic, of substituted aliphatic and of aromatic acids may be employed for the preparation of new thiacarbocyanines (I, Y = S) where G represents a higher alkyl, a substituted alkyl or an aryl group, according to the ortho ester used.[4]



I

Ortho esters of propionic, *n*-butyric, *n*-valeric, *n*- and isocaproic, phenylacetic, phenoxyacetic and benzoic acids have been made and used in the course of this work, and of these the majority are new. The general method used in the preparation of these ortho esters consists in allowing an alcohol to act upon an imino-ester hydrochloride (preferable to "imino-ether hydrochloride"), prepared in turn from a nitrile. This

method was first applied to the preparation of ethyl orthoformate by Pinner,[5] and to that of ethyl orthoacetate and ethyl orthopropionate by Reitter and Hess.[6] Improved methods for the preparation of these two last ortho esters have since appeared,[7,8] whilst ethyl orthophenylacetate was prepared by Staudinger and Rathsam[9] and later by Sah, Ma and Kao.[10] Ethyl orthobenzoate has been obtained by the interaction of sodium ethylate and benzotrichloride,[11] but in the present work it, too, was prepared by the general method.

In the case of 2,2′,8-triethylthiacarbocyanine iodide (I, G = R = Et), a good yield of dye was obtained when 1-methylbenzothiazole ethiodide (2 mols) and ethyl orthopropionate (3 mols, *i. e.*, 200% excess) were allowed to react together in boiling pyridine solution, but the yield was much poorer if methyl orthopropionate (3 mols) was used, the product, furthermore, being otherwise unsatisfactory for the reason given below. If, however, 1-methylbenzothiazole etho-*p*-toluenesulfonate was employed, the dye being subsequently converted into the iodide, good yields were obtained using both the methyl and ethyl orthopropionates, the former in fact giving the somewhat higher yield. Similar results were obtained in the preparation of 8-ethyl-2,2′-dimethyl- and of 2,2′-diallyl-8-ethylthiacarbocyanine iodide. The yields are given in Table I.

TABLE I

PERCENTAGE YIELDS OF 8-ETHYLTHIACARBOCYANINE DYES

	Quaternary iodide orthopropionate		Quaternary *p*-toluenesulfonate orthopropionate	
Dye	Methyl	Ethyl	Methyl	Ethyl
8-Ethyl-2,2′-dimethylthiacarbocyanine iodide	13 (—)	67 (56)	69 (56)	50 (41)
2,2′,8-Triethylthiacarbocyanine iodide	29 (—)	52 (41)	51 (42)	45 (38)
2,2′-Diallyl-8-ethylthiacarbocyanine iodide	9 (—)	47 (30)		

In each column the yield of crude dye is given, followed in parentheses (except in the first column) by the recrystallized yield. In each of the three cases in the first column the product was found to consist of a mixture of two dyes. In the attempted preparation of 2,2′,8-triethylthiacarbocyanine iodide which resulted in the 29% yield, the product was resolved by fractional crystallization into two fractions, the more soluble of which was proved to be true 2,2′,8-triethylthiacarbocyanine iodide, the less soluble fraction being identical with 2,2′-diethyl-8-methylthiacarbocyanine iodide (I, G = Me, R = Et). This latter fact was established using the means already detailed,[12] when it was shown that 2,2′-diethyl-8-methylthiacarbocyanine iodide is produced when 1-methylbenzothiazole ethiodide is heated alone in pyridine, the =CMe— group at the center of the dye molecule being provided by a breakdown of a portion of the quaternary salt used. There is no doubt that this dye is so produced in the present instance and it is significant that it was not encountered in the three preparations of the 2,2′,8-triethyl dye in which high yields of product were obtained, but only in that in which the yield of crude dye was relatively low. An explanation of these facts is that in the three cases, the reaction between ortho ester and quaternary salt is more rapid than that in which 8-methyl dye is formed from the quaternary salt alone, but in the remaining case, the ortho ester is slow to react with the salt and the latter is available to undergo the reaction which gives the 8-methyl dye.

In the preparation of 8-ethyl-2,2′-dimethylthiacarbocyanine iodide from the quaternary iodide using methyl orthopropionate the dye appeared to be largely that sought for, with some contamination with the related 8-methyl dye, but in the attempted corresponding preparation of 2,2′-diallyl-8-ethylthiacarbocyanine iodide the product, after one recrystallization, appeared to consist almost entirely of the 2,2′-diallyl-8-methyl dye. No attempts were made to isolate the individual components of the mixtures in these two cases.

In the preparation of dyes containing higher alkyl groups (I, G = *n*-Pr, *n*-Bu, *n*- and *i*-Am), 1-methylbenzothiazole alkyl *p*-toluenesulfonates were used in conjunction with the appropriate methyl ortho esters, it being convenient to use these latter, since the methyl imino-ester hydrochlorides from which they are prepared are easier

to isolate than the corresponding ethyl compounds.[13]

In the preparation of thiacarbocyanines containing substituted aliphatic groups (I, G = $C_6H_5CH_2$, $C_6H_5OCH_2$), or an aromatic group (I, G = C_6H_5) in the 8-position, the corresponding ethyl ortho esters gave satisfactory results when used with 1-methylbenzothiazole alkyl *p*-toluenesulfonates.

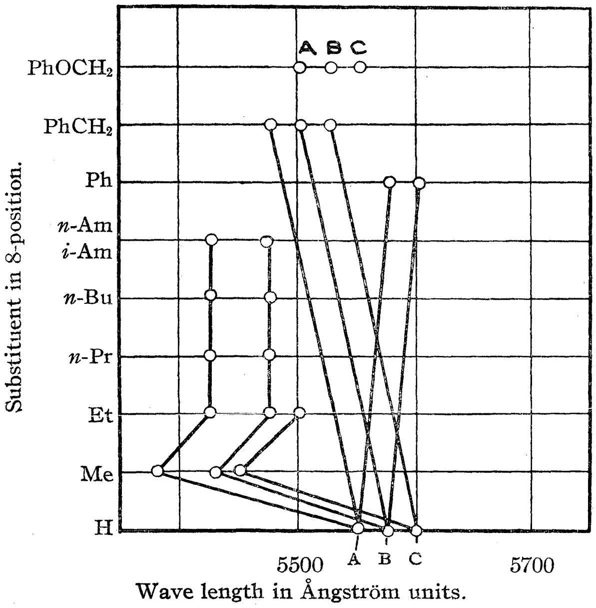

Fig. 1.—Absorption maxima of thiacarbocyanines (I, Y = S): A, 2,2′-dimethyl series; B, 2,2′-diethyl series; C, 2,2′-diallyl series.

The absorption curves of the new dyes showed a well-defined principal band in every case, with, as is often met in cyanine dyes, evidence of a weaker and usually ill-defined secondary band nearer the blue. The positions of the absorption maxima of the main absorption bands are given in Table II, and for comparison there are added the corresponding figures for the related unsubstituted and 8-methyl substituted dyes.

Ph	5575	5600			

In Fig. 1 the positions of maximum absorption have been plotted for the 2,2′-dimethyl, 2,2′-diethyl and 2,2′-diallyl series against the groups in the 8-position, these groups being arranged in the order of increasing complexity. There are striking regularities in these curves.

It has already been noted that replacement of 8-hydrogen in 2,2′-dimethylthiacarbocyanine iodide by methyl, results in a shift of 170 Å. of the absorption maximum toward the blue.[12] We now find that replacement of 8-methyl by 8-ethyl shifts the maximum back toward the red by about 45 Å., but replacement of 8-ethyl by higher aliphatic groups brings about no further shift. Introduction of 8-benzyl and 8-phenoxymethyl into 2,2′-dimethylthiacarbocyanine causes shifts toward the blue of 75 and 50 Å., respectively. The 8-phenyl group, on the other hand, causes a shift toward the red of 25 Å. Very similar relationships have been found in the 2,2′-diethyl series, but these dyes invariably have their absorption maxima somewhat nearer the red than those of the corresponding 2,2′-dimethyl dyes, the amount of the difference varying from 25 to 50 Å. In order to ascertain whether members of the 2,2′-di-*n*-propyl and 2,2′-di-*n*-butyl series would have absorption maxima still further toward the red, three members of each series were prepared, these dyes having in the 8-position, hydrogen, methyl and ethyl, respectively. The two dyes with unsubstituted trimethenyl chains, however, had absorption maxima identical in position with that of 2,2′-diethylthiacarbocyanine iodide, but dyes of the 2,2′-di-*n*-propyl and 2,2′-di-*n*-butyl series containing 8-methyl and 8-ethyl groups had their absorption maxima, as a rule, somewhat nearer the red than the corresponding dyes of the 2,2′-diethyl series.

Three dyes of the 2,2′-diallylthiacarbocyanine series were also examined, these being the unsubstituted dye and the 8-methyl and 8-ethyl derivatives. Within this series, the same general relations held as were found to apply in the 2,2′-dimethyl and 2,2′-diethyl series, but the 2,2′-diallyl derivatives had their absorption maxima consistently nearer the red than the corresponding 2,2′-diethyl compounds.

The new dyes described act as photographic sensitizers for the green and yellow portions, and,

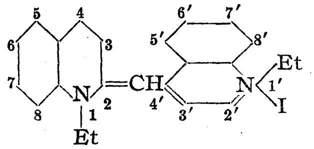
---

[13] Compare Hill and Rabinowitz, THIS JOURNAL, **48**, 732 (1926).

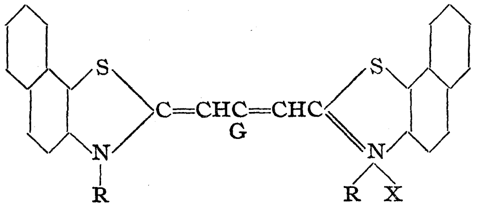
to a varying extent, the red portion of the spectrum.[14]

It was pointed out by Mills and Pope[15] that substitution of a methyl, phenyl or cyano grouping in the 2'-position of 1,1'-diethyl-2,4'-cyanine iodide (II) gave dyes with greatly reduced sensitizing power, the depressant effect of the three groups increasing in the order given. They suggested that this was due to the loading effect of the substituent on the ethylenic chain joining the two nitrogen atoms, the ability of the molecule to interact with light waves being inhibited. From this it might have been expected that loading the ethylenic chain in 2,2'-diethylthiacarbocyanine iodide by the introduction of substituents in the 8-position would materially depress the sensitizing action, but this is not the case.

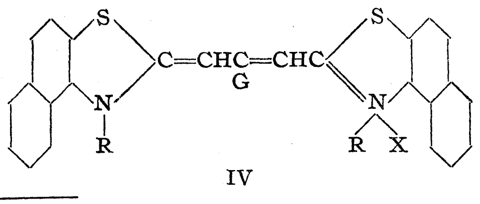
II



8-Methylthiacarbocyanine dyes derived from the methyl-α- and β-naphthothiazoles have previously been described.[12,16] Using ortho esters of propionic and of benzoic acids in conjunction with the alkyl *p*-toluenesulfonates of the two bases, eight more dyes have now been prepared, these being the 8-ethyl and 8-phenyl-5,6,5',6'-dibenzothiacarbocyanines (III) and the 8-ethyl and 8-phenyl-3,4,3',4'-dibenzothiacarbocyanines (IV), the 2,2'-dimethyl and 2,2'-diethyl derivatives being prepared of each of the four types.[17]



III



IV

On account of the insolubility of the iodides of these dyes, the bromides were prepared except in the case of 2,2',8-triethyl-5,6,5',6'-dibenzothiacarbocyanine iodide, which was sufficiently soluble.

In Table III are given the positions of the maximum absorption of these dyes together with similar data on related unsubstituted and 8-methyl substituted dyes.

TABLE III

ABSORPTION MAXIMA OF DIBENZOTHIACARBOCYANINES (III AND IV) IN Å.

(a) 5,6,5',6'-dibenzothiacarbocyanines

G (III)	R (III) Me	R (III) Et
H	5900	5925
Me	5660	5725
Et	5675	5750
Ph	5920	5925

(b) 3,4,3',4'-dibenzothiacarbocyanines

G (IV)	R (IV) Me	R (IV) Et
H	5925	5950
Me	5700	5750
Et	5750	5775
Ph	5950	5925

If these values are plotted against the groups occupying the 8-positions of the dyes, curves are obtained which, in their general characteristics, are very similar to those given in Fig. 1. Figure 2 deals with the 5,6,5',6'-dibenzothiacarbocyanines and Fig. 3 with the 3,4,3',4'-dibenzothiacarbocyanines.

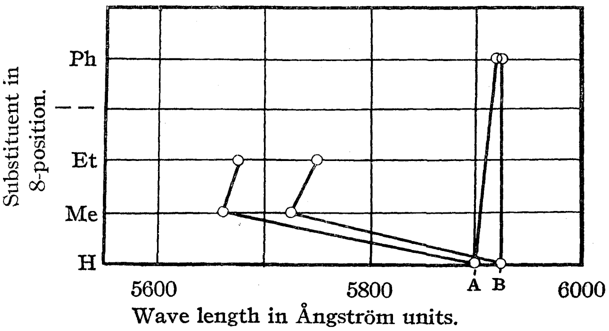


Fig. 2.—Absorption maxima of 5,6,5',6'-dibenzothiacarbocyanines (III): A, 2,2'-dimethyl series; B, 2,2'-diethyl series.

From these curves it is seen that, as in the simple thiacarbocyanines, introduction of an 8-methyl group into a dibenzothiacarbocyanine brings about a marked shift of the absorption maximum toward the blue. This shift is partially canceled if the 8-methyl group is replaced by an 8-ethyl group. The 8-phenyl dyes have

maxima either identical with or very close to those of the related unsubstituted dyes, but in the 3,4,3′,4′-dibenzo series the usual relative positions of the 2,2′-dimethyl and 2,2′-diethyl dyes are reversed. In every case except this, a 2,2′-dimethyl dye has its absorption maximum nearer the blue than the corresponding 2,2′-diethyl dye. In every case but one, also, a 3,4,3′,4′-dibenzothiacarbocyanine has its absorption maximum somewhat nearer the red than the corresponding 5,6,5′,6′-dibenzothiacarbocyanine.

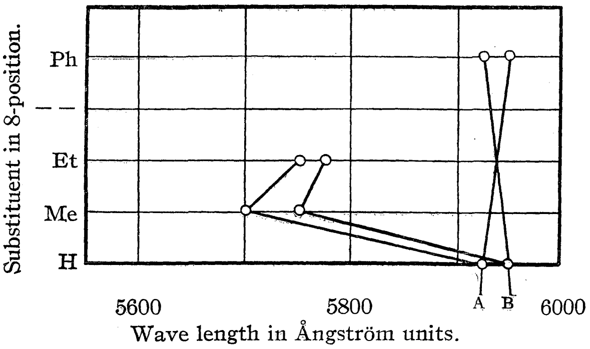

Fig. 3.—Absorption maxima of 3,4,3′,4′-dibenzothiacarbocyanines (IV): A, 2,2′-dimethyl series: B, 2,2′-diethyl series.

All the new dyes derived from the methylnaphthothiazoles act as photographic sensitizers, some of them being exceedingly powerful.[18] They sensitize further in the direction of longer wave length than the corresponding dyes derived from 1-methylbenzothiazole. It is a striking generalization that every one of the eight carbocyanine dyes derived from 2-methyl-β-naphthothiazole is a stronger sensitizer than the related isomeric dye derived from 1-methyl-α-naphthothiazole.

An 8-methylselenacarbocyanine dye (I, R = Et, G = Me, Y = Se, X = I) has recently been described,[12] and the 8-ethyl-2,2′-dimethyl- and 2,2′,8-triethylselenacarbocyanine iodides and the two corresponding 8-phenylselenacarbocyanines have now been prepared.[19] In these syntheses 1-methylbenzoselenazole alkyl *p*-toluenesulfonates were employed. The absorption maxima of these dyes as well as those of the related unsubstituted[20] and 8-methyl substituted dyes are given in Table IV.

Made up into Fig. 4, these values give curves very similar in general appearance to those already obtained. The same sharp recession toward the blue is noticeable upon introducing an 8-methyl group as was found in the previous instances, and on proceeding to the 8-ethyl compounds the absorption maxima advance again toward the red. Introduction of an 8-phenyl group brings about a shift in the absorption maximum toward the red by an amount greater than has been encountered hitherto. It is also worthy of note that in this series the unsubstituted 2,2′-dimethyl- and 2,2′-diethyl dyes both have their maximum absorption at the same wave length.

Table IV

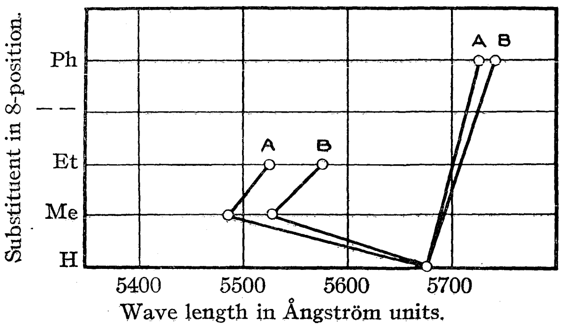

Fig. 4.—Absorption maxima of selenacarbocyanines (I, Y = Se): A, 2,2′-dimethyl series: B, 2,2′-diethyl series.

The new selenacarbocyanines are photographic sensitizers, their sensitizing bands extending somewhat further into the red than those of the corresponding thiacarbocyanines.[21]

In the oxacarbocyanine series an 8-methyl derivative (I, G = Me, R = Et, Y = O, X = I) has been obtained,[12] triethylamine being used in addition to pyridine in its preparation. Using this same device the 8-ethyl-2,2′-dimethyl- and 2,2′,8-triethyloxacarbocyanine iodides have now been prepared. The absorption maxima of these dyes, as well as those of the unsubstituted oxacarbocyanines, are given in Table V and Fig. 5 is based on these values.

The curves in Fig. 5 differ markedly from those preceding it in that introduction of an 8-methyl group into an unsubstituted oxacarbocyanine pro-

duces a shift toward the red. This advance is continued on introducing an 8-ethyl group. The differences between the positions of the maxima of corresponding members of the 2,2′-dimethyl and 2,2′-diethyl series are very slight and, indeed, the values for the two 8-ethyl dyes are identical.

The new oxacarbocyanines are photographic sensitizers for the blue-green and green.[22]

All the absorption curves used in the present paper were determined for methyl alcoholic solutions using the means already detailed.[12]

[a] The crude ortho ester fraction, b. p. 130–140° (8.5 mm.), was well washed with water to remove amide. Benzene was added, the solution again washed with water and the benzene layer dried with anhydrous sodium sulfate and fractionated.

Experimental

Ortho Esters.—For the preparation of the imino-ester hydrochlorides, the method of Hill and Rabinowitz[13] and of Sah[7] was used, a mixture of the nitrile (1 mol) and the alcohol (1 mol) in ether being treated at 5–10° with hydrochloric acid gas (1.05–1.1 mols), it being of the utmost importance that the materials should be as free from water as possible. The imino-ester hydrochlorides (listed in Table VI) usually set to a cake of crystals after standing for some days at 0° (Table VI, Days A) and this was well crushed, washed with absolute ether, and the excess of hydrochloric acid removed by standing in a vacuum over powdered potassium hydroxide, a separate dish of phosphorus pentoxide being also included. This treatment was continued until a small quantity of the salt, dissolved in absolute alcohol no longer affected moistened Congo red paper (Table VI, Days B). The hydrochlorides so obtained formed colorless crystals which had no true melting points but decomposed with gas evolution after shrinking.

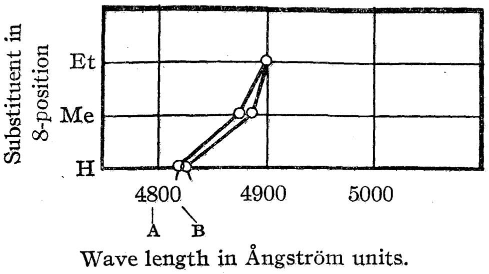

Fig. 5.—Absorption maxima of oxacarbocyanines (I, Y=O): A, 2,2′-dimethyl series; B, 2,2′-diethyl series.

The imino-ester hydrochlorides are unstable compounds and were converted directly into the corresponding ortho esters by treatment at room temperature, with occasional shaking, with the appropriate alcohols for periods which varied from a few days to a few weeks. The solid which separated (largely ammonium chloride) was removed by filtration. The filtrate was distilled from the steam-bath under reduced pressure, a residue of amide usually remaining. The distillate was then repeatedly fractionated, it being necessary in some cases to remove accompanying

---

(22) Brooker, U. S. Patent 1,962,124.

normal ester. By this procedure all the ortho esters were obtained analytically pure, and those not previously described are given in Table VII. For convenience they are numbered as shown.

Ortho esters used in addition to the above are ethyl orthoformate, OE1; ethyl orthoacetate, OE2; ethyl orthopropionate,[6,8] OE4; ethyl orthophenylacetate,[9,10] OE11.

Quaternary Salts.—The quaternary salts used are numbered for convenience as follows:

QS1	1-Methylbenzothiazole methiodide
QS2	1-Methylbenzothiazole ethiodide
QS3	1-Methylbenzothiazole *n*-propiodide
QS4	1-Methylbenzothiazole *n*-butiodide
QS5	1-Methylbenzothiazole alliodide
QS6	1-Methylbenzothiazole metho-*p*-toluenesulfonate
QS7	1-Methylbenzothiazole etho-*p*-toluenesulfonate
QS8	1-Methyl-α-naphthothiazole metho-*p*-toluenesulfonate
QS9	1-Methyl-α-naphthothiazole etho-*p*-toluenesulfonate
QS10	2-Methyl-β-naphthothiazole metho-*p*-toluenesulfonate
QS11	2-Methyl-β-naphthothiazole etho-*p*-toluenesulfonate
QS12	1-Methylbenzoselenazole metho-*p*-toluenesulfonate
QS13	1-Methylbenzoselenazole etho-*p*-toluenesulfonate
QS14	1-Methylbenzoxazole metho-*p*-toluenesulfonate
QS15	1-Methylbenzoxazole ethiodide

QS12 and 14 were prepared by heating equimolecular proportions of base and methyl-*p*-toluenesulfonate at 100° for several hours. QS13 was similarly prepared, the mixture being heated for three days. These salts were used without purification. Other new quaternary salts are given in Table VIII, the normal methods of preparation being used.[12] In all cases the crude products were ground with acetone and washed with this solvent and were then sufficiently pure for dye formation. The yields given correspond to this stage. For analysis and melting point determinations those salts which were iodides were recrystallized from methyl alcohol. The *p*-toluenesulfonates were dissolved in hot methyl alcohol and precipitated by adding acetone. The salts were all colorless or almost colorless solids.

Dyes.—The quaternary salts were condensed with the ortho esters in boiling anhydrous pyridine solution, the period of heating varying from ten to ninety minutes. In general, a 200% excess of orthoester was used except that a 100% excess was used of OE5, 6, 7 and 8. When the quaternary salt was an iodide, separation of the dye from

[a] The bromide of this dye was described by Hamer.[2] [b] When methyl orthopropionate (4.02 g.) was used in place of the ethyl ortho ester, the yield of dye was 0.65 g. (13% calculated as 8-ethyl dye). The iodine content was somewhat high (found: I, 25.91) which would correspond to a certain degree of contamination with the 2,2′,8-trimethyl dye. [c] When methyl orthopropionate (4.02 g.) was used instead of the ethyl ortho ester, the method otherwise being the same, the yield of crude dye was 1.52 g. (29% calculated as 2,2′,8-triethyl dye). When a solution of the product in methyl alcohol was allowed to evaporate slowly, large greenish crystals separated together with smaller coppery crystals. These were separated mechanically, and the two fractions were purified by repeated fractional crystallization. The more soluble fraction was identical in properties with the analyzed 2,2′,8-triethyl compound (appearance, melting point and mixed melting point, absorption and sensitizing action) (found: I, 24.47). The less soluble fraction was similarly found to be identical with the 2,2′-diethyl-8-methyl dye (found: I, 25.11. $C_{22}H_{23}IN_2S_2$ required I, 25.07). [d] When the specimen was heated from room temperature. [e] Use of methyl orthopropionate gave a yield of only 9% (calculated as 8-ethyl dye). After one recrystallization (about 200 cc. per gram), the dye was identical with the 8-methyl dye. (Found: I, 23.89. 8-Methyl dye requires I, 23.93.) [f] Bromide. [g] After a further recrystallization. [h] Iodide of this dye was prepared by Hamer.[16] [i] Described by Hamer,[16] who gives melting point 274° (dec.). [j] Iodide. [k] After two recrystallizations from 95% EtOH and two from glacial acetic acid. [l] Plus 2.2 g. NEt_3. [m] Plus 0.5 g. NEt_3.

APPEARANCE OF THE DYES

D1	Bright, bronze needles.
D2	Prism reflecting green and purple.
D3	Dark purplish felt.
D4	Dark crystals with purplish reflex.
D5	Minute purplish-bronze crystals.
D6	Dark crystals reflecting blue and purple.
D7	Minute crystals with green reflex.
D8	Beautiful prisms with double blue and green reflex.
D9	Clusters of greenish crystals.
D10	Granular green crystals.
D11	Dark prisms, some faces reflecting purple, others brilliant bronze.
D12	Minute purplish crystals.
D13	Brilliant greenish-bronze prisms.
D14	Purplish needles with blue reflex.
D15	Pale bronze granular crystals.
D16	Brownish needles (transmitted light) with very brilliant blue reflex
D17	Granular greenish-bronze crystals.
D18	Purplish-brown granular crystals with green reflex.
D19	Prisms with double blue and green reflex.
D20	Small reddish - brown needles.
D21	Magnificent emerald-green prisms.
D22	Beautiful greenish - blue prisms.
D23	Felted mat of minute purplish-brown needles.
D24	Reddish-coppery crystals.
D25	Beautiful green prisms.
D26	Bronze needles.
D27	Greenish-bronze crystals.
D28	Dark purplish felted mat.
D29	Dark greenish needles.
D30	Minute emerald - green crystals.
D31	Dark greenish - bronze needles.
D32	Small purplish crystals with blue reflex.
D33	Minute greenish - bronze crystals.
D34	Dull purplish felted crystals.
D35	Minute dull purplish crystals.
D36	Greenish-bronze felt.
D37	Minute lustrous green needles.
D38	Minute greenish crystals.
D39	Minute glittering crystals with greenish-bronze reflex.
D40	Minute greenish - bronze crystals.
D41	Minute greenish crystals.
D42	Bluish-purple felt.
D43	Minute greenish crystals.

D44 Prisms with double blue and brassy-green reflex.
D45 Greenish-bronze needles.
D46 Metallic greenish prisms.
D47 Beautiful garnet - red prisms.
D48 Orange-red powder.
D49 Orange-red prisms.

the reaction mixture was facilitated by the addition of ether, the crude product being treated with hot acetone and the suspension chilled and filtered. This procedure removed tarry impurities. Any unchanged quaternary salt was removed by washing with water and the dye was finally recrystallized from methyl alcohol. This procedure is referred to as Method A. When the quaternary salt was a *p*-toluenesulfonate, one of two procedures was used. In Method B, the hot reaction mixture was treated directly with excess of hot aqueous potassium bromide or iodide, the precipitated dye washed with water, treated with acetone and then recrystallized as in Method A. In Method C, the dye was precipitated from the cooled reaction mixture as the *p*-toluenesulfonate by the addition of ether. The residue was redissolved in the minimum quantity of hot methyl alcohol and converted into the bromide or iodide by treatment with excess of an aqueous solution of the appropriate potassium salt, the further treatment being the same as in Method B.

The dye condensations are summarized in Table IX. The yield of crude product is given in each case, followed by the yield of recrystallized dye. Methyl alcohol was used as a solvent for recrystallization in all cases except one and the amount required is indicated. The melting points were determined as described in Part I.[12]

Summary

1. Thiacarbocyanines containing various groups attached to the central carbon atom of the three-carbon chain have been prepared utilizing the appropriate ortho esters for the purpose. The following are the groups so introduced: Et, *n*-Pr, *n*-Bu, *n*- and *i*-Am, $PhCH_2$-, $PhOCH_2$- and Ph. Selena- and oxacarbocyanines containing certain of these groups have also been prepared.

2. The following ortho esters are described for the first time: methyl orthopropionate, methyl ortho-*n*-butyrate, methyl ortho-*n*-valerate, methyl ortho-*n*-caproate, methyl orthoisocaproate, ethyl orthophenoxyacetate.

3. Substitution of hydrogen in the molecule of a thiacarbocyanine dye derived from 1-methylbenzothiazole by an 8-methyl group causes the absorption maximum in methyl alcohol to shift about 150 Å. toward the blue, but replacement of 8-methyl by 8-ethyl shifts the maximum about 50 Å. back toward the red. Replacement of 8-ethyl by higher aliphatic groupings up to *n*- and isoamyl causes no further shift. Replacement of hydrogen by 8-benzyl causes a shift (75 Å.) toward the blue, but replacement by 8-phenyl causes a slight shift (25 Å.) toward the red.

4. Somewhat similar relationships to those summarized above can be traced in the 3,4,3′,4′- and 5,6,5′,6′-dibenzothiacarbocyanine series and in the selenacarbocyanines. The oxacarbocyanines are exceptional.

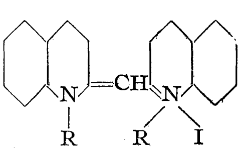
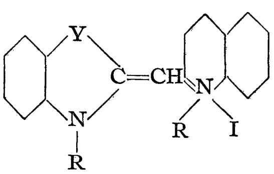
Studies in the Cyanine Dye Series. III. Improvements in the 2′-Cyanine Condensation

BY L. G. S. BROOKER AND G. H. KEYES

Kaufmann and Vonderwahl[1] were the first to observe the formation of a dye of the 2,2′(or ψ)-cyanine class (I) and Fischer and Scheibe[2] succeeded in isolating the 1,1′-dimethyl compound by the action of potassium hydroxide on a mixture of 2-iodoquinoline methiodide and quinaldine methiodide. Higher yields of dyes of this type were obtained by Hamer,[3] who showed further that the reaction was a general one in that the quinaldine alkiodide could be replaced by quaternary salts of other bases containing a reactive methyl group. Alkyl iodides of 1-methylbenzothiazole were found to yield thia-2′-cyanines (II, Y = S) and 2,3,3-trimethylindolenine alkyl iodides yielded indo-2′-cyanines (II, Y = C-$(Me)_2$).



I



II

We have now found that if the method of Hamer is employed for the preparation of the hitherto unknown 1′,2-diethyloxa-2′-cyanine iodide (II, Y = O), using 1-methylbenzoxazole ethiodide and 2-iodoquinoline ethiodide, the yield of purified

product is only 3% and is not improved by substituting sodium ethylate for potassium hydroxide. If, however, the quaternary salts are heated together in dimethylaniline or especially diethylaniline, the yield of dye is enormously increased, being 89% with the latter.[4]

If used for effecting other 2′-cyanine condensations, however, the dialkylanilines are not so satisfactory, but triethylamine has been found to be a good general condensing agent, being markedly superior to potassium hydroxide and giving better yields in every case studied.[5] The following yields of purified dyes are those obtained using triethylamine, the figures in parentheses being the corresponding yields using potassium hydroxide: 1,1′-diethyl-2,2′-cyanine iodide, 87% (72%); 1′,2-diethylthia-2′-cyanine iodide, 88% (72%); 1′,2-diethyloxa-2′-cyanine iodide, 43% (3%); 1′,2-diethylselena-2′-cyanine iodide (II, Y = Se), 72% (55%); 1,1′-diethyl-2,4′-cyanine iodide, 92.5% (73.5%). In the experiments which gave these yields, the crude dyes were recrystallized and the purity of the first crops established by analysis. The mother liquors were then concentrated and second, in some cases third, crops obtained, the purity of which was established by melting point determinations, carried out side by side with specimens of the analyzed materials. In no case did a second or third crop melt lower than four degrees below the corresponding first crop.

The preparation of 1′,2-diethylselena-2′-cyanine iodide has been described by the I. G. Farbenindustrie A.-G.[6] and the preparation of the 2,4′ (or iso)-cyanine using 2-iodoquinoline ethiodide has been described by Hamer.[3]

The absorption of 1′,2-diethyloxa-2′-cyanine iodide has been determined as well as the absorptions of the 1′,2-diethylthia- and 1′,2-diethylselena-2′-cyanine iodides, dyes containing ethyl groups being chosen for comparison here as well as in the rest of this paper for the sake of uniformity, and the three curves are shown in Fig. 1.

It is now well known that replacement of sulfur in a cyanine dye by selenium produces but a slight shift in the position of the absorption maximum,[7,8] and this is further illustrated in the present instance, the maximum for the thia-2′-cyanine being at 4850 Å.,[9] while that for the selena-2′-cyanine is at 4875 Å. In each case there is indication of a less well-defined secondary band nearer the blue. The absorption curve of the oxa-2′-cyanine likewise reveals the presence of two overlapping bands, but in this case it is the band nearer the blue end of the spectrum which is the more pronounced, and this has its maximum at 4350 Å. The positions of the maxima are indicated by the arrows in Fig. 1. It will be noted that the difference between the maximum of the oxa-2′-cyanine and that of the thia-2′-cyanine, amounting to 500 Å., is enormously greater than that between the latter and that of the selena-2′-cyanine.

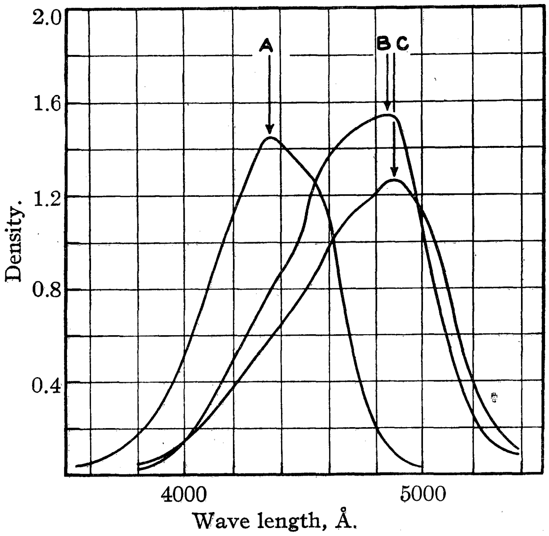

Fig. 1.—Absorption curves of 1:60,000 solutions of 2′-cyanines: A, 1′,2-diethyloxa-2′-cyanine iodide; B, 1′,2-diethylthia-2′-cyanine iodide; C, 1′,2-diethylselena-2′-cyanine iodide.

1′,2-Diethyloxa-2′-cyanine iodide is a photographic sensitizer. In a chloride emulsion its effect extends to about 5100 Å. for moderate exposures with a maximum at 4750 Å. It must be remembered, however, that sensitizing dyes behave very differently with different photographic emulsions, and that general statements as to sensitizing power must be considered in the light of this qualification.

Dyes related to the 2′-cyanines but containing pyridine and β-naphthoquinoline nuclei have been described by Hamer and Kelly,[10] who employed

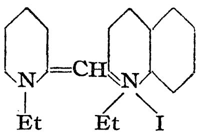
[9] Two absorption curves of 1′,2-diethylthia-2′-cyanine iodide have previously been published [Bloch and Hamer, *Phot. J.*, **68**, 21 (1928); *ibid.*, **70**, 374 (1930)] but differ from one another.

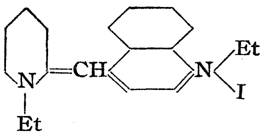
[10] Hamer and Kelly, *J. Chem. Soc.*, 777 (1931).

2-iodopyridine alkyl iodides and 2-iodo-β-naphthoquinoline alkyl iodides, respectively, in their preparation. The general name of 2′-pyridocyanine is now suggested for dyes derived from 2-iodopyridine alkyl iodides.

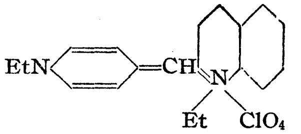
The use of triethylamine results in higher yields of the dye III, for which the name 1,1′-diethyl-2-pyrido-2′-cyanine iodide is proposed. As was pointed out by Hamer and Kelly, this dye is theoretically obtainable by two methods, that which consists in condensing α-picoline ethiodide with 2-iodoquinoline ethiodide being found by them to be fruitless when potassium hydroxide was used. Using triethylamine, however, this method gives a 35% yield of pure dye. The second method, in which 2-iodopyridine ethiodide and quinaldine ethiodide are condensed together, was found by Hamer and Kelly to give a yield of 10% after recrystallization, but optical and photographic tests revealed the presence of impurity. Using triethylamine we have obtained a 41% yield of the pure dye by this method. The specimens obtained by both methods were identical in their appearance, solubility, melting point, absorption and sensitizing effects, thus affording additional evidence of the virtual tautomerism of the cyanine dyes.[3,11]



III



IV



V

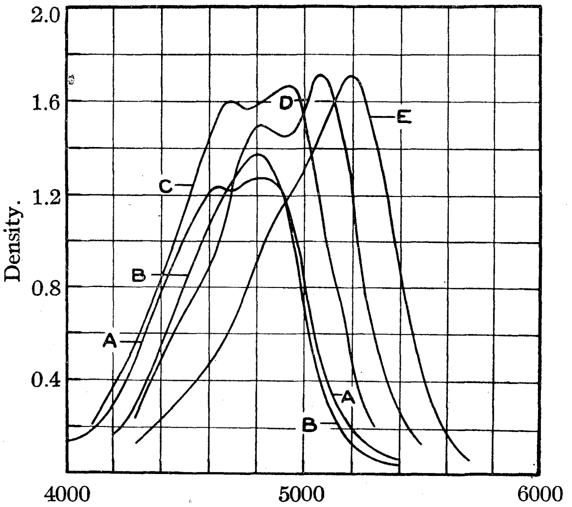


Fig. 2.—Absorption curves: A, 1,1′-diethyl-2,2′-pyridocyanine iodide (1:70,000); B, 1,1′-diethyl-2,4′-pyridocyanine iodide (1:100,000); C, 1,1′-diethyl-2-pyrido-2′-cyanine iodide (1:60,000); D, 1,1′-diethyl-4-pyrido-2′-cyanine perchlorate (1:100,000); E, 1,1′-diethyl-2-pyrido-4′-cyanine iodide (1:75,000).

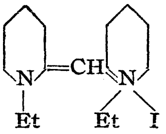
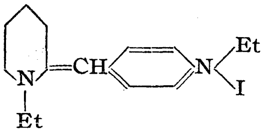
By condensing 2-iodopyridine ethiodide with lepidine ethiodide, 1,1′-diethyl-2-pyrido-4′-cyanine iodide (IV) was similarly obtained, while an isomeric dye was prepared by condensing γ-picoline etho-*p*-toluenesulfonate with 2-iodoquinoline ethiodide. The dye was, however, easier to purify as the perchlorate (V) and was isolated as such.

Hamer and Kelly were unable to prepare the dye VI by the condensation of α-picoline ethiodide and 2-iodopyridine ethiodide using potassium hydroxide, but it is readily obtainable using triethylamine, it being advantageous to use *n*-propyl alcohol as a solvent here and in a number of the other condensations. This dye, for which the name 1,1′-diethyl-2,2′-pyridocyanine iodide is proposed, may be regarded as the simplest cyanine. The corresponding 1,1′-dimethyl compound was similarly prepared.[12]



VI



VII

Condensation was also effected between 2-iodopyridine ethiodide and γ-picoline etho-*p*-toluenesulfonate giving 1,1′-diethyl-2,4′-pyridocyanine iodide (VII).

The absorption curve of VI (Fig. 2, A) consists of two overlapping bands, that nearer the red with its head at 4825 Å. being only slightly stronger than the second band with its head at 4650 Å. The absorption curve of the corresponding 1,1′-dimethyl compound is very similar in general shape, there being two bands of almost equal strength but situated nearer the blue, the maxima being at 4775 and 4550 Å. The curve of VII differs in shape from that of VI and apparently consists of but a single band with its head at 4800 Å. (Fig. 2, B). It is remarkable that the maximum absorption of VII should be nearer the blue

[11] Mills and Braunholtz, *J. Chem. Soc.*, **121**, 1489 (1922).

[12] *Cf.* Moir, *ibid.*, **127**, 2338 (1925).

than that of VI, since in the related dyes of the quinoline series the maximum absorption of 1,1′-diethyl-2,4′-cyanine iodide is 350 Å. nearer the red than that of 1,1′-diethyl-2,2′-cyanine iodide.

The absorption curve of III (Fig. 2, C) is very similar in shape to that of VI, there being two overlapping bands of almost equal strength, that nearer the red being the stronger; the maxima are at 4925 and 4700 Å. The absorption curve of V (Fig. 2, D) shows well-marked heads at 4825 and 5075 Å., the latter being the stronger. The maximum of IV (Fig. 2, E) is at 5200 Å., but there is evidence of a less well defined secondary band nearer the blue. Both IV and V may be considered as derived from VII by attachment of a benzene residue to one or the other of the pyridine nuclei of VII. The curves show that the deepening of color brought about by attaching the benzene residue to that pyridine nucleus of VII which is linked through its 4-position, giving IV, is greater than that produced by attaching a benzene residue to the other pyridine nucleus of VII, giving V. All of dyes III to VII show photographic sensitizing action.

Experimental

The condensations are summarized in Table I. In every case a mixture of one mol of each of the quaternary salts, suspended in absolute ethyl or *n*-propyl alcohol, was treated with 2.1 mols (5% excess) of triethylamine and the whole refluxed with constant shaking where ethyl alcohol was used or heated at 100° where *n*-propyl alcohol was used, the time of reaction varying from ten to forty minutes. Dye (D1–9), usually separated during the reaction or on cooling. The yield of crude washed (acetone, water) dye is given in each case followed by the yield after recrystallization, the volume of solvent required for this being indicated. In every case the dye melted with decomposition. The absorptions were measured in methyl alcoholic solutions.

TABLE I

	Dye	Quaternary Salt	g.	NEt_3	Solvent, cc.	Heated, min.	Yield, %	Solvent, cc./g.	M. p., °C., dec.	Formula	Analyses, % Calcd.	Found

[a] This dye was also obtained when the finely pulverized salts were heated with freshly distilled diethylaniline at 100° with frequent shaking for two and one-half hours; the yield after washing was 89% (71% after purification). With dimethylaniline the corresponding yields were 75% (51%), with quinoline 63% (47%). The dye formed orange-yellow needles. [b] Red needles with a blue reflex; the dye acts as a green sensitizer. [c] Two crops. [d] Reddish-brown crystals with green reflex. [e] After two recrystallizations. [f] Reddish-brown tablets, some faces with a green reflex. [g] Beautiful dark red crystals with a double blue and green reflex. [h] The dye iodide was precipitated from the reaction mixture by adding ether and the residue was dissolved in hot water and precipitated as the perchlorate by adding excess of hot aqueous potassium perchlorate (3 g.). [i] Light orange-brown crystals with pale-green reflex. Moir[12] stated that the compound he obtained corresponding to this dye gave absorption maxima at 4280 and 4050 Å. (in, presumably, aqueous solution). We find that in a 1:80,000 aqueous solution the absorption of our dye is similar to that in methyl alcohol except that the two maxima are less widely separated, the crests in water being at 4600 and 4725 Å., the former being now somewhat the stronger. [j] A colorless solid was removed by washing with water. [k] Crystals similar to D6. [l] After three recrystallizations. [m] Reddish-brown needles with a bluish luster. [n] Dull reddish flakes.

The quaternary salts (QS1 to 11) used in the condensations are numbered as follows.

QS1	2-Iodoquinoline ethiodide
QS2	2-Iodopyridine methiodide
QS3	2-Iodopyridine ethiodide
QS4	1-Methylbenzoxazole ethiodide
QS5	1-Methylbenzoselenazole ethiodide
QS6	Quinaldine ethiodide
QS7	Lepidine ethiodide
QS8	α-Picoline methiodide
QS9	α-Picoline ethiodide
QS10	γ-Picoline metho-*p*-toluenesulfonate
QS11	γ-Picoline etho-*p*-toluenesulfonate

QS10 was prepared by heating equimolecular proportions of γ-picoline and methyl-*p*-toluenesulfonate at 100° for fifteen minutes. QS11 was similarly prepared from ethyl-*p*-toluenesulfonate, heating at 100° for ninety minutes. Both salts were used without purification.

Summary

1. Triethylamine is superior to potassium hydroxide as a condensing agent for the preparation of 2′-cyanines. Thus, 1′,2-diethyloxa-2′-cyanine iodide is obtainable in a yield of 43% using triethylamine, whereas with potassium hydroxide the yield is only 3%. A selena-2′-cyanine has also been prepared.

2. The use of triethylamine also greatly facilitates the preparation of 1,1′-diethyl-2-pyrido-2′-cyanine iodide; a 2-pyrido-4′-cyanine and a 4-pyrido-2′-cyanine have likewise been prepared by its aid.

3. The failure of potassium hydroxide in the preparation of dyes of the 2,2′-pyridocyanine series has been recorded previously, but using triethylamine these dyes are readily available. Two 2,4′-pyridocyanines have also been prepared.

4. The absorption characteristics of the new dyes are given.

ROCHESTER, NEW YORK RECEIVED SEPTEMBER 5, 1935

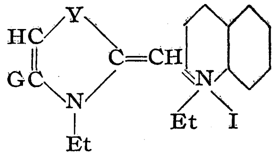
[COMMUNICATION NO. 564 FROM THE KODAK RESEARCH LABORATORIES]

Studies in the Cyanine Dye Series. IV

BY L. G. S. BROOKER, G. H. KEYES AND F. L. WHITE

Up to the present no 2′-cyanine has been described in which the nucleus linked to quinoline consists of a simple 5-membered ring. In a number of instances it has been found that cyanine dyes containing single ring nuclei are difficult to prepare. For example, the thiazolocarbocyanines derived from 2,4-dimethylthiazole were obtained in very much smaller yields than the thiacarbocyanines derived from 1-methylbenzothiazole, and furthermore, whereas the latter base readily gave rise to thiacyanines, the simple thiazolocyanines could not be prepared by the same method.[1]

We have now found, however, that when an equimolecular mixture of 2-methylthiazole ethiodide and 2-iodoquinoline ethiodide is treated with triethylamine, the simplest member of a new group of cyanine dyes, the thiazolo-2′-cyanines, is produced.[2] This dye, 1′,3-diethylthiazolo-2′-cyanine iodide (I, Y = S, G = H) is formed in excellent yield, and 2,4-dimethylthiazole ethiodide and 2-methyl-4-phenylthiazole ethiodide likewise give good yields of the corresponding dyes.



I

These new thiazolo-2′-cyanines give yellowish-orange solutions. The absorption maximum of the 1′,3-diethyl compound is at 4650 Å., and there is a secondary band nearer the red (Fig. 2, B). Introduction of a 4-methyl group shifts the maximum to 4725 Å. (Fig. 1, B) and there is still a secondary band nearer to the red, but in this case it is less pronounced. Replacement of 4-methyl by 4-phenyl produces no further shift, a fact which is worthy of notice, considering that the methyl and phenyl groups have very different effects as 8-substituents in dyes of the thia- and selenacarbocyanine series.[3]

Dyes of the 2′-cyanine series containing the benzoxazole and benzoselenazole nuclei have been described[4] and we have now prepared certain related dyes containing the simple oxazole and selenazole nuclei. 2-Methyloxazole has not itself been prepared, but certain of its substituted derivatives have been known for a long time. Of

these, 2,4-dimethyloxazole was prepared by Schuftan[5] and 2-methyl-4-phenyloxazole by Blümlein.[6] Quaternary salts of these bases also react with 2-iodoquinoline alkyl iodides, giving oxazolo-2′-cyanines.[2] Thus, 2,4-dimethyloxazole etho-*p*-toluenesulfonate gives 1′,3-diethyl-4-methyloxazolo-2′-cyanine iodide (I, Y = O, G = Me) while 2-methyl-4-phenyloxazole etho-*p*-toluenesulfonate similarly yields 1′,3-diethyl-4-phenyloxazolo-2′-cyanine iodide (I, Y = O, G = Ph). These dyes give yellow solutions and their absorption curves are almost identical; the maxima are at 4350 Å. and in each case there is evidence of a secondary band nearer the red (Fig. 1, A).

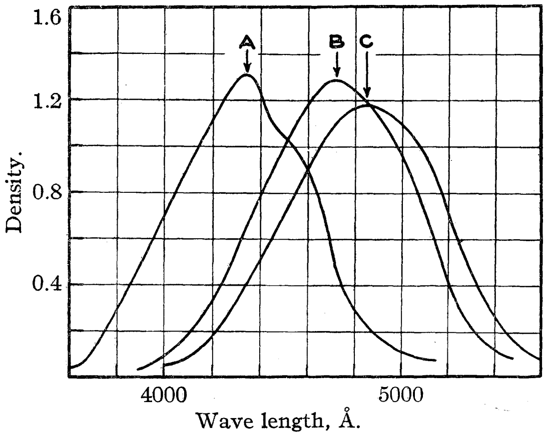

Fig. 1.—Absorption curves of 1:60,000 solutions of 2′-cyanines: A, 1′,3-diethyl-4-methyloxazolo-2′-cyanine iodide; B, 1′,3-diethyl-4-methylthiazolo-2′-cyanine iodide; C, 1′,3-diethyl-4-methylselenazolo-2′-cyanine iodide.

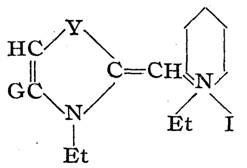
Bases of the 2-methylselenazole series have not hitherto been described but we have prepared 2,4-dimethylselenazole[7] by the action of chloroacetone on selenoacetamide.[8] The new base has an odor very like that of 2,4-dimethylthiazole and its ethiodide underwent condensation with 2-iodoquinoline ethiodide to give 1′,3-diethyl-4-methylselenazolo-2′-cyanine iodide[2] (I, Y = Se, G = Me). The absorption curve of this dye shows a principal maximum at 4850 Å. and has a secondary band nearer the red (Fig. 1, C). The effect of replacing the sulfur atom in 1′,3-diethyl-4-methylthiazolo-2′-cyanine iodide by selenium is therefore to shift the absorption maximum 125 Å. toward the red, this being a greater difference than that between the absorption maxima of the related thia- and selena-2′-cyanines.[4] The difference between the positions of maximum absorption of the oxygen and sulfur containing dyes of the series shown in Fig. 1 is again considerably greater than that between the sulfur and selenium containing dyes.

Triethylamine has also been applied to the condensation of quaternary salts of the 2-methylthiazoles with 2-iodopyridine alkyl iodides. Thus, from 2-methylthiazole ethiodide there was obtained 1′,3-diethylthiazolo-2′-pyridocyanine iodide (II, Y = S, G = H), the absorption maximum of which is at 4425 Å. (Fig. 2, A). The related 4-methyl and 4-phenyl dyes were similarly prepared, and these two dyes have similar absorption curves but with maxima at 4475 Å. From 2,4-dimethylselenazole ethiodide there was similarly prepared 1′,3-diethyl-4-methylselenazolo-2′-pyridocyanine iodide (II, Y = Se, G = Me), the absorption maximum of which is at 4550 Å.



II

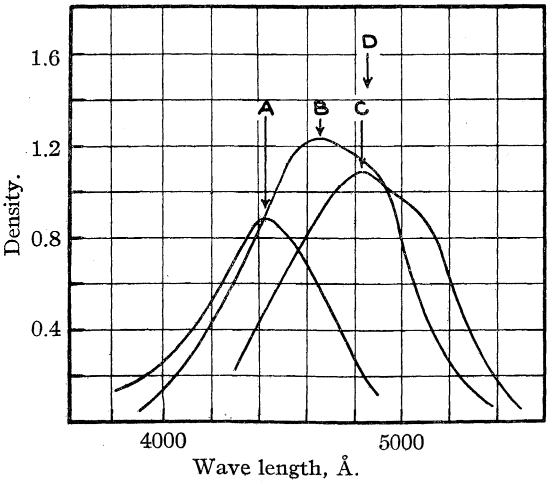


Fig. 2.—Absorption curves of dyes derived from 2-methylthiazole ethiodide: A, 1′,3-diethylthiazolo-2′-pyridocyanine iodide (1:75,000); B, 1′,3-diethylthiazolo-2′-cyanine iodide (1:60,000); C, 1′,3-diethyl-5′,6′-benzo-thiazolo-2′-cyanine iodide (1:75,000).

Triethylamine also proved satisfactory for the condensation of quaternary salts of the 2-methylthiazoles with 2-iodo-β-naphthoquinoline alkyl

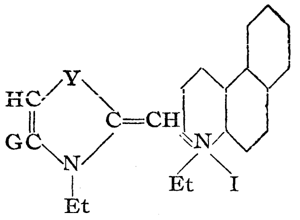
[8] Kindler, *Ann.*, **431**, 187 (1923).

iodides. Thus, 2-methylthiazole ethiodide yielded 1′,3-diethyl-5′,6′-benzo-thiazolo-2′-cyanine iodide (III, Y = S, G = H); maximum absorption 4830 Å. (Fig. 2, C).



III

It will be seen from Fig. 2 that if a benzene residue is attached to 1′,3-diethylthiazolo-2′-pyridocyanine iodide (A) so as to give the thiazolo-2′-cyanine (B) the absorption maximum undergoes a shift toward the red of 225 Å. If a benzene residue is attached in turn to 1′,3-diethylthiazolo-2′-cyanine iodide (B) so as to give the 5′,6′-benzo-thiazolo-2′-cyanine iodide (C) the absorption maximum is shifted 180 Å. nearer the red. It is interesting to note that this is very near the position of maximum absorption of the isomeric 1′,2-diethylthia-2′-cyanine iodide (Fig. 2, arrow D) (Fig. 1, B in Part III of this series[4]).

From the appropriate quaternary salts there were also obtained 1′,3-diethyl-4-methyl- and 1′,3-diethyl-4-phenyl-5′,6′-benzo-thiazolo-2′-cyanine iodides and both of these have absorption maxima at 4875 Å. All three of the 5′,6′-benzo-thiazolo-2′-cyanines have secondary bands nearer the red.

By a similar reaction 2-methyl-4-phenyloxazole gave rise to 1′,3-diethyl-4-phenyl-5′,6′-benzo-oxazolo-2′-cyanine iodide (III, Y = O, G = Ph), which has its maximum absorption at 4475 Å. and 1′,3-diethyl-4-methyl-5′,6′-benzo-selenazolo-2′-cyanine iodide (III, Y = Se, G = Me) was prepared from 2,4-dimethylselenazole ethiodide. The broad absorption band of this dye has its maximum at 5000 Å. Both of these last named dyes have secondary absorption bands nearer the red.

The new dyes act as photographic sensitizers for the blue and green portions of the spectrum and details are given in the Experimental Section.

The absorption curves were determined for methyl alcoholic solutions, the methods used being those already detailed.[9] We wish to acknowledge our indebtedness to Mr. E. E. Richardson and Dr. L. A. Jones, who furnished the curves shown in this paper and in Parts II and III. We are also very grateful to Dr. L. T. Hallett, who carried out the analyses for all three papers, and to several other colleagues for sensitizing data.

Experimental

Selenoacetamide was prepared by a modification of Kindler's method,[8] and we are much indebted to Dr. R. H. Bullard for advice and help with this preparation. The hydrogen selenide, generated by heating a mixture of ferrous selenide and 12 *N* sulfuric acid, was first passed through a series of traps standing in a freezing mixture to remove excess moisture and then through a calcium chloride tower. About 90 g. of the gas (roughly three-quarters of the calculated amount) was dissolved in the chilled (−10°) mixture of acetonitrile (61.5 g.) and absolute ethyl alcohol (1 liter) in which sodium (4.5 g.) had previously been dissolved, all air having already been swept out of the apparatus with a current of nitrogen. After allowing to stand in the freezing mixture overnight, the flask was connected to a mercury manometer and gradually heated to 60°, being maintained at this temperature until the absorption of hydrogen selenide was practically complete. At no time did the excess pressure exceed 720 mm. of mercury. This process required, on an average, a total of about nine hours' heating. The reaction mixture was filtered after allowing it to cool slowly overnight, the filtrate evaporated to dryness under reduced pressure and the residue extracted with boiling benzene. The selenoacetamide crystallized out on chilling the solution and was removed and freed from adhering solvent by standing in a vacuum desiccator. The average yield of several experiments, based on the amount of hydrogen selenide added, was 60%, the highest being 77%. The unstable selenoacetamide was used as soon as possible.

2,4-Dimethylselenazole.—A mixture of chloroacetone (22.7 g., 1 mol) and absolute ethyl alcohol (10 cc.) was warmed on the steam-bath and selenoacetamide (30 g., 1 mol) added in small portions with shaking. A vigorous reaction occurred after each addition. After a further ten minutes' heating, the mixture was allowed to cool and water (100 cc.) was added followed by excess of 45% sodium hydroxide solution. The base was extracted with ether, the ethereal layer dried over anhydrous potassium carbonate, filtered, and the solvent removed by evaporation. The base was purified by fractionation; yield 41%, b. p. 55–58° (13 mm.). After a further fractionation the main portion of the base passed over at 54–55° (12 mm.).

Anal. Calcd. for C_5H_7NSe: C, 37.45; H, 4.40. Found: C, 38.10; H, 4.48.

Quaternary Salts.—The quaternary salts used in the condensations are numbered as follows

QS1 2-Iodoquinoline ethiodide
QS2 2-Iodopyridine ethiodide
QS3 2-Iodo-β-naphthoquinoline ethiodide
QS4 2-Methylthiazole ethiodide
QS5 2,4-Dimethylthiazole ethiodide[1]
QS6 2-Methyl-4-phenylthiazole ethiodide
QS7 2,4-Dimethyloxazole etho-*p*-toluenesulfonate
QS8 2-Methyl-4-phenyloxazole etho-*p*-toluenesulfonate
QS9 2,4-Dimethylselenazole ethiodide

In the preparation of QS7, equimolecular proportions of the base and ethyl *p*-toluenesulfonate were heated at 100° for one day. QS8 was similarly prepared, but the components were heated for two days. In both cases

---

[9] Brooker and White, This Journal, 57, 547 (1935).

viscous melts were formed and were used without purification. Three new ethiodides are listed in Table I. These were obtained by the usual method of heating the base on the steam-bath under reflux with excess of ethyl iodide (10% excess for QS4, 100% excess for QS6 and QS9) with exclusion of light and moisture. The products were ground with and well washed with solvent (ether for QS4, acetone for QS6 and QS9) and the nearly colorless powders were sufficiently pure for further use. The yields given correspond to this stage.

[a] A small amount of unused QS1 was removed from the hot reaction mixture by filtration and the filtrate deposited the dye on cooling. [b] After two recrystallizations. [c] 10 cc. of *n*-PrOH used as solvent, reaction mixture being heated at 100°. [d] The dye was precipitated from the reaction mixture with ether and impurities removed with acetone. [e] The solution of the dye in hot water was twice refluxed for five minutes with norite, taking of this, on each occasion, one-twentieth of the weight of the dye. [f] The crude dye required treating with hot water and a little piperidine to remove unchanged QS3; it was then recrystallized three times from EtOH. [g] The dye was precipitated by adding ether (100 cc.) with chilling and was washed with water.

Dyes.—The dye condensations are listed in Table II. They were carried out as already detailed.[4] The yields of crude and of purified dyes are given and the volume of solvent required for recrystallization.

D1 formed red needles with a blue reflex, 2 and 3 being similar; 4 and 5 consisted of yellow-brown prisms, 6 reddish-brown needles, 7 yellow-orange tablets, 8 brownish-yellow crystals, 9 light-brown prisms; 10 consisted of amber needles; 11 formed minute orange-brown crystals with a green reflex, and 12, 13 and 15 all consisted of reddish-brown needles with a green reflex; 14 formed reddish-brown crystals.

The dyes were tested photographically by incorporation in a chloride emulsion. The maximum effect of D1 is at about 5175 Å., the effect extending to about 5500 Å. for the moderate exposure given. D2 and 3 both have maxima at 5250 Å., and D6 at 5350 Å. D4 and 5 both have maxima at 4775 Å. The order in which these dyes fall is the same, therefore, whether absorption or sensitizing maxima are considered with respect to increasing wave length, and the difference between corresponding absorption and sensitizing maxima varies from 425 to 525 Å.

In the 2′-pyridocyanine series the sensitizing maxima of D7 to 10 lie at 4700, 4750, 4750, and 4825 Å., respectively, and in the series D11 to 15 the corresponding figures are 5250, 5300, 5300, 4900 and 5400 Å., respectively.

Summary

1. Triethylamine has proved to be an excellent condensing agent for the preparation of the hitherto unknown thiazolo-2′-cyanines from quaternary salts of the 2-methylthiazoles and 2-iodoquinoline ethiodide. Three dyes of this series are described.

2. By using 2-iodopyridine ethiodide and 2-iodo-β-naphthoquinoline ethiodide there have likewise been prepared the corresponding thiazolo-2′-pyridocyanines and 5′,6′-benzo-thiazolo-2′-cyanines, respectively.

3. Bases of the 2-methyloxazole series have been used for the preparation of certain oxygen-containing dyes related to the above, and 2,4-dimethylselenazole has been synthesized and similarly applied to the formation of corresponding cyanine dyes.

4. Four dyes have been prepared in which there is a methyl substituent in the 4-position of the thiazole (or oxazole) nucleus. In every case the absorption maximum occurs at the same wave length as that of the related dye containing a 4-phenyl group. Further absorption relationships are discussed.

5. The new dyes are all photographic sensitizers and details of their action are given.

A Study of Some Urea Derivatives in the Terpene Series

BY ROBERT L. BATEMAN AND ALLAN R. DAY

In connection with certain studies of urea and its derivatives, it was thought that the preparation and examination of some terpenyl ureas might be of interest. While certain of the terpenes and their derivatives are employed medicinally, little experimental work has been carried out with the purpose of modifying their properties by structural changes and little effort has been made to introduce terpene radicals into compounds of known physiological properties.

Menthyl and bornyl ureas and certain of their derivatives were chosen because of the known physiological properties of substituted ureas and because of the medicinal importance of menthol and camphor which were the starting materials. Menthol is known to possess mild antiseptic and anesthetic properties, while camphor acts as a depressant on the central nervous system and as a stimulant on the circulatory system. If these properties, in greater part, are inherent in the functional groups (hydroxyl and carbonyl, respectively) the introduction of the menthyl and bornyl radicals into urea would not be expected to produce marked effects, as the functional groups are absent. However, if their physiological properties depend in part on their cyclic structure, a definite modifying influence should be observed.

It will be noted that all but one of the derivatives prepared contain the simple menthyl or bornyl group. In order to determine the influence of the functional group, 2-keto-3-carbamidocamphane was prepared. This urea contains in its substituent not only the cyclic structure common to borneol and camphor, but also the functional group of camphor.

The terpenylureas were obtained in satisfactory

yields by the interaction of nitrourea and terpenylamine

$$RNH_2 + H_2NCONHNO_2 = RNHCONH_2 + N_2O + H_2O$$

A number of acyl derivatives as well as the chloral addition products of the above ureas were also prepared for the purpose of modifying the physiological properties of the terpenylureas.

Experimental

***l*-Menthylurea.**[1]—To 20 g. of *l*-menthylamine hydrochloride[2] and 20 g. of nitrourea[3] in 600 cc. of water was slowly added with stirring a slight excess of sodium bicarbonate and after twelve hours the colorless reaction product was recrystallized from dilute alcohol; yield 78%.

A similar procedure was followed in the preparation of *d*-bornylurea[4,5,6] and a yield of 90% was obtained.

The menthyl as well as the bornylurea was acylated directly with acetic anhydride and in benzene solution with bromoacetyl bromide, cinnamoyl chloride and *p*-nitrobenzoyl chloride. The yields were almost the theoretical except in the case of bromoacetylmenthylurea. In the latter case it dropped to 20%. In general the crude products were readily purified by recrystallization from alcohol. *d*-Cinnamoylbornylurea was recrystallized from acetone and *d*-*p*-nitrobenzoylurea from a mixture of glacial acetic acid (2 parts) and acetone (8 parts).

Chloral Addition Products of *l*-Menthyl and *d*-Bornylurea.—Five grams of chloral was slowly added to 5 g. of the urea with stirring and the mixture allowed to stand for one hour in the absence of moisture. The excess chloral was removed with a little ligroin and the crude product recrystallized from alcohol. The compounds were quite stable and did not hydrolyze readily in the presence of water; yields, 80–86%.

1-*p*-Aminobenzoylmenthylurea and *d*-*p*-Aminobenzoylbornylurea.—Seven grams of the corresponding nitro compound was partially dissolved in 60 cc. of hot alcohol and 60 cc. of 6 *M* ammonium sulfide added. After two hours' refluxing on a water-bath, the solution was diluted with water and the crude product recrystallized from alcohol; yield, about 90%. The corresponding hydrochlorides were prepared by saturating an ether solution of the free base with dry hydrogen chloride. They were obtained as colorless powders and were quite insoluble in the common solvents.

***d*-2-Keto-3-carbamidocamphane.**—This compound was prepared by the reduction of the stable (*syn*) form of isonitrosocamphor[7] with zinc dust and acetic acid to the corresponding amine[8] and the latter then converted to the corresponding urea by the nitrourea method. The crude product was recrystallized from hot water; yield, 75–80%, based on the hydrochloride used. Its analysis indicated the probable presence of water of hydration which could not be removed by drying in vacuum or by heating below its decomposition point. Its *p*-nitrobenzoyl derivative analyzed correctly for $C_{18}H_{21}N_3O_5$. Calcd.: N, 11.70. Found: N, 11.63.[9]

The physical constants and analytical data for the various compounds prepared are given in Table I.

Pharmacological Tests

Some preliminary tests on six of these derivatives have been carried out by Dr. Carl F. Schmidt of The Pharmacology Department of the Uni-

---

[1] O. Wallach, *Ann.*, **300**, 279 (1898). Wallach obtained a 30% yield by the action of potassium cyanate on menthylamine hydrochloride, m. p. 134–136°.

[8] Claisen and Manasse, *Ann.*, **274**, 79 (1893).

[9] Rupe [*Ber.*, **27**, 584 (1894); **28**, 778 (1895)] obtained this urea by the action of potassium cyanate on *d*-3-aminocamphor hydrochloride and reported its melting point as 169°.

versity of Pennsylvania School of Medicine. The compounds were dissolved in ethylene glycol and injected intraperitoneally in white rats.

Menthyl urea in dosage of 220 mg. per kg. caused profound unconsciousness with the abolition of all reflexes. The narcosis appeared at the end of fifteen minutes and was undiminished seven hours after injection. At the end of twenty-two hours the animal had recovered completely and appeared normal. In dosage of 63 mg. per kg. there was definite drowsiness without visible muscular incoördination. The animal was easily aroused at all times and seemed normal when aroused. At twenty hours it was quite normal.

The low solubility of bromoacetylbornylurea and *p*-aminobenzoylmenthylurea made adequate testing impracticable. They had no demonstrable narcotic effects in the dosage used. Larger amounts of the solutions caused ethylene glycol poisoning.

Chloral menthylurea was clearly the most potent. It was the most toxic, slowest acting and most persistent of those tested.

Bornylurea and 2-keto-3-carbamidocamphane acted slowly and weakly with considerable muscular incoördination and the latter seemed to be intensely irritant locally.

Summary

1. *l*-Menthylurea, *d*-bornylurea and 2-keto-3-carbamidocamphane have been prepared by the nitrourea method.

2. The following new derivatives of *l*-menthylurea and *d*-bornylurea have been prepared: acetyl, bromoacetyl, chloral addition product, *p*-nitrobenzoyl and *p*-aminobenzoyl.

3. Preliminary tests on the narcotic effects of some of these ureas indicated that menthylurea was the most promising and may have some value. It acted rapidly without evident after-effects.

Esters of the Aldehydrol Form of Sugars

BY M. L. WOLFROM

Diacetates of aliphatic aldehydes, $RCH(OAc)_2$, have long been known but have been little studied. Some of the earliest work was carried out by Geuther,[1] who prepared these derivatives by heating aliphatic aldehydes with acetic anhydride at relatively high temperatures (180°). Later work[2] showed that the reaction was greatly accelerated by zinc chloride or sodium acetate. Aceto-halogen compounds of aliphatic aldehydes, $RCHOAc \cdot X$, have also been prepared.[3] From the standpoint of organic structural theory, compounds of this type may be considered as esters of the aldehydrol, $RCH(OH)_2$, irrespective of whether the aldehydrol is an intermediate in their formation.

In the sugar series, the first representative of this type of compound was the crystalline triacetate of gycolaldehyde prepared by H. O. L. Fischer and Dangschat[4] by treating vinyl acetate dibromide with potassium acetate and also directly from the sugar by heating with acetic anhydride. Micheel and co-workers[5] have reported the synthesis of the *d*- and *d,l*- forms of *aldehydo*-galactose heptaacetate as incidental to their important synthetic experiments in the transformation of hexoses into inositols.

Aldehydo-galactose pentaacetate readily forms crystalline carbonyl addition compounds with alcohols and water, the reaction product with the latter being a true aldehydrol.[6] This addition takes place readily at room temperature. We have now found that acetyl halide addition compounds of *aldehydo*-galactose pentaacetate can be readily formed. The resulting compounds are the open chain analogs of the cyclic sugar acetohalogen derivatives and may be named, for example, *aldehydo*-1-chloro-*d*-galactose hexaacetate. In the work herein reported the chloride, bromide and iodide are described. Their rota-

tions increase in the above order, as could be predicted from the careful work of Brauns[7] on the cyclic acetohalogen sugars. Although these open chain acetohalogen compounds are quite stable, they tend to lose the acyl halide when subjected to metathetical reactions. The ease of carbonyl addition shown by *aldehydo*-galactose pentaacetates, is a property not shared by the other known aldehydo-acetates, but probably such derivatives could be prepared by the use of catalysts and work in this direction is in progress.

We have found that when the *aldehydo*-sugar acetates are subjected to further acetylation, the carbonyl diacetate compounds are obtained. We wish to report herein the glucose and arabinose derivatives, which may be named *aldehydo-d*-glucose heptaacetate and *aldehydo-l*-arabinose hexaacetate. These compounds are very much more stable than the corresponding free carbonyl compounds and are more easily isolated. They may be expected to be formed occasionally in reactions involving cyclic sugar derivatives. On the other hand, Montgomery and Hudson[8] isolated the free carbonyl form of *aldehydo-d-α*-mannoheptose hexaacetate by a relatively mild acetylation of the free sugar with acetic anhydride and sodium acetate. The acetylation methods we have used involve the use of acetic anhydride with pyridine or zinc chloride, the reactions being carried out at room temperature.

Experimental

Aldehydo-1-chloro-*d*-galactose Hexaacetate.[9]—*Aldehydo*-galactose pentaacetate ethyl hemiacetal[6a] (5 g.) was dissolved in 50 cc. of hot acetyl chloride and the cooled solution poured with stirring into about a liter of ice and water. The product separated at once as colorless crystals which were filtered and washed with ice water; yield, 3.4 g. Pure material was obtained after several recrystallizations from ethanol; m. p. 174–175°; $[\alpha]^{27}_{D}$ −44° (*c*, 4.0; CHCl$_3$). The substance crystallized in individual diamond-shaped plates and showed no tendency to decompose on standing. It was soluble in chloroform and acetone, sparingly so in hot ethanol, and was practically insoluble in ether and petroleum ether.

Anal. Calcd. for $C_6H_7O_6(COCH_3)_6Cl$: Cl, 7.57; saponification value (7 equivalents), 14.9 cc. 0.1 *N* NaOH per 100 mg.; mol. wt., 469. Found: Cl, 7.33; 14.7 cc. 0.1 *N* NaOH; OEt, negative; mol. wt. (Rast), 476.

The same substance was obtained by starting either with the free carbonyl or aldehydrol forms of *aldehydo*-galactose pentaacetate.

Aldehydo-1-bromo-*d*-galactose Hexaacetate.[10]—This substance was prepared as described for the corresponding chloride, except that less acetyl bromide (one-third of the amount used for the corresponding chloride) was employed. The substance showed a tendency to react with ethanol but could be recrystallized from benzene–petroleum ether, acetone–ice water, or chloroform (alcohol free)–petroleum ether. The purified substance crystallized in clusters of needles; m. p. 179–181°; $[\alpha]^{27}_{D}$ −79° (*c*, 4.0; CHCl$_3$, alcohol-free).

Anal. Calcd. for $C_6H_7O_6(COCH_3)_6Br$: Br, 15.58; saponification value (7 equivalents), 13.6 cc. 0.1 *N* NaOH per 100 mg. Found: Br, 15.62; 13.7 cc. 0.1 *N* NaOH.

That the acetyl halide in this compound was attached on carbon one was determined by shaking the substance (dissolved in 1:1 chloroform–ethanol) with silver carbonate, filtering from silver salts and crystallizing the reaction product (after solvent removal) from ethanol. The reaction product was identified as *aldehydo*-galactose pentaacetate ethyl hemiacetal.

Aldehydo-1-iodo-*d*-galactose Hexaacetate.[10]—*Aldehydo*-galactose pentaacetate (4 g.) was added with stirring to 17 g. of acetyl iodide and the resultant thin paste was poured into ice and water. The yellow crystals that separated were purified by repeated recrystallization from chloroform (alcohol-free) by the addition of petroleum ether; m. p. 152–153°; $[\alpha]^{25}_{D}$ −111° (*c*, 2; CHCl$_3$, alcohol-free). These constants are provisional as the substance was unstable and difficult to purify.

Anal. Calcd. for $C_6H_7O_6(COCH_3)_6I$: I, 22.66. Found: I, 22.10.

Aldehydo-*d*-glucose Heptaacetate.[11]—*Aldehydo*-glucose pentaacetate[12] (10 g.) was dissolved in 250 cc. of dry pyridine, the solution allowed to stand for two hours and then 125 cc. of acetic anhydride added and the whole allowed to stand overnight (fifteen hours). The dark solution was then poured into one liter of ice and water and the clear aqueous solution extracted with chloroform. The extract was washed with 5% sulfuric acid until free from pyridine, followed by washing with a solution of sodium bicarbonate and finally with water. The extract was dried and after removal of the chloroform the resultant sirup was dissolved in hot ethanol (carboraffin) and on cooling this solution a mass of fine white crystals separated. Further crops could be obtained by concentration of the mother liquor; yield (3 crops), 2.8 g. The substance was readily recrystallized from warm ethanol, the pure material showing the constants: m. p. 118.5–119.5°; $[\alpha]^{25}_{D}$ +8° (*c*, 4; CHCl$_3$).

The substance crystallized in prisms and rather large crystals (3 mm. long) could be formed on slow evaporation of an alcoholic solution. The substance was very soluble in chloroform, acetone, glacial acetic acid; was soluble, when heated, in water, ethanol, ether, and heptane; and was practically insoluble in petroleum ether.

Anal. Calcd. for $C_6H_7O_7(CH_3CO)_7$: C, 48.76; H, 5.74; acetyl, 14.2 cc. 0.1 *N* NaOH per 100 mg. Found: C, 48.79; H, 5.65; acetyl, 14.2 cc.

[11] R. L. Whistler, M. Sc. Thesis, The Ohio State University, Aug., 1935.

[12] M. L. Wolfrom, This Journal, **51**, 2188 (1929).

That the substance was not an acetylated enolic or alkali-interconverted sugar was determined by the fact that it did not decolorize a solution of bromine in carbon tetrachloride and on deacetylation with sodium ethylate followed by reacetylation with warm acetic anhydride and sodium acetate, β-glucose pentaacetate (m. p. 131°; $[\alpha]_D$ +4°, $CHCl_3$) was produced.

The substance was also formed, although in lower yield, by the room temperature acetylation of *aldehydo*-glucose pentaacetate with acetic anhydride and zinc chloride. *Aldehydo*-glucose pentaacetate (2 g.) was added to a solution of 1 g. of freshly fused zinc chloride in 40 cc. of acetic anhydride and the solution allowed to stand overnight (fifteen hours). The solution was then poured on cracked ice and neutralized with sodium bicarbonate, extracted with chloroform and the extract washed with water and dried. The sirup obtained after solvent removal was crystallized from hot ethanol (carboraffin); yield, 0.2 g.; m. p. 117.5–118.5°; $[\alpha]_D$ +8° (*c*, 3; $CHCl_3$).

Aldehydo-*l*-arabinose Hexaacetate.[11]—*Aldehydo-l*-arabinose tetraacetate[13] (20 g.) was acetylated with a solution of 20 g. of zinc chloride (freshly fused) in one liter of acetic anhydride as described above for the preparation of glucose heptaacetate. The resultant sirup was crystallized from hot ethanol; yield, 9 g.; m. p. 85°. Pure material was obtained by solution in just sufficient hot ethanol so that no crystallization occurred on cooling and repeatedly adding water in small quantities to the above solution at ice box temperature; m. p. 89.5°; $[\alpha]^{27}_D$ −27° (*c*, 4; $CHCl_3$). The solubilities of this substance were similar to those of the corresponding glucose compound.

Anal. Calcd. for $C_5H_6O_6(CH_3CO)_6$: C, 48.57; H, 5.76; acetyl, 14.3 cc. 0.1 *N* NaOH per 100 mg. Found: C, 48.57; H, 5.68; acetyl, 14.3 cc.

The experimental work herein reported was carried on in this Laboratory rather incidentally over a considerable period of time and I wish to make due acknowledgment to the assistance rendered by Messrs. W. M. Morgan, J. L. Quinn, R. L. Whistler and M. Konigsberg.

Summary

1. The chloride, bromide and iodide forms of *aldehydo-d*-galactose hexaacetate 1-halide have been synthesized in crystalline form. It is pointed out that these substances are the open chain analogs of the cyclic acetohalogen sugars.

2. *Aldehydo-d*-glucose heptaacetate and *aldehydo-l*-arabinose hexaacetate have been synthesized in pure crystalline form. It is pointed out that these compounds may be expected to be formed in reactions involving the cyclic forms of the sugars, rather than the free carbonyl or *aldehydo*-structures.

Iodine Substitution Products of Vanillin and Some of their Derivatives

BY L. CHAS. RAIFORD AND EUGENE H. WELLS

In work published from this Laboratory[1] the chlorine and bromine substitution products of vanillin demanded by theory were prepared and characterized by a study of their interactions with typical amino compounds. Steric hindrance[2] was noted only when both ortho positions in the aldehyde were substituted, and was then less pronounced than expected. In the present work the iodine derivatives have been examined. The high yields of products indicated little, if any, hindrance.

The Action of Iodine on Vanillin.—Carles[3] treated vanillin with warm alcoholic solutions of iodine of different concentrations and obtained products that analyzed for mono- and diiodovanillin, respectively. He did not determine the structures of these compounds or study them further, and they are recorded as having the halogen in unknown positions.[4] The monoiodo derivative was reported to melt at 174° and was probably an impure sample of that, m. p. 180°, obtained by Hann[5] and reported as 5-iodovanillin, but without proof of structure. No melting point was given for the diiodo compound. Carles' work has been repeated and, while the monoiodo

[2] Hantzsch [*Ber.*, **23**, 2776 (1890)] could not condense *sym*-tribromo- and trinitroaniline with benzaldehyde, but Lowy and co-workers [THIS JOURNAL, **43**, 1961 (1921)] found that when the nitro radical was in the aldehyde, condensation with aniline did take place, though they studied no aldehyde containing a substituent other than the nitro radical. Their results may not be typical for Meyer [*Z. physik. Chem.*, **24**, 219 (1897)] found that while hindrance in esterification of *o*-substituted benzoic acids was often proportional to the weight of the o-substituent, that produced by the nitro group was much greater than expected. On the other hand, Fischer and Giebe [*Ber.*, **31**, 546 (1898)] found that the *o*-nitro radical in benzaldehyde favors acetal formation.

compound only was obtained by his method, both were prepared in other ways and their structures established.

To determine the position of iodine in the first product here studied the start was made with the nitrovanillin, m. p. 137°, first obtained by Pschorr and Sumuleanu.[6] In later work, the hydroxyl group of this compound was methylated, and the resulting product was oxidized into a nitroveratric acid. The latter was reduced, the resulting amine diazotized and converted by the Sandmeyer method into a cyanide that on hydrolysis gave hemipinic acid.[7] The starting material must therefore have been 2-nitrovanillin (CHO = 1). In the present work this nitro compound was reduced and the resulting amino radical replaced by iodine in the usual way.

The position of iodine in the monoiodo compound reported by Carles was oriented as follows. That nitro compound, m. p. 175–176°, obtained by direct nitration of vanillin[8] and proved by Vogl[9] to have the nitro radical in position 5, was in our work reduced by stannous chloride and hydrochloric acid. Though the free amine was not obtained, the hydrochloride and the stannic chloride double salt were isolated, and from the former several derivatives were prepared. The salt was diazotized and separate portions were subjected to the Sandmeyer reaction with cuprous chloride, cuprous bromide and potassium iodide, respectively. In the first two cases 5-chloro- and 5-bromovanillin, in which the position of halogen had previously been determined by a different method, were obtained. In the third case Carles' monoiodovanillin was isolated, which proves that it is 5-iodovanillin.

By methods described below, 5-iodovanillin was converted into acetyl-5-iodovanillin, and into 3-methoxy-4-acetoxy-5-iodobenzal diacetate. Nitration of these products gave the same compound, acetyl-2-nitro-5-iodovanillin. The acetyl group was removed by hydrolysis, the nitro compound was reduced, the resulting amine was diazotized and the diazonium salt treated with potassium iodide. The diiodovanillin formed melted at 199–200°,[10] and was identical with that obtained by direct iodination of 2-iodovanillin.

With the hope of obtaining 6-iodovanillin, acetylvanillin was treated with iodine[11] and with iodine monochloride,[12] respectively. Only 5-iodovanillin and starting material were obtained. Similarly, treatment of 3-methoxy-4-acetoxybenzal diacetate[13] failed to give the desired product.

Experimental Part

2-Iodovanillin.—Twenty grams of 2-aminovanillin[14] was dissolved in 350 cc. of 15% hydrochloric acid, cooled to 0° and diazotized. A cold solution of 30 g. of potassium iodide was added, and the mixture kept at about 0° for two hours, and some tar that had separated was removed and examined. The remainder was heated on the steam-bath for an hour, then boiled over a free flame to remove free iodine; yield 54%. After boiling the alcoholic solution with norite and filtering, addition of hot water to the filtrate and cooling gave nearly colorless needles; m. p. 155–156°.

Anal. Calcd. for $C_8H_7O_3I$: I, 45.68. Found: I, 45.53.

2-Iodo-3,4-dimethoxybenzaldehyde.—To a potassium hydroxide solution of 2-iodovanillin held between 50 and 60°, excess of dimethyl sulfate was slowly added with shaking; yield 84%. Crystallization from dilute alcohol gave pale yellow needles; m. p. 82°.

Anal. Calcd. for $C_9H_9O_3I$: I, 43.49. Found: I, 43.65.

Analytical data for other derivatives are given in Table I.

Stannic Chloride Double Salt of 5-Aminovanillin.—To a boiling suspension of 160 g. of 5-nitrovanillin[15] in 750 cc. of alcohol there was added in small portions a solution of 800 g. of stannous chloride in 800 cc. of concentrated hydrochloric acid. After addition of a few portions the heat of reaction kept the mixture boiling. When all the reducing agent was in, 1500 cc. of concentrated acid was added and the mixture allowed to cool. When the resulting solid was dissolved in hot 2.5 *N* hydrochloric acid, and one volume of concentrated acid was added, orange crystals were obtained; yield 88%.

Anal. Calcd. for $C_{16}H_{20}O_6N_2SnCl_6$: N, 4.19; Cl, 31.88. Found: N, 4.24; Cl, 31.61.

5-Aminovanillin Hydrochloride.—A hot dilute hydrochloric acid solution of the tin salt indicated above was treated with hydrogen sulfide as long as change took place, the mixture filtered, the filtrate mixed with two volumes of concentrated hydrochloric acid, and cooled in ice; yield 70%. Recrystallization as indicated above gave yellowish-brown prisms.

[a] Purification was accomplished by extraction of foreign material by alcohol. [b] It was heated to about 335° but gave no melting point.

Anal. Calcd. for $C_8H_{10}O_3NCl$: N, 6.87; Cl, 17.44. Found: N, 6.68; Cl, 16.55.

3 - Methoxy - 4 - acetoxy - 5 - acetylaminobenzaldehyde.—A portion of the amino hydrochloride was dissolved in 10% solution of potassium hydroxide by gentle warming, cooled to room temperature and shaken with an ether solution of acetic anhydride; yield 66%. Crystallization from water gave colorless needles; m. p. 174–176°.

Anal. Calcd. for $C_{12}H_{13}O_5N$: N, 5.57. Found: N, 5.36.

3 - Methoxy - 4 - benzoxy - 5 - benzoylaminobenzaldehyde.—This was obtained in 75% yield by treatment of an alkaline solution of the base with benzoyl chloride. Crystallization from alcohol gave colorless needles; m. p. 161–162°.

Anal. Calcd. for $C_{22}H_{17}O_5N$: N, 3.73. Found: N, 3.83.

5-Iodovanillin.—Five grams of the amino hydrochloride was suspended in 20 cc. of dilute hydrochloric acid, cooled below 0° and diazotized. To the clear liquid a cold solution of potassium iodide was added, the mixture warmed slowly and finally boiled to remove free iodine; yield 79% of brown solid. Repeated crystallization from dilute alcohol gave light brown needles, m. p. 179–180°, and identical with Carles' product.[16] Data for derivatives are given in Table II.

Acetyl-2-nitro-5-iodovanillin.—Eighty grams of acetyl-5-iodovanillin was dissolved in 175 cc. of fuming nitric acid at 6° or below with stirring, the solution held at this temperature for half an hour, and the dark red liquid poured into a liter of ice and water. The oil that separated solidified on standing, was washed free from acid and boiled with water to remove a little free iodine; yield 83%. Crystallization from acetic acid, using norite, gave nearly colorless plates, m. p. 124–125°. The same product was obtained by nitration of 3-methoxy-4-acetoxy-5-iodobenzal diacetate.

Anal. Calcd. for $C_{10}H_8O_6NI$: I, 34.79. Found: I, 34.97.

---

[16] This compound was also obtained by the action of iodine monochloride an vanillin.

TABLE IV

DERIVATIVES OF 2,5-IODOVANILLIN

Compound	Yield, %	Solvent	Crystal form	M. p., °C.	Formula	Halogen, % Calcd.	Halogen, % Found
Acetyl	97	Dil. alcohol	Square prisms	127–128	$C_{10}H_8O_4I_2$	56.95	57.22
Oxime	95	Dil. alcohol	Needles	174.5–175.5	$C_8H_7O_3NI_2$	60.62	60.47
Semicarbazone	96	Alcohol	Needles	235 (dec.)	$C_9H_9O_3N_3I_2$	55.09	55.36
p-Nitrophenylhydrazone	95	Acetic acid	Orange	252–253 (dec.)	$C_{14}H_{11}O_4N_3I_2$	47.12	46.97
Bis-benzidine	83	[a]	Powder	[b]	$C_{28}H_{20}O_4N_2I_4$	53.13	52.17

[a] Could not be crystallized. [b] Gave no melting point.

Hydrolysis of this product with caustic potash solution gave 2-nitro-5-iodovanillin. Crystallization from 30% acetic acid gave colorless rods; m. p. 146–147°.

Anal. Calcd. for $C_8H_6O_5NI$: I, 39.30. Found: I, 39.57.

Data for derivatives are given in Table III.

2-Amino-5-iodovanillin.—Thirty-four grams of the nitro compound was reduced by ferrous hydroxide in the presence of ammonia water; yield 69%. Repeated crystallization from dilute alcohol, using norite, gave light brown needles, m. p. 155°.

Anal. Calcd. for $C_8H_8O_3NI$: I, 43.34. Found: I, 43.56.

Treatment of the diazonium salt from the above amine with potassium iodide gave 2,5-diiodovanillin, which was also obtained in another way and characterized as indicated below.

2,5-Diiodovanillin.—A mixture of 15 g. of 2-iodovanillin, 8 g. of anhydrous sodium acetate, 80 g. of acetic acid and 14 g. of iodine was kept at about 60° with continual stirring for twenty-four hours, one liter of water was then added and the mixture boiled to remove free iodine; yield 69%. Repeated crystallization from alcohol gave colorless rods; m. p. 200°.

Anal. Calcd. for $C_8H_6O_3I_2$: I, 62.87. Found: I, 62.87.

Treatment of this product with dimethyl sulfate under the conditions described for the monoiodo compound gave a 33% yield of 2,5-diiodo-3,4-dimethoxybenzaldehyde, while 60% of starting material was recovered. The new product was obtained as colorless needles by addition of hot water to the hot alcoholic solution, and cooling; m. p. 94°. Data for derivatives are given in Table IV.

Anal. Calcd. for $C_9H_8O_3I_2$: I, 60.76. Found: I, 60.56.

Summary

Several iodine substitution products of vanillin, including Carles' compounds, have been prepared and their structures determined. The behavior of these products toward typical amino compounds has been tested. No pronounced steric hindrance was noted in the latter reactions.

The relation between the numerical values of the melting points and the positions of the halogen atoms in the iodine derivatives, so far as they have been obtained, is in good agreement with that observed in the cases of the chlorine and bromine compounds, *viz.*, that the lowest value is found for position 2, the next higher for 5 and the highest for 6. Likewise, for a given position the lowest is found for the chloride, the next higher for the bromide and the highest for the iodide.

Further work is in progress.

Investigations of the Effects of Some Factors on Rhythmic Crystallization[1]

BY MAJEL M. MACMASTERS, JULIA E. ABBOTT AND CHARLES A. PETERS

In 1853, Sir David Brewster[2] reported the first recorded cases of rhythmic crystallization from aqueous solution. Since that time, numerous investigators have reported similar instances of periodic banding, although but little has been done to explain the cause of the phenomenon or the influence of factors affecting it.

The rhythmic crystallization of potassium dichromate from aqueous solution, first reported by Miers[3] in 1908, is typical of the phenomenon and is easily reproduced. This is described in detail by Hedges.[4]

Experimental

Ordinary non-corrosive white glass microscope slides were used as surfaces on which crystallization took place. Preliminary tests showed that the method of cleaning did not effect crystallization on the slide. Slides prepared at 23 or 25° were placed in a constant temperature room; slides prepared at 50°, or above, were kept at constant temperature in a Freas electric oven. All salts used were C. P. Baker's Analyzed.

Coarse Rhythm, Fine Rhythm and X-Rhythm.—Miers' method gives rows of dendritic crystals alternating with areas more or less devoid of crystalline material. This we shall call *coarse rhythm.* Occasionally there appear small areas of very narrow alternating bands of thickly crystalline area (crests) and thinly crystalline areas (troughs). A crest and a trough comprise a period. This we shall call *fine rhythm.* In fine rhythm the periods are very small, usually 0.005 to 0.01 mm. Fine rhythm is often overlooked unless polarized light is used for the examination of the slides. Coarse rhythm is often irregular, and in many instances occurs over only comparatively small areas, while fine rhythm is extremely regular and usually occurs over large areas. Forms simulating coarse rhythm are often caused by shocks affecting the slide during crystallization, but fine rhythm is never counterfeited by shocks. Areas of fine rhythm crossed by a second system of fine rhythm approximately at right angles to the first have been observed. We shall call this *x-rhythm.*

Influence of Temperature and of Concentration.—The influence of change of temperature and of concentration upon the rhythmic crystallization of potassium dichromate was first investigated by a modification of Miers' method. For this purpose 0.0017, 0.017 and 0.136 M solutions of potassium dichromate were used. Each solution was allowed to crystallize at constant temperatures of 25, 50 and 100°. Slide and solution were kept at constant temperature for some time before the solution was placed on the slide; this temperature was maintained until crystallization was complete. The solution was transferred to the slide by means of a pipet, also at the required temperature.

In the slides made with 0.0017 M potassium dichromate dendrites became less common as the temperature rose, and massive circular crests at the edge of the drop became more common. The amount of simple fine rhythm present was greatest in slides run at 100°, and did not much vary in those run at 50° from those run at 25°. All slides, at all three temperatures, showed good fine rhythm and well defined areas of x-rhythm. Temperature did not affect the period of fine rhythm; periods of 0.005 and 0.01 mm. were most common.

The slides made with 0.0170 M potassium dichromate solution showed an increasing tendency to form heavy crests with increase of temperature. Dendrites were more common at lower temperatures than at 100°. Coarse rhythm decreased in amount with increase of temperature. Fine rhythm was present at all temperatures and did not appear to vary in amount with change of temperature. Only one case of x-rhythm was noted, on a slide made at 23°.

All slides made with 0.136 M potassium dichromate solution were dendritic. At 50 and at 100° numerous small circular crystals were formed. Rhythm decreased with increase of temperature; at 100° there was no evidence of rhythm.

---

(1) This paper includes portions of the work offered in partial fulfilment of the requirements for the degree of Master of Science by Julia E. Abbott, 1933, and for the degree of Doctor of Philosophy by Majel M. MacMasters, 1934, at the Massachusetts State College.

(4) Hedges, "Liesegang Rings and Other Periodic Structures," Chapman and Hall, London, 1932.

The influence of concentration was obvious. Slides made with 0.0017 *M* potassium dichromate solution showed much fine rhythm and x-rhythm; those made with 0.017 *M* potassium dichromate solution showed much fine rhythm, but practically no x-rhythm; while slides made with 0.136 *M* potassium dichromate solution showed very little rhythm of any type. Within the limits studied, fine rhythm and x-rhythm occur most frequently in dilute solutions and at low temperatures; the heavy crests formed by concentrated solutions are too thick for observation of rhythm; similar crests are formed by dilute solutions allowed to crystallize at high temperatures.

If all the data are considered, it appears at once that coarse rhythm is often irregular and never constant enough to serve as the criterion of periodicity. It becomes plain, on the other hand, that temperature and concentration differences, within the wide limits studied, have no influence upon the production of fine rhythm, providing only that the solution is not too strong and the temperature not too high for the production of a film of crystals. With a concentrated solution run at a high temperature crystallization proceeds rapidly with the formation of heavy crests which, by their massiveness, prohibit the detection of rhythm which might be present. The periods most commonly observed were those of 0.005 and 0.01 mm.; these were constant over wide areas on slides made at varying temperatures, with different concentrations of the solution. The crest and trough were, in general, of equal width; where this was not the case, the crest was that of one period, while the trough was that of another period either one-half or double the width of the first. All commonly observed periods were either 0.005 mm. in width or some common multiple of this width. x-Rhythm appears to be a special case of fine rhythm, in which periods of fine rhythm have developed in two directions.

New Method.—The method of Miers seemed open to criticism, because it involves motion, strong convection currents and exposures to contaminated atmosphere; the following method, therefore, was developed.

The 0.5 *M* solution of potassium dichromate to be examined was brought to boiling temperature; the cleaned slide was drained from distilled water and dipped, without wiping, into the boiling solution. Of each set of five slides, two were allowed to crystallize while held above the hot solution, while the other three were placed, on edge, on a glass plate to crystallize. A temperature difference in the surrounding atmosphere was thus introduced. In no case did there appear to be any difference between the two slides and the three, and in most cases these films showed periodic banding. This method gives, consistently, large areas of fine rhythm.

Influence of Specific Impurities.—Preliminary tests showed that typical rhythm was formed in the presence of 12% ethyl alcohol, 4% sodium hydroxide or small quantities of various acids.

Sodium dichromate and ammonium dichromate were introduced, in turn, in order to study the effect of a single foreign ion upon rhythmic crystallization. Further investigation showed, however, that each of these salts exhibited rhythmic crystallization from aqueous solution. The banding shown by ammonium dichromate was very similar to that exhibited by potassium dichromate. Sodium dichromate gave finer but less continuous rhythm. The rhythmic crystallization of these salts has not hitherto been reported.

Specific Effect of Anions.—This part of the work was undertaken assuming that the cation was the most important factor in rhythmic crystallization. This assumption arose from the observation that potassium dichromate and ammonium dichromate, with similar cations, showed very similar rhythmic crystallization, while sodium dichromate, with a smaller cation, showed finer spacing of the periods, and finally, introduction of sufficient hydrogen ion, a very small cation, completely inhibited fine rhythm. The results obtained were surprising; apparently the foreign cation has little or no effect on the rhythm, while anion has a specific inhibitory effect.

A 0.5 *M* potassium chloride solution was mixed with the 0.5 *M* potassium dichromate solution to give molar ratios of chloride ion to dichromate ion varying from 10/2 to 10/7, increasing always by whole numbers. The tests showed that a 10/5 molar ratio of chloride ion to dichromate ion had a slight effect upon the rhythmic crystallization of potassium dichromate, while a 10/3 molar ratio completely inhibited the rhythmic crystallization of potassium dichromate. When the large amounts of the chloride ion were present, potassium dichromate built dendritically upon cubic crystals of potassium chloride, and no fine rhythm found when all of the dichromate was used in building such dendrites. Under the influence of the potassium chloride coarser dendrites of the potassium dichromate appeared coincident with the disappearance of fine rhythm. It seems probable, therefore, that potassium chloride inhibited fine rhythm by modifying the surface attractions of the potassium dichromate crystals. The period of fine rhythm when present was always that normally shown by pure potassium dichromate solutions.

The effect of the presence of 0.5 *M* sodium chloride upon the rhythmic crystallization of 0.5 *M* potassium dichromate was investigated in a similar way. Inspection of the various sets of slides in this series showed that the period of fine rhythm did not decrease, but remained constant at the normal value for potassium dichromate; it may be concluded from this that sodium dichromate did not form to any large extent, as preliminary tests had shown that sodium dichromate crystallizes rhythmically with a period smaller than that of the potassium salt. Fine rhythm persisted only slightly longer in this series than in that in which potassium chloride was used as impurity. A molar ratio of chloride ion (or sodium ion) to dichromate ion of 10/4 caused appreciable decrease in the amount of fine rhythm present, while a ratio of 10/2 caused complete absence of fine rhythm.

It appeared desirable to try the effect of the presence of a divalent cation; for this purpose a series of slides was made and examined, using a 0.25 *M* solution of calcium chloride as the specific impurity. When the molar ratio of chloride ion to dichromate ion was 10/4 fine rhythm was still present, but when the ratio was 10/3 fine rhythm was not typical, although a transitional type of rhythmic branching of dendrites was observed.

The transition from parallel branching of dendrites to typical fine rhythm is of especial interest, as it indicates more clearly the ultimate cause of fine rhythm. Fine rhythm is due to very regular branching of dendrites. The present writers have observed the crystals in crest and trough to be lying at right angles to each other; the branch lies at right angles to the parent stem.

The molar ratio of chloride ion to dichromate ion at disappearance of fine rhythm was 10/2, 10/3, 10/3, in the presence of sodium chloride, potassium chloride and calcium chloride, respectively. The charge on the cation cannot be an important factor, since the effect of the chloride ion is constant, no matter whether it is introduced with monovalent cation as sodium or potassium or with a divalent cation as calcium. There is also further substantiation of the view that the anion alone affects the inhibition of fine rhythm, in this case at least, since the ratio of chloride ion to dichromate ion is constant in the presence of sodium ion, calcium ion or excess potassium ion. These results were unexpected in view of the preliminary work.

Potassium nitrate, 0.5 *M*, was used with the 0.5 *M* potassium dichromate solution to introduce a monovalent anion other than the chloride ion. All fine rhythm of the series showed the usual period for potassium dichromate. Definite curtailment of fine rhythm did not appear until the molar ratio of nitrate ion to dichromate ion was 6/15; with a ratio of 7/15 fine rhythm was entirely suppressed. The corresponding ratio of chloride ion to dichromate ion was 10/3; the nitrate ion is, therefore, far more effective than the chloride ion in the inhibition of rhythmic crystallization of potassium dichromate from aqueous solution.

Potassium sulfate, 0.5 *M*, was used with 0.5 *M* potassium dichromate to determine the effect of the sulfate ion, a divalent anion, upon the periodic crystallization of potassium dichromate. The period of the fine rhythm was not affected. When the molar ratio of sulfate ion to dichromate ion was 1/1 the amount of fine rhythm formed began to decrease. When the ratio was 4/3 rhythm was almost completely inhibited. The sulfate ion is, therefore, more effective in inhibiting the formation of fine rhythm by potassium dichromate than is the chloride ion, but is less effective than the nitrate ion. From this evidence it would further appear that the charge on the anion is not a prime factor in the effect of the anion on rhythmic crystallization.

Spacing of Periods from the Center of Crystallization.—No data concerning the spacing of rings from the center of crystallization in cases of rhythmic crystallization from solution have been found in the literature. Such measurements are often difficult, as in some cases the center is surrounded by a large, irregular area of undifferentiated or dendritic precipitate; in other cases the arc of crystallization is so great

TABLE I

DATA ON SPACING OF PERIODS FROM CENTER OF CRYSTALLIZATION

No.	Soln. used	Dist. of period from center, mm.	Values of A $\frac{h_3 - h_2}{h_2 - h_1} = A$	Agreement with Jablczynski	Agreement with Hughes (see Fig. 1)
1	150 cc. 0.5 M $K_2Cr_2O_7$ with 100 cc. 0.5 M K_2SO_4	0.045 0.070 0.095 .125 .155	1.00 1.20 1.00	Partial	Fair

that the center would lie at a considerable distance off the slide. Measurements were undertaken, however, in an attempt to determine whether potassium dichromate, in the solutions under investigation, gave rhythmic bands similar in arrangement to those found by Jablczynski[5] in Liesegang rings, or by Hughes[6] and Dippy[7] in melts which crystallized rhythmically.

Jablczynski found the ratio between rings formed by metathesis of silver nitrate and potassium dichromate in gelatin gel to be constant, expressed by $(h_3 - h_2)/(h_2 - h_1) = A$, when h_n is the distance of the nth ring from the point of entrance of the diffusing silver nitrate solution.

Hughes and Dippy investigated cases of rhythmic crystallization from the melt, found that by plotting the logarithm of N, the number of rings counted from the center against the logarithm of r, the distance of the ring from the center, a straight line was obtained with the general equation

$$\log N = a \log r + \log K$$

when N and r are defined as above, a is the slope of the line to the axis of log r, and log K is the intercept on the axis of log N.

Slides were chosen at random, but only areas where the center of crystallization was clearly defined, and in which fine rhythm progressed evenly in all directions from the center of crystallization were used. Data and comparison with Jablczynski and with Hughes are given in Table I. The graph, Fig. 1, developed from Table I shows agreement with the work of Hughes.

Slides 2, 3 and 5, Table I, showed perfect agreement with the Liesegang ring relationship found by Jablczynski, while slides 1 and 4 showed partial agreement. Slide 6, however, showed negative agreement. The relationship apparently holds for many cases of rhythmic crystallization from solution, but may not be universally true.

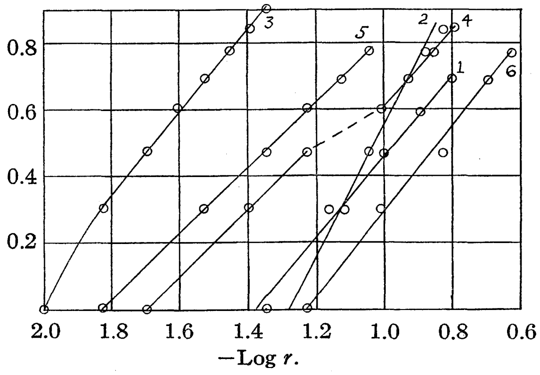

Fig. 1.—Log of number of period plotted against log of distance from center.

When the data from slides 1, 2 and 3, Fig. 1, are plotted as suggested by Hughes, they show a tendency to give a curve when the data are taken from near the centers of crystallization (curve 3), but the data as a whole give a statistically straight line. Only the statistically straight lines given by the data as a whole have been drawn in for slides 1 and 2. Many more cases would have to be investigated to prove that the tendency to give a curve from data near the center of crystallization is significant. Slide 4 shows two lines, both excellently straight, one from data near the center of crystallization, the other from data more re-

moved from the center. Slides 5 and 6 show statistically straight lines, in good agreement with the work of Hughes.

If slides had been taken exhibiting the usual fine rhythm of extremely constant spacing over wide areas in large arcs such that the theoretical center of crystallization would be situated off the slide, no distances from the center could have been measured. If the first period formed had been used as a center of crystallization, and measurements made from it, however, a regular series like those in slides 2, 3 and 5 would have been found in those numerous cases in which the periods are of equal width over large areas. These cases would give perfect agreement with the work of Jablczynski and good agreement with the work of Hughes and of Dippy.

For suggestion of the subject of research, acknowledgment and thanks are due to Professor Cecil H. Desch, George Fisher Baker lecturer in Chemistry at Cornell University, October, 1931, to January, 1932.

Summary

Distinction has been made between *coarse rhythm* and *fine rhythm* produced by crystallization of potassium dichromate from aqueous solutions. Fine rhythm has been shown to be the true criterion of periodicity. A method has been described by which very regular fine rhythm can be obtained over large areas.

It has been shown that differences in temperature and in concentration do not, within wide limits, materially affect the rhythmic crystallization of potassium dichromate from aqueous solution.

The rhythmic crystallization of ammonium dichromate and of sodium dichromate from their aqueous solutions has been reported.

The specific influence of a foreign anion in inhibiting the formation of fine rhythm of potassium dichromate has been shown. It has been determined that the nitrate ion is more effective than the sulfate ion, while the sulfate ion is more effective than the chloride ion. The molar ratio of each of these ions to dichromate ion necessary completely to inhibit formation of rhythm has been reported.

It has been shown that the spacing of periods from the center of crystallization, in rhythmic crystallization of potassium dichromate from aqueous solution, agrees, roughly, with the spacing of Liesegang rings reported by Jablczynski, and with the spacing of rhythmic banding resulting from crystallization from the melt, as reported by Hughes and substantiated by Dippy. This would indicate that there may be a common cause underlying the formation of Liesegang rings, rhythmic banding from the melt and rhythmic crystallization from solution.

Additions to Conjugated Systems in the Anthracene Series. III. Factors Influencing the Mode and Extent of Reaction of the Grignard Reagent with Ketones

BY PERCY L. JULIAN, WAYNE COLE AND THOMAS F. WOOD[1]

When benzalanthrone (I) is treated with methylmagnesium iodide, the main product (II) isolated is the one formed by 1,2-addition. The reaction was puzzling for a long time, first of all because it is difficult to duplicate results unless the proper concentration of reactants is consistently maintained. Secondly, the behavior of our product (II) toward bromine, as well as behavior on attempted rearrangement into the isomer with the anthracene structure,[2] were not what we had expected. All these results appear, however, to find satisfactory explanation in the ease with which (II) loses water, possessing as it does a very reactive hydroxyl group.

The product secured on treatment of (II) with one mole of bromine in the cold indicates addition of two atoms of bromine and elimination of a molecule of water. It is highly fluorescent in solution, and both bromine atoms are very reactive, as is shown by the ease with which the dibromide is converted into a diacetate. We are suggesting structure (V) for it, and (III) and (IV) as logical intermediates. The diacetate would then have the structure (VI). On further treat-

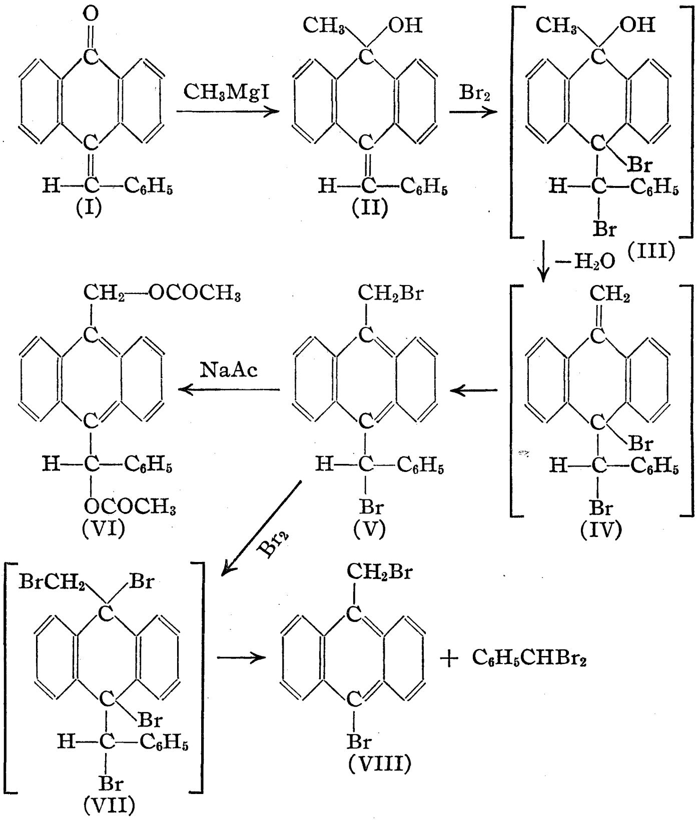
ment with bromine in the cold (V) absorbs, somewhat more slowly than (II), a second molecule of bromine, the compound (VIII) being deposited, a substance identical with one of the products secured by Barnett and Matthews[3] on brominating 9-methylanthracene and assigned this structure. The residue on evaporation of the mother liquor is hydrolyzed on warming with water into benzaldehyde and hydrogen bromide. Compound (VII) is suggested as the intermediate in the formation of (VIII) from (V).



With the behavior of (II) satisfactorily explained, our attention was directed to the original object of these investigations, namely, a study of the factors influencing different types of addition of the Grignard reagent to ketones of the anthracene series. It was conceivable that, in view of the fact that a small quantity of anthraquinone is always secured on working up the product from the reaction between phenylmagnesium bromide and benzalanthrone (indicating in all probability formation of a small amount of 1,6-addition product), the action of methylmagnesium iodide might result in a larger percentage of 1,6-addition.[4]

Actually on working up the reaction products on treatment of benzalanthrone with methylmagnesium iodide, an appreciable quantity of anthraquinone was always obtained. Accordingly we employed the usual procedure[2,5] for isolation of peroxides and obtained a very small quantity of a highly insoluble crystalline substance, which decomposed violently at 74° without melting, and yielded anthraquinone. Since its isolation in workable quantities was difficult and no criterion of its purity was available, we decided to undertake the preparation of this same compound by the action of phenylmagnesium bromide on ethylidene anthrone (IX).

The only reference to ethylidene anthrone in the literature is that of Liebermann.[6] Employment of his procedure as well as several other methods which should lead to a compound of this structure yielded invariably anthraquinone. The conclusion was inevitable that ethylidene anthrone (IX) is easily oxidized by atmospheric oxygen to anthraquinone. That atmospheric oxygen should cleave a carbon–carbon double linkage of this type is hardly conceivable in view of the stability of methylene anthrone and benzalanthrone. Since it has been shown[2,5b] that atmospheric oxygen readily converts anthranols into peroxides, it seemed reasonable, proceeding from the principle of vinylogy,[7] to expect that the fundamental difference in behavior between ethylidene anthrone (IX) and methylene and benzalanthrone resides in the ability of the former to exist in the anthranol modification (X), which would be expected to undergo oxidation by atmospheric oxygen to anthraquinone and vinyl alcohol *via* the peroxide (XI).

To test out this hypothesis we undertook the identification of vinyl alcohol as acetaldehyde. A sample of ethyloxanthrone (XII) was dissolved in glacial acetic acid, a few drops of sulfuric acid added and the solution allowed to stand under

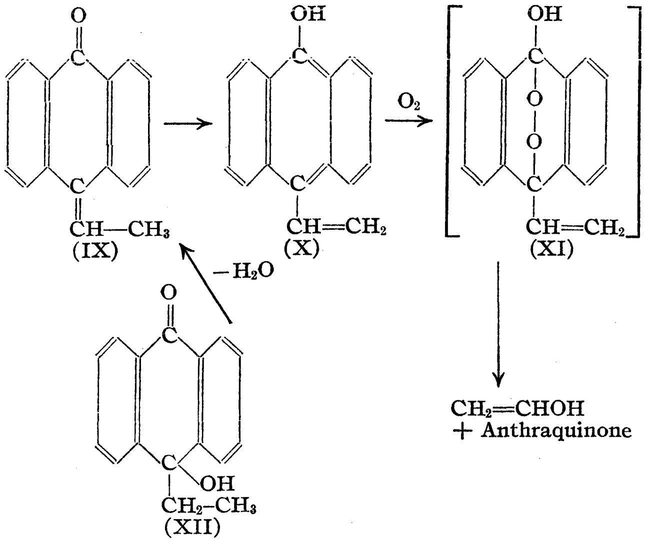
oxygen in a closed system. Acetaldehyde was distilled from the reaction mixture and identified by its odor, by means of Tollens' reagent, and by conversion into ethylidene-β-dinaphthyl oxide.[8]



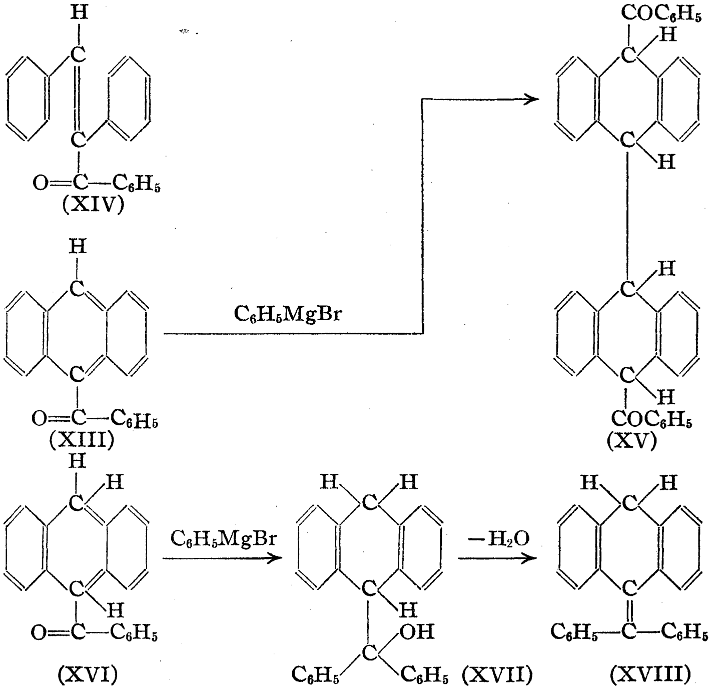
(IX) (X) (XI) (XII)

Ethylidene anthrone was obtained as a red oil by destructive distillation of ethyloxanthrone in an atmosphere of nitrogen at ordinary pressure. On redistillation in vacuum this oil boiled constantly at 245–247° at 20 mm.; on attempting to distil this material under atmospheric conditions, however, considerable decomposition took place, yielding anthraquinone and a combustible gas which was collected over water and identified as acetylene. The formation of acetylene is further proof of the proposed oxidation mechanism, since vinyl alcohol formed in this manner at high temperature would be expected to lose water rather than rearrange to acetaldehyde.

The properties of ethylidene anthrone and related anthrones are being further investigated in these laboratories, and our studies of the influence on the mode of reaction with the Grignard reagent, occasioned by substitution of the hydrogen atoms in the methylene group of methylene anthrone, must await the results of these investigations.

We, therefore, turned our attention to the other side of the problem, namely, the influence of the anthracene nucleus on the mode of reaction, selecting as starting material anthraphenone (XIII). Viewed from the standpoint of meso-unsaturation this substance resembles benzaldesoxybenzoin (XIV) and phenylbenzaldesoxybenzoin. Since 1,2-addition of phenylmagnesium bromide seemed highly improbable in view of the sluggish character of the carbonyl group (anthraphenone gives none of the typical ketone reactions),[9] it was expected that either 1,4-addition into the phenyl ring might occur, or what was less probable 1,6-addition to the conjugated system extending to the 9-carbon atom of the anthracene nucleus, yielding a dihydroanthracene derivative. In fact neither of these reactions occurred, instead dimolecular 1,6-reduction took place yielding 10,10′-dibenzoyl-9,9′,10,10′-tetrahydro-9,9′-dianthranyl (XV), a compound already described by Cook and secured by reducing anthraphenone with zinc and acetic acid.[10]

In the case of dihydroanthraphenone (XVI) in which the meso-unsaturation is removed, all hindrance to 1,2-addition disappears and phenylmagnesium bromide gives the expected carbinol (XVII) in practically quantitative yield. The in-



(XIV) (XIII) (XV) (XVI) (XVII) (XVIII)

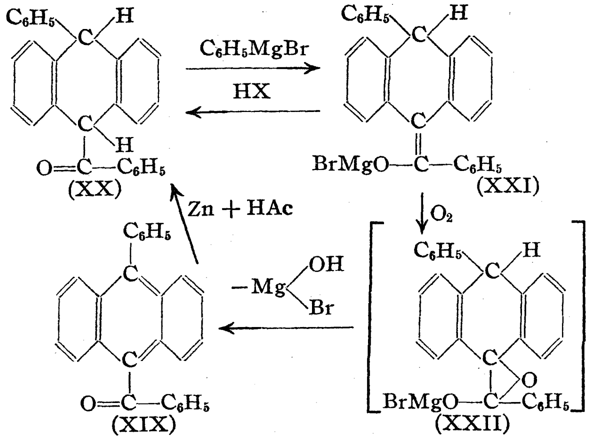
[10] Cook, *ibid.*, 1680 (1926).

fluence of this meso-unsaturation upon the additive powers of the carbonyl group is in striking analogy to the difference in behavior, reported by Kohler, between phenylbenzaldesoxybenzoin and its saturated derivative, α,β,β-triphenylpropiophenone.[11] The structure of the carbinol (XVII) was proved by elimination of water to form the hydrocarbon (XVIII), the latter oxidized with chromic acid to one mole of anthraquinone and one mole of benzophenone.

Following up the analogy between these meso-unsaturated anthracene ketones and α,β-unsaturated ketones, we next investigated 9-phenylanthraphenone (XIX). Despite numerous attempts we have been unable to isolate any pure products from the reaction between this substance and phenylmagnesium bromide. Most of the material is recovered unchanged. A quantity of gum was always obtained and this is still under investigation. We are therefore not prepared to state with certainty that no reaction takes place in view of the difficulty often experienced in the isolation of pure products from Grignard reactions involving highly phenylated unsaturated compounds.

Here again the situation is quite different when the meso-unsaturation is removed by hydrogen. The dihydro derivative (XX) reacts readily with phenylmagnesium bromide in ether solution, but on working up in the usual manner the products consisted of unchanged material (XX) and phenylanthraphenone (XIX). The reaction was carefully checked, perfectly pure dihydro compound (XX) containing no phenylanthraphenone being employed. The results were consistent, (XX) and (XIX) representing the products. To explain this peculiar oxidation of (XX) during the course of the Grignard reaction, we again call attention to Kohler's experience with an analog of (XX), namely, α,β,β-triphenylpropiophenone.[12] The reactions are entirely analogous, especially in view of the fact that Cook[9,10] has called attention to the similarity in enolizing power between (XX) and diphenylacetophenone. This enolizing power of our compound (XX) constitutes the main difference between our substance (XX) and α,β,β-triphenylpropiophenone of Kohler, enabling the substance (XX) to form a magnesium derivative (XXI) directly on treatment with phenylmagnesium bromide.



It is understood in the abbreviated flow sheet that the oxide (XXII) has been formed from the action of a peroxide of (XXI) on (XXI) itself, something as Kohler has indicated for his highly phenylated ketones. We are at present engaged in attempts to isolate compounds of the type represented by (XXII), a feat involving difficulty because of the ease with which dihydroanthracene derivatives lose constituents across the ring, passing over into anthracene derivatives with the true aromatic structure.

Our present inadequate understanding of "steric" influences does not allow an explanation of the influence of unsaturation upon the additive power of a carbonyl group; such as is revealed in these results. Taken together with those recorded by Kohler and Nygaard[11] they show this influence to be a definitely indisputable factor in determining both extent and mode of reaction with the Grignard reagent.

The authors acknowledge gratefully a generous grant to one of them from the Rosenwald Fund, and likewise their indebtedness to their first teacher of Chemistry, Dean W. M. Blanchard, Head of the Department, whose untiring efforts have made possible this research program.

Experimental Part

Action of Methylmagnesium Iodide on Benzalanthrone.—The procedure described herewith is that found satisfactory for isolation of the maximum quantity of the carbinol (II). Fourteen grams of powdered benzalanthrone was added gradually to a Grignard reagent prepared from 3.6 g. of magnesium and 22 g. of methyl iodide in 700 cc. of ether. The ketone dissolved to yield a clear, green-yellow fluorescent solution. The solution was stirred cold for three hours, decomposed with ammonium chloride and oxygen passed into the washed ethereal solution; 0.3 gram of colorless, compact crystals separated and was filtered. They decomposed at 74° with separation

of anthraquinone, and were insoluble in any solvents boiling lower than this temperature. Analysis of the crude material giving results which could not be interpreted, further investigation of this substance was postponed, pending our results with ethylidene anthrone. From the ethereal solution on concentration and addition of petroleum ether, 13 g. of crude carbinol (II) was obtained. Recrystallized from ether–petroleum ether, 12 g. of material melting at 148° was secured.

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.59; H, 6.09. Found: C, 88.75; H, 6.25.

In the Grignard machine it gave 1 mole of gas and consumed one mole of reagent. On oxidation with chromic acid it gave anthraquinone and benzoic acid.

Behavior of Carbinol (II) toward Bromine.—To a well-cooled solution of 3 g. of carbinol (II) in 20 cc. of chloroform, a solution of 1.6 g. of bromine in 10 cc. of chloroform was added dropwise. The bromine was momentarily absorbed without evolution of hydrogen bromide. Allowed to stand in the cold for one hour, the solvent was removed under diminished pressure, ether added to the residue, which on stirring crystallized. Recrystallized from chloroform–ether, the substance (V) weighed 4 g. and melted at 168° with decomposition.

Anal. Calcd. for $C_{22}H_{16}Br_2$: C, 60.00; H, 3.64. Found: C, 59.57; H, 3.75.

Bromination of 1 g. of (V) in exactly the same manner with 0.5 g. of bromine yielded 0.6 g. of hard yellow crystals, m. p. 200° (VIII).

Anal. Calcd. for $C_{15}H_{10}Br_2$: C, 51.43; H, 2.86. Found: C, 51.11; H, 3.00.

A mixture of 2.5 g. of the dibromide (V), 2.5 g. of fused sodium acetate and 25 cc. of glacial acetic acid was refluxed for forty minutes. The warm acetic solution was filtered and 2 cc. of water was added (no turbidity). On cooling and scratching 1.6 g. of light yellow crystalline material separated, m. p. 188°, recrystallized from chloroform–methyl alcohol, which solutions displayed strong blue fluorescence. It gave no test for halogen.

Anal. Calcd. for $C_{26}H_{22}O_4$: C, 78.39; H, 5.60. Found: C, 77.90; H, 5.60.

Attempts to Prepare Ethylidene Anthrone

(a) Adapted from Procedure for Preparation of Methylene Anthrone.[13]—Twenty cc. of a 40% solution of acetaldehyde in water was added portionwise to a warm mixture of 10 g. of anthrone, 50 cc. of methyl alcohol and 5 drops of piperidine. After a small quantity of the acetaldehyde had been added the anthrone dissolved to yield a clear yellow solution. Obtaining no crystalline material on cooling the solution, 10 cc. of water was added, precipitating a yellow oil which solidified on standing. Attempts to recrystallize it gave only anthraquinone in large quantity.

(b) From Ethyl Oxanthrone.—The preparation of ethyl oxanthrone in workable quantities is best achieved as follows. To a stirred suspension of 140 g. of anthraquinone in 800 cc. of dry benzene, a Grignard reagent prepared from 13 g. of magnesium and 65 g. of ethyl bromide in 300 cc. of ether was added from a dropping funnel in the course of two and one-half hours. After addition was complete the mixture was stirred at room temperature for one hour, poured onto ice and hydrochloric acid and filtered through glass wool to remove anthraquinone. The filtrate was separated, and the washed and dried benzene layer was concentrated to about 200 cc. Petroleum ether was added and 65 g. of crude ethyl oxanthrone precipitated. Recrystallized from ether–petroleum ether it gave colorless prisms, m. p. 107°.

Attempt was first made to eliminate water by passing dry hydrogen chloride into a benzene solution of ethyl oxanthrone. On concentrating and adding petroleum ether, the tertiary chloride crystallized out, 1.6 g. out of 2 g. of the oxanthrone, m. p. 85°. On heating to about 120–130° this chloride lost hydrogen chloride and left behind a yellow oil which could not be crystallized and on standing deposited crystals of anthraquinone.

Two grams of ethyl oxanthrone was dissolved in 6 cc. of glacial acetic acid and 6 drops of sulfuric acid added. On standing for fifteen hours at room temperature, approximately 1 g. of anthraquinone was deposited, and on attempting to work up the mother liquors only more anthraquinone could be obtained.

Eight grams of ethyloxanthrone was dissolved in 15 cc. of glacial acetic acid, 1 cc. of concentrated sulfuric acid added, the flask filled with oxygen under pressure and carefully stoppered. After standing overnight, it was warmed gently and volatile material collected in a receiver cooled in a freezing mixture. Various tests already referred to were made on the distillate to demonstrate the presence of acetaldehyde, the most convincing one being its conversion into ethylidene-β-dinaphthyl oxide, m. p. 173°, which compound gave no depression with a sample prepared from an authentic specimen of acetaldehyde.

The formation of acetylene by distillation of ethylidene anthrone in the presence of atmospheric oxygen has been described in foregoing paragraphs. The acetylene was identified by its odor and by conversion into cuprous acetylide.

Action of Phenylmagnesium Bromide on Anthraphenone.—When the ketone was added to 4 moles of reagent in ether solution, allowed to stand overnight and worked up in the usual way, the solid material from 5 g. of ketone consisted of 1.1 g. of reduction product (XV) and 3.5 g. of unchanged anthraphenone. The latter was removed from the mixture by continued extraction with warm ether. The reduction product was recrystallized from benzene, m. p. 265°. With a specimen prepared by the method of Cook[9,10] it gave no depression. When benzene was substituted for the ether and the substance heated with the Grignard reagent in this solvent, the proportions of the products were unaltered. Phenylmagnesium iodide gave the same results. With methylmagnesium iodide, the original ketone was recovered quantitatively, no reaction taking place.

Action of Phenylmagnesium Bromide on Dihydroanthraphenone.—Five grams of the dihydro product (XVI) —prepared according to the method of Cook[10]—dissolved in ether was added to the Grignard reagent prepared from 1.4 g. of magnesium and 9.5 g. of bromobenzene in 200 cc. of ether. A noticeable warming of the reaction mixture accompanied the addition. Worked up in the usual way,

---

(13) Barnett and Matthews, *Ber.*, **59**, 767 (1926).

the ethereal solution on concentration and addition of petroleum ether gave 4 g. of pure material (XVII), m. p. 173°, recrystallized from ether–petroleum ether or from methyl alcohol.

Anal. Calcd. for $C_{27}H_{22}O$: C, 89.50; H, 6.08. Found: C, 89.30; H, 6.19.

The product (XVII) examined in the Grignard machine gave one mole of gas and consumed one mole of reagent.

Elimination of Water from (XVII) to Give (XVIII).—Eight drops of concentrated sulfuric acid was added to a solution of 2 g. of carbinol (XVII) in 35 cc. of glacial acetic acid. On allowing to stand for three days 1.5 g. of material (XVIII) was deposited. Recrystallized from chloroform–methyl alcohol it gave colorless, glistening flakes, m. p. 258°.

Anal. Calcd. for $C_{27}H_{20}$: C, 94.13; H, 5.87. Found: C, 94.10; H, 5.79.

Half a gram of the hydrocarbon on oxidation with 0.5 g. of chromic acid in glacial acetic acid solution yielded 0.3 g. of anthraquinone and 0.2 g. of benzophenone.

Action of Phenylmagnesium Bromide on Dihydrophenylanthraphenone (XX).—Three and one-half grams of (XX) dissolved in ether was added to a Grignard solution from 0.72 g. of magnesium and 5.7 g. of bromobenzene. On first addition the solution was deep violet in color, gradually changing to red and on continued stirring to pale yellow. Worked up in the usual manner 2.0 g. of crystalline product was obtained, which was separated by fractional crystallization from ether into 1.2 g. of starting material and 0.7 g. of phenylanthraphenone.

Summary

1. Benzalanthrone gives mainly 1,2-addition with methylmagnesium iodide.
2. Ethylidene anthrone exists in an enolic modification involving a 1,7-shift of hydrogen, the anthranol suffering oxidation to a peroxide, which cleaves spontaneously to anthraquinone and vinyl alcohol.
3. Anthraphenone undergoes 1,6-dimolecular reduction on treatment with phenylmagnesium bromide or iodide, and no reaction with methylmagnesium iodide. Dihydroanthraphenone gives normal 1,2-addition.
4. No clean products could be isolated from the reaction between phenylanthraphenone and phenylmagnesium bromide. Dihydrophenylanthraphenone yielded with phenylmagnesium bromide phenylanthraphenone and unchanged material.
5. Striking analogies have been brought forward between meso-unsaturated anthracene ketones and α,β-unsaturated ketones. The analogies are likewise maintained when the unsaturation is removed in both types of ketones.

The Preparation and Tinctorial Properties of Certain Benzoxazole Dyes[1]

BY VLADIMIR J. MIKESKA AND MARSTON TAYLOR BOGERT

In a previous article,[2] we have pointed out certain of the similarities and dissimilarities which appear on comparing the chemical properties of the structurally related series of oxazoles, thiazoles and imidazoles.

Having been interested for several years in the connection between chemical constitution and tinctorial properties in the thiazole series,[3] we have conducted some experiments also in the oxazole field and the present communication records the results. Our prior paper[2] described the syntheses of the necessary intermediates.

From the standpoint of the dye chemist, the thiazole derivatives of most interest are the intermediates dehydrothio-*p*-toluidine (II) and primuline (III), from which are manufactured dyes of the Thioflavine (IV) (Colour Index No. 815) or Chloramine Yellow (V) (Colour Index No. 814) types; or azo derivatives like the so-called "Ingrain colors" (Colour Index No. 812), prepared by diazotizing (II) or (III), or their sulfonates, and combining with suitable couplers.

Our own experiments in the benzoxazole series have been mainly with the azo derivatives and dyes of the Chloramine Yellow class.

In so far as azo dyes of the oxazole, thiazole and imidazole series are concerned, all three yield substantive cotton dyes, which show generally about the same fastness to light, acids or alkalies.[4]

The azo derivatives of benzoxazole described beyond carry the azo grouping either in the *p*-position on the 2-phenyl nucleus, or in position 5 on the benzoxazole portion. One object in preparing these two series was to learn what effect this difference in the location of the azo group would have upon the tinctorial properties of the resulting dyes.

In this part of our research, the investigations of Lellmann and his associates were of especial interest, for Lellmann and Haller[5] prepared an imidazole analog of dehydrothio-*p*-toluidine (II) which, when diazotized and coupled, gave azo dyes as fast to cotton as the corresponding thiazole dyes. This was followed in 1895 by the work of Lellmann and Ebel,[6] who synthesized an oxazole analog (I) from *m*-nitro-*p*-cresol, then diazotized and coupled it. The azo compounds resulting closely resembled the analogous thiazole and imidazole derivatives in the color and fastness of their dyeings.

Our azo dyes, therefore, differed from those of Lellmann and Ebel[6] in carrying a phenyl in place of a methyl group on the benzene portion of the benzoxazole molecule, and from dehydrothio-*p*-toluidine in having this substituent in position 5 instead of 6. It was believed that the phenyl would have certain advantages over the methyl group in increasing the stability of the derivatives and in giving deeper shades on dyeing. The researches of Bogert and Allen,[3,7] in the benzothiazole series, have shown that such a change in the location of the hydrocarbon radical has but little influence upon the color or fastness of the dyeings obtained, and the results reported by Lellmann and his co-workers, in the benzoxazole series, lend support to this view. The replacement of sulfur by oxygen is ordinarily hypsochromic, so far as tinctorial effects are concerned, whereas the substitution of a methyl by a phenyl group, as just mentioned, generally exerts a bathochromic influence. In the case of the dyes synthesized by us, it was interesting to find that the former factor was the more potent one, for all of them gave paler shades than the corresponding dehydrothio-*p*-toluidine derivatives; and a repetition of the work of Lellmann and Ebel[6] showed that neither the depth of shade, nor the fastness of the dyeing, was greatly affected by whether the hydrocarbon radical in position 5 was a methyl or a phenyl.

Of the two amines (or their sulfo acids) used as initial materials for the production of our dyes, *viz.*, 2-*p*-aminophenyl-5-phenylbenzoxazole (A) and 2,7-diphenyl-5-aminobenzoxazole (B), both yielded azo dyes which were substantive for cotton and could be applied either direct or developed in the fabric. Of the two sets of dyes, those prepared from (B) were much the weaker. In other words, the azo grouping in the *p*-position on the 2-phenyl nucleus gives much better dyes than when this same grouping is in position 5 on the benzoxazole nucleus. On silk or wool, however, the (B) dyes also gave good deep shades by either method.

This influence of the position of the azo grouping upon the affinity of these dyes for cotton, coincides with the experience of Kym,[8] who investigated a few azo dyes of these types and found that the dyeings on cotton were much weaker when the azo grouping was moved from the *p*-2-phenyl position to the benzoxazole nucleus.

The same was true in the case of the Chloramine Yellow types obtained from (A) and from (B), those from the former being far superior as direct cotton dyes. Both could be developed in the fabric to deep shades. There was but little difference in depth of color, whether the dyeings were made on cotton, wool or silk, in the case of the (A) dyes; but the dyeings obtained with the (B) dyes on cotton were much paler than those on wool or silk.

In so far as the method of dyeing was concerned, examination of the dyed samples after the lapse of five years, showed in every case that the direct dyed fabric held its color much better than those samples dyed by the "ingrain" process.

Experimental

To economize space in what follows, the two dye intermediates used, *i. e.*, 2-*p*-aminophenyl-5-

phenylbenzoxazole and 2,7-diphenyl-5-aminobenzoxazole, will be referred to respectively as (A) and (B), and their sulfo acids similarly as (A^1) and (B^1).

I. Azo Dyes from (A) or (A^1)

These dyes are akin to the so-called "Ingrain Colors" of Green,[9] and were prepared in the customary way, by diazotizing the intermediate and combining the diazo product with suitable couplers, the basic dyes being coupled in acid and the acid ones in alkaline solution. All of these products gave good deep shades on cotton, either as direct or as developed dyes.

The direct dyeing was carried out with 1 g. of unbleached cotton, 20 cc. of 0.1% dye solution, 4 drops of 10% sodium carbonate solution, 15 cc. of 1% sodium chloride solution and 25 cc. of water, the bath being heated for thirty minutes. Silk was dyed in a weakly acid bath.

For the developed dyeings, with the sulfo acids for example, the cotton was boiled for thirty minutes in a 5% solution of (A^1) or (B^1), after neutralization with sodium carbonate, and to the boiling solution there was added 5% (by weight) of sodium chloride. After this impregnation, the cloth was washed thoroughly in cold water, to avoid surface colors and subsequent bleeding, and was passed through a bath containing 1 g. of sodium nitrite in 400 cc. of water and faintly acid with sulfuric acid. Diazotization was completed in about twenty minutes and, after washing in cold water, the cotton was immersed in a bath of the coupler selected. If a red color (Oxazole Red) was desired, a 1% solution of beta-naphthol was used dissolved in the calculated amount of caustic alkali and containing an excess of sodium carbonate. The color developed rapidly and after five minutes the cloth was removed and freed from surface dye by thorough washing with cold water and soap. Amines were coupled in acid solution.

The results with the developed dyes can be tabulated as follows.

TABLE I

DEVELOPED AZO DYEINGS FROM (A) OR (A^1)

	Base	Coupler	Shade on cotton	Type
(1)	(A)	α-Naphthol	Bluish-red	Mono-azo
(2)	(A^1)	Phenol	Yellow	Mono-azo
(3)	(A^1)	β-Naphthol	Orange-red	Mono-azo
(4)	(A^1)	Resorcinol	Orange	Mono-azo
(5)	(A^1)	α-Naphthylamine	Purple	Mono-azo
(6)	(5)	α-Naphthylamine	Black	Bis-azo

Through the courtesy of Professor Hal T. Beans and Dr. A. Dingwall, of the Columbia University Department of Chemistry, the two beta-naphthol azo dyes were examined spectrographically and their absorption curves plotted, as shown on Fig. 1. Of these two dyes, the one designated "Ingrain Red" was prepared by diazotizing dehydrothio-*p*-toluidine and coupling with beta-naphthol. The analogous "Oxazole Red" was prepared similarly from (A^1). An examination of the graph will show the similarity of the two curves. Both show maximum absorption at about 4980 Å. Practically all of the blue and none of the red is absorbed in each case. Both transmit a portion of the yellow, so that the dyes have an orange shade, but the oxazole transmits more and is therefore a lighter orange-red than the thiazole dye. Further, the thiazole dye has a wider absorption range and this accounts for its greater intensity. These results are in harmony with previous observations made on the tinctorial properties and the colors of solutions of such dyes. It is quite clear, therefore, that the bathochromic effect of the benzothiazole is slightly but definitely greater than that of the benzoxazole nucleus in dyes of analogous structure.

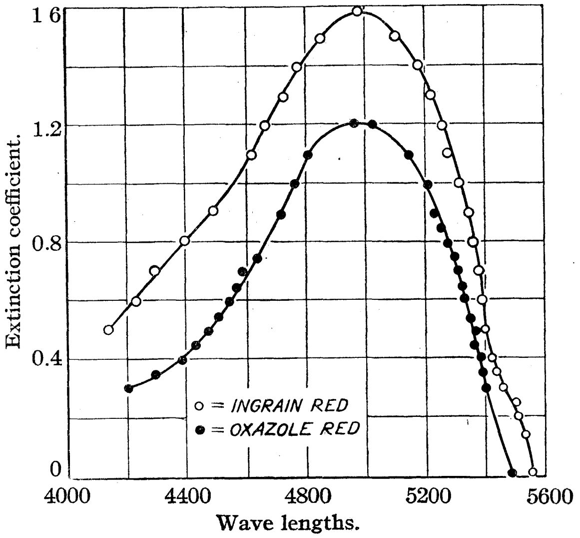

Fig. 1.—Absorption spectra curves.

The solvent for both dyes was 95% ethanol. The concentration of the oxazole was 1:37,500; of the thiazole, 1:50,000.

The fastness of these developed dyes on cotton was tested with the results exhibited in Table II. The dyes are represented by the Arabic numerals used in Table I.

For purposes of comparison, a similar set of developed azo dyes was prepared from 2-*p*-aminophenyl-5-methylbenzoxazole (I), as described by Lellmann and Ebel,[6] and subjected to similar tests for fastness. The results are given in Table III, the Arabic numerals used for the column headings representing the same type of dye as in Table II.

In general, these azo dyes were much the same as the original "Ingrain Colors" of Green,[9] in the thiazole series, prepared from Primuline. Although Green's results showed that there was but little difference between the corresponding dyes prepared from Primuline and from dehydrothio-*p*-toluidine sulfo acid, nevertheless we prepared the same series of dyes as listed above from the latter and our results were in entire accord with his.

Identical dyeings were carried out with the corresponding azo dyes from dehydrothio-*p*-toluidine sulfo acid and from the oxazole analog (A^1). In general, the shade of the thiazole was deeper than that of the corresponding oxazole dye; the red dyes were fastest in both series; in both, the purples were turned brown by alkali, but the original color was restored by acid; the orange dyeings were less fast, and the yellow ones lost most of their color when boiled with 10% sodium hydroxide.

Bleaching	Bleached	Bleached	Fair	Fair	Browns	Fast
Light	Fugitive	Fugitive	Fair	Fugitive	Fair	Fair

II. Azo Dyes from (B) or (B^1)

These were prepared and used in essentially the same manner as already recorded for the azo dyes from (A) or (A^1), *i. e.*, either as direct or as developed dyes ("ingrain colors"), and gave good deep shades on wool or silk by either process. As substantive cotton dyes, however, they were far inferior to those obtained from (A) or (A^1), the shades produced being weak and poor.

The results secured with these as developed dyes, are given in Table IV.

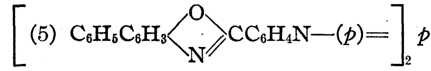
TABLE IV

DEVELOPED AZO DYEINGS FROM (B) OR (B^1)

	Base	Coupler	Shade on cotton	Type
(7)	(B)	α-Naphthol	Saffron	Mono-azo
(8)	(B^1)	Phenol	Yellow	Mono-azo
(9)	(B^1)	β-Naphthol	Orange-red	Mono-azo
(10)	(B^1)	Resorcinol	Orange	Mono-azo
(11)	(B^1)	α-Naphthylamine	Purple	Mono-azo
(12)	(11)	α-Naphthylamine	Black	Bis-azo

Subjected to the same fastness tests as shown in Tables II and III, the results given in Table V were obtained, in which table the Arabic numerals stand for the same dyes as in Table IV.

III. Chloramine Yellow Dyes



$$\left[(5)\ C_6H_5C_6H_3\genfrac{<}{>}{0pt}{}{O}{N}CC_6H_4N\text{—}(p)=\right]_2$$

***p,p'*-(5-Phenyl-benzoxazole-2)-azobenzene.**—A solution of 2 g. of 2-*p*-aminophenyl-5-benzoxazole in 500 cc. of alcohol was treated, at 0–10°, for twenty-four hours with a freshly prepared solution of sodium hypochlorite, the precipitated azo compound collected, washed thoroughly with water, dried and extracted with small portions of hot glacial acetic acid and of toluene, to remove impurities. The insoluble material crystallized from nitrobenzene gave an amorphous brownish-red powder, which did not melt but decomposed above 300°; yield, 1.2 g., or 65.5%.

Anal. Calcd. for $C_{38}H_{24}O_2N_4$: C, 80.21; H, 4.23. Found: C, 79.26; H, 4.22. This low figure for carbon was due to difficulties in eliminating final traces of impurities and in completely burning the compound, because of its azo character and high molecular weight.

The compound was difficultly soluble or insoluble in most of the usual neutral organic solvents. In concentrated sulfuric acid it dissolved to a deep blood-red solution, which color reaction appeared to be a very sensitive one.

A Chloramine Yellow from *p,p'*-(5-Phenyl-benzoxazole-2)-azobenzene.—To a solution of 2 g. of the above azo compound in 4 cc. of concentrated sulfuric acid at 20°, there was added 10 cc. of fuming (50% free sulfur trioxide) sulfuric acid. After standing for twenty-four hours, the mixture was poured upon ice, the orange-red precipitate collected, washed with a cold 15% salt solution, dissolved in dilute sodium hydroxide and the sodium salt precipitated by the addition of alcohol. The dry product was nearly black, but was a deep orange when pulverized. In water, it dissolved freely to an orange-red solution. Its analysis showed it to be a disulfonate.

Anal. Calcd. for $C_{38}H_{22}O_8N_4S_2Na_2$: N, 6.62; S, 8.16. Found: N, 7.25; S, 8.94.

The impossibility of obtaining accurate analytical figures for such dyes is recognized by all dye chemists. The purpose of the analysis was to determine whether our product was a di- or a tetra-sulfo acid, and this it does.

A minute amount was sufficient to impart to concentrated sulfuric acid a deep blood-red color. It dyed cotton, wool or silk, a direct yellow, corresponding closely to com-

TABLE V

FASTNESS OF DEVELOPED AZO DYEINGS FROM (B) OR (B^1)

Reagent	(7)	(8)	(9)	(10)	(11)	(12)

mercial Chloramine Yellow in fastness, although somewhat lighter in shade.

The direct dyeing on cotton was carried out as already described for the direct azo dyes.

A Chloramine Yellow from 2-*p*-Aminophenyl-5-phenylbenzoxazole Disulfonic Acid.—A solution of 5 g. of the disulfonic acid in 500 cc. of an aqueous solution of excess of sodium carbonate was boiled for thirty minutes, cooled and filtered. The filtrate was subjected to the action of a freshly prepared sodium hypochlorite solution, at 0–10°, for twelve hours, maintaining a slight excess of hypochlorite (as indicated by potassium iodide paper), or until the solution became yellowish-orange, after passing through an intermediate red stage. The dye was then salted out, washed with a 15% salt solution, dissolved in dilute sodium hydroxide and the sodium salt precipitated by the addition of alcohol. The final product resembled closely the dye described in the immediately preceding paragraph, except that the shade produced on cotton was a very pale greenish-yellow. Chemically it differed from the latter in being a tetra- instead of a di-sulfonic acid.

A Chloramine Yellow from 2-*p*-aminophenyl-5-methylbenzoxazole was also prepared by the customary procedure of sulfonation and hypochlorite oxidation and was found to resemble closely the above dye, in its direct dyeings on cotton, both as to shade and fastness.

A Chloramine Yellow from 2,7-diphenyl-5-aminobenzoxazole sulfonic acid, prepared similarly, dyed both wool and silk good deep shades. Its direct dyeings on cotton, however, were much paler and weaker than those obtained with the Chloramine Yellows from the 2-*p*-aminophenyl-5-phenyl- or 5-methylbenzoxazole sulfo acids.

Summary

1. From 2-*p*-aminophenyl-5-phenylbenzoxazole, 2,7-diphenyl-5-aminobenzoxazole, and their sulfo acids, azo dyes have been prepared, of mono- or bis-azo type, as well as some of Chloramine Yellow structure.

2. The tinctorial properties of these new dyes have been studied and it has been shown that those in which the azo grouping is in the *p*-position on the 2-phenyl nucleus are far better substantive cotton dyes than those having this grouping in position 5 on the benzoxazole portion of the molecule.

3. Azo dyes of Ingrain Red type, in the thiazole and oxazole series, were examined spectroanalytically. The curves plotted from these observations paralleled each other closely.

4. In general, these benzoxazole dyes resemble the analogously constituted benzothiazoles but, as expected, give lighter shades.

The Structure of the Metallic Derivatives Which Are Formed by Adding Grignard Reagents to Unsaturated Ketones

BY E. P. KOHLER, M. TISHLER AND H. POTTER

It is known that when a Grignard reagent is added to an α,β-unsaturated ketone which has a hydrocarbon residue in the α position, the product is an enolate in which a magnesium halide group is joined to oxygen. In all other addition products obtained in this manner the location of the halide residue is uncertain. Magnesium compounds of the type of these addition products can now be obtained in other ways. Thus the magnesium bromide derivative of β,β-diphenylpropionylmesitylene may be prepared by any of the three reactions which are represented by the equations

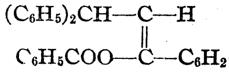
(1) $C_6H_5CH{=}CHCOC_6H_2(CH_3)_3 + C_6H_5MgBr \longrightarrow [(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3]MgBr$

(2) $(C_6H_5)_2CHCH_2COC_6H_2(CH_3)_3 + C_2H_5MgBr \longrightarrow [(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3]MgBr + C_2H_6$

3) $(C_6H_5)_2CHCHBrCOC_6H_2(CH_3)_3 + C_2H_5MgBr \longrightarrow [(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3]MgBr + C_2H_5Br$

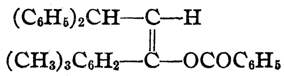
In appearance, in solubility and in many of their chemical properties the magnesium derivatives which are obtained in these various ways seem to be identical but their reactions with benzoyl chloride show that they are not. When the derivative that is formed in the first reaction is treated with benzoyl chloride at least 96% of the product is a benzoyl derivative which melts at 161°, while similar treatment of the magnesium derivative obtained by either of the other two methods leads to an equally high yield of an isomeric benzoyl derivative melting at 148°. These results are not affected by the solvents used or the temperature at which the successive operations are conducted. And in the case of the second and third reactions the nature of the Grignard reagent is likewise of no moment. These reactions—the one addition and the other substitution—therefore give rise to two isomeric magnesium compounds.

The two benzoyl derivatives that are formed from these magnesium derivatives must both be benzoates because both are much more easily hydrolyzed than the isomeric diketone which can be synthesized by a different method. These benzoates are evidently the geometrical isomers represented by formulas I and II and the magnesium halides from which they are formed must be the corresponding enolates. In the case of benzal acetomesitylene, therefore, addition of a Grignard reagent to the conjugated system C═C—C═O gives rise to an –OMgX compound even though there is no hydrocarbon residue in the α position.



$$\begin{array}{c}(C_6H_5)_2CH—C—H \\ \| \\ C_6H_5COO—C—C_6H_2(CH_3)_3\end{array}$$

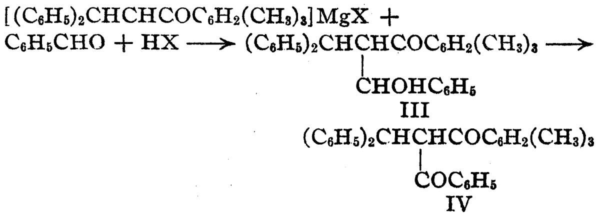
I



$$\begin{array}{c}(C_6H_5)_2CH—C—H \\ \| \\ (CH_3)_3C_6H_2—C—OCOC_6H_5\end{array}$$

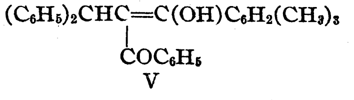
II

The isolation of these stereomeric magnesium derivatives supports the views of Michael and Ross[1] who obtained stereomeric O-carbmethoxy keto esters by treating the sodium compounds of benzoyl acetone with chlorocarbonic ester and concluded that solutions of the sodium derivatives contain the corresponding stereomeric enolates. The magnesium enolates, even though they give almost exclusively O-benzoyl derivatives, can nevertheless be added to benzaldehyde in the same manner as simple Grignard reagents. Ability to combine with aldehydes, therefore, is no criterion for the structure of a magnesium halide derivative. This reaction with aldehydes provides an excellent method for securing the β-diketone corresponding to the benzoates



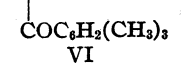
$$[(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3]MgX + C_6H_5CHO + HX \longrightarrow \underset{\underset{\text{III}}{CHOHC_6H_5}}{(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3} \longrightarrow \underset{\underset{\text{IV}}{COC_6H_5}}{(C_6H_5)_2CHCHCOC_6H_2(CH_3)_3}$$

This diketone, like most other alkylated di-aryl β-diketones does not enolize to a detectable extent in solution but as it is not easily cleaved it can be converted without difficulty into one of two possible enolic modifications



$$\underset{COC_6H_5}{(C_6H_5)_2CHC}{=}C(OH)C_6H_2(CH_3)_3$$

V

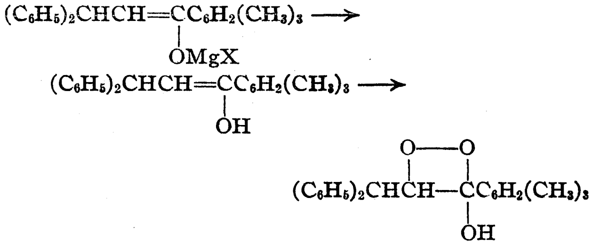


$$\underset{COC_6H_2(CH_3)_3}{(C_6H_5)_2CHC}{=}C(OH)C_6H_5$$

VI

The enol has remarkable vitality; in solid form it appears to be completely permanent and it can be crystallized from all common solvents without recognizable change. Even in glacial acetic acid it retains for weeks its power of giving a color reaction with ferric chloride. It however reverts rapidly to the diketone in solutions containing traces of alkalies or piperidine. The unusual lack of mobility in this enol, doubtless, is due largely to the mesityl group, because one of the phenyls of the benzhydryl groups can be replaced with methyl without materially affecting the mobility but when the mesityl group is replaced with phenyl the mobility becomes normal, the enol of benzhydryl dibenzoylmethane ketonizing as rapidly as the corresponding methyl and ethyl compounds.

If the relative stability of the enolic form of the diketone is really due to the influence of the mesityl group, then this group should exercise a similar influence upon the enol of the mono ketone. It does. Its effect is sufficiently great to permit the formation of the type of peroxides which, heretofore, could be obtained only from the enols of mono ketones that have hydrocarbon residues in the α-position.



$$(C_6H_5)_2CHCH{=}\underset{OMgX}{C}C_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2CHCH{=}\underset{OH}{C}C_6H_2(CH_3)_3 \longrightarrow (C_6H_5)_2CH\overset{O—O}{CH—\underset{OH}{C}}C_6H_2(CH_3)_3$$

VII

As will be evident from the foregoing account, a considerable variety of mono ketones can be acylated by means of their magnesium halide derivatives. For various reasons it is possible to follow these acylations much more accurately than those with sodium or potassium compounds. A series of selected ketones, turned into magnesium bromide derivatives and benzoylated under similar conditions, gave the following percentages of diketones, the remainder of the product being composed mainly of benzoates representing O-acylation.

$(C_6H_5)_2CHCH_2COC_6H_5$	100
$(C_6H_5)_2CHCH(C_6H_5)COC_6H_5$	0
$CH_3COC_6H_2(CH_3)_3$	100
$C_6H_5CH_2CH_2COC_6H_2(CH_3)_3$	12
$C_6H_5CH(CH_3)CH_2COC_6H_2(CH_3)_3$	8
$(C_6H_5)_2CHCH_2COC_6H_2(CH_3)_3$	1.5

---

[1] Michael and Ross, THIS JOURNAL, 53, 2394 (1931).

To judge from this limited number of cases there is a certain degree of correlation between the complexity of the hydrocarbon residues surrounding the carbonyl group, the stability of the enol and the mode of acylation. The results therefore lend some support to the view that C-acylation is preceded by ketonization of the metallic derivative or its ion.

Experimental Part

The general methods employed for preparing the isomeric magnesium derivatives have been described in earlier papers.[2] In order to ensure comparable conditions, all reactions were conducted in an atmosphere of nitrogen and the resulting solutions or suspensions were boiled until most of the magnesium compound had separated in solid form. After the addition of the acid chloride the mixture was boiled again until the benzoylation was manifestly complete. The magnesium derivatives were then treated with iced acid in the usual manner.

In the quantitative experiments the entire product was dissolved in cold dilute methyl alcoholic sodium hydroxide, separate experiments with the pure substances having shown that in these conditions the diketones are not affected while the benzoates are hydrolyzed with great rapidity. The separation of the resulting mixtures presented no great difficulty. After acidification all the organic components were collected in ether, and from this ethereal solution the benzoic acid was removed with bicarbonate and the diketone or its enol by successive extractions with methyl alcoholic sodium hydroxide or sodium methylate—leaving only the mono ketone and other indifferent materials to be separated by physical methods.

The Isomeric Benzoates of Benzhydryl Benzoyl Acetomesitylene.—The higher melting benzoate crystallizes from acetone in large transparent prisms melting at 162°, the lower melting isomer, which is much more soluble, in needles melting at 142°.

Anal. Calcd. for $C_{31}H_{28}O_2$: C, 86.3; H, 6.5. Found (162°): C, 86.2; H, 6.5. (142°): C, 86.0; H, 6.7.

Alcoholic solutions of sodium hydroxide rapidly hydrolyzed both benzoates to diphenylpropionyl mesitylene and sodium benzoate. Toward acid they are much more stable but they can be hydrolyzed by prolonged heating in sealed tubes with methyl alcoholic hydrochloric acid, the lower melting being destroyed much more rapidly than its isomer. They are not interconvertible by protracted heating above the melting point or by exposure to sunlight. It has not been possible thus far to devise any method for determining the configuration of these benzoates.

The Magnesium Halide Derivatives.—The stereometric magnesium compounds are of special interest because they show that both addition to the conjugated system and the enolization of the mono ketone are controlled by mechanisms that lead to products which have definite configurations. Benzoylation of the derivative which is obtained by addition (equation 1) usually gave along with the lower melting benzoate and from one to two per cent. of diketone, a very small quantity of the higher melting benzoate. Neither the amount of diketone nor that of the isomeric benzoate were increased by prolonged boiling in ether–benzene before benzoylation. By treatment with bromine both magnesium derivatives were converted into α-bromo-β,β-diphenylpropionyl mesitylene.

Acetylation with Trimethylbenzoyl Chloride, $(C_6H_5)_2CH—CH{=}C(C_6H_5)OCOC_6H_2(CH_3)_3$.—When the magnesium compound of diphenylpropiophenone obtained by the third reaction was acylated in the usual manner with trimethylbenzoyl chloride it gave a mixture which was separated by crystallization from methyl alcohol and petroleum ether. One of the products was the same β-diketone (IV) which had been obtained by benzoylating the mesitylenic ketone. The second product was an isomer which was readily hydrolyzed by bases to diphenylpropiophenone and mesitylene carbonic acid—therefore a trimethyl benzoate due to O-acylation. It crystallizes in flattened needles and melts at 93°. As nearly as can be estimated from the results of a separation that was not very accurate 40% of the product was diketone and at least 95% of the remainder was the trimethylbenzoate.

α-Benzhydryl-β-phenyl-β-hydroxy Propionyl Mesitylene, III.—To a magnesium compound obtained by boiling 20 g. of α-bromo-β,β-diphenyl propionyl mesitylene with a solution of ethylmagnesium bromide containing 1.5 g. of magnesium was added 5.5 g. of benzaldehyde. The mixture was boiled for two hours, then decomposed in the usual manner. After the removal of excess of benzaldehyde there remained a yellow solution which yielded 18 g. of condensation product—the balance being a yellow oil and a small quantity of diphenyl propionyl mesitylene. The hydroxyl compound crystallizes well from ether–petroleum ether in colorless plates and it melts at 132°.

Anal. Calcd. for $C_{32}H_{30}O_2$: C, 85.7; H, 6.9. Found: C, 85.7; H, 7.1.

Benzhydryl Benzoylacetomesitylene, IV.—The oxidation of the hydroxyl compound to the diketone presents considerable difficulty. The best results were obtained by the following procedure. To a solution of 5 g. of the hydroxyl compound in 40 cc. of glacial acetic acid was added 1 cc. of a solution of 2.5 g. of chromic acid in 2.5 g. of water and 7.5 g. of glacial acetic acid. The mixture was warmed until oxidation was rapid, then the remainder of the oxidizer was added and the mixture was kept at the oxidizing temperature for five minutes before it was poured on ice. The result was a mixture of diketone and some complex yellow polymer from which the diketone was most easily isolated by repeated extraction with cold petroleum ether.

[2] Kohler and Tishler, THIS JOURNAL, **54**, 1594 (1931); Kohler and Baltzly, *ibid.*, **54**, 4015 (1931).

Anal. Calcd. for $C_{31}H_{28}O_2$: C, 86.3; H, 6.5. Found: C, 86.3; H, 6.5.

The diketone crystallizes well from petroleum ether in small colorless prisms or tables and it melts at 107°. It was subsequently obtained in small quantities in the benzoylation of the magnesium derivatives of diphenyl propionyl mesitylene and in much larger quantities by treating the magnesium derivative of diphenyl propiophenone with trimethylbenzoyl chloride. The diketone is unusually insensitive to alkalies; practically all of it was recovered after it had been boiled for six hours with 40% methyl alcoholic potassium hydroxide but by boiling it for ten hours with 50% aqueous sodium hydroxide most of it was hydrolyzed to diphenyl propiophenone and sodium trimethyl benzoate.

Enolization, V or VI.—The diketone dissolves freely in methyl alcoholic sodium hydroxide but unlike the corresponding dibenzoylmethane derivative it is not reprecipitated by diluting the solution with water. When the cold aqueous alcoholic solution is acidified with a mineral acid it precipitates an isomeric compound which crystallizes in minute colorless prisms and which melts at 137°.

Anal. Calcd. for $C_{31}H_{28}O_2$: C, 86.3; H, 6.5. Found: C, 86.3; H, 6.6.

This isomer is evidently one of the enolic forms of the diketone; it reacts instantaneously with bromine, gives with ferric chloride the blue-purple color reaction which is characteristic of mono-alkylated β-diketones, and forms a green copper compound when its ethereal solution is shaken with aqueous copper acetate. In small quantities the enol is most easily recrystallized from ether–petroleum ether, in larger quantities from methyl alcohol. It can also be recrystallized from glacial acetic acid–water but in the presence of piperidine or other organic bases it reverts quantitatively to the diketone. As it could neither be reduced catalytically nor ozonized in such a manner as to secure significant products it could not be definitely related to either of the possible formulas.

α-Benzoyl-β-phenylbutyro Mesitylene, $CH_3CH(C_6H_5)CH(COC_6H_5)COC_6H_2(CH_3)_3$.—An ethereal solution of benzalacetomesitylene was added to excess of methylmagnesium iodide and the resulting magnesium compound was benzoylated in the usual manner. The product was an oil which could not be induced to crystallize. It was therefore treated with cold methyl alcoholic methyl hydroxide and thus converted into benzoic acid and one of the enolic modifications of the diketone. The yield of enol was only 8%, all the rest of the product being benzoate.

Anal. Calcd. for $C_{26}H_{26}O_2$: C, 84.4; H, 7.0. Found: C, 84.5; H, 6.9.

The enol is readily soluble in all common organic solvents including petroleum ether from which it crystallizes in small prisms melting at 128°. Its chemical properties are the same as those of the corresponding benzhydryl compound.

The Diketone.—When the foregoing enol is recrystallized from methyl alcohol containing piperidine it is converted into the diketone which crystallizes in thin needles and melts at 130°. Solutions of the diketone do not contain enough enol, if any, to give a color reaction with ferric chloride.

Anal. Calcd. for $C_{26}H_{26}O_2$: C, 84.4; H, 7.0. Found: C, 84.5; H, 7.2.

Benzyl Acetomesitylene, $C_6H_5CH_2CH_2COC_6H_2(CH_3)_3$.—The saturated ketone was prepared by shaking benzal acetomesitylene with hydrogen and Adams catalyst until the calculated quantity of hydrogen was absorbed. It was obtained as a very pale yellow, viscous oil which boiled at 191–2° under a pressure of about 5 mm.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 85.6; H, 7.9. Found: C, 85.5; H, 7.8.

Benzyl Benzoylaceto Mesitylene $C_6H_5CH_2CH(COC_6H_5)COC_6H_2(CH_3)_3$.—Benzyl aceto mesitylene was converted into the magnesium bromide derivative with ethylmagnesium bromide and the solid magnesium compound was boiled with excess of benzoyl chloride. The product—a colorless viscous oil—was hydrolyzed in the usual manner with methyl alcoholic sodium hydroxide. It was thus converted into sodium benzoate and a solid which crystallized from petroleum ether in flat colorless needles and which melted at 118°.

Anal. Calcd. for $C_{25}H_{24}O_2$: C, 8.43; H, 6.8. Found: C, 84.2; H, 7.2.

The product has the composition of an enol and it both gave the characteristic color reaction of these enols with ferric chloride and formed a copper derivative but it could not be converted into an isomeric diketone by the usual treatment with piperidine. A titration with bromine by the method of Kurt Meyer showed that fresh solutions in methyl alcohol contain relatively small quantities of enol (4–6%), that the proportion of enol increases gradually with time and that 4% solutions in methyl alcohol which have been equilibrated with piperidine contain nearly equal quantities of enol (49.3%) and diketone.

As the mobility of this keto–enol system was quite unexpected we prepared the benzyl compound by benzylating the sodium derivative of benzoyl acetomesitylene with benzyl chloride. The product was identical in every respect with the substance obtained by acylation. Finally we decided to prepare the benzyl derivative by a third method which was devised to give as pure a product as it is possible to make. To this end we first prepared benzal benzoylaceto mesitylene by condensing benzaldehyde with benzoylacetomesitylene by the general method of Knoevenagel.[3]

Benzal Benzoylaceto Mesitylene, $C_6H_5CH{=}C(COC_6H_5)COC_6H_2(CH_3)_3$.—The unsaturated diketone crystallized well from methyl alcohol in large yellow crystals. The yield was poor.

Anal. Calcd. for $C_{25}H_{22}O_2$: C, 84.6; H, 6.2. Found: C, 84.6; H, 6.3.

The unsaturated ketone was easily reduced, catalytically, and the benzyl compound which was prepared in this manner was likewise identical with the substance that was obtained by acylation.

Benzoylation of Mesityl Phenyl Propiophenone, $(CH_3)_3C_6H_2CH(C_6H_5)CH = C(C_6H_5)OCOC_6H_5$. — Trimethylbenzal acetophenone was added to phenylmagnesium bromide and the resulting magnesium compound was benzoylated in the usual manner. The product was separated into a solid and an oil which has not been identified. The

(3) Knoevenagel, *Ber.*, **36**, 2131 (1903).

solid crystallized from methyl alcohol in small prisms and melted at 110°.

Anal. Calcd. for $C_{31}H_{28}O_2$: C, 86.3; H, 6.5. Found: C, 86.3; H, 6.6.

This solid is evidently a benzoate because cold methyl alcoholic sodium hydroxide hydrolyzes it rapidly to mesityl phenyl propiophenone. The yield was about 50%.

α-Mesityl-γ,γ-diphenyl Propenol Peroxide, VII.—To a solution of phenylmagnesium bromide containing 1.9 g. of magnesium was added 10 g. of benzalaceto mesitylene. The mixture was boiled for fifteen minutes, then decomposed with iced hydrochloric acid. The ethereal layer was diluted with about five times its volume of petroleum ether and washed thrice with ice water. A rapid stream of oxygen was then passed through the moist solution. It gradually caused the precipitation of a solid which separated in microscopic needles. The solid was purified by solution in ether and reprecipitation with petroleum ether. The yield was 9 g.

Anal. Calcd. for $C_{24}H_{24}O_3$: C, 80.1; H, 6.7. Found: C, 80.6; H, 6.5.

In a capillary tube the peroxide melts quietly with decomposition at 116–117°. Heated in larger quantity on a spatula it decomposes with a flash, one of the decomposition products being mesitylene carbonic acid. Like other peroxides of this type it liberates iodine from alcoholic solutions of iodides.

Summary

A study of the magnesium halide derivatives of a series of related mesitylenic ketones showed that the mesityl group in some manner decreases the speed of the processes represented by  $\mathrm{>C{=}\underset{\substack{|\\ OH}}{C}{-}R \rightleftarrows >CH{-}\underset{\substack{\|\\ O}}{C}{-}R}$. It also showed that there is a certain degree of correlation between the complexity of the hydrocarbon residues surrounding a carbonyl group, the stability of the enolic form and the mode of acylation.

Some Derivatives of Beta-Sulfopropionic Acid[1]

BY LUCIUS A. BIGELOW, HUGH W. SIGMON AND DAVID H. WILCOX, JR.

The original point of interest which led to the choice of β-sulfopropionic acid as a subject for study, was the fact that it is the aliphatic analog of *o*-sulfobenzoic acid, the imide of which is the well-known sugar substitute, saccharin. While the latter acid has been the subject of intensive and detailed research, our knowledge concerning the former is very meager and incomplete. The purpose of this paper is to present the results of a study of a number of the simpler derivatives of this interesting aliphatic sulfonic acid.

β-Sulfopropionic acid was originally described by Rosenthal[2] in 1886. He also prepared a large number of the salts, the ethyl ester, and an impure acid chloride, to which he assigned the formula  $\begin{array}{l}\mathrm{CHCl{-}COCl}\\ |\\ \mathrm{CH_2SO_2Cl}\end{array}$ on the basis of rather unsatisfactory evidence. His work includes practically all that is known about the compound or its derivatives, although certain of them have been mentioned indirectly by Kohler[3] and others.

In the present work, barium β-sulfopropionate was prepared from β-iodopropionic acid, and subsequently converted into the silver salt, which, in turn, was treated with the appropriate alkyl halides to form the corresponding neutral methyl-, ethyl-, *n*-propyl- and *n*-butyl esters. These were colorless liquids at room temperature, crystallized from ether at low temperatures and melted at 17, 4, −7 and −25° (all ± 1°), respectively. The methyl ester boiled with slight decomposition at 132–3° at 1 mm., and the others could not be distilled.

In the hope of obtaining a solid ester, the silver salt was treated with benzyl bromide, benzyl iodide and phenacyl bromide, but without results. Phenylethyl iodide, however, reacted normally, yielding the neutral phenylethyl ester in white needles, melting at 59°. This ester, on saponification with barium hydroxide, yielded the barium salt of the acid, in 73% yield, apparently identical, under the microscope, with the corresponding salt obtained from β-iodopropionic acid.

When the dry potassium salt of the acid, in benzene suspension, was treated with phosphorus pentachloride, it yielded, ultimately, a light colored oil, thermally unstable even at 0°, which, when crystallized from ether at low temperatures

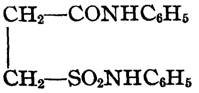
(3) Kohler, *Am. Chem. J.*, **19**, 732 (1897).

deposited as a white solid, melting at −9° (±1°). It was undoubtedly the acid chloride, since on hydrolysis with barium hydroxide solution it regenerated the original barium salt in 77% yield, and on treatment with phenylethyl alcohol it formed the phenylethyl ester, melting at 58° although in small yield.

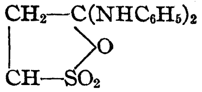
This chloride, when treated in benzene solution with aniline, gave rise to the corresponding dianilide, melting at 161°. This compound presumably had the structure I rather than II

I



$$\begin{array}{l} CH_2\text{—}CONHC_6H_5 \\ | \\ CH_2\text{—}SO_2NHC_6H_5 \end{array}$$

II

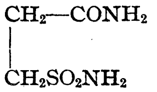


$$\begin{array}{l} CH_2\text{—}C(NHC_6H_5)_2 \\ |\qquad\quad \rangle O \\ CH\text{—}SO_2 \end{array}$$

because it was similar in properties to the well-known symmetrical dianilide of *o*-sulfobenzoic acid, and not to the corresponding unsymmetrical isomer. On hydrolysis with sulfuric acid, it formed the free sulfonic acid, recovered in 69% yield as the barium salt. The fact that the anilide contained no chlorine indicated that the acid chloride from which it was derived was not substituted in the carbon chain, contrary to Rosenthal.[2]

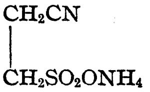
When anhydrous ammonia gas was passed through a solution of the chloride in benzene, a white solid was precipitated quantitatively. After removing the inorganic salts, the product was crystallized from alcohol in white prisms melting at 164–168° with some decomposition.

On theoretical considerations this product could have three reasonably possible configurations, representing it as β-sulfopropiondiamide III, ammonium β-cyanoethyl sulfonate IV or ammonium β-sulfopropionimide V.



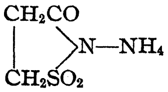
$$\begin{array}{l} CH_2\text{—}CONH_2 \\ | \\ CH_2SO_2NH_2 \end{array}$$

III



$$\begin{array}{l} CH_2CN \\ | \\ CH_2SO_2ONH_4 \end{array}$$

IV



$$\begin{array}{l} CH_2CO \\ |\qquad \rangle N\text{—}NH_4 \\ CH_2SO_2 \end{array}$$

V

Formula III was eliminated readily since the compound had definite salt-like properties, being insoluble in organic solvents, highly soluble in water and having a fairly high melting point. In addition, on analysis by the Van Slyke method for amide and amino nitrogen, it evolved less than one-fourth of its total nitrogen content. The structure IV, derived from the possible unsymmetrical acid chloride, seemed improbable, especially since the compound could be converted readily into a corresponding barium salt in almost quantitative yield, while Remsen and Karslake[4] have found that ammonium *o*-cyanobenzene sulfonate tended to undergo hydrolysis under these conditions. Consequently, the product has been assigned provisionally the structure V, making its formation strictly analogous to that of the ammonium salt of saccharin under comparable conditions.

The salt V, dissolved in water, yielded no precipitate with acids, and was not sweet. When the corresponding barium salt, mentioned above, was treated in aqueous solution with one equivalent of sulfuric acid, the free imide was not produced. Instead, hydrolysis occurred, with the formation in part of the diammonium salt of β-sulfopropionic acid.

An effort was made, also, to obtain the free imide by the pyrolysis of pure ammonium β-sulfopropionate. When this salt was heated for forty to ninety hours at 111° and 3–4 mm. it lost 0.8–1.0 mole of ammonia per mole of sample, yielding a solid product having the composition of the corresponding acid ammonium salt, which on treatment with barium hydroxide regenerated the ordinary barium salt. However, when the temperature of the pyrolysis was increased to 184°, a slow but complete disruption of the molecule took place, and the desired imide was not formed.

Experimental Part

Barium β-Sulfopropionate.—This salt was prepared according to the method of Rosenthal,[2] using a 20% excess of fresh ammonium sulfite and separated from water as colorless plates, in 60–70% yield after dehydration at 150–170°.

Silver Salt.—A sample of 15.5 g. of the anhydrous barium salt was dissolved in 500 cc. of water and one equivalent of sulfuric acid added. After filtration, 13.7 g. of silver oxide (10% excess) was added, and the mixture again filtered. On cooling and subsequent concentration the silver salt separated in gray crystals, weighing 15.7 g., which is 78%. A sample dried over calcium chloride did not lose weight when further dried over phosphorus pentoxide for forty hours at 2 mm., and was therefore anhydrous, contrary to Rosenthal.[2]

Anal. Calcd. for $C_3H_4O_5SAg_2$: Ag, 58.7. Found: Ag, 58.7, 58.6.

Methyl Ester.—Exactly 15.0 g. of the silver salt was heated with 15 cc. of methyl iodide in a sealed tube for six and one-half hours at 100°. The product was diluted with ether, filtered, extracted with 1% sodium sulfite solution, dried over anhydrous sodium sulfate and the solvent removed under reduced pressure at room temperature, leaving 5.77 g. of a yellow oil, which is 77%. The crude ester was crystallized twice from 15-cc. portions of

---

(4) Remsen and Karslake, *Am. Chem. J.*, **18**, 819 (1896).

dry ether at about −65° (solid carbon dioxide–ether bath). The mother liquor in each case was withdrawn by means of a small suction tube with a cloth filter. The product separated in white crystals, which were freed from ether by allowing them to melt, and aspirating the colorless liquid with dry air for one hour at 50° and 1 mm. The pure ester boiled at 132–133° at 1 mm., with slight decomposition, and melted at 17°.

Other Esters.—The ethyl ester was synthesized by refluxing the silver salt with ethyl iodide. It was analyzed by Rosenthal[2] but he did not report the melting point. The *n*-propyl ester formed readily on refluxing the silver salt with *n*-propyl iodide, but in the case of the *n*-butyl ester the salt was heated with the corresponding halide for seven hours at 100°. The phenylethyl ester was made by heating the salt with phenylethyl iodide for ten hours at 100°. The halide in this case was prepared by refluxing 20 g. of phenylethyl bromide with an equal weight of sodium iodide in 100 cc. of acetone for four hours. After filtration and rectification the iodide was obtained in 71% yield, b. p. 117–121°. The phenylethyl ester, being solid at room temperature, was crystallized from ethanol.

When 0.20 g. of the phenylethyl ester was refluxed with a mixture of 2 cc. of sulfuric acid and 25 cc. of water for three and one-half hours it was hydrolyzed readily, and the free acid recovered as the barium salt, in 73% yield, identical with that obtained from β-iodopropionic acid.

TABLE I

ANALYTICAL AND OTHER DATA FOR THE ESTERS OF β-SULFOPROPIONIC ACID

Ester	Crude yield, %	M.p., °C.	Calculated		Found			
			S, %	Mol. wt.	S, %		Mol. wt. (K, 5.12)	
Methyl	78	17	17.6	182	17.6	17.7	188	194
Ethyl	78	4	..	...	..	..	...	...
n-Propyl	86	− 7	13.4	238	13.4	13.4	236	235

Phenylethyl	64	59	8.9	362	9.0	9.0	366	366

The Acid Chloride.—Pure potassium β-sulfopropionate was prepared, in quantitative yield, by treating the barium salt in aqueous solution, with an equivalent of potassium sulfate. It was dried for several hours at 150–170°. Then 47 g. of the potassium salt was suspended in 250 cc. of dry benzene, in a 1-liter 3-necked flask equipped with a mechanical stirrer, and 85 g. of phosphorus pentachloride (2 moles) added all at once. Reaction set in immediately, and the mixture was stirred and refluxed for two hours after which it was filtered by suction through asbestos. The light straw colored solution was then extracted at room temperature with 2-liters of water in 200-cc. portions, which freed it completely from phosphorus compounds (molybdate test). After drying the mixture with anhydrous sodium sulfate, the solvent was removed, first by aspirating with dry carbon dioxide at 15 mm., finally for one-half hour at 1–2 mm., at room temperature. There remained a light pink oil, together with a small quantity of white solid, weighing in all 15.5 g., which is 39%. The solid was removed by filtration through a cotton plug, using a suction tube, and the liquid product kept frozen at −65°, or in solution, as it decomposed thermally on standing at room temperature evolving hydrogen chloride. The chloride was then dissolved in 50 cc. of dry ether, in an atmosphere of dry carbon dioxide, cooled to −65°, and seeded, when a small crop of crystals separated, which were removed and discarded, this process being repeated five times. Then the solvent was evaporated under reduced pressure at 0°, and the remaining oil crystallized twice from 20-cc. portions of dry ether, in a carbon dioxide atmosphere at −65°. Finally the white solid was allowed to melt, and the solvent removed completely by keeping the mixture at 2 mm. and −5° for three and one-half hours. A U-tube filled with sulfuric acid, and placed in the train, did not increase in weight after the first two hours. The final product was a light colored oil, which on cooling froze to a white solid, melting at −9° (±1°).

In spite of this extremely careful purification, the chloride still retained a little of the free acid, presumably, as chlorine and sulfur analyses showed it to be only about 92% pure. However, when a sample was hydrolyzed by boiling for ten minutes with 7% $Ba(OH)_2 \cdot 8H_2O$ solution, the original barium salt was recovered readily in 77% yield. Also, when the chloride was treated with an excess of phenylethyl alcohol, which was later distilled off at 101–104° at 2 mm., the residue solidified on cooling. The solid was crystallized from ethanol and separated as white needles melting at 58°. When these were mixed with an authentic sample of the phenylethyl ester, the melting point was not depressed. The yield was 17% of the theoretical.

The Dianilide.—A sample of crude acid chloride, weighing 5.8 g., was dissolved in 100 cc. of dry benzene, and cooled in an ice-bath. Then a solution of 12 cc. of aniline in 25 cc. of benzene was added, drop by drop, with shaking, which caused the separation of a pasty solid. The liquid was decanted and evaporated, but contained no residue. The solid product was extracted with 1% hydrochloric acid solution, until the extract failed to give a test for aniline. Then it was dissolved in 25 cc. of boiling 50% ethanol, and separated on cooling as white crystals which contained no chlorine, weighing 2.1 g., which is 22% of the theoretical. After recrystallization twice from 10-cc. portions of 50% ethanol, it deposited as white leaflets, which melted sharply at 161°.

Anal. Calcd. for $C_{15}H_{16}O_3N_2S$: S, 10.5; N, 9.2; mol. wt., 304. Found: S, 10.4, 10.6; N, 9.2, 9.1; mol. wt., 316.

On refluxing the anilide with a mixture of 2 cc. of sulfuric acid and 25 cc. of water for five hours it was hydrolyzed, and the acid was recovered as the original barium salt in 69% yield.

Ammonium β-Sulfopropionimide.—A sample of the phosphorus-free acid chloride weighing 15.5 g. was dissolved in 200 cc. of dry benzene, cooled in an ice-bath and saturated with dry ammonia gas. A white solid separated, which dissolved completely when the mixture was subsequently extracted with 150 cc. of water. The benzene layer, on evaporation, left no appreciable residue. Then the aqueous solution was triturated, in portions, with solid silver carbonate, until it was entirely free from Cl^-. After the excess silver carbonate and the silver chloride had been removed, the filtrate was saturated with hydrogen sulfide and filtered again. The final filtrate was evaporated to dryness on a water-bath under reduced pressure, and left a yellow viscous oil, which solidified completely on cooling. The solid, which contained neither silver nor chlorine, was crystallized from 50 cc. of ethanol, and separated in white prisms, melting at about 162°, and weighing 6.64 g., which is 53%. After many crystallizations, the melting point varied irregularly from 164–168°, due to decomposition, as the compound evolved some ammonia even at 110°.

Anal. Calcd. for $C_3H_8O_3N_2S$: S, 21.0; N, 18.4. Found: S, 21.0, 21.0; N, 18.4, 18.3.

It should be mentioned that repeated crystallization of the original precipitate from dry *n*-propyl alcohol until the product was free from chlorine yielded the same compound, although in much less yield.

Barium Salt of the Imide.—A sample of the ammonium salt weighing 3.47 g. was dissolved in 100 cc. of water and treated with barium hydroxide solution, equivalent to half the nitrogen contained in the sample. No precipitate was formed, so the mixture was evaporated to dryness under reduced pressure. The white residue was crystallized from 20 cc. of dilute ethanol, and separated as white needles, in practically quantitative yield. After one more crystallization it was quite pure.

Anal. Calcd. for $C_6H_8O_6S_2N_2Ba$: Ba, 33.7; N, 6.9. Found: Ba, 33.8, 33.5; N, 6.9, 6.9.

When this barium salt in aqueous solution was treated with one equivalent of ammonium sulfate, ammonium β-sulfopropionimide was regenerated in 63% yield, melting at 167–168°. On admixture with the original ammonium salt, the melting point was not depressed.

Attempt to Prepare the Free Imide.—A solution of 4.5 g. of barium β-sulfopropionimide in 25 cc. of water was treated with the calculated quantity of dilute sulfuric acid. The filtrate was evaporated to dryness under reduced pressure, and left a solid residue, which on crystallization three times from methanol separated as white crystals which contracted at 170°, and melted at 175–176°. The compound contained neither barium nor chlorine, and seemed to be the diammonium salt of β-sulfopropionic acid.

Anal. Calcd. for $C_3H_{12}O_5N_2S$: N, 14.9. Found: N, 14.7.

Pyrolysis of Diammonium β-Sulfopropionate.—This compound was prepared by treating an aqueous solution of the barium salt with one equivalent of ammonium sulfate. After filtration, the solution was evaporated to a small volume, during which time it gave off ammonia. Finally the mixture was saturated with ammonia gas, and the crystals which deposited on standing in the cold, filtered off, washed with ethanol and dried to constant weight over sulfuric acid, at 2 mm. The yield was 68–70%, and, under these conditions, was anhydrous and not very hygroscopic.

Anal. Calcd. for $C_3H_{12}O_5N_2S$: S, 17.0; N, 14.9. Found: S, 16.9, 17.2; N, 15.0, 14.6.

For the pyrolysis, a weighed sample of the salt was placed in a boat contained in an oven tube so arranged that it could be entirely surrounded by the vapors of boiling toluene (111°). It was connected to a train consisting of a U-tube filled with solid potassium hydroxide, and two U-tubes containing glass beads and sulfuric acid. The pressure in the system was reduced to 3–4 mm., the sample heated to 111°, and its loss in weight observed, as well as the corresponding gain in the absorption tubes. Blank runs were made each time, and adequate corrections applied. The potassium hydroxide gained very little weight under these conditions. The results are expressed in the table below.

The writers take pleasure in expressing their thanks to Mr. John G. Womack, for his contribution to this work.

Summary

A study has been made of a number of derivatives of β-sulfopropionic acid, including a series of esters, the chloride, the anilide and the ammonium salt of the imide, which is the aliphatic analog of the corresponding salt of saccharin. This last substance was not sweet.

The free imide underwent complete hydrolysis when formed in aqueous solutions, and it was not produced by the pyrolysis of diammonium β-sulfopropionate at 111° and 3–4 mm., which yielded the acid ammonium salt almost quantitatively.

Seven new compounds have been characterized.

DURHAM, NORTH CAROLINA RECEIVED AUGUST 22, 1935

The Potential of the Ag(s), Ag_2CrO_4(s), $CrO_4^=$ Electrode[1]

BY JESSIE Y. CANN AND GRETCHEN B. MUELLER

The purpose of this investigation was to determine, by means of electromotive force measurements, the potential of the Ag(s), Ag_2CrO_4(s), $CrO_4^=$ electrode.

A search of the literature revealed that very little work had been done on this electrode.[2] No description of an electrolytic deposition of silver chromate could be found.

Method and Apparatus

In this investigation the cell Ag(s), Ag_2CrO_4(s), K_2CrO_4(aq), KCl(aq), AgCl(s), Ag(s) was measured. The apparatus used was suggested by the work of Randall and Cann.[3] The electrodes were placed in the outer arms of the electrode vessels so as to prevent the flow of liquid over the electrodes.[4]

The cell was placed in the usual oil thermostat, regulated at 25°, and measurements were made with a shielded Leeds and Northrup Type K potentiometer.

Materials

All solutions were made up by weight, moles per 1000 g. of water in vacuum, from high grade "analyzed" salts and conductivity water. Either pure hydrogen or nitrogen was bubbled through the solutions to remove traces of oxygen.

The Ag(s), AgCl(s) spiral electrodes were made according to the method of Randall and Young.[5]

The Ag(s), Ag_2CrO_4(s) spiral electrodes were also made electrolytically. Many trials showed that the best results were obtained with a 0.02 molal chromic acid solution using an e. m. f. of 1.5 volts for about two hours. A solution of chromic acid instead of potassium chromate was used to prevent contamination by the potassium ion. The electrodes were then washed in distilled water and short-circuited together for some hours. When not in use they were kept in a dilute solution of potassium chromate, for according to Margosches[6] the solubility of silver chromate is less in potassium chromate than in water. Immediately before being introduced into the cell the electrodes were placed in the particular potassium chromate solution to be used and evacuated for about thirty minutes, with gentle heating, to make sure of the complete removal of all oxygen.

Experimental Results

The molality of the potassium chloride was twice that of the potassium chromate in order to have the same concentrations of potassium ions in the two solutions. This is necessary for the Lewis and Sargent[7] formula for liquid junction potentials. Table I gives the average values of at least ten cell readings for each concentration used. The readings in general did not vary from the average by more than ±0.5 millivolt, except in the most dilute solutions, where the maximum variation was ±1.0 millivolt.

The liquid junction potential was calculated for each concentration by using the Lewis and Sargent[7] formula for common cations, *i. e.*

$$E = -\frac{RT}{F} \ln \Lambda_{\mathrm{KCl}}/\Lambda_{1/2\mathrm{K_2CrO_4}}$$

The values for the individual ion conductances were taken from the "International Critical Tables."[8]

In order to determine the potential of the silver–silver chromate electrode from the cell readings, it is necessary to know the potential of the silver–silver chloride electrode for each dilution used. Since both silver and silver chloride

are solids, this value is calculated for each concentration by means of the equation

$$E = E^0 - (RT/F) \ln (m\gamma)_{Cl^-}$$

and since it is generally assumed that the activity coefficients of the potassium and chloride ions are equal, the activity coefficients of potassium chloride may be used for those of the chloride ion. These values were taken from Lewis and Randall.[9]

The value of E^0 for the silver–silver chromate electrode was calculated from the values listed in Table I. Since the electrode reaction is

$$2Ag(s) + CrO_4^= \longrightarrow Ag_2CrO_4(s) + 2e$$

we may write

$$E = E^0 - \frac{RT}{2F} \ln \frac{1}{a_{CrO_4^=}} = E^0 - \frac{RT}{2F} \ln \frac{1}{(m\gamma)_{CrO_4^=}}$$

By subtraction of $(RT/2F) \ln m$ from both sides of the equation

$$E - \frac{RT}{2F} \ln m = E^0 - \frac{RT}{2F} \ln \frac{1}{\gamma_{CrO_4^=}}$$

At infinite dilution the activity coefficient is equal to one, and the last term drops out; thus

$$E - (RT/2F) \ln m = E^0$$

We therefore determine E^0 by plotting $(E - (RT/2F) \ln m)$, *i. e.*, $E - 0.02958 \log m$ against the molality and extrapolating the curve to infinite dilution. The values so determined are given in Table II. From the plot of these values E^0 was taken as -0.4463 v. This gives $\Delta F^0 = 20{,}596$ cal.

TABLE II

Molality of K_2CrO_4	E. m. f., v.	0.02958 log *m*, v.	E. m. f. −0.02958 log *m*, v.	C. & M. $\gamma_{CrO_4^=}$	H. & J. $\gamma_{CrO_4^=}$

.00375	− .5223	− .0718	− .4505	.72	
.0025	− .5256	− .0770	− .4476	.83	

Combining

$$2Ag(s) + CrO_4^= \longrightarrow Ag_2CrO_4(s) + 2e; \quad \Delta F^0 = 20{,}596$$

and

$$2Ag(s) \longrightarrow 2Ag^+ + 2e; \quad \Delta F^0 = 36{,}896$$

we have

$$2Ag^+ + CrO_4^= \longrightarrow Ag_2CrO_4(s); \quad \Delta F^0 = -16{,}300 \text{ cal.}$$

The activity coefficients of the chromate ion were calculated by the equation

$$E = E^0 - \frac{RT}{2F} \ln \frac{1}{(m\gamma)_{CrO_4^=}}$$

The temperature coefficient was determined for the cell containing 0.05 *M* KCl and 0.025 *M* K_2CrO_4. The values listed in Table III are the averages of at least five readings at each temperature. From the plot of these values $dE/dT = -0.000228$.

Hence, since

$$E + \frac{\Delta H}{n\,F} = T \frac{dE}{dT}$$

$\Delta H_{298.1}$ for the reaction was found to be 6225 cal.

TABLE III

°C	E. m. f., v.
14.8	−0.2102
25.0	− .2078
30.0	− .2069
35.0	− .2060
40.0	− .2044
45.0	− .2023

To obtain the heat of formation of silver chromate, we make the combinations

$2AgCl(s) + CrO_4^= \longrightarrow Ag_2CrO_4 + 2Cl^-; \quad \Delta H^0 = 6225$ cal.

$2Ag^0 + Cl_2 \longrightarrow 2AgCl; \quad \Delta H^0 = -60{,}540$ cal.[10]

$2Ag^0 + Cl_2 + CrO_4^= \longrightarrow Ag_2CrO_4 + 2Cl^-; \quad \Delta H^0 = -54{,}315$ cal.

$Cl_2 \longrightarrow 2Cl^-; \quad \Delta H^0 = -79{,}166$ cal.[11]

$2Ag^0 + CrO_4^= \longrightarrow Ag_2CrO_4; \quad \Delta H^0 = 24{,}851$ cal.

$Cr^0 + 2O_2 \longrightarrow CrO_4^=; \quad \Delta H^0 = -203{,}952$ cal.[12]

$2Ag^0 + Cr^0 + 2O_2^0 \longrightarrow Ag_2CrO_4; \quad \Delta H^0 = -179{,}101$ cal.

Thus the heat of formation of silver chromate from its elements is

$$\Delta H^0_{298.1} = -179{,}101 \text{ cal.}$$

It is also interesting to calculate the heat of formation of silver chromate from its ions. We combine

$2Ag^0 + CrO_4^= \longrightarrow Ag_2CrO_4; \quad \Delta H^0 = 24{,}851$ cal.

$2Ag^0 \longrightarrow 2Ag^+; \quad \Delta H^0 = 49{,}724$ cal.[13]

$2Ag^+ + CrO_4^= \longrightarrow Ag_2CrO_4; \quad \Delta H^0 = -24{,}873$ cal.

The entropy change for this reaction is obtained from

$$\Delta F^0 = \Delta H^0 - T\Delta S^0$$

$$-16{,}300 = -24{,}873 - 298.1\ \Delta S^0$$

$$\Delta S^0_{298.1} = -28.75$$

Discussion of Results

Abegg and Cox[2] measured the cell

$$Ag(s),\ Ag_2CrO_4(s),\ K_2CrO_4\ (0.1\ N),\ KCl(N),\ Hg_2Cl_2,\ Hg$$

and found it to give an e. m. f. of −0.227 v. at

[13] Ref. 8, Vol. V, p. 188.

25°. Using the value −0.2800 v.[5,14] for the normal calomel electrode, we obtain for Ag(s), Ag_2CrO_4(s), 0.1 N $CrO_4^=$ the value E = −0.507 v. This is in good agreement with our value of −0.5050 v. Next, calculating the value of E^0 from Abegg and Cox's results, we obtain −0.448 which again agrees with our value of −0.4463.

Bolam and MacKenzie[2] measured the cell Ag, $AgNO_3$(0.1 N), NH_4OH(10 N), K_2CrO_4(0.1 N), Ag_2CrO_4, Ag and obtained the value 0.2247 v. Lewis[15] found E = −0.399 v. for the cell Ag, $AgNO_3$(0.1 M), KNO_3(0.1 M), KCl(0.1 M) Hg_2Cl_2, Hg. Noyes and Brann[16] found for this same cell E = −0.3992 v. Lewis and Randall,[9] (p. 414) on the basis of these results, corrected for the liquid junction and obtained E = −0.3985 v. Since the value of the decinormal calomel electrode is −0.3351 v., we thus obtain for Ag(s), Ag_2CrO_4(s), CrO_4 = (0.1 N) the value E = −0.5089 v. This gives E^0 = −0.4504 v.

The standard electrode potential calculated from the data of Hass and Jellinek[2] is E^0 = −0.462 v.

The change in free energy for the reaction

$$Ag_2CrO_4(s) \longrightarrow 2Ag^+ + CrO_4^=$$

may be calculated from the solubility product as well as from the standard electrode potentials. Values calculated from various data are summarized in Table IV. Hass and Jellinek[2] measured the potential of the silver–silver chromate electrode in order to calculate the activity coefficients of the chromate ion. Their values, compared with ours, are listed in Table IV.

TABLE IV

Investigator	E^0, v.	K s. p.	ΔF^0 $Ag_2CrO_4 \rightarrow 2Ag^+ + CrO_4^=$ cal.
Hass and Jellinek[2]	−0.462		15,576
Bolam and MacKenzie[2]	− .4504		16,111
Abegg and Cox[2]	− .448		16,222

[b] *Z. physik. Chem.*, **64**, 149 (1908).

[c] THIS JOURNAL, **29**, 1641 (1907).

The variation in these values may be due to the fact that electrolytic silver chromate was used in the present work, whereas Hass and Jellinek used the precipitated salt. The thermodynamic properties of substances prepared by dissimilar methods may be very different.

Summary

The cell Ag(s), Ag_2CrO_4(s), K_2CrO_4(aq), KCl(aq), AgCl(s), Ag(s) was investigated.

The normal electrode potential of Ag(s), Ag_2CrO_4(s), $CrO_4^=$ was found to be E^0 = −0.4463 v.; ΔF^0 = 20,596 cal.

The Adsorption of Hydrogen and Deuterium on Copper at Low Pressures[1]

BY RALPH A. BEEBE, GEORGE W. LOW, JR., EDWIN LINCOLN WILDNER AND SEYMORE GOLDWASSER

Attention has been called by Pace and Taylor[2] to the fundamental importance which is attached to experimental studies of the relative velocities of the activated adsorption of hydrogen and deuterium on catalytically active surfaces. These authors have found no difference in the rates of adsorption for the two isotopes on the hydrogenating catalysts chromium oxide, zinc oxide–chromium oxide and nickel at one atmosphere pressure and over the temperature range 110–184°. This observation was unexpected because, on account of the difference in zero point energies, the activation energy should be greater for deuterium than for hydrogen, and the rate of adsorption correspondingly less for deuterium.

More recently direct experimental evidence has been presented by Klar,[3] and indirect evidence based upon the interpretation of the rates of catalytic reactions has been presented independently by Klar,[4] and by Fajans[5] to show very definite differences in the adsorption of the two hydrogen isotopes on active nickel.

Because of the apparent discordance among the

results which have been described above, it seems advisable at this time to present our data on the adsorption of the two gases by copper, although we feel that more detailed experimental work will be needed before a satisfactory explanation of all our results will be possible. Our measurements have extended over the temperature range −78 to 125° and the pressure interval, 0 to 2 mm. In agreement with Klar's work we have found great differences in the behavior of the two gases, both in the rates of adsorption and in the amounts adsorbed. In the course of this work we have also determined, by direct measurement, the heats of adsorption of the two gases at 0°. An interesting by-product of the work has arisen from a detailed study of the rates of adsorption at −78° on a comparatively bare copper surface. Under these conditions it has been found that the adsorption process is autocatalytic.

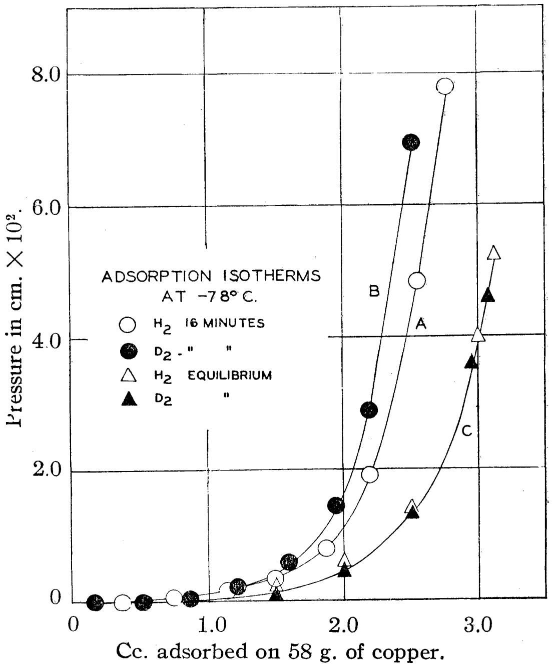

Fig. 1.

Experimental Details

Apparatus.—The general apparatus assembly and experimental procedure were in most details identical with those previously used by Beebe.[6] In the heat measurements smoother time–temperature curves were obtained by protecting strained portions of the constantan thermocouple wire from chance changes in room temperature. Moreover the sensitivity of the thermometric system was approximately tripled by use of a more sensitive galvanometer and a longer optical arm. The velocity of adsorption was measured on a McLeod gage by observing the rate of decrease of pressure in the system after admission of gas.

Materials.—Copper No. 1, used in most of the experiments, was prepared by reduction of high grade copper oxide granules in a stream of pure, dry hydrogen first at 120 and finally at 170°. After each series of adsorption measurements, the catalyst was degassed at 170° by use of a mercury diffusion pump over a period of five to fifteen hours. The copper, protected from mercury vapor by a trap containing cadmium turnings and gold foil, maintained a constant adsorptive capacity after several months of use. Copper No. 2 was prepared in exactly the same manner as No. 1, but a different sample of copper oxide was used. Copper samples No. 1 and 2 had approximately equal adsorptive capacity.

Copper No. 3, a much less active sample than the others, was prepared from copper powder made by rapid deposition from a solution of copper sulfate at high current density. This powder, supplied through the courtesy of Dr. F. H. Willard, was reduced in the same manner as were the others to remove surface oxide.

Electrolytic tank hydrogen was purified by passing it over copper at 450°, solid potassium hydroxide, and anhydrous magnesium perchlorate in sequence.

The deuterium gas, kindly supplied by Professor H. S. Taylor, was made by electrolysis of 99% heavy water produced in the Princeton Laboratory of Chemistry. A part of the work reported in this paper was done with a sample of deuterium received in February, 1934. Because of the unexpected differences between the results obtained and those of Pace and Taylor on other adsorbents another sample was requested from Professor Taylor. This deuterium, received in September, 1934, yielded results entirely consistent with those from the earlier sample.

The source of helium, used to measure the dead space in the apparatus, has been described previously.[7]

Experimental Results

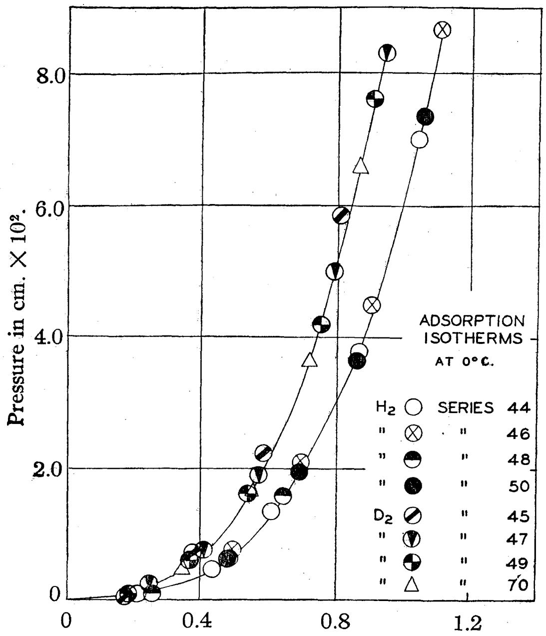
Comparison of Hydrogen and Deuterium.—That our experiments very definitely demonstrate differences in the adsorption of the two hydrogen isotopes will be seen from the data which follow. In Fig. 1 are shown the isotherms for hydrogen and deuterium at −78° on copper No. 1. Increments of gas were admitted at thirty-minute intervals. Curves A and B are plotted from data taken sixteen minutes after admission of each increment of gas. That the difference in the isotherms A and B is due entirely to a difference in the rates of adsorption is shown by curve C. Each point on this curve represents data taken after the pressure had remained constant for twelve hours or more indicating that equilibrium had been reached. The coincidence of the data for hydrogen and deuterium on curve C indicates that, at equilibrium, the two gases are adsorbed in equal amounts at −78° although their rates of

---

(6) Beebe, *Trans. Faraday Soc.*, **28**, 761 (1932).

(7) Beebe and Wildner, This Journal, **56**, 642 (1934).

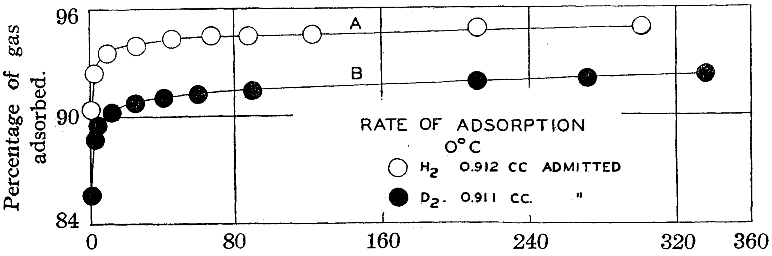
adsorption differ, the rate for deuterium being slower. These conclusions were confirmed by direct rate measurements.



Cc. of gas adsorbed on 58 g. of copper.

Fig. 2.

At 0° and higher temperatures the nature of the adsorption phenomena appears to be more complex than at −78°. It seems probable that a single type of sorption occurs at −78°, but that two types occur at the higher temperatures.[8] In obtaining the data at 0° for the isotherms shown in Fig. 2, increments were admitted to the catalyst at fifteen-minute intervals and readings were taken five minutes after each admission. That the isotherms do not represent equilibrium conditions is shown in Fig. 3, curve A. Ninety-two per cent. of the hydrogen admitted was adsorbed after five minutes, yet adsorption proceeded at a slow rate so that 2% more of the gas initially admitted had disappeared after six hours. Curve B shows similar results for deuterium. At first it seemed probable that the difference in the isotherms at 0° was due only to a difference in the rates of adsorption of hydrogen and deuterium, as was true at −78°. However, comparison of curves A and B in Fig. 3 reveals that there was still a definite difference in the amount of gas adsorbed under identical conditions even after six hours. In fact the two rate curves remained parallel at the end of five days although both hydrogen and deuterium were being adsorbed very slowly even then. As a further check of this apparent greater adsorption of hydrogen than of deuterium, rate measurements were repeated on copper No. 3. The results, which are entirely consistent with those of copper No. 1 at 0°, are shown in Fig. 4, (two curves at top).



Time in minutes.

Fig. 3.

Investigation of the adsorption process in the temperature range 0 to 125° revealed a rather surprising temperature inversion in the ratio of the amounts of the two isotopes adsorbed under identical conditions. The data measured on copper No. 3 are shown in Fig. 4. In all experiments 0.74 cc. of gas was admitted to a previously degassed sample weighing 45 g. which had been brought to the desired temperature. Experiments not shown were also performed at 19 and 125°. These yielded results which were entirely consistent with those which are shown for 0, 56 and 100°. The order of experiments was H_2 at 0°, D_2 at 0°, H_2 at 0°, H_2 at 19°, D_2 at 19°, H_2 at 56° D_2 at 56°, D_2 at 100°, H_2 at 100°, H_2 at 125°, D_2 at 125°, D_2 at 0°, H_2 at 0°.

It is important to observe that the points at 0° indicated by triangles were obtained at the end of the series of experiments, whereas those represented by circles were obtained at the beginning of the series. It is therefore demonstrated that no change had occurred in the copper surface during the whole series. Moreover, it seems improbable that any effects due to exchange reaction could have been present. Otherwise one would not expect identical results for the initial experiment for deuterium at 0° (Fig. 4) conducted after a hydrogen experiment at 0°, and the final experiment for deuterium at 0° conducted after a deuterium experiment at 125°. The tempera-

---

[8] Ward, *Proc. Roy. Soc.* (London), **A133**, 506 (1931).

ture inversion was also observed on copper No. 2 in experiments at 0 and 100°.

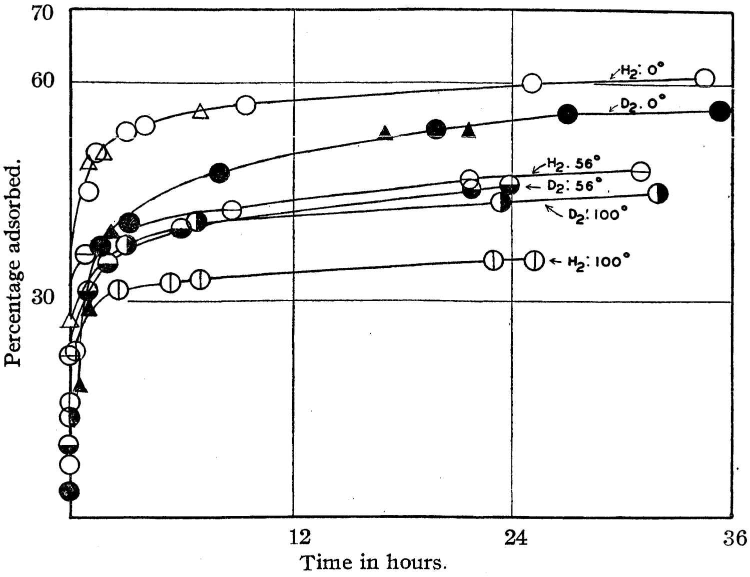


Fig. 4.—○ and ●: initial experiments; △ and ▲: final experiments.

Rates of Adsorption for Initial Stages.—A detailed study at −78° of the rates of adsorption of the two gases in the initial stages upon a comparatively bare copper surface revealed the surprising fact that the rate *increased* with increasing amounts of adsorbed gas on the surface. In other words, the process was autocatalytic. This point is best understood from Table I. A typical experiment (expt. 3 for H_2) will be described. To a newly degassed surface of copper No. 1, was admitted 0.387 cc. (increment 1); after four minutes 0.298 cc., or 77%, had been adsorbed, and after thirty minutes the whole 0.387 cc. was adsorbed. At this point increment 2, approximately equal in volume to 1, was admitted; after four minutes 97% was adsorbed, and after thirty minutes 100%. Increment 3 now followed and was 97.6% adsorbed after four minutes and 100% adsorbed after thirty minutes.

TABLE I

RATES OF ADSORPTION OF H_2 AND D_2 ON COPPER (58 G.) AT −78°

Expt.	Gas adsorbed	Cc. added	% adsorbed at 4 min.
3	H_2	0.387	77.0
		.369	97.0
		.383	97.6

		.378	95.2
		.371	96.2
8	D_2	.387	53.5
		.394	95.0
		.366	96.0
9[a]	D_2	.381	46.5
		.393	95.2
		.387	96.2
6	D_2	.166	66.2
		.179	92.2
		.164	98.2

[a] Experiment 9 was made after another D_2 experiment, Expts. 4, 8 and 6 were made after H_2 experiments.

Examination of the data in Table I shows that deuterium exhibits the same unexpected rate phenomenon. The difference in rate between the first and second increments is even more marked than in the case of hydrogen. More details are to be seen in Fig. 5 showing the percentages adsorbed at two, four, six and eight minutes for experiments 3 and 4. It is also obvious from Fig. 5 that the velocity of adsorption on the comparatively bare surface at −78° is definitely less for the heavier isotope.

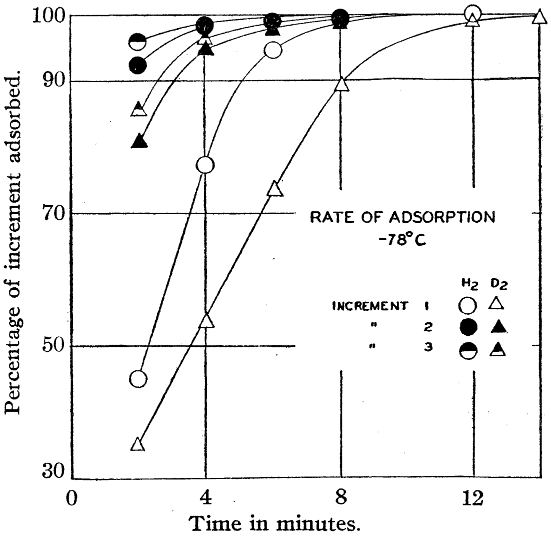

Fig. 5.

Owing to the rather striking results shown in Fig. 5 and in Table I, the authors have made a critical examination of the experimental procedure to see if the data could in any way be traced to experimental error. No such source of error was found. The obvious objection that the abnormal results could arise because the copper might not have cooled to −78° at the beginning of each experiment is eliminated because the catalyst tube was always left immersed in the bath at −78° overnight before each experiment. That this was sufficient time for thermal equilibrium was shown by the thermo-element which was used in the heat measurements.

Heats of Adsorption.—Altogether six series of measurements of differential heats of adsorption were made for hydrogen and five series for deuterium on two different samples of copper No. 1 weighing 67 and 58 g., respectively. Typical data are shown in Table II. The heats of adsorption are approximately 11,000 calories per mole of gas. No measurable difference was detected for the two gases. This observation is consistent with a calculated difference of 200 calories per mole, based on the values of the zero point energies of the H_2 and D_2 molecules and of the Cu–H and Cu–D bindings given by Eyring and Sherman.[9] The differential heats of adsorption for both isotopes decreased slightly with increasing amounts of gas already adsorbed. This decrease was not so marked, however, as was the case previously reported[10] for carbon monoxide on copper.

TABLE II

SERIES 23, ADSORPTION OF H_2 ON COPPER AT 0°

Discussion of Results

Difference in Behavior of Hydrogen and Deuterium.—Our results like those of Klar and of Fajans previously cited appear to be in disagreement with the work of Pace and Taylor.[2] However, it should be mentioned that all of our measurements were carried out at low pressures (0 to 2 mm.), whereas those of Pace and Taylor were at 760 mm. It therefore seems possible that measurements on Pace and Taylor's active adsorbents at low pressure may very well uncover differences between hydrogen and deuterium which have been masked at 760 mm. On the basis of their observations Pace and Taylor have drawn certain conclusions concerning the probable rate determining factors in the adsorption process. Because of the apparent disagreement mentioned above, these conclusions should be reserved pending further experimental work.

Special attention is called to the similarity between our results and the data of Klar[4] on the relative rates of hydrogenation of ethylene over iron catalyst by the two hydrogen isotopes. The latter author reports that although the hydrogenation rate is greater for hydrogen than for deuterium at 0°, the reverse is true at temperatures above 100°; and suggests as a tentative explanation the possibility of a temperature inversion in the ratio H_2/D_2 adsorbed entirely analogous to that directly observed by us in the case of copper. Pease and Wheeler[11] recently have reported preliminary data on the rates of hydrogenation of ethylene over copper catalyst. They have found for the ratio of rates H_2/D_2 a value of 1.59 at 0°, 1.34 at 184° and 1.04 at 306°. They suggest the possibility that their results may be accountable to an exchange reaction absent at 0°, but increasingly present at higher temperatures. It seems possible to us that an explanation similar to that offered by Klar in the case of iron catalyst may be applied to Pease and Wheeler's results. Our data show that deuterium is relatively more strongly adsorbed with increasing temperature as compared to hydrogen. It may be that the higher energy of activation for the deuterium reaction causing a slower rate of hydrogenation of ethylene at 0°, is increasingly compensated with rising temperature by the relatively greater adsorption of deuterium as compared to hydrogen.

It is difficult at this time to attain a satisfactory theoretical explanation of the complex

differences in the adsorption data for the two gases. All of our data on rates of reaction were obtained by measuring change of pressure with time. Because changes in pressure effect changes in the activation energies of adsorption processes,[12] no attempt has been made to calculate activation energies from the velocity curves. It is highly desirable to procure velocity data at constant pressure using a method for pressure control during the adsorption in the low pressure region (0 to 2 mm.).

Autocatalytic Adsorption at −78°.—One other example of autocatalytic adsorption has been observed previously by Benton and White[13] for hydrogen on iron at 0°. In these cases of autocatalytic adsorption the gas is apparently more readily adsorbed on those portions of the surface which are adjacent to atoms or molecules already adsorbed. There is little doubt that the adsorption of either hydrogen isotope on copper at −78°, which we have found to be autocatalytic, is of the activated type.[14] This possibility of an autocatalytic activated adsorption process presents a complicating factor which must be considered in connection with any adsorption theory of catalysis.

Summary

1. Very definite and complex differences have been found between the adsorptions of light and heavy hydrogen on active copper at low pressures (0 to 2 mm.).

2. At −78° the rate of adsorption is less for deuterium than for hydrogen, but equal amounts of the two isotopes are adsorbed at equilibrium.

3. In the temperature interval 0 to 125° the ratio H_2/D_2 adsorbed undergoes an inversion, hydrogen being more strongly adsorbed at the lower temperatures and less strongly at the higher temperatures.

4. The differential heats of adsorption have been measured by a direct calorimetric method, and are identical for the two isotopes within the limits of experimental error.

5. The early rate of adsorption of hydrogen at −78° is autocatalytic. The same is true for deuterium.

[13] Benton and White, *ibid.*, **54**, 1820 (1932).

[14] At −78° the adsorption proceeded at a measurably slow rate and the residual pressure, even after the third increment of gas, was less than 10^{-3} cm. Both these observations together with evidence not detailed here, indicate activated adsorption. See also Benton and White, *ibid.*, **53**, 3304 (1931).

The Coefficient of Expansion of Silver Iodide and of the Halides of Thallium

BY GRINNELL JONES AND FREDERIC C. JELEN

Introduction

Silver iodide has been reported to have a negative cubical coefficient of expansion. Since this property is almost unique it seemed desirable to test the reliability of the reports by a new experimental method and to measure the expansion of several analogous salts in the hope that another similar case might be found. In this paper data on silver iodide and the halide salts of thallium are reported.

The coefficient of expansion of silver iodide was determined many years ago by Fizeau,[1] and by Rodwell[2] with very discordant results, although both agree as to the negative sign.[3] Fizeau, using an optical interference method, obtained agreeing results on a cylinder which had been previously fused and therefore consisted of closely packed crystals and on precipitated silver iodide which was compressed into a cylinder. He found the cubical coefficient to be -4.1×10^{-6} at a mean temperature of 40°. A single large crystal gave -2.7×10^{-6}. Rodwell who measured the cubical coefficient by a dilatometer method obtained a much larger value, namely -55.7×10^{-6} between 21 and 67°. Klemm, Tilk and v. Müllenheim,[4] using a dilatometer method have found the cubic coefficient of expansion from 20 to 120° of thallous chloride to be 1.68×10^{-4}, and of thallous bromide to be 1.72×10^{-4}.

Outline of the Principle of the New Method.—Our method was suggested by the Richards[5]

method for the determination of the compressibility of solids and liquids, which it resembles in principle. The glass dilatometer is first weighed and then filled with mercury and the exact temperature needed to bring the mercury meniscus to a reference mark in a capillary tube is determined. Then a weighed drop of mercury is added and a new lower temperature determined which will bring the greater quantity of mercury to the same reference mark. This step may be repeated as often as is desired until the range of temperature to be studied has been covered. The total weight of mercury present is then found by weighing the dilatometer and its contents. It is evident that these data permit a computation of the difference between the coefficient of expansion of mercury and of glass per gram of mercury and per degree centigrade averaged over each temperature interval used in the experiments. Then a large part of the mercury in the dilatometer is replaced by a known weight of some other solid or liquid substance and the measurements repeated. By taking the difference between these series of measurements the effect of the variation in volume of the glass dilatometer is eliminated and the result is the difference between the cubical coefficient of expansion of the solid or liquid under investigation and that of an equal volume of mercury. The cubical coefficient of expansion of mercury,[6] which is known more precisely than that of any other substance (with the possible exception of water) may then be added to this experimental result to give the coefficient of expansion of the solid or liquid.

The principle of the method is simple and direct, but mercury does not wet most solids so it is necessary to have present a small amount of some wetting liquid. The necessity of determining the amount of wetting liquid present complicates the procedure and diminishes the precision of the result. Toluene was chosen for the wetting liquid because it does not dissolve any of the salts to be investigated and its boiling point and volatility are suitable for the purpose. Its coefficient of expansion was of course determined separately in our dilatometer.

Another novel feature of our method is that the dilatometer serves also as a thermo-regulator and automatically adjusts its own temperature so that the dilatometer is completely filled to the reference mark. This feature contributes greatly to the convenience of the experimentation and the precision of the final result.

Experimental

The dilatometer, which is shown in Fig. 1(D), was made of Pyrex glass and had an internal diameter of 2 cm. and a volume up to the point, P, of about 60 cc. It had two pieces of platinum, P and Q, extending into side tubes as shown in the figure. A little mercury in the side tubes served to make electrical contact and to make the platinum seals gas-tight. The stiff platinum rod P has a sharp point which is located in the center of the capillary at the height where it commences to flare. It will be sufficiently obvious from the figure that when the dilatometer is filled with mercury in whole or part it will also serve as a regulator and automatically adjust the temperature of a thermostat in which it is immersed so that it will be completely filled up to the tip of the pointed platinum rod, P.

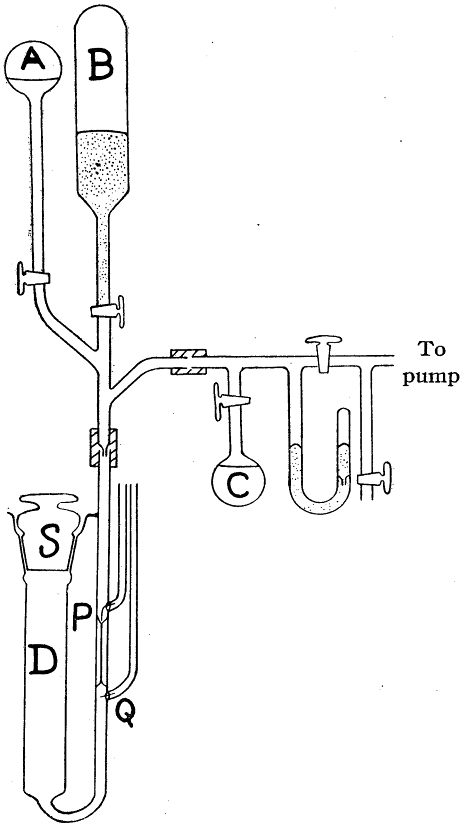

Fig. 1.—Dilatometer and filling device.

In order that the location of the stopper, S, should be as definite and reproducible as possible it was made with somewhat greater taper than the standard grindings and was rotated to a standard position by the aid of suitable guide marks. Our experience showed that determinations of the total volume were reproducible within 0.02 cc., which is sufficiently precise. It is of much greater importance that the stopper should not move vertically with reference to the jacket during a series of measurements. It was found impossible to get the desired precision without

the use of a sealing compound which is solid at the highest temperature used in the measurements (about 60°).

When toluene is used as a wetting liquid, organic waxes or resins are excluded on account of their solubility. Having found that anhydrous metaphosphoric acid may be used, a suitable quantity of molten metaphosphoric acid was placed on the upper part of the grinding of the stopper where it immediately froze. The stopper was then inserted into the dilatometer (either empty or containing a weighed amount of salt) and the upper part of the instrument heated in a free flame until the acid melted, whereupon the stopper was pressed into place and then on cooling the metaphosphoric acid froze and held the stopper completely immobile during the experiment. To prevent solution of the metaphosphoric acid in the water of the thermostat melted "arochlor" (Swann Chemical Company) was poured into the annular channel above the ground glass joint. Arochlor is sufficiently stiff at 60° and insoluble in water and adheres to glass so it served its purpose well.

A good grade of thallous nitrate was twice recrystallized. Iodine was purified by distillation from a solution of an iodide, washed and converted into hydriodic acid by reaction with yellow phosphorus and water, and the resulting hydriodic acid distilled twice. Dilute solutions of thallous nitrate and of hydriodic acid (in excess) were mixed and the precipitated thallous iodide washed repeatedly. The salt was then fused in a Pyrex test-tube and allowed to solidify from the bottom upward. There were a few minute cracks in the material which toluene could penetrate but mercury could not. The other salts were prepared by a similar procedure. Thallous bromide and thallous iodide were prepared by the addition of ammonium bromide and hydrochloric acid solutions, respectively, to thallous nitrate solutions. Silver iodide was precipitated from a nitrate solution by the addition of a potassium iodide solution.

Since the coefficient of expansion of gases is very great in comparison with liquids and solids it is necessary to fill all of the space in the dilatometer not occupied by salt with mercury or with toluene and without any air bubbles. This was accomplished by the device shown in Fig. 1. After the salt had been placed in the dilatometer, the stopper frozen in place and the contents weighed, it was connected to the filling device by a stout rubber connection as shown. All air had been removed completely from the bulbs A, B, C in advance. The air in the dilatometer was replaced by toluene vapor by alternately exhausting and opening the cock of bulb C. This was repeated about a dozen times, thus removing the air completely. Then about a gram of liquid toluene was run into the dilatometer by opening the cock of bulb A, followed by opening the cock of bulb B to admit sufficient mercury to seal the lower bend in the dilatometer. The liquid toluene in the narrow arm of the dilatometer was then evaporated. More mercury was added, thus completely filling the dilatometer. During this process the layer of toluene on top of the mercury rises and wets every particle of salt. The filling was not considered a success unless there was a slight surplus of liquid toluene visible under the stopper and no air bubbles were present. The dilatometer was then separated from the filling device. The capillary in the dilatometer was cleaned by treatment in succession with nitric acid, water, and acetone, followed by evaporation of the acetone. The amount of mercury was adjusted until it would fill the instrument at approximately 60°, and the total weight of the instrument and contents was determined. The dilatometer was then placed in the thermostat where it functioned as a thermostat regulator and adjusted its own temperature until the mercury meniscus came exactly to the platinum tip, P. A thyratron tube was used instead of the usual electromagnetic relay.

The proper amount of mercury to require a lowering of about 10° in the temperature was then weighed out and added to the dilatometer, which again functioned as a regulator and established a new lower temperature of about 50°, which was read as before. In a similar manner readings were taken at about 40, 30 and 20°.

Then without disturbing the stopper the bulk of the mercury and toluene were removed into a weighed Pyrex dish. The toluene remaining inside the dilatometer was removed by evaporation at room temperature by repeatedly exhausting and admitting air. The dish was placed in a vacuum desiccator and the toluene removed in a similar manner. The loss in weight gives the weight of toluene.

Weight of mercury filling dilatometer at 59.807° = 844.32 g.

Results on Pyrex Glass.—The data of one typical experiment with mercury alone in the dilatometer are given in sufficient detail in Table I to permit a judgment in regard to the factors which control the precision of the results and to make clear how the data are interpreted. The results of other similar experiments are given only in a summarized form in Table II.

In this experiment it was found that when the dilatometer contained 844.32 g. of mercury (corrected to vacuum) it was completely full up to the point P at 59.80_7°. Then 1.4102 g. of mercury was added which required a drop in temperature to 50.03_4°, to permit the extra mercury to enter the instrument. Then in succession the several amounts of mercury shown in column 2 were added and the equilibrium temperature after each addition of mercury is shown on the line below in the first column. The weights of mercury which would have been required for successive drops of exactly 10°, assuming that the initial temperature had been exactly 60°, are shown in column 4. The weight of mercury required to fill the dilatometer at each ten-degree interval is easily computed from these data. By using the known values for specific volume of mercury given in column 5, the volume at each temperature may be computed. The increase in volume of the dilatometer from 20°, ΔV_D, is shown in column 6. The total expansion per cubic centimeter of dilatometer at 20° is given in column 7. This is of course a measure of the expansion of Pyrex glass.

TABLE II

SUMMARY OF CHANGES IN VOLUME OF PYREX DILATOMETER FROM 20° TO t° PER CC. OF VOLUME AT 20°. $\Delta V/V_{20} \times 10^6$

	Temp., °C.				
	20	30	40	50	60
	0	99.0	195.9	293.5	392.3
	0	100.5	198.7	296.2	393.8
	0	98.5	197.7	294.4	393.9
	0	99.4	196.2	291.5	389.9
	0	98.3	198.9	297.7	396.3
Average	0	99	197	295	393

The equation $V_t = V_{20}[1 + 9.85 \times 10^{-6}(t - 20)]$ agrees with these results within the experimental error. These experiments therefore give $9.8_5 \times 10^{-6}$ as the cubical coefficient of expansion of Pyrex glass over the range from 20 to 60°. The linear coefficient of expansion of Pyrex glass is given in the "International Critical Tables" on the authority of the Corning Glass Company as 3.2×10^{-6} over the range 19 to 350°. This corresponds to a cubical coefficient of 9.6×10^{-6}.

Results on Toluene.—Four complete experiments were carried out in which the dilatometer contained toluene for about three-fourths of its volume. The results are summarized in Table III.

The figures given in Table III are the volumes which 1 cc. of toluene measured at 20° would occupy at the temperatures specified at the top of the columns. These results may be expressed within the limit of error of the experiments by the equation $V_t = V_{20}[1 + 0.001069(t - 20) + 0.00000169(t - 20)^2]$ as shown in the last line of Table III. The true coefficient of expansion dV/Vdt, at any temperature is readily found by differentiation of the above equation. The values are as follows: 20°, 0.001069; 30°, 0.001091; 40°, 0.001112; 50°, 0.001133; 60°, 0.001151.

Results on Salts.—The data for one typical experiment on a salt are given in sufficient detail in Table IV to permit a judgment of the factors which control the precision of the results, and the results of the other experiments are given only in summarized form in Table V. In our first experiment with thallous bromide, the dilatometer contained 229.51 g. of thallous bromide, 1.09 g. of toluene and, when completely filled at 20°, it contained 391.68 g. of mercury. The volume of the dilatometer at 20° was 60.994 cc., of which 1.09/0.866 = 1.259 cc. was occupied by toluene; and 391.68 × 0.0738233 = 28.915 cc. was occupied by mercury. The volume of the thallous bromide was therefore 60.994 − 1.259 − 28.915 = 30.820 cc. The significance of the first four columns will be sufficiently obvious by analogy with Table I. The change in volume of the dilatometer is computed from our special experiments with mercury alone in the instrument. Column 6 gives the change in volume of the mercury present. The seventh column gives the change in volume of the toluene which is computed from the weight of toluene and its coefficient of

expansion already determined. It is obvious that the change in volume of the salt $\Delta V_S = \Delta V_D - \Delta V_T - \Delta V_{Hg} = +0.04698$. Column 9 gives the volume of the salt at temperature, t, relative to the volume at 20°; $(V_S + \Delta V_S)/V_S = V_{S,t}/V_{S,20} = (30.820 + 0.04698)/30.820 = 1.00152_4$.

The experimental error in the determination of the weight of mercury required to be added for each ten-degree interval may be as much as 0.1% since the error in measuring this interval may be as much as 0.01°. Errors in temperature, however, are not cumulative. In this experiment an error of 0.1% in the weight of mercury for a change of 10°, will cause an error of 0.00011 cc. in the ΔV_{Hg} and hence in ΔV_S. On the other hand, an error of as much as 0.8 g. in the total weight of mercury present would be required to cause an equally great error (0.00011 cc.) in ΔV_{Hg} but since the weight of mercury can be determined within about a centigram the error from this cause is negligible. Further, an error of 0.01 g. in weight of toluene used would make an error of 0.00013 cc. in ΔV_T and therefore in ΔV_S. It is evident that great care must be taken in the determination of the weight of toluene and the unavoidable error in finding the weight of toluene used is probably the greatest single source of error in the final result. Table V summarizes the results for the four salts studied.

These results may be expressed in the form

$$V_t = V_{20}\,[1 + a(t - 20) + b(t - 20)^2]$$

for AgI; $V_t = V_{20}\,[1 - 0.0000016\,(t - 20)]$

for TlI; $V_t = V_{20}\,[1 + 0.00013419\,(t - 20) + 0.0000000321\,(t - 20)^2]$

for TlBr; $V_t = V_{20}\,[1 + 0.00015182\,(t - 20) + 0.0000000493\,(t - 20)^2]$

for TlCl; $V_t = V_{20}\,[1 + 0.00015754\,(t - 20) + 0.0000000586\,(t - 20)^2]$

These equations agree with our experimental data over the range from 20 to 60° with an average deviation of less than three parts in a million for thallous iodide, and within one part in a million for the other three salts. The true coefficient of expansion at any temperature, t, would be

$$\frac{dV}{Vdt} = \frac{a + 2b\,(t - 20)}{1 + a\,(t - 20) + b\,(t - 20)^2}$$

The coefficients of expansion of these salts are as follows:

TABLE VI

A discussion of the correlation of the coefficient of expansion with the compressibility and other properties will be postponed until data on more salts are available.

Summary

1. A new form of differential weight dilatometer for the determination of the cubical coefficient of expansion of solids and liquids is described. The instrument functions simultaneously as a thermostat regulator and controls its own temperature so that it is exactly filled.

2. Measurements have been made on six substances between 20 and 60°, giving the following mean cubical coefficients of expansion: Pyrex glass, $9.8_5 \times 10^{-6}$; toluene, 1.111×10^{-3}; silver iodide, $-1._6 \times 10^{-6}$; thallous chloride, 1.59×10^{-4}; thallous bromide, 1.53×10^{-4}; thallous iodide, 1.35×10^{-4}.

An Unknown Property of the Calomel Half-Cell and the Estimation of Bromide–Chloride Mixtures

By F. L. Hahn

It is a well-known fact that calomel reference electrodes, although prepared in the same manner and with carefully purified salts, do not always show exactly the same potential and they sometimes change as to their potential some months after their formation. The reasons for this change are not known. The author has found that rather small amounts of bromide contained in the potassium chloride vary the potential of the electrodes to such a degree that no one could anticipate it.

Furthermore, it was found that commercial potassium chloride always contained bromide, up to a degree of 0.1 and 0.01% or occasionally somewhat more even in the purest grades.[1] Potassium chloride free from bromide may be prepared by precipitating a saturated solution several times with alcohol. The calomel used will also contain varying quantities of bromides. In all cases where for this reason the solid phase is not in equilibrium with the solution the electrodes will not be stable.

Experiments

I. Eight tubes like A and B in Fig. 1 were filled with equal quantities of mercury, calomel and 1 *N* potassium chloride. They were connected with each other by a siphon filled with potassium chloride and agar. The e. m. f. of these cells was measured by a compensation apparatus; the measurements could be made with no more error than 0.2 mv. No difference of potential was found between two of these half-cells during a period of five days. Then 1 *N* potassium bromide solution was added to the tubes and the following differences of potential were measured with tube 1 as a reference electrode (Table I).

Table I

Tube	1	2	3	4	5	6	7	8
Mole % KBr	0	0.02	0.05	0.1	0.2	0.5	1	0
E. m. f. (mv.)	..	− .7	−0.9	−3.0	−3.7	−6.2	−12.8	0
Two days later	..	− .5	−0.9	−1.8	−2.7	−5.3	− 6.2	0

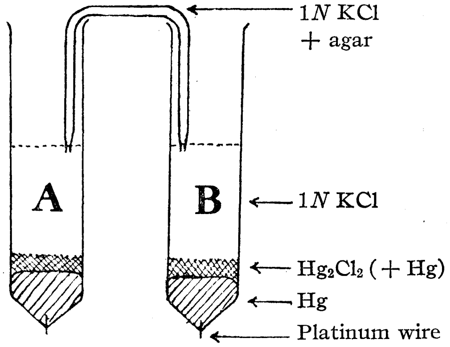

Fig. 1.

II. A calomel half-cell was used as a reference electrode. The siphon of the cell was finely drawn out on the exterior end and stopped by addition of agar. One cc. of mixtures of 1 *N* potassium chloride and bromide was poured into tubes like those in Fig. 1 but smaller, and one drop of a phosphate buffer solution ($p_H \sim 6$) and one drop of 0.01 *N* mercurous perchlorate were added thereto. The e. m. f. of the cell formed in this way was measured by compensation. By standardizing this combination, using mixtures of known percentages of bromide, it was possible to estimate the composition of unknown mixtures within a few minutes.

Summary

1. The potential of a calomel half-cell is strongly influenced by even the smallest contents of bromide in the potassium chloride used.

2. It is possible to use this effect in order to obtain a rapid estimation of bromide in chloride.

Reaction of Organic Anions with Basic Thorium Chloride Hydrosols. Reversal of Charge with Salts of the Hydroxy Acids and with Nitric Acid

BY ARTHUR W. THOMAS AND CHESTER B. KREMER

A previous investigation[1] dealing with the effect of neutral salt solutions upon thorium oxychloride hydrosols has established an order of reactivity for twelve anions in respect to their ability to displace hydroxo groups from the micellar complex, the increase in *p*H of the hydrosol upon addition of the salt solutions serving as a measure of this displacement. It was found that, as in the case of other "oxide" hydrosols, this action of different anions varied widely; citrate and oxalate being very potent, while chloride and nitrate had but slight effect. Since displacement of hydroxo groups from the complex may be considered to constitute chemical combination of the displacer with the central metallic atom, the reactivity of these anions should be determined by the number and position of combining groups present in each. For the purpose of investigating the influence of chain length and number of carboxyl groups, the potassium salts of the aliphatic monocarboxylic series from formate to valerate, inclusive, and the potassium salts of the aliphatic dicarboxylic series from oxalate to pimelate, inclusive, were studied.

Preparation of the Hydrosols.—The hydrosols used in this investigation were prepared either by the peptization of hydrous thorium dioxide with dilute hydrochloric acid (Sols D, E, F) or by the addition of ammonia to thorium chloride solutions until a permanent turbidity was produced (Sols A and B). All sols were dialyzed against distilled water for varying lengths of time. The micelles of the sols thus prepared were charged positively. These five hydrosols, of which A, B and F were turbid and D and E cloudy in appearance, are described in Table I.

TABLE I

COMPOSITION OF HYDROSOLS

Sol	Thorium, milliequiv. per liter	Chloride, milliequiv. per liter	Eq. Th/Eq. Cl	*p*H[a]
A	51.8	7.3	7	4.02
B	62.8	11.6	5	4.06
D	37.3	3.9	10	3.89
E	63.9	5.7	11	3.97
F	100.9	13.1	8	4.16

[a] *p*H values are those obtained immediately at the completion of dialysis.

Reactions with Salt Solutions.—By means of a technique previously described[1] the *p*H increasing effect of various salts was measured. The results with the potassium monocarboxylates for Sols A and D (typical of all) are given in Table II. It is seen that the difference in reactivity between these homologous anions is slight. This is as expected, since their combination in the complex is controlled by the same factor, *i. e.*, the single carboxyl group.

TABLE II

*p*H INCREASING EFFECT OF POTASSIUM MONOCARBOXYLATES UPON BASIC THORIUM CHLORIDE HYDROSOLS

Final concn. of salt (N)	Formate	Acetate	Propionate	Butyrate	Valerate
		Sol A			
0.0000	3.3	3.3	3.3	3.3	
.0025	3.9	4.4	4.5	4.4	
.0050	4.6	5.2	5.3	5.2

.0250	6.4	6.6	6.5	6.4	6.5
.0500	6.6	6.8	6.6	6.4	6.5

The results with the potassium dicarboxylates are shown for Sol A (typical of all) in Fig. 1. Oxalate is the most reactive of the dicarboxylic anions tried. Malonate is easily seen to be somewhat more reactive than succinate; glutarate, adipate and pimelate are practically the same in reactivity and only slightly less active than succinate. It seems apparent that from glutarate upward in the homologous series the carboxyl groups are too far away to have any effect upon each other and these higher members act more like the monocarboxylates. It also follows from these results that the closer the carboxyl groups are to each other, in the lower members of this series, the more reactive they are as complex formers.

---

[1] A. W. Thomas and C. B. Kremer, THIS JOURNAL, 57, 1821 (1935).

Comparative Action of Isomeric Salts.—It follows from the experiments cited that anions containing the same number of combining groups in the same relative position (or separated sufficiently so as to be without effect upon one another) should exhibit essentially the same reactivity with basic thorium chloride hydrosols; but if the relative positions of the combining groups differ, then the reactivity differs and the one with the combining groups in closest proximity should be the more reactive. A study of the following isomeric salts offered an opportunity to test the above statement: (1) isomers in the monocarboxylic series—potassium butyrate and isobutyrate, potassium valerate and isovalerate; (2) optical isomers—the potassium salts of the inactive tartaric and malic acids and the salts of *d*-tartaric and *l*-malic acids; (3) *cis–trans* isomers—potassium maleinate and potassium fumarate.

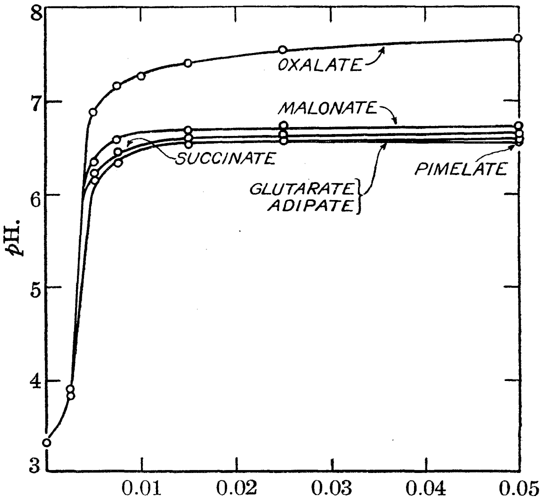

Fig. 1.—Effect of potassium salts of dicarboxylic acids upon the *p*H value of a basic thorium chloride hydrosol.

The ability of the monocarboxylic isomeric salts to raise the *p*H value of the sols was found to be identical throughout the concentrations used. The same was true for optical isomers. The fact that no measurable difference in effects between butyrate–isobutyrate and valerate–isovalerate existed, was not unexpected since the variation between each pair is restricted to that end of the molecule which does not enter into combination with the metal atoms of the micellar complex.

With the *cis–trans* isomers, however, potassium maleinate proved to be more effective than potassium fumarate. The results obtained with these two isomers upon two of the hydrosols (typical of all) are depicted in Fig. 2. It is interesting to note in this connection that in the crystalloidal chemistry of certain metals, the *cis* acid, citraconic, is a more active complex former than the *trans* acid, mesaconic.[2] Likewise, when the combining groups are hydroxylic rather than carboxylic, the *cis* diols are more active than the *trans* diols.[3]

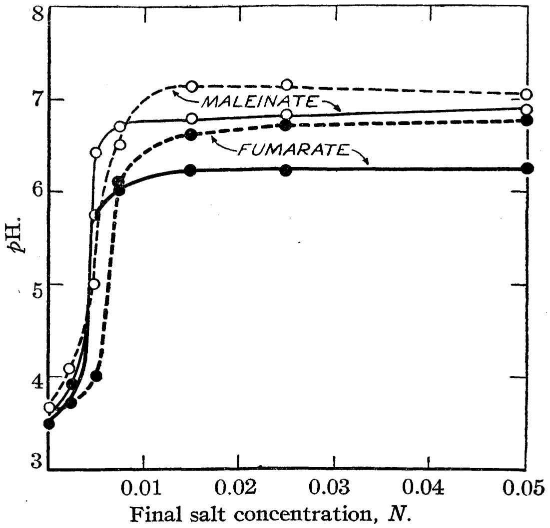

Fig. 2.—Effect of potassium maleinate and fumarate upon *p*H values of basic thorium chloride hydrosols: – – – –, Sol F; ————, Sol E.

Action of Hydroxy Organic Anions.—When certain salts, such as potassium citrate, tartrate, malate, glycolate, lactate and mucate were added to basic thorium chloride hydrosols, small amounts produced precipitation followed by redispersion upon further addition of the electrolyte. Electrophoresis experiments upon the redispersed solution showed that the charge on the micelles (originally positive) had become negative. Other organic anions, not containing hydroxy groups, did not cause charge reversal with the exception of malonate which showed a slight tendency at higher concentrations which may be explained by the existence of the enol form.

Since the potassium salts of hydroxy acids produced negatively charged micelles when added to basic thorium chloride sols, it was thought probable that negatively charged hydrosols could be produced by action upon hydrous thoria. Hy-

(3) J. Böeseken, *Bull. soc. chim.*, **53**, 1332 (1933).

drous thoria was prepared by precipitation from thorium chloride with ammonia and was washed free of chloride by distilled water with the aid of a centrifuge. Portions of the purified hydrate were then placed in 250-cc. "Non-Sol" bottles, 200 cc. of 0.1 N salt solution added and the mixture rotated at 7 r. p. m. at 25 ± 0.2° for forty-eight hours. At the end of that period the mixture was centrifuged (1200 r. p. m., 42 cm. radius) for one hour and the charge on the dispersed material determined in an electrophoresis "U" tube. The salts used, potassium, citrate, tartrate, glycolate, mucate and malate, all produced turbid dispersions containing negatively charged micelles.

Action of Concentrated Acids.—It was noted, upon the addition of 12 molar nitric acid to a thorium oxychloride sol, that the latter was first precipitated; then on further addition of the acid, the precipitate redispersed forming a solution as turbid as the original sol. When water was then added to this turbid solution, reprecipitation occurred and on adding a small excess of water, a solution resembling the original sol in turbidity, was produced. Addition of concentrated nitric acid again first produced a precipitate, then a turbid liquid; and water again reversed the procedure as described above.

The sol produced on addition of excess concentrated nitric acid existed at room temperature for only ten or fifteen minutes, when it changed to a clear crystalloidal solution. The sol produced by adding excess water to the acid sol was much more stable, dispersing to a clear solution after standing a few hours at room temperature. Electrophoresis experiments showed that the acid sol micelles were negatively charged; while the micelles of the sol obtained upon addition of excess water to the acid sol, were positively charged.

The following explanation is advanced for what has been described. Nitrate ion has but slight tendency to be coördinatively bound to the central atom. Increasing the concentration, however, will cause such a weak "penetrator" to enter the micelle, but it will only remain in the complex if a high concentration of nitrate ion be maintained. Thus when concentrated nitric acid is added to the sol, the increasing concentration of nitrate ion forces some of this anion into the micelle, replacing aquo groups mainly, while the hydrogen ion converts hydroxo groups in the complex to aquo groups. Replacement of water molecules by nitrate ions results in a diminution of charge on the cation, leading eventually to precipitation. Upon further addition of acid, continued penetration of the nitrate ion takes place and the charge on the micelle becomes negative. After this has happened, addition of water decreases the concentration of nitrate ion present. Nitrate ion therefore moves out of the complex and is replaced by water molecules. This continues upon further dilution and is accompanied by a decrease in negative charge on the micelle until once again the vicinity of zero charge is reached and precipitation occurs. Excess water causes further replacement of nitrate by water molecules and now the charge on the particles becomes positive and the precipitate redisperses.

While the above is happening, deolation is also occurring owing to the high hydrogen-ion activity of the solution. Continued deolation leads to the crystalloidal state. Stiasny[4] working with the crystalloidal chromium complexes, has pointed out that order of tenacity with which certain anions are held to the metal atom and the resulting deolating effect is $SO_4 > Cl > NO_3$. In the case of hydrous alumina[5] and with basic zirconium chloride hydrosols[6] it has also been shown that deolation occurs more readily when the aluminum oxide is treated with acids or the zirconium sol with salts containing strongly coördinative binding anions. The increased attraction of the metal atom for these anions apparently lessens the strength with which it holds the ol groups and deolation by acid is thereby facilitated. The metal atom in this case has little attraction for nitrate and therefore the ol bonds are considerably stronger than if chloride or sulfate were in the complex. It should therefore be expected, with acids of comparable strength as to hydrogen ion, that the order for deolation and subsequent formation of the crystalloidal state should be $H_2SO_4 > HCl > HNO_3$. That this is true for basic thorium sols has been demonstrated qualitatively. The deolating reaction described above with 12 M nitric acid, required from ten to fifteen minutes for completion.[7] When 12 molar hydrochloric acid was used, precipitation occurred and further addition of this acid caused redispersion as in the case of nitric acid but deolation to the crystalloidal state was much

(7) There are individual differences in sols.

apid. Dilution with water tended to effect al reversal, but this procedure could not be ed as in the case of nitric acid. When the sed was 6 molar sulfuric, precipitation re- followed by rapid conversion to a clear lloidal solution on addition of more acid and ersibility with water could be effected.

Summary

reactivity of an organic anion with basic m chloride hydrosols depends not only on mber of combining groups present, but on elative positions, and the closer the com- groups are to each other, the more active anion.

Hydroxy organic anions reverse the charge of basic thorium chloride (cationic) micelles producing aniono thoreate micelles. Peptization of hydrous thorium dioxide by the potassium salts of these anions also results in the production of hydrosols containing negatively charged micelles.

Concentrated nitric acid reverses the charge of basic thorium chloride micelles producing short-lived nitrato thoreate micelles.

The order of deolation of basic thorium chloride sols and subsequent formation of the crystalloidal state with concentrated inorganic acids has been found to be sulfuric > hydrochloric > nitric.

A New Organic Reagent for Cadmium

BY ALFRED W. SCOTT AND ELEANOR G. ADAMS

Introduction

lack of a specific easily recognizable test for um ion in the presence of cupric ion has rise to many difficulties, especially in ele- ry classes in qualitative analysis. Copper ally converted into the cyanide complex or itated as the sulfide. The cyanide separa- s dangerous for inexperienced students, and dmium sulfide precipitated by the second d is often masked by traces of impurities. nvestigation was undertaken in an attempt pare a new organic reagent which would be c for cadmium ion, characterized by a d precipitate, sensitive to fairly low concen- ns of the metallic ion and not too easily ed by interfering ions.

eral new organic compounds containing were prepared by combining organic radi- hich are present in reagents that have been useful in detecting cadmium ions. These tested as analytical reagents with nitrate ons of the cations met in qualitative analy- The most effective precipitant prepared was uinolyl)-4-allyl thiosemicarbazide. A satu- solution of this reagent in 50% alcohol, in resence of potassium iodide, gave a yellow itate with cadmium ion as dilute as one part nillion. Cadmium was detected in the pres- of copper (in the absence of ammonia and sulfate) by the addition of potassium iodide solution, thiosemicarbazide solution, and ammonium hydroxide; cadmium gave a yellow precipitate, while copper gave a blue solution.

Experimental

Materials.—Allyl isothiocyanate, 2-aminoresorcinol hydrochloride (practical), 2-amino-4-nitrophenol, and 2-quinolylhydrazine, all were from Eastman Kodak Company.

$C_3H_5NHCSNHC_6H_3(OH)_2$, **N-Allyl-N′-2,6-dihydroxyphenyl thiourea,** was prepared from equimolar solutions of allyl isothiocyanate and 2-aminoresorcinol hydrochloride in 95% alcohol. The brown needles from alcohol–ether decomposed at 230°. This compound is too insoluble in water for use as a precipitant.

$C_3H_5NHCSNHC_6H_3(OH)(NO_2)$, **N-Allyl-N′-2-hydroxy-5-nitrophenyl thiourea,** was prepared from equimolar solutions of allyl isothiocyanate and 2-amino-4-nitrophenol in ether. The orange-red needles, melting at 122°, are soluble in alcohol, and somewhat soluble in water and in chloroform. The saturated water solution of this reagent added to nitrate solutions of the cations gave precipitates only with cadmium, copper, iron and nickel, the first three being yellow and the last white. The use of a 1% solution of the reagent in alcohol makes the precipitation of cadmium more complete and more sensitive, but care must be taken that excess reagent itself does not precipitate because of its slight solubility in water.

$C_3H_5NHCSNHNHC_9H_6N$, **1-(2-Quinolyl)-4-allyl-thiosemicarbazide,** was prepared from 10 cc. of allyl isothiocyanate and 16 g. of crystalline 2-quinolylhydrazine in ether; yield 20 g. Slow recrystallization from ether gave colorless crystals, melting at 158°, fairly soluble in ether alcohol, and benzene, slightly soluble in cold water. The molecular weight of the thiosemicarbazide was estimated by the Rast camphor method to be approximately 258. Element analyses proved the presence of C, H, N and S.

Anal. Calcd. for $C_{13}H_{14}N_4S$: C, 60.47; H, 5.43; N, 21.72. Found: C, 59.69; H, 5.41; N, 21.77.

The saturated solution of this reagent in 50% ethyl alcohol (0.05 g. per 100 cc.) added to normal nitrate solutions of the cations gave yellow precipitates with cadmium, zinc, and mercurous mercury, and brown precipitates with copper, nickel, cobalt, and silver. The presence of various anions (chloride, bromide, iodide, sulfate, cyanate, and thiocyanate) was found to affect the completeness of precipitation and the appearance of the precipitate to some extent. The most satisfactory test was secured in the presence of iodide ions, when a bright greenish-yellow precipitate was formed even with traces of cadmium ions. This precipitate contained cadmium, nitrogen, sulfur, potassium and iodine.

The sensitivity of the cadmium thiosemicarbazide iodide precipitation was tested by adding 1 cc. of 50% aqueous alcohol (saturated with the thiosemicarbazide and with potassium iodide) to 10 cc. each of solutions con respectively, 1, 0.05 and 0.01 mg. of cadmium ion.

$Cd(NO_3)_2 \cdot 4H_2O$, g./l.	Cd^{++}	Effect
0.278	1/10,000	Filterable precipitate
.0139	1/200,000	Filterable precipitate
.00278	1/1,000,000	Opalescence; precipitate after two minutes

The detection of cadmium ions in the presence o ions was accomplished by a modification of th procedure, in the absence of the ions of zinc, nic cobalt. Interfering ammonia and sulfate, if prese removed by boiling off ammonia and precipitat sulfate with barium chloride. To this solution wa saturated potassium iodide solution and brown iodide precipitated. Without filtering, the add saturated thiosemicarbazide solution (50% alcoh cipitated the yellow cadmium thiosemicarbazide complex. Upon addition of ammonium hydrox copper salt dissolved but not the cadmium c Thus a blue solution indicated copper, while a yell cipitate indicated cadimum.

Summary

1. N-Allyl-N′-2,6-dihydroxyphenyl tl and N-allyl-N-2-hydroxy-5-nitrophenyl were prepared and tested as analytical re

2. 1-(2-Quinolyl)-4-allyl thiosemicarb prepared. It is a sensitive precipitant cadmium ion, and a good qualitative re cadmium in the presence of copper.

Activity Coefficients of Sulfuric Acid in Anhydrous Ethyl Alcohol from Electrom Force Data

BY A. W. SCHOLL,[1] A. WITT HUTCHISON AND G. C. CHANDLEE

In continuation of the work in this Laboratory on the properties of non-aqueous solutions it was thought that a study of the activity coefficients of sulfuric acid in ethyl alcohol solutions would be of interest. Data were obtained by the electromotive force method using the cell H_2, H_2SO_4, Hg_2SO_4s, Hg. Activity coefficients were calculated from these data by the use of the Debye–Hückel first approximation and also by the use of the extended equation of Gronwall, La Mer and Sandved.

Experimental

All electromotive force measurements were made with a Leeds and Northrup type K potentiometer by the null method. A Weston standard cell was used as a reference. It was checked from time to time during the course of the experiments against several other cells of the same type recently calibrated at the Bureau of Standards. A type R galvanometer was used as an indicating inst All lead wires and the standard cell were shielded.

The thermostat was maintained at a tempera 25 ± 0.01°. The cells were placed in a copper tan with oil, suspended in the thermostat water.

The cells were of the H type and were made by c ing two Pyrex test-tubes by means of a short p Pyrex tubing. A piece of 7-mm. tubing was seale bottom of each test-tube and bent so that it becam lel to the tube. One tube then became the m mercurous sulfate half-cell, and connection was m it by means of a platinum wire dipping into the m The test-tubes were fitted with well ground, gas tigh stoppers. Through the one stopper two tubes were into the ends of which platinum wires were sealed t as the platinum electrodes. Hydrogen was bubl through the bottom of the hydrogen half cell and e from the top through an alcohol trap. It was sa with alcohol by bubbling it through a wash bott mersed in the thermostat, containing the solutio measured.

The more concentrated solutions were prepared addition of sulfuric acid from a weight pipet to a w

---

[1] From a thesis presented by A. W. Scholl in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1934.

amount of the alcohol. The others were prepared by dilution of the stronger solutions. The electrodes were freshly platinized before each run. It was found that the cells reached a constant electromotive force (±0.2 mv.) after hydrogen had bubbled through them for about one hour. In the several cases studied the cells maintained this value for at least five or six hours. In general when the value had been constant for ninety minutes it was assumed that equilibrium had been reached.

Materials.—Ninety-five per cent. ethyl alcohol was purified by distilling from concentrated sulfuric acid (15 cc. of acid per liter of alcohol) to remove amines and most of the water. The distillate was next distilled from alkaline silver nitrate (5 g. per liter) to remove the aldehydes and similar oxidizing bodies. Finally, the last trace of water was removed by refluxing with fresh calcium oxide and then fractionated from aluminum ethoxide. The alcohol thus obtained had a specific conductivity of 1.5×10^{-7} mhos.

Anhydrous sulfuric acid was made by mixing concentrated acid with fuming acid of Baker's Analyzed Grade, as described by Kendall and Carpenter.[2] It had a freezing point of 10.46°.

Mercurous sulfate[3] was made electrolytically from redistilled mercury and dilute sulfuric acid. It gave results in good agreement with those obtained by using Baker's C. P. grade.

Mercury of C. P. grade was further purified by washing with dilute nitric acid, dilute alkali and water and then by vacuum distillation.

Electrolytic hydrogen was passed over finely divided platinum in a furnace at approximately 600° to remove the oxygen. The hydrogen was then dried with phosphorus pentoxide and passed into the cell through a saturating trap kept at the thermostat temperature.

Results and Discussion

The experimental values of the electromotive forces corrected to a partial pressure of hydrogen of one atmosphere together with the corresponding molalities are listed in Table I. In the third column are listed values of the square root of the ionic strength calculated from the volume concentration on the assumption that the sulfuric acid is completely dissociated. The concentrations were obtained from the molalities by use of the expression $C = M/(V_0 + K\text{M})$, where V_0 is the specific volume of pure alcohol and where K was given the value of 0.034 corresponding to its value in aqueous solutions of sulfuric acid.

In order to calculate the activity coefficient by the use of the well-known equation $E = E_0 - (3RT/2F) \ln \gamma M4^{1/3}$, it is necessary to evaluate E_0. This is ordinarily done by extrapolating to zero concentration a plot of E_0' against some function of the concentration where $E_0' = E + (3RT/2F) \ln M4^{1/3}$. Examination of the lower curve of Fig. 1 where the open circles represent experimental values of E_0' plotted against the square root of the ionic strength show that a simple extrapolation would yield an uncertain value

of E_0 in this case. If it is assumed that the Debye–Hückel equation[4]

$$-\log \gamma = \frac{2.96\ Z_1Z_2\ \sqrt{\mu}}{1 + .592 \times 10^8\ a\ \sqrt{\mu}}$$

with a reasonable value of the ion diameter is applicable to these solutions a value of E_0 may be calculated from each experimental measurement. The constancy of these values indicates the validity of the assumptions made. In columns five and six of Table I values of $-\log \gamma$ and of the corresponding E_0 are listed. These calculations were made with a value of 2.5×10^{-8} cm. for the ion diameter. In the figure the solid curve represents a plot of E_0' calculated from the values of $-\log \gamma$ and the value of 0.420 for E_0. The slope of the limiting law is also indicated on the figure. As may be seen from the figure and also from Table I the calculated and experimental values are in reasonably good agreement in the dilute solutions except for the first point.

Since the dissociation of the second hydrogen ion from sulfuric acid is not complete even in water solutions it might reasonably be assumed to be even less so in the solutions of alcohol. The limiting case would of course be one in which only the primary dissociation would be considered. The equation for the electromotive force, from this point of view, becomes $E = E_0 - (2RT/2F) \ln \gamma M$ and the ionic strength is equal to the concentration. Calculations from this point of view were made using the extended equation of Gronwall, La Mer and Sandved,[5] and an assumed ion diameter of 1.7×10^{-8} cm. The shaded circles of the figure represent the experimental points, the full curve the calculated values and the straight line the limiting law on this basis. Results of these calculations showed that the equation is not convergent for this small ion diameter in alcohol. However, a larger value for the ion diameter would not be in agreement with the experimental values.

Since the experimental curve lies above the limiting law in dilute solutions it is obvious that the application of the first approximation of Debye and Hückel will not account for the experimental curve. Although the extended equation does give constant values for E_0 on this basis the significance of this is perhaps questionable in view of the non-convergence of the series.

Summary

Activity coefficients of sulfuric acid solutions in ethyl alcohol have been determined by measurement of the cell H_2, H_2SO_4, $Hg_2SO_4(s)$, Hg. The data have been treated by the Debye–Hückel equation and by the extended equation of Gronwall, La Mer and Sandved.

The Nature of the Surface of Copper Catalysts

BY W. WALKER RUSSELL AND LEONARD G. GHERING[1]

Experimental evidence concerning the nature of catalytic surfaces is conflicting. Kinetic measurements are in general consistent with the concept of a uniformly active catalytic surface, while adsorption phenomena for the most part require a surface of non-uniform nature. This apparent conflict would largely disappear were it found that the reaction catalyzed proceeded predominantly on a relatively few surface types out of many existing on a surface. It is well recognized that a knowledge of the different qualities of catalytic surface present and their distribution is vital to any theory of the catalytic surface or mechanism of catalysis.

By studying the changes in catalytic activity produced by controlled, selective poisoning, much can be learned about the nature of a catalyst surface. Studies have been made of synthetic ammonia catalysts[2] using oxygen and water as poisons; of thoria as a catalyst using water and acetaldehyde to poison the decomposition of

ethyl alcohol;[3] and of platinum[4] employing mercury ions as poison for hydrogen peroxide decomposition and for hydrogenation of several unsaturated organic compounds in the liquid phase. In this last work the activity of the catalyst was found to decrease in a linear manner as the extent of poisoning increased, and this has been interpreted to mean that the catalytic surface of platinum is predominantly uniform in character.

Previous work[5] had shown oxygen to be strongly sorbed by active copper catalysts, and since the heats of sorption decreased with increasing sorption, at least some selectivity in the sorption process was to be anticipated. Furthermore, sorbed oxygen was known[5] to be capable of completely suppressing the hydrogenating activity of copper at 0° and yet to be easily removed by subsequent reduction at higher temperatures. Because of these facts, it was decided to use oxygen as a poison in the study of the nature of the catalyst surface which the well-known ethylene–hydrogen reaction finds active at 0°. Although ease of manipulation has caused this reaction to be employed frequently in a static system, a flow method has been used throughout the present work in order that the results should be free from errors due to adsorption, induction periods,[6] transitory fluctuations in catalytic activity,[7,8] and the like. The principal significance of the work which follows lies in its elucidation of the nature of the surface of catalytically active copper in the light of three different methods of oxygen poisoning as well as measurements of heats of oxygen sorption.

Apparatus and Experimental Method

Apparatus.—The apparatus used in the controlled poisoning of the catalysts was similar to that used earlier[9] except that provision was now made for admitting gases to either one or both ends of the catalyst bulb. The reaction velocity measurements necessitated ethylene and hydrogen flow-meters which were cut in ahead of the catalyst bulb and trap. These flow-meters were filled with dibutyl phthalate. To the exit tube of the catalyst bulb there was attached a constant-head gas collecting buret[10] so designed that measured volumes of the exit gases could be collected without producing any disturbance of gas flow in the system.

The Bunsen ice calorimeter used for the thermal measurements was essentially of the type already used by others[11] except that the capillary was permanently sealed in place and the stopcock and mercury reservoir for adjusting the position of the mercury thread were omitted. Also, because the calorimeter construction prevented direct observation of the ice mantle, an indicator manometer was temporarily attached to the outer end of the capillary during the formation of the mantle. After a quick movement of the manometer mercury signaled the formation of a mass of ice crystals, heat was introduced until the original manometer reading was nearly reached thus leaving but a few ice nuclei. Upon cooling a second time the mantle formed slowly and the amount of mercury in the calorimeter was such that a suitable mantle thickness was obtained when the mercury thread was well out on the scale. Otherwise the method of using and calibrating the calorimeter was the same as before.[5]

Preparation and Purification of Gases.—The treatment of the helium, hydrogen and oxygen was the same as already described[9] except that in the reaction velocity measurements the hydrogen was further purified by passage over a thoria promoted nickel scrubbing catalyst heated to 250°. Cylinder ethylene was passed at room temperature over a similar scrubbing catalyst after first going through activated charcoal at about 25°. After metering, both gases were further dried and mixed in a tube containing anhydrone and then passed through a trap cooled with solid ammonia before admission to the catalyst. Cylinder nitrous oxide was purified by passing through caustic potash solution, calcium chloride, phosphorus pentoxide and then into a liquid air trap from which only the middle raction was used.

Preparation of Catalysts.—Granular copper catalysts were prepared by sifting Kahlbaum granular cupric oxide "for analysis" so as to retain only particles of about 2–4 mm. diameter, and then reducing slowly with hydrogen at 250°. Cu XXI weighed 36.28 g. Cu XXII was produced by again reducing Cu XXI after accidental admission of air to the latter at 180°. Cu XXII proved more active yet sorbed somewhat less oxygen than Cu XXI. Cu XXIII and Cu XXV were approximately half portions of Cu XXII and weighed 19.83 g. and 16.45 g., respectively. Cu XXIV was produced from Cu XXIII by sintering the latter at 400°.

Procedure for Reaction Velocity Runs.—The reaction velocity runs were made, on either poisoned or unpoisoned surfaces, by admitting hydrogen to the evacuated catalyst at 0° and immediately displacing it with the metered, one-to-one ethylene–hydrogen reaction mixture at a constant rate of flow, *e. g.*, 10 to 20 cc. per minute. Zero time was taken as the instant of admitting the reaction mixture, and after five minutes the conversion was computed from the flow meter readings and the time required to collect 10 or 20 cc. of exit gases. Similar data were taken at ten-minute intervals for from one and one-half to two hours, the period of the run. At the end of the run the catalyst was flushed with hydrogen at 0° for half an hour, and then

heated slowly to the temperature of reduction at which the hydrogen flow was continued for the necessary time. The catalyst was then evacuated.

Direct Oxygen Poisoning.—In order to obtain reliable and reproducible catalyst activities with this and the other methods of poisoning, it was necessary to employ a strictly standardized method of procedure. The well-evacuated catalyst was cooled to 0°, a small amount of helium added, and then an accurately measured amount of oxygen was admitted slowly in small increments to both ends of the catalyst bulb. As previously found[5] the oxygen was instantaneously, completely and irreversibly sorbed until saturation of the surface was closely approached. Then sorption became less instantaneous. Because some slow sorption occurred near saturation, the oxygen sorptive capacity of the copper could not be very accurately determined, but was taken arbitrarily as the total amount sorbed when an increment equal to about 2% of the previous sorption required as long as five minutes to drop to a pressure of 0.05 mm. After a reaction velocity run on the oxygen poisoned surface, reduction with hydrogen was carried out at 275° for one hour followed by evacuation at 225° for two hours. Following a run on an unpoisoned surface the temperature of reduction was 225.°

Indirect Poisoning with Oxygen.—Indirect poisoning was accomplished by three methods of selective reduction. Selective reduction (1), used for Cu XXI, comprised flushing the catalyst for one hour at 275° followed by evacuation for two hours at 225°; cooling to 0° in helium and sorbing an accurately measured amount of oxygen (15 cc. equal to about 85% saturation) from both ends of the catalyst bulb; adding a known increment of hydrogen (5 to 6 cc.); raising the temperature to 50° in the first half hour, to 75° in the second half hour, to 100° in the next hour (about 95% of the hydrogen had now disappeared), and finally to 125° for two hours in order to make the hydrogen disappear completely; closing off the catalyst and removing water from the trap (solid ammonia removed) then evacuating the catalyst for one half hour at 150°; then repeating the procedure with successive increments of hydrogen until a surface poisoned with the desired amount of oxygen remained; and finally evacuating for three hours at 160° prior to a reaction velocity run. The amount of oxygen poisoning was considered to be the difference between the amount of oxygen initially sorbed and the oxygen equivalent of the hydrogen admitted to the catalyst. A very small correction was necessitated for any traces of hydrogen not reacting. The most completely unpoisoned surfaces were prepared by flow reduction of sorbed oxygen for ten hours at 160° followed by evacuation for three hours at the same temperature.

Selective reduction (2), used for Cu XXII, differed from selective reduction (1) in that only 10 cc. of oxygen (67% saturation) were initially sorbed; in that the successive increments of hydrogen were somewhat smaller (3 to 4 cc.); and in that the time intervals were an half hour each at 25, 50, 75 and 100°. Probably due to the lower maximum temperature, about 5% of the hydrogen did not react under this treatment so that the oxygen remaining on the surface could not be as confidently calculated as before. Therefore, the amount of oxygen poisoning was determined also at the end of a velocity run by weighing the amount of water retained by a phosphorus pentoxide tube during the subsequent reduction at 275°. This "gravimetric" determination of oxygen poisoning has an advantage over the "buret" method in that it is direct, and it constitutes a valuable check on the latter method.

Selective reduction (3), used for Cu XXIII, differed from selective reduction (2) in that the reduction was prolonged for an additional hour at 100° and followed by an hour at 125°. The amount of oxygen poisoning was determined by the gravimetric method and also by the buret method since the hydrogen again reacted practically completely. The agreement of the two methods is apparent from experimental points shown on Curve 6, Fig. 2.

Nitrous Oxide Poisoning.—Direct poisoning by nitrous oxide was accomplished by two methods. Nitrous oxide poisoning (1), used for Cu XXIV, comprised flushing the surface with hydrogen for five hours at 300° and evacuating for two hours at 375°; cooling to liquid ammonia temperature; admitting a measured amount of nitrous oxide; raising the temperature to 300° for one hour; and then cooling to 0°. The amount of oxygen poisoning was determined after the velocity run by the gravimetric method.

Nitrous oxide poisoning (2), used for Cu XXV, differed from nitrous oxide poisoning (1) in that the copper was flushed with hydrogen first at 275° for two hours, then at 225° for three hours and finally was evacuated for two hours at 225°. Furthermore, the nitrous oxide was heated only to 160°, which was the highest temperature to which sorbed oxygen was exposed in any of the selective reductions.

Experimental Results

A. Preliminary Work.—Although a number of copper catalysts both promoted and unpromoted, and in pulverulent and supported form were investigated, the granular copper[12] produced by the reduction of Kahlbaum cupric oxide proved to be the most active for the hydrogenation of ethylene at 0°. The reaction velocity–time curves obtained with all catalysts had a characteristic form when hydrogen was the gas to be displaced by the reaction mixture. During the first half hour the percentage conversion decreased at a diminishing rate and then remained constant, or at most showed a very gradual decrease with time (indicating that the scrubbing catalysts required regeneration). If ethylene were the gas displaced by the reaction mixture, the curve rose from a low initial conversion during the first half hour and then followed the course of the normal curve. It may be noted that the same type of curve was obtained for this reaction with a nickel catalyst down to −50°. Even with this metal when a steady state of conversion had been reached at 0° it was only necessary to displace temporarily the reacting gases with

---

hydrogen in order to cause a marked increase in conversion which, however, soon dropped back to the lower value. The initial period of diminishing catalytic activity in the velocity runs appears to be due to a rather slow removal of adsorbed hydrogen by interaction and displacement with ethylene in the establishment of a steady state. This same phenomenon has been found for this reaction using copper in static systems by others.[7,8]

Preliminary studies using copper poisoned with oxygen sorbed at 0° showed that while there was an extremely slow removal of sorbed oxygen at 20°, in the reaction velocity runs, no sorbed oxygen disappeared at 0°. This was particularly important to establish because former work[5] with thoria promoted, pulverulent copper indicated that some of the oxygen sorbed at 0° could, if not subsequently heated, react with hydrogen at this temperature. In the present work even a slow loss of sorbed oxygen, in the steady state, would have been indicated in the velocity runs by an ascending section in the velocity–time curve, and this never occurred at 0°. Furthermore, the amounts of oxygen found present at the end of the velocity runs agreed, within the experimental error, with the amounts of oxygen present before the runs.

It became apparent early in the present work that the catalyst surfaces were extremely sensitive to slight variations in their mode of production. For example when oxygen was sorbed at 0° and then removed by hydrogen at a lower temperature than that used in the production of the surface, marked activation occurred. However, subsequent evacuation of this surface at this lower temperature caused a considerable loss (sintering) in this activation. In order to ensure reliable and reproducible catalyst activity, therefore, all details of procedure were strictly standardized.

B. Direct Oxygen Poisoning.—The effects of different amounts of oxygen poisoning upon the activity of Cu XXI are shown graphically in Curve 5, Fig. 2. The oxygen was admitted to both ends of the catalyst bulb at 0°. Catalytic activity was determined here, and in all of the remainder of this work, by use of the ethylene–hydrogen reaction at 0° employing a one to one reaction mixture. The recorded catalyst activity refers always to the steady state. Oxygen appears to be a uniformly effective poison and a slight extrapolation of Curve 5 shows catalytic activity to disappear completely at 40% (6.3 cc. of oxygen sorbed) saturation of the surface with oxygen. The linear relation shown by Curve 5 would not be expected in view of the fact that the heats of oxygen sorption on copper decrease with increasing sorption,[5] unless the reaction were proceeding on uniform catalytic surface, or the oxygen poisoning were non-preferential. The latter possibility seemed the more probable.

C. Heats of Oxygen Sorption.—In order to gain information about the distribution of oxygen throughout the catalyst mass in the direct poisoning experiments, oxygen was now admitted to only the top or the bottom of the catalyst bulb. Such a procedure should make no difference in the successive values of the heat of sorption if the oxygen were uniformly distributed. The experimental results obtained on Cu XXI are shown graphically in Fig. 1. Curve 4 is taken from earlier work on copper (Cu 11)[5] for purposes of comparison and represents a case where the oxygen has been admitted to the catalyst bulb entirely from one end. Also, in the case of Curve 2 oxygen was admitted to Cu XXI entirely at the top of the bulb. The somewhat lower initial heats of sorption shown by Curve 2 may be attributed to the slightly lower temperature of outgassing used, while the still lower values shown on Curve 4 may be explained, in part perhaps, by the fact that Cu 11 was in pulverulent rather than in granular form. It is at once apparent from a comparison of the smooth Curves 2 and 4 with Curves 1 and 3, that the different method of

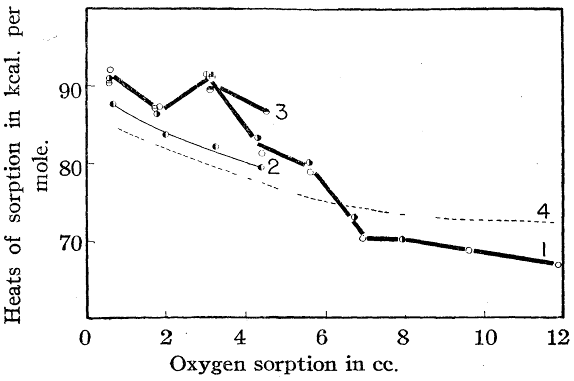

Fig. 1.—Heats of oxygen sorption on copper. Symbols indicate to which end of catalyst oxygen was admitted. Curve 1: ◑ bottom, ⦶ top, Run 138, Cu XXI; ○ top, ◡ bottom, Run 139, Cu XXI. Curve 2: ◐ top, Run 143, Cu XXI. Curve 3: ⊖ top, ◓ bottom, Run 144, Cu XXI. Curve 4: top, earlier work on Cu 11.

admitting oxygen employed for the latter curves has been responsible for the introduction of maxima and minima. In the case of the composite Curve 1 all of the oxygen except the third increment was admitted to the same end of the catalyst bulb. Curve 3 differs in that both the third and fourth (last) increments were admitted to the same end.

The interpretation of these curves seems fairly clear if, when an increment of oxygen is admitted to one end of a cylindrical copper catalyst, it is assumed that although the gas is pretty largely sorbed upon the first portions of the catalyst encountered, yet some preferential sorption occurs and a sorption gradient is set up in which the concentration is greatest on those parts of the catalyst surface first contacting the oncoming oxygen molecules. A larger and larger part of each successive increment of oxygen admitted to the given end will be sorbed upon previously, partially saturated surface with the observed decrease in the heats of sorption, which can be neither strictly integral nor differential values. A comparison of the fourth points on Curves 1 and 3 indicates the additional decrease in heat of sorption which an increment of oxygen suffered when it had to encounter surface which had been partially saturated by two, rather than one earlier increment of oxygen. When in addition to traversing surface partially saturated by earlier increments from the same end, an increment of oxygen meets surface saturated in part by oxygen admitted to the other catalyst end, an abnormally large decrease in heat of sorption would be anticipated. With Curve 1 it is clear that the third increments of oxygen were sorbed upon surface entirely unreached by the first and second increments admitted from the other end. It was not until five increments were admitted from one end, that the drop in this curve indicates that oxygen had penetrated to surface which sorbed the single increment admitted to the other end. When increments of oxygen were added alternately to the two ends of the granular copper catalyst, a curve (not shown) was obtained which showed a sharp drop at roughly 70 k. cal. and about 5 cc. of oxygen sorbed. From a slight extrapolation of Curve 5, Fig. 2, it is clear that when oxygen was admitted to both ends simultaneously, no more than 6.3 cc. was necessary for complete penetration of the catalyst. From the foregoing it appears that from 5 to 6 cc. of oxygen was required in the direct oxygen poisoning experiments before all parts of the catalytically active surface of the granular catalyst came into contact with any oxygen. Thus as far as surface capable of catalyzing the ethylene–hydrogen reaction is concerned, the direct sorption of oxygen proves to be largely, if not entirely, non-preferential. Therefore, no significant correlation can be expected between catalytic activity and either extent of direct oxygen poisoning, or heats of sorption, and the linear relation shown in Curve 5, Fig. 2, need give no true picture of the catalyst surface.

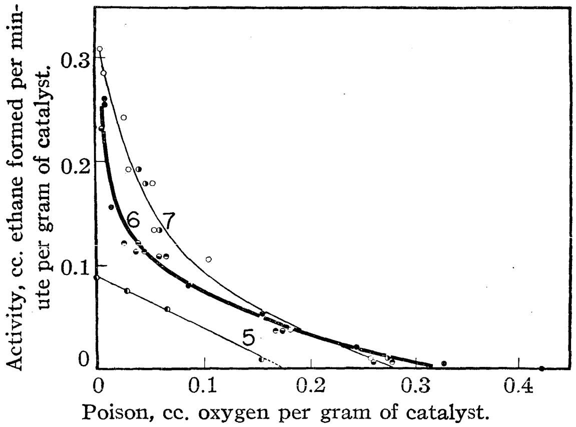

Fig. 2.—Direct and indirect oxygen poisoning. Direct poisoning: Curve 5, Runs 131–137 on Cu XXI at gas flow (cc. per min.) of H_2 = 5.9 and C_2H_4 = 5.6.

(3), ◓ "buret" method, ◒ "gravimetric" method, Runs 180–185 on Cu XXIII at gas flow of H_2 = 5.9 and C_2H_4 = 5.6. Curve 7, S.R. (2), ◑ "buret" method, O "gravimetric" method, Runs 166–174 on Cu XXII at a gas flow of H_2 = 11.6 and C_2H_4 = 11.2.

D. Indirect Oxygen Poisoning.—Inasmuch as it was clear from the work already done that a preferential poisoning of copper had not been achieved, it was decided to investigate the possibility of a selective removal of oxygen from a previously poisoned surface. Curves 6 and 7, Fig. 2, relate catalytic activity and various amounts of oxygen poisoning produced by the successive removal of larger and larger portions of previously sorbed oxygen by means of the careful, low-temperature reductions with measured amounts of hydrogen, described in detail under Experimental Method. Curve 7 was obtained with Cu XXII, which was Cu XXI after it had been accidentally activated, and thus its major portion lies above Curve 6. Because of the experimental arrangements, the hydrogenation of ethylene on the nearly unpoisoned surface of Cu XXII was now close to 100%. The two uppermost points on Curve 7 are, therefore, somewhat too low and thus displace the curve too far to the left. The various symbols employed on Curves 6 and 7 indicate the experimental method used in determining the amount of oxygen poisoning. The "buret" and "gravimetric" methods agree within their experimental errors. The lowest points on Curves 6 and 7, which were obtained after heating the sorbed oxygen to 160° for three hours and prior to any reduction, indicate that 15 cc. of oxygen poisoned Cu XXI completely while Cu XXII and XXIII showed a slight activity for 10 and 5.5 cc. of oxygen, respectively. Comparison of Curves 5 and 6 indicates that about twice as much oxygen was required completely to poison Cu XXI in the latter case. This decrease in the poisoning efficiency of oxygen may be attributed to a partial "regeneration" of the poisoned copper by the heating at 160°, a phenomenon encountered in earlier work.[5]

Inasmuch as not quite all of the oxygen poisoning could be removed even by very prolonged flow reduction at 160°, no experimental values could be obtained for completely unpoisoned surfaces. Complete removal of sorbed oxygen could be effected at 275° but this caused the loss in activity apparent from a comparison of the ordinates of the highest portions of Curves 5 and 6. The phenomenon of activating copper by alternate oxidation and reduction at successively lower temperatures is well known, and it now appears that oxygen sorption at 0° followed by reduction at 160° produced a more active surface than when reduction occurred at 275°, and when reduction was carried out at 90° about twice the activation noted above in Fig. 2 occurred. Furthermore, the activities of these surfaces were strictly reproducible. It is suggested that the activations in the present work are associated with a displacement of surface copper atoms during the highly exothermic oxygen sorption. It appears, therefore, that the surface uncovered in the selective reductions was not exactly the same surface which was previously poisoned, and it is not known whether the former would be more or less active than that produced by a similar reduction of normal copper oxide. Although the Cu XXI of Curve 6 is not quite the Cu XXI of Curve 5, it is believed that the two surfaces are not unrelated. The general form of Curves 6 and 7 shows that the removal of sorbed oxygen was accompanied by an exponential increase in the catalyst activity. It appears, therefore, that various portions of the sorbed oxygen differed in ease of reducibility. It is believed that this is to be attributed to the presence of different surface types on the copper upon which sorption occurred. It is felt that in the successive selective reductions the factor for regeneration was kept constant, and also that appreciable penetration of sorbed oxygen below the available surface of the catalyst was unlikely because the copper was only partially saturated with strongly held oxygen at 0° and became much less saturated at higher temperatures, and furthermore were the oxygen last removed, in the successive reductions, from the interior of the catalyst, it would seem necessary to associate the greatest catalyst activity with this location. It seems reasonable to conclude, therefore, that the successive reductions were selective in that surface less active in the ethylene–hydrogen reaction was released first and increasingly more active surface thereafter.

E. Nitrous Oxide Poisoning.—Because of the desirability of finding a direct method for poisoning copper it was decided to investigate the possibilities of decomposing nitrous oxide at the catalyst surface. Preliminary studies with a catalyst similar to Cu XXI at temperatures up to 75° indicated that decomposition occurred with no increase in pressure and that, therefore, most probably one atom of oxygen was sorbed for each molecule of nitrogen liberated. This mechanism, which also occurs in the case of silver,[13] was supported by later work with Cu XXIV and XXV. The preliminary studies also indicated that a portion of the nitrous oxide was decomposed probably instantaneously at −78°, and after sintering the copper at 400° some still decomposed similarly at −45°. In an endeavor to make the poisoning as selective as possible, Cu XXIII was now sintered at 400° thereby producing Cu XXIV, and the nitrous oxide was in all cases admitted at about −40°. To ensure more complete decomposition and a strong sorption of oxygen the temperature was then raised to 300° for Cu XXIV and to 160° for Cu XXV.

The effects of various amounts of poisoning

---

[13] A. F. Benton and C. M. Thacker, THIS JOURNAL, **56**, 1300 (1934).

from nitrous oxide upon the catalytic activity of Cu XXIV are shown in Curve 8, Fig. 3. The considerable horizontal portion of this curve indicates that some 3.5 cc. of oxygen was taken up by the catalyst before its capacity for hydrogenating ethylene under the experimental conditions was diminished. Curve 8 falls fairly rapidly once poisoning starts but its form is obviously uncertain in the vicinity of the last point. Even though relatively large excesses of nitrous oxide were employed more complete poisoning was not achieved.

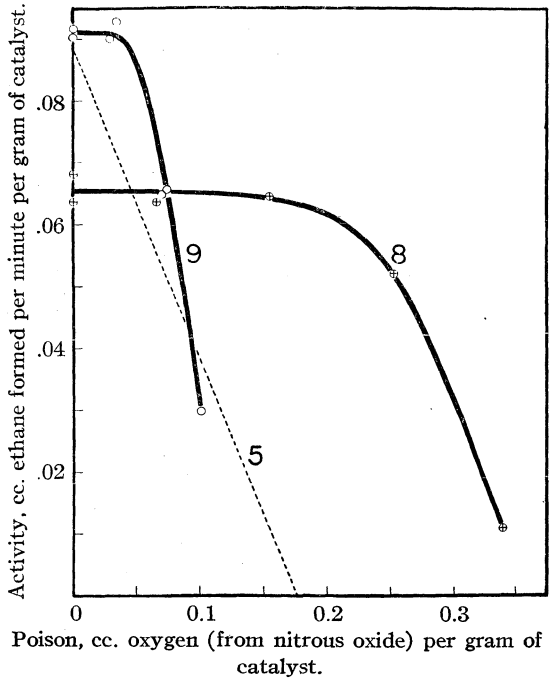

Fig. 3.—Nitrous oxide poisoning. Gas flow (cc. per min.): $H_2 = 4.6$; $C_2H_4 = 4.5$; Curve 8: nitrous oxide poisoning (1); Runs 190–195, Cu XXIV. Curve 9: nitrous oxide poisoning (2); Runs 204–211, Cu XXV. (Curve 5: direct oxygen poisoning (Fig. 2).)

Curve 9, Fig. 3, shows the effects of poisoning Cu XXV with nitrous oxide at the lower maximum temperature of 160°. In a comparison of unpoisoned surfaces the relative position of Curve 5 in Figs. 3 and 2 clearly shows the absence on Cu XXV of the activation characteristic of the indirect poisoning (Curve 6). While the displacement of Curve 9, Fig. 3, above Curve 8 is to be attributed to the greater activity of Cu XXV, the considerable lateral displacement of the former curve toward the left must be due, for the most part, to the increased efficiency of the nitrous oxide when decomposed at the lower temperature of 160°. Although the horizontal portion of Curve 9 is much shorter, it should be noted that it still proves to be roughly the same fraction of the total abscissa of its curve, so that its relative length is little changed. At all points except the last on Curve 9 decomposition was considered complete, in that the amount of oxygen poisoning found by the "gravimetric" method after a velocity run agreed with the oxygen present in the charge of nitrous oxide admitted. Since at the last point on Curve 9 nitrous oxide decomposition was incomplete at 160°, this curve was not extended farther and no extrapolation appears justified on the basis of the present experimental evidence. Since an excess of nitrous oxide was present at the last points on both Curve 8 and 9, it appears that the surfaces were completely poisoned for further nitrous oxide decomposition at the temperatures employed. It seems important to note, however, that the remaining unpoisoned surface was still active enough to catalyze the hydrogenation of ethylene at 0°. From this it appears that more active surface is required for nitrous oxide decomposition than is required for the ethylene–hydrogen reaction, although there must be some overlapping as is evident from the fact that nitrous oxide acts as a poison at all for the latter reaction. Further evidence for the selective nature of the nitrous oxide poisoning rests upon the interpretation of the horizontal portions of Curves 8 and 9. While regeneration must be a considerable factor at 300°, it becomes smaller at 160°, and one experiment gave qualitative evidence that the horizontal portion is present when the maximum temperature of nitrous oxide decomposition was 25°. Inasmuch as the decomposition of nitrous oxide is a surface reaction, it appears hardly probable that the horizontal portions of the curves resulted from the diffusion of all the oxygen into the catalyst interior leaving the surface bare. It seems reasonable, therefore, to assume that the nitrous oxide poisoning was selective in nature.

Discussion

Evaluation of the curve obtained in the direct oxygen poisoning experiments, in the light of the work on heats of oxygen sorption, clearly shows that this curve need not constitute a true picture of the catalytic surface of copper. Thus caution must be employed in the interpretation of experiments involving strongly sorbed poisons. Only if the poison is capable of being preferentially or selectively sorbed (portions of a non-uniform surface are progressively poisoned in the order of their relative activities) will a linear relation between activity and extent of poisoning constitute proof for a uniform surface.

All of the evidence in the present work may be considered support for a non-uniform copper surface. Thus (a) the direct oxygen poisoning experiments reveal that a large fraction of the surface was catalytically inactive, (b) the heats of oxygen sorption diminished as sorption increased, (c) the indirect oxygen poisoning experiments released a surface having portions of widely different hydrogenating capacities, and (d) the nitrous oxide poisoning experiments also appear to require the existence of a surface which is non-uniform in catalytic activity.

The experimental work furnishes evidence that the ethylene–hydrogen reaction at 0° proceeded on a portion of the catalyst surface having intermediate activity. Thus a slight extrapolation of the linear curve obtained in the direct oxygen poisoning experiments indicates that about 60% of the surface, which sorbed oxygen strongly, possessed no catalytic activity for the reaction studied. This does not mean, however, that all of the remaining 40% of the surface was catalytically active. In fact the non-selective nature of the direct oxygen sorption makes this unnecessary and, furthermore, the initial horizontal portions of the curves for nitrous oxide poisoning (Curves 8 and 9, Fig. 3) appear to constitute direct evidence that some of the copper surface was too active to contribute to the catalysis of the hydrogenation of ethylene. This too active surface, which preferentially decomposed nitrous oxide, may well be wholly or in part that which is inhibited by the known strong sorption of ethylene during the hydrogenation reaction at 0°.[14] At higher temperatures, due to desorption of ethylene, this "too active" surface may actively participate in the catalysis.

Taken together, Curves 6 to 9 (Figs. 2 and 3) constitute evidence as to the nature of the catalyst surface upon which the low-temperature hydrogenation of ethylene proceeded. It is highly improbable that the removal of sorbed oxygen by the selective reductions was entirely preferential. Also regeneration appears to have decreased the poisoning efficiency of the oxygen. A correction for both of these factors should have the effect of diminishing the horizontal length of Curve 6, while causing the curve to rise even more slowly in the region of large amounts of poisoning, and still more rapidly for the smaller amounts. The possibility that such a curve might bend sharply from the rapidly rising portion to a nearly horizontal portion, similar to that found experimentally in Curve 9, is not excluded. In fact, this might be expected if in the selective reductions none but the most active surface were released at the end. In the present work the general form of Curve 6 appears to constitute the best experimental evidence for the nature of the surface capable of catalyzing the hydrogenation of ethylene under the experimental conditions, and is consistent with an exponential distribution of reaction centers such as has been postulated by Constable on copper,[15] the bulk of the reaction occurring on relatively few centers of low activation energy. However, as has been noted above, these most active centers for the hydrogenation of ethylene appear not to be those centers most active in the decomposition of nitrous oxide.

Because of the different schools of thought concerning the structure and behavior of catalyst surfaces, the experimental details of this work have been rather fully presented in order to afford adequate basis for independent interpretation. While the foregoing interpretation appears to us simple and in accord with the present evidence, it is realized that more evidence is highly desirable and, therefore, further work is being undertaken with this end in view.

Summary

1. Active, granular, copper catalysts have been poisoned to various degrees with oxygen both directly and indirectly, and with nitrous oxide. The catalytic activity of both poisoned and unpoisoned surfaces has been measured by means of the ethylene–hydrogen reaction at 0° using a flow method.

2. As the amount of oxygen directly sorbed by the copper at 0° was increased, both the heats of oxygen sorption and the catalytic activity of the surface decreased, the latter in a linear manner.

3. By means of suitable heat of oxygen sorption measurements it was shown that active copper sorbed oxygen at 0° in an almost non-

selective manner and, therefore, that the linear relation in 2 need give no true concept of the catalyst surface.

4. An indirect method of poisoning active copper with oxygen appears to be selective in character.

5. Direct poisoning of active copper with nitrous oxide also appears to be selective.

6. All of the experimental evidence is considered to indicate (a) that the copper surface is non-uniform and (b) that at 0° the hydrogenation of ethylene proceeds almost exclusively on a relatively few surface types, probably of intermediate character.

7. The interpretation of the experimental evidence is consistent with an exponential distribution of centers active at 0° in catalyzing the ethylene–hydrogen reaction.

A Study of the Dehydration of Hydrated Cobaltic Oxide

BY H. ARMIN PAGEL, WILLIAM K. NOYCE AND MYRON T. KELLEY

The literature[1,2,3,4] gives various temperatures, ranging from about 150 to 385°, at which hydrated cobaltic oxide begins to decompose into Co_3O_4, oxygen and water. The observations made in this Laboratory indicate the reason for the apparent disagreement of the investigators.

Experimental

Various lots of hydrated cobaltic oxide were prepared by alkaline decomposition of chloropentammino-cobalti chloride, as recommended by Hüttig and Kassler[1] except that the colloidal oxide was isolated by centrifuging instead of using a membrane filter. The oxide was then dried two days over concentrated sulfuric acid in a vacuum desiccator and ground in an agate mortar. Analyses of the partially dehydrated oxides showed the practical absence of divalent cobalt, and a water content corresponding to about $Co_2O_3 \cdot 1.6H_2O$, or a calculated value of about 15% water and 85% of the hypothetical anhydrous Co_2O_3. The oxide thus prepared was then dehydrated at various temperatures. This was done by passing highly purified air over the oxide samples while the latter were constantly agitated with a mechanical shaker to provide uniform conditions. The approximate progress of the dehydration was determined at twelve or twenty-four-hour intervals by weighing the amount of water collected in dehydrite absorption tubes connected to the air exhaust. Each run was continued until the loss of water decreased to about 0.5 mg. in twenty-four hours. This usually required from two to four days. The oxide was then analyzed for trivalent cobalt by the oxalate–permanganate method as recommended by LeBlanc and Möbius[5] and for water by heating the oxide to red heat in a combustion furnace, using a dehydrite absorption tube to collect the water.

TABLE I

RESULTS OF EXPERIMENTS

Temp., °C., ±3°	% Co_2O_3[a] remaining	% H_2O remaining	% H_2O, calcd. for $Co_2O_3 \cdot 1H_2O$
155	35.3	4.6	3.83
168	19.0	3.8	2.06
177	17.3	2.7	1.88
195	13.3	3.1	1.44
205	19.3	2.3	2.09
220	9.7	1.5	1.05
235	10.3	1.4	1.12
260	15.7	2.2	1.70

[a] Hypothetical anhydrous oxide.

It was noticed in all cases that the rate of dehydration is very slow up to 90°, but in the range from 100 to 180° rapid dehydration takes place. For example, a 1.5-g. sample heated for twenty-four hours at 105° lost 0.006 g.; during the next forty-eight hours at 180° it lost an additional 0.163 g.; then during the next eighty-four hours at 250°, only 0.003 g. additional. In some cases, however, the dehydration at the end of 200° treatment was not nearly as complete as shown above for 180°, and a considerable amount of water continued to be evolved at still higher temperatures.

Further information was obtained in attempts to prepare anhydrous Co_2O_3 by oxidation with

dry oxygen at relatively high pressures. Large samples of dry Co_3O_4, prepared by igniting cobaltous carbonate in air, were placed in an electrically heated high pressure bomb. These were subjected to about 100 atm. of oxygen pressure at various temperatures ranging from 200 to 400°, followed by rapid cooling to room temperature at full pressure. The results were negative throughout. Further experiments were then carried out as follows. A large porcelain boat containing about 5 g. of very pure, partially hydrated, cobaltous carbonate was placed in the hot end of the bomb, and another boat containing freshly ignited calcium oxide was placed in the cooler end to absorb carbon dioxide and water. One experiment (A) of this type was carried out at 330° for sixty-eight hours at 107 atm.; another (B) at 275° for forty-four hours at 72 atm. A different type of experiment (C) was then tried in which partially dehydrated cobaltic oxide was heated for twenty hours with calcium oxide as dehydrating agent at 315° and 127 atm.; followed by twenty hours with phosphorus pentoxide as dehydrating agent at the same temperature and pressure. The following results were found:

TABLE II

	% Co_2O_3* remaining	% H_2O remaining	% H_2O calcd. for $Co_2O_3 \cdot H_2O$	% CO_2
(A)	9.5	1.15	1.03	0.5
(B)	15.3	2.03	1.66	.6
(C)	7.9	1.05	0.86	

Conclusions

Table I shows that decomposition takes place slowly in the 150° temperature region as claimed by Hüttig and Kassler.[1] Both Tables I and II furnish evidence in support of their observations that cobaltic oxide is stable only with a minimum water content corresponding to the monohydrate. The irregularities in "% Co_2O_3 remaining" at increasing temperatures (Table I) are believed to be due to the differences of speed with which water vapor could be physically removed from the various samples having different physical properties. Since no attempt was made to centrifuge the various hydrated oxide preparations the same length of time, their porosity and particle size, no doubt, varied enormously. It should be noted that Hüttig and Kassler in their study of the water vapor equilibrium pressures also found decided variations with different samples.

Since the hydrated oxide sample used in (C) contained about 85% hypothetical Co_2O_3 and about 15% water before dehydration at 315°, it appears that the oxygen dissociation pressure of anhydrous Co_2O_3, formed by the dehydration, is greater than 127 atm. at 315°. Experiments (A) and (B) show, however, that the reaction is reversible in presence of water, and that the amount of divalent cobalt which can be oxidized to cobaltic oxide is, in general, proportional to the amount of water still available to form the monohydrate.

The observations throughout seem to indicate that the prolonged existence of rather large amounts of residual hydrated cobaltic oxide, at temperatures much higher than the 150° region, can be explained on the basis of a retarded rate of dehydration in the inner regions of the oxide particles, due to a very slow rate of outward diffusion of the liberated water. It would therefore seem plausible that wet hydrated cobaltic oxide might be dried for short periods of time, at the higher temperatures mentioned by some investigators, without appreciable decomposition into Co_3O_4, provided the physical conditions are unfavorable for the rapid and complete escape of the liberated water.

Reduction of Organic Compounds by Ethanolamines

BY M. MELTSNER, C. WOHLBERG AND M. J. KLEINER

During an investigation of the properties of triethanolamine the senior author noticed that the ethanolamines reduced aqueous solutions of silver, lead, mercury and other metallic salts. The literature records do not mention this reaction. The present paper reports the results of some experiments on the reduction of organic compounds of different types by the ethanolamines.

The reactions are very easily carried out, requiring the heating of the organic compound with one of the ethanolamines, preferably the diethanolamine. While all the end-products have not as yet been isolated, the reaction depends on the decomposition of the amino alcohol into ammonia and an aldehyde.

Table I records the compounds reduced and the reduction products isolated and identified.

TABLE I

Name of compound	Reduction products
Anthraquinone	Anthranol
Acetone	Isopropyl alcohol
Azobenzene	Aniline
Chrysoidine	1,2,4-Triaminobenzene
Nitrobenzene	Azobenzene, azoxybenzene, aniline
o-Nitrotoluene	*o*-Azotoluene, *o*-azoxytoluidine, *o*-toluidine

TABLE II

Nitro compound	Weight, g.	Amino alcohol	Weight, g.	NaOH	Time, hours	Yield, g.		
						Azo	Azoxy	Amino
Nitrobenzene	25	Monoethanolamine	48	None	4	1.9		2
Nitrobenzene	25	Diethanolamine	84	None	2	5.1		1.7
Nitrobenzene	25	Diethanolamine	64	None	2	3.5		1
Nitrobenzene	10	Diethanolamine	25	15 g.	2	6	1	Trace
Nitrobenzene	25	Diethanolamine	84	5 g.	2	9.3		0.7
Nitrobenzene	25	Triethanolamine	84	None	4	1.7		1
Nitrobenzene	10	Triethanolamine	25	20 g.	2	4	3	Trace
o-Nitrotoluene	27	Diethanolamine	84	None	2	1.9		2.6
o-Nitrotoluene	13	Diethanolamine	21	5 g.	2	0.2	6	0.3
o-Nitrotoluene	13	Diethanolamine	21	10 g.	2	.2	8.4	Trace
o-Nitrotoluene	13	Diethanolamine	21	15 g.	2	8.2		Trace

Table II shows the results of a more extended investigation of the reduction of the nitro group. It will be noticed that the nitro group on reduction yields azo, azoxy and amino compounds, the yields of each being dependent on the presence or absence of alkali, the amino alcohol and the time of reaction.

Experimental Part

Reduction of Anthraquinone.—Ten grams of anthraquinone and 32 g. of triethanolamine are heated in an oil-bath at 185° for six hours. The mixture is extracted with water and filtered. The insoluble portion is extracted with benzene and the benzene evaporated. The residue of anthranol is recrystallized and identified by its melting point and oxidation to anthraquinone.

Reduction of Azobenzene.—Thirty-two grams of triethanolamine and 10 g. of azobenzene are heated in an oil-bath at 185–190° for four hours. The resulting mixture was steam distilled. The excess azobenzene is filtered off from the distillate which after acidification with hydrochloric acid is evaporated to dryness. The residue was identified as aniline hydrochloride.

Reduction of Acetone.—Thirty-two grams of triethanolamine and 10 g. of acetone were refluxed for six hours. The solution was distilled and a fraction between 75–85° was collected. Isopropyl alcohol was identified by conversion into the 3,5-dinitrobenzoic ester.

Reduction of Nitrobenzene with Amino Alcohol and Alkali.—Ten grams of nitrobenzene and 25 g. of diethanolamine are mixed with a solution of 15 g. of sodium hydroxide in 10 cc. of water and heated with a small flame for two hours. After cooling, water is added and the mixture filtered. The solid residue is fractionally crystallized from alcohol and yields azobenzene (6 g.) and azoxybenzene (1 g.). The aqueous filtrate is steam distilled, the distillate acidified with hydrochloric acid and evaporated to dryness to yield aniline hydrochloride.

Conclusions

1. Ethanolamines have been found to act as reducing agents for inorganic salts and for some classes of organic compounds.
2. Nitro compounds when reduced with ethanolamines yield azo, azoxy and amino compounds.

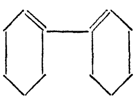
Synthesis of Certain Hydrogenated Phenanthrenes

BY E. E. GRUBER[1] AND ROGER ADAMS

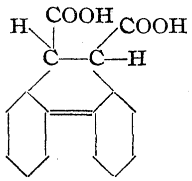
A recent communication by Barnett and Lawrence[2] describes the condensation of maleic anhydride and benzoquinone with the dienes obtained from the pinacols of cyclopentanone and cyclohexanone. A similar study has been under way for some time in the University of Illinois laboratories and occasion, therefore, is taken now to present some of these results which are closely related to the work of Barnett and Lawrence.

The British authors have neglected to mention that di-$\Delta^{1,1}$-cyclohexene (I) had previously been prepared by Wallach and Pauly[3] through dehydration of the corresponding pinacol with diluted sulfuric acid and indeed the yield by the latter procedure was found by us to be fully as satisfactory as that reported by Barnett and Lawrence using dehydrated alum as a catalyst.

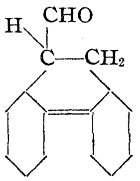
Condensation between maleic anhydride and the diene (I) mentioned, takes place readily with formation of the $\Delta^{4a,5a}$-dodecahydrophenanthrene-9,10-dicarboxylic acid anhydride (II).



I



II



III

The anhydride may be converted into the free acid, and the imide.

The diene (I) also readily condenses with acrolein with the formation of $\Delta^{4a,5a}$-dodecahydrophenanthrene-9-al (III), a product now being used by us in another investigation.

Experimental

1,1′-Dihydroxy-1,1′-dicyclohexyl.—In place of the aluminum used by Barnett and Lawrence in the synthesis of this compound, magnesium was employed.

To 94.6 g. of magnesium turnings and one liter of dry benzene in a 5-liter, two-necked flask (equipped with a reflux condenser and separatory funnel) was added 170 g. of mercuric chloride dissolved in 603 g. of dry cyclohexanone. Heat was applied to initiate the reaction, which then continued with increasing vigor until it was necessary to cool with an ice-bath. After the first vigorous reaction had subsided, the reaction mixture was heated on a steam cone for two hours, was broken up and 450 cc. of water was slowly added. Heating with occasional shaking was continued for about three hours longer. After filtering off the liquid, the residue in the flask was extracted with two 400-cc. portions of hot benzene. The combined filtrates were fractionally distilled *in vacuo*. About 308 g. of cyclohexanone was recovered. The fraction 140–175° (6.5 mm.) was chiefly the desired diol and was purified by recrystallization from high-boiling petroleum ether as white needles, m. p. 128.5–129.5°. Zelinsky[4] reports m. p. 128–129° and Barnett and Lawrence[2] report m. p. 130°. The yield was 35% based on cyclohexanone actually used.

It was found that by allowing the reaction to proceed as rapidly as possible and by avoiding a large excess of cyclohexanone, the major by-product cyclohexenylcyclohexanone was reduced in amount.

Di-$\Delta^{1,1}$-cyclohexene (I).—By heating under reflux for four hours a mixture of 132 g. of the dihydroxycyclohexyl in 600 cc. of 10% sulfuric acid,[2] then subjecting it to steam distillation, a colorless oil was obtained which was extracted with low boiling petroleum ether; b. p. 101–102° (5.5 mm.); d_{20} 0.9581; $n^{20}\text{D}$ 1.5322; yield 88 g. (82%).

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid Anhydride (II).—A solution of 10 g. of dicyclohexene and 6 g. of powdered maleic anhydride in 12 cc. of benzene was warmed gently for a few minutes until the anhydride dissolved. After four hours of standing the solvent was evaporated and the oily crystalline mass thus obtained was washed with high-boiling petroleum ether and finally with 2 cc. of benzene. The anhydride was recrystallized from high-boiling petroleum ether and thereby obtained as colorless prismatic needles, m. p. 122.5–123.5°. Barnett and Lawrence[2] report the same m. p.; yield 5.5 g.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.8; H, 7.74. Found: C, 73.5; H, 7.96.

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid.—A solution of 20 g. of the powdered dodecahydrophenanthrene-9,10-dicarboxylic anhydride in 250 cc. of 5% sodium hydroxide was refluxed until the anhydride dissolved, filtered and cooled to about 5°, and then diluted with about 200 cc. of cold water. Dilute acetic acid was added slowly with stirring and the gummy precipitate was transferred to 250 cc. of hot glacial acetic acid, in which it solidified and then dissolved. Upon cooling it crystallized out as colorless prisms; m. p. 242° (bloc Maquenne); yield 12 g.

The aqueous solution from the neutralization was still milky and upon standing and diluting yielded more of the above acid in a white powdery form; yield 5 g.

Anal. Calcd. for $C_{16}H_{22}O_4$: C, 69.02; H, 7.97. Found: (I) C, 68.96; H, 8.37; (II) C, 69.41; H, 8.09.

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9,10-dicarboxylic Acid Imide.—A mixture of 0.5 g. of anhydride and 5 cc. of

concentrated aqueous ammonia was heated slowly under reflux to about 250–300°. At this temperature the reaction reached a homogeneous melt. Anhydride, which sublimed into the condenser, was pushed back with a glass rod. After cooling, 95% alcohol was added and the solution filtered. Addition of water to the alcoholic solution precipitated a light tan solid, m. p. 145–150° (yield 0.3 g.). For purification it was dissolved in ethyl alcohol and water added to the hot solution until almost cloudy. Upon cooling prismatic needles separated. After recrystallizing three times from benzene and low boiling petroleum ether, the product formed colorless needles, m. p. 182–183°.

Anal. Calcd. for $C_{16}H_{21}O_2N$: N, 5.40. Found: N, 5.36.

$\Delta^{4a,5a}$-Dodecahydrophenanthrene-9-al (III).—A mixture of 17 g. of the dicyclohexene in 15 cc. of dry benzene and 6 g. of pure acrolein was heated under reflux for twenty-two hours at 50–60°. The benzene and the unreacted acrolein were removed and the residue fractionally distilled in vacuo. After distilling off all of the unreacted dicyclohexene (up to 126° (6.5 mm.)), the residue was dissolved in a small amount of ether and shaken with a 10% solution of sodium bisulfite. The solid which formed was filtered, washed with a little alcohol and decomposed with warm dilute aqueous sodium carbonate. The oil which separated was extracted with ether. The aldehyde was a colorless oil and was distilled in an atmosphere of nitrogen, b. p. 136–137° (4 mm.); yield, 4.2 g. (20%).

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.50; H, 10.65. Found: C, 82.87; H, 10.49.

The semicarbazone, purified from dilute alcohol, melted at 179–180°.

Anal. Calcd. for $C_{16}H_{25}ON_3$: N, 15.21. Found: N 14.99.

Summary

Addition of maleic anhydride and acrolein to di-$\Delta^{1,1}$-cyclohexene gives the hydrogenated phenanthrene derivatives, $\Delta^{4a,5a}$-dodecahydrophenanthrene-9,10-dicarboxylic acid anhydride and $\Delta^{4a,5a}$-dodecahydrophenanthrene-9-al.

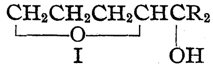
The Preparation and Reactions of Tertiary Tetrahydrofurylcarbinols

BY A. L. DOUNCE, RALPH H. WARDLOW[1] AND RALPH CONNOR[2]

Two methods are available for the synthesis of tertiary tetrahydrofurylcarbinols (I): (1) the action of the appropriate Grignard reagent upon ethyl tetrahydrofuroate, obtained by the hydrogenation of ethyl furoate over nickel, or (2) the reaction of the Grignard reagent with ethyl furoate, followed by the hydrogenation over nickel of the furyldialkylcarbinols thus obtained. Both of these methods have been used for the preparation of tetrahydrofuryldiethylcarbinol (II) and tetrahydrofuryldi-*n*-butylcarbinol (III). The former method gave



$CH_2CH_2CH_2CHCR_2$ (ring O; OH) I

II, R = $—C_2H_5$
III, R = n-C_4H_9
IV, R = $—C_6H_5$

in over-all yields of 71% (II), 50% (III) and 77% (IV) and is to be preferred to the latter, which gave 52% (II) and 45% (III). Because of the well-known tendency[3] for hydrogenolysis of the carbon–oxygen bond in the α-position to aromatic nuclei, the latter method is not applicable to such compounds as IV.

Dehydration of these carbinols was readily accomplished by heating with magnesium sulfate until the theoretical amount of water had distilled. The product obtained by the dehydration of tetrahydrofuryldi-*n*-butylcarbinol (III) was a mixture of isomers which could not be separated by fractional distillation. With tetrahydrofuryldiphenylcarbinol (IV), however, the sole product isolated was 1,1-diphenyl-2,5-epoxy-1-pentene (V). The structure of the latter was established by the isolation of benzophenone and γ-butyrolactone from the hydrolysis of the ozonide; examination of the ozonolysis products failed to show any evidence of the formation of a dihydropyran during the dehydration.

$CH_2CH_2CH_2C{=}C(C_6H_5)_2$ V

$CH_2CH_2CH_2CH{=}CH$ VI

$CH_2CH_2CH_2C{=}CH_2$ VII

The fact that no ring enlargement occurred under the conditions used in the dehydration of IV is in contrast to the results of Paul,[4] who obtained a dihydropyran (VI) by the catalytic dehydration of tetrahydrofurfuryl alcohol at 370–380°. Fur-

(1) A portion of this communication is abstracted from the thesis submitted by Ralph H. Wardlow in partial fulfilment of the requirements for the degree of Master of Science at Cornell University in June, 1933.

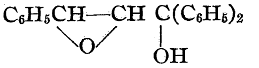
(2) Present address, Harrison Laboratory, University of Pennsylvania, Philadelphia, Pa.

(3) *Cf.* Covert, Connor and Adkins, THIS JOURNAL, **54**, 1660 (1932).

(4) Paul, *Bull. soc. chim.*, [4] **53**, 417 (1933); *ibid.*, **1489** (1933); *Compt. rend.*, **196**, 1409 (1933); *Bull. soc. chim.*, [5] **2**, 311 (1935); *ibid.*, 745 (1935).

thermore, a comparison of the properties of V with the properties of 2,5-epoxy-1-pentene (VII), obtained by Paul by the action of alkaline reagents upon tetrahydrofurfuryl bromide, shows that they are markedly different. The former (V) was very stable; it was distilled without decomposition (b. p. 195° at 10 mm.), was stored for several months without decomposition or polymerization, and was recovered unchanged from contact with dilute sulfuric acid. The product (VII) isolated by Paul was a very unstable and reactive substance; it was hydrolyzed almost instantly by dilute acid, was attacked by oxygen of the air, and was not obtained in an analytically pure state. The conjugation of the olefinic double bond of V with the aromatic nuclei may be responsible for its greater stability.

The formation in excellent yields of tetrahydrofuryldiphenylcarbinol (IV) by the reaction of phenylmagnesium bromide with ethyl tetrahydrofuroate in ether solution indicated that cleavage of the tetrahydrofuran ring did not occur to any appreciable extent during the reaction. It therefore seemed of interest to test the stability of the ring under "forced" conditions. It was found, however, that when IV was refluxed for fifty-two hours in boiling xylene with three equivalents of phenylmagnesium bromide there were no indications of cleavage. Instead, an 87% yield of the dehydration product (VII) was obtained. That the dehydration product was formed after hydrolysis of the reaction mixture was indicated by the facts (a) that water appeared in the distillate *after* most of the xylene had been distilled (at atmospheric pressure), (b) that α,β-unsaturated ethers react with the Grignard reagent,[5] and (c) that in another experiment in which the time of refluxing was nine hours and in which the xylene was removed under diminished pressure, 76% of IV was recovered unchanged along with a small amount of impure dehydration product. The stability of V toward phenylmagnesium bromide is interesting in comparison with the reactivity of the α-oxido carbinol (VIII) which suffers cleavage both of the oxide ring and the carbon chain.[6] The two carbon atoms between which cleavage occurs in VIII bear substituents similar to those on the corresponding carbon atoms in IV; the well-known difference in the stability of three-and five-membered rings undoubtedly is responsible for the difference in the reactions of these compounds.



VIII

Experimental

Ethyl Tetrahydrofuroate.—Ethyl furoate was hydrogenated[7] in the presence of the Raney catalyst[8] at 150°, using pressures of 100–130 atmospheres. With 15 g. of catalyst and 200 g. of ethyl furoate, hydrogenation was complete in four hours; average yield from five hydrogenations, 93.3%, b. p. 188–190° (740 mm.).

Furyldiethylcarbinol.[10]—An ethereal solution of 0.5 mole of ethylmagnesium bromide was prepared in the usual manner and a solution of 35 g. (0.25 mole) of ethyl furoate in anhydrous ether was added to the solution, the rate of addition being determined by the vigor of the reaction. The reaction mixture was refluxed on a water-bath for three hours, cooled, poured into a mixture of 200 g. of cracked ice with 200 ml. of a saturated aqueous solution of ammonium chloride, stirred vigorously, allowed to stand for three hours, the ethereal layer separated, and the aqueous layer extracted twice with ether. The combined ether extracts were then washed with 100 ml. of saturated ammonium chloride solution, dried with magnesium sulfate and distilled. There was obtained 28.5 g. (77%) of furyldiethylcarbinol, b. p. 92–95° (14 mm.). The distillation residue was tarry and was larger in quantity when heating during distillation was prolonged.

Furyldi-*n*-butylcarbinol.—The procedure was exactly like that described above for furyldiethylcarbinol. The yield was 40.9 g. (78%), b. p. 128–131° (14 mm.), n^{25}_D 1.4703, d^{25}_{25} 0.9251, MR'_D found 63.30, MR'_D calcd. 62.29.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 74.28; H, 10.47. Found: C, 74.47; H, 10.60.

Tetrahydrofuryldiphenylcarbinol (IV).—To a solution of phenylmagnesium bromide prepared from 8.2 g. (0.34 gram atom) of magnesium in 500 ml. of dry ether was added with stirring 24.5 g. (0.17 mole) of ethyl tetrahydrofuroate at such a rate as to maintain gentle refluxing. The reaction mixture was refluxed with stirring on the water-bath for one hour, cooled, and added to a mixture of 200 g. of cracked ice and 20 ml. of 1:1 sulfuric acid. The ether layer was washed with a cold 5% solution of sulfuric acid, dried with anhydrous magnesium sulfate, concentrated on the steam-bath and the solid residue recrystallized from petroleum ether (b. p. 60–70°). The product weighed 41 g. (83%), m. p. 79–80° (uncorr.).

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.31; H, 7.08. Found: C, 80.38; H, 7.20.

Tetrahydrofuryldiethylcarbinol (II).—This preparation was carried out like that of IV, except that 1.0 mole of ethyl tetrahydrofuroate (with correspondingly larger amounts of the other materials) was used. The yield was 120 g. (76%), b. p. 200–203° (740 mm.). The product was a colorless liquid with an agreeable ethereal odor, d^{25}_{25} 0.9744, n^{25}_D 1.4552, MR'D found 44.01, MR'D calcd. 44.75.

Anal. Calcd. for $C_9H_{18}O_2$: C, 68.35; H, 11.39. Found: C, 68.20; H, 11.41.

Hydrogenation of 18.0 g. of furyldiethylcarbinol in the presence of 5.0 g. of Raney nickel catalyst and 25 ml. of absolute ethanol at an initial hydrogen pressure of 115 atmospheres was complete in three hours at 150°. Some tarry material was formed but there was also obtained 12.0 g. (67%) of II, b. p. 203° (740 mm.).

Tetrahydrofuryldi-*n*-butylcarbinol (III).—This preparation was carried out like that of II. The yield was 114.5 g. (53.4%), b. p. 151–152° (24 mm.), 251–252° (740 mm.), d^{25}_{25} 0.9219, n^{25}_D 1.4543, MR'D found 62.90, MR'D calcd. 63.18.

Anal. Calcd. for $C_{13}H_{26}O_2$: C, 72.89; H, 12.14. Found: C, 72.84; H, 12.20.

Hydrogenation of 11.8 g. of furyldi-*n*-butylcarbinol in the presence of 1.5 g. of Raney nickel catalyst and 25 ml. of absolute ethanol at an initial hydrogen pressure of 120 atmospheres was complete in one and one-half hours at 175°. A small amount of low-boiling material was formed, presumably hydrogenolysis products, along with 7.0 g. (58%) of III, b. p. 254° (740 mm.), n^{25}_D 1.4545.

1,1-Diphenyl-2,5-epoxy-1-pentene (V).[11]—Tetrahydrofuryldiphenylcarbinol (IV) was dehydrated under a variety of conditions and the following procedure was found to be the most satisfactory. To 101.6 g. (0.4 mole) of IV was added 5.0 g. of anhydrous magnesium sulfate and the mixture heated in a 100-cc. round-bottomed flask until the theoretical amount of water had distilled through a Vigreux column 8 cm. long and 1.5 cm. in diameter. The dark residue which solidified on cooling was crystallized once from alcohol with decolorizing charcoal, once from alcohol alone and once from petroleum ether, b. p. 60–70°. After these recrystallizations the product was slightly yellow and melted at 107.5–108.5° (uncorr.). Further recrystallizations rendered it white but did not change the melting point. The yield was 52.6 g. (56%). The compound reduced alkaline potassium permanganate solution, decolorized a 5% solution of bromine in carbon tetrachloride and could be distilled without decomposition, b. p. 195° (10 mm.).

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.44; H, 6.77. Found: C, 86.10; H, 6.87.

Ozonolysis of 1,1-Diphenyl-2,5-epoxy-1-pentene.—The ozonide prepared from 1.5 g. of V dissolved in 35 ml. of a 50–50 mixture of petroleum ether, b. p. 30° and b. p. 60–70° was hydrolyzed, after removal of the solvent under diminished pressure, by gentle boiling with 2 to 3 ml. of superoxol. The insoluble material was then extracted with ether and an insoluble compound,[12] m. p. 210–214° (dec.) removed by filtration. Distillation of the ether solution gave 0.5 g. (50%) of benzophenone, b. p. 156° (10 mm.), m. p. 46–48°, m. p. of oxime 139–140°. A sample of authentic benzophenone, m. p. 47–48.5°, boiled at 153–154° (10 mm.) in the same apparatus and the melting point of benzophenone oxime (140–141°) was not altered by mixture with the oxime of the ozonolysis product.

The ozonide prepared by passing ozone through a solution of 23.6 g. (0.1 mole) of V in 175 ml. of dry carbon tetrachloride was hydrolyzed with zinc and water, using hydroquinone and silver nitrate as catalysts by the recently described method.[13] The water-insoluble portion of the product was removed by extraction with ether, the zinc removed from the water layer by filtration, the ether distilled from the water-insoluble layer and the residue added to the aqueous filtrate to remove water-soluble materials. The water insoluble layer was separated and distilled. The sole product was benzophenone (b. p. 140–150° (10 mm.), m. p. 46.5–48.5°, m. p. of oxime, 141.5–142°) the identity of which was confirmed by its mixed melting point with an authentic sample of benzophenone and by the mixed melting point of its oxime with benzophenone oxime. The melting points of the mixtures were 46.5–48.5° and 141–142°, respectively. The aqueous layer from which the benzophenone had been separated was distilled through a small indented column until a sirupy residue remained. This residue contained zinc chloride (because of the incomplete removal of carbon tetrachloride before decomposition of the ozonide) and was extracted repeatedly with ether and the ether extracts dried and distilled. The ether extracts contained enough zinc chloride to cause considerable decomposition during distillation but there was obtained 0.5 g. of pure γ-butyrolactone, b. p. 95° (15 mm.).

γ-Butyrolactone.—Two hundred grams of ethyl succinate was heated at 250° with 18 g. of copper–chromium–barium oxide catalyst[14] (37KAF) for ten hours at a pressure of 90 to 130 atmospheres. Fractional distillation of the product through a very efficient fractionating column gave 10 g. (10%) of γ-butyrolactone, b. p. 92–94° (18–19 mm.).

Hydrazide of γ-Hydroxybutyric Acid.—The procedure was exactly like that previously used[15] with ε-caprolactone. The solid product obtained from the reaction of hydrazine hydrate with the γ-butyrolactone prepared from the hydrogenation of ethyl succinate gave, upon recrystallization from ethanol, a small amount of the dihydrazide of succinic acid,[16] m. p. 165–166° (uncorr.), and a much larger amount of the hydrazide of γ-hydroxybutyric acid, m. p. 89–90° (uncorr.).

Anal.[18] Calcd. for $C_4H_{10}O_2N_2$: N, 23.7. Found: N, 24.03, 24.05.

---

[11] The authors wish to express their gratitude to Professor J. R. Johnson for his interest and advice during this portion of the work.

[12] The same compound was formed from the ozonolysis of unsymmetrical diphenylethylene under these conditions.

[13] Whitmore and Church, THIS JOURNAL, **54**, 3711 (1932); Church, Whitmore and McGrew, *ibid.*, **56**, 178 (1934).

[14] Connor, Folkers and Adkins, *ibid.*, **54**, 1138 (1932).

[15] Van Natta, Hill and Carothers, *ibid.*, **56**, 456 (1934).

[16] This melting point was unchanged when the product was mixed with an authentic sample of the hydrazide of succinic acid.[17] This shows that γ-butyrolactone was not completely separated from ethyl succinate by the fractional distillation. This dihydrazide is quite insoluble in alcohol, while the hydrazide of the hydroxy acid is very soluble.

[17] Schöfer and Schwan, *J. prakt. Chem.*, **51**, 190 (1895).

[18] The micro-Dumas analyses were made by Dr. M. T. Bush.

The reaction of hydrazine hydrate with the ozonolysis product believed to be γ-butyrolactone gave a solid hydrazide, m. p. 90.5–92° (uncorr.). The mixture of this product with the hydrazide of the γ-butyrolactone prepared from ethyl succinate melted at 90.5–91.5° (uncorr.).

Dehydration of Tetrahydrofuryldi-*n*-butylcarbinol.—A mixture of 10 g. of the carbinol (III) with 0.5 g. of magnesium sulfate and 0.5 g. of potassium hydroxide was heated under a small Vigreux column. Water and an oil with an ethereal odor distilled and the residue in the flask became tarry. The experiment was repeated with similar results using lime in place of the magnesium sulfate. The combined dried products from both experiments distilled between 40 and 150° (740 mm.) with a uniform temperature rise.

Tetrahydrofuryldiphenylcarbinol with Phenylmagnesium Bromide.—To a solution of 0.6 mole of phenylmagnesium bromide in 400 ml. of ether was slowly added in small portions 48.5 g. (0.2 mole) of tetrahydrofuryldiphenylcarbinol (IV). To the reaction mixture was then added 500 ml. of dry xylene, the reflux condenser replaced by a short fractionating column with a condenser set downward for distillation and the mixture heated on an oil-bath until the vapors reached a temperature of 131°. The reflux condenser was then replaced and the xylene refluxed for fifty hours. After the reaction mixture was cooled it was poured into a mixture of cracked ice with 40 ml. of 1:1 sulfuric acid and the xylene layer separated and distilled at atmospheric pressure. Water appeared in the distillate near the end of the distillation. The residue (50 g.) solidified upon cooling and after recrystallization from petroleum ether (b. p. 60–70°) and from alcohol gave 41 g. (87%) of pure material, m. p. 107.5–108.5° (uncorr.). This melting point was unchanged when the material was mixed with a sample of V prepared by the dehydration of IV. In another experiment in which the time of refluxing was nine hours and in which the xylene was removed under reduced pressure, 76% of IV was recovered unchanged (m. p. 77–79°) along with 4 g. of an oil (b. p. 250°) which decolorized bromine in carbon tetrachloride and was apparently impure dehydration product.

Summary

Tetrahydrofuryldialkylcarbinols have been synthesized by the reaction of alkylmagnesium halides with ethyl tetrahydrofuroate and by the catalytic hydrogenation of furyldialkylcarbinols. Tetrahydrofuryldiphenylcarbinol was readily dehydrated to give 1,1-diphenyl-2,5-epoxy-1-pentene; in contrast to the dehydration of furfuryl alcohol, there was no indication of ring enlargement. The dehydration product was much more stable than 2,5-epoxy-1-pentene. Tetrahydrofuryldiphenylcarbinol was not cleaved by phenylmagnesium bromide under "forced" conditions.

The Preparation of Some of the Lower Alkyl Sulfonic Acids

BY D. L. VIVIAN AND E. EMMET REID

Much work has been done by earlier investigators on the preparation of alkyl sulfonic acids by various procedures, but very little effort has been made to isolate and characterize the anhydrous acids. Two exceptions occur in the work of Noller and Gordon[1] on the acids containing from nine to fourteen carbon atoms, and in that of Berthoud[2] on methyl sulfonic and ethyl sulfonic acids. The present paper gives data on the four straight-chain primary sulfonic acids containing from three to six carbon atoms.

The propyl, amyl and hexyl sulfonic acids were prepared from barium salts remaining from a previous investigation[3] by precipitating the barium with sulfuric acid. The butyl sulfonic acid was prepared by oxidation of *n*-butyl mercaptan[4] by dropping 48 g. of it into 180 cc. of concentrated nitric acid with mechanical stirring and evaporating on the steam-bath until the oxides of nitrogen were completely removed. The crude acid was diluted with ten volumes of water, neutralized with lead carbonate, filtered and the filtrate evaporated to dryness. The crude lead salt obtained in 72–96% yields was recrystallized from 80% alcohol and then decomposed in aqueous solution with hydrogen sulfide. After removing the lead sulfide the aqueous solution was concentrated on the steam-bath.

The pure anhydrous sulfonic acids were obtained from the concentrated aqueous solutions as colorless liquids after four or five distillations at 1 mm. Their hot vapors attack rubber but a coating of sodium silicate on the stoppers prevents this. The pure acids soon darken even in a vacuum.

The average purity of these acids as determined by two concordant titrations with methyl orange

(4) This acid was also prepared by converting butyl mercaptan into disulfide (b. p. 107–109° at 12 mm.) and oxidizing this with nitric acid, but the yield was not quite as good.

TABLE I

PROPERTIES OF THE ALKYL SULFONIC ACIDS

Acid	B. p. Temp., °C.	B. p. Pressure, mm.	M. p., °C.	Density$^{25}{}_4$
Methyl sulfonic[2]	167	10	+20	1.4844
Ethyl sulfonic[2]	...	..	−17	1.3341
n-Propyl sulfonic	136	1	+ 7.5	1.2516
n-Butyl sulfonic	147	0.5	−15.2	1.1906[a]
n-Amyl sulfonic	163	1	+15.9	1.1226
n-Hexyl sulfonic	174	1	+16.1	1.1047

[a] $d^0{}_4$ 1.2117.

as indicator was as follows: propyl, 99.2; butyl, 100; amyl, 100; hexyl, 99.8%. Presumably the propyl acid still retained a trace of moisture.

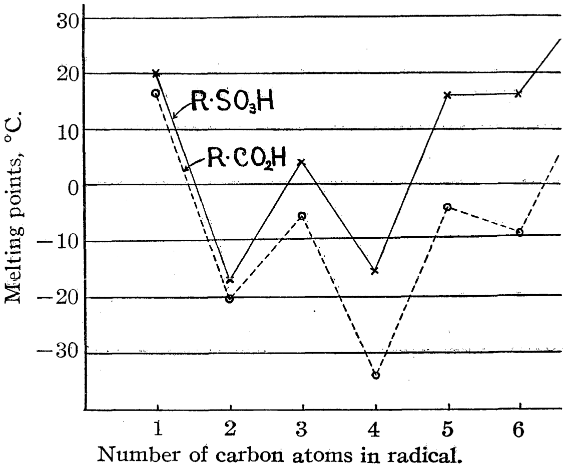

Fig. 1.—Melting points of sulfonic and carbonic acids.

The physical data obtained with these acids, together with the corresponding data for methyl and ethyl acids, are given in Table I.

These melting points are plotted along with those of the carboxy acids containing the same radicals in Fig. 1. The alternation is remarkably alike in the two series.

The acid chloride of the butyl sulfonic acid was prepared by the action of phosphorus pentachloride on the potassium salt. It boiled at 90° at 11 mm.,[5] and had $d^{25}{}_4$ 1.2140, and $d^0{}_4$ 1.2404.

It was thought that butyl sulfonic acid might resemble sulfuric acid in substitution reactions, but it did not react with benzene at 80°. Aniline sulfate rearranges to sulfanilic acid, but the aniline salt of butyl sulfonic acid did not undergo any change when heated several hours at 130°. This salt is readily made by adding aniline to the acid and warming slightly. After one recrystallization it melted at 162°. Gilman and Morris[6] give m. p. 159° for this salt obtained by the reaction of thionylaniline with butylmagnesium bromide.

Summary

n-Propyl, *n*-butyl, *n*-amyl and *n*-hexyl sulfonic acids have been prepared and characterized.

The Isolation and Some Properties of an Alkaloid from *Crotalaria spectabilis* Roth[1]

BY W. M. NEAL, L. L. RUSOFF AND C. F. AHMANN

The literature relative to the toxic species of the *Crotalariae* was reviewed in another paper,[2] in which the toxicity of *C. spectabilis* Roth was established. Previously known toxic species included *C. sagittalis* L., *C. juncea* L., *C. burkeana* Benth., *C. dura* Wood and Evans, and *C. globifera* E. Mey. Still other species have been suspected. Bessey and Stalker[3] suspected the toxic principle of *C. sagittalis* to be an alkaloid. Timson[4] found the seeds of *C. juncea* to give reactions suggesting the presence of an unidentified alkaloid. In no case had a specific alkaloid been isolated from any member of the genus.

This is a report of the isolation and some of the properties of an alkaloid isolated from *C. spectabilis*. Because of the large number of species (over 600) of *Crotalaria*, several of which have proven toxic, the name *monocrotaline* is suggested for this alkaloid. Succeeding alkaloids from this genus can then be named *dicrotoline*, *tricrotaline*, etc., following Couch's[5] recommendation for the lupine alkaloids.

(5) Couch, THIS JOURNAL, **56**, 155 (1934).

Experimental

The first extracts of the seeds of *C. spectabilis* were made by soaking them in 1.25% sulfuric acid. The filtrate was shaken with Lloyd's alkaloid reagent. The basic material was liberated from the reagent with 0.1 *N* sodium hydroxide. This solution was extracted with successive portions of chloroform. Opaque crystals remained upon evaporation of the solvent.

Later extracts were made by soaking the seeds in 5% ammonium hydroxide for forty-eight hours, and extracting the filtrate with successive portions of chloroform. The crystals obtained upon evaporation of the solvent were dissolved in 1:1 hydrochloric acid, the solution thus formed was made alkaline with ammonium hydroxide, and extracted as above. Further purification was by repeated recrystallization from chloroform or absolute alcohol. Crystals from the alcohol were transparent. Crude extracts equivalent to 0.4, 0.07 and 0.015% of the dry weights of the seeds, leaves and stems, respectively, of *C. spectabilis* were prepared.

The extracted substance is soluble in chloroform and alcohol, slightly soluble in ether and very slightly soluble in water.

The compound slowly decolorizes potassium permanganate, and gives a yellowish color with Fröhde's (sulfomolybdic acid) reagent. It yields a yellowish precipitate with picric acid, a reddish-brown precipitate with Wagner's iodide reagent, a white precipitate with Mayer's reagent and a yellowish-white precipitate with Sonnenschein's phosphomolybdic acid reagent. It forms precipitates with salts of the heavy metals. All the tests were characteristic of alkaloids.

Melting point determinations of the purified compound were between 196 and 197° (uncorr.).

Anal. Calcd. for $C_{16}H_{26}O_6N$: C, 58.51; H, 7.98; N, 4.27. Found: C, 57.97; H, 7.85; N, 4.15.[6] The molecular weight, by the above formula, is 328.3. The determination of the neutral equivalent indicated a molecular weight of 324.

Pharmacologically, it lowers the blood pressure in dogs, and decreases the rate and amplitude of terrapin heart *in situ*. This decrease was observed even when the vagus nerve was severed. The rate of contraction of isolated heart muscle strips from terrapin is stimulated immediately, followed by a decrease in rate and amplitude.

The same lesions were observed in experimental animals administered lethal doses when either the whole seeds or alkaloid *per se* was used. This would indicate that the alkaloid isolated is the toxic principle of this plant. The twenty-four-hour lethal dose for chickens is 65 mg./kg. live weight.

Summary

The initial isolation of a specific alkaloid from the genus *Crotalaria* is reported. This compound has been named *monocrotaline* and was isolated from *C. spectabilis* Roth.

The compound melts at 196–197°, and has been given the empirical formula $C_{16}H_{26}O_6N$, tentatively.

The identity of the compound as the toxic principle of *C. spectabilis* has been established.

Energy Levels in Electrochemistry

BY WILDER D. BANCROFT AND JAMES E. MAGOFFIN

When measured against any standard electrode the changes $Cu \rightleftharpoons Cu^{++}$ and $Fe^{++} \rightleftharpoons Fe^{+++}$ are practically reversible. The change $H_2 \rightleftharpoons 2H^+$ is practically reversible at platinum black; but may show a large difference at zinc or mercury because the rate of change of atomic hydrogen to molecular hydrogen is rapid at platinum and relatively slow at zinc or mercury. To pass from hydrogen ion to molecular hydrogen, the system may have to pass through a higher energy level than molecular hydrogen. Given a substance which can be reduced at a lower energy level than that of molecular hydrogen, and it will be reduced at a platinum cathode. If the required energy level is above the molecular hydrogen level and below the atomic hydrogen level which we get with a zinc or mercury cathode, the substance cannot be reduced at a platinum cathode but can be at a zinc or mercury cathode. If the required energy level is above that to be reached with a zinc or mercury cathode, the substance cannot be reduced electrolytically in aqueous solution. Nobody is surprised at not being able to reduce methyl alcohol to paraffin; but no explanation has ever been given why it is impossible to reduce aqueous sodium sulfate or dilute sulfuric acid to sodium sulfite or sulfurous acid. The facts were known to Faraday. We have sealed up a sodium sulfate solution with platinum and hydrogen for six months without anything being formed in that time that would decolorize potassium permanganate.

This is the more remarkable because sodium sulfate and sulfurous acid can easily be oxidized electrolytically and can also be reduced electrolytically under suitable conditions. The answer is that in trying to go electrolytically from sodium sulfate to sodium sulfite, the system must pass through an energy level which is higher than any one can get with nascent hydrogen at a mercury cathode. The same thing holds true for sulfuric acid with this exception that the energy hump disappears experimentally if the sulfuric acid solution is made concentrated enough or hot enough.

We electrolyzed a 25 *N* solution of sulfuric acid with a smooth platinum foil anode and a platinized wire cathode at 50, 80 and 130°. At 50° no reduction of the sulfuric acid took place and the reaction products were hydrogen and oxygen. At 80° hydrogen and hydrogen sulfide were formed at the cathode because the rate of reduction was so slow compared with that of sulfurous acid that the latter was reduced as fast as formed. At 130° hydrogen and sulfur were formed, showing that the rate of reduction of sulfuric acid is fast enough to build up an appreciable concentration of sulfurous acid which then reacted with hydrogen sulfide to form sulfur. With a plain platinum foil cathode reduction of the sulfuric acid was not accomplished until a temperature of 130° was reached, at which temperature the products were hydrogen and hydrogen sulfide when a zinc cathode was used, reduction was obtained at 100°, sulfur and hydrogen being the products. The fact that platinized platinum accomplishes the reduction at a lower temperature than plain platinum indicates that absorption and activation of the sulfuric acid are important factors in the lowering of the energy hump of sulfuric acid.

One may ask why the reverse reaction is not identical with the forward reaction except in sign. The answer is that electrolysis sets free or tends to set free ions. There is no direct decomposition of an ion, such as $SO_4^{=} = SO_3^{=} + O$ or $NO_3^- = NO_2^- + O$. The forward reaction in the oxidation of a sulfite may be written: $SO_3^{=} + O = SO_4^{=}$ and the reverse reaction may be written $SO_4^{=} + 2H = SO_3^{=} + H_2O$; but the two reactions are not the same and are possibly never the same when there is a change in the composition of the ion. This concept of an intermediate energy level which may be higher than that of nascent hydrogen is quite different from the assumptions made by Conant and Lutz[1] of a reversible electrolytic process and a practically irreversible nonelectrolytic one.

It is well known that among metallic oxides the higher ones are stronger oxidizing agents and are more acidic than the lower oxides. With oxygen in the complex anion, this is not always true. Sulfuric acid is an oxidizing agent only at high concentrations or high temperatures, as in the oxidation of naphthalene and even there a catalyst is a great help. Potassium chlorate and perchlorate are weaker oxidizing agents at moderate temperatures than potassium hypochlorite, because of the high intermediate energy levels that must be passed through.

By changing the catalytic surface it is possible to do almost anything with sodium nitrate and nitrite.[2] Nitrate and nitrite are reduced about equally readily at a smooth platinum or copper cathode. Nitrite is reduced more readily than nitrate at a platinized cathode, and nitrate than nitrite at a pulverulent copper or silver cathode. With boiling solutions sodium nitrate can be reduced very effectively to nitrite either at a mercury cathode or with sodium amalgam. Measurements of the cathode potentials showed that overvoltages were a minor factor and that the phenomenon was a function of the nature and structure of the cathode.

At 25° there is practically no reduction of sodium chlorate at a smooth platinum cathode. On the other hand, Gladstone and Tribe[3] found, nearly sixty years ago, that pulverulent platinum or copper, saturated with hydrogen, reduced sodium chlorate to chloride. This could not be a question of electromotive force and experiment showed that there was a specific catalytic effect due to the form of the metal. Decomposition voltage curves were determined for 25 and 80°. Even at 25° there is a marked break in the curve for platinized platinum at a voltage at which no break can be detected in the corresponding curve for smooth platinum. At 80° with the platinized cathode there is first a curve representing reduction of the chlorate. Suddenly the cathode goes apparently passive and the curve changes to that for the evolution of hydrogen. This is due to impoverishment of sodium chlorate in the pores of

the platinized cathode. The effect comes on later and is more marked at the higher temperature owing to the higher rate of diffusion. The cathode can also be made to stay active longer by rotating it, thus increasing the rate of diffusion. The effect of rotation was not so striking as we had hoped that it would be.

Chlorate is evidently adsorbed and activated more strongly by pulverulent platinum or copper than by the smooth metals. This adsorption and activation of sodium chlorate by copper accounts for the puzzling reduction of chlorate by hydrazine in presence of pulverulent copper. Hodgkinson[4] reports that hydrazine can be boiled with a solution of sodium or potassium chlorate without any reduction of the chlorate taking place. In the presence of tarnished copper, quantitative reduction is obtained, apparently at room temperature. Only traces of copper are corroded, so the action must be catalytic. This is in accord with the electrolytic results. The tarnished copper is reduced to pulverulent copper which adsorbs and activates the chlorate so that it is reduced by the hydrazine. It is not the dissolved cuprous salt which acts catalytically, because we have shown that ammoniacal cuprous sulfate will not reduce chlorate. It is essential to oxidize all the cuprous salt with air before testing for chloride, because it was found that some chlorate is reduced if the solution is acidified before all of the cuprous salt has been removed.

With perchlorates the energy level to which the system must be raised is evidently much higher than with chlorates because nobody has yet succeeded in reducing perchlorates electrolytically in neutral or alkaline solutions. Williams[5] has shown that sodium perchlorate can be reduced by boiling with titanous sulfate and sulfuric acid. Since boiling sulfuric acid, if sufficiently concentrated, will decompose perchlorates,[6] there should be no difficulty in reducing perchlorates electrolytically near the boiling point if the right concentration of sulfuric acid is taken.

Chilesotti[7] found that molybdic acid, MoO_3, is reduced more rapidly to Mo_2O_3 at a platinized cathode than at a smooth platinum cathode; but that the reduction goes farther at a smooth platinum cathode. The first stage must be due to adsorption and activation; but it should be shown that the second stage calls for a higher voltage. Tafel[8] showed that in a sulfuric acid solution caffeine is reduced more readily at a mercury cathode than at a lead cathode, while the reverse is true for succinimide. This reversal must be due to selective adsorption in one or the other case, perhaps in both cases.

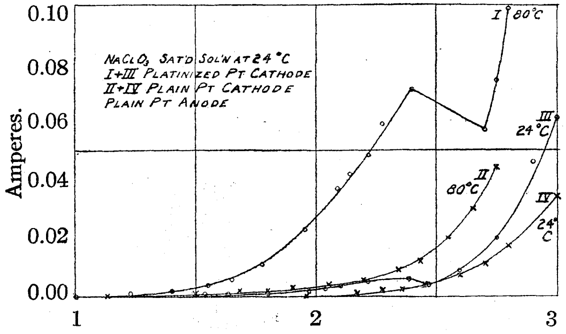

Fig. 1.

Conant and Cutter[9] have observed what appears to be a striking case of adsorption and activation. Dimethylacrylic acid is reduced by platinum and hydrogen but not by a chromous chloride solution, even though the latter is a stronger reducing agent than hydrogen by about 0.3 volt. Evidently the platinum activates the dimethylacrylic acid. If platinum is kept in a suitable chromous chloride or acetate solution until all the hydrogen is given off, that solution will undoubtedly reduce dimethylacrylic acid in presence of platinum. It is not yet necessary to differentiate in principle between hydrogenation and reduction.

People have become so used to speaking of electromotive forces of reversible reactions that most physical chemists believe that an irreversible reaction—assuming one to exist—cannot give a definite electromotive force. This is wrong. A given solution of sodium sulfite is at a definite energy level and changes to another energy level when it is oxidized to sodium sulfate. Since this reaction can be made to take place electrolytically under practically constant conditions, it must and does give a definite electromotive force.

If the sulfite–sulfate electrode were reversible, the limiting, ideal potential difference at a sulfite–sulfate electrode at constant *p*H would be given by the equation

(9) Conant and Cutter, THIS JOURNAL, **44**, 2651 (1922).

$$nFE = RT \ln \frac{P \cdot p_{SO_3}}{p_{SO_4}}$$

where p_{SO_3} and p_{SO_4} are the osmotic pressures of the sulfite and sulfate ions, respectively, and ln P is the Nernst integration constant. If the reaction is not reversible, the concentration of the sulfate ions has theoretically no effect, and the equation becomes

$$nFE = RT \ln P' \times p_{SO_3}$$

The same formula is obtained if the concentration of sulfuric acid is kept constant and this equation has been verified by Lewis, Randall and Bichowsky,[10] who did not know that the reaction was irreversible. They say that "equilibrium conditions apparently were not reached with great rapidity; but, upon standing, steady values were obtained reproducible to within about a millivolt."

"An iridized platinum electrode over which bubbled sulfur dioxide (diluted with air) was used in a solution of sulfuric acid. The other electrode was of mercury covered with mercurous sulfate in the same acid."

Their data are given in Table I.

In the cells in which the sulfuric acid concentration was kept constant at 0.8946 M, the equation describes with surprising accuracy the effect of changing the pressure of sulfur dioxide from 0.007 atm. to 0.109 atm., a ratio of more than fifteen to one. Increasing the concentration of the sulfuric acid decreases the electromotive force. We believe that this is not due to the change in the concentration of the sulfate ion, but to a change in the concentration of the hydrogen ion for which no term occurs in the equation. The experiment confirms the part of the theory which is right and disproves the parts that are wrong. Conant and Lutz[11] apparently obtained similar results for their irreversible reduction, though their wording is unnecessarily obscure.

We have confirmed the general results obtained by Lewis in our experiments on sodium sulfite, which of course gives a larger electromotive force against a calomel electrode than an equimolecular solution of sulfurous acid does. Some of our data are given in Table II. The calomel electrode is always cathode and no correction has been made for the liquid junction.

Changing from tenth molar to molar sodium sulfite increases the observed electromotive force from 0.131 to 0.146, which is in the right direction. Adding sodium sulfate increases the electromotive force instead of decreasing it, as would be the case if the reaction were reversible. The fact that tenth molar sodium sulfate increases the electromotive force more, to 0.153, than does molar sodium sulfate, to 0.149, shows that at least two factors are at work. We have not yet tried to determine what the second one is. It was sufficient for the present to show that addition of the reaction product in considerable amounts did not lower the voltage. Addition of molar caustic soda raised the electromotive force from 0.156 to 0.271, which was in the direction to be expected.

Experiments with other salts were very interesting, as there is apparently a marked Hofmeister series, the electromotive force decreasing in the order: $I > OH > CNS > Br > Cl > SO_4$, with iodide coming above thiocyanate as it should do when adsorption is eliminated. The difference is very marked, $E_c = 0.149$ volt for sulfate and 0.302 volt for iodide. It is a question to what extent caustic soda owes its position to the pH or to displacing the water equilibrium. There are no facts which would have enabled us to predict that the electromotive force would be larger in iodide solutions rather than smaller.

One thing that must be done as soon as possible

[11] Conant and Lutz, *ibid.*, **46**, 1256 (1924).

is to devise methods for determining, at least approximately, the intermediate energy levels for sulfates, chlorates, perchlorates, etc. It should be clear that the difficulties that we have with these electrolytes are similar in principle to the difficulties that we have with organic compounds. Most of the passive resistances to change will prove to be energy humps.

Summary

The general results of this paper are:

1. The oxidation of dilute aqueous sulfurous acid or sodium sulfite is an irreversible reaction because, for reduction to take place, the system must pass through an energy level or energy hump which is higher than the energy level for nascent hydrogen as obtained by electrolysis.

2. With sulfuric acid solutions, and presumably with all other solutions, the energy hump decreases with increasing concentration, rising temperature and activating adsorption.

3. The stabilities of sodium chlorate and sodium perchlorate relatively to sodium hypochlorite are due to the intermediate energy levels which must be surmounted if reduction is to take place.

4. Sodium chlorate is adsorbed and activated so much by pulverulent copper that it can then be reduced by hydrazine.

5. An irreversible reaction may give a definite electromotive force. The limiting, ideal equation for the irreversible sulfite-sulfate electrode at constant pH is $nFE = RT \ln P' \times p_{\mathrm{SO_3}}$.

6. All of Conant's work on irreversible reduction falls into line if one rejects the two assumptions of a reversible electrolytic step and a practically irreversible, non-electrolytic step. There is no experimental evidence for either, and both are superfluous. There is no reason at present for making any fundamental distinction between hydrogenation and reduction.

A Procedure for the Separation of the Six Platinum Metals from One Another and for their Gravimetric Determination[1,2]

BY RALEIGH GILCHRIST AND EDWARD WICHERS

In a paper[3] from this Laboratory, presented at the Ninth International Congress of Pure and Applied Chemistry in Madrid, April, 1934, a group of reactions was described which can be used for the quantitative separation of the six platinum metals from one another, and for their determination. The paper likewise contained a discussion of the analytical methods most generally used, and of certain others of special interest.

In this new system of analysis, the detailed procedure of which is given in the present paper, precipitation with ammonium chloride, fusion with pyrosulfate and extraction of metallic residues with acids are avoided entirely. The separation of platinum from palladium, rhodium and iridium is accomplished by controlled hydrolytic precipitation. When a boiling solution containing these four metals as chlorides, and in addition sodium bromate, is neutralized to approximately pH 7, the hydrated dioxides of palladium, rhodium and iridium precipitate quantitatively, leaving platinum in solution. A second precipitation of the dioxides suffices to effect complete removal of platinum. This method is applicable not only to the joint separation of palladium, rhodium and iridium from platinum, but also to the individual separation of these metals from platinum. It has a very great advantage over the older method by which platinum is separated from palladium, rhodium and iridium by precipitation with ammonium chloride. The hydrolytic method effects a clean separation of the platinum, whereas that in which the platinum is precipitated as ammonium chloroplatinate involves at least two inherent types of error. One type of error results from the persistent contamination of the platinum salt by rhodium and iridium (even though tervalent) and, to a less extent, by palladium. The other error occurs be-

[3] R. Gilchrist and E. Wichers, "A New System of Analytical Chemistry for the Platinum Metals." Paper No. 178 of the Scientific Program of the Ninth International Congress of Pure and Applied Chemistry. As the proceedings of the Congress have not been published, reprints of this paper are not yet available.

cause ammonium chloroplatinate is appreciably soluble. It is true that the solubility of the platinum salt can be reduced to an amount which may be negligible in some analytical procedures by adding a large excess of ammonium chloride and digesting the solution. These conditions, however, greatly increase the contamination of the salt by other platinum metals. The same criticism applies to the separation of quadrivalent iridium from rhodium and palladium, by means of ammonium chloride. A full discussion of the shortcomings of the traditional methods of separating the platinum metals from one another cannot be given in this paper, but will be found in detail in the paper presented at the International Congress.

Palladium is readily and completely separated from rhodium and iridium, in chloride solution, by precipitation with dimethylglyoxime, a single precipitation being sufficient.

Rhodium is separated from iridium by reducing it to metal with titanous chloride in a boiling solution of the sulfates in diluted sulfuric acid. The metallic rhodium is dissolved in hot sulfuric acid and precipitated a second time, to remove iridium completely.

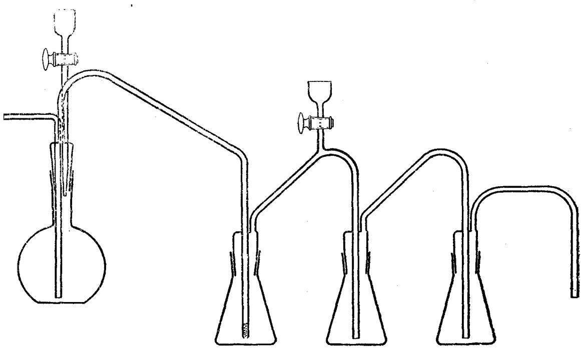

Fig. 1.—Distilling flask with train.

When this new procedure is applied to the separation of all six of the platinum metals from one another, osmium is the first metal which is isolated. This is accomplished by distilling its volatile tetroxide from a nitric acid solution. Ruthenium is next isolated by distilling its tetroxide from a solution of the sulfates in diluted sulfuric acid to which sodium bromate is added. A very suitable reagent for the absorption of osmium tetroxide, and also of ruthenium tetroxide, is 6 *N* hydrochloric acid saturated with sulfur dioxide.

In the recovery and determination of each of the six metals, the new features of the procedure consist in the precipitation of osmium, of ruthenium and of iridium, as hydrated oxides, with final ignition to metal. Rhodium, and also platinum, are recovered as sulfides, and ignited to metal. Palladium is recovered as the glyoxime compound, in which form it may be weighed, or it may be determined as metal, after ignition of the glyoxime precipitate.

The accuracy of this new method is comparable to that of the best analytical procedures for the common metals. The reagents used are generally available, and no special equipment is required. While the operations must be performed carefully, they do not involve technique unfamiliar to a trained analyst.

The individual procedures upon which the general scheme for the group as a whole is based are to be found in the papers to which the references in this paper are given. These papers also contain a detailed account of the experimental work upon which the individual procedures were developed. They should be consulted for details which obviously cannot be included in the present paper. The general procedure, as given in this paper, was tested by analyzing solutions containing, simultaneously, known quantities of the six pure metals. The procedure is designed for the analysis of the platinum group, in the absence of other metals.

Consideration of the elements occurring in crude platiniferous materials will be taken into account in the extension of this scheme to their analysis.

Procedure Recommended for the Analysis of the Platinum Group

I. Separation and Determination of Osmium[4]

1. Distilling Apparatus.—The distilling apparatus, which is shown in Fig. 1, consists of three main parts, namely, a 700-ml. distilling flask, a set of three 300-ml. absorbing flasks and a train of inlet and delivery tubes which are sealed into one piece. The thistle tube, closed by a stopcock and placed between the first and second absorbing flasks, serves to replenish the absorbing solution with sulfurous acid if an unusual amount of nitric acid is distilled and also, at the end of the operation, to rinse the tube connecting the two flasks. The entire apparatus is constructed of Pyrex glass. The joints must be very carefully ground, and it is advantageous if they are made so that the flasks are interchangeable. It is important to note that these joints are sealed with a film of water only and not with lubricating grease, because the latter would cause reduction of some osmium tetroxide to dioxide

---

[4] R. Gilchrist, *Bur. Standards J. Research*, **6**, 421 (1931); RP 286.

which cannot be readily recovered. It was found necessary to grease the stopcock in the tube used for the introduction of nitric acid into the distilling flask, but this constitutes the only exception. During distillation, this delivery tube is frequently flushed with water in order to remove any osmium tetroxide which may have diffused into the column of water held in it. Three absorbing flasks are used, but the absorption of osmium tetroxide is practically complete in the first flask, and no osmium has been found to escape the second flask.

2. **Separation of Osmium by Distillation as Osmium Tetroxide.**—Place 150 ml. of diluted hydrochloric acid (1 + 1),[5] which has been freshly saturated with sulfur dioxide, in the first absorbing flask and 50 ml. of the same reagent in each of the other two flasks. Place the solution containing the platinum metals in the distilling flask and make sure that the separate parts of the entire apparatus are properly connected. If necessary, dilute the solution in the distilling flask to about 100 ml. with water, and add through the inlet tube 40 ml. of diluted nitric acid (1 + 1). Flush the thistle tube and stopcock with 10 ml. of water. Pass a slow current of air through the apparatus and heat the solution in the distilling flask to boiling. Continue the distillation for one hour. This length of time should be sufficient to ensure complete elimination of osmium from solutions in which it was originally present as an alkaline osmate or bromoosmate. If, however, the osmium is present as chloroosmate, the time required will be from seven to eight hours. In this case, it is preferable to distil from concentrated sulfuric acid, thereby greatly reducing the time required, or, if ruthenium is known to be absent, from concentrated sulfuric acid to which a few milliliters of nitric acid is added.

3. **Recovery of Osmium by Precipitation as the Hydrated Dioxide.**—Unite the portions of the absorbing solution and evaporate as far as possible on the steam-bath in a clean, unetched beaker. It is important, in precipitating the platinum metals hydrolytically, that the beakers used do not have an etched surface. An etched beaker often becomes stained with the precipitate, and this stain cannot always be removed readily. Digest the residue with 10 ml. of hydrochloric acid for fifteen minutes, and evaporate a second time. Repeat the digestion with hydrochloric acid and the evaporation three times more. This is done to ensure complete decomposition of any sulfite compounds of osmium. Dissolve the residue from the last evaporation in 150 ml. of water. Heat the resulting solution to boiling, and add to it a filtered 10% solution of sodium bicarbonate until a precipitate appears and suddenly coagulates. Add a few drops of brom phenol blue indicator solution (0.04%) to the hot solution. This indicator changes from yellow to blue at *p*H 4. Add the bicarbonate solution dropwise until the indicator assumes a faint bluish color. Finally, boil the solution for five to six minutes to ensure complete precipitation of the hydrated osmium dioxide.

4. **Determination of Osmium as Metal.**—Filter the solution through a Munroe platinum crucible,[6] carefully pouring the supernatant liquid through first. Transfer the precipitate, and wipe the inner walls of the beaker and also the glass rod with a rubber policeman which has been thoroughly wetted so that the precipitate will not cling to it. It should be borne in mind that filter paper must not be used to wipe the beaker, although it is used when handling precipitates of any of the other five platinum metals. Wash the precipitate thoroughly with a hot 1% solution of ammonium chloride, and then cover it with solid ammonium chloride. Moisten the ammonium chloride with a few drops of the wash solution and saturate the precipitate by applying suction. If desired, a saturated solution of ammonium chloride may be used to impregnate the precipitate. Continue the suction until the bottom of the crucible is coated with solidified ammonium chloride. Wipe off this coating of salt and place the platinum cap on the bottom of the crucible.

Cover the crucible with a Rose lid, preferably of quartz. Ignite a stream of hydrogen from a Rose delivery tube, likewise of quartz, and regulate the stream so that a very small flame is produced. Then insert the tube through the opening in the lid. The hydrogen flame will probably become extinguished by this operation and must be reignited. This is done by momentarily placing a burner flame under the crucible. The hydrogen will now burn as it emerges from under the lid at the edge of the crucible. The ignited hydrogen generates the requisite amount of heat to dehydrate the osmium compound without causing deflagration. After five minutes, gradually heat the crucible with the burner flame until all of the ammonium chloride is expelled. Ignite the osmium residue strongly in hydrogen for ten minutes. Remove the burner and allow the crucible to cool somewhat. Extinguish the hydrogen flame by momentarily breaking the current of hydrogen, and allow the crucible to cool to room temperature. Finally, displace the hydrogen with a current of carbon dioxide without even momentary access of air. If the hydrogen is not displaced by an inert gas, such as carbon dioxide, the reduced metal will be rapidly attacked when first exposed to the air, with significant loss of osmium. Weigh the residue as metallic osmium.

II. Separation and Determination of Ruthenium[7,8]

1. **Preparation of the Solution.**—Evaporate to dryness on the steam-bath the solution which remains in the distilling flask after the elimination of osmium. Add 5 to 10 ml. of hydrochloric acid and again evaporate. Repeat the evaporation with hydrochloric acid until oxides of nitrogen are no longer evolved. Dissolve the residue from the last evaporation in about 20 to 30 ml. of water. Add 10 ml. of sulfuric acid and evaporate the resulting solution carefully until vapors of sulfuric acid are evolved. Trans-

---

[5] Throughout this paper, whenever acids are mentioned, hydrochloric acid will mean the concentrated acid of specific gravity 1.18; nitric acid, the concentrated acid of specific gravity 1.42; sulfuric acid, the concentrated acid of specific gravity 1.84. Diluted acids will be designated as follows: for example, diluted hydrochloric acid (1 + 1) will mean one volume of the concentrated acid of specific gravity 1.18 diluted with one volume of water.

[6] The chief disadvantage in the use of a Gooch crucible with an asbestos pad is the difficulty encountered during the ignition of the dioxide to metal. Even when the Gooch crucible is protected from the burner flame by setting it in a circle of asbestos board in a larger porcelain crucible, one is not always able to extinguish the hydrogen flame readily. Another disadvantage is the inadequate protection of the reduced metal from attack by air diffusing through the holes in the bottom of the crucible.

[7] Gilchrist, *Bur. Standards J. Research*, **3**, 993 (1929); RP 125.

[8] Gilchrist, *ibid.*, **12**, 283 (1934); RP 654.

fer the solution, and any residue of platinum which may have separated, to the distilling flask that was used for the distillation of osmium tetroxide. Dilute the solution in the distilling flask to 100 ml. with water.

2. **Separation of Ruthenium by Distillation as Ruthenium Tetroxide.**—Place 150 ml. of diluted hydrochloric acid (1 + 1), freshly saturated with sulfur dioxide, in the first receiving flask and 50 ml. of the same reagent in each of the other two flasks. Add 100 ml. of a filtered 10% solution of sodium bromate through the thistle tube to the distilling flask. This tube should be flushed with water occasionally in order to remove any ruthenium tetroxide which dissolves in the column of liquid held in the tube. In order to maintain an excess of sulfur dioxide in the absorbing solution, a saturated solution of sulfur dioxide in water should be added from time to time through the thistle tube situated between the first and second receiving flasks. Pass a gentle current of air through the apparatus, and heat the solution in the distilling flask to boiling. Distil[9] in this fashion for one and one-half hours. Add 25 ml. of the bromate solution, and continue to distil for an additional hour.

3. **Recovery of Ruthenium by Precipitation as a Hydrated Oxide.**—Combine the portions of the absorbing solution and evaporate to a moist residue on the steam-bath. Add 10 ml. of hydrochloric acid and digest the solution, in a covered beaker, on the steam-bath for one-half hour. Add 50 ml. of water and heat the solution to boiling in order to dissolve completely the somewhat difficultly soluble ruthenium compound formed on evaporation. When the ruthenium compound is completely dissolved, filter the solution and wash the filter with diluted hydrochloric acid (1 + 99). Filtering ensures the elimination of a small amount of silica which may be present. Dilute the ruthenium solution to 200 ml., heat it to boiling and add a filtered 10% solution of sodium bicarbonate until a precipitate begins to form. Add 3 or 4 drops of brom cresol purple indicator solution (0.04%). Continue neutralization of excess acid by adding the bicarbonate solution dropwise until the indicator changes from yellow to blue. Boil the solution for five to six minutes to coagulate the precipitate.

The precipitate which is formed is a hydrated oxide of ruthenium, probably of tervalent ruthenium. In general appearance, it resembles other hydrated oxides of tervalent platinum metals. It does not settle as quickly nor appear as compact as the precipitate formed on the hydrolysis of compounds of quadrivalent ruthenium. However, it is quantitatively precipitated, and no difficulty is encountered in handling it.

4. **Determination of Ruthenium as Metal.**—Filter the solution and wipe the inner walls of the beaker and also the glass rod with a small piece of ashless filter paper. Wash the filter and the precipitate thoroughly with a hot 1% solution of ammonium sulfate. Finally, wash three or four times with a cold (room temperature) 2.5% solution of ammonium sulfate.

Place the filter and precipitate in a porcelain crucible, dry them and char the filter slowly. The dried filter will usually char completely when once it begins to smoke. This operation should be done carefully in order to prevent loss of ruthenium by deflagration. Ignite the residue strongly in air and then in hydrogen. The ignition in hydrogen is made in a manner similar to that described for the determination of osmium. Cool the resulting metal in hydrogen and leach it well with hot water. This is done to ensure the removal of traces of soluble salts. It is well to leach the residue in the crucible first and then to transfer it to a filter. Ignite the filter and metal sponge in air and in hydrogen. Cool the residue in hydrogen and weigh it as metallic ruthenium.

III. Separation and Determination of Platinum[10]

The solution which remains in the distilling flask after the elimination of ruthenium contains the four metals, platinum, palladium, rhodium and iridium, together with sulfuric acid, sodium sulfate or acid sulfate, bromine and undecomposed bromate. Experience shows that the platinum, rendered partly insoluble in the preparation of the solution for the distillation of ruthenium, is entirely dissolved during the distilling operation. A trace of iridium sometimes separates as the dioxide toward the end of the distilling period.

1. Preparation of the Solution

a. **Treatment of the Solution from the Distilling Flask.**—In order to prepare the solution for subsequent operations, transfer the contents of the distilling flask to a liter beaker. Cautiously decompose the remaining bromate with hydrochloric acid. Unless precaution is taken in this treatment, mechanical loss may occur owing to the vigorous evolution of gas. Evaporate the solution when it has become quiescent. Make certain that any bromate remaining is decomposed, by evaporating with hydrochloric acid. Occasionally, the distilling flask is found to be slightly stained with iridium dioxide near where the level of the solution has stood. It is well, therefore, always to clean the flask with 5 to 10 ml. of aqua regia, which then must be evaporated with hydrochloric acid to decompose nitroso compounds before it is added to the main solution. Finally, evaporate the solution as far as possible on the steam-bath, and then dilute it to 200 ml. with water.

---

(9) See original paper for a discussion of various solutions from which to distil ruthenium. The usual way is to distil from an alkaline solution which is saturated with chlorine. If this procedure is used, one can never be sure that the elimination of ruthenium is complete, even though additional alkali is added and the distilling process repeated, owing to the precipitation, near the neutral point, of iridium hydroxide which carries with it some ruthenium. It is necessary, therefore, in order to prevent the precipitation of iridium, to distil from an acid solution. The distillation of ruthenium tetroxide may be made immediately after the elimination of osmium, without removing the contents of the distilling flask, by adding a solution of sodium bromate. From 5 to 10 ml. of nitric acid should be added to increase the acid concentration of the solution. The minimum time required for complete removal of ruthenium from a boiling solution is about three and one-half hours. Although the solution requires some preparation, distillation from a solution of ruthenium sulfate in diluted sulfuric acid, as given in the procedure, is preferable. The elimination of ruthenium tetroxide from such a solution is much more rapid than from a solution containing the ruthenium as chlororuthenate. A further advantage is gained by being able to conduct the entire distillation at the boiling temperature without danger of depositing ruthenium dioxide on the walls of the flask and delivery tube, since the cause of such deposition, namely, hydrochloric or hydrobromic acid, is removed during the preparation of the solution for distillation.,

(10) Gilchrist, *Bur. Standards J. Research*, **12**, 291 (1934); RP 655.

b. Treatment of a Solution which has not Contained Osmium or Ruthenium.—If the solution being analyzed is known not to contain either osmium or ruthenium and the parts of the general procedure referring to these metals have not been followed, evaporate it to a moist residue on the steam-bath. If the solution has contained nitric acid, add 5 ml. of hydrochloric acid and again evaporate, repeating this operation to ensure the decomposition of nitroso compounds. Add 2 g. of sodium chloride and 5 ml. of hydrochloric acid and evaporate this time to dryness on the steam-bath. Add 2 ml. of hydrochloric acid and dilute the solution to 300 ml. with water.

2. Separation of Platinum by Joint Precipitation of Palladium, Rhodium and Iridium as Hydrated Dioxides.—Heat the solution containing platinum, palladium, rhodium, and iridium to boiling, and add to it 20 ml. of a filtered 10% solution of sodium bromate. Carefully add a filtered 10% solution of sodium bicarbonate until the dark green solution shows evidence of the formation of a permanent precipitate. Test the acidity of the hot solution from time to time by allowing a drop of brom cresol purple indicator solution (0.01%) to run down the stirring rod into the drop which clings to it as it is lifted from the solution. Enough bicarbonate has been added when the color of the indicator changes from yellow to blue. At this stage, add 10 ml. more of the bromate reagent and boil the solution for five minutes. Increase[11] the *p*H of the solution slightly by carefully adding dropwise bicarbonate solution until a faint pink color is produced in the test drop by a drop of cresol red indicator solution (0.01%). Again add 10 ml. of the bromate reagent and boil for fifteen minutes.

On removing the beaker from the source of the heat, the mixed precipitate will settle quickly, leaving a mother liquor containing the platinum. Filter the solution by suction, using a porcelain filtering crucible[12] having solid walls and a porous base.

It is highly desirable to avoid the use of filter paper when repeated precipitations are to be made. The material of which the paper is composed undoubtedly reacts with acids and probably forms small quantities of organic compounds with the platinum metals which are not easily hydrolyzed. Iridium dioxide, which dissolves much less readily than either palladium or rhodium dioxide, tends to stain paper pulp. The stain cannot always be removed by washing. These difficulties are avoided if the porcelain filtering crucible is used. Furthermore, such crucibles have the advantage that concentrated hydrochloric acid can be used to dissolve the hydrated dioxides, and considerable time is saved in preparing the solution for subsequent treatment.

Pour the supernatant liquid through first, then transfer the precipitate. Rinse the beaker and wash the precipitate with a hot 1% solution of sodium chloride, the acidity of which has been adjusted to between *p*H 6 and 7. Place the crucible with the precipitate, and also the stirring rod, in the beaker used for the precipitation. It may be necessary to remove a small amount of the precipitate which has crept over the lip of the beaker during filtration. It is preferable to do this with moistened crystals of sodium chloride, on the finger, rather than to use paper or a rubber policeman. Replace the watch glass and add from 10 to 20 ml. of hydrochloric acid, pouring most of it into the crucible. Place the covered beaker on the steam-bath. The rhodium and palladium compounds will dissolve quickly, the iridium dioxide much more slowly. Carefully lift the crucible with the stirring rod, wash it with water and place it in a 250-ml. beaker. Pour 5 ml. of hydrochloric acid into the crucible. Cover the beaker with a watch glass and set it on the steam-bath. This treatment will usually leach out the small quantity of metal chlorides in the porous bottom. This operation should be repeated with fresh acid to ensure complete removal. Combine the leachings with the main portion of the dissolved precipitate, add 2 g. of sodium chloride, and evaporate to dryness on the steam-bath. Add 2 ml. of hydrochloric acid, dilute the solution to 300 ml. with water, and repeat the precipitation of the hydrated dioxides. Two such precipitations are sufficient ordinarily to effect the complete separation of platinum from palladium, rhodium and iridium.

3. Recovery of Platinum by Precipitation with Hydrogen Sulfide.—Add 20 ml. of hydrochloric acid to each of the filtrates obtained from the hydrolytic precipitation of the dioxides of palladium, rhodium and iridium. Carefully warm the solutions until they become quiescent. Partially concentrate the filtrates, combine them and then evaporate to dryness. Make certain that all of the bromate is destroyed, by evaporation with hydrochloric acid. Dilute the yellow platinum solution somewhat and filter it. Wash the filter with diluted hydrochloric acid (1 + 99). Dilute the filtered solution to about 400 ml. with water and have it contain 5 ml. of hydrochloric acid in each 100 ml. volume.

Precipitate the platinum, in a hot solution, with hydrogen sulfide, using a rapid stream. Continue the passage of hydrogen sulfide as the solution cools somewhat, to ensure complete precipitation.

4. Determination of Platinum as Metal.—Filter the solution and wash the precipitate with diluted hydro-

---

[11] Since previous publication on this subject [*Bur. Standards J. Research*, **12**, 291 (1934); RP 655], it has been found that, whereas a *p*H of 6 ensures complete precipitation of rhodium and of iridium, this acidity is on the borderline with respect to the precipitation of palladium. In the procedure as finally recommended, hydrolytic precipitation is made, during the first boiling period, at a *p*H value (approximately *p*H 6) corresponding to the change in color of brom cresol purple (0.01%) when a drop of the indicator solution is allowed to react with a drop of the boiling solution. A second boiling period, at a *p*H value (approximately *p*H 8) corresponding to the change in color of cresol red (0.01%), ensures quantitative precipitation of palladium. It is preferable to perform the precipitation in two stages in order to be able to observe the faint pink color of cresol red in the test drop. It was determined experimentally, with solutions made to contain the same quantity of acid and salts as do those which result from the removal of osmium and ruthenium by distillation, that no interference is encountered in the precipitation of palladium, rhodium and iridium. It was further observed that rhodium and iridium are quantitatively precipitated under the conditions specified for precipitating palladium, and that platinum does not contaminate the precipitated dioxides to any greater extent than when the hydrolytic operation is conducted at *p*H 6 alone. In the absence of palladium, it is recommended that the hydrolytic precipitation be made at the color change of brom cresol purple (*p*H 6).

[12] This type of crucible is manufactured by the State Porcelain Works, Berlin, Germany. A crucible of convenient size is one having a height of 45 mm., a diameter at the top of 40 mm. and a capacity of 30 ml. The crucible designated by the mark "A1" filters rapidly and allows no trace of the precipitate to escape. Crucibles marked "A2," but somewhat smaller in size, were found to be perfectly satisfactory. No doubt glass crucibles of suitable porosity could also be used.

chloric acid (1 + 99). Ignite the dried filter and precipitate in a porcelain crucible. Leach the metal residue with diluted hydrochloric acid, transfer it to a filter and wash it thoroughly with hot water. Ignite the filter and metal again strongly in air. Weigh the residue as metallic platinum. The metal so obtained will usually contain a small but significant amount of sulfur[13] which cannot be eliminated by ignition in either air or hydrogen.

If the highest accuracy is desired, dissolve the metallic platinum, obtained by ignition of the sulfide, in aqua regia. Destroy nitroso compounds by evaporation with hydrochloric acid. Filter the solution into a clean, unetched beaker. Wash the filter with diluted hydrochloric acid (1 + 99). Dilute the solution to 100 ml., heat it to boiling and add to it a solution containing 3 g. of sodium acetate and 1 ml. of formic acid for each 0.25 g. of platinum. Boil the resulting solution gently until the precipitated metallic platinum is well coagulated and the supernatant liquid is colorless. Filter the solution and wash the metallic deposit with a hot 1% solution of ammonium chloride. Place the filter and the spongy metal in a porcelain crucible and ignite them strongly in the air. Leach and wash the ignited metal as previously directed. This precaution is taken to ensure the removal of soluble salts. Finally ignite the platinum in air again. Weigh the residue as metallic platinum, which will now be free from sulfur.

It is far better to precipitate the platinum first by hydrogen sulfide, and then to reprecipitate it by formic acid in a buffered solution, than it is to attempt to precipitate the platinum directly by formic acid. The precipitation with hydrogen sulfide eliminates the relatively large amount of sodium salts which cause trouble in the formic acid reduction.

IV. Separation and Determination of Palladium[10]

1. Separation of Palladium by Precipitation with Dimethylglyoxime.—Dissolve the precipitate of the hydrated dioxides of palladium, rhodium and iridium in hydrochloric acid as previously directed. Filter the solution and dilute it to a volume of about 400 ml. Add a sufficient volume of a 1% solution of dimethylglyoxime in 95% ethyl alcohol to precipitate all of the palladium (2.2 g. of the solid reagent is required for 1 g. of palladium). An excess of the reagent amounting to 10% should be added to ensure complete precipitation. Let the solution stand for one hour and then filter it. The manner of filtration will depend upon the form in which the palladium is to be determined. Wash the precipitate with diluted hydrochloric acid (1 + 99), and finally with hot water. The precipitate can be washed with a considerable volume of water without a trace of it dissolving. A single precipitation of the palladium is sufficient to separate it completely from rhodium and iridium.[14]

2. Determination of Palladium

a. As Palladium Dimethylglyoxime.—Palladium dimethylglyoxime is sufficiently stable and constant in composition to be dried and weighed. If the determination is to be made in this manner, catch the precipitate in a porcelain or glass filtering crucible, using suction. Wash the precipitate as previously directed and dry it at 110° for one hour. Calculate the quantity of palladium, using the theoretical factor, 0.3167.

b. As Metal.—If the palladium is to be determined as metal, which in certain cases may be more convenient, catch the precipitate on an ashless filter. Wipe the inner walls of the beaker and also the glass rod with a small piece of ashless paper. Wrap the filter and precipitate in a second filter and place them in a porcelain crucible. Dry them, and ignite them carefully in the air. Only sufficient heat should be supplied to keep the papers smoking gently. Ignite the charred residue strongly in air, and then in hydrogen. Ignite the metallic palladium in carbon dioxide[15] for two minutes and cool it in carbon dioxide. Weigh the residue as metallic palladium.

V. Separation and Determination of Rhodium[10,16]

1. Preparation of the Solution.—Place the solution containing the rhodium and iridium as chlorides, together with the excess of dimethylglyoxime remaining from the precipitation of palladium, in a 500-ml. Erlenmeyer flask. Place a short-stemmed funnel in the mouth of the flask. Add 10 ml. of sulfuric acid and 2 to 3 ml. of nitric acid, and evaporate until heavy vapors of sulfuric acid are evolved. To ensure complete destruction of organic matter, add a small quantity of nitric acid from time to time and continue to heat over a free flame, keeping the solution in constant motion. Dilute the cooled solution with 20 ml. of water and again evaporate it until vapors of sulfuric acid appear. This is done to destroy nitroso compounds which may interfere in the precipitation of rhodium by titanous chloride.

2. Separation of Rhodium by Precipitation with Titanous Chloride.—Transfer the sulfate solution to a clean, unetched beaker, dilute it to 200 ml. and heat it to boiling. Add dropwise a solution of titanous chloride (a 20% solution of this reagent may be purchased) until the supernatant liquid appears slightly purple. If the solution is placed over a 100-watt light and stirred, observation of the end-point is greatly facilitated. The metallic rhodium which is precipitated quickly coagulates into a spongy mass. If much iridium is present, the end-point can be determined by the lack of formation of any further precipitate and the appearance of an orange color in the solution. Boil the solution for two minutes and filter it.

---

(13) In 17 experiments, the weights of platinum (0.25-g. portions) recovered by ignition of the sulfide in air exceeded those taken by amounts which ranged from 0.0 to 1.0 mg., and averaged 0.5 mg. The retention of sulfur by palladium is very marked, and the sulfide may even fuse into globules which cannot be completely decomposed by ignition. Therefore, palladium must not be determined by ignition of its sulfide. No significant amount of sulfur is retained when rhodium sulfide is ignited.

(14) If, for any reason, it is desired to reprecipitate the palladium, catch the precipitate on paper. Transfer the washed filter and precipitate to an Erlenmeyer flask, closed with a short-stemmed funnel and decompose them in a mixture of sulfuric and nitric acids. Heat the solution until vapors of sulfuric acid are evolved, dilute it somewhat and filter it. Precipitate the palladium from the diluted solution of its sulfate with dimethylglyoxime.

(15) Palladium possesses the property of absorbing a considerable quantity of hydrogen, so that it is difficult to obtain constant weight. If the absorbed hydrogen is eliminated by igniting the metal so obtained in an inert gas, no difficulty is encountered. Strong ignition in air is sufficient to decompose all oxides of palladium, without resort to hydrogen, but the gray metal tarnishes as it cools unless an inert gas protects it. The error involved, however, amounts to only 0.1 mg. with quantities of palladium weighing 100 mg.

(16) Gilchrist, *Bur. Standards J. Research*, **9**, 547 (1932); RP 489.

Wipe the walls of the beaker and also the stirring rod with a piece of ashless filter paper. Wash the filter and precipitated metal thoroughly with cold (room temperature) diluted sulfuric acid (2.5 + 97.5).

Place the filter with its contents in a 500-ml. Erlenmeyer flask, add 10 ml. of sulfuric acid, char gently, add 5 ml. of nitric acid and digest the solution on a hot plate. Usually, the rhodium dissolves fairly readily. Complete the solution of the rhodium by heating the flask over a free flame, keeping the contents of the flask in constant motion. Ensure the destruction of organic matter and the elimination of nitroso compounds. If some black specks remain, dilute the solution, filter it and return the filter to the flask. Wipe down the walls of the flask with a piece of ashless filter paper. Add 5 ml. of sulfuric acid, char the paper, and destroy all organic matter with nitric acid. Heat the solution until heavy vapors of sulfuric acid are evolved. This treatment will dissolve any remaining metal and will leave only a slight deposit of colorless silica.

Precipitate the rhodium a second time in the manner described above. Redissolve the rhodium as before, dilute the sulfuric acid solution with 20 ml. of water and 10 ml. of hydrochloric acid and boil the resulting solution for fifteen minutes. This treatment is necessary to convert the rhodium into a form which will allow complete precipitation by hydrogen sulfide. During this treatment, the color of the solution will change from yellow to rose. Filter the solution and wash the filter with diluted hydrochloric acid (1 + 99). Finally, dilute the solution to a volume of from 400 to 500 ml.

3. Recovery of Rhodium by Precipitation with Hydrogen Sulfide.—Precipitate the rhodium as sulfide from a solution, kept just at the boiling point, by passing a rapid stream of hydrogen sulfide through it. Allow the solution to cool somewhat, with the hydrogen sulfide still passing through it.

4. Determination of Rhodium as Metal.—Filter the solution and wash the precipitate with diluted sulfuric acid (2.5 + 97.5), and finally with diluted hydrochloric acid (1 + 99). Place the filter with the sulfide precipitate in a porcelain crucible. Ignite the dried precipitate carefully in air. Finally, ignite the oxidized residue in hydrogen, cool the resulting metal in hydrogen and weigh it as metallic rhodium.

VI. Recovery and Determination of Iridium[10,16]

Iridium may be determined in either of two ways. If the solution containing both rhodium and iridium can be divided conveniently into aliquot parts, the determination of iridium is greatly simplified and the precipitations of titanium by cupferron avoided. The rhodium and iridium in one portion of the solution can be recovered by hydrolytic precipitation as described in the procedure for the separation of platinum. If this is done, the mixed precipitate of rhodium and iridium dioxides is washed with a hot 1% solution of ammonium chloride, neutral to brom thymol blue (pH 7), instead of with a solution of sodium chloride. The dried filter and precipitate are impregnated with a few drops of a saturated solution of ammonium chloride, in order to prevent deflagration, and carefully ignited to a mixture of the anhydrous oxides. The oxidized residue is ignited and cooled in hydrogen, and weighed as a mixture of metallic rhodium and metallic iridium. In order to calculate the quantity of iridium, it is necessary, in addition, to determine rhodium as previously described in a separate portion of the solution.

If the iridium cannot be determined in this way, it is necessary to recover it from the filtrates resulting from the precipitation of rhodium by titanous chloride.

1. Elimination of Titanium by Precipitation with Cupferron.—Dilute the combined filtrates from the precipitation of rhodium by titanous chloride to 800 ml. Cool the solution by placing the beaker in crushed ice. Add a chilled, filtered, freshly prepared 6% solution of cupferron (ammonium salt of nitrosophenylhydroxylamine, $C_6H_5N{\cdot}NO{\cdot}ONH_4$) in slight excess. Filter the solution and wash the titanium precipitate with chilled diluted sulfuric acid (2.5 + 97.5) containing some cupferron. The cupferron precipitate is usually slightly contaminated by iridium, but the amount does not exceed 1 mg. when about 0.2 g. of iridium is being handled. Return the filter and precipitate to the beaker, add 20 ml. of nitric acid, and heat until the precipitate is mostly decomposed. Add 20 ml. of sulfuric acid and heat the solution until vapors of sulfuric acid appear. Destroy the remaining organic matter by adding nitric acid, and heating. Dilute the resulting solution to 800 ml. and repeat the precipitation of the titanium. Unite the filtrates from the cupferron precipitations and evaporate until approximately 10 ml. of sulfuric acid remains. Ensure the destruction of all organic matter. Dilute the solution somewhat and filter it.

2. Recovery of Iridium by Precipitation as the Hydrated Dioxide.—Dilute the solution to 200 ml. with water and neutralize most of the acid contained in it with a filtered solution of sodium bicarbonate. Heat the solution to boiling and complete its neutralization with bicarbonate to the end-point of brom cresol purple, as described in the procedure for the separation of platinum. Add 20 ml. of a filtered 10% solution of sodium bromate, and boil the solution for twenty to twenty-five minutes. Be sure that sufficient bromate is present to oxidize all of the iridium to the quadrivalent state. Filter the solution and wash the precipitate thoroughly with a hot 1% solution of ammonium chloride.

3. Determination of Iridium as Metal.—Place the filter and precipitate in a porcelain crucible. Dry them somewhat and then moisten them with a few drops of a saturated solution of ammonium chloride. Ignite the filter and precipitate carefully in the air and then in hydrogen. Leach the metallic residue with diluted hydrochloric acid, then transfer it to a filter, and wash it with hot water. Ignite the filter and metallic residue in air. Finally, ignite the resulting oxidized metal in hydrogen, cool it in hydrogen and weigh it as metallic iridium.

The procedure as herein written is designed for the highest degree of accuracy. If, however, one is not interested in such accuracy, the procedure may be shortened in a number of places. For instance, some of the reprecipitations which are recommended may be omitted. Time can be saved by making only one hydrolytic precipitation of palladium, rhodium and iridium, in separating them from platinum, and by determining platinum by simply igniting its sulfide. The second reduction with titanous chloride might be dispensed with, and also the precipitations with cupferron can be avoided by determining rhodium and iridium together in aliquot portions of the solution at this stage. It must be remembered, however, that in so doing errors of varying magnitude will be introduced, depending upon the relative proportions of the metals present.

Accuracy of the Proposed Method

The accuracy which can be attained with the procedure described in this paper is best illustrated by means of data which have been taken from the publications cited and compiled in the accompanying table. In addition, the results of the complete analysis of three solutions, to which all six of the metals were added, are included.

In the development of the various parts of the general procedure, given in detail in the original papers cited, it was found by chemical means that no ruthenium, platinum, palladium, rhodium or iridium appeared in the absorbing solutions under the conditions established for distilling osmium tetroxide. In the separation of platinum from rhodium, no platinum was detected by means of ammonium chloride in the solutions of the second hydrolytic precipitate of rhodium, whereas, in solutions of known platinum content, 0.1 mg. of platinum was readily detected, and a precipitate was formed with 0.05 mg. of platinum. Rhodium was detected in only one of the five residues of platinum, obtained in the same experiments, by a test which is capable of detecting an extremely small amount of rhodium, namely, the greenish discoloration of the small amount of ammonium chloroplatinate which remains in solution when the bulk of the redissolved platinum is precipitated by ammonium chloride. In the separation of platinum from palladium, no palladium was detected with dimethylglyoxime in the dissolved platinum residues, nor was any platinum found, by means of ammonium chloride, in the filtrates from the precipitation of the palladium with dimethylglyoxime. In the separation of plati-

[a] This figure is that of the combined determination of rhodium and iridium.

iridium, a quantity of iridium less than was detected, in one experiment, in the s obtained from the precipitation of plati- first by hydrogen sulfide and then by formic , whereas no iridium was detected in the two er experiments.

In order to ascertain, in the separation of thenium by the recommended procedure, hether any of the other platinum metals reached the absorbing solutions, the ruthenium recovered from each of the three complete analyses was examined spectrochemically by Bourdon F. Scribner for osmium, platinum, palladium, rhodium and iridium, but no trace of these metals was detected.

The results of 31 experiments are given in Table I. Those reported in Nos. 1 to 24, inclusive, are taken from previous publications cited in this paper. Experiments Nos. 25 to 29, inclusive, were conducted according to the recommended procedure, except that brom cresol purple was used to determine the end-point for the hydrolytic precipitation. In these experiments some palladium escaped precipitation and was subsequently separated from the platinum by means of dimethylglyoxime. The results in Nos. 30 and 31 were obtained by following the procedure as herein written. Although osmium and ruthenium were not included, the solutions were, nevertheless, subjected to the same treatment as if they had been present, except that the distilling operations were omitted, in order to duplicate conditions which normally obtain at the end of the ruthenium distillation. In these two experiments, rhodium and iridium were not separated from each other but were recovered together by hydrolytic precipitation. The mixed precipitate was washed with a hot 1% solution of ammonium chloride, neutral to brom thymol blue (*p*H 7), and ignited to a mixture of metallic rhodium and iridium. The final filtrates obtained in these two experiments were found to be free from the four metals concerned.

The quantities of metal listed in the table can be conveniently handled, analytically. In the case of platinum, 2 g. of this metal is easily handled, and 5 g. should introduce no difficulties.

Summary

1. A new and reliable procedure is described for the separation, recovery and determination of each of the six platinum metals.

2. The accuracy of this new method is comparable to that of the best analytical procedures for the common metals. No special equipment or reagents are necessary and the operations do not involve technique unfamiliar to a trained analyst.

Structural Changes Taking Place upon Aging of Freshly Prepared Crystalline Precipitates. V. The Thermal Aging of Freshly Prepared Lead Sulfate

BY I. M. KOLTHOFF AND CHARLES ROSENBLUM

In papers III and IV of this series[1] it has been shown that the rapid internal perfection of the crystalline particles of freshly precipitated lead sulfate on aging in the supernatant mother liquor at room temperature is to be attributed to a rapid recrystallization process by way of the solution[2] and not to a free mobility of the lead ions in the amicronic particles within the microcrystals as originally concluded from the results reported in papers I and II.[3] Aside from the aging in liquid media it appears reasonable to expect that aging will occur in the dry state as well, provided that the fresh precipitate is heated to temperatures high enough to increase the thermal energy of the ions at the active surface. The results of this study are reported in this paper.

We may distinguish between two principal types of thermal aging.

1. **Microscopic Aging.**—At the higher temperatures a *sintering* of the microscopic particles may occur, resulting in a decrease of the external surface. The magnitude of this surface can be determined from the dimensions of the particles as seen with a microscope. Since the precipitates used in these studies were highly heterodisperse,

---

[1] THIS JOURNAL, **57**, 597, 607 (1935).

[2] This matter will be dealt with in detail in a subsequent paper of this series.

[3] THIS JOURNAL, **56**, 1264, 1658 (1934).

more accurate results were obtained by calculating the external surface from the amount of wool violet adsorbed on shaking the crystals with a solution of the dye of a concentration sufficient to assure a saturated surface layer.[4]

2. **Internal Aging.**—At temperatures much lower than where the sintering takes place, an internal aging may occur, resulting in an internal perfection of the microscopic crystals. An indication of the extent of this kind of aging was obtained from the speed with which thorium B distributes itself through the precipitate.[1,3]

Experimental

Preparation of Lead Sulfate Samples.—A main supply of 70 g. of fresh lead sulfate was prepared by fairly slow precipitation at a speed which approximated the rate of formation of earlier samples.[1] To avoid excessive aging when in contact with the supernatant liquid, the precipitate was prepared in 3-g. batches by adding 98.6 ml. of 0.1 M potassium sulfate to 103.5 ml. of 0.1 M lead nitrate solution, while stirring with an electrically driven stirrer. Immediately after precipitation each portion of precipitate was filtered on a Gooch crucible, washed rapidly (suction) with water and absolute ethanol, and then air-dried.[1a] The precipitates thus obtained from the different batches were mixed and kept in a desiccator over sulfuric acid at room temperature. From previous investigations[3] it was known that under such conditions a fresh precipitate remains practically unaged. However, to eliminate any uncertainty, blanks were run on the dye adsorption and the Th B exchange at frequent intervals throughout the investigation. For the sake of brevity these results will not be reported since it appeared that within the given periods of time no distinct aging could be detected in the product stored at room temperature. Various other batches of lead sulfate prepared in a similar way were used to ascertain the validity of all effects encountered.

Adsorption of Wool Violet.—Eight-tenths to one-gram portions of lead sulfate were shaken for thirty minutes with 25 ml. of a wool violet solution containing 250 mg. of the dye and 40 mg. of lead sulfate per liter. It was shown that at this dye concentration the surface of the lead sulfate was saturated with wool violet, since the same amount of dye was adsorbed when the concentration in solution was increased to 350 and 500 mg. per liter, respectively. The quantity of wool violet left in the solution after shaking and centrifuging was determined colorimetrically in an aliquot part of the supernatant liquid. All determinations were run in duplicate at least and the average result is reported.

Exchange with Thorium B.—Exactly the same technique was followed as described in previous papers.[1,3] Approximately 0.3-g. portions of lead sulfate were shaken with 23.53 ml. of a solution of thorium B containing 0.00162 mole of lead nitrate and 0.065 mole of potassium nitrate per liter, corresponding to the composition of the solution in previous work.[1,3] Samples were shaken in paraffined containers for fifteen minutes and three hours and portions of supernatant liquid were withdrawn with a pipet after centrifuging. All determinations wer duplicate at least and the average value is reporte

It should be realized that the reproducibility w aged or slightly aged precipitates, especially after f minutes of shaking, is not very good. Great accura hardly to be expected under these conditions, since thorium B distributes itself very quickly, and a sli change in the experimental conditions may have a mark effect. For the reasons mentioned, slight changes foun in the amounts of lead exchanged do not indicate a definit aging. Such experimental errors are insignificant in comparison with the magnitude of the effects reported.

Losses in Weight of the Samples During Heating.—Weighed samples (varying between 5 and 10 g.) of the air-dried lead sulfate were placed in wide weighing bottles and heated at different temperatures in an electric oven, the temperature of which could be kept constant within 5°. At noted intervals of time the bottles were removed, cooled in a sulfuric acid desiccator and weighed with ground glass covers in place. The losses in weight were found to be very small: at 105° after two hours of heating 0.02%, after twenty-seven hours 0.03%; at 200° after two and one-half hours 0.08%, after twenty-eight hours 0.095%; at 250° after one hour 0.12%, after four hours 0.14%, after twenty-seven hours 0.15%; at 305° after one-half hour 0.14%, after three hours 0.18%, after twenty hours 0.25%; at 400° after one hour 0.24%, after four hours 0.29%; after twenty-seven hours 0.46%. Since the losses in weight were very small, a more elaborate and accurate study is desirable with regard to their proper interpretation.

The results obtained in the study of the microscopic and internal aging on heating of the fresh precipitate are summarized in Table I.

TABLE I

THERMAL AGING OF LEAD SULFATE

Temp. of heating, °C.	Time of heating, hours	Wool violet adsorbed in mg./1 g. of PbSO$_4$	Lead exchanged in mg./1 g. PbSO$_4$ after shaking with Th B for 15 minutes	3 hours
Unheated	..	1.45	38–45	600–800
105	2	..	33	790
105	27	1.57	25	800
200	2.5	..	39	780

400	27	0.39	8	17

Discussion

1. The results show clearly the difference between the external and the internal aging. On heating the fresh lead sulfate to temperatures

---

(4) THIS JOURNAL, **56**, 832 (1934).

between 100 and 200° and even for short periods to 305°, a slight but definite increase of the external surface was found as indicated by the increase of the adsorption of wool violet. This might be attributed to a slight decrepitation of the precipitate which in the fresh form is highly porous. From the figures given in the third column of the table it follows definitely that no sintering occurs at temperatures below 250°, and even after heating for twenty-seven hours at 250° there was only a very slight decrease of the external surface. The sintering becomes more pronounced but is still very slow upon heating at 300°. After heating for one hour at this temperature no indication of sintering was found, but it was very definite after twenty hours of heating at this temperature. At 400° the sintering became very pronounced, even after one hour of heating. After twenty-seven hours at this temperature the total external surface as measured by the wool violet adsorption had decreased about four times.

2. The internal aging occurs at much lower temperatures than the microscopic sintering. Thus it is evident from the data that after heating for twenty-seven hours at 200° a marked aging had occurred. On the other hand, after heating for two and one-half hours at this temperature there was no indication of an internal aging. From this behavior one would infer that there is a certain incubation period before the perfection starts. A drastic aging was found on heating to 250°, the fresh samples appearing quite "old" after having been kept for twenty-seven hours at this temperature. Apparently it is possible to perfect crystals of lead sulfate by heating to temperatures far below the sintering temperature. This conclusion will be substantiated by x-ray studies.

3. The internal aging of fresh lead sulfate at temperatures far below the sintering temperature may be compared with that of the various active catalysts, which show a marked decrease of catalytic activity when heated to considerably below sintering temperatures.[5] It has been shown[1,3] that our fresh precipitates are porous and have a large internal surface development. The mobility of the ions at the active surface will be greater than that of the ions in the inside of the normal lattice, where they are completely surrounded by lattice ions of opposite electrical charge. In the terminology of I. Langmuir and of Taylor,[6] the heat of evaporation of the ions will decrease as they become less saturated with neighboring ions. Langmuir and Taylor concluded that the rate of evaporation will fall off exponentially as the number of atom linkages increases. The thermal aging is thus attributed to a high mobility of lattice ions on the active surface, these ions moving to less active surface spots, resulting in a perfection of the crystals.

According to the above it is to be expected that after a certain time of heating at a given temperature a final state of perfection corresponding to that particular temperature will be found. In order to obtain a further aging the temperature has to be raised. From the results in Table I it is seen that virtually a final state of perfection is reached after heating for three hours at 305°. At 400° a much more drastic aging is found, a final state being reached after about four hours of heating. The experiments have been repeated with four different batches of lead sulfate, yielding qualitatively the same results. Incidentally it may be mentioned that during the thermal aging the crystals become more compact and less porous as indicated by their decreasing capacity of absorbing water when kept at room temperature at a relative humidity of 0.85 after the heating.

4. *The most striking and unexpected result of this study is that, upon heating at 250°, a much more pronounced aging was obtained than when heated at 300° and even at 400° for the same length of time.* A precipitate heated for twenty-seven hours at 400° behaved as though it were less aged internally than when heated for the same period at 250°, in spite of the fact that in the former case a pronounced sintering had occurred. Moreover it is of great interest to notice that the extent of aging at 250° depends upon the duration of heating, and that no final state was reached even after twenty-seven hours. At 300 and at 400°, on the other hand, maximum aging is attained after several hours.

From experiments reported in Table II it is seen that no further aging occurs at 305°, once the fresh lead sulfate has been heated for twenty-four hours at 250°. On the other hand, a 305° sample can be further aged at 250°. A new batch of lead sulfate different from that used in the experiments of Table I was used. Clearly, aging at 250° is more effective than at 305°.

TABLE II

Treatment of sample	Lead exchanged in mg./1 g. $PbSO_4$ 15 min.	3 hours
24 hours at 250°	3.1	14.1
30 minutes at 305°	6.3	26.7
20 hours at 305°	9.0	23.5
24 hours at 250°, then 0.5 hour at 305°	3.3	12.6
24 hours at 250°, then 20 hours at 305°	4.7	14.7

It was thought at first that lead nitrate coprecipitated with lead sulfate during precipitation might be responsible for the peculiar results. It was thought possible that coprecipitated lead nitrate might decompose at temperatures of 300° and above. The lead oxide formed might then be able to protect the crystals from further aging. In order to test this point the nitrate content in the fresh product and after heating for twenty-four hours at 105, 200, 250, 305 and 400° was determined. The samples were decomposed with sodium carbonate solution and the nitrate in the filtrate measured colorimetrically according to the procedure developed by Kolthoff and Noponen.[7] It was shown that no decomposition of the coprecipitated nitrate occurred at temperatures of 300° and below, whereas the greatest part of the nitrate was removed after heating for twenty-four hours at 400°. In addition it was shown that no nitrite was formed after heating to temperatures of 300° and below. Hence the coprecipitated lead nitrate is not responsible for the fact that less aging is found when samples are heated for long periods of time at 300 to 400° than at 250° and even at 200°.

The only other impurity present in the lead sulfate is water in the adsorbed and occluded state. (See losses in weight upon heating, reported earlier in this paper.) Water present in the adsorbed state may promote the thermal aging of lead sulfate. There are indications that the adsorbed water is not removed at 250°, but is removed at temperatures of 300° and above. The presence of such a film of adsorbed water could be responsible for certain of the observations being reported, *i. e.*, that a continuous aging is found at a temperature of 250°, and that the aging is much more pronounced after longer times of heating at 250 than at 300° and even at 400°. From the results recorded in Table III it is quite evident that the coprecipitated water is responsible for the continuous and drastic aging at 250°. A new batch of fresh lead sulfate was prepared for these experiments. Duplicate samples were heated for varying times at 305°. One of the samples was removed from the oven, while the other was left in the oven and the temperature quickly readjusted to 250°. The heating was then continued at this temperature. After cooling, the exchange with Th B solutions was determined in the usual way. In addition the adsorption of wool violet was measured.

TABLE III

AGING OF LEAD SULFATE WHEN FIRST HEATED TO 305° AND THEN AT 250°

Treatment of sample	Lead exchanged in mg./1 g. $PbSO_4$ after shaking with Th B for 15 min.	3 hours	Wool violet adsorbed in mg./1 g. $PbSO_4$
2 hours at 305°	8.7	59	1.75
2 hours at 305°, then 24 hrs. at 250°	7.7	30	1.7
45 hours at 250°	2.9	8.2	1.75
21 hours at 305°	7.3	23	1.45
21 hours at 305°, then 21 hrs. at 250°	6.7	23	1.4

The last two results given in Table III are especially conclusive. Once the lead sulfate had been heated for twenty-one hours at 305°, no further aging occurred if the sample was maintained for twenty-one hours at 250°, and provided the solid had not been removed from the furnace. The final product remained fresher than when heated for twenty-one hours at 250° only. Apparently long periods of heating at 305° cause the removal of adsorbed and occluded water.

That the water actually is responsible for the continuous aging at 250° was shown conclusively by the following experiment. A sample of the fresh lead sulfate was heated for twenty-one hours at 305°, then for twenty-one hours at 250°, and finally cooled and placed in a desiccator over a deliquescent sodium sulfate decahydrate for a week. A similar sample was kept for the same time over concentrated sulfuric acid. Both samples were heated again at 250° for twenty-one hours. The amounts of lead exchanged after the final heating after fifteen minutes and three hours of shaking at room temperature were 1.0 and 7.3 mg., respectively, for the sample which had been stored over deliquescent sodium sulfate and 5.0 and 26 mg., respectively, for the sample kept over sulfuric acid.

The experiments reported in Table III have been repeated with a number of different batches

---

[7] I. M. Kolthoff and G. Noponen, THIS JOURNAL, **55**, 1448 (1933).

of lead sulfate. All conclusions drawn from these abbreviated data have been substantiated by experiments with each independently prepared batch.

Summary

Fresh lead sulfate appears to undergo three distinct types of thermal aging.

1. *Microscopic aging by a sintering of the particles.* A pronounced sintering has been found at temperatures of 400°, and a very slow sintering at 300°.

2. *Internal thermal aging* at temperatures far below that of sintering. This aging is attributed to the high speed of evaporation of lattice ions on the active surface (Taylor and Langmuir). After a sufficiently long heating period the "age" approaches a final state which is characteristic for each temperature.

3. *Thermal aging promoted by adsorbed and occluded water.* This aging occurs at temperatures below the point where internal aging begins. It proceeds continuously with the time of heating. It accounts for the much more pronounced perfection after heating for twenty hours at 250° than after the same time of heating at 305 and 400°.

Structural Changes Taking Place During the Aging of Freshly Formed Precipitates. VI. The Perfection and Aging of Lead Sulfate Precipitated under Various Conditions

BY I. M. KOLTHOFF AND CHARLES ROSENBLUM

In previous studies the aging of fresh lead sulfate obtained by mixing 0.1 *M* solutions of lead nitrate and potassium sulfate has been reported. In the present study, the effect of varying conditions of precipitation upon the perfection and the speed of aging of lead sulfate has been investigated.

Designation of the Various Precipitates of Lead Sulfate

1. **Lead Sulfate from 0.025 M Solutions.**—To 103.6 cc. of 0.025 *M* lead nitrate, 98.6 cc. of 0.025 *M* potassium sulfate was added in about five or six minutes. Four such precipitations were performed and the four portions of solid combined. The precipitate formed slowly, about half a minute being required before it appeared. One minute after the addition of the sulfate, the precipitate was filtered on a Büchner funnel, and treated further as sample 2. The "fresh" precipitate was thirteen to fourteen minutes old after washing with alcohol. Another sample was prepared by gently rotating the precipitate in the supernatant liquid for an hour before filtration.

2. **Lead sulfate from 0.1 M solutions** was prepared as described in a previous paper.[1]

3. **Lead Sulfate from 0.4 M Solution.**—To 53 cc. of 0.4 *M* lead nitrate was added 50 cc. of 0.4 *M* potassium sulfate while stirring. After the precipitation was complete, half of the suspension was decanted and placed in a rotatory shaker for one hour. The remainder was filtered immediately, washed with four 20-cc. portions of water, then with alcohol and finally air-dried. The fraction of the precipitate which had been shaken for one hour was treated in a similar way. Both the filtration and the washing process were rather slow, because the fine precipitate tended to cake on the filter and clog it. The "fresh" precipitate after the washing with water was twenty-four to twenty-five minutes old.

4. **Lead Sulfate from Extremely Dilute Solutions.**[2]—To 25 cc. of conductivity water were added simultaneously and dropwise from two dropping pipets 50 cc. of 0.1 *M* lead nitrate and 50 cc. of 0.1 *M* potassium sulfate, the suspension being stirred continuously during the precipitation. The precipitate which settled readily was filtered, washed and air-dried. The "fresh" precipitate was twelve minutes old.

5. **Lead Sulfate from 0.1 M Solutions at Boiling Temperature.**—To 103.6 cc. of 0.1 *M* lead nitrate heated to boiling was added in about five to six minutes 98.6 cc. of 0.1 *M* potassium sulfate solution at a temperature of about 95–100°. After precipitation, half of the suspension was decanted and placed on a rotatory shaker for

DISTRIBUTION OF THORIUM B THROUGH, AND ADSORPTION OF WOOL VIOLET BY LEAD SULFATE PRECIPITATED UNDER VARIOUS CONDITIONS

Sample of lead sulfate	Age of lead sulfate	Amount of PbSO shaken with Th B, g.	Mg. of Pb exchanged per 1 g. $PbSO_4$ after shaking in Th B for 5 min.	15 min.	1 hr.	3 hrs.	Wool Violet adsorbed in mg. per 1 g. $PbSO_4$
I 0.025 *M* Sol; R. T.	Fresh (14 min.)	0.300		0.75		5.3	0.43
	74 min.	.300		.57		4.2	.43
II 0.1 *M* Sol; R. T.	Fresh (9 min.)	.300	50		500	700	1.8
	50 min.	.300	20	30	80	350	
III 0.4 *M* Sol; R. T.	Fresh (24 min.)	.300		95		460	2.8
	84 min.	.300		31		180	2.6
IV Hahn; R. T.	Fresh (12 min.)	.300		4.0	7.8	11.4	.6
V 0.1 *M* Sol; hot	Fresh (14 min.)	.300	10	16		85	1.2
	74 min.	.300	2.4	2.5		3.4	.95

one hour, the suspension slowly cooling in the air. The remainder was filtered two minutes after addition of lead nitrate, washed and made air-dry. After washing with the water, the "fresh" precipitate was fourteen to fifteen minutes old.

Experimental Procedures

Adsorption of Wool Violet.—The relation between the magnitudes of the external surfaces of the various precipitates was found from the amounts of wool violet adsorbed in the saturated state.[3] Weighed portions of the air-dried precipitates were shaken for thirty to forty minutes with 20 cc. of a wool violet solution containing 0.25 g. of dye per liter. After shaking, the suspension was centrifuged and the dye concentration determined colorimetrically. The sample of dye used was different from that in previous experiments.[1,3]

Distribution of Thorium B.—Weighed portions of the air-dried precipitates were shaken violently (400 phases p. m.) at room temperature for various periods of time with 23.53 cc. of a radioactive lead nitrate solution which was 0.00162 molar in lead nitrate and 0.065 molar in potassium nitrate. The amounts of thorium B taken up by the precipitates were measured as usual.[1] The results obtained are reported in a condensed form in Table I.

Discussion

From the results it appears that the concentrations of the reacting lead nitrate and potassium sulfate solutions are important factors in determining the size and the perfection of the precipitated lead sulfate crystals. The surface of a precipitate obtained from 0.025 molar solutions is about four times smaller than that from 0.1 *M* solutions, whereas that of the latter is about half as great as the surface of the lead sulfate from 0.4 *M* solutions. These conclusions follow from the amounts of wool violet adsorbed by the various precipitates.

The degree of perfection of a fresh precipitate obtained from 0.025 *M* solutions is relatively great; consequently the speed of its further perfection is relatively small. By carrying out the thorium B distribution experiments at a smaller lead-ion concentration in the solution, the progress of the perfection on aging of this precipitate could be shown more conclusively than by the data reported in Table I. To 10.30 cc. of 0.025 *M* lead nitrate in paraffined containers was added 9.82 cc. of 0.025 *M* potassium sulfate. After aging for one minute and one hour, respectively, after precipitation, 9.94 cc. of a stock thorium B solution in 2.5 $\times$ 10^{-5} molar lead sulfate was added and the whole shaken for various periods of time. The results obtained are given in Table II.

TABLE II

PROGRESS OF AGING OF LEAD SULFATE PRECIPITATED FROM 0.025 *M* SOLUTIONS AT ROOM TEMPERATURE

Amount of lead sulfate 0.0745 g.; lead concentration in solution 5.5 $\times$ 10^{-4} *M*.

Age of precipitate	Mg. of Pb exchanged per 1 g. of $PbSO_4$ after shaking with Th B for 5 min.	15 min.	1 hour	3 hours
1 minute	34	70	175	320
1 hour	7	10	26	60

The results of the experiments reported in Table I regarding the perfection and the speed of aging of precipitates obtained from 0.4 *M* solutions are not entirely conclusive. It is to be expected that the crystals obtained from 0.4 *M* solutions would be much less perfect than those formed on mixing of 0.1 *M* solutions. The results in the table seem to indicate just the opposite. It is possible that the speed of distribution of the thorium B, which is a direct function of the speed

---

(3) I. M. Kolthoff, W. von Fischer and C. Rosenblum, THIS JOURNAL, **56**, 832 (1934).

of recrystallization, is greater with a precipitate obtained from 0.1 *M* solutions than from 0.4 *M* solutions. Thus, it has been shown by Roller[4] that the dissolution factor of calcium sulfate crystals reaches a maximum at a size of 2.8 microns, and decreases with increasing and decreasing size of the particles. However, it should be realized that the results are but qualitative in nature since the precipitate obtained from 0.4 *M* solutions is hard to filter and wash and has a tendency to cake together in the air-dried state after washing with alcohol. Therefore, during the filtration and washing, it might have been subjected to a drastic aging process, and the specific surface might have been greater in the unfiltered than in the filtered and air-dried state. Moreover, it should be mentioned that the "fresh" precipitate was twenty-four minutes old and was compared with a nine-minute old precipitate obtained from 0.1 *M* solutions. If the latter had been twenty-four minutes old the speed of distribution of thorium B would have been found of the same order as that found with precipitate III.

It has been ascertained that the unexpected results are not due to an excessive coprecipitation of lead nitrate by precipitate III. Such a contamination would increase $Pb_{soln.}$ so that the true $Pb_{exch'ged}$ value might actually exceed values obtained with precipitate II. "Fresh" precipitates obtained from 0.1 and 0.4 *M* solutions were filtered, washed and air-dried in the usual manner. Three-tenth-gram portions were shaken with the "standard" solution, which is 0.00162 molar in lead nitrate and 0.065 molar in potassium nitrate, and the supernatant liquids analyzed for lead. In all cases the total lead concentration was found to be $1.72\ (\pm\ 0.02) \times 10^{-3}$ *M*. Subsequent work, designed to study in greater detail the degree of perfection of a precipitate obtained from 0.4 *M* solutions, is planned.

A precipitate obtained by F. Hahn's extreme dilution method is fairly coarse but still highly imperfect. As a matter of fact, it appears that the precipitate obtained at room temperature from 0.025 *M* solutions is more perfect than a precipitate formed according to Hahn from 0.1 *M* solutions.

It is of great interest to notice that the effect of concentration of the reacting solutions exerts a greater influence upon the degree of perfection of the separated lead sulfate than does the temperature. A precipitate rapidly formed at higher temperatures from 0.1 molar solutions is much less coarse and much less perfect than when obtained from 0.025 *M* solutions at room temperature. The former, when aged in the slowly cooling liquid, is subjected to a rapid perfection process. This is to be expected since the speed of recrystallization rapidly increases with the temperature.

Summary

A preliminary study was made of the degree of perfection and the speed of aging of lead sulfate as a function of the concentrations of lead nitrate and potassium sulfate and of the temperature during the precipitation. A precipitate obtained from 0.025 *M* solutions is much more perfect and coarser than a precipitate obtained from 0.1 *M* solutions. A precipitate obtained from 0.1 *M* solutions at boiling temperature in the fresh state is much less perfect and has a smaller size than a precipitate obtained from 0.025 *M* solutions at room temperature.

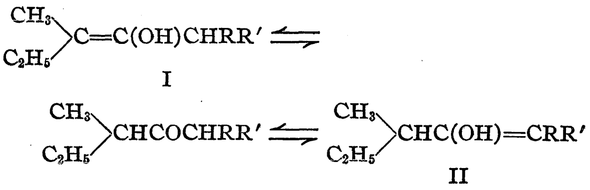
Enolization as Directed by Acid and Basic Catalysts. III. The Acid-Catalyzed Enolization of Some Secondary Butyl Ketones

BY PAUL D. BARTLETT AND CHARLES H. STAUFFER

Qualitative facts in the literature indicate that the activity of hydrogen in the alpha position to a carbonyl group varies in a manner that is not understood according as the alpha carbon atom is primary, secondary or tertiary. For example, the product of monochlorination of methyl ethyl ketone in a slightly acid medium, either at room temperature or at 70°, contains about 80% of 3-chloro-2-butanone and only 20% of 1-chloro-2-butanone;[1] the chlorination and bromination of menthone and carvomenthone have led to tertiary halogen compounds[2] as the only identified products. Such facts convey an impression that hydrogen in the alpha position to a carbonyl group is most active toward substitution when tertiary and least active when primary. Results from a study of the base-catalyzed Michael condensation,[3] which also depends upon the activity of hydrogen, lead to the opposite view. In the condensation of methyl ethyl ketone with benzaldehyde, it is reported[4] that the use of an acid catalyst leads to condensation at the methylene group, while a basic catalyst brings about condensation at the methyl group.

It is not surprising that no simple parallelism among these results should appear. In a two-step reaction, the yield alone affords no clue as to the equilibria and rates of the two steps involved, and the dependence of the rates on different catalysts. In the halogenation of an unsymmetrical ketone, the yields of the two products may well be affected, not only by the relative rates of formation of the two possible intermediate enols,[5] but by the possibility of establishment of an equilibrium between the products, altering the original ratio in which they were formed.[6] If, as is commonly postulated, enols and enolates are involved in the aldol, Claisen, Claisen–Schmidt, Michael and Perkin condensations, then the yields in these reactions may be functions of the rate and equilibrium of enolization, and also the rate and equilibrium of the further reaction of the enol. No one of these variables can be singled out and alone correlated with the final yield.

The reactions dependent upon active hydrogen are of wide enough importance to render a quantitative study of the first of these factors—the competitive rates of enolization—of interest, even though it is but a partial attack upon the problem of "reactivity" of such hydrogen atoms. We have applied the method of the first paper of this series[5] to the determination of the relative rates of formation of the enols I and II in a series of optically active secondary butyl ketones.



$$\begin{matrix}CH_3\\ C_2H_5\end{matrix}\!\!>C{=}C(OH)CHRR' \rightleftharpoons \quad \text{I}$$

$$\begin{matrix}CH_3\\ C_2H_5\end{matrix}\!\!>CHCOCHRR' \rightleftharpoons \begin{matrix}CH_3\\ C_2H_5\end{matrix}\!\!>CHC(OH){=}CRR' \quad \text{II}$$

Conditions of acid catalysis similar to those of the first paper were used; glacial acetic acid was the solvent, and nitric acid (1.19 *N*) served the double purpose of a catalyst for enolization and an oxidizing agent to ensure irreversible iodination. The rate of racemization divided by the rate of iodination, measured under identical conditions, is then a measure of the relative rates of formation of the enols I and II.

These experiments were carried out with phenyl secondary butyl ketone as a check upon the method, for this ketone has only one hydrogen available for enolization and the rates of iodination and of racemization should be identical. This question was tested by Ingold and Wilson[7] for the racemization and bromination of 2-*o*-carboxybenzylindanone-1; in our case, as in theirs, the rates are identical within the experimental error. At 36.75°, the velocity constant for iodination of phenyl *s*-butyl ketone is 0.0298, that for racemization, 0.0296.

The rates of iodination and racemization for $RCOCH(CH_3)C_2H_5$, where R is methyl, ethyl,

[7] Ingold and Wilson, *J. Chem. Soc.*, 773 (1934).

and benzyl, were measured at different temperatures from 15 to 40°, with the intention of resolving the rates into action and activation constants. The low optical rotations of the ketones prevented sufficiently accurate racemization runs for this purpose. As far as can be judged from the data, the relative rates of the two modes of enolization of a ketone do not vary with temperature.

Table I shows the results of the reaction rate measurements, together with an estimate of their precision, obtained by taking the mean deviation of the results of individual runs from the weighted mean, at each temperature. In Fig. 1 the logarithm of the rate constant is plotted against the reciprocal of the absolute temperature, to show the similar slopes of all lines and the agreement of the data for the methyl and ethyl ketones with the Arrhenius equation.

TABLE I

RATES OF IODINATION AND RACEMIZATION OF RCOCH-$(CH_3)C_2H_5$

R	Temp., °C.	$k_{\text{Iod.}}$	No. of runs	% deviation	$k_{\text{Rac.}}$	No. of runs	% deviation
CH_3	15	0.578	2	7.8			
	25	1.41	2	3	0.248	4	29
	38.75	4.54	2	6			
	38.95	4.61	2	5.4			
	38.7				1.3	1	3.5
C_2H_5	15	0.33	2	9			
	25	.852	3	4.2	0.103	4	10
	38.75	2.74	2	3	.339	2	21
$C_6H_5CH_2$	24.45	.309	4	10			
	25				.0118	1	14
	38.75	1.325	1	3			
	44.6				.0708	1	28
Cyclohexyl	25	.026	1	50	.0183	2	20

For the purpose of interpreting the results, the standard temperature of 25° was taken, since the competitive enolizability of different active hydrogens seems but little affected by temperature. To get an expression of the mobility of a single hydrogen atom in the position in question, a statistical correction needs to be made by dividing the fractional velocity by the number of equivalently situated hydrogen atoms, as has been done in Table II.

TABLE II

COMPETITIVE ENOLIZATION VELOCITY OF HYDROGEN IN SECONDARY BUTYL KETONES, $RCOCH(CH_3)C_2H_5$, 25°

R	$k_{\text{Iod.}}$	$k_{\text{Rac.}}$	v_R	v_H
CH_3	1.41	0.248	4.68	1.56
C_2H_5	0.852	.103	7.27	3.63
Benzyl	.324	.0118	26.4	13.2
Cyclohexyl	.026	.0183	0.42	0.42

In this table v_R is the enolization velocity of all the active hydrogen in the group R, relative to that of the secondary butyl hydrogen taken as unity; v_H is the enolization velocity of a single active hydrogen atom in the group R, relative to that of the secondary butyl hydrogen as unity.

The competitive velocities per hydrogen in the four ketones measured vary over a 31-fold range. It is not surprising that benzyl hydrogen should be the most active competitively; but the result is unexpected that under these acid catalytic conditions the tertiary hydrogen atoms are less active, as regards rate of enolization, than either primary or secondary hydrogen. This is directly contrary to the indications of Part I of this series, wherein it was found that, using our present notation, v_H for one of the secondary hydrogen atoms of position 2 of menthone is only 0.13 relative to the tertiary hydrogen of position 4.

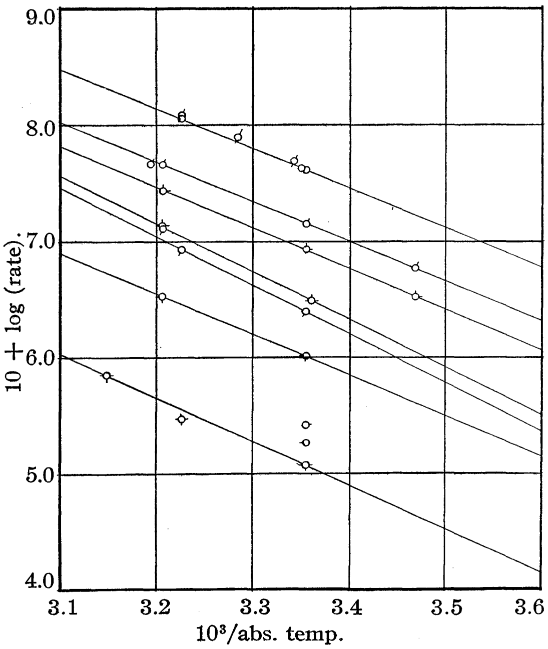

Fig. 1.—The common logarithms of the rate constant plotted against the reciprocal of the absolute temperature: Ọ́ iodination of *l*-menthone; O racemization of *l*-menthone; Ó iodination of methyl *s*-butyl ketone; Ọ racemization of methyl *s*-butyl ketone; Ȯ- iodination of ethyl *s*-butyl ketone; -Ọ racemization of ethyl *s*-butyl ketone; -Ȯ- iodination of benzyl *s*-butyl ketone; -Ọ- racemization of benzyl *s*-butyl ketone; O- iodination of cyclohexyl *s*-butyl ketone; -O racemization of cyclohexyl *s*-butyl ketone; -ϕ- iodination and racemization of phenyl *s*-butyl ketone.

This striking contrast between acyclic and cyclic ketones led us to repeat the earlier work on menthone, with a resulting revision of the figures, which, however, widens the difference between menthone and the secondary butyl ketones. For the iodination of menthone at 25° we now get a unimolecular rate constant of 4.08, and for the racemization we get 4.27. Allowing for experimental uncertainties we may say that v_H for the methylene hydrogen is not greater than 0.04 relative to the tertiary hydrogen. We cannot account for the difference between this result and the earlier one; the only known differences of conditions in the present experiments were the use of 1.19 *N* instead of 0.955 *N* nitric acid, closer temperature control on both kinds of run, and the use of a spectrophotometer instead of a colorimeter, which resulted in these new iodination runs being very intensely illuminated with white light. The runs did not show the departure from first order kinetics observed in Part I,[5] (p. 4994, 4995) which bears out the suggestion there made that the iodination of the enol may be photochemically promoted. The necessity of revising the figures for menthone is also a warning that these results may have only qualitative significance.

Discussion.—The isolated cases of the acid-catalyzed enolization of menthone and the base-catalyzed enolization of chloracetone[8] supported a mechanism undertaking to account for the direction of enolization in terms of the nature of the catalyst and the alpha-substituted groups and two electronic mechanisms of enolization. The results of the present work show that such a formulation is entirely too simple and is incapable of affording reliable predictions concerning rates of reaction or energies of activation in the enolization process. The ethyl and isopropyl groups are both feebly electron-repelling, relative to hydrogen. One of these, introduced into a cyclohexanone, strongly enhances the competitive enolization rate of the neighboring hydrogen atom; the other, introduced in the alpha position into diethyl ketone, markedly *diminishes* the competitive enolization rate of the neighboring hydrogen atom. In both cases the conditions of study are so strongly acid that there can scarcely be any question of the basic mechanism of enolization coming into play. This work affords a possible further example of the unique character of cyclohexanones, which it might be profitable to investigate in connection with the other abnormalities of these ring compounds.

It is noteworthy also, as Table II shows, that the rates of enolization of the *s*-butyl ketones do not in any sense run parallel to the competitive enolization rates of the groups introduced. Although the benzyl group, for instance, has a v_R five times as great as that of the methyl group, benzyl *s*-butyl ketone enolizes only one-fourth as fast as methyl *s*-butyl ketone.

Experimental

The acetic acid used as solvent was prepared by fractional distillation of acid obtained from the Baker and Adamson Co. The nitric acid was purified by distillation from an equal volume of concentrated sulfuric acid, followed by removal of oxides of nitrogen by passage of dried air through the distilled acid. The iodine used had been resublimed.

Methylethylacetic acid was prepared by the method of "Organic Syntheses,"[9] with the time-saving modification that the *s*-butylmagnesium chloride was carbonated by dropping onto excess solid carbon dioxide. This reduced the yields from 86 to 72%, but was very much more rapid.

Methylethylacetic acid was resolved with brucine as described by Schütz and Marckwald.[10] No attempt was made to carry the resolution to a maximum, acid of a specific rotation as high as +7.2° being obtainable from the mother liquors from which several fractions of the brucine salt had been crystallized. The maximum rotation at 20° for the D line of sodium is reported as −16.67° by Schütz and Marckwald.

The ketones were prepared by the same procedure as was followed by Conant and Carlson[11] in preparing a series of optically active ketones. The active acid was converted into the acid chloride by refluxing with thionyl chloride, this reagent having been purified by distillation first from quinoline, and then from linseed oil.[12] The acid chloride boiled at 118° at 760 mm. pressure. Grignard reagents prepared respectively from methyl iodide, ethyl bromide, benzyl chloride, cyclohexyl chloride and bromobenzene, were treated with equivalent amounts of freshly fused zinc chloride dissolved in dry ether. Magnesium chloride was precipitated and the resulting solutions of organozinc compounds were treated, with warming, with the methylethylacetyl chloride, the solution hydrolyzed after a few minutes with dilute sulfuric acid, the ether layer washed with sodium carbonate solution and water, and dried with sodium sulfate. There was evidently always some racemization in the formation of the ketones, for successive samples of the same ketone showed varying ratios between their optical rotations and the rotations of the acid from which they were prepared. Hydrolyzing the product of the coupling reaction with ammonium chloride instead of dilute sulfuric acid did not eliminate this racemization. In spite of care in removing acids and bases from the ketones, all except menthone were

found to undergo racemization in ordinary glass-stoppered bottles over a period of several days. The following are the rotations of the samples of ketone actually used for the racemization measurements, immediately before use.

TABLE III

SPECIFIC ROTATIONS OF SECONDARY BUTYL KETONES, C_4H_9COR

R	$[\alpha]^{25}_D$ of acid	$[\alpha]^{25}_D$ of ketone
CH_3-	+5.4°	+8.15°
C_2H_5-	+5.0	+8.5
C_6H_5-	+5.7	+9.27
$C_6H_5CH_2$-	+4.5	+4.3
Cyclohexyl	+7.2	+4.4

Measurements of racemization were made in all-glass polarimeter tubes. For the slow racemizations the tubes were simply kept in a thermostat between readings; for the rapid ones water from the thermostat was circulated through the tube jackets. Iodination measurements were carried out with a Keuffel and Esser color analyzer, using a wave length of 620 mμ. The same concentrations of ketone and nitric acid were used in the racemizations as in the iodinations; the amount of iodine used in the latter never exceeded 3% of the total amount of ketone, nor 2% of the total nitric acid present. The period of observation for the racemizations extended until the rotations were too small to measure, and included from five to ten readings; readings were made on the iodination runs up to total disappearance of the iodine, and numbered between ten and twenty to a run.

The velocity constants were determined graphically as the slope of the straight line drawn through the points when the logarithm of the molal concentration of ketone (or of the optical rotation) was plotted against time. The constants were corrected to the basis of natural logarithms, and are expressed in minutes as the time unit. In averaging the results of different check runs, the runs were weighted since they varied among themselves in precision. Most of the runs necessarily consist of determinations made at about equal time intervals, and there is no way of pairing the points for calculation of deviations of the constants calculated from different pairs without unduly weighting those which are close together. We therefore adopted a purely graphical method of assigning weights to the different runs: the lines of maximum and minimum slope were taken which could be reasonably drawn through the points, and the runs were given weights inversely proportional to the individual differences between the maximum and minimum slopes. Figure 2 illustrates this procedure.

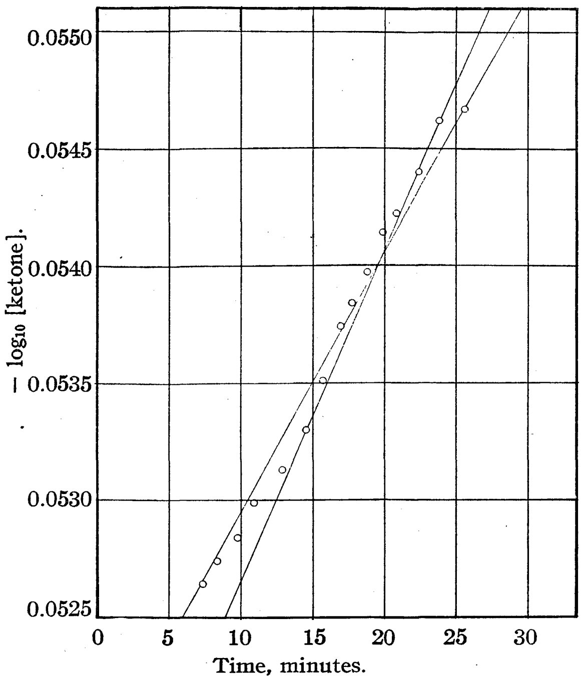

Fig. 2.—An iodination of the benzyl *s*-butyl ketone on which the estimated uncertainty is 20%, showing the two lines of greatest and least slope which might reasonably be drawn through the experimental points.

Summary

1. The competitive rates of enolization in the two possible manners have been measured for the ketones *d*-$C_2H_5(CH_3)CHCOR$, where R is methyl, ethyl, cyclohexyl and benzyl, in glacial acetic acid solution with nitric acid as catalyst.

2. The method has been checked with the observation that under these same conditions the rates of iodination and racemization of *d*-methylethylacetophenone are identical.

3. The relationship between alkyl substitution and competitive enolization rate of an active hydrogen does not bear out any simple hypothesis of enolization mechanism previously advanced.

4. The relationship between alkyl substitution and competitive enolization rate is opposite in menthone to what it is in the acyclic secondary butyl ketones.

Kinetics of the Friedel–Crafts Reaction, and Activity of Mixed Catalysts in the Reaction of Benzoyl Chloride with Toluene

BY LAWRENCE F. MARTIN, PHILIP PIZZOLATO AND LYNN S. MCWATERS

It has been observed frequently that relatively impure, technical aluminum chloride is a more active catalyst for certain Friedel–Crafts reactions than the C. P. reagent. The activity of a catalyst is here considered as the velocity of a given reaction produced by it as distinguished from the yield of product obtained. The latter point has been investigated by Riddell and Noller,[1] who determined the yields of a number of ketones and hydrocarbons obtained with various mixtures of ferric and aluminum chlorides, and by Boswell and McLaughlin,[2] who determined the total amounts of hydrogen chloride evolved by the reaction of chloroform and benzene using similar mixtures. Studies of the velocity of reaction of benzoyl and benzyl chlorides with toluene, using pure aluminum chloride and pure ferric chloride, have been made by Steele,[3] and of similar reactions with benzene by Olivier.[4] Both concluded that these reactions involve complexes of catalyst and reagent, and that the reactions are unimolecular when less than one mole of catalyst is used, if the toluene is in large excess. The reactions proceeded smoothly to completion, and Riddell and Noller,[1] using mixed catalysts, also obtained good yields in the synthesis of benzophenone.

Steele's method in which the hydrogen chloride was removed by a constant stream of hydrogen and titrated was more rapid and convenient than Olivier's, in which the unreacted benzoyl chloride had to be hydrolyzed and the benzoic acid extracted with ether for titration. Olivier adopted the latter procedure after criticizing the uncertainty of Steele's analytical method, the uncertainty of the simpler method being due obviously to the possibility that the hydrogen chloride is not removed completely by the hydrogen. We found that the removal of the acid from solution is in fact much slower than was supposed by Steele, who plotted a curve for the desaturation of a saturated solution of hydrogen chloride in toluene and corrected his titrations by adding the amounts remaining dissolved at corresponding times as read from this curve. Actually the removal of the hydrogen chloride is approximately a unimolecular process, the rate of removal being proportional to the concentration in solution. If the initial reaction is unimolecular there are two consecutive unimolecular processes, and the amount, x, removed and titrated in time t is given by the equation

$$x = a - ak_2e^{-k_1t}/(k_2 - k_1) + ak_1e^{-k_2t}/(k_2 - k_1) \quad (1)$$

in which k_1 is the velocity constant of the initial reaction, a is the initial concentration of the reacting complex in the Friedel–Crafts reaction, and k_2 is the velocity constant for the desaturation of the solution.[5] Solving for the required velocity constant gives

$$k_1 = -(1/t)\ \ln\{(k_1/k_2)(e^{-k_2t} + (x - a)/a) - (x - a)/a\} \quad (2)$$

for which values of k_1 must be found by approximation. The value of the constant obtained from the simple unimolecular law for the later stages of the reaction is a useful first approximation, as it differs only slightly from k_1 when t is large; two successive applications of Newton's method usually yield a value of k_1 which is within the limits of accuracy of the experimental data.

The desaturation of the solution by hydrogen is only approximately unimolecular under suitable conditions and k_2 depends upon the volume of solution used. If c is the variable concentration of hydrogen chloride in solution, its partial pressure in the gas in equilibrium is $p_{HCl} = Kc$, from Henry's law. The respective volumes of gases and vapor in unit volume of saturated gas are

$$V_{HCl} = p_{HCl}/760$$
$$V_T = p_T/760$$
$$V_{H_2} = (760 - p_T - p_{HCl})/760$$

The volume of toluene vapor, V_T, is practically constant as the toluene is in large excess and its concentration does not change appreciably. Unit volume of dry hydrogen leaves the solution as saturated gas of volume $760/(760 - p_T - p_{HCl})$, in which the volume of hydrogen chloride is $p_{HCl}/(760 - p_T - p_{HCl})$. Substituting for the partial pressure of hydrogen chloride in terms of

its concentration gives $Kc/(760 - p_T - Kc)$, and since p_T is practically constant it is possible to put $b = (760 - p_T)/K$, obtaining for the rate of removal of hydrogen chloride

$$dx/dt = kc/(b - c)$$

If the constant term b is large compared to c, as is the case in the experiments under consideration, the denominator may be combined with the velocity constant k to give

$$dx/dt = k_2c$$

In these equations x is the amount of hydrogen chloride removed and titrated, while c is its concentration in solution, and in order to integrate either it is necessary to express c and the initial concentration of reacting complex, in terms of x and the initial amount, a, of reacting complex, and the volume of solution, v. This leads in the simpler case to a unimolecular equation

$$k_2/v = (1/t) \ln a/(a - x)$$

except that the volume of solution must be taken into account in the manner indicated if it is not the same in all experiments, as was the case in Steele's investigation.

The experiments to be described in this report were concerned with three objectives: first, to determine the relative activities of several samples of aluminum chloride in two distinct types of the Friedel–Crafts reaction; second, to determine the activity as measured by the reaction velocity of benzoyl chloride with toluene of a series of mixtures of aluminum and ferric chloride covering a wide range of composition; and third, to investigate the significance of the data obtained by Steele's method when the constants are calculated by equation (2). Since commercial aluminum chloride containing iron was most active in the benzoyl chloride reaction, it seemed likely that ferric chloride might be responsible for the higher activity. This is further indicated by the variations in the yield curves of the reactions studied by Riddell and Noller[1] when ferric chloride was added, showing that it affects the course of the reactions in a specific manner. It has also been claimed that aluminum chloride is activated for use in the Gattermann–Koch synthesis by small additions of titanium chloride or mixtures of titanium and ferric chlorides.[6]

Experimental

Apparatus and Procedure.—The apparatus was the same as that used by Steele[3] except for the supply of hydrogen which was drawn from a commercial cylinder through a suitable system of reducing valves, dried by sulfuric acid, and measured by a calibrated flowmeter. In order to obtain a constant reading the gas passed through the meter under a static pressure of 50 to 75 mm., for which the necessary correction was made in each experiment. Variations in the rate from one experiment to another were corrected on the basis that the desaturation velocity constant varies in direct proportion to the hydrogen rate, other conditions being constant.

We found it preferable to weigh the catalysts used in thin glass bulbs which were broken by a plunger at the instant the watch was started, which minimized the absorption of moisture and permitted more accurate determination of the zero time. The benzoyl or benzyl chloride was dissolved in the toluene, the first increment of 2.5 or 5.0 cc. of standard sodium hydroxide was run into the absorber, and phenolphthalein added. The hydrogen was next turned on and adjusted and finally the catalyst bulb was broken. Benzoyl or benzoyl chloride was not carried over into the absorber in amounts sufficient to give an appreciable titer either while adjusting the hydrogen rate or after the reaction was complete.

Materials.—The toluene was C. P., sulfur-free grade, dried by standing over sodium.

The benzoyl and benzyl chlorides were C. P. grade, and were freshly distilled in quantities sufficient for each series of experiments, a constant boiling middle third fraction being collected in each case in glass-stoppered bottles which were kept in a desiccator. Samples were weighed rapidly into a weighing bottle.

Aluminum chloride samples of several grades were used: (1) Mallinckrodt C. P. grade specified to contain 0.1% Fe; (2) Mallinckrodt C. P. containing 0.005% Fe; (3) a purer sample prepared by action of dry hydrogen chloride on the purest aluminum powder available and resublimed, which contained less Fe than the sample marked 0.005%; and (4) Gulf technical grade specified to contain 92.6% $AlCl_3$, 3.6% $FeCl_3$, 1.04% $TiCl_4$ and 0.28% $SiCl_4$.[7]

Ferric chloride was prepared by the action of chlorine on C. P. iron powder and resublimed.

Mixed catalysts were prepared by weighing the required quantities of Mallinckrodt aluminum chloride containing 0.005% Fe and ferric chloride into small narrow necked tubes. A rod passed through a rubber tube fitted to the neck was used to grind and mix the chlorides until they were sufficiently homogeneous. Samples were transferred directly from the tubes into bulbs exactly as in weighing

material for the experiments, and analyzed for aluminum and iron. The mixtures used are given in Table I.

The excess over 100% in the total percentages is a measure of the extent of hydrolysis which unavoidably occurred in weighing and mixing the preparations. The mole percentages were calculated on the basis of the ferric chloride, which was determined directly by electrometric titration. More elaborate precautions to obtain greater accuracy of composition did not seem to be justified at present by the accuracy with which the velocity constants can be determined.

Determination of Desaturation Velocity.—Results of two experiments to determine the constant k_2 are given in Table II.

TABLE II

DESATURATION VELOCITY CONSTANTS

70.0	..	..	∞	..
Average		0.554		0.587

Using 20.0 cc. of toluene saturated with hydrogen chloride at 25°, Steele[3] obtained the value 1.46 for a hydrogen velocity of 250 cc./min. On calculating this value and the two values given above to the uniform basis of 50.0 cc. of toluene and 250 cc./min. of hydrogen, the values of k_2 are: Steele, 0.584; 1st experiment, 0.491; and 2d experiment, 0.528. These results are in fair agreement, and we used the average of our values, $k_2 = 0.510$, in computing our velocity constants, while the higher value given by Steele was used in recalculating his results.

Determination of Reaction Velocities.—Table III gives the data of experiment 16 on benzoyl chloride with Gulf technical aluminum chloride as catalyst, which are typical of the results obtained by Steele's method. The values of k obtained by means of the simple unimolecular equation are to be compared with those of k_1 calculated from equation (2). In this particular experiment the initial reaction is fairly rapid, k_1 being almost as large as k_2, and both the trend in the k values and the difference in the magnitude of the two constants are emphasized. In experiments in which k_1 is much smaller than k_2 the discrepancy is less, but is always significant. The values of k_1 are sufficiently constant to permit of averaging with reasonable accuracy for the purposes of the present investigation.

TABLE III

DETAIL OF TYPICAL EXPERIMENT—No. 16

Toluene = 50.0 cc. (0.47 mole), temp. 30°. Catalyst = 0.6741 g. (0.00505 mole). C_6H_5COCl = 1.4926 g. (0.0106 mole). Hydrogen = 256 cc./min. $k_2 = 0.525$.

Average (excluding last point) 0.381
Mole ratio $HCl/AlCl_3$ = 1.16

The results of all experiments are summarized in Table IV. The first group of eight experiments shows the velocity of reaction of benzyl and of benzoyl chloride with each of the three commercial grades of aluminum chloride and the resublimed sample. The next nine experiments are those made with the mixed catalysts of Table I, while the last three were made to determine the effect of concentration in increasing the reaction velocity.[4]

Recalculation of Steele's Results.—Velocity constants for several representative experiments were recalculated using equation (2) with the results shown in Table V. As Steele gave corrected titrations, the "corrections" were deducted to obtain the original values, but in experiment 17 this was impossible as the "correction" was larger than most of the recorded titers. The average k values reported by Steele do not differ greatly from k_1 in experiments 1 and 5, in which k_2 is large. In the experiments with benzyl chloride 30 cc. of toluene was used, making k_2 smaller, and the discrepancy is greater. In addition most of Steele's benzyl chloride experiments do not yield constants for k_1, but show a steady drift between the extreme values given below. We cannot account for this in view of the very satisfactory constants obtained in our experiments with this reagent, even in cases when k_2 was smaller than k_1.

Discussion

Comparison of the Reactions of Benzoyl Chloride and Benzyl Chloride.—The first eight experiments in Table IV show that the behavior of the three technical samples and the resublimed aluminum chloride is quite different with each of these reagents. With benzoyl chloride the reaction velocity increases as the percentage of ferric chloride present is increased. On the other hand, experiments with benzyl chloride and the same four catalysts show that, while the velocity constant is greatly increased by very small percentages of ferric chloride, it decreases again when substantial amounts are present as in the Gulf technical sample. Steele's observation is confirmed that approximately one mole of catalyst is required per mole of ketone formed, while fifteen to twenty moles of hydrocarbon are produced per mole of catalyst.

RECALCULATION OF STEELE'S DATA

Expt.	Reagent	Catalyst	k_2	k (Unimol.)	k_1 (Eq. 2)
1	C_6H_5COCl	$AlCl_3$	1.46	0.129	0.138
5	C_6H_5COCl	$AlCl_3$	1.46	.080	.084
18	$C_6H_5CH_2Cl$	$AlCl_3$	0.974	.533	.757
17	$C_6H_5CH_2Cl$	$AlCl_3$	.974	.258	.580–.315
21	$C_6H_5CH_2Cl$	$FeCl_3$	.974	.104–.260	.140–.301
22	$C_6H_5CH_2Cl$	$FeCl_3$	.974	.037–.112	.044–.114

Activity of Mixed Catalysts.—In the ketone synthesis studied all of the mixed catalysts are much mole active than either of the samples from which the mixtures were prepared. A significant result of the experiments in this group is the decrease in the ratio of moles of hydrogen chloride produced to the total moles of metal chlorides used, as the percentage of ferric chloride is increased. Pure ferric chloride produces almost exactly one mole of hydrogen chloride per mole of catalyst, as does the aluminum chloride. This indicates that, with mixed catalysts, the ketone formed removes both aluminum and ferric chlorides in the form of a stable complex, and that the reacting substance also probably consists of a complex such as $C_6H_5COCl \cdot AlCl_3 \cdot FeCl_3$, at least in part. In the case of the catalyst containing 16.4 mole per cent. ferric chloride (experiments 28 and 23) the ratio $HCl/AlCl_3$ is very nearly unity, which agrees with a mechanism in which all of the ferric chloride is combined as $C_6H_5COC_6H_4CH_3 \cdot AlCl_3 \cdot FeCl_3$, while the remaining aluminum chloride is removed as $C_6H_5COC_6H_4CH_3 \cdot AlCl_3$. The other mixtures do not give results agreeing with such a simple mechanism, but all of them definitely indicate the formation of larger complexes involving both chlorides in the molecule.

This explanation is not contradictory to the observation of Riddell and Noller[1] that good yields of benzophenone are obtained with similar mixed catalysts, as their experiments were made with excess of catalyst and at higher temperatures at which the complexes postulated may be unstable. Further evidence in favor of the removal of ferric chloride as part of the final complex is found in Steele's results with benzyl chloride in conjunction with our own. Steele showed that ferric chloride acts practically as a true catalyst in the hydrocarbon synthesis, forming 2500 moles of product per mole of catalyst. If even the small percentage of ferric chloride in the Gulf chloride used for experiment 6 were free to catalyze the reaction independently, it would be sufficient to convert all of the benzyl chloride present. Actually the ratio of product to catalyst is about the same as that obtained with the purest sample of aluminum chloride, and the reaction stops when considerable excess benzyl chloride still is unconverted.

As Olivier has shown,[4] and we have confirmed, the reaction velocity increases markedly with increase of the concentration of the reacting substance. If the reacting molecules are composed in part of the larger complex involving both chlorides, the effective concentration is less than the total concentration of metal chlorides present. The average velocity constants for the mixed catalysts are plotted against mole per cent. ferric chloride in Fig. 1; curve I is that obtained for experiments in which the total concentration of the metal chlorides was constant, while curve II represents experiments in which the effective concentration of reacting complex was approximately the same, as measured by the hydrogen chloride evolved. The latter curve indicates the large increase in activity of mixed catalysts at comparable concentrations as ferric chloride is added. The scale is enlarged for the first 0.25% to include constants for the purer technical samples. The Gulf aluminum chloride is much more active than can be accounted for by its ferric chloride content alone, and its greater activity is probably due in part to the titanium tetrachloride which it contains, the latter being claimed as an activator of aluminum chloride catalysts.[6]

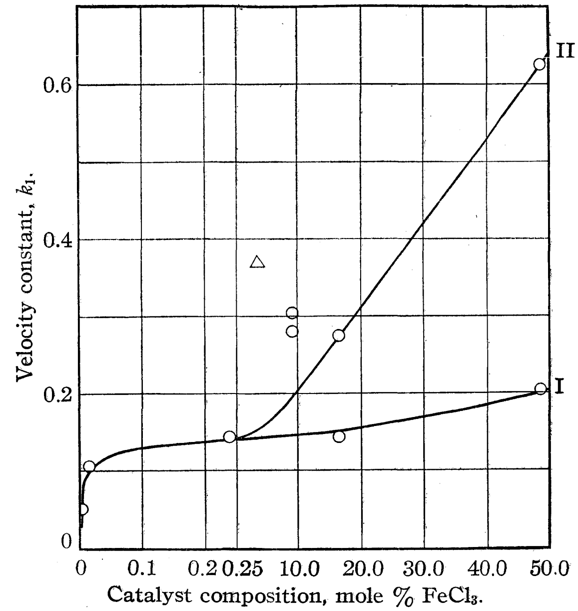

Fig. 1.—(Table IV) Variation of reaction velocity with catalyst composition: △, Gulf tech. $AlCl_3$; I, concn. of metal chloride constant; II, concn. of active complex constant.

Effect of Concentration and Order of Reaction.—The last three experiments in Table IV together with experiments 15 and 17, all of which were made with the same grade of catalyst, show the effect of concentration in increasing the reaction velocity. In Fig. 2 the average velocity constants are plotted against the mole fraction of catalyst used. The increase in k_1 is almost the same in magnitude as that found by Olivier[4] in his work on benzoyl chloride and benzene, and can be represented over the ten-fold range of concentration by $k_1 = 0.075 + 2.395c + 60.5c^2$, in which c is the mole fraction of the reacting substance. The complete reaction is, of course, bimolecular and the constants are understood to represent the pseudounimolecular mechanism obtained by using a large excess of toluene. For this reason the constant would be expected to vary with concentration, but the variation given by $k_{\text{bimol.}} = k_1/b$, in which b is the approximately constant concentration of toluene for each experiment, would be much smaller and in the opposite direction, k_1 decreasing with an increased concentration of catalyst.[8] If it is possible, as postulated above, for the aluminum chloride complex to form a larger complex with ferric chloride which has a higher

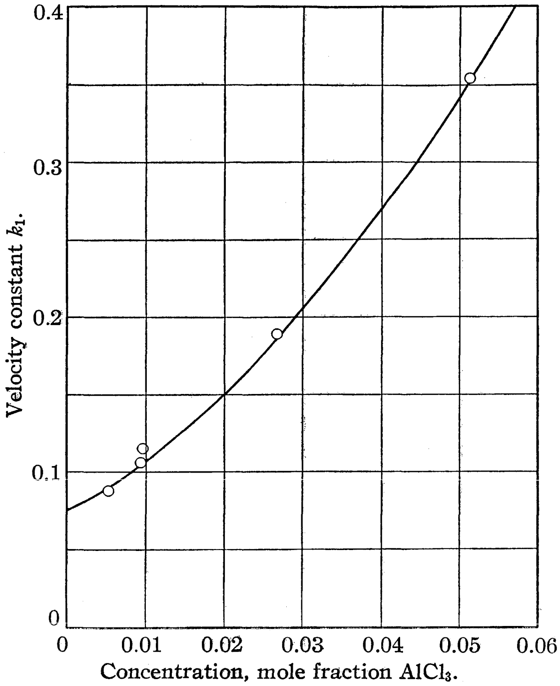

Fig. 2.—(Table IV) Variation of reaction velocity with concentration for $AlCl_3$ containing 0.005% Fe.

---

[8] F. O. Rice in Taylor, "Treatise on Physical Chemistry," 1925, Vol. II, 874.

activity, Olivier's explanation[4] of association of the aluminum chloride complex itself would seem tenable in accounting for the higher reaction velocity at higher concentrations. Except for this variation, in regard to which independent evidence would be desirable, our method of calculation leads to results in good agreement with a unimolecular reaction order, and may be taken as supporting the mechanism of this Friedel–Crafts reaction previously advanced by Steele.

Summary

1. A correct method of calculating velocity constants from data obtained by Steele's method has been applied to experiments on the Friedel–Crafts reactions of benzoyl and benzyl chlorides with toluene.

2. The relative order of activity of various catalysts depends upon the type of reaction, and in the case of benzoyl chloride the activity increases with increasing percentage of ferric chloride.

3. Mixed catalysts covering a wide range of composition of aluminum and ferric chlorides have been investigated in respect to the reaction of benzoyl chloride with toluene. At comparable concentrations the activity increases with increasing mole percentage of ferric chloride and reaches a maximum at percentages in excess of 50 mole per cent.

4. The mixed catalysts have been shown to produce less than one mole of product for each mole of total metal chlorides present. Evidence is given in support of the explanation that this is due to the removal of the catalyst in the form of a bimetal complex with the reaction product, such as $C_6H_5COC_6H_4CH_3 \cdot AlCl_3 \cdot FeCl_3$.

5. Variation of the reaction velocity over a ten-fold range of concentration, the toluene being always in large excess, has been determined, and is of the same order of magnitude as that reported in a similar reaction by Olivier. The present work furnishes evidence in support of the explanation of this effect as being due to association of the reacting complex.

6. The new experimental data and method of calculation lead to results in satisfactory agreement with a unimolecular order for the reaction, and thus lend support to the mechanism proposed by Steele.

The Chemistry of Mold Tissue. X. The Phospholipides of Aspergillus Sydowi[1]

BY D. W. WOOLLEY, F. M. STRONG, W. H. PETERSON AND E. A. PRILL

While several papers have been published dealing with the simple lipides of molds, no report has been found regarding the characterization of the compound lipides. A few workers have reported preliminary analyses of the phospholipides,[2] but no detailed study of these compounds has been reported. In a previous paper[3] the simple lipides of *A. sydowi* have been described; the examination of the phospholipides of this same organism is herein described.

Experimental Part

Extraction and Purification.—The mold was grown for ten days on glucose–inorganic salt medium in large sterilized incubators.[4] While still growing it was removed from the medium, washed with cold water, squeezed out by hand and dried rapidly at 30–60° in air. Two batches of mycelium were grown at intervals of eight months and the phospholipides of each batch examined separately. The phospholipides from the first batch will be designated as A, and those from the second batch as B. A was extracted from 7.27 kg., and B from 3 kg. of dry mold.

The mold was extracted continuously for about a week in a Lloyd type extractor. A was obtained by extraction with alcohol, and B by extraction with alcohol–ether (1:1). The solution from the extractor was evaporated, and the residue redissolved by adding water and ether. (In this and subsequent operations air was excluded by a stream of carbon dioxide.) The two layers were separated, filtered and the water layer discarded. A very small amount of matter remained undissolved in both preparations. The water layer contained only traces of nitrogen and phosphorus, and contained mannitol.

The ether layer was concentrated, and poured into a

large volume of acetone. In the preparation of A, alcoholic magnesium chloride was added, but by concentrating the ether solution sufficiently precipitation was effected in the case of preparation B without the use of any inorganic salt. After standing for a few days in the cold the precipitate was filtered, washed with acetone and redissolved in ether. After centrifuging,[5] the clear solution was precipitated by pouring into cold acetone. A was precipitated six times and B five times. The purified phospholipides were stored in ether solution under carbon dioxide. 54.26 g. of A (0.73% of the mold, and 9.2% of the crude lipides) was obtained and 12.74 g. of B (0.43% of the mold and 6.15% of the crude lipides). The remaining simple lipides contained only a trace of phosphorus.

Anal. Preparation A: N, 1.71; P, 3.65; N/P, 1.03. Preparation B: N, 1.68; P, 3.78; N/P, 0.99; ash, 2.8.

Hydrolysis.—The phospholipides were hydrolyzed in 5 to 6 g. lots by refluxing for about six hours with 5% sulfuric acid. Ether was added, and the layers separated and filtered. The ether layer contained only traces of nitrogen and phosphorus.

For the separation of the water-soluble constituents the scheme of Newman and Anderson[6] was employed, with a few slight modifications. The crude barium glycerophosphate was purified by precipitating it as the lead salt, decomposing the latter with hydrogen sulfide in the presence of excess barium hydroxide, passing in carbon dioxide to remove excess barium, and reprecipitating the barium glycerophosphate with alcohol. A pure white product was obtained.

Anal.:[7] Calcd. for $C_3H_7O_6PBa \cdot {}^1/_2H_2O$: Ba, 43.4; P, 9.8. Found: Preparation A, Ba, 43.7; P, 9.8. Preparation B, Ba, 43.3; P, 9.8.

The presence of glycerol was shown by the specific test proposed by Eegruive.[8] The intensity of the test as compared to that given by an equal quantity of barium α-glycerophosphate indicated that a mixture of α- and β-glycerophosphates was present.

Choline was separated as the chloroplatinate, after removing barium glycerophosphate.[6] Choline chloroplatinate from A melted at 241–243° with decomposition, and from B at 242–243° with decomposition. *Anal.* Calcd. for $(C_5H_{14}ON)_2PtCl_6$: Pt, 31.42. Found: Pt, 31.64.

Cholamine was precipitated by picrolonic acid after removing barium glycerophosphate and choline chloroplatinate.[6] Cholamine picrolonate from A melted at 223–225° with decomposition, and from B at 222–226° with decomposition.[6]

Anal.: Calcd. for $C_{12}H_{15}O_6N_5$: NH_2-N, 4.31. Found: NH_2-N, 4.3.

By continued steam distillation of another portion of the aqueous hydrolysate made alkaline with sodium hydroxide, a small amount of cholamine was separated and was identified as the picrolonate. This afforded additiona evidence for the presence of cholamine in the hydrolysate

NITROGEN DISTRIBUTION IN THE AQUEOUS HYDROLYSATE

	Total water soluble N, % In A	In B
Ammonia N[9]	13.8	7.86
Amino N (Van Slyke)	50	57.8

By the method of Lintzel[10] all the N other than ammonia-N and primary amino N was approximately accounted for as choline.

The Ether Solution.—This made up 62% of the phospholipides in A, and 56.2% in B. Of this material, 14.4% in A was insoluble in petroleum ether. This insoluble material was acidic, and black in color, and was perhaps a decomposition product, since with rapidly prepared phospholipides (preparation B) it amounted to only 0.44%. Also, the amount of petroleum ether insoluble material seemed to increase with the age of the phospholipides.

The ether-soluble fatty acids of B were separated by the lead soap–ether method[11] into 13.8% saturated acids having an iodine number of 6[12] and 86.2% unsaturated acids having an iodine number of 95.7.

The saturated acids melted at 55.5–56.5° and had a neut. eq. of 276. Hence, they were probably a mixture of about equal parts of palmitic and stearic acids.[13]

On hydrogenation of the unsaturated acids in ethanol with a Raney nickel catalyst under about 100 atmospheres at 25–125°,[14] followed by one recrystallization from acetone of the hydrogenated acids, an acid melting at 69.5°, showing no depression of the melting point with pure stearic acid, and with a neut. eq. of 284.2 (calcd. for stearic acid, 284.3) was obtained.

On oxidation[15] of the unsaturated acids with cold permanganate only a trace of acids insoluble in chloroform was obtained. The chloroform soluble product melted at 130°[16] and showed no depression of the melting point with pure 9,10-dihydroxystearic acid.

On bromination of the unsaturated acids from A only traces of petroleum ether-insoluble acids were produced. The main product was a dark oil, presumably dibromostearic acid.

On fractionation of the ethyl esters of the unsaturated acids from 17.6 g. of A, a main fraction boiling at 175–177° (3 mm.) having an iodine number of 83.5, and a smaller fraction boiling at 175–180° (3 mm.) having an

---

[5] The solid matter was a light-colored solid, insoluble in ether. It contained nitrogen and phosphorus, and preliminary work indicated that it consisted of two compounds of very peculiar composition. The study of these compounds is being continued.

iodine number of 97 were obtained. Ethyl oleate has an iodine number of 82.

Hence, oleic acid was the chief unsaturated acid; traces of a more unsaturated acid were also present. No palmitoleic acid was found.

Summary

The ether-soluble phospholipides of *A. sydowi* were found to be a mixture of lecithin and cephalin. From the mycelium 0.4–0.7% of phospholipides was isolated. Glycerophosphoric acid, choline, cholamine and oleic acid were identified as the chief hydrolysis products. Stearic, palmitic, and a more unsaturated acid were also probably present in small amounts.

An x-Ray Investigation of the Solid Solution Nature of Some Nitrate Contaminated Barium Sulfate Precipitates[1]

BY GEORGE H. WALDEN, JR., AND M. U. COHEN

Almost from the inception of quantitative analysis the contamination of precipitates by foreign substances has been a universal difficulty encountered by analytical chemists. The cause of the phenomenon has been assigned[2] in general to (1) inclusion of the mother liquor in the precipitate mass, (2) adsorption on the crystal faces, both "inner" and "outer," (3) compound formation and (4) solid solution. That such theories have been purely speculative in character is demonstrated by the fact that their application has varied with different workers from the assumption of one such theory to explain all cases of contamination, almost to the assumption of all such theories to explain any particular case.

The resulting confusion in a field as complex as this is easily understood when the experimental evidence is examined. This has been almost entirely confined to analytical studies of precipitate contamination as a function of the medium in which the precipitates have been formed, or even to the purely pragmatic study of the weight relations of contaminated precipitates. It is clear from a survey of the literature that such methods by themselves cannot furnish conclusive evidence for the mechanism of contamination, and that a truly critical evaluation of the various possibilities awaits the development of experimental methods of an entirely different character. It is further desirable that such experimental methods be applicable almost universally, and not limited either to certain precipitates or to certain contaminants. In these respects the method of radioactive indicators, for example, is severely limited. However, a very positive and direct experimental test is available, at least for theories (3) and (4), in the combination of chemical analysis with x-ray diffraction studies.

In the application of this method to precipitate contamination, that which is due to inclusion and adsorption will lead to no observable changes in the diffraction pattern. Compound formation will lead to the formation of a new solid phase which if present in sufficient amount will manifest itself by the appearance of new lines in the diffraction pattern. Finally, the entrance of a contaminant by the process of solid solution will cause a change in the lattice dimensions dependent on the proportion of contaminant present in the precipitate without affecting the lattice symmetry of the latter.

The great power of this method has been recognized in the case of crystals prepared from melts particularly in metallic systems,[3] and the very numerous studies in that field prove beyond question its validity and utility. There has been, however, but very meager application to crystals formed by precipitation from solution. As part of a systematic investigation by Grimm[4] and his students of solid solutions in ionic crystals, Wagner[5] studied the system $BaSO_4$–$KMnO_4$ with the help of the x-ray technique and established its solid solution nature.

---

[1] This article is based upon part of a dissertation submitted by M. U. Cohen in partial fulfilment of the requirements for the degree of Doctor of Philosophy under the Faculty of Pure Science of Columbia University, May, 1935. The material was presented at the New York Meeting of the American Chemical Society, April, 1935.

[2] I. M. Kolthoff, *J. Phys. Chem.*, **36**, 860 (1932); *Chem. Weekblad*, **31**, 102 (1934), and following papers.

[3] Westgren, *Trans. Am. Inst. Min. Met. Eng.*, Inst. Metals, p. 13 (1931); Jette, *ibid.*, **111**, 75 (1934).

[4] (a) Grimm, "Handbuch der Physik," **24**, 1096 ff. (1933); (b) Dahlmann, Diss., Wurzburg, 1930; (c) Peters, Diss., Wurzburg, 1930.

[5] Wagner, *Z. physik. Chem.*, **2B**, 27 (1929).

In order to form "mixed crystals," *i. e.*, solid solutions, in such systems, their constituents, Grimm asserts, must possess: (1) identical types of chemical structure, *e. g.*, $BaSO_4$–$KMnO_4$; (2) identical types of crystal structure, *e. g.*, $BaSO_4$ and $KMnO_4$ are both orthorhombic and in the same space group, V_h^{16}; (3) nearly identical lattice parameters.

Such requirements may perhaps be valid for the occurrence of complete miscibility, but their force is certainly weak in the case of limited solubility. Thus in metallic systems a necessary condition for complete miscibility is that the components be of identical lattice type. On the other hand, for a limited range of solid solution no such condition is necessary, and as a matter of fact systems which fail to meet this requirement are fully as numerous as those which do comply.[3] While the very different nature of the metallic and the ionic types of bond makes any wide-spread analogy between ionic and metallic systems a very dangerous one, the fact is that in ionic systems also the available evidence[4a] points to the absence of such conditions of isomorphism for limited solid solubility. It is precisely this case, rather than that of complete miscibility, which is of most interest in the problem of precipitate contamination.

It is our aim to study, without regard to the limitations imposed by such rules as those of Grimm, the possible incidence of solid solution of foreign ions in analytical precipitates. As an initial study, the analytically important example has been chosen of barium sulfate precipitated in the presence of nitric acid.

While it has been known for a long time that such precipitates may contain quite large amounts of nitrate, the mode of entrance of this contaminant has been quite unknown, and indeed even the actual amount of nitrate in such precipitates has hardly been investigated.[6] To these facts may be added the additional one that, while the chemical nature and crystal structure of the contaminant are unknown, it is certainly not of the same chemical type as barium sulfate (MXY_4), and therefore according to Grimm should not form a solid solution. Further, Wagner reported[5] that barium nitrate did not form solid solutions with barium sulfate, stating that the contaminated crystals showed diffraction patterns identical with those from barium sulfate prepared in other ways.

All of these points total to the sum that the contamination of barium sulfate in the presence of nitric acid is a very interesting case for study, and one likely to prove most illuminating for the interpretation of precipitate contamination in general.

Since the proof or disproof of the existence of solid solution in any system depends entirely on the precision of the x-ray work, it should be emphasized that methods of the highest precision are essential. The greatest variation in the lattice parameters of the precipitates here investigated is about 0.3%, and this would have been overlooked entirely as being within the experimental error, if the usual type of powder camera and method of calculation had been used. The apparatus to be described, when used in conjunction with the method of interpretation developed by one of us,[7] permits the measurement of lattice parameters with a precision of at least 0.01%. This greatly extends the application of the x-ray method into the dilute solid solution range, the region of interest in connection with precipitate contamination.

Experimental

x-Ray Apparatus.—The self-rectifying gas x-ray tube used in this investigation was designed to provide for high asymmetry of the anode–cathode parts to give good rectifying and focusing properties; for efficient cooling of all parts of the tube to give high power dissipation; and for simplicity in construction and assembly.

Fig. 1 shows a longitudinal section through the corners of the tube and a top view with the plate B removed. Cooling water flows through tube b into the annular chamber A and then through the four longitudinal holes t drilled in the corners of the anode block to connect A with the water jacket D. The body of the tube and the 0.01-mm. aluminum windows are thus cooled very effectively. These aluminum foil windows are placed on three of the tube faces, the fourth face being occupied by 1.9-cm. flexible metal tubing (American Flexible Metal Hose Co.) which serves to connect the tube with the vacuum pumps. The tube is mounted vertically when used with the focusing cameras described below.

A simple regulator (Fig. 2) holds the tube current very constant. The solenoid is shunted across a tapped resistance placed in series with the primary of the high voltage transformer. An increase in the tube current increases the current in the transformer primary and therefore changes the current in the solenoid, causing the iron armature to rise. The resulting increase in the effective pumping speed of the diffusion pump reduces the gas pressure in the tube, bringing the current back to its original value. On the other hand, a decrease in the

---

(7) For the theory of these cameras see M. U. Cohen, *Rev. Sci. Instr.*, **6**, 68 (1935).

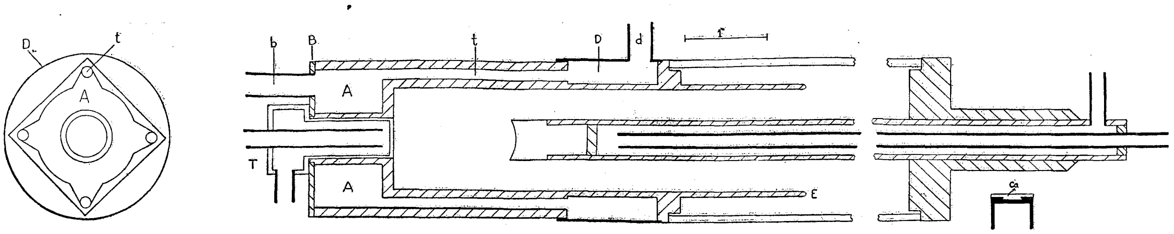

Fig. 1.

tube current lowers the armature, increasing the gas pressure and again restoring the original current. Changes in the equilibrium current are made by varying the proportion of the tapped resistance shunted across the solenoid.

Other supplementary equipment which may be of interest in view of its utility and the inexpensiveness includes a synchronous AC time clock and switch (New Haven), a solenoid-controlled water valve (General Electric No. CR9507-C1B), and a pressure-controlled switch (Detroit Lubricator No. 250) which opens the electrical circuits if the water pressure drops below a safe value. The inclusion of such auxiliary apparatus is invaluable because the operating time of the x-ray equipment may thereby be safely extended to periods when no personal attention is available.

The Precision Camera.—The design of the symmetrical focusing powder camera[7] for high angle reflections used in this investigation was conditioned by the difficulties encountered in securing x-ray photograms of barium sulfate powders which could be measured with sufficient precision. These crystals are orthorhombic and have relatively large lattice parameters. The use of long wave length x-rays is therefore indicated; short x-rays will be reflected only from planes so complicated that the intensity of the reflected beam will be very low and not very much greater than that of the general background. As a matter of fact copper radiation ($\lambda \sim 1.5$ Å.) gives very poor films; those taken with chromium are somewhat better; but really satisfactory photograms are secured only when resort is had to the use of calcium metal targets. This is the first extensive use reported of such radiation for powder work.[8]

Since the wave length of the calcium K lines is about 3.3 Å. they are very strongly absorbed and scattered by air. This makes it necessary to use an evacuated camera. The large size of the crystal grains leads to very spotty reflections if the sample is kept stationary during the exposure, and it is desirable therefore to arrange for continuous motion *in vacuo* of the powder under investigation. Constructional details of the camera designed with these points in mind will be evident from the photograph, Fig. 3.

The inner camera rings 6 and 6′ are machined to a diameter equal to that of the case 1 minus twice the film thickness, the latter being held to very close tolerances in the process of manufacture. Only the upper ring 6′ need be removed in loading the film 4. To facilitate this operation the diaphragm system 5, into which is inserted the replaceable lead slit 5′, is also removed. By means of the sector 3′ the sample 2 is pressed against the sample holder 3, the radius of the arc on which it is held being equal to that of the inner rings. The mechanism 9 for oscillating the sample holder operates through a stuffing box 10 and has the advantages that the sample holder is easily removable and that the need for a vacuum-tight central bearing is eliminated. The opening in the case through which the x-rays enter the slit system is covered by a cellophane window. The cover 8 carries a rubber gasket which forms a vacuum-tight seal when the camera is evacuated by a Hyvac pump connected to the outlet 7. The powder is mounted for exposure by dusting it on a sheet of mica on which a thin film of rubber cement has been allowed to set. The photograms obtained are excellent, the lines being very sharp and giving good contrast with the background.

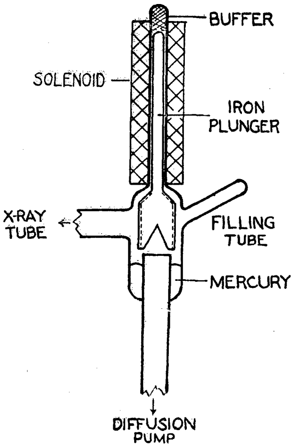

Fig. 2.

A millimeter scale for measuring purposes is printed on the single-coated x-ray film directly under the exposed portion. The original scale which serves as a negative was ruled on a Société Génévoise dividing engine by cutting through the blackened emulsion of a photographic plate. A vernier scale (10 divisions = 9.00 mm.) prepared in a similar way was printed on a photographic plate. Line distances on the photograms are measured by setting the zero of this vernier scale on the center of the line, tenths of a millimeter being given by coincidence of a vernier division with the millimeter scale printed on the film. The precision of such a setting is ±0.1 mm. and the distance between two lines is therefore precise to ±0.2 mm. The precision of the lattice constant determinations is discussed below for the case of the contaminated precipitates.

Preparation of the Precipitates.—The contaminated barium sulfate precipitates used in the present research have been prepared by the slow addition of sulfuric–nitric acid solutions to boiling barium nitrate–nitric acid

---

(8) By the pressure exerted in a vise a calcium metal disk may be squeezed into good contact with the brass target body, if this is machined as indicated in Fig. 1. Such a target will carry 15 ma. at 40 kv. [*cf.* Haag, *Z. Krist.*, **A86**, 246 (1933), and Kersten and Maas, *Rev. Sci. Instr.*, **4**, 381 (1933)], but for continuous service it is better to use somewhat less power. At 5 ma. and 35 kv. good photograms of the cubic metals are obtainable in thirty minutes. Under these conditions the exposure time for the barium sulfate precipitates is about eight hours. The authors are indebted to Prof. H. T. Beans for pointing out that metallic calcium is sufficiently inert to be used in this way. Single targets have given several hundred hours of service over a period of months.

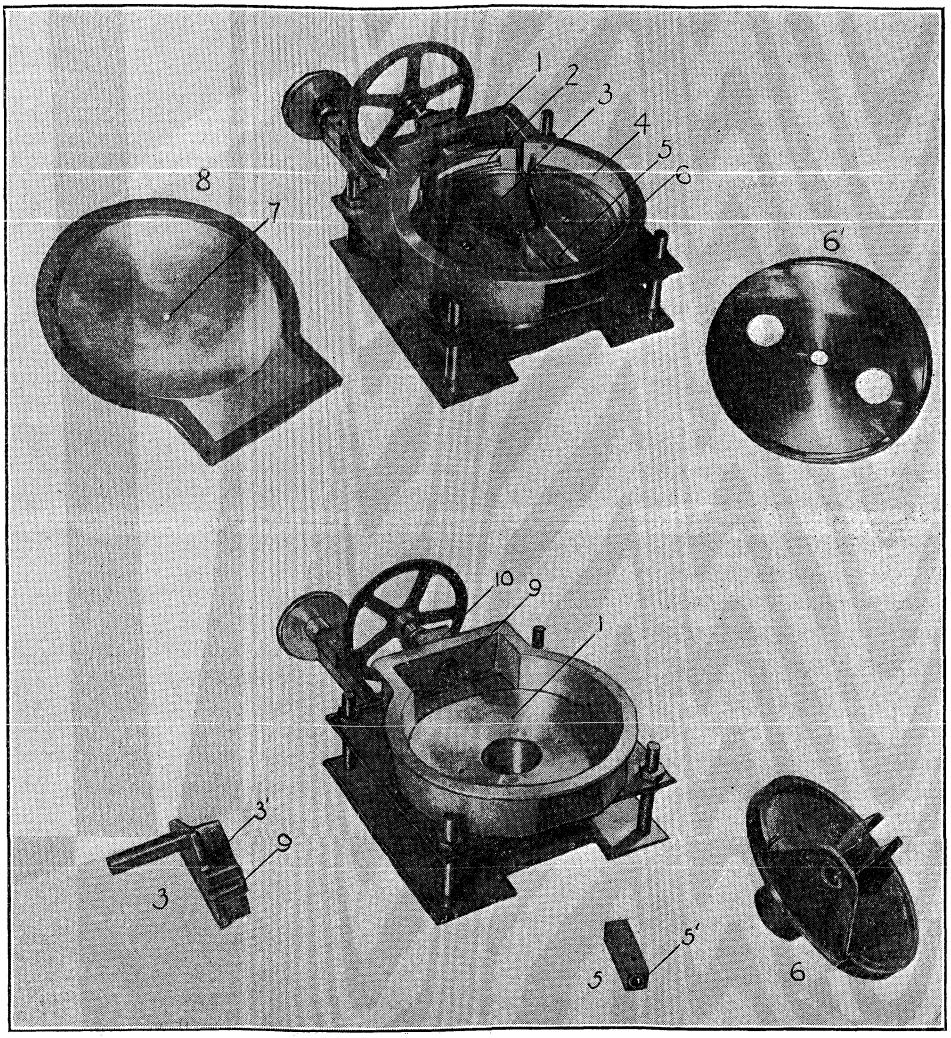

Fig. 3.

solutions with vigorous mechanical stirring. The ratio of sulfuric acid to barium nitrate was so chosen that only one-half of the initial barium ion was precipitated. The concentration of nitric acid in the sulfuric acid solution was adjusted to give the same concentration of nitrate ion as existed in the barium nitrate–nitric acid solution. This arrangement allowed the precipitates to form in the presence of a constant concentration of nitrate ion and a not too greatly varying concentration of barium ion. The precipitates were thoroughly washed by decantation with boiling water until the washings were neutral. They were then collected on a Büchner funnel and after air-drying preserved in glass-stoppered bottles.

Experience with a number of preliminary preparations led us to make the final precipitates in fairly large quantities; these are indicated in Table I. Five-liter flasks were used in the preparations, the sulfuric–nitric acid solutions being added from a separatory funnel drawn down to give a thirty-minute rate of addition. Digestion of the precipitates at the boiling point extended for thirty minutes, after which they were washed six times by decantation with boiling water and several times after transfer to the filter. The total volume of wash water was about four liters.

TABLE I

COMPOSITION OF PRECIPITATING SOLUTIONS

Ppt.	Solution A Concn., *M* Ba^{++}	NO_3^-	Solution B Concn., *M* NO_3^-	$SO_4^=$	Moles $BaSO_4$ precipitated
11	0.2	3.2	3.2	0.5	0.4
12	.2	1.6	1.6	.5	.4
13	.2	0.8	0.8	.5	.4
14	.2	.4	.4	.5	.4
15	.02	.32	.32	.05	.04
18	.02	.04	.04	.05	.04

Total volume A = 4 l. B = 0.8 l.

The precipitates prepared with nitric acid present in solution A were extraordinarily coarse and their crystalline character obvious. On the other hand, precipitates formed with only barium nitrate present in solution A (14 and 18) were much finer and about twice as bulky in the air-dried state as the others. As a matter of fact they took much longer to dry than any of the others, and for analytical purposes No. 14 had to be dried at 110° for a short time. Professor P. F. Kerr of the Department of Mineralogy, Columbia University, reports that microscopic examination shows No. 14 to consist of crystals which are smaller and not as well formed as No. 11, whose crystal grains are quite uniform and perfect. In neither case is there any evidence of the presence of more than one phase.

The standard barium sulfate No. 1, later referred to as "pure" barium sulfate, was prepared by the slow addition of barium chloride to an excess of boiling dilute sulfuric acid. The washed precipitate was treated with 18 *M* sulfuric acid, the excess being fumed off in a platinum crucible. The word "pure" is here used for convenience rather than as a claim.

Nitrate Analysis.—The complete analysis of the precipitates offers various difficulties, and the nitrate content alone is here reported. Even this determination is not simple, because of the lack of a completely satisfactory method for small quantities of nitrate, coupled with the insolubility of the substances in question. The method evolved after extensive trials of other schemes depends on the release of the nitrate from the precipitates by metathesis of the barium sulfate with concentrated sodium carbonate–sodium hydroxide solution, followed by determination of the nitrate in the alkaline solution by the Devarda method.[9]

That digestion with boiling sodium carbonate solution is effective in metathesizing barium sulfate to the carbonate has been shown previously.[10] It is evidenced further by the fact that the residue after digestion dissolves practically completely in dilute acid, a faint opalescence being the only sign of incomplete conversion. The solution of the residue also gives a negative ring test for nitrate with diphenylamine.

A sample of about 1 g. was digested in a 300-ml. Kjeldahl flask for one-half to one hour with 150 ml. of a boiling solution containing 12 g. of sodium hydroxide and 30 g. of sodium carbonate. When the contents of the flask were sufficiently cool, 3 g. of Devarda's alloy was introduced, and the mixture warmed gently until the reduction was complete. Distillation of the ammonia was then started and continued until 75–100 ml. of the solution had passed over into a cylindrical separatory funnel in which there was held 25.00 ml. of standard 0.1 *N* hydrochloric acid. At the conclusion of the distillation, the stopcock of the funnel was opened and the distillate run into a 500-ml. flask. The funnel was then washed down, and the contents of the flask titrated with standard 0.1 *N* sodium hydroxide solution. In these titrations brom cresol purple (2 drops of a 0.1% solution in 20% ethanol per 100 ml.) was used. It does not appear to be generally recognized that brom cresol purple is an excellent indicator for this titration; the color change, while fleeting, is so sharp as to be unmistakable.

All apparatus used in the analytical work was calibrated. The hydrochloric acid was standardized against a Bureau of Standards sample of potassium acid phthalate.

The nitrate determinations were made on the air-dried precipitates in all cases but No. 14, as indicated above. This sample, dried for one hour at 110° is numbered 14.2. The results of the determinations are expressed in weight per cent. of nitrate ion, Table II.

TABLE II

NITRATE CONTENT OF THE PRECIPITATES, WT. %

Ppt.	Determination 1	2	Mean, %
11	4.43	4.41	4.42
12	4.51	4.56	4.53
13	4.21	4.30	4.25
14.2	3.53	3.68	3.61
15	1.42	1.44	1.43
18	1.29	1.26	1.28

A very striking feature of these results, and one hardly to be anticipated, is that the nitrate content of the precipitates is practically independent of the nitrate content of the precipitating solutions. An eight-fold variation in the nitrate concentration of the solutions produces in precipitates 11 and 14 (Table I) a change only from 4.42 to 3.61% in nitrate content. Nos. 15 and 18 exhibit a similar phenomenon. To be noted however is the fact that the nitrate content of the precipitates varies with the barium ion concentration; in Nos. 11–14 the solutions were ten times as concentrated as in Nos. 15 and 18 (Table I).

Attempts to extend the range of concentrations for further study will lead in the more dilute region to the use of very large volumes or microanalytical methods; in the more concentrated range the precipitates settle as muds which are difficult to wash and filter, and which give poor x-ray photograms.

Lattice Constants.—The lattice constants of the contaminated barium sulfate precipitates have been measured using the precision focusing camera. All the x-ray photograms were taken with calcium K radiation. In most cases every measurable line was used in the computations, but the overlapping of two sets of doublets with varying composition caused these to be neglected in some of the films. At any rate, no fewer than fourteen pairs of lines have been used in any film, and as many as nineteen pairs have been utilized in the case of the pure barium sulfate preparation. A typical set of data is shown in Table III.

One of the authors has derived[7] a very general method for the calculation of lattice constants from x-ray powder photograms whereby account is taken of the inevitable presence of various systematic errors which have hitherto severely

$a_0 = 8.8625 \pm 0.0002$ Å.

$b_0 = 5.4412 \pm 0.0001$ Å.

$c_0 = 7.1401 \pm 0.0002$ Å.

[a] $\sin^2 \Theta \longrightarrow K\alpha_1 = (\lambda\, K\alpha_1/\lambda_i)^2 \sin^2 \Theta_i$.

limited the precision obtainable, particularly in non-cubic systems. The complete elimination of systematic errors by this method is very well shown by the random distribution of the difference of experimental and calculated $\sin^2 \Theta$ values given as Δ in Table III, 10 units in Δ representing approximately 0.1 mm. With the complete elimination of systematic error the data may be combined by the method of least squares, thus reducing to a minimum the effect on the lattice parameters of accidental errors of measurement. A very great advantage of this method is the fact that the probable errors as defined in the theory of least squares[11] may also be determined and thus a purely objective statement can be made of the precisions of the derived lattice parameters.

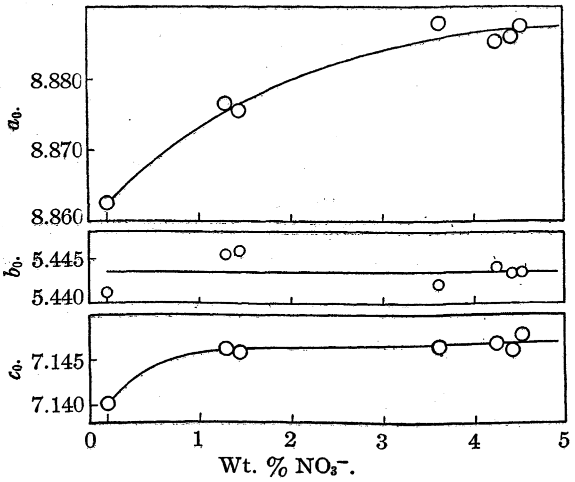

Fig. 4.

The approximate range of the probable errors on the various films is $a_0 = \pm 0.002$–0.01%, $b_0 = \pm 0.002$–0.004%, $c_0 = \pm 0.002$–0.004%. In practically every case values of the lattice parameters obtained from different films of the same precipitate check within the probable errors calculated from the individual films. The parameters reported here are values from the best photograms of the various preparations. However, because of differences in the temperature and perhaps other influencing factors under which the various exposures were made, comparison of the results is probably valid only within 0.01–0.02%.

In Fig. 4, which shows the relation between the lattice parameters and the nitrate content of the crystals, the radius of the circles is equivalent to 0.01%. Table IV gives the numerical values of the parameters.

TABLE IV

LATTICE PARAMETERS OF THE PRECIPITATES (Å.) (23–26°)

Ppt.	a_0	b_0	c_0
1	8.8625	5.4412	7.1401
18	8.8763	5.4455	7.1462
15	8.8753	5.4459	7.1458
14	8.8876	5.4422	7.1465
13	8.8849	5.4441	7.1469
11	8.8856	5.4434	7.1461
12	8.8871	5.4435	7.1478

Visual comparison of the x-ray photograms has been shown by the experience gained in this work to have semi-quantitative significance. In this way two interesting observations have been made. In the first place, drying the precipitates at 110° produces no visible change in the diffraction pattern. In the second place, when the nitrate content of the precipitates is eliminated by fuming with sulfuric acid, the residues show a pattern and relative spacing identical with that of pure barium sulfate.

Discussion

In the contaminated barium sulfate precipitates prepared as described in this work, there is no doubt but that the phenomenon of solid solution

---

(11) Wright and Hayford, "Adjustment of Observations," D. Van Nostrand Co., New York.

appears. The orderly variation of the lattice spacing with the nitrate content shown in Fig. 4, and the regular change in the volume of the unit cell shown in Fig. 5, are conclusive evidence for the expansion of the fundamental barium sulfate lattice. Such an expansion, it has been pointed out in the introduction, is due to the entrance of foreign ions into the lattice. It cannot conceivably be due to any adsorption or occlusion process known at present. That such mechanisms may account for part of the contamination is of course not ruled out by the present investigation, but even this may be questioned because of the remarkably homogeneous and strain-free character of the precipitates.

It is abundantly clear from the extensive literature of the subject that such essentially *ad hoc* theories as adsorption or occlusion have been of relatively slight value in the problem of precipitate contamination. That this failure is due to the absence of critical and positive experimental evidence for them has already been pointed out.

On the other hand, theories of a more or less *a priori* character, such as the Grimm rules for solid solution formation, have had a tendency to control the direction in which, it was thought, the existence of solid solution might profitably be investigated. As a result, its possible importance in precipitate contamination has been largely neglected. In the precipitates examined in this investigation the entrance of the contaminant as a solid solution emphasizes the fact that such considerations of isomorphism have little bearing for small ranges of solubility, and that therefore solid solution phenomena may play a very large part. The extent and importance of such a mechanism in other cases of precipitate contamination are impossible to predict. The function of the present research has been to show that this question may be decided in certain cases with a high degree of certainty, and by the use of a physical method whose evidence can scarcely be misinterpreted.

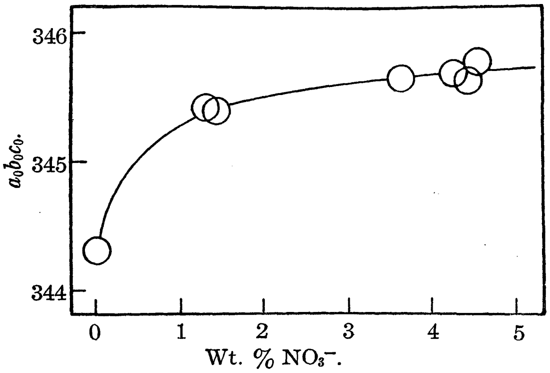

Fig. 5.

Summary

1. Apparatus is described which when used with a method of calculation previously developed makes it possible to determine the lattice parameters of powdered crystals with a precision of better than 0.01%. A feature of this apparatus is the use of a vacuum focusing camera in conjunction with long wave length x-rays from a calcium metal target.

2. A series of nitrate-contaminated barium sulfate precipitates has been prepared in the absence of all foreign cations except hydrogen ion, and in such a manner as to avoid large changes in the composition of the precipitating media.

3. The nitrate content of these precipitates has been determined by an adaptation of Devarda's method. Their compositions depend primarily on the barium ion concentration of the precipitating solutions, and only to a slight extent on the nitrate ion concentration.

4. The lattice parameters of the precipitates have been determined and correlated with their nitrate content.

5. The evidence indicates that the contaminant enters the barium sulfate lattice with the formation of a solid solution.

6. The role of such solid solution formation in the general problem of precipitate contamination has been discussed.

Kinetics of Ethylene Polymerization. II[1]

By H. H. Storch[2]

Effect of Oxygen

In a preliminary paper[3] the author showed that the rate of ethylene polymerization was increased markedly by minute amounts of oxygen. Subsequent experiments, which are described below, were designed to eliminate this impurity and to redetermine the rate, temperature coefficient, and character of primary products in oxygen-free ethylene.

Several procedures were tried in an effort to obtain oxygen-free ethylene, namely: (1) passage over a large surface of metallic sodium. This is the method used in preliminary experiments.[3] (2) Removal of oxygen from redistilled "anaesthesia" grade ethylene by slow passage over reduced metal oxide and thoria mixtures, such as Ni–ThO_2 (used at 25–150°) and Cu–ThO_2 (used at 300–350°). These mixtures contained about 5% ThO_2 and were prepared by precipitation with ammonia from a solution of the nitrates and subsequent heating of the washed hydrated oxides at 100 to 200° and finally at 500° before use.

(3) Preparation of ethylene by the reaction of ethylene bromide and zinc, both reactants being outgassed carefully by heating and evacuation before the reaction was started. The reaction rate was controlled by the rate of distillation of the ethylene bromide onto the zinc. It was found desirable to add about 0.1% of copper to the 40-mesh zinc by washing with a cupric chloride solution. The ethylene was fractionated by distillation before use.

(4) Preparation of ethylene by the dehydration of ethyl alcohol by passage over a thoria catalyst at 350°, the alcohol and catalyst being outgassed by heating and evacuation. The ethylene was fractionated by distillation before use.

All the experiments of Table I were made using the same apparatus[4] and procedure as described in the preliminary paper.[3] In the experiments with ethylene made by procedure 2 the Ni (or Cu) + ThO_2 tube was sealed directly onto an 8-liter storage vessel, so that the ethylene always was passed through the bed of reduced metal oxide plus thoria at a slow rate upon withdrawal from or admission to the reservoir.

Table I

Polymerization Rates of Ethylene Prepared by Different Methods

Temperature, 377° Pressure 142 cm.
Reaction volume 1700 cc.

C_2H_4 prepn. procedure no.	1	2 (Cu)	2 (Ni)	3	4
ΔP in 2 hours, mm.	15.0	10.1	10.8	15.7	2.0
Cc. of product (760 mm. and 27°)	16.4	11.0	11.1	17.3	1.8

Because the polymerization rate of ethylene prepared by procedure 4 was so much lower than that of ethylene obtained by any other method, a large number of experiments were made with this ethylene preparation. The rate increased slowly upon prolonged storage of the ethylene, and it was found that detectable amounts of hydrogen sulfide were present in the gas. This compound was probably formed by the reduction of traces of sulfur compounds present in the thoria catalyst. Upon introducing a tube containing sodium hydroxide sticks in the apparatus for procedure 4 to remove hydrogen sulfide from the gas as it left the catalyst tube, the resulting sulfur-free ethylene yielded a polymerization rate about equal to that prepared by procedure 3. It was therefore suspected that hydrogen sulfide was acting as an antioxidant and destroying the accelerating influence of the minute amounts of oxygen present. The origin of this oxygen is somewhat uncertain, especially in procedures such as nos. 3 and 4 (plus sodium hydroxide sticks) of Table I. The preparation and storage apparatus was tested repeatedly after prolonged evacuation, and it was found to be as vacuum-tight as one can reasonably expect without baking at a red heat which is necessary to secure and retain very high vacua. It is probable that very small amounts of oxygen were being desorbed continuously from the glass walls. It is also conceivable that the many necessary operations of the mercury valves "dragged" thin films of gas into the system. Tank nitrogen containing 0.5% oxygen was used to raise the mercury.

(4) Except that all stopcocks were replaced by mercury valves.

After considerable experimentation it was apparent that even if oxygen-free ethylene could be prepared it could not be kept free of contamination by traces of oxygen in the apparatus used. Hence it was decided to add small amounts of ethyl mercaptan to the ethylene used in each experiment and to assume that the reaction kinetics of this mixture is quantitatively identical with that of oxygen-free ethylene.

The plausibility of this assumption was indicated by the following experiments.

Tank ethylene of anaesthesia grade was passed through alkaline pyrogallol, 60% aqueous sulfuric acid solution, and solid potash fragments, and then condensed at liquid nitrogen temperatures. The ethylene was subsequently distilled at about 2 cm. pressure, the first and last thirds of the distillate being discarded. Experiments at 142 cm. C_2H_4 plus 1.4 mm. C_2H_5SH pressure and 393° were made which yielded rate data reproducible to within about 5% of the mean value. The same batch of ethylene was used in all such experiments, the portion used to fill the reaction vessel (about 75% of the total ethylene in the reservoir) being recovered by fractional distillation which separated the ethylene from the polymerization products and from the ethyl mercaptan. After about fifteen experiments with the same batch of ethylene another rate determination was made omitting the mercaptan. The polymerization rate obtained in this experiment was practically identical with that of the last experiment using 1.4 mm. of mercaptan.

It was also found that additions of more than about 0.1 per cent. of mercaptan to the ethylene did not decrease the rate of polymerization any further, hence this concentration of mercaptan was used in all subsequent experiments.

Induction Period

The apparent autocatalytic nature of ethylene polymerization has been indicated elsewhere.[3] Similar results were obtained with ethylene to which 0.1% of ethyl mercaptan had been added. This is shown in Table II. The yields were measured as described in the first paper.[3] The data given for item (a) are the average results of eight experiments for the one- and two-hour intervals and of six experiments for the three-hour periods. The average and maximum deviations from the mean are 6 and 10%, respectively, for both the one-hour and two-hour intervals and 3 and 8%, respectively, for the three-hour intervals. The data for the other items in Table II represent single experiments.

The pressure decreases for the second hour are, with the exception of item (c), identical for the various gas mixtures used. This indicates that the same steady state has, in cases (a), (b), (d) and (e), been reached before the end of the first hour.

TABLE II

DATA ON AUTOCATALYSIS IN ETHYLENE POLYMERIZATION

Temperature, 393°. Initial pressure, 142 cm. Volume of reaction bulb, 4400 cm.

Time intervals	a C_2H_4 + 0.1% C_2H_5SH	b a + 1.3 mm. C_3H_6	c a + 1.7 mm. C_3H_6	d a + 1.4 mm. C_4H_8[a]	e a + 4.5 mm. C_4H_8[a]
	Pressure drop in mm.

Third hour	3.8	...	...	...	...
	Volume of product, cc. at 760 mm. and 27°				
Two hours	12.1	7.5[b]	11.3[b]	9.8[b]	18.8[b]
Three hours	21.7	...	...	...	...
Time interval ratios	Ratios of pressure drop for different time intervals				
Second/First (hour)	2.8	3.7	1.5	1.8	1.7
Third/Second (hour)	0.87	...	...	...	...

[a] 1-Butene was used in these tests. Similar tests with the low-boiling isomer of 2-butene gave identical results.

[b] Includes any unreacted propylene or butylene. Correction for C_2H_5SH is made in all cases (a) to (e).

The introduction of small amounts of propylene or butylene does not eliminate the increased pressure drop in the second hour compared with that of the first hour. The apparent reduction in the ratio of pressure drop for the second to the first hour in (c), (d), and (e) probably is due to a somewhat more rapid rate of reaction of propylene and butylene with ethylene. In fact, this must be true, for otherwise it would not be possible to explain the smaller volume of the products in items (b), (c), and (d). Item (e) apparently has a larger volume of products than item (a), but unquestionably this is due to the fact that the butylene added initially was almost equal to the amount of polymer obtained in item (a).

The data for the second and third hours of item (a) in Table II, when compared with the similar data in Table I of the preliminary paper,[3] show that the addition of mercaptan apparently has eliminated the autocatalysis after the first hour. The results with varying amounts of mercaptan from 0.05 to 0.15% show that after 0.1% has been added, further additions do not change the pressure decreases in any of the time intervals. Hence it seems that the polymerization reaction may have an induction period of its own, independent of any of the catalytic effects of small amounts of oxygen. The intermediary compounds whose rates of formation result in the induction period are stable enough to survive the condensation of the reaction mixture[5] after about ninety minutes reaction time and subsequent revaporization into the reaction chamber. In such an experiment, using C_2H_4 + 0.1% C_2H_5SH, the reaction rate a few minutes after revaporization was identical with that during the sixty- to ninety-minute interval. This evidence shows that the building up of any chain involving only free radicals or only energy-rich molecules as chain carriers is not responsible for the induction period. It is therefore certain that the rate of formation of a moderately stable intermediate compound must be the source of the induction period. Energy chains or free radical chains may of course be involved also in the reaction mechanism, but they cannot be of any importance in explaining the origin of the induction period.

Temperature Coefficient

The time necessary to obtain the same volume of reaction product at 377° as is obtained in 2 hours at 393° was found to be 4.5 hours. The pressure was the same (142 cm.) in both cases. The activation energy calculated in the usual way from these two data is 43,500 cal. The value previously reported by the author[3] for ethylene prepared by procedure 1 was 42,000 cal., and that reported by Pease[6] for tank ethylene of "anaesthesia" grade was 35,000 cal. It seems reasonable to conclude that the presence of oxygen lowers the apparent heat of activation and that 43,500 cal. is closer to the true value than any of the other values.

A calculation, using 43,500 + $RT/2$ as the activation energy (rate in pressure units = Const. $T^{-1/2}e^{-E/RT}$) and the average pressure drop 6.0 mm. of Table II for the two-hour experiments at 393° and 142 cm. initial pressure, shows that about 4.0% of all collisions with the requisite energy are efficient in polymerization. A similar calculation made for the data presented by Pease[7] on the hydrogen-ethylene reaction shows that about 14% of all collisions are efficient.[8] The calculations for ethylene polymerization are, however, of doubtful significance in view of the fact that the reaction is not a simple bimolecular process.

Order of the Reaction

Pease[5] showed that for tank ethylene of "anaesthesia" grade the reaction is second order in the range from 2.5 to 10 atmospheres. He also makes the statement that "at one atmosphere there is some evidence of a fall in rate more rapid than would be expected of a second-order reaction."

Two experiments were made; one at 71 cm. C_2H_4 pressure plus 0.1% C_2H_5SH, and the other with 71 cm. C_2H_4 + 71 cm. CH_4 + 0.1% C_2H_5SH. The temperature was 393°, and the time necessary to obtain the same pressure drop as is obtained at this temperature in two hours at 142 cm. C_2H_4 pressure was found to be exactly eight hours; this would indicate precisely a second-order reaction. However, the yields obtained in these two experiments were 6.5 cc. and 7.5 cc. for the 71-cm. C_2H_4 and the 71-cm. C_2H_4 + 71-cm. CH_4 experiments, respectively. These yields are considerably smaller than the 12.1 cc. obtained in two hours at 142 cm. C_2H_4 pressure. Since the pressure drops were identical, these lower yields indicate that the molecular weight of the products of the 71-cm. C_2H_4 pressure experiments was much higher than for the 142-cm. rate measurement; hence, the percentage of ethylene polymerized must have been much greater in the latter experiments. This conclusion supports Pease's statement that the order at about atmospheric pressure drops faster than would be predicted for a second-order reaction. The somewhat higher yield obtained with 71 cm. C_2H_4 + 71 cm. CH_4 would seem to indicate that although methane helps a little in keeping the rate up it is not very efficient in stabilizing the "hot" molecules of butylene. This fact also shows that if energy chains are present CH_4 is not very efficient in stopping them, for the yield when CH_4 is present is somewhat larger than when CH_4 is absent, whereas one would expect the reverse, namely, a considerably lower yield in the presence of this diluent if gas-phase breaking of energy chains occurred.

Analysis

Reaction Products.—Owing to the relatively small amounts (100 to 150 cc. of gas at normal temperature and pressure) of product available for analysis, no attempt at fractional distillation with controlled reflux was made. Four separations of the Shepherd–Porter type by fractional distillation without reflux were made for each

---

(5) A small bulb attached to the mercury valve which closed off the reaction vessel from the rest of the system served as a receiver for the liquefied gases. The mercury valve was lowered until the connection to this bulb was open, and the bulb immersed in a bath of liquid nitrogen.

(7) Pease, *ibid.*, **54**, 1876 (1932).

(8) A calculation made by Vaughan, *ibid.*, **55**, 4115 (1933), is erroneous due to the use of 40,300 cal. as the activation energy instead of 44,000 cal.

olefin. Measurements of gas density made by a magnetic gas-density balance showed that three separations were not sufficient, as 1 to 5% of the olefin one carbon atom lower in the series was present.

Owing to the presence of relatively large amounts of ethyl mercaptan in the C_6 fraction, it was necessary to find a satisfactory method for separating C_2H_5SH and C_6H_{12}. Condensation on a bright surface of metallic sodium was found fairly satisfactory. Experiments made with pure C_2H_5SH showed that at temperatures between 0° and −10° hydrogen and sodium mercaptate were the main products, only a few per cent. of diethyl sulfide being obtained. The analytical data are given in Table III.

TABLE III

ANALYSIS OF REACTION PRODUCTS, PER CENT.

Compound	2-hour experiments	3-hour experiments
Propylene	34.4	39.2
Butylenes	31.4	29.1
Pentenes	29.0	14.4
Hexenes	2.8	14.4
Higher olefins	2.4	2.9
Ratio of propylene to butylene	1.1	1.35

The increase in the C_3H_6/C_4H_8 ratio in the third hour seem to confirm the evidence presented in the first paper[3] concerning the primary product of the reaction. The question is, however, not answered, for even in the two-hour sample corresponding to polymerization of only about 1% of the total ethylene present the fractions of C_3H_6 and C_5H_{10} are of the same order as that of C_4H_8.

Summary

Several methods of preparation of "pure" ethylene were tried in an unsuccessful effort to obtain reproducible rates of polymerization. It was found that the addition of small amounts (about 0.1 per cent.) of ethyl mercaptan to ethylene prepared by fractionation of "anaesthesia grade" tank ethylene, decreased the rate of polymerization about tenfold; and the C_2H_4 + C_2H_5SH mixture polymerized at rates which were reproducible to within about 5%. These rates were in good agreement with the lowest rates obtained in the absence of the mercaptan. The addition of mercaptan did not eliminate the induction period observed in ethylene to which no mercaptan had been added; but did cut down markedly the duration of this induction period. The latter appears to be due to the rate of formation of some intermediate compound which survives freezing to −180° and subsequent revaporization into the reaction chamber at 393°. The polymerization of ethylene is probably not a simple bimolecular reaction. The evidence as to the nature of the primary product is not conclusive but indicates that butylene precedes propylene. The activation energy is 43,500 cal.

The Partial Molal Volumes of Ammonia and Hydrogen in Liquid Ammonia–Hydrogen Mixtures under Pressure at 100°

BY R. WIEBE AND T. H. TREMEARNE

Ångström[1] measured the change of volume of water and various other organic liquids when hydrogen and other gases were dissolved in them. From his measurements he calculated

$$\Delta V/\Delta V_g = \delta \qquad (1)$$

wherein ΔV_g denotes the volume of gas at standard temperature and pressure dissolved, and ΔV the attending increase in the volume of solvent at constant temperature and pressure. He found that under atmospheric pressure, δ remained constant with varying V_g, Horiuti[2] extended the work of Ångström and confirmed the constancy of δ with concentration in the low pressure region, with sulfur dioxide in various organic liquids an exception.

Upon multiplying both sides of Eq. (1) by V_0, the volume of a mole of the dissolved gas at standard temperature and pressure we obtain $\Delta V/(\Delta V_g/V_0) = \Delta V/\Delta n_2 = V_0\delta$, which leads at once to the relation

$$(\mathrm{d}V/\mathrm{d}n_2)_{P,T} \equiv \bar{v}_2 = V_0 \qquad (2)$$

first stated explicitly by Horiuti[2] (p. 136).

Ångström and Horiuti both worked at low concentrations. At the relatively high concentra-

tions used in the present work it is found that for hydrogen in liquid ammonia, $\bar{v}_2$, and hence δ also, is positive and increases with the concentration of hydrogen except at the lowest pressure. Then because[3] $N_1(\mathrm{d}\bar{v}_1/\mathrm{d}N_1)_{P,T} = -N_2(\mathrm{d}\bar{v}_2/\mathrm{d}N_2)_{P,T}$, it follows that the partial molal volume $\bar{v}_1$ of ammonia decreases as the concentration of hydrogen increases.

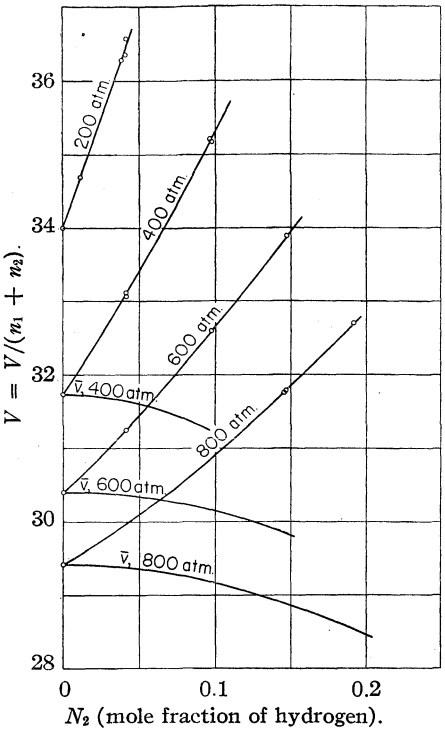

Fig. 1.—Molal volume of liquid ammonia hydrogen mixtures and partial molal volumes of liquid ammonia.

Apparatus and Procedure

The apparatus was identical with one used previously[4] except for a section of tubing fitted with a valve at each end and connected with the lower part of the high pressure bomb. At frequent intervals the volume of this section of tubing was measured by filling it with hydrogen at 100 and 200 atmospheres. In each experiment a sample of the equilibrium mixture from the bomb was turned into this calibrated section, and cut off. The amount of each constituent contained therein could then be determined, following methods previously outlined.

This device permits samples to be made up at concentrations intermediate between pure solvent (liquid ammonia) and saturation. The mixture in the calibrated tube—taken, for example, from a 400 atmosphere equilibrium mixture—can be raised quickly to a higher pressure, say 600 atmospheres, by increasing the pressure of the gas above the solution in the bomb to this figure. This new pressure is transmitted instantly to the contents of the tube, which then unsaturated can be cut off and analyzed as before.

The mixture in the bomb is itself unsaturated when it is suddenly subjected to a new pressure, whereupon diffusion begins at once, attended by a downward creep in pressure. The pressure reading is taken at the moment of cut-off. Diffusion to the bottom of the bomb is slow and there is sufficient opportunity to make one or two analyses before the composition of the samples is affected.

Results

The data are given in Table I and the figure. The molal volumes for pure liquid ammonia were calculated from the results of Keyes.[5] The first

column of Table I gives the number of individual runs from which the data were computed. The partial molal volumes were calculated from the relations[3] (p. 38)

$$\bar{v}_1 = v - N_2\,(\mathrm{d}v/\mathrm{d}N_2)$$
$$\bar{v}_2 = v + N_1\,(\mathrm{d}v/\mathrm{d}N_2)$$

$v = V/(n_1 + n_2)$ being the molal volume of the mixture and N_1 the mole fraction of ammonia, both of which are given in Table I. The derivative $\mathrm{d}v/\mathrm{d}N_2$ was obtained from suitable equations representing the molal volume *vs.* N_2 curves in the figure. Table II and the figure show the partial molal volumes.

We wish to point out briefly the thermodynamic significance of the work. At equilibrium where

$$\mathrm{d}\bar{F}_1 = \mathrm{d}\bar{F}_1' \qquad (3)$$

$\bar{F}_1$ and $\bar{F}_1'$ being the partial molal free energies of constituent 1 in the liquid and gas phases respectively, we have at constant temperature[3] (p. 216)

$$(\mathrm{d}\bar{F}/\mathrm{d}P)_{N_1}\,\mathrm{d}P + (\mathrm{d}\bar{F}_1/\mathrm{d}N_1)_P\,\mathrm{d}N_1 = (\mathrm{d}\bar{F}_1'/\mathrm{d}P)_{N_1'}\,\mathrm{d}P + (\mathrm{d}\bar{F}_1'/\mathrm{d}N_1')_P\,\mathrm{d}N_1'$$

Transposing and noting that

$$(\mathrm{d}\bar{F}_1/\mathrm{d}P)_{N_1} = \bar{v} \text{ and } (\mathrm{d}\bar{F}_1'/\mathrm{d}P)_{N_1'} = \bar{v}_1'$$

we obtain at constant temperature

$$(\mathrm{d}N_1/\mathrm{d}P)_{\mathrm{sat.}} = (\bar{v}' - \bar{v}_1 + (\mathrm{d}\bar{F}'/\mathrm{d}N')_P\,(\mathrm{d}N'/\mathrm{d}P)_{\mathrm{sat.}})/(\mathrm{d}\bar{F}_1/\mathrm{d}N_1)_P$$

The values of $(\mathrm{d}N_1/\mathrm{d}P)_{\mathrm{sat.}}$ are readily calculated from previous work[6] and are given in Table III. The value of $\bar{v}_1$ is known from the present work. Further work on the gas phase at this Laboratory will supply directly $\bar{v}_1'(\mathrm{d}\bar{F}_1'/\mathrm{d}N_1')_P$ and $(\mathrm{d}N_1'/\mathrm{d}P)_{\mathrm{sat.}}$. The solubility $(\mathrm{d}N_1/\mathrm{d}P)_{\mathrm{sat.}}$ could be calculated indirectly provided we knew the value of $(\mathrm{d}\bar{F}_1/\mathrm{d}N_1)_P$ at one isobar.

TABLE III

Total pressure, in atm.	Mole fraction of ammonia N_1	$\mathrm{d}N_1/\mathrm{d}P$
75	0.9956	0.00031
100	.9882	30

900	.7917	20
1000	.7723	19

This scheme has already been used for liquid–solid system under pressure by Adams and Gibson.[7]

Summary

The volumes of ammonia–hydrogen mixtures in the liquid phase have been measured.

The partial molal volumes of both constituents were calculated.

The thermodynamic significance of the data has been discussed and the desirability of further measurements pointed out.

Transition Cases in the Distribution of Ions

BY RAYMOND M. FUOSS

Introduction

In a recent paper,[1] it was stated that "the conductance of incompletely dissociated binary electrolytes as a function of concentration obeys the equation

$$\Lambda = \gamma(\Lambda_0 - \alpha\sqrt{c\gamma}) \qquad (1)$$

exactly up to concentrations at which specific ionic interactions of higher order than pairwise become appreciable." Equation (1) is derived on the assumption that free ions and ion pairs are the only molecular species present. Using a distribution function for ion pairs, derived by the author,[2] it is possible to show that a critical concentration

$$c_0 = \frac{1000}{4\pi N}\left(\frac{DkT}{\epsilon^2}\right)^3 e^{-x}\, x^3(2 - x) \qquad (2)$$

where

$$x = 3 - \sqrt{3} \qquad (3)$$

exists, above which interactions of higher order than pairwise become significant. This concentration agrees with the concentration found experimentally above which deviations between observed conductances and values calculated from (1) exceed the experimental error.

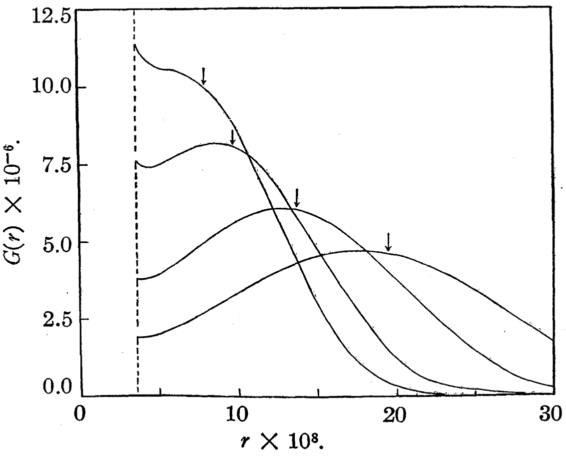

Fig. 1.—Distribution curve for $D = 78.6$; $a = 3.67 \times 10^{-8}$; $c = 0.025, 0.05, 0.10, 0.15$; arrow marks $1/\kappa$.

Derivation and Discussion

The distribution function mentioned above gives the probability that a given positive ion will have a negative ion in dr at r such that the negative ion is the nearest otherwise unpaired ion to the central positive ion. The mathematical form of the function is

$$G(r) = \frac{4\pi N}{V} r^2 \exp.\left(\frac{\beta}{r} - \frac{4\pi N}{V}\int_a^r e^{\beta/x}\, x^2\, \mathrm{d}x\right) \qquad (4)$$

where N = total number of positive ions of charge ϵ in a total volume V, r = center to center distance between ions, $\beta = \epsilon^2/DkT$, D = dielectric constant, k = Boltzmann constant, T = absolute temperature and a = ion size.

Examples of the distribution function are given in Figs. 1 and 2. For Fig. 1, $D = 78.57$, $t = 25°$ and $a = 3.67 \times 10^{-8}$ cm.; the example thus refers to aqueous solutions. The lowest curve corresponds to $c = 0.025$. Here $G(r)$ has a maximum at 18×10^{-8} cm. and the distribution to both sides of the maximum is fairly symmetrical. Pairs for which $r = 18 \times 10^{-8}$ are better than twice as probable as pairs in contact, so that association is negligible. The next two higher curves correspond to $c = 0.05$ and $c = 0.10$, respectively; with increasing concentration the maximum moves to smaller pairwise distances and at $c = 0.15$ the maximum has practically vanished. At higher concentrations, the shorter the pairwise distances, the greater the probability for the configuration. This effect is not to be con-

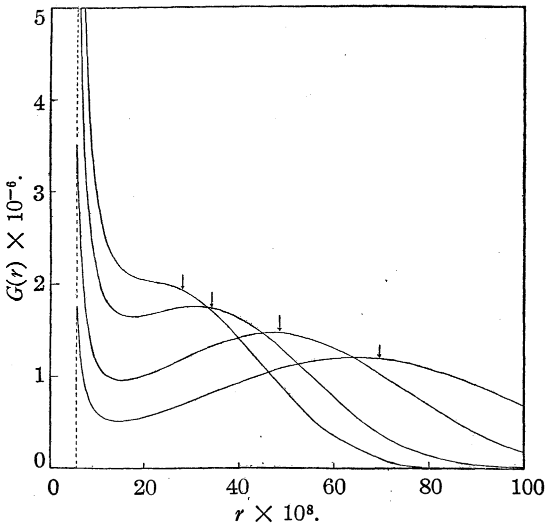

Fig. 2.—Distribution curve for $D = 20$; $a = 5.57 \times 10^{-8}$; $c = 0.5, 1, 2, 3 \times 10^{-3}$.

---

sidered an association due to Coulomb forces; it is simply a space crowding. In Fig. 2, we have an example of true association. Here $D = 20$, $t = 25°$, $\beta = 27.8 \times 10^{-8}$, $a = 5.57 \times 10^{-8}$ cm. The lowest curve is for $c = 5 \times 10^{-4}$; it has a long range maximum corresponding to high probability for free ions and also an exponential peak at $r = a$ corresponding to a high probability for associated short range pairs. As concentration is increased, the long range maximum moves to shorter distances, and the peak at $r = a$ climbs rapidly, so that the long range maximum eventually vanishes. Above $c = 3 \times 10^{-3}$, the pair probability is greater, the shorter the distance. Here we have both Coulomb attraction and space crowding responsible for the disappearance of the free ion maximum.

The general behavior of these curves reminds one somewhat of the isotherms for a van der Waals gas near the critical point. At low concentrations there are, in general, two well-defined peaks, one corresponding to free ions and one to associated. As concentration is increased, a concentration is finally reached at which the maximum, the minimum and the included inflection point coincide. Above this concentration, free and associated ions, as defined on the basis of $G(r)$, become indistinguishable, and we should expect that equations based on the classification of ions by means of $G(r)$ relating properties and concentration would fail at concentrations of this critical order of magnitude, no matter how closely they reproduced experimental data at lower concentrations.

The critical concentration can be found very easily. We have, on differentiating (4)

$$\frac{\mathrm{d}G}{\mathrm{d}r} = G(r)\left(\frac{2}{r} - \frac{\beta}{r^2} - \alpha r^2 e^{\beta/r}\right) \tag{5}$$

$$\frac{\mathrm{d}^2G}{\mathrm{d}r^2} = G(r)\left(\frac{2}{r^2} - \frac{2\beta}{r^3} + \frac{\beta^2}{r^4} - 6\alpha r e^{\beta/r} + 3\alpha\beta e^{\beta/r} + \alpha^2 r^4 e^{2\beta/r}\right) \tag{6}$$

where

$$\alpha = 4\pi N/V \tag{7}$$

Setting $\mathrm{d}G/\mathrm{d}r = 0$, we obtain

$$\alpha e^{\beta/r} = 2/r^3 - \beta/r^4 \tag{8}$$

and setting $\mathrm{d}^2G/\mathrm{d}r^2 = 0$ and substituting (8) to eliminate the transcendental, we obtain the equation

$$x^2 - 6x + 6 = 0 \tag{9}$$

where

$$x = \beta/r \tag{10}$$

as the condition which must be fulfilled at the critical point. The root of (9) which has physical meaning is

$$x = 3 - \sqrt{3} \tag{11}$$

Substituting in (8) we finally obtain, after rearrangement

$$c_0 = \frac{1000}{4\pi N}\left(\frac{DkT}{\epsilon^2}\right)^3 e^{-x}\, x^3(2 - x) \tag{2}$$

which is the result announced in the introduction. At 25°

$$c_0 = 3.2 \times 10^{-7}\, D^3 \tag{12}$$

for 1-1 electrolytes.

Another derivation of (2) can be obtained by requiring that the two roots of (5) coincide; by writing (5) in the form

$$r = \beta/2 + \alpha r^4 e^{\beta/r}/2 = f(r) \tag{13}$$

it is obvious that this condition will be fulfilled when $\mathrm{d}f/\mathrm{d}r = 1$. Combining this requirement with the vanishing of (6), a fourth degree equation is obtained, which, of course, has $(3 - \sqrt{3})$ as one of its roots.

The value, r_0, of r at $c = c_0$ is given by

$$r_0 = 0.789\beta = (440/D) \times 10^{-8}\ \text{cm. at } 25°$$

In water, this corresponds to 5.6×10^{-8} cm. and the critical concentration is 0.155 N, with $1/\kappa = 7.7 \times 10^{-8}$ cm. Here $1/\kappa$ is the characteristic distance of the Debye–Hückel theory

$$\kappa^2 = 8\pi N\epsilon^2/VDkT$$

If we assume that ordinary ions have diameters about equal to 3×10^{-8} cm. in water, then at 0.155 N, the maximum charge in the ionic atmosphere would be roughly two diameters away from a given ion. It seems dangerous, therefore, to extrapolate the concept of ionic atmosphere or equations based on it into concentrations greater than the critical; the ions are too close together to permit a time average treatment of their interaction.

Incidentally, $1/\kappa$ agrees in order of magnitude with ρ, the distance at which $G(r)$ has its long range maximum. At $r = r_0$

$$\kappa r_0 = 2/\sqrt{e^x(4/x - 1)} = 0.7228$$

which, as a numerical constant, is the same for all 1-1 electrolytes in all solvents. With decreasing concentration, both $1/\kappa$ and ρ increase; the ratio of these distances, $\kappa\rho$, is approximately 18.7 $c^{1/6}D^{-1/2}$ for $\rho > 2\, r_0$. Since $c^{1/6}$ changes only very slowly with concentration, we see that over quite a wide range of concentration, $\kappa\rho$ remains in order of magnitude unity. At very low concentrations, $1/\kappa >> \rho$, but when such concentrations are reached, the interionic effects become negligible practically in that they become unobservable experimentally. The ionic atmosphere thus appears as an approximation device for the average effects of free ions on free ions, where the average distances are of the order of $(V/2\pi N)^{1/3}$.

Let us now consider a typical example of the application of our result. The conductance of potassium chloride in liquid ammonia ($D = 22.38$ at $-33.35°$)[3] obeys equation (1) at low concentrations[4] but deviations larger than experimental error begin to appear at several thousandths normal. For liquid ammonia at $-34°$

$$c_0 = 1.8 \times 10^{-3} \qquad (14)$$

In Table I are given the conductance data, together with the deviation between Λ observed and Λ calculated from (1) using $\Lambda_0 = 347.85$ and $K = 8.73 \times 10^{-4}$. At 1.8×10^{-3} N, the deviation is well beyond the experimental error, but as concentration decreases, exact agreement is found.

TABLE I

$c \times 10^5$	Λ (obsd.)	% deviation
2.471	334.27	−0.12
3.957	328.27	− .04
5.766	322.00	+ .02
9.320	311.77	+ .02
12.030	305.08	+ .03
15.619	297.48	− .04
24.021	282.42	+ .01
33.413	268.63	+ .03
50.79	250.93	+ .02
80.52	229.28	− .03
104.20	216.62	+ .05
137.60	202.81	+ .30
209.91	182.23	+ .69
313.94	163.74	+1.16
453.25	147.42	+1.99
702.29	130.21	+2.86
973.98	118.45	+4.14

In ethylene chloride ($D = 10.2$), the deviations between calculated and observed values become significant at several ten thousandths normal;[5,6] in anisole ($D = 4.29$) at several hundred thousandths;[5,7] and in benzene ($D = 2.27$), divergence from simple binary properties appears at several millionths normal.[8] In every case, equation (2) predicts the concentration above which conductance data cannot be computed by means of (1).

It is of interest to consider the physical interpretation of the result. Using the distribution function $G(r)$, we have divided the ions into several groups: free ions, which have no unpaired ion in the immediate neighborhood, associated ions, which have a single partner of opposite charge at a distance of molecular dimensions, and transition ions, which are those for which the pair distance is of the order of that corresponding to the probability barrier at $r = \beta/2$, the Bjerrum radius. Assuming that the equilibrium betweeen free and associated ions may be treated by the law of mass action, if allowance is made for the long range interaction of free ions on free ions, a conductance equation (1) is derived which is in exact agreement with data at low concentrations. In other words, as long as free ions have a relative maximum probability in terms of $G(r)$, we find properties which can be ascribed to an association equilibrium of the following type

$$A^+ + B' \rightleftharpoons AB$$

When, according to (3), free ions are no longer definable, a new set of properties appears; in the conductance curves, for example, Λ becomes larger with increasing concentration than (1) allows, and eventually a minimum in the Λ–c curve appears, after which conductance *increases* with increasing concentration. This effect has been explained in terms of higher association to triple ions;[9] the same hypothesis can be arrived at if we consider the approximations made in the derivation of $G(r)$. Long range interaction of short range pairs with free ions was neglected as a $1/r^2$ energy, compared to the $1/r$ energy of free ion-free ion interaction, but when a large fraction of the solute is present as short range pairs, it is clear that this interaction must be taken into account. If we redefine free ions to be those which are relatively far from either another free ion or from an ion pair, then we can again predict properties, but now five (+, −, + −, + − +, − + −) rather than only three molecular species are assumed to be present. Counting part of the solute present as triple ions is in effect removing some area (ions) from the $G(r)$ curve near $r = \beta/2$, and the maximum is thus restored.

Summary

Using the ion pair distribution function previously derived by the author, a critical concentration is shown to exist, above which free and pairwise associated ions become indistinguishable. This concentration, $3.2 \times 10^{-7} D^3$ at 25° for 1-1

electrolytes, is experimentally the concentration above which the simple laws of dilute solutions of electrolytes are no longer obeyed, so that a numerical significance is attached to the phrase "at low concentrations." At higher concentrations, higher types of association must be considered for the case of non-aqueous solutions.

The Potentiometric Determination of Quadrivalent Osmium with Chromous Sulfate

BY WILLIAM R. CROWELL AND HARLAN L. BAUMBACH

In previous papers we have presented a direct[1] and an indirect[2] method of determining quadrivalent osmium. The former method is highly inaccurate, and the latter has the disadvantages of having two volatile constituents involved and of being applicable only to dilute acid solutions. The work of Thornton and Sadusk[3] suggested to us the possibility of using chromous sulfate as the reducing agent and the present work deals with the use of solutions of this salt. As in the case of titration with titanous salts the osmium is reduced from the quadrivalent to the trivalent state.

Because of the rapid reaction between chromous sulfate and oxygen we found it most satisfactory to have the apparatus all of glass as far as possible, to have all rubber connections of best quality heavy rubber, and all joints sealed with a suitable material such as lacquer cement. Of lesser importance is the tendency for chromous sulfate to react with hydrogen ion. Asmanoff[4] states that solutions may be as high as 10 N in sulfuric acid or 3 N in hydrochloric acid before any appreciable evolution of hydrogen takes place. Thornton and Sadusk state that they prepared 0.07 N solutions 0.18 N in sulfuric acid which remained unchanged in titer for two months. The solutions used by us were not greater than 0.03 N in sulfuric acid.

Reagents

The chromous sulfate solution was prepared by a method developed by Messrs. Stone and Beeson of the Chemistry Department at the University of California at Los Angeles. A solution of 0.01 M chrome alum 0.01 N in sulfuric acid was reduced by passage over amalgamated zinc. The yield of chromous ion was nearly 100% and the acid concentration was practically unchanged by the process.

The potassium bromoosmate and the potassium chloroosmate were prepared from osmium tetroxide in much the same manner that Gilchrist[5] prepared the ammonium bromo and chloro compounds in his determination of the atomic weight of osmium. A potassium hydroxide solution of osmium tetroxide was prepared as previously described.[6] The solution was acidified with sulfuric acid, the osmium tetroxide distilled into hydrobromic or hydrochloric acid, and the procedure carried out according to the method of Gilchrist except that potassium instead of ammonium salts were used.

The hydrobromic acid was prepared from red phosphorus and bromine. The middle fraction of the distillation of the products of the reaction was redistilled several times until a water-white liquid was obtained.

The constant boiling hydrochloric acid was obtained by twice distilling a mixture of equal volumes of concentrated hydrochloric acid and distilled water and retaining the middle fraction of the second distillation.

The potassium ferricyanide and potassium iodate used in standardizing the chromous sulfate and the sodium thiosulfate were recrystallized from the chemically pure salts.

Apparatus, Experimental Procedure and Results

The titration beaker consisted of a heavy-walled Pyrex beaker of about 125-cc. capacity. The cover consisted of a large rubber stopper which was cemented in place. In this stopper were openings for a mercury-sealed stirrer calomel and platinum electrodes, carbon dioxide inlet and outlet, burets, apparatus for introducing solids, and apparatus for treating and transferring solutions. In the bottom of the beaker was sealed a heavy stopcock to allow solutions to be withdrawn and the beaker to be rinsed without admitting air.

Figure 1 shows a diagram of the apparatus used for storing and handling the chromous sulfate solution. The system was flushed with nitrogen and the standard solution forced into the 5-liter flask A and stored under a total pressure of about 1.5 atm. of nitrogen. The nitrogen was purified by passing it through a strong solution of chromous sulfate. The capacity of the flask was about two liters of solution. E, F and G are heavy stopcocks. The solution was allowed to flow into the buret C and fill the bulb B. I was sealed off and after standing long enough to remove all adsorbed oxygen from the walls of the buret and bulb, the solution was displaced by nitrogen at

one atmosphere pressure by passing the gas through D and allowing the solution to flow out through E and F. The solution in A was shaken over the walls of the flask occasionally over a period of a day or two and it was ready for use. Solutions stored in such a manner remained unchanged in titer for a month.

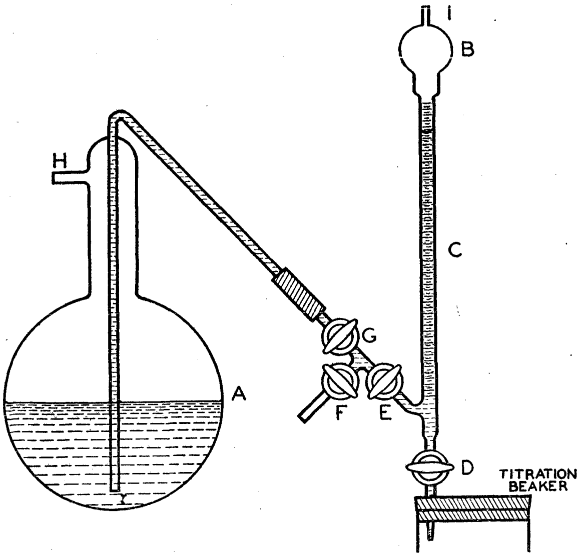

Fig. 1.—Apparatus for storing and titrating chromous sulfate solutions.

The oxygen-free water and acids were stored in bottles provided with heavy rubber stoppers and connected by siphon tubes to the side arms of burets. A slight pressure of carbon dioxide was maintained over the solutions in the bottles, burets and titration beaker at all times. The carbon dioxide was purified by passage through chromous sulfate solution.

The chromous sulfate solution, which was approximately 0.01 *N*, was standardized with solid potassium ferricyanide and with potassium dichromate solution. The high equivalent weight of potassium ferricyanide, the ease with which it can be prepared in the pure state, and the sharp end-point obtainable with it recommended its use as a standard. About 80 mg. of the crystals dried at 130° was introduced into an apparatus similar to that shown in Fig. 2 except that the tube connecting with the titration beaker was larger and attached in such a manner that the sample could be washed directly into the beaker with water. After carbon dioxide had been passed over the crystals for fifteen minutes, they were washed into the beaker with 20–40 cc. of oxygen-free water, 5 cc. of 2 *N* hydrobromic acid added, and the solution titrated potentiometrically with chromous sulfate. About 25 cc. of the reducing agent was required. It was not necessary to add zinc salt because the presence of the zinc ions in the reducing agent had sufficient influence on the potential of the solution to produce an end-point change of 600–800 millivolts per 0.1 cc. of reagent.

The normality of the dichromate solution was determined by means of thiosulfate standardized with potassium iodate. 0.9980 cc. of 0.2297 *N* dichromate was pipetted into the apparatus shown in Fig. 2 and 5 cc. of 6 *N* sulfuric acid added. Carbon dioxide was bubbled through the solution slowly from the titration beaker, escaping by way of the two-way stopcock while the solution was boiled gently for fifteen minutes to remove all oxygen. After cooling, the solution was forced into the beaker by connecting with a higher pressure of carbon dioxide than that in the beaker. Finally the flask was rinsed with 20–40 cc. of water and the contents of the beaker titrated. The end-point potential change was 400–600 millivolts per 0.1 cc.

In the titration of six chromous sulfate solutions with ferricyanide the average deviation of each normality from the mean was 0.05%. In the titration of three solutions with dichromate the average deviation was 0.02%. The difference between the averages of two ferricyanide and three dichromate titrations was 0.03%.

Table I shows the results of determinations of the equivalent weights of potassium bromoosmate and potassium chloroosmate. About 150 mg. of the salt was introduced into the beaker in the same manner as the ferricyanide and sufficient acid added to furnish the concentration stated in column 3. The titration was conducted with the chromous sulfate which had been standardized with ferricyanide. The volume of reagent required was about 19–24 cc. in the case of bromoosmate and 21–33 cc. in the case of chloroosmate.

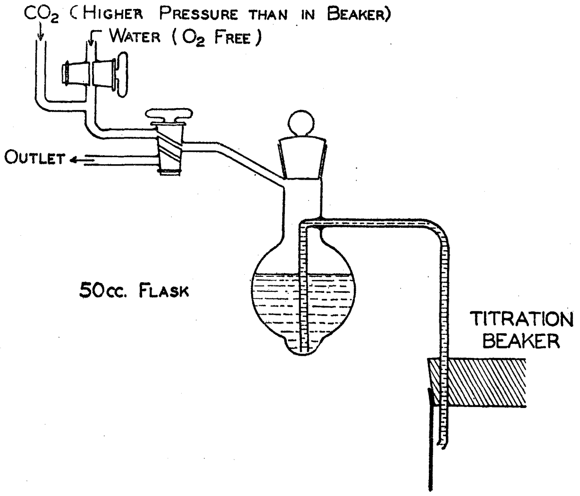

Fig. 2.—Apparatus for treating and transferring solutions.

The potential change per 0.1 cc. at the end-point was about 75 millivolts for the bromoosmate in 1 *N* hydrobromic acid, 130 millivolts in 0.1 *N* hydrobromic acid, and for the chloroosmate 80–100 millivolts in the 0.8 *N* hydrochloric acid. In column 4 are shown the values of the equivalent weights calculated from the titration data, and in the last column the percentage differences between these values and those calculated by use of Gilchrist's atomic weight of osmium. The results indicate that the acid concentration should not be below 0.1 *N* in the case of bromoosmate and 0.5 *N* in the case of chloroosmate.

At the foot of the table are shown the average deviations of the values of the equivalent weights obtained with the two salts. In spite of the fact that the percentage deviation in the values of the corresponding atomic weights of osmium is multiplied by about four in the case of bromoosmate and 2.5 in the case of chloroosmate, it is interesting to note how closely the two averages agree with that reported by Gilchrist.

TABLE I

THE DETERMINATION OF THE EQUIVALENT WEIGHTS OF POTASSIUM BROMOOSMATE AND POTASSIUM CHLOROOSMATE

Salt used	Detns.	Acid used and its concn., *N*	Average equiv. wt. by titrn.	Av. diff. between equiv. wt. found and Gilchrist's value, %
K_2OsBr_6	3	0.02–0.05 HBr	752.7	+0.45
K_2OsBr_6	8	0.13–0.25 HBr	749.1	− .03
K_2OsBr_6	2	0.60–0.95 HBr	749.8	+ .07
K_2OsCl_6	4	0.10–0.40 HCl	484.4	+ .39
K_2OsCl_6	8	0.50–0.80 HCl	482.6	+ .02

Average deviation last 10 results with K_2OsBr_6 = 0.10%
Average deviation last 8 results with K_2OsCl_6 = 0.10%
Average atomic weight of osmium by K_2OsBr_6 = 191.5
Average atomic weight of osmium by K_2OsCl_6 = 191.7
Gilchrist's value of atomic weight of osmium = 191.55

Since considerable difficulty due to hydrolysis was experienced when solutions of the osmium salts were heated to remove the last traces of oxygen, several solutions of the bromoosmate were treated in the apparatus shown in Fig. 2, and titrated in the same manner as the dichromate solutions. It was found that the concentration of the hydrobromic acid in the flask during boiling could be as low as 2 *N* without decomposition of the osmium salt taking place. Six 20.00-cc. portions of bromoosmate ranging in normality from 0.01333 to 0.01335 were titrated with 0.01187 *N* chromous sulfate and the maximum difference between the titrated value of the normality and that based on the amount of salt in the solution was less than 0.2%.

Summary

Apparatus and procedure are described for storing and handling chromous sulfate solutions, for standardizing these solutions with potassium ferricyanide and potassium dichromate, and for determining the osmium in potassium bromoosmate and potassium chloroosmate by potentiometric titration.

Solutions stored as described remained constant in titer for a month. Standardizations of chromous sulfate by the two methods agreed within 0.1% and the error in the osmium determinations was less than 0.2%.

The Preparation of Potassium Molybdo- and Molybdicyanides[1]

BY HOBART H. WILLARD AND R. C. THIELKE

In attempting to prepare potassium molybdocyanide, $K_4Mo(CN)_8 \cdot 2H_2O$, the methods previously used were found to give very poor yields. This investigation was undertaken to find a more satisfactory method for preparing this compound. The methods of Rosenheim and co-workers,[2] Chilesotti,[3] later used by Bucknall and Wardlaw,[4] were found to be unsatisfactory. The method of Jakob and Turbiewicz[5] was not tried because it seemed to offer difficulties. Sand and Burger[6] reported that ammonium thiocyanate and molybdate when dissolved in dilute hydrochloric acid and reduced electrolytically gave a product which could be extracted by ether and which was precipitated by pyridine from the dry ethereal solution. The oil after separation from ether solidified to a dark solid which melted at 189°. This reaction was modified to prepare potassium molybdocyanide.

(6) Sand and Burger, *Ber.*, **38**, 3384 (1905).

Experimental

Preliminary experiments showed that molybdic oxide dissolved in 8 *N* hydrochloric acid was not completely reduced by shaking with mercury for several hours. However, the octocyanide could be obtained with a 50% yield from the reduced molybdenum solution by following a procedure similar to that of Sand and Burger.[6]

Electrolytic reduction was finally adopted as the most convenient and rapid method. The cathode consisted of a hollow lead tube 0.5 cm. in diameter and of 126 ml. capacity. A graphite rod in a porous cup served as the anode. The anolyte was a 15% hydrochloric acid solution. A current of 5–10 amperes was used and the cathode was water cooled. Ten per cent. solutions of molybdic oxide in 8 *N* hydrochloric acid were used for most of the reductions. Carbon dioxide was bubbled through the solution to maintain an inert atmosphere. It was found that when trivalent molybdenum chloride was added to thiocyanate a green solution was produced instead of the characteristic blood-red thiocyanate complex, and that none of the molybdenum complex was extracted by ether. When the reduction was stopped at an apparent valence of four, as found by removing samples from time to time and titrating with permanganate, the blood-red complex was obtained when the molybdenum chloride was added to thiocyanate, and two-thirds of it could be extracted by ether. If a sample was completely reduced to the trivalent form, treated with the theoretical quantity of molybdic oxide to oxidize the molybdenum to the quadrivalent state, then treated with thiocyanate and extracted with ether, it was found that roughly one-tenth of the complex was extracted. These experiments explain the low yields obtained in the preparation of the octocyanide when this procedure was used with trivalent or quadrivalent molybdenum.

Preliminary experiments showed that a pyridine molybdenum thiocyanate complex could be precipitated from the thiocyanate solution by making it slightly alkaline with ammonia after the addition of pyridine. With trivalent molybdenum the aqueous solution contained about two-thirds of the molybdenum. The pyridine complex could not be successfully converted into the octocyanide. Quadrivalent molybdenum, however, was nearly quantitatively precipitated. A representative run contained only 0.03 g. of Mo in the aqueous solution. With this as a basis many experiments were performed to determine the best procedure for converting the complex to the octocyanide, separation of the complex cyanide from the reaction products and the final purification of the compound.

The following procedure has been found to be best and gives a 70–75% yield of potassium molybdocyanide based on the molybdic oxide used. Fifteen grams of pure molybdic oxide or an equivalent amount of the 85% material is dissolved in 150 ml. of warm 8 *N* hydrochloric acid. The solution is electrolytically reduced to trivalent molybdenum in the apparatus described and is then treated with 7.5 g. of molybdic oxide dissolved in 75 ml. of 8 *N* hydrochloric acid. The green solution assumes a reddish color at this stage. The mixture is added to a concentrated solution of 95 g. of ammonium thiocyanate. Sixty grams of pyridine is added and the solution is then made slightly alkaline with ammonia. These operations are best carried out in the absence of oxygen. Saturating the solutions with carbon dioxide has been found to work very well. A black oil is formed during the neutralization. After cooling in ice the black tar is separated from the aqueous solution by decantation and washed. The black tar is added slowly to a hot saturated solution of ten molecular proportions of potassium cyanide. The reaction mixture is concentrated until crystallization starts, is cooled in ice and filtered. The mother liquor is further concentrated and the double cyanide precipitated by adding alcohol with rapid swirling. The impure product is dissolved in a little water, heated with charcoal, filtered, concentrated and again precipitated with alcohol. The golden yellow crystals are then quite pure but still contain traces of thiocyanate. This may be removed by another crystallization. The yield of $K_4Mo(CN)_8 \cdot 2H_2O$ is about 55 g.

It was noticed that in some cases the crystals of the octocyanide were golden yellow and in other cases they were a bright yellow. Analyses of both showed them to be identical. Both were titrated to molybdicyanide with standard permanganate with the following result.

Yellow, % Mo	19.51	
Golden yellow, % Mo	19.56	Calcd. 19.35

A sample of each was decomposed with concentrated sulfuric acid by evaporation to fumes, diluted, reduced to the trivalent sulfate in a Jones reductor and titrated with standard permanganate.

Yellow, % Mo	19.51
Golden yellow, % Mo	19.97

Preparation of Potassium Molybdicyanide

The method given in the literature for the preparation of potassium molybdicyanide, $K_3Mo(CN)_8$, is very troublesome. It consists in oxidizing the molybdocyanide in acid solution with permanganate, precipitating in the dark gelatinous silver molybdicyanide and converting this into the potassium salt by treatment with potassium chloride. It is extremely difficult to obtain a pure solution because of the instability of the silver salt.

A quantitative yield of potassium molybdicyanide in solution is obtained by the following procedure. The molybdocyanide is oxidized in a slightly acid solution with permanganate until the purple tint is faintly perceptible, then two-thirds of an equivalent amount of permanganate is added in excess. Upon making the solution slightly alkaline with potassium hydroxide, the excess permanganate oxidizes the manganous ion and is itself reduced to manganese dioxide which is removed by filtration through asbestos. In order to make the resulting molybdicyanide solution more stable, it should again be slightly acidified. Even then, however, the solution is quite unstable. A solution which was prepared by the above method, stored in a brown bottle and kept from strong light was found to be decomposed to the extent of 20% after ten days. The preparation of the crystalline salt was not attempted.

Summary

1. Quantitative studies showed that the trivalent and quadrivalent molybdenum thiocyanate

complexes were only partially extracted by ether, resulting in a poor yield of molybdocyanide.

2. A quadrivalent molybdenum pyridine thiocyanate is almost completely precipitated in ammoniacal solution. By treatment of this with potassium cyanide a 70–75% yield of $K_4Mo(CN)_8 \cdot 2H_2O$ was obtained.

3. Quantitative yields of potassium molybdicyanide in solution were obtained by oxidizing potassium molybdocyanide with permanganate in acid solution and removing the manganese by oxidation to dioxide with permanganate after making the solution alkaline.

Studies on Hydrazine: Heats of Solution of Hydrazonium Salts at 25°. II

BY E. C. GILBERT AND V. C. BUSHNELL

The heat of solution of a number of hydrazonium salts has recently been reported from this Laboratory.[1] To complete the series the heats of solution of hydrazonium dibromide (anhydrous), hydrazonium sulfate, and hydrazonium dibromide (hydrated) have now been determined. That of the sulfate has also been determined by Bach[2] at a lower temperature.

Experimental

Apparatus.—The calorimeter was the same as previously used and the procedure was unchanged. It was again checked by measuring the heat of solution of sodium chloride.

Materials.—The salts were prepared from the free base and acids and purified by repeated crystallization. The anhydrous bromide was prepared from the hydrate by drying over phosphorus pentoxide. The preparation of the hydrate with exactly two molecules of water is somewhat difficult. It is very soluble in water and addition of nonaqueous solvents like alcohol removes one equivalent of acid, precipitating the monobromide. This peculiarity likewise precludes washing the crystals with anything but water. Forced drying practically always results in a slight loss either of water or hydrobromic acid. The samples used were analyzed both for hydrazine and for bromide. The preparation of the hydrated bromide used indicated by such analysis the presence of 0.2% of the monobromide. Samples of different origin were used in different runs and the heat quantities showed good agreement among themselves.

Results and Calculations

The results are shown in Table I. Specific heats for the bromide solutions were taken from the work of Cobb and Gilbert.[3] The specific heat of solutions of the sulfate is not found in the literature, hence it has been determined over a limited concentration range by the same method (3) and is given in Table II. From the values of the total molal heat of solution ΔH in Column 4 of Table I,

TABLE I

HEATS OF SOLUTION AT 25° (IN 15° CAL.)

The molality of the dibromide is expressed in every case as moles of anhydrous salt in 1000 g. of water in the resulting solution.

Molality Initial m_1	Final m_2	Heat absorbed per mole of salt dissolved	Total molal heat of solution m_2
	Hydrazonium Sulfate		
0.00	0.0576	8132	8132

[3] Cobb and Gilbert, THIS JOURNAL, **57**, 35 (1935).

the partial molal heat of solution of the solute and the relative partial molal heat content of the solvent were computed for the bromide solutions by the methods of the previous paper.[1] They are shown in Table III.

TABLE III

PARTIAL MOLAL HEATS OF SOLUTION OF SOLVENT AND SOLUTE AT 25° IN 15° CAL.

Molality	$\overline{H}_2 - H_2(s)$	$\overline{H}_1 - \overline{H}_1^0$
	Hydrazonium Dibromide	
0.1	4849	0.0427
.2	4712	.4268
.3	4571	1.059
.5	4265	3.216
.8	3870	7.739

Discussion

The low solubility of the sulfate limited this study to small concentrations. The most disturbing aspect of the problem, however, was the extreme slowness with which this salt dissolved even at concentrations considerably removed from saturation. The runs on the sulfate took from ninety to one hundred twenty minutes for completion. This resulted in a relatively large correction for heat of stirring, and required the use of small samples (5 g.) with attendant small temperature effects. For this reason the probable error in the heat of solution of the sulfate is larger than for any other salt in the series investigated.

Examination of the results obtained for the two series of chlorides and bromides (from this and the previous paper[1]), in which hydrazine functions, respectively, as a mono- and di-acid base, and comparison with other salts reveals some interesting correlations. In Table IV have been collected the differences in the molal integral heats of solution for a number of chlorides and bromides of the alkali and alkaline earth groups.[4] Inspection of this table of rounded values shows that salts of the monovalent hydrazonium ion $N_2H_5^+$ exhibit a behavior analogous to those of potassium, ammonium, rubidium and cesium, in that the bromide absorbs *more* heat than the chloride. In the hydrazonium salts containing two equivalents of acid, however, the bromide absorbs *less* heat than the chloride, a behavior similar to that of lithium, sodium, barium, strontium, and other hydrated cations. This difference in heat of solution, however, may be almost quantitatively accounted for by the difference in the heats of solution of the additional mole of halogen acid. The further similarity of the hydrated hydrazonium dibromide to the other bromides shown in the table is not so easily explained, but re-emphasizes[5] the similarity of the behavior of hydrazonium and sodium salts.

TABLE IV

COMPARISON OF MOLAL INTEGRAL HEATS OF SOLUTION: BROMIDES AND CHLORIDES OF THE ALKALI AND ALKALINE EARTH GROUPS, AND HYDRAZINE

Data for Li, Rb and Cs are given for 15°; Na, Ba, Sr, K and NH_4, 18°; hydrazine salts, 25°. Concentration in all cases except NH_4 is *ca.* 1 mole of salt to 400 or more moles of water; for NH_4, 1 to 200.

Element	$\Delta H(Br^-) - \Delta H(Cl^-)$	$\Delta H(Br^- \cdot 2H_2O) - \Delta H(Br^-$ Anhyd.)
Li	−2900	(*ca.*) +12000
Na	−1100	+ 4900
Ba	−2900	+ 9160
Sr	−4880	+ 9825
$N_2H_6^{++}$	−1164	+ 6250
K	+ 680	
NH_4^+	+ 550	
Rb	+1500	
Cs	+2000	
$N_2H_5^+$	+1100	

Summary

New data are reported on the heats of solution in water at 25° of hydrazonium dibromide, anhydrous and hydrated, and of hydrazonium sulfate.

The partial molal heat of solution of the solute and the solvent have been computed for the bromide.

The specific heat capacity of hydrazonium sulfate solutions at 25° has been determined.

Photochemical Responses of the Wheat Plant to Spectral Regions

BY E. J. LEASE AND W. E. TOTTINGHAM[1]

An earlier paper[2] reported increased absorption of nitrate by the young wheat plant when exposed to radiation from the carbon arc, as a supplement to winter sunlight. This response was later[3] obtained to the extent of 30%, with plants three weeks of age, by supplementing the mazda lamp with an arc of high amperage. Refinement of characterization for radiation of the later test gives an increase to 15-fold in radiation of the region 3100–4000 Å., by use of the arc, or to essentially 6% of the total between 3100 and 14,000 Å. In the region 4000 to 5000 Å. the increase was 270%, or to essentially 12% of the total. Apparently the value originally attributed[4] to this radiation was too high and should be revised to about 1200 f. c.

In the earlier study nitrate absorption was associated with the appearance of organic forms of nitrogen at the expense of sugar content and yield of dry matter. The present paper deals in greater detail with compositional responses of the plant to increases in proportion of the shorter rays of light.

Experimental

By the use, under water cells, of selective filters supplied by the Corning Glass Works, the spectrum emitted by the mazda lamp was altered to exclude radiation shorter than about either 3900 or 5200 Å. Space beneath was inclosed to exclude daylight. A range comparable with sunlight was obtained by use of the sunlight lamp[5] installed above a water cell of Corex D glass, and with a frosted pane of this glass to reduce the intensity of radiation. Adjustment of lamps was made to give, at the predominant leaf level, essentially equal intensities of about 1200 f. c. Forced ventilation of the plant chambers and surrounding greenhouse maintained a temperature range of essentially 17–18°. Earlier tests[6] placed these values of temperature and radiation as fairly favorable for the young wheat plant, with reference to production of dry matter. The plants were exposed nightly to a 15-hour period of irradiation, with a flow of about 1 cm. depth over the water cell.

A comparison of the forms of radiation transmitted to the plants is shown in Fig. 1, together with a distribution curve for mid-day, summer sunlight.[7] These graphs show marked deficiency of blue-violet and discontinuity of ultraviolet in our substitute for sunlight as compared with the normal. As shown in Fig. 2,[8] the cutoff of filters under the sunlight lamp conformed closely to the lower limit of sunlight. The total effective radiation was measured by a thermopile supplied for the purpose by the Eppley Laboratory. Distribution of the radiation is given in Table I.

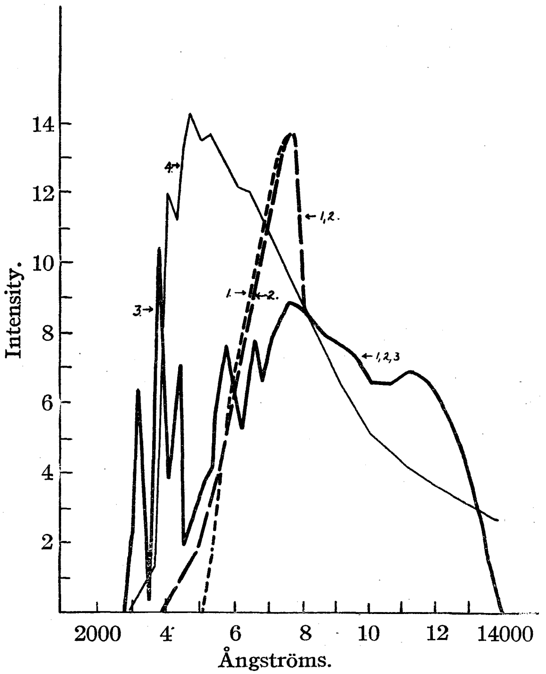

Fig. 1.—Effective radiation: 1 = No. 349 filter - - - - -; 2 = Noviol O filter —— ——; 3 = Sunlight lamp ━━━; 4 = Unfiltered sunlight ——.

Irradiation was continued daily for three weeks

5200	20.0	19.6	4.1	22.0	34.2

The decline of yield with exposure to shorter wave lengths of light was anticipated from differences in stem diameter, and especially from the stunted form, of plants under the sunlight lamp. There was no external evidence of injury in the latter case but the tissue was characterized by a sharp increase of lipide content and a prominent decline in the percentage of crude fiber. Had this response of lipides depended upon the "wax" content of an increased proportion of plant surface it should have been much greater. The more available carbohydrates, as represented by the nitrogen-free extract, decreased relatively uniformly with extension of spectral exposure. Protein shows the opposite response, for evidence in Table II indicates that the sharp maximum of crude protein in Table I was probably affected by non-protein nitrogen. Irradiation was without effect upon the proportion of mineral elements in the tissue.

As suggested by the preceding results, the following determinations were selected. Pentosans were determined by the method of McCance[10] on samples prepared by extraction with acetone, ether and hot 80% alcohol. Uronic anhydrides were determined by the procedure of Dickson, Otterson and Link[11] on the extract obtained by boiling with 2.0% hydrochloric acid for two and one-half hours, after extraction of the tissue by ether and water. The first of these constituents was determined on two crops, the second on one. Nitrate and nitrite were determined on fresh tissue by colorimetric procedure,[12] data for the former representing six crops and the latter three. The results appear in Table IV.

TABLE IV

SELECTED DETERMINATIONS ON WHEAT TOPS OF PERCENTAGES IN DRY MATTER

creases of pentosans and increases of uronic acids are about proportional to the introduction of blue-violet, as shown in Table I, but this does not exclude possible functioning of ultraviolet. Supplementary to the present evidence, we found in another investigation a 20% increase of uronic acid in the wheat stem at prebloom in association with a heavy application of nitrate to the soil. In the present relation this constituent appears to arise as a product of oxidation associated with the reduction of nitrate. It might be expected that ascorbic acid should increase in parallel with uronic acid, but limited titrimetric data obtained by the method of Birch, Harris and Ray[13] indicated very small amounts of this constituent. This situation can be understood on the basis of the observation of Karrer and Bendas[14] that the former constituent reduces nitrite. The results for xylan indicate that the path by which pentosans are formed, commonly supposed to involve decarboxylation of uronic acids, is partially diverted by extensive absorption of nitrates. Press sap from three crops was examined for content of reducing sugars by the Shaffer–Hartman method and for hydrogen ion concentration by use of the quinhydrone electrode. The data, as shown in Table V, are in agreement with those just discussed as indicating increased oxidation of sugars to acids under the influence of shorter visible and longer ultraviolet radiation.

TABLE V

Minimal effective radiation, Å.	2900	3900	5200
Reducing sugars, %	2.0	3.2	3.8
*p*H	4.9	5.2	5.4

A search was made for constituents which might serve as trigger mechanisms in the above effects. Several enzyme forms which function in oxidation–reduction relations were inappreciably affected as to activity by the differences in radiation, but it was not feasible to examine dehydrogenases. Three crops of wheat reared under minimal radiation of 2900, 3900 and 5200 Å. gave by titration with potassium iodate according to the procedure of Okuda and Ogawa[15] relative proportions in glutathione of 100, 91 and 68, respectively. Similar results were obtained for the sulfhydryl group in tomato leaves irradiated for three hours daily by the sunlight lamp as a supplement to July sunlight under glass. Six samples showed an increase of about 100% by this exposure as compared with supplementary use of the mazda lamp as a control. In this case the method of Guthrie[16] was applied, excepting that the alcoholic extract was inactive and the whole tissue was exposed to reaction with colloidal sulfur. In view of the absorptive capacity of cystine for both blue-violet and ultraviolet light, as observed by Ward,[17] it is suggestive to find here a reduction product of that form of sulfur. Szent-Gyorgyi[18] has shown that glutathione reduces hexuronic acids, a relation which might confer upon sulfhydryl compounds in the present instance significance in the utilization of sugars for nitrate assimilation under shorter rays of light.

Some attention was devoted to the leaf pigments. Six samples gave the average data of Table VI, by colorimetric procedure.

TABLE VI

PERCENTAGES OF PIGMENTS IN LEAF DRY MATTER OF WHEAT PLANTS 25 DAYS OLD

Minimal effective radiation, Å.	Chlorophylls	Carotenes	Xanthophylls
2900	0.74	0.10	0.19
5200	.61	.09	.18

The lesser content of chlorophylls where shorter radiations were excluded could be anticipated by color differences of the leaves. It agrees with previous observations[19] of ineffectiveness of red and infra-red rays in synthesis of these pigments. This increase of pigment in plants receiving the more complete spectrum may be highly significant in relation to increased nitrate assimilation. Substantial physiological information indicates that it could function through stimulating respiration,[20] the latter process in turn providing for reduction of nitrate.[21]

Large-scale lipide preparations were recovered by ether from plants exposed to April sunlight under glass, supplemented by the use of either mazda or sunlight lamps. These were found to have the same proportion and character of wax fraction under the differences of radiation. Fatty acids recovered from the non-waxy fraction were

somewhat less saturated under the sunlight lamp than under the mazda, with iodine numbers of 106.6 and 103.9, respectively. Sterols were recovered as digitonides to the extent of 37 and 34 mg. per 100 mg. of dry tissue in these respective samples. These data supply limited evidence of increased dehydrogenation under the higher proportion of short-wave radiation.

Summary

Elimination of wave lengths shorter than about 3900 or 5200 Å. from radiation resembling sunlight decreased the assimilation of nitrate and conserved carbohydrates in young wheat plants. The primary factors to which increased reducing power under shorter radiation could be attributed were increased tissue contents of chlorophylls and sulfhydryl compounds. Paths are indicated by way of which these factors could function as trigger mechanisms in the reduction of nitrate. Depression of pentosan formation was associated with increased assimilation of nitrate. Most of the compositional effects in the tissue could be attributed to variations in the proportion of blue-violet light, but the reduction of nitrate to nitrite was more distinctly associated with long ultraviolet radiation. Apparently the high proportion in sunlight of radiation from 3900 to 4920 Å. and the low proportion above 8000 Å., in comparison with the light sources here tested, favor the assimilation of nitrate by plants.

The Dimorphism of Rotenone

BY ERNEST L. GOODEN AND CHARLES M. SMITH

The fact that rotenone occurs in two forms characterized by melting points of 163° and about 180° was briefly referred to by Butenandt and Hildebrandt[1] and later considered more fully by Cahn.[2] This phenomenon has also been studied in the Insecticide Division and, since certain characteristics of the two materials not previously recorded have been determined, the results of this study are given here.

No attempt has been made to confirm the statement of Butenandt and Hildebrandt that the higher melting form of rotenone can be prepared from the ordinary form by grinding, but the transition during melting-point determinations and the melting and resolidification of rotenone that was rapidly heated to a temperature between the two melting points have been observed. Neither of these two methods of preparation gives a product suitable for microscopical study, but the higher melting material can be prepared easily in well-crystallized form by the process given in the following section.

Preparation of Materials

The sample of low-melting rotenone was obtained from cubé root, being crystallized once from carbon tetrachloride as the solvate, and then twice from a 1:1 mixture of acetone and water as rotenone itself.

The high-melting rotenone was prepared from this sample by immersing it in a petroleum oil less volatile than kerosene and heating to 140–150°. The mixture was maintained in this temperature range, with frequent stirring, at least until examination with a polarizing microscope showed apparently complete transformation of the original thin six-sided plates to chunky, granular crystals.[3] The petroleum oil was decanted, and the crystals were washed by decantation with petroleum ether and dried at room temperature. Four batches were prepared in this manner, with different periods of heating, lasting from one to five hours. None of the batches was pure white, as it is presumed they should have been, but the one heated least was the best looking preparation and was considered most nearly pure.

That this material was not a solvate was proved by microanalysis[4] and a determination of the opti-

---

[2] Cahn, *J. Chem. Soc.*, 1129 (1934).

(3) No method of proving the completeness of the transformation was devised. The writers feel certain that it was nearly enough complete to demonstrate a difference in density if any considerable difference existed. The optical data are, of course, not affected by this uncertainty, for they were determined on individual crystals known to be of the high-melting form.

(4) The writers wish to thank Dr. J. R. Spies for determinations of carbon and hydrogen.

cal rotatory power in acetone at 20° (*i. e.*, below the transition temperature), both of which agreed within experimental limit with the values for the low-melting form.

The failure of Cahn to get crystalline high-melting rotenone by working in tetralin and in xylene at 100° was very likely due to the fact, considered later, that the transition temperature is apparently above 100°. Even if it is below this, his method would probably fail because of the very rapid retransformation which occurs in such good solvents as tetralin and xylene. For example, if a mount of high-melting rotenone is made in amyl acetate, and examined under the microscope, the transformation is seen to begin almost immediately, small crystals of the low-melting form appearing in the liquid surrounding each crystal of the high-melting form. Further, in one experiment ethyl ether was used to wash, by decantation, a lot of high-melting rotenone prepared by the method described in this paper, and the entire mass transformed before the washing could be completed. It is only the very low solubility of rotenone in petroleum fractions that accounts for the success of our method.

General Appearance

Figure 1 shows the most characteristic habit of the ordinary low-melting form, the small faces beveling two opposite edges being commonly present. Thicker crystals have at times been obtained, and these might be difficult to differentiate from those of the high-melting form by casual inspection. The crystals of the high-melting form, shown in Fig. 2, contain the same faces as those of the low-melting form, and others in addition. A comparison of the two compounds with respect to the plane angles of the faces that are parallel to the optic axial planes shows large differences, indicating a distinct difference in crystallographic axial ratios.

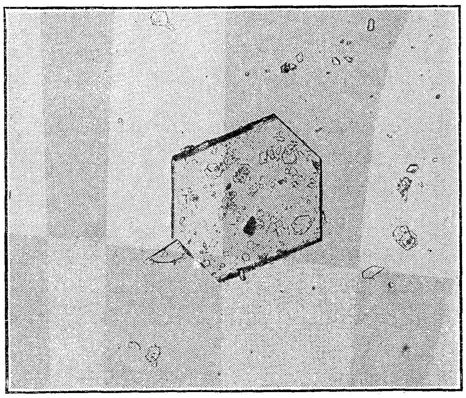

Fig. 1.—Low-melting rotenone (the common form) × 60.

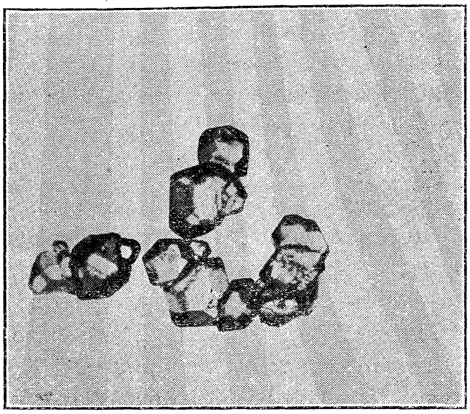

Fig. 2.—High-melting rotenone (the unstable form) × 60.

Optical Characteristics

The crystals of low-melting rotenone have symmetrical extinction and are biaxial with the axial plane parallel to the large face upon which the crystals normally lie.

The crystals thus permit the direct determination of the α- and γ-indices, which were found to be 1.616 and 1.662, respectively, in good agreement with the values given by Clark.[5] The α-index is shown when the beveled edges are parallel to the vibration direction of the polarizer. Pieces suitable for the measurement of β are difficult to obtain, but by working with thick crystals grown especially for the purpose it was possible to determine it as being 1.635. The accuracy of these figures (±0.003) is not great enough for determining the optical character, nor could this character be determined from the interference figures. From the parallelism of the optical directions and the principal crystallographic directions it is inferred that the crystals belong to the orthorhombic system.

High-melting rotenone is also biaxial with symmetrical extinction, and again many crystals lie upon a face which is parallel to the axial plane, so that, except for the greater thickness, the general aspect is similar to that of ordinary rotenone. The indices of refraction are, however, significantly different, having the following values:

---

(5) Clark, *Science*, **70**, 478 (1929).

$\alpha = 1.600$, $\beta = 1.650$, $\gamma = 1.685$. The various indices are shown in the same comparative positions as with low-melting rotenone. The interference figures definitely prove the substance to be optically negative, which fact is in accord with the relative values of the indices. The optic axial angle is greater than 65°, the limit of the microscope used. From these data it appears probable that high-melting rotenone also belongs to the orthorhombic system.

Density

Density determinations on both forms of rotenone were first made by the displacement method in a pycnometer, the immersion medium being a 0.3% water solution of gelatin which improved the wetting power of the water and prevented the retention of air bubbles. The two forms were found to be indistinguishable in density within the limits of accuracy of the procedure. the value being 1.33 g. per cc. at 20°.[6]

This result was checked by suspension experiments with solutions of potassium iodide which had densities the same as and slightly different from that of the solids. No difference in behavior could be demonstrated.

Melting Point

Practically all observers agree in assigning a melting point of 163° to ordinary rotenone, and this figure was obtained on the material used in this investigation. Butenandt and Hildebrandt[1] found a melting point of 176° for the high-melting rotenone prepared by them by grinding the ordinary form, and Cahn[2] observed melting points of from 176 to 183° for material prepared by dry heating. At various times in this Laboratory values of 179 to 181° have been observed with samples of ordinary rotenone that evidently were converted during the course of the melting-point determination. Attempts to establish the melting point more definitely on the material used in this investigation failed. A series of observations conducted in a manner similar to that usually employed in this Division gave a range of 5°, with a mean of 175°. Then a series of tests was made in which the melting-point tube was plunged into a bath previously adjusted to some temperature between 170 and 180°, and in one instance prompt melting occurred at 174°. When the tubes were put into a bath previously brought to 170° (approximately) and then slowly heated, melting points of 174, 174 and 175° were obtained on three separate batches. The behavior was such, however, that we feel these values are too low, and are inclined to suspect that the samples may have contained small amounts of impurities either decomposition products formed during the heating of the rotenone or some petroleum oil dissolved or entrained in the crystals at the time of their formation.

Transition Temperature

There seems to be no doubt that the rotenone melting at 163° is the stable form at room temperature; for, as stated before, the transformation of the high-melting form into it can be watched under the microscope in a mount prepared with a good solvent such as amyl acetate. No estimate of the transition temperature has been published except the figure 125° given by Roark,[6] and that figure was based on some work by one of the writers in which portions of low-melting rotenone were immersed in white oil (a petroleum fraction) and maintained at various fixed temperatures, the occurrence of transformation being watched for by periodic microscopic examination. Transformation was plainly evident at 131°, and apparently did not take place at 120°. In the absence of definite knowledge that the white oil does not affect the transition point, it cannot be said that the true transition temperature will have the estimated value of 125°.

Summary

Rotenone exists in two enantiotropic forms, with melting points of 163° and approximately 180°, respectively.

Both forms apparently belong to the orthorhombic system and develop with similar habit except for a greater tendency of the low-melting form to appear in crystals tabular parallel to the optic plane.

The refractive indices are as follows: for low-melting rotenone, $\alpha = 1.616$, $\beta = 1.635$, $\gamma = 1.662$; for high-melting rotenone, $\alpha = 1.600$, $\beta = 1.650$, $\gamma = 1.685$. The high melting form is optically negative, the other practically without sign.

Both forms have a density of 1.33 g. per cc. at 20°.

The transition temperature has not been determined.

WASHINGTON, D. C. RECEIVED JUNE 17, 1935

---

[6] Note that this is appreciably higher than the 1.27 given for low-melting rotenone by R. C. Roark [*Ind. Eng. Chem.*, **25**, 639–642 (1933)]. That figure was merely a rough approximation.

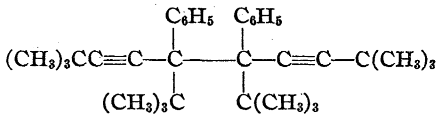
Rearrangements of Polyynes. VII.[1] Formation of Allenes

BY J. H. FORD, C. D. THOMPSON AND C. S. MARVEL

Previous work has shown that many hexasubstituted ethanes of the type  $RC{\equiv}C{-}C(R')(R''){-}C(R')(R''){-}C{\equiv}CR$ undergo rearrangement to produce more stable hydrocarbons of unknown structure and that the ease with which this rearrangement occurs in any given case is largely determined by the nature of R′ and R″. The aim of the present work was to obtain diphenyldi-*t*-butyldi-*t*-butylethynylethane (I)

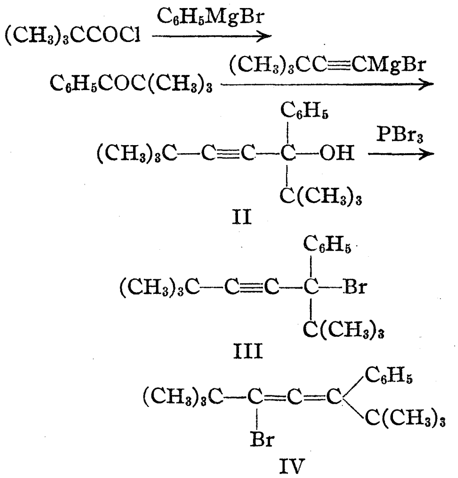


$$(CH_3)_3CC{\equiv}C{-}C(C_6H_5)(C(CH_3)_3){-}C(C_6H_5)(C(CH_3)_3){-}C{\equiv}C{-}C(CH_3)_3$$

I

in which R′ is a phenyl group and R and R″ are *t*-butyl groups. Some interesting rearrangements were observed in the reactions which were used in the synthesis of the desired ethane and these seem to offer some clues as to the nature of the rearrangements of the polyynes themselves.

Phenyl-*t*-butyl-*t*-butylethynylbromomethane (III) was synthesized by the series of reactions



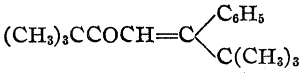
$$(CH_3)_3CCOCl \xrightarrow{C_6H_5MgBr} C_6H_5COC(CH_3)_3 \xrightarrow{(CH_3)_3CC{\equiv}CMgBr} (CH_3)_3C{-}C{\equiv}C{-}C(C_6H_5)(C(CH_3)_3){-}OH\ \text{(II)} \xrightarrow{PBr_3}$$

$$(CH_3)_3C{-}C{\equiv}C{-}C(C_6H_5)(C(CH_3)_3){-}Br\ \text{(III)}$$

$$(CH_3)_3C{-}C(Br){=}C{=}C(C_6H_5)(C(CH_3)_3)\ \text{(IV)}$$

IV

The carbinol (II) did not react readily with phosphorus trichloride to give an organic chloride but the bromide (III) was formed without difficulty. The bromide had an abnormally high molecular refraction and the bromine was not easily removed by silver, which suggested that possibly the compound did not have the acetylenic structure but was a rearranged allenic bromide of structure IV. However, structure III was established for the bromide by hydrolysis with moist silver oxide to give the carbinol (II). The



$$(CH_3)_3CCOCH{=}C(C_6H_5)(C(CH_3)_3)$$

carbinol structure was checked by converting it to the unsaturated ketone by the action of sulfuric acid in acetic acid.[2]

The bromide (III) did not couple to yield a hydrocarbon when it was treated with silver or copper. The carbinol (II) did not reduce to give a coupled hydrocarbon when it was treated with titanous chloride solution. The bromide did react with magnesium in dry ether to give about an 80% yield of the Grignard reagent and 10–15% of a mixture of hydrocarbons which had the molecular formula $C_{34}H_{46}$ corresponding to the desired ethane (I). When this Grignard reagent was treated with water, carbon dioxide or methyl chlorocarbonate the resulting product in each case was an allene derivative. The structures of the products were established by ozonization. The product of the action of water on the Grignard reagent was 2,2,6,6-tetramethyl-3-phenyl-3,4-heptadiene (V) as was shown by the fact that on ozonization and oxidative hydrolysis of the ozonide, it yielded trimethylacetic acid and phenyl *t*-butyl ketone. That the phenyl *t*-butyl ketone was not a secondary oxidation product of phenyl-*t*-butylacetic acid was established by synthesizing this acid and showing that it did not oxidize to phenyl *t*-butyl ketone under the conditions used in oxidizing the allene (V). The structure of the 2,2,6,6-tetramethyl-3-phenyl-5-carbomethoxy-3,4-heptadiene (VII) was established by the fact that it yielded methyl trimethylpyruvate $(CH_3)_3CCOCO_2CH_3$ on ozonization. The structure of the acid (VI) follows from the fact that it has been obtained by hydrolysis of the ester (VII).

The formation of an allenic hydrocarbon (IX) by the action of water on diphenyl-*t*-butylethynylmethyl sodium[3] (VIII) has been observed before. It is of some interest to note that 4,4-dimethyl-1,1-diphenyl-1,2-pentadiene (IX) readily dimerizes

---

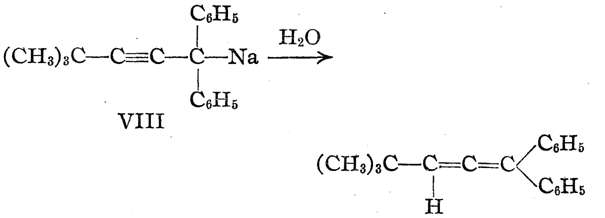
V

VI

VII

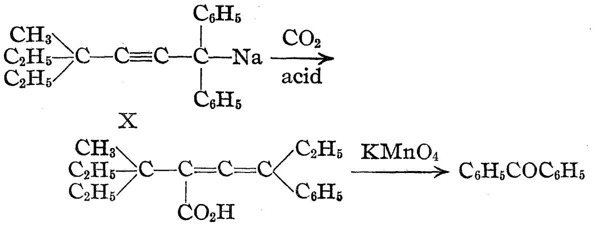
whereas 2,2,6,6-tetramethyl-3-phenyl-3,4-heptadiene (V) does not. Apparently the addition reactions of the allene group are blocked by the two *t*-butyl groups in this latter molecule.



VIII

IX

Many acids and esters[4] have been prepared in this Laboratory by the action of carbon dioxide or methylchlorocarbonate on metallic derivatives of the type $R-C\equiv C-\overset{R'}{\underset{R'}{C}}-\text{metal}$ and these have been assumed to be the acetylenic acids $R-C\equiv C-\overset{R'}{\underset{R'}{C}}-COOH$. The present work leads us to believe that all of these compounds may also be allene derivatives of the type $R-\underset{COOH}{C}=C=\overset{R'}{\underset{R'}{C}}$. In fact Harmon and Marvel[4g] did observe that the acid (XI) obtained by the action of carbon dioxide on diphenyl-(3-methyl-3-ethylpentynyl-1)-methyl sodium (X) yielded benzophenone

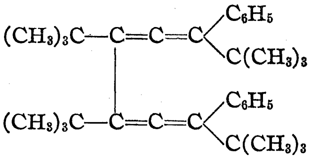


X

XI

on oxidation with neutral permanganate. Benzophenone would be expected from an acid of structure XI, whereas an acid of acetylenic structure would be expected to give diphenylmalonic acid or, by loss of carbon dioxide, diphenylacetic acid.

Since the bromide (III) was inert toward silver and copper, an attempt was made to convert it to the sodium derivative in order to obtain the ethane (I) by the method of Ziegler and Schnell.[5] It was found that 40% sodium amalgam in ether converted the bromide into a mixture of hydrocarbons and that no sodium derivative could be demonstrated to be present. One hydrocarbon which was isolated from the reaction mixture was the allene (V) which had been obtained by the action of water on the Grignard reagent prepared from the bromide. This allene must have been produced by the formation of some of the desired sodium derivative which then reacted with the ether present to give the allene.[6] In addition to the simple allene, the same mixture of coupled hydrocarbons of the formula $C_{34}H_{46}$ which was formed as a side reaction in the formation of the Grignard reagent, was isolated from the reaction of the bromide and sodium amalgam. Apparently there were two isomeric hydrocarbons in this mixture. One, the less soluble, was isolated in a pure condition but the other, more soluble one, was never completely freed from the less soluble isomer. We believe these two hydrocarbons are stereoisomers of each other but whether they represent the meso and racemic forms of the acetylenic ethane (I) or of a rearrangement product which by analogy to the other derivative obtained from the Grignard reagent would be the diallene (XII) cannot as yet be said. The fact



XII

that this mixture of hydrocarbons is formed by the action of sodium amalgam on the bromide and that the hydrocarbons are therefore not cleaved by this reagent seems to be evidence in favor of the diallenic structure.

Experimental Part

Phenyl *t*-Butyl Ketone.—In a 2-liter three-necked flask fitted with a stirrer, separatory funnel and reflux condenser was placed a solution of 129 g. of trimethylacetyl chloride in 400 cc. of dry ether. The mixture was cooled in an ice-salt bath. A slow stream of dry nitrogen was passed over the surface of the solution to avoid oxidization and 1050 cc. of a 1.6 *N* ether solution of phenylmagnesium bromide was added from the separatory funnel during five hours. The reaction mixture was hydrolyzed with dilute acid and the ether solution was washed with sodium bicarbonate solution to remove trimethylacetic acid. On distillation the ketone boiled at 80–84° at 3 mm. The yield was 116 g. (67%), n^{20}_D 1.5102. The physical properties check those previously reported for the ketone as prepared by other methods.[7]

The 2,4-dinitrophenylhydrazone was prepared by the method of Allen[8] and after two crystallizations from 95% alcohol the yellow needles melted at 194–195°.

Anal. Calcd. for $C_{17}H_{18}O_4N_4$: N, 16.37. Found: N, 16.14.

Phenyl-*t*-butyl-*t*-butylethynylcarbinol.—A solution of 162 g. of phenyl *t*-butyl ketone in 250 cc. of dry ether was added over a period of three hours to the Grignard reagent prepared from 82 g. of *t*-butylacetylene[9] in about 700 cc. of ether. After ten hours the reaction mixture was worked up in the usual manner and the carbinol was very carefully fractionated. The yield was 200 g. (68%) of a viscous liquid, b. p. 125–128° (4 mm.); n^{20}_D 1.5025; d^{20}_4 0.9334. M_D calcd., 76.65; found, 77.27.

Anal. Calcd. for $C_{17}H_{24}O$: C, 83.54; H, 9.91. Found: C, 83.46; H, 10.09.

2,2,6,6-Tetramethyl-3-phenyl-3-heptene-5-one.—The carbinol was converted to the unsaturated ketone by heating a few grams of it in a glacial acetic acid solution containing a few drops of sulfuric acid. The ketone boiled at 96–97° (1 mm.); n^{20}_D 1.5063; d^{20}_4 0.9309; M_D, calcd., 76.67; found, 77.98. On cooling the liquid to about −40° it crystallized to a solid which melted at 30.5°.

Anal. Calcd. for $C_{17}H_{24}O$: C, 83.54; H, 9.91. Found: C, 83.70; H, 10.16.

The 2,4-dinitrophenylhydrazone was a bright orange-red solid melting at 150–151°.

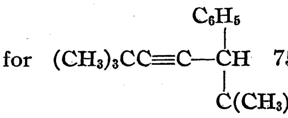
Anal. Calcd. for $C_{23}H_{24}O_4N_4$: N, 13.39. Found: N, 13.40.

Phenyl-*t*-butyl-*t*-butylethynylbromomethane.—To a solution of 30 g. of the carbinol in 150 cc. of low boiling petroleum ether was added 5.4 cc. of phosphorus tribromide. After standing overnight, a layer of phosphorous acid had separated. The upper layer was separated, washed throughly with sodium bicarbonate, dried over magnesium sulfate and distilled. The yield was 34.4 g. (91%) of a slightly yellow liquid, b. p. 115–117° (1 mm.); n^{20}_D 1.5400; d^{20}_4 1.1081; M_D calcd., 82.89; found, 86.93.

Anal. Calcd. for $C_{17}H_{23}Br$: C, 66.43; H, 7.55; Br, 26.02; mol. wt., 307.1. Found: C, 66.54; H, 7.47; Br, 25.75; 25.82; mol. wt. (Rast.), 282.

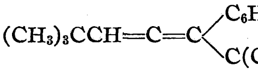
A small amount of the bromide was hydrolyzed by boiling a solution in acetone with a suspension of moist silver oxide.[10] The product was separated by distillation; b. p. 105–110° (1 mm.); n^{20}_D 1.5028; d^{20}_4 0.9332, and was identical with the carbinol from which the bromide had been prepared.

2,2,6,6-Tetramethyl-3-phenyl-3,4-heptadiene.—The Grignard reagent was prepared from 58 g. of the bromide and 5 g. of magnesium turnings in 500 cc. of ether. Iodine was used to start the reaction. The Grignard reagent was then decomposed by adding water and finally a little hydrochloric acid and ice. The ether layer was separated and distilled. After removal of the solvent, the main portion boiled at 78–80° (1 mm.). The yield of the hydrocarbon was 35 g. (82%); n^{20}_D 1.5039; d^{20}_4 0.8808; M_D calcd. for



$(CH_3)_3CC\equiv C-CH(C_6H_5)C(CH_3)_3$

75.13; calcd. for



, 76.19; found, 76.67.

Anal. Calcd. for $C_{17}H_{24}$: C, 89.40; H, 10.60; mol. wt. 228.2. Found: C, 89.26; H, 10.71; mol. wt. (Rast.), 222.

This hydrocarbon was heated to 145° in a sealed tube for about ninety hours and then vacuum distilled.[11] About 85% of the hydrocarbon was recovered unchanged and no definite products could be obtained from the residue.

The original high boiling residue which remained after distilling the allene, slowly solidified. Crystallization gave two products, one melting at 148° and one melting at 115–125°, which were identified as coupled products and will be described in more detail later.

Ozonolysis of the Allene.—A solution of 5 g. of the above allene in 100 cc. of carbon tetrachloride was cooled to −20° and ozonized oxygen was passed through the solution for about ten hours at the rate of 0.5 liter per minute. A white sticky solid separated from solution during this treatment. The reaction mixture was decomposed by adding 75 cc. of water and stirring for several hours at 25°. An excess of sodium bicarbonate solution was then added and the mixture stirred for a short time. The carbon tetrachloride solution was evaporated and the residue treated with 2,4-dinitrophenylhydrazine. The product of this reaction melted at 193–194° and proved to be the 2,4-dinitrophenylhydrazone of phenyl *t*-butyl ketone. The water layer was acidified and distilled with steam. The volatile acid was converted to the *p*-bromophenacyl ester which melted at 75–76° and proved to be identical with the *p*-bromophenacyl ester of trimethylacetic acid.[12]

Phenyl-*t*-butylacetic Acid.—Phenyl *t*-butyl ketone was reduced to the carbinol by the method of Ramart-Lucas[13] in yields of 95%, and this carbinol was converted to the bromide by the method of Lepin[14] in yields of 93%.

The Grignard reagent, prepared from 10 g. of this bromide and 1.2 g. of magnesium in 100 cc. of dry ether, was treated with carbon dioxide and the organic acid isolated in the usual manner. The yield was 1.1 g. (13%) of a product m. p. 105° after two crystallizations from dilute alcohol and one from low-boiling petroleum ether.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.38; neut. equiv., 192.1. Found: C, 74.74; H, 8.37; neut. equiv., 192.8.

The main portion of the bromide reacted with the magnesium to yield diphenyldi-*t*-butylethane, m. p. 185–186°.[15]

A solution of phenyl-*t*-butylacetic acid in carbon tetrachloride was treated with ozonized oxygen under the conditions used for the ozonolysis of the allene. Only about one-fourth of the acid was recovered from the mixture but no phenyl *t*-butyl ketone could be detected in the mixture.

2,2,6,6-Tetramethyl-3-phenyl-5-carbomethoxy-3,4-heptadiene.—The Grignard reagent prepared from 30.7 g. of phenyl-*t*-butyl-*t*-butylethynylbromomethane and 2.5 g. of magnesium in 250 cc. of ether was added during one hour to a solution of 9.45 g. of methyl chlorocarbonate in 100 cc. of dry ether. The reaction mixture was cooled to 0° and nitrogen was passed through the flask to avoid oxidation. The reaction mixture was worked up in the usual way. The yield was 18.5 g. (64%) of a colorless liquid, b. p. 116–120° (2 mm.); n^{20}_{D} 1.5029; d^{20}_{4} 0.9584; M_D calcd., 87.08; found, 87.84.

Anal. Calcd. for $C_{19}H_{26}O_2$: C, 79.67; H, 9.15. Found: C, 79.62; H, 9.02.

A solution of 2 g. of this ester in 50 cc. of carbon tetrachloride was ozonized in the usual manner. The neutral fraction from the decomposition of the ozonide was treated with 2,4-dinitrophenylhydrazine and a lemon-yellow solid, m. p. 205–206° (after recrystallization from alcohol) was isolated. This product was identical with the 2,4-dinitrophenylhydrazone of the methyl trimethylpyruvate described below. Indications of the presence of the 2,4-dinitrophenylhydrazone of phenyl *t*-butyl ketone were also obtained, but since this hydrazone is more soluble than the one isolated above, it could not be purified sufficiently for positive identification.

2,4-Dinitrophenylhydrazone of Methyl Trimethylpyruvate.—Trimethylpyruvic acid was obtained from pinacolone in 50% yields by the method of Richard.[16] Its 2,4-dinitrophenylhydrazone was prepared and melted at 169–171° with decomposition.

Anal. Calcd. for $C_{12}H_{14}O_6N_4$: N, 18.01. Found: N, 18.17.

Methyl trimethylpyruvate was formed in 70% yields by direct esterification of the acid with methyl alcohol[16] and its 2,4-dinitrophenylhydrazone was prepared in the usual manner. This product melted at 205–206°. It could be crystallized from alcohol but acetone was a better solvent. This product showed no depression in melting point when mixed with the material obtained from the ozonolysis of the methyl ester of the allenic acid.

Anal. Calcd. for $C_{13}H_{16}O_6N_4$: N, 17.29. Found: N, 17.46.

2,2,6,6-Tetramethyl-3-phenyl-5-carboxy-3,4-heptadiene.—The Grignard reagent prepared from 47 g. of phenyl-*t*-butyl-*t*-butylethynylbromomethane and 4 g. of magnesium in 400 cc. of dry ether was carbonated and the reaction mixture was worked up in the usual way. The yield of crude solid acid was 30 g. (72%). Two crystallizations from benzene gave a product melting at 160–161°. The acid was quite weak and only slightly soluble in sodium bicarbonate solution, although readily soluble in either sodium carbonate or sodium hydroxide solution.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.35; H, 8.88; mol. wt., 272.2. Found: C, 79.21; H, 9.02; mol. wt. (titration) 274, (ebullioscopic in acetone) 275, 220.

This same acid was obtained by boiling a solution of 2 g. of the ester obtained from the Grignard reagent and methyl chlorocarbonate and 2 g. of potassium hydroxide in 30 cc. of methyl alcohol for two hours. From this mixture 1.7 g. of the ester was recovered, but a small amount of acid melting at 159–160° was separated by acidification of the alkaline solution. A sample of this material mixed with some of the acid obtained by direct carbonation of the Grignard melted at 160°.

Action of 40% Sodium Amalgam on Phenyl-*t*-butyl-*t*-butylethynylbromomethane.—A solution of 20 g. of the bromide in 200 cc. of dry ether was shaken for about thirty-five hours with 25 cc. of 40% sodium amalgam in an atmosphere of dry nitrogen. The amalgam was frozen, the green colored ether solution was decanted into another nitrogen-filled flask and water was added. On working up the ether solution in the usual manner, a white solid and a yellow oil were obtained. By crystallization from absolute alcohol about 5.12 g. (34%) of solid material was obtained. By fractional crystallization from a mixture of absolute alcohol and petroleum ether, about one-fourth of this solid material was obtained as a pure hydrocarbon, m. p. 148–149°.

Anal. Calcd. for $C_{34}H_{46}$: C, 89.80; H, 10.20; mol. wt., 454.4. Found: C, 89.88; H, 10.38; mol. wt. (Rast.), 435.

The remaining solid was crystalline but melted over a range of ten degrees (115–125°). It contained some of the compound just described and an isomeric hydrocarbon.

Anal. Calcd. for $C_{34}H_{46}$: C, 89.80; H, 10.20; mol. wt. 454.4. Found: C, 89.84; H, 10.44; mol. wt. (Rast.), 436.

The yellow oil which was obtained from the original alcoholic solution was distilled under reduced pressure. The first fraction (2.1 g.) boiled at 83–85° (1 mm.); n^{20}_{D} 1.5090 and proved to be the allene 2,2,6,6-tetramethyl-3-phenyl-3,4-heptadiene.

Anal. Calcd. for $C_{17}H_{24}$: C, 89.40; H, 10.60. Found: C, 89.70; H, 10.44.

The second fraction (4.4 g.) boiled at 190–198° (1 mm.) and on long standing a few crystals separated. Analysis showed it to be a mixture of the two hydrocarbons of the composition $C_{34}H_{46}$ which had been obtained from the solid fraction.

In some preliminary experiments the bromide was treated with 40% sodium amalgam and to this mixture tetramethylethylene bromide was added. The same mixture of hydrocarbons was produced as was obtained in the

---

(15) Conant and Blatt, THIS JOURNAL, **50**, 556 (1928).

(16) Richard, *Ann. chim.*, [8] **21**, 360 (1910).

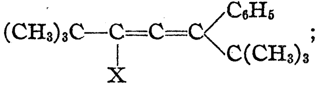
experiment described above. Hence the tetramethylethylene bromide apparently was not concerned in the reaction.

Action of Other Metals on the Bromide.—Silver and copper had no effect on solutions of the bromide. Lithium reacted with an ether solution of the bromide to give the same products that were obtained by the action of sodium amalgam. Reduction of the bromide with zinc dust in alcohol also gave the same mixture of hydrocarbons.

Properties of the Hydrocarbons $C_{34}H_{46}$.—Neither the pure hydrocarbon (m. p. 147–148°) nor the mixture (m. p. 115–125°) showed any sign of cleavage with alkali metals. Neither hydrocarbon could be converted to the other isomer by the action of heat. Neither hydrocarbon showed the property of absorbing oxygen. Both products showed signs of slow oxidation when heated in boiling xylene in the air, but no definite products were isolated. Attempts to ozonize these hydrocarbons gave only tarry products similar to the products previously obtained by the ozonization of other rearranged polyynes.

Summary

1. The Grignard reagent prepared from phenyl-*t*-butyl-*t*-butylethynylbromomethane reacts with water, methyl chlorocarbonate and carbon dioxide to give allene derivatives of the type



$$(CH_3)_3C{-}C(X){=}C{=}C(C_6H_5)C(CH_3)_3$$

; where X represents the group introduced into the organic molecule by the reaction.

2. Phenyl-*t*-butyl-*t*-butylethynylbromo-methane reacts with 40% sodium amalgam but does not give a stable sodium alkyl. Instead some of the bromide is reduced to the allene and some of it is coupled to give two isomeric hydrocarbons of the composition $C_{34}H_{46}$ which are thought to be diallenic hydrocarbons.

The Action of Sulfuric Acid on Butanol-2[1]

BY NATHAN L. DRAKE AND FLETCHER P. VEITCH, JR.

In continuation of our study of the conversion of alcohols to higher olefins by acid catalysts, we have examined the effect of sulfuric acid on butanol-2.

When treated with 75% sulfuric acid under conditions which were found to be most favorable for converting methylisopropylcarbinol into a mixture of decenes,[2] butanol-2 yielded no octene. It was likewise impossible to obtain appreciable yields of octene by use, at atmospheric pressure, of any concentration of acid from 50 to 100%, although time of heating was varied from twenty minutes to forty-eight hours, and reaction temperature from 25 to 100°. Acid of higher than 90% concentration caused the formation of a quantity of high boiling material, probably a mixture of substances of the composition $(C_4H_8)_x$ where x is greater than 2.

The failure to obtain any octene in the experiments cited is unquestionably due to the fact that at the temperatures investigated the formation of butene takes place more readily than does its polymerization, with the consequence that the butene produced escapes before it has had the opportunity to polymerize.

It seemed logical, therefore, to study the effect of operating in a closed system, and preliminary experiments demonstrated that if the butene formed was not allowed to escape, but held in contact with the acid, slow formation of octene took place. Various conditions for effecting the polymerization under pressure were studied, and it was found that with our particular apparatus (see experimental part) the best yield of octene was obtained by the action of 75% sulfuric acid at 80° for forty-eight hours.

The formation of higher polymers from the dimer takes place very readily; distillation of the octene in the presence of a very small quantity of acid results in the formation of substances of higher molecular weight.

A quantity (2.5 kg.) of product having a boiling range which would include any octenes formed, (110–125°) was prepared and subjected to fractional distillation, from which it became apparent that there were at least two chemical individuals present.

Ozonolysis of several fractions of nearly constant refractive index yielded acetaldehyde and methyl *s*-butyl ketone. From these facts it became apparent that the octene present in the fractions ozonized was 3,4-dimethylhexene-2.

---

[1] From the Ph.D. dissertation of Fletcher P. Veitch, Jr.

[2] Drake, Kline and Rose, THIS JOURNAL, **56**, 2076 (1934).

When a quantity of a higher boiling fraction was subjected to ozonolysis, it was found that only a very small quantity of unsaturated material was present. This unsaturated material (3,4-dimethylhexene-2) was removed by ozonolysis, and the resulting substance subjected to fractional distillation. The physical properties of the product indicated that it was di-*s*-butyl ether. Further investigation left no doubt as to the identity of the ether.

Exploratory ozonolyses of various other fractions failed to yield any evidence of the presence of any unsaturated substance other than 3,4-dimethylhexene-2.

Experimental

Apparatus and Method.—A lead-lined, steel autoclave of about four liters capacity was used. The desired temperature was maintained by means of an electrically heated water jacket controlled by a thermostat. Because of mechanical difficulties it was impossible to stir the charge. The temperature of the reaction mixture was determined by means of a thermometer located in a well which extended some distance below the surface of the charge.

Sixteen hundred and sixty grams of 75% sulfuric acid and 800 g. of *s*-butyl alcohol were heated at 80° for forty-eight hours. These conditions had been found to give the best yield of product of the desired boiling range. The autoclave was then allowed to cool, opened and the hydrocarbon layer siphoned off. A considerable quantity of butene escaped when the autoclave was opened and during the purification of the product. After treatment to remove the acid and water the product was distilled through a short column and the fraction from 110 to 125° (188 g.) collected for investigation as described below. An additional 100 g. of distillate boiling above 125° was also collected.

Purification and Fractionation of Reaction Products.—Two and a half kilograms of material (boiling range 110–125°), prepared from 6 kg. of *s*-butyl alcohol, was refluxed over sodium for fifty hours; the mixture was distilled from the sodium and 2 kg. of distillate was collected between 116 and 125°. A careful fractionation[3] of this mixture yielded 32 fractions of approximately 50 ml. each and a residue of 300 ml. The total volumes, b. p. (barometer varied from 751 mm. to 762 mm.) and $n^{25}\text{D}$ were as follows: Nos. 1–6, 355 ml., to 114.5°, 1.4065–1.4145; Nos. 7–14, 468 ml., to 116.6°, 1.4152 to 1.4156; Nos. 15–23, 560 ml., to 121.6°, 1.4142 to 1.4017; Nos. 24–32, 496 ml., to 122.5°, 1.3992–1.3931; residue, 300 ml., above 122.5°, 1.4118.

Ozonolysis of Fractions 7–14.—These fractions were ozonized in portions of 56 g. each dissolved in 180 ml. of ethyl acetate. The ozonizer furnished ozone at the rate of 0.03 to 0.04 mole/hr. when oxygen was supplied at the rate of 16.3 liters/hour; the temperature of the olefin was maintained between −15 and −25°. Only the amount of ozone theoretically required was supplied. The ozonide was decomposed[4] without removal of the solvent. The water layer from the decomposed ozonide gave a strong aldehyde reaction with fuchsin reagent, but a negative test for formaldehyde using resorcinol. The presence of acetaldehyde was demonstrated by the formation of a *p*-nitrophenylhydrazone which showed no depression of melting point when mixed with the *p*-nitrophenylhydrazone of acetaldehyde. The ethyl acetate layer was dried over anhydrous sodium sulfate and fractionated through a 50-cm. Widmer column to remove the ethyl acetate. The residue (250 ml.) was then subjected to careful fractionation in a Podbielniak[5] column. A considerable quantity of acetic acid was found in all fractions of the distillate, but after the removal of this acid by treatment with alkali, approximately 100 g. of a substance (A) boiling at 116.2° at 758 mm. was obtained.

Identification of A as Methyl *s*-Butyl Ketone.—(A) gave no color with Schiff's reagent, but gave a positive haloform reaction when tested in dioxane solution.[6] It was apparent, therefore, that (A) was a methyl ketone. The physical properties of (A) correspond very closely with those recorded[7] for methyl *s*-butyl ketone, and differ considerably from those of the other possible six carbon methyl ketones: for (A) b. p. 116.2°, d^{25} 0.812, $n^{18}\text{D}$ 1.4000; for methyl *s*-butyl ketone b. p. 117.8, d^{20} 0.815, $n^{20}\text{D}$ 1.3990.

Product (A) yielded a 2,4-dinitrophenylhydrazone which melted at 71.2°. No depression of melting point was observed when this product was melted mixed with the 2,4-dinitrophenylhydrazone prepared from pure methyl *s*-butyl ketone obtained synthetically via an acetoacetic ester synthesis.

Conversion of (A) to Methylethylacetic Acid.—In order to confirm our belief in the identity of (A) and methyl *s*-butyl ketone, (A) was degraded in the usual way by alkaline hypobromite to an acid whose amide agreed in melting point (110.9°) with that described for the amide of methylethylacetic acid, and whose *p*-phenylphenacyl ester possessed the composition required; 10 g. of (A) yielded 7 g. of acid.

The 2,4-Dinitrophenylhydrazone of (A).—This product which is not described in the literature melts at 71.2°.

Anal. Calcd. for $C_{12}H_{16}N_4O_4$: C, 51.42; H, 5.71. Found: C, 51.31, 51.56; H, 5.60, 5.86.

The *p*-Phenylphenacyl Ester of Methylethylacetic Acid.—The ester, prepared in the usual way, melts at 70.6°.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.03; H, 6.75. Found: C, 76.76, 76.98; H, 6.93, 6.83.

Purification of Fractions 24–31.—Five hundred milliliters of material representing fractions 24–31 inclusive was ozonized until no more ozone was absorbed. After decomposition of the ozonide the water-insoluble layer was dried and distilled; 435 ml. was distilled and 395 ml. of distillate (B) whose $n^{25}\text{D}$ varied from 1.3927 to 1.3930 was

---

[3] We wish to express our thanks to S. Schicktanz and the others of the Petroleum Research Section of the Bureau of Standards for their valuable assistance in fractionating this mixture; see Schicktanz [*Bur. Standards J. Research*, **11**, 89 (1933)] for a description of the still used; *cf.* also *ibid.*, **7**, 851 (1931).

[4] Whitmore and Church, THIS JOURNAL, **54**, 3710 (1932).

[5] Podbielniak, *Ind. Eng. Chem.*, *Anal. Ed.*, **5**, 119 (1933).

[6] Fuson, *Chem. Rev.*, **15**, 775 (1934).

[7] "Int. Crit. Tables," Vol. I, pp. 203, 276; Beilstein, 4th Ed. Julius Springer, Berlin, 1918, Vol. I, p. 694.

obtained. The density of the distillate was 0.759 at 25° and its boiling point 121° at 760 mm.

Anal. Calcd. for $C_8H_{18}O$: C, 73.84; H, 13.84; mol. wt. 130. Found: C, 73.86; H, 13.84; mol. wt. 126.

From the analytical data and the fact that (B) did not react with sodium, it seemed likely that (B) was a dibutyl ether.

Conversion of (B) to *s*-Butyl Bromide.—Forty grams of (B) was saturated with hydrogen bromide and heated under reflux for three hours. The product was washed with water and saturated sodium bicarbonate solution, dried and distilled; 68.5 g. of a bromide with the following physical properties was obtained (81.2%): b. p. 90–91° at 757 mm.; $n^{25}\text{D}$ 1.4341; d^{25} 1.250. From these physical constants[8] it is apparent that the bromide formed is probably *s*-butyl bromide.[8]

This conclusion is strengthened by a comparison of densities and boiling points of the three known di-butyl ethers with those of (B).[9]

Preparation of the 3,5-Dinitrobenzoate of *s*-Butyl Alcohol from (B).—One milliliter of (B) was mixed with 0.5 g. of 3,5-dinitrobenzoyl chloride and 0.15 g. of anhydrous zinc chloride and refluxed for one hour. After purification 0.1 g. of ester melting at 75.5° was obtained. This dinitrobenzoate was shown by the method of mixed melting points to be identical with the ester obtained directly from *s*-butyl alcohol and 3,5-dinitrobenzoyl chloride.

Discussion

The theory of the mechanism of the polymerization of olefins by acid catalysts suggested by Whitmore[10] would predict the formation of 3,4-dimethylhexene-2 and 3,4-dimethylhexene-1 from *s*-butyl alcohol under the conditions studied, with the latter olefin present in smaller quantity than the former. We have been unable to detect the presence of formaldehyde after ozonization of any of the fractions of the reaction product, and must conclude that 3,4-dimethylhexene-1 is not formed under the condition studied.

The theory of the mechanism of polymerization of olefins suggested by Kline[11] would likewise lead to the prediction of two products only one of which was found. In this case, however, the product expected in greatest abundance, *viz.*, 4,5-dimethylhexene-2 is not the one actually produced.

Summary

1. The formation of 3,4-dimethylhexene-2 and di-*s*-butyl ether by the action of 75% sulfuric acid on *s*-butyl alcohol at 80° under pressure has been demonstrated.

2. The theory of the mechanism of polymerization by acids suggested by Whitmore explains the observed facts better than that of Kline.

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF ST. JOHN'S UNIVERSITY AND WASHINGTON SQUARE COLLEGE OF NEW YORK UNIVERSITY]

Studies in the Synthesis of Certain Alkyl and Aryl Cryptophenols[1]

BY MARTIN E. MCGREAL AND JOSEPH B. NIEDERL

Introduction

Since *p*-*t*-octylphenol (*p*-(2,2,4,4-tetramethyl)-butylphenol)[2] has a rather high phenol coefficient (150), it was one of the objects of this investigation to prepare and study the yet unreported *p*-*t*-hexyl and *p*-*t*-heptylphenols. These phenols were prepared by condensing dimethylisopropylcarbinol (I) (b. p. 116–120°) and dimethyl-*n*-butylcarbinol (II) (b. p. 130–130.5°) with phenol in the presence of zinc chloride, utilizing the method of Liebmann, Fischer and Gruetzner.[3]

The condensation of diisobutyl alcohol (2,2,4-trimethylpentanol-4) (b. p. 145–149°) with phenol under identical reaction conditions, however, did not yield the expected *p*-*t*-octylphenol, but *p*-*t*-butylphenol as the main reaction product.[4]

The second object was to investigate the applicability of these condensations to primary, secondary and tertiary aromatic alcohols, and the following carbinols were therefore studied: phenyl (VI), phenylmethyl (VII), benzyl (VII), phenylmethylethyl (VIII) and phenylmethylisopropyl (IX). The last was prepared by the action of isopropylmagnesium bromide on acetophenone.[5]

The condensation products with phenol (VIII

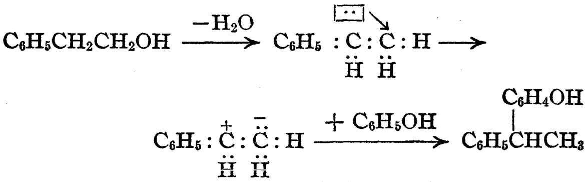
and IX) of the last two compounds were also prepared by the addition of phenol to β-phenyl-β-butylene and phenyl-β-amylene[5,6] using the method of Niederl and co-workers.[7]

In the condensation of β-phenylethyl alcohol (benzylcarbinol) with phenol, apparently simultaneous rearrangement took place as the end-product does not appear to be the expected 4-hydroxydibenzyl but the *p*-(α-phenylethyl) phenol (VII).

Interpretation of this rearrangement phenomenon seems to involve the electronic postulations of Whitmore, Kline and Drake and others[8] and would indicate that dehydration of the β-phenylethyl alcohol precedes the addition of the phenol. The dehydration would activate the alpha carbon of the intermediary styrene as follows.



$$C_6H_5CH_2CH_2OH \xrightarrow{-H_2O} C_6H_5 : \underset{H}{\underset{\cdot\cdot}{C}} : \underset{H}{\underset{\cdot\cdot}{\overset{\boxed{\cdot\cdot}\searrow}{C}}} : H \longrightarrow$$

$$C_6H_5 : \underset{H}{\underset{\cdot\cdot}{\overset{+}{C}}} : \underset{H}{\underset{\cdot\cdot}{\overset{-}{\ddot{C}}}} : H \xrightarrow{+\ C_6H_5OH} C_6H_5\overset{C_6H_4OH}{\overset{|}{C}}HCH_3$$

1-phenyl-1-(4-hydroxy)-phenylethane

Under the influence of the cationoid condensing agent it can be assumed that on account of incipient ionization of the phenol, or the phenol-condensing agent addition compound, the positive *p*-hydrogen ion would have to add on to the negative primary carbon atom, consequently addition of the negatively charged phenol ion would then have to take place at the secondary carbon atom with the incomplete electron octet thus yielding the above 1-phenyl-1-(4-hydroxy)-phenylethane. The repeatedly observed rearrangements in the butyl series to *t*-butyl compounds may be interpreted in an analogous manner.[3a,9]

The third object in these studies was to extend these condensations to the alkylated cyclohexanol series. Here positive condensations were observed in all the cases investigated. The condensation system of the three isomeric methylcyclohexanols, the hydrogenation products of the three cresols (1-methylcyclohexanol-2 (III), 1-methylcyclohexanol-3 (IV), 1-methylcyclohexanol-4 (V)) proved to be positive in all instances and the corresponding (methylcyclohexyl)-phenols (III, IV and V) were obtained, with the para substituted phenol forming the major reaction product.

An exception again was the condensation of the 4-*t*-octylcyclohexanol-1 (prepared by catalytic hydrogenation of *p*-*t*-octylphenol). In this case, not the expected *p*-(4-*t*-octyl)-cyclohexylphenol, but *p*-*t*-butylphenol again appeared to be the main reaction product, an observation which is entirely in harmony with the experimental findings of Gilman and Burtner[9c] who observed the formation of the *t*-butyl group in their alkylation reactions in the furan series not only involving a butyl, but also an amyl, a hexyl and even an octadecyl radical.

Experimental Part

The molar mixture of the alcohol and of phenol was first warmed to about 150° and to this preheated mixture 1.5 moles of finely powdered, anhydrous zinc chloride was added and the whole refluxed for several hours at 180° (two to ten hours depending upon the reactivity of the alcohol). The reaction mixture, while still warm, was then poured into warm water (80°) acidified with hydrochloric acid. Slowly the phenolic condensation products separated and were then dissolved in toluene following the procedure of Behaghel and Freiensehner.[10] This toluene extract was shaken out first with acidified water and then repeatedly with Claisen solution (50% aqueous potassium hydroxide solution mixed with an equal volume of methyl alcohol).[11] The combined Claisen solution extracts, containing the phenolic condensation products, were washed once with toluene and then acidified with dilute hydrochloric acid (10%). The phenolic condensation products thus separated were then dissolved in ether. This ether extract was dried over calcium chloride and allowed to stand until a clear solution resulted. After removal of the ether by distillation, the residue was repeatedly fractionated under diminished pressure. The solid condensation products were recrystallized from diisobutylene; yield 40–80%.

The above phenol coefficients are the average of four to five determinations employing the standard phenol coefficient technique (30% alcoholic

solutions at 37°) using *Staphylococcus aureus*. The authors desire to thank Dr. Wm. A. Feirer of Sharp and Dohme, Philadelphia, for performing these determinations.

Summary

1. The Liebmann method of condensing alcohols with phenols in the presence of zinc chloride has been extended to include *t*-hexyl, *t*-heptyl and *t*-octyl alcohols, giving in the first two cases the corresponding substituted phenols, while *p*-*t*-butylphenol was obtained from 2,2,4-trimethylpentanol-4.

2. Application of the same method to aromatic alcohols led to positive results in all cases, encountering a rearrangement in the case of β-phenylethyl alcohol.

3. Methylcyclohexanols also could be condensed with phenols by this method, with the *t*-octylcyclohexanol again giving *p*-*t*-butylphenol, instead of the expected *t*-octylcyclohexylphenol.

Some Alkyl Derivatives of Certain Aryl Substituted Thiazolidones[1]

BY JOHN A. DAVIS AND F. B. DAINS

In a recent paper by Eberly and Dains[2] it was shown that the alkylation of the mono-aryl thiazolidones,  $\overset{1}{S}—\overset{2}{C}(NHR)=\overset{3}{N}—\overset{4}{C}O—\overset{5}{C}H_2$, gave two isomeric products, one of the 2-aryl-2-alkylthiazolidone and the other the 2-aryl-3-alkylthiazolidone; results not in harmony with the structure assigned by Beckurts and Frerich,[3] *viz.*, 2-alkyl-3-arylthiazolidone. This paper is a further study of nine aryl substituted thiazolidones in order to determine the structure of the alkylation products and to determine the effect both of the aryl groups and of different alkyl halides on the amount of the two possible isomers.

A. Two methods were used in preparing the thiazolidones.

(1) **From $RNHCOCH_2Cl$ and KSCN.**—Equal molecular quantities of the two were dissolved in alcohol and refluxed for one to five hours. In certain cases this method gave a tarry product and a poor yield.

---

[1] From a thesis presented to the Graduate School of the University of Kansas by John A. Davis in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Eberly and Dains, THIS JOURNAL, **55**, 3859 (1933).

[3] Beckurts and Frerich, *Arch. Pharm.*, **253**, 233–265 (1915).

(2) **From the Mono-aryl Thiourea.**—This when refluxed in alcohol for one to three hours with equal molecular quantities of pyridine and ethyl chloroacetate usually gave a product free from tar.

B. **Preparation of the Sodium Salt.**—The thiazolidones were soluble in hot 5% sodium hydroxide and on cooling the sodium salts crystallized from the solution.

C. **Alkylation** occurred when an alcohol solution of the sodium salt was heated with an alkyl halide. The 2-alkyl thiazolidone was separated from the 3-alkyl derivatives by the solubility of the former in dilute hydrochloric acid.

Hydrolysis of these alkyl substituted thiazolidones usually resulted in complete rupture of the ring, but it has been found that the 5-benzal derivatives are much more stable, hydrolysis usually yielding 5-benzal-2,4-thiazoledione or 5-benzal-3-alkyl-2,4-thiazoledione, thus affording a convenient method of determining the nature of the group at 2. Hydrolysis was carried out by boiling the benzal derivative in alcoholic hydrochloric acid for five to twenty-five hours.

The benzal derivatives were prepared by a few minutes of heating of a saturated alcohol solution of the thiazolidone and benzaldehyde with a trace of alkali.

Experimental

Following the general methods outlined above, thiazolidones were prepared from the following amines: *o*- and *p*-phenetidines, *o*-, *m*- and *p*-anisidines, pseudocumidine, 2-amino-*p*-cymene, 2,4-diiodoaniline and *p*-iodoaniline. Each of these was then ethylated by heating an alcohol solution of the corresponding sodium salt with ethyl iodide for two or three hours. The alcohol and excess ethyl iodide were then removed with steam and the oily residue dissolved in ether and repeatedly extracted with dilute hydrochloric acid (5–10%). Neutralization of the acid solution caused the separation of the 2-alkyl-2-aryl compound, while evaporation of the ether solution yielded the isomeric 2-aryl-3-alkyl derivative. The latter derivative was also synthesized in each case by two to three hours of heating of an alcohol solution of equal molecular quantities of ethyl chloroacetate, pyridine and the corresponding N-alkyl-N′-aryl thiourea. Ethylation in each case, with the exception of the thiazolidones from pseudocumidine, 2-amino-*p*-cymene and 2,4-diiodoaniline produced two isomeric products: one the 2-ethyl-2-aryl-4-thiazolidone, and the other the 2-aryl-3-ethyl compound. With pseudocumidine and 2-amino-*p*-cymene only the 2-alkyl-2-aryl derivatives were isolated, while with 2,4-diiodoaniline, only the 2-aryl-3-ethyl derivative was isolated.

The following table gives the percentage yields of the isomers obtained on ethylation of the thiazolidones.

Thiazolidone from	% Yield of 2-ethyl-2-aryl compound	% Yield of 3-ethyl-2-aryl compound
o-Phenetidine	68	1
p-Phenetidine	50	1
o-Anisidine	65	0.6
m-Anisidine	46	6
p-Anisidine	55	1
Pseudocumidine	56	0.0
2-Amino-*p*-cymene	65	0.0
p-Iodoaniline	74	16
2,4-Diiodoaniline	0	85

The 2-ethyl-2-aryl compounds obtained from *o*- and *p*-anisidine, *p*-phenetidine and pseudocumidine were identical with the corresponding compounds obtained by Beckurts and Frerich[3] and to which they assigned the erroneous structure, 2-ethyl-imino-3-aryl-4-thiazolidones. However, Beckurts and Frerich in their investigation had overlooked the occurrence of the 2-aryl-3-ethyl isomers.

The sodium salt of the thiazolidone from *p*-iodoaniline was treated with various alkyl halides and the following percentage yields of isomers were obtained.

Alkyl halide	% Yield of 2-alkyl-2-aryl compound	% Yield of 3-alkyl-2-aryl compound
Methyl iodide	60	7.5
Ethyl iodide	74	16
Amyl iodide	34	4
Benzyl chloride	60	4

Proof of structure was obtained in each case by acid hydrolysis of the corresponding 5-benzal derivative using a mixture of equal volumes of alcohol and concentrated hydrochloric acid. The 2-alkyl-2-aryl compounds gave 5-benzal-2,4-thiazoledione[4] and a secondary amine while the 2-aryl-3-alkyl compounds yielded a 5-benzal-3-alkyl-2,4-thiazoledione and the aryl amine. The thiazolediones separated during hydrolysis from the hot solutions, while the amines were obtained by neutralization of the acid after removal of the alcohol.

---

(4) Ref. 2, p. 3861.

The thiazolidones were also found to condense with *p*-nitrosodimethylaniline in the same manner as with benzaldehyde. A saturated alcohol solution of 2-ethyl-2-*p*-iodophenylamino-4-thiazolidone when heated with *p*-nitrosodimethylaniline and a trace of alkali gave a dark yellow crys-

(5) Prepared from ethylamine and the corresponding substituted phenyl isothiocyanate.

(6) From ethyl isothiocyanate and pseudocumidine.

(7) From methyl isothiocyanate and pseudocumidine.

(8) Prepared by evaporation to dryness of a water solution of aminocymene hydrochloride and potassium thiocyanate.

(9) From ethyl isothiocyanate and 2,4-diiodoaniline.

(10) From methylamine and *p*-iodophenyl isothiocyanate.

(11) From amyl isothiocyanate and *p*-iodoaniline.

(12) From benzyl isothiocyanate and *p*-iodoaniline.

(13) Best prepared from the corresponding mono-thiourea and ethyl chloroacetate.

(14) Compound XIX first separated as an oil so the corresponding methyl derivative was prepared from IV for comparison.

(15) Best prepared from mono-*p*-cymyl thiourea and ethyl chloroacetate. Attempts to prepare this compound from ω-chloroacetoamino-*p*-cymene and chloroacetyl chloride led to the formation of a very tarry product. ω-Chloroacetoamino-*p*-cymene was prepared by treating an acetone solution of 2-amino-*p*-cymene with equal molecular quantities of chloroacetyl chloride and pyridine, m. p. 85°. *Anal.* Calcd. for $C_{12}H_{16}ClON$: N, 6.21. Found: N, 6.16.

(16) Chloroacetyl chloride added to an acetone solution of 2,4-diiodoaniline and pyridine gave 2,4-diiodo-ω-chloroacetanilide, m. p. 153°. *Anal.* Calcd. for $C_8H_6ClI_2ON$: N, 3.33. Found: N, 3.26. The latter when dissolved in alcohol and heated with KSCN yielded XXIX.

(17) Prepared from N-amyl-N′-phenyl thiourea and ethyl chloroacetate.

(18) Prepared from N-benzyl-N′-phenyl thiourea and ethyl chloroacetate.

Summary

The alkylation of nine different aryl substituted thiazolidones has been studied. Certain of the compounds described by Beckurts and Frerich as 2-alkyl-3-aryl thiazolidones were shown, in fact, to be 2-alkyl-2-aryl thiazolidones, thus confirming the work of Eberly and Dains.

In most cases it was found that alkylation produced two isomeric alkyl derivatives: one, the 2-alkyl-2-aryl thiazolidone and the other the 2-aryl-3-alkyl compound. The effect of the aryl group on the amounts of isomers obtained was noted as was also the effect of various alkyl halides.

The Development of the Air-Driven Spinning Top as Transparent Ultracentrifuge

BY JAMES W. MCBAIN AND CARROLL M. O'SULLIVAN, S. J.

An ultracentrifuge is any centrifuge of low or high power in which convection does not occur, and in which it is possible to measure any redistribution of the contents.[1] Up to last year, Svedberg alone had developed such convectionless ultracentrifuges. Further, the contents could be submitted to optical observation while in motion. Svedberg and his collaborators have extended their application from the largest respiratory proteins down to the smallest molecules in aqueous solution. To observe sedimentation equilibrium with the former, a very low power is obligatory since sedimentation outward must be exactly balanced by diffusion inward. For sedimentation equilibrium of ordinary molecules, powers ranging from 100,000 to 1,000,000 times gravity are essential. Still higher powers will be required for observing their sedimentation velocity.[2]

The remarkable results obtained at the Upsala laboratories in the last few years have made abundantly evident the important place the ultracentrifuge now occupies in chemical research. Unfortunately, the enormous cost of these elaborate high-powered machines has, up to now, necessarily confined them to one laboratory. The urgent need of a far less expensive type of ultracentrifuge, which would yet completely duplicate the achievements of those of Svedberg, impelled us to attempt during the past four years the task of developing the air-driven spinning top of Henriot and Huguenard[3] as a quantitative ultracentrifuge. One of us has elsewhere called attention to the almost unlimited possibilities in applying their original top to the study of systems which are inherently convectionless, such as jellies, curds and liquid crystals.

The essential features of the air-driven spinning top itself have already been sufficiently described in the literature.[3,4,5,6] The modifications that we have introduced in order to convert it into an ultracentrifuge and the auxiliary apparatus that we have used in the problem can all be discussed under seven heads: Stability, Speed, Transparent Rotor and Stator, Cell, Temperature Control, Light Source and Optical System.

Stability

Any form of vibration in an ultracentrifuge will tend to cause convection currents in the liquid under examination and make sedimentation difficult or impossible, according to the magnitude of the convection in relation to the strength of the restoring field. We found that the instability of the spinning top is of three kinds: precession, vertical vibration and horizontal wobble.

Precession is caused by an unlevel stator or by uneven propulsion (*e. g.*, a plugged air-port or nozzle), and is easily avoided by keeping the stator carefully leveled and by building into the manifold of the stator a very fine mesh strainer. For a stator with air-ports made with a number 73 drill (0.024″), we found a 100 mesh strainer works very well.

Vertical vibration has been treated fully by Girard and Chukri.[5] At high speeds the vacuum under the rotor becomes great enough to overcome the supporting effect of the exhausting air and cause the rotor momentarily to touch the stator. The phenomenon is periodic and produces a loud note of rather low frequency. It is eliminated by simply admitting a little atmospheric air to the space between the rotor and the stator through a valve connected to the apex of the cone of the stator. The method of adjustment is to open the valve rather too much at first, then, when the rotor has attained the desired speed, to close it slowly until the vibration just begins to be heard (or felt in the stator with the hand), at which point the valve is opened again very slightly. This adjustable arrangement is preferable to the uncontrolled opening lately adopted by Beams and his co-workers[4] because the admission of more air than is actually needed slightly reduces the speed and noticeably increases the horizontal wobble.

We have found it impossible to attach to the central air inlet a long tube of any description or a

short tube of soft rubber without causing excessive wobble. As will be described later, we have taken the air for the central air inlet out of the guard. The connecting tube is of glass, about 15 cm. long, and attached to the inlet by the shortest possible section of rubber tubing. The adjustment is made with a screw clamp on the tubing.

Horizontal wobble is the name we have given to that form of instability in which, while the axis of rotation remains perfectly vertical, the whole rotor moves horizontally in spasmodic jerks. The phenomenon is not periodic. It has two causes. The first results from the fact that the rotor, like any spinning top, rotates not on its center of figure but on its center of gravity. Since these centers do not, in general, coincide, the periphery of the rotor necessarily revolves eccentrically. If the stator is rigidly mounted, this eccentricity becomes cumulative, causing the rotor finally to touch the stator and leap out. If the stator is flexibly mounted it is able to follow the eccentric running of the rotor and the danger of the rotor's jumping out is eliminated. However, the customary slightly flexible stator mounting still leaves another horizontal wobble of smaller amplitude and higher frequency. We found that greatly increasing the flexibility of the stator mounting and reducing the mass of the stator and manifold as much as possible reduced the wobble to about 0.02 or 0.04 mm. (as measured with a low power microscope) a few times a second. The second cause of the horizontal wobble is turbulence in the exhausting air, which becomes quite noticeable when higher pressures and greater volumes of air are used. The turbulence may be eliminated by mounting on the stator (not on the guard) three vertical and radial metal strips which we have called the "baffle strips." Nearly filling the space between the walls of the guard and the sides of the rotor, they are adjusted to clear the sides of the rotor by about 1 mm. As long as they do not extend within the "boundary layer" of air carried by the rotor, which is a little less than 1 mm. thick, their effect on the speed of the rotor is negligible. For a rotor 37 mm. in diameter running in a stator having 12 air-ports made with a number 73 drill, the effect of the baffle strips on the stability was to make the horizontal wobble wholly imperceptible under the microscope at 50 lb. air pressure, and about 0.01 mm. in amplitude at 100 lb. pressure. At still higher pressures the wobble is proportionally greater.

Speed

Measuring the Speed.—Our method of measuring the speed of the rotors is to adjust the note made by a calibrated beat-frequency oscillator to zero-beat with the note made by the running rotor. In order to prove that the note made by the running rotor is quantitatively the same as its number of revolutions per second, and also as an auxiliary method for doubtful cases, we employ the following procedure. The top surface of the rotor is painted black half way around; light from outdoors or from a direct current lamp (flash light) is reflected from the rotor into a photoelectric cell; the resulting pulsating electric current is amplified to audible proportions, the output being connected to the same head-phones to which is connected the output of the beat-frequency oscillator. The amplitudes of both notes can be adjusted to equality, making it easy to bring the two notes to coincidence to within 0.1 beat per second. If the black paint on the top of the rotor is blended out at its edges so that there is really one point of maximum blackness and one point of maximum brightness with regions of gradual change between, the current in the photoelectric cell approximates a sine wave more closely, harmonics are suppressed and it is comparatively easy to select the correct octave of the note of the beat-frequency oscillator. If the correct octave is still doubtful, a mechanical stroboscope used once will settle the doubt permanently, especially if the rotor is marked in one spot only.

Increasing the Speed.—Contrary to first expectations, one cannot achieve unlimited rotational speed with an air-driven spinning top of given diameter by indefinitely increasing the air pressure, because the velocity of air flowing through an orifice quickly approaches a limiting value. For a compressible fluid flowing through a frictionless orifice of ideal design, the relation between the downstream velocity and the upstream and downstream pressures is given by the equation[7,8,9,10,11]

$$u_2 = \sqrt{2gp_1v_1\,[1 - (p_2/p_1)^{k-1/k}]\;k/k - 1}$$

where u_2 = downstream velocity (upstream velocity is considered negligible), g = acceleration of gravity, k = ratio C_p/C_v for the gas in question, p_1 = the upstream pressure, p_2 = the downstream pressure and v_1 = the specific volume of the gas at the pressure p_1.

For dry air at 20° this equation reduces to

$$u_2 = 764\sqrt{1 - (p_2/p_1)^{0.288}} \text{ meters per second}$$

If we take p_2 = 0.967 atm. (1 kg./sq. cm.) this equation gives the curve of Fig. 1. The curve shows that it is scarcely economical to use more than 14 kg./sq. cm. (200 lb. per sq. in.). As a matter of fact, we seldom use more than 100 lb. per sq. in. because of the increase in wobble at higher pressures.

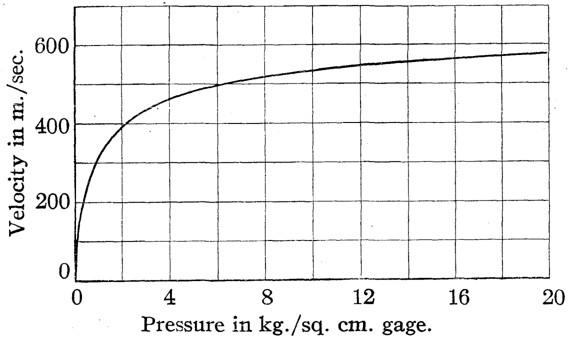

Fig. 1.—Theoretical velocity of air flowing through an ideal orifice as a function of the upstream pressure.

It will be noted from the above equations that the velocity of the air increases not only with increasing p_1 but also with decreasing p_2. We made one attempt to utilize this fact. An ordinary paper pill-box, larger in diameter than the rotor by about 4 mm., and having a hole cut in its bottom over which a glass disk was cemented to serve as a window, was inverted over a rotor while it was running and lightly fastened so that it could not turn. The box was pulled down to the top surface of the stator with great force by the escaping air until it was only a small fraction of a millimeter from it, indicating the establishment of a partial vacuum inside the box. Very low rotors ran about 8% faster inside the pill-box and with no observable instability under the microscope even at 100 lb. pressure. Higher rotors, even those only just high enough to take the lowest of our ultracentrifuge cells, refused to run at all. This, together with the fact that with all rotors there was a noticeable heating of the pill-box due to air friction, induced us temporarily to discontinue experimentation along this line.

The pressure, p_2, between the stator and the rotor can also be reduced and the velocity of the air through the air-ports correspondingly increased by increasing the ratio between the angle of the stator cone and the angle of the rotor cone. Unfortunately, this results in an increase in vertical vibration which can only be eliminated by permitting more air to enter through the central air inlet valve, which in turn increases horizontal wobble. We found the best values for these angles to be 100 to 102° for the rotor cone and 90° for the stator cone.

Since for a given pressure the velocity of the air through the air-ports is constant, it follows that the angular velocity of different rotors will be in inverse proportion to their diameters. For ease of experimentation we chose the comparatively large diameter of 37 mm.

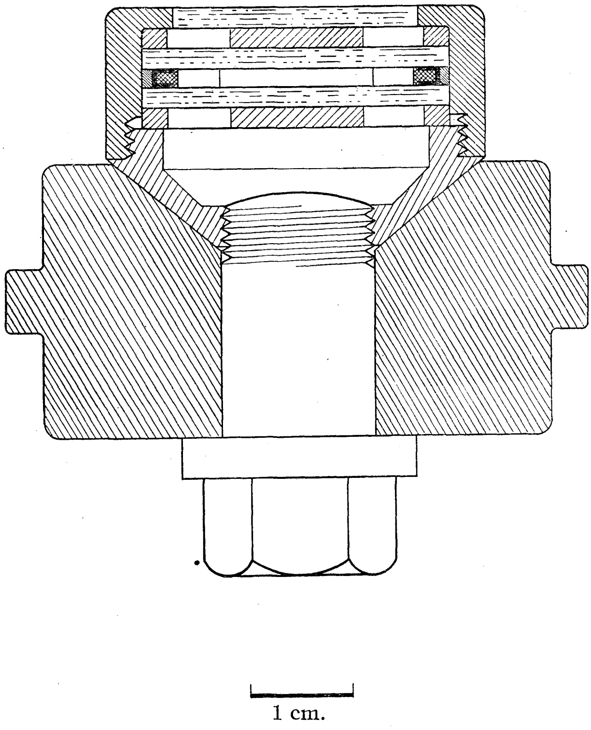

Fig. 2.—The first type of rotor described in the text (shown with the jig which is used to hold the cone of the rotor while the rotor is being assembled—a plumber's strap-wrench is used on the upper part).

Other factors in the design of the stator which affect the speed of the rotors are the total area of the cross sections of the air-ports (regulating the volume of air used), their shape and their orientation. Increasing beyond a certain point the volume of air used increases the horizontal wobble. We found that 12 air-ports 0.024″ in di-

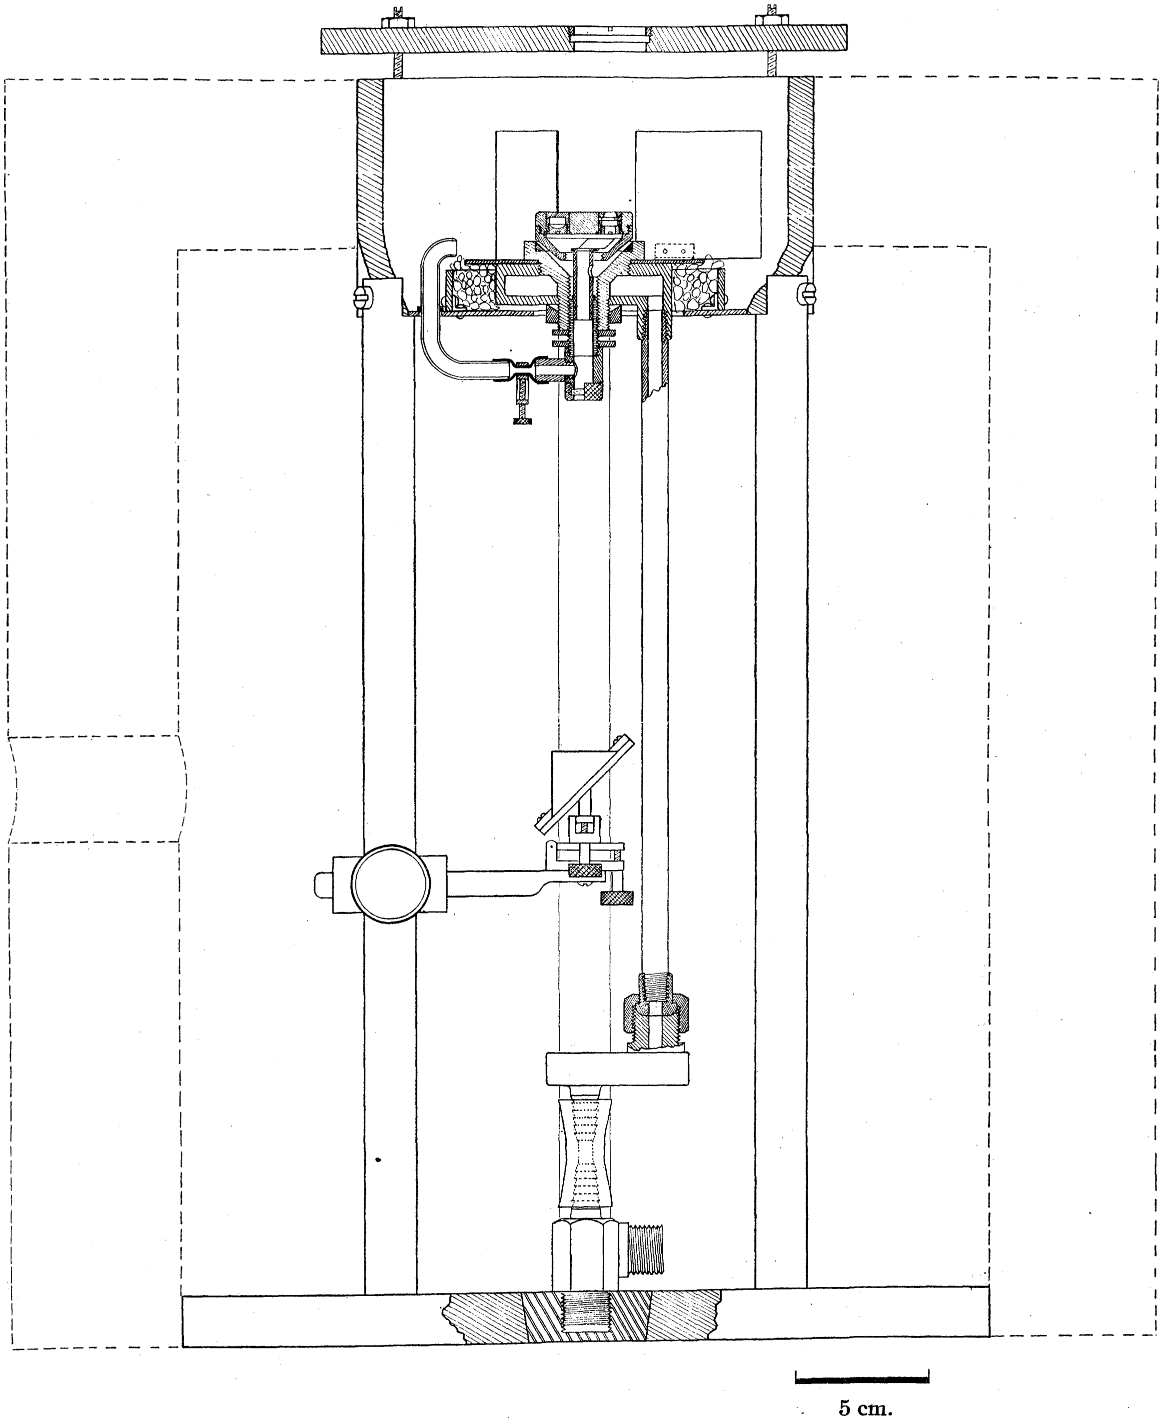

Fig. 3.—The complete assembly. The dashed lines indicate the position of the wool-filled insulating cover.

ameter (No. 73 drill) worked best for a 37-mm. stator.

Theoretically, the air-ports should be shaped like de Laval nozzles, their converging and diverging angles being calculated exactly for the actual conditions of operation. In practice we found that straight drill-hole nozzles, slightly beveled on the upstream side, gave the highest efficiency as far as speed was concerned. Assuming that the mean circle of impact on a 37-mm. rotor is 30 mm. in diameter and that the ratio of the peripheral velocity of the mean circle of impact

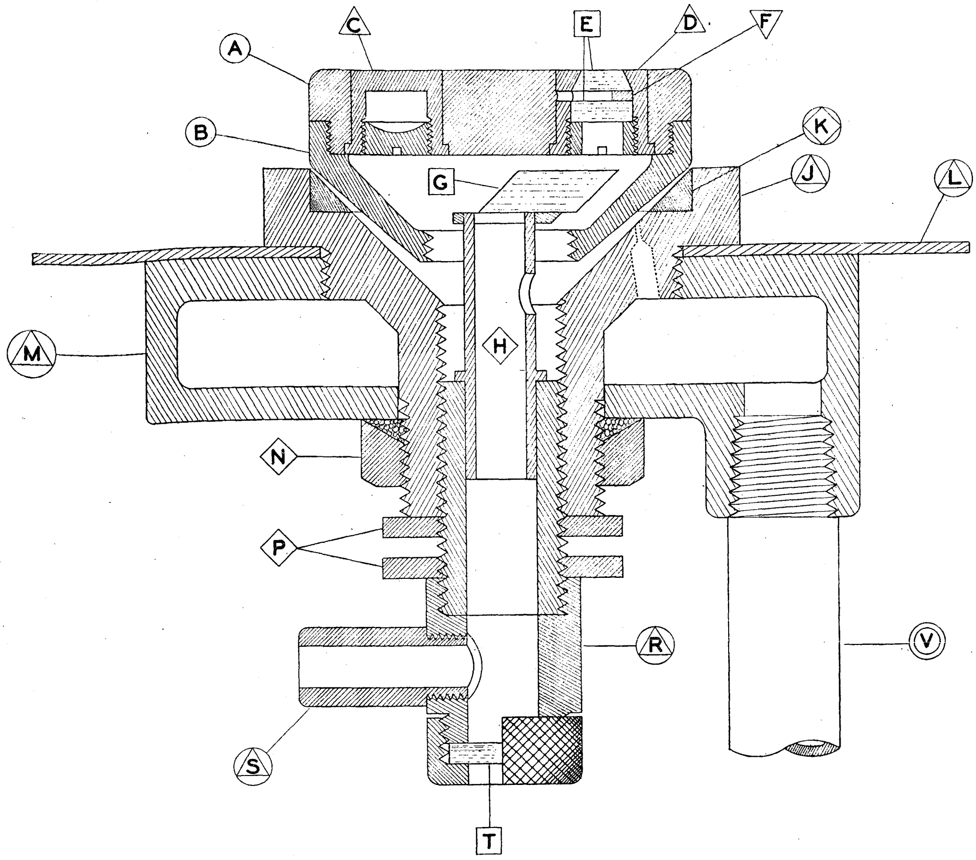

Fig. 4.—Details of rotor (second type described in text), stator, and periscope: A, cell-holder; B, rotor cone; C, dummy cell; D, cell; E, quartz disks; F, hard rubber separator, G, periscope prism; H, periscope tube; J, stator; K, bronze insert; L, disk to which baffle strips are fastened; M, manifold; N, packing nut; P, lock-nuts; R, holder for central air inlet and window; S, connection to central air inlet; T, window; V, high pressure supply tube. The symbols indicate the materials of construction: ○, Republic Steel Corporation's UMA 4, hardened and ground; △, Monel Metal; □, quartz; ▽, hard rubber; ◇, brass; ○△, duralumin (17ST); ⊙◇, bronze; ◎, aluminum.

to the velocity of the air is 1 to 2, the ratio of maximum energy transfer (this neglects the angle the air-jets make with the tangent plane), then a stator with straight drill-hole nozzles has an efficiency of 85%, whereas a stator with nozzles having a divergence of 3° beyond the throat had an efficiency of 71% and a stator with nozzles having a divergence of 6° had an efficiency of only 54%.

The optimum orientation of the air-ports was studied by Garman.[6] Their orientation can be described by two angles, the angle with the horizontal and the angle with a vertical plane through the center of the outlet of the air-port and the axis of the stator. In conformity with our experience, the first should be 35°. For the second we have adopted Garman's value of 65°.

A final and rather obvious factor influencing the speed of the rotors is their skin resistance. To reduce this to a minimum, the rotors must be made as low as possible, be free from anything like eccentric open holes or radial slots and must be highly polished. These features will be noted in the rotors to be described later.

The best material for the construction of the rotors is a high tensile strength alloy tool steel. We have finally adopted Republic Steel Corporation's UMA 4, a chrome–manganese alloy steel. If oil-quenched from 1525°F. and drawn at 600°F., it attains an ultimate tensile strength of 250,000 lb./sq. in. and a yield point of nearly 220,000 lb./sq. in. As the highest speed we have ever attained with a rotor as large as 37 mm. is 3000 r. p. s., and as the stress in a thin steel ring (the shape experiencing maximum stress under rotation) rotating at that speed is only about 130,000

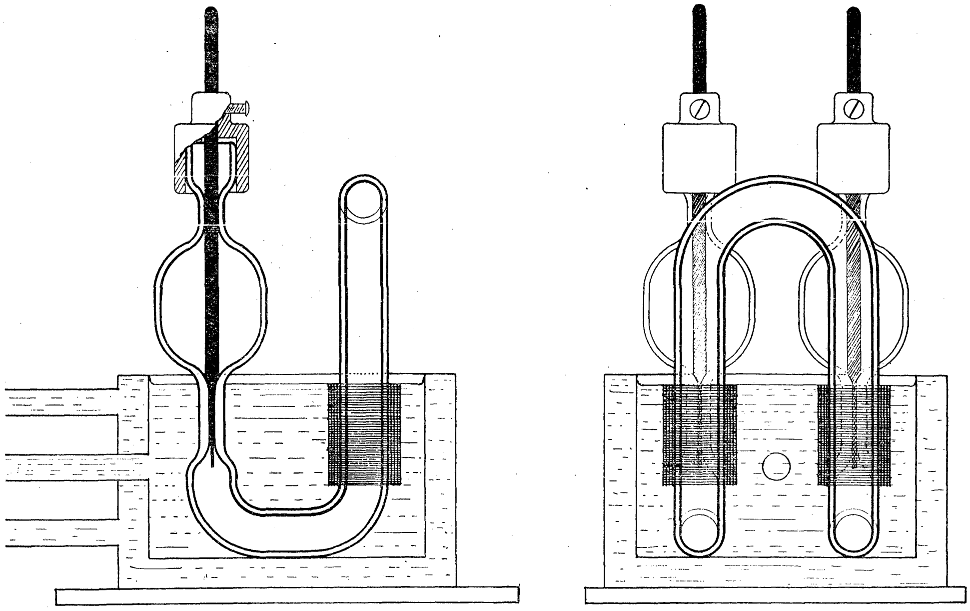

Fig. 5.—Modified Forbes quartz high pressure mercury arc.

lb./sq. in., it is better to draw the steel at 850°F. This gives a tensile strength of about 200,000 and a yield point of about 175,000 lb./sq. in. and an increased resistance to shock. Duralumin, despite the fact that it is nearly three times lighter than steel, compares unfavorably with the alloy steels. The strongest of the wrought Duralumin alloys is 17ST, with an ultimate tensile strength of 58,000 and a yield point of 35,000 lb./sq. in. Its density is 2.79 which is about 0.354 the density of steel. Thus its *effective* tensile strength in the centrifuge in terms of steel is 58,000/0.354 = 163,500 lb./sq. in.

Controlling the Speed.—For any given set of experimental conditions the speed of the rotor is a function only of the air pressure. Hence the attainment of the speed constancy so important in an ultracentrifuge is merely a matter of achieving constant air pressure.[12] Our method is to employ two tanks with a reducing valve between them. A General Electric Co. pressure control switch starts the compressor (a Rix two-stage water-cooled compressor) when the pressure in the first tank falls to 500 lb. and stops it when the pressure reaches 550 lb. The reducing valve, a Fisher Pressure Governor,[13] pilot operated, keeps the second tank at 400 lb. The accuracy of the Fisher valve varies with the load. Under the usual load, the variation of the second tank is ± 0.5 lb., the "hunting" having a period of about five minutes. Under some loads the variation may be as much as ±2 lb., or as little as ±0.05 lb. As a usual operating pressure is 100 lb., the variation of the second tank is reduced to one-fourth at the throttle valve. Furthermore, the pressure–speed curve is already rather flat at 100 lb. so that the final effect on the rotor speed is slight. By setting the beat-frequency oscillator to zero beat with the rotor's note, listening to it for some time and measuring the frequency of the beat note that gradually appears, one can measure exactly the constancy of the rotor speed. The variation is generally much less than 0.1%.

Transparent Rotor and Stator

Two types of transparent rotors were developed. Each consists of two parts, the upper, cylindrical part, containing the cell for the liquid, and the lower, conical part which is the air-turbine proper. In both types the lower part is truncated and hollow and has a 13-mm. threaded hole through the truncated bottom. When the rotor is running, a stationary periscope projects up through the hole into the hollow rotating cone. The head of the periscope is a single quartz prism[14] whose cross section at right angles to the light

---

[12] W. R. Hewlett of the Electrical Engineering Department at Stanford University has found definite indication that even with varying air pressure the speed may be held constant by means of synchronous impulses applied to a magnet or probably to laminations carried in the rotor.

[13] Supplied by the Fisher Governor Company, Los Angeles.

[14] We are indebted to the Fred C. Henson Company, Pasadena, Calif., for the care and precision with which crystalline quartz of best optical quality cut so as to be singly refracting has been supplied for all our optical equipment.

beam is a square 4 mm. on a side, and whose cross section parallel to the light beam is a 45° rhomboid with an over-all length of 13.5 mm. The purpose of the periscope is to offset a distance of 9.5 mm. the light beam which comes up through the center of the stator, 9.5 mm. being the distance from the center of the rotor to the average radius of the liquid column in the cell. The head of the periscope has a minimum clearance of 2 mm. inside the hollow cone of the rotor. The presence or absence of the periscope has only a very minute effect on the speed and temperature of the rotor, provided the under side of the upper half of the rotor is smooth. This is insured by inserting a disk of celluloid between the halves (or a disk of cellophane when light of $\lambda < 3000$ Å. is used). An additional advantage of this disk will be described later.

The stator extends entirely through the manifold, being made pressure tight below with a packing nut. This part of the stator is cylindrical and is threaded inside as well as outside. Into it screws a short brass tube, furnished with a lock nut, into which tube, in turn, drops the periscope tube from above with a smooth sliding fit. The periscope tube has a shoulder part way down its side which rests on the top of the other tube, and a key-way which engages a pin near the top of the other tube. The pin determines the orientation of the periscope. The orientation and the height of the periscope can be adjusted by loosening the lock nut on the other tube. The periscope tube has a hole in its side just under the quartz prism to permit the entrance of air to the space between the rotor and stator from the central air inlet valve, as described before. To the other end of the tube into which the periscope tube drops is screwed a Duralumin tube having the central air inlet valve in its side and a small quartz window at the bottom.

The hole in the bottom of the rotor is large enough to permit the passage of the head of the periscope when the periscope is lifted a little and the rotor is tipped slightly to one side.

Below the window in the bottom of the stator a right-angled reflecting quartz prism is attached to one of the legs of the guard by means of an adjustable mounting. The high pressure supply to the manifold is offset, so as to clear the reflecting prism. A high degree of flexibility in the high pressure supply is achieved by making the metal tube attached to the manifold very long, bringing it back to the center line below the reflecting prism, and attaching it to the pressure supply nipple at the base by a very short section of $^1/_4''$ high pressure hose (Linde). The hose is made very short to reduce to a negligible amount the contraction of the hose due to increase in pressure. The manifold is kept centered by the rubber sponge which surrounds it to damp out vibrations.

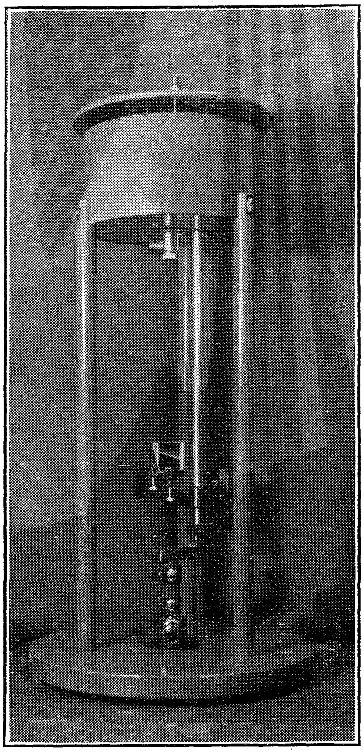

Fig. 6.—The assembly shown in Fig. 3.

Cells

In the first type of transparent rotor the cell is composed of two quartz disks 30 mm. in diameter and 2 mm. thick, fitting into a steel shell which screws on the lower part of the rotor. The liquid is confined between the disks by a special rubber seal made as follows. A 5-mm. slice of a finger of a rubber glove is stretched over the edge of a hard rubber ring 27 mm. outside diameter and 15 mm. inside diameter and about 1.1 mm. thick. The hard rubber ring has four 12° radial slots 4 mm. long cut in it from the inner circumference toward the outer. Outside the hard rubber ring with the soft rubber gasket stretched over its edge is placed an annealed brass ring 30 mm. outside diameter, 28 mm. inside diameter and 1.8 mm. thick. Several brass rings differing in thickness from 1.4 to 1.9 mm. are kept on hand to accommodate different thicknesses of rubber glove. When this assembly is placed between the two quartz disks, (about) three drops of liquid added, and the whole spun in the centrifuge, the hydrostatic pressure of the liquid expands the soft rubber against the quartz above and below and against the brass on the outside, forming a seal that only improves with increasing speed.

At first the brass ring was not used outside the seal. Instead the other parts were made a little larger in diameter and the rubber was allowed to expand against the steel wall of the rotor. Blowouts were frequent because the quartz disks were not perfectly round, because some disks did not fit the rotor exactly, and because the steel of the rotor, being under a stress nine times greater than the stress in the quartz, expanded more than the quartz. The brass ring eliminated these troubles.

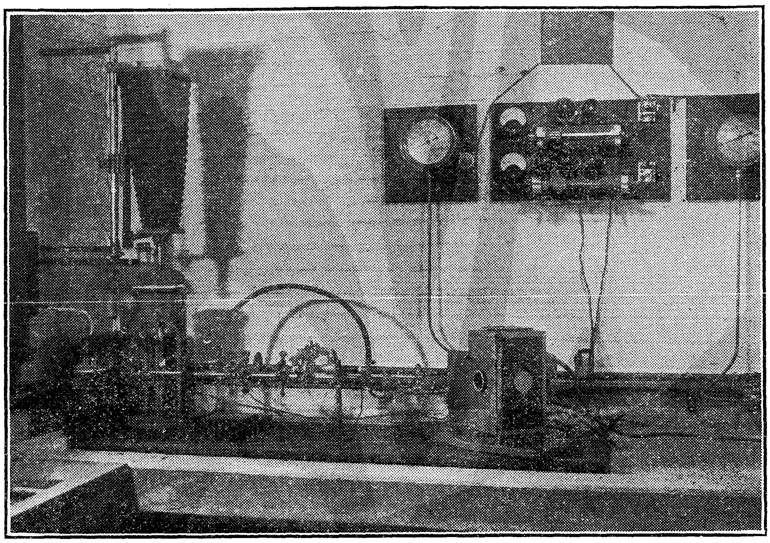

Fig. 7.—The complete centrifuge and optical system before the wool-filled cover and the thermostat for the driving air had been adopted.

To help the quartz disks bear the hydrostatic pressure of the liquid, two steel disks, 30 mm. in diameter and 2 mm. thick, and having four holes each, 6 mm. in diameter, 90° apart and 9.5 mm. from center of disk, are added, one above the upper quartz and one below the lower. The four holes in each disk are aligned with the four slots in the hard rubber ring. The lower steel disk has two pins which engage slots in the steel rotor cover and keep the assembly aligned while the rotor is being screwed together. To eliminate the air friction of the holes in the steel disk, the upper is covered with a 25-mm. disk of quartz and the lower with a 30-mm. disk of celluloid (or cellophane). The addition of these steel disks increases over 30% the speed at which the quartz disks break, giving over a 70% increase in centrifugal acceleration.

Various treatments were tried on the quartz and glass disks in an effort to increase their strength. By far the most successful was the following: besides the plane faces of the disks, their cylindrical sides were also optically polished and the edges formed by the plane faces and the cylindrical sides were slightly rounded and optically polished. Thus the disks were optically polished all over. This made an additional increase in the speed at which they broke of nearly 50%, or an increase in the acceleration of nearly 125%. Thirty-millimeter crystalline quartz disks so polished and supported against hydrostatic pressure by the two steel disks should spin 3000 r. p. s. without breaking (maximum 540,000 times gravity). Despite that fact, however, this type of cell cannot be safely used above 1500 r. p. s. No matter how carefully the quartz disks are handled, it seems impossible to avoid scratching them slightly, thus lowering their breaking speed enormously. Disks that have made many runs at 2500 r. p. s. will unexpectedly burst at 1700 r. p. s. Disk failures are costly because they generally cause the loss of the periscope also. Even at 1500 r. p. s. the factor of safety is low.

The second type of cell is somewhat similar to the cells in Svedberg's latest oil-turbine ultracentrifuges. The upper half of the rotor is a solid steel cylinder 37 mm. in diameter and 8.2 mm. high. Near the bottom it is reduced in diameter and threaded to screw into the rotor cone. The steel cylinder has two vertical holes on a diameter, each 8.6 mm. in diameter and 10 mm. from its center to the center of the cylinder. Into these are pushed from below two monel metal tubes, each of which has a flange 0.5 mm. wide which fits into a recess in the bottom of the large steel cylinder. When pushed all the way in, the tubes are flush with the upper and lower surfaces of the steel cylinder. One of the monel tubes (the dummy) is solid on the upper end and closed on the lower end with a brass screw whose weight is adjusted until the tubes balance. The other monel tube contains the cell, which is composed of seven parts: a slotted hard rubber separator, two thin soft rubber gaskets, two quartz disks, a brass washer and a hollow screw which keeps the assembly under pressure. The hard rubber separator is 6 mm. in diameter and 1 mm. thick. The 6° radial slot which forms the cell proper is 4 mm. long, cut in from the side toward the center of the rotor. The soft rubber gaskets which go between the separator and the quartz windows are cut from very thin sheet rubber to the shape and size of the separator, except that the slot must be a little larger to prevent the soft rubber from being pressed out into the slot in the hard rubber. The upper quartz disk is a truncated cone, 2 mm. thick, its upper diameter being 4 mm., its lower 6 mm. The top 2 mm. of the monel tube is tapered to fit the quartz cone so that the quartz, the monel and the steel are all quite flush on top. The lower quartz disk is a cylinder 2 mm. thick and 6 mm. in diameter. The brass washer is very thin and goes between the lower quartz disk and the hollow screw. In assembling the cell, pressure is applied to the parts by an external press. The office of the hollow screw is merely to maintain this pressure. The liquid is introduced into the cell through a small hole in the side of the monel tube opposite the end of the slot in the hard rubber separator. The liquid is covered with a small amount of pure paraffin oil to prevent evaporation. The cell is quickly taken apart for cleaning and reassembled. No trouble has ever been experienced from leaking, or from breaking of the quartz disk. This rotor, being lower than the previous type, runs 17% faster.

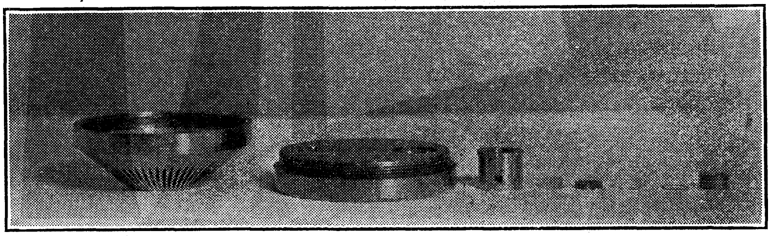

Fig. 8.—The second type rotor apart. From left to right the parts are: the rotor cone, the cell-holder, the shell of the cell, the upper (conical) quartz window, the hard rubber separator with the sectorial slot, the lower (cylindrical) quartz window, the brass washer and the hollow screw.

Temperature Control

In order to determine approximately the temperature of the two walls of the cell, three copper–constantan thermocouples are used. The cold junctions are kept at 0°. One hot junction is suspended directly over the center of the top surface of the spinning rotor, about 0.5 mm. above it. A second hot junction is mounted inside the hollow cone of the rotor, as close as possible to the center of the under side of the upper half of the rotor. Its leads enter through the wall of the stator inside a glass tube about 1 mm. in outside diameter. The glass tube then runs up alongside the periscope tube but without touching it. The third hot junction gives the temperature of the stator.

If the air used to spin the rotor is allowed to expand from room temperature, it will be found that when the rotor is being run at 100 lb. pressure the air in contact with the top of the rotor is about five degrees warmer than the air inside the hollow cone, and about seven degrees warmer than the stator. Such a temperature gradient between the two walls of the cell would cause convection currents and make sedimentation impossible. We eliminate the temperature gradient in the following way. To protect the top of the rotor from the slowly descending current of room air caused by the expanding exhaust, the guard is covered with an asbestos lined metal plate having a quartz window directly over the part of the rotor to be photographed. The plate rests on three screws which raise it about 10 mm. above the top edge of the guard. Less clearance causes instability in the rotor. The high pressure supply is thermally insulated from the stand and guard at the only point where they come in contact, *viz.*, at the base, by a large Bakelite bushing. The stand and guard are further insulated from the room air by a thick hood filled with lamb's wool which slips over the whole assembly, its top being flush with the top edge of the guard.

The driving air is heated by being passed through a large coil of 9.5 mm. copper tubing immersed in a water thermostat. By varying the room temperature, or the temperature of the water thermostat, or the driving pressure (and therefore the speed), it is possible to bring the temperatures above and below the cell to exact equality and to hold them thus indefinitely with a variation of less than ± 0.1°. With the room at 26°, the driving pressure at 100 lb./sq. in. we find that the water thermostat should be at 27°. Only about 70 watts are required to maintain the driving air at this temperature. The air for the central air inlet is taken out of the guard to ensure constancy of temperature.

From the standpoint of uniformity of temperature, the second type of rotor described above has two decided advantages over the first type. (1) In the second type, the cell is as entirely surrounded by metal as the exigencies of transparency will permit. This tends to short-circuit any temperature gradient existing between the top and bottom of the cell. (2) When the disk of celluloid or cellophane is inserted between the halves of the rotor, a dead air space 3 mm. high and 4 mm. in diameter is formed immediately below the lower quartz disk. This helps to insulate the quartz from temperature fluctuations in the cone of the rotor.

Light Source

The light source is a modified form of the high pressure mercury arc developed by Forbes and his collaborators.[15] The bridge placed by Forbes and Heidt between the mercury bulbs to permit the mercury transported to the cathode to flow back to the anode was found unnecessary.[16] If the bridge is omitted, the ionic transfer gradually raises the level of the cathode above the level of the water-bath until the mercury begins to boil. The boiling then compensates for the transfer and the arc reaches a steady state.

The opening used by the same authors for introducing the mercury into the quartz tube, a ground-in plug at the mid-point of the arc, was likewise found unnecessary.

Below each mercury bulb a short section of capillary tubing, about 1.6 mm. inside diameter, has been reintroduced. The electrodes are 3.2 mm. pure iron rods, slipping easily through the small tubing above the bulbs and turned down for part of their length to slip easily also through the capillary tubing below the bulbs. The shoulder on the iron rods where the two diameters meet is turned to a 45° angle and ground into the quartz with very fine carborundum. Across the face of the resulting valve is cut a single slot roughly 0.2 mm. wide and of the same depth. Heavy brass dust caps set-screwed to the top of the iron electrodes keep the valves seated during operation of the arc but permit them to open when the arc is started. The slots permit the pressure in the arc to remain atmospheric. The part of the iron electrodes having the smaller diameter must be long enough to extend entirely through the capillaries to prevent arcing therein.

The water-bath is double, a static bath of distilled water immediately surrounding the arc, and another of circulating tap water outside the first. The constancy of the level of the water-bath is extremely important in maintaining constant intensity. A constant drip and overflow device, situated at a distance from the lamp-house, proved most satisfactory. The water around the quartz tube tends to boil at the surface. It was found advantageous to surround each leg of the tube with several loose turns of copper gauze. This steadies the level of the water around the quartz by lowering the temperature at the surface.

A Weston photronic cell is mounted permanently in a water-cooled holder built into the transite lamp-house and protected from condensation from the water-bath by a Pyrex window. A 0 to 1.5 ma. milliammeter connected to the photronic cell gives a permanent check on the arc's intensity. With the above modifications the arc is as constant as the current source, a 550 volt d. c. motorgenerator whose variation is less than ±1%.

Optical System

The high intensity of the Forbes arc permits the use of a prism monochromator, a valuable asset for absorption photography. Starting from the arc, the optical system consists of a slit 0.3 mm. wide, a quartz collimating lens 5 cm. in diameter and 12 cm. focal length, a pair of 30° right-angled quartz prisms cut from the same crystal with the 60° angles in contact and 120° between the two hypotenuses, a focusing lens 5 cm. in diameter and 12 cm. focal length, a second slit (a hole 0.3 mm. in diameter), a second collimating lens 2 cm. in diameter and 4.8 cm. focal length, a right-angled reflecting quartz prism (directly under the center of the stator), the periscope, cell and camera lens. A fluorescent screen surrounding the second slit facilitates the selection of any line of the mercury arc.

Stage of Development

An idea of the range of usefulness of the machine in the present state of its development can be gained from the following. Without heating the air or attempting in any way to control the natural temperature gradient existing in the rotor, the second type of rotor herein described sedimented at every trial such heavy molecules as the respiratory protein of the earthworm (5% solution; 1% in potassium chloride).[17] With the first crude air heating arrangement tried (manually adjusted electric heater inside the air supply tubing) which enabled us to keep the temperatures above and below the cell at the same value to within ± 0.3°, the same rotor easily sedimented molecules as small as the hemp seed protein edestin (molecular weight about 208,000). With the driving air arbitrarily thermostated to within ±0.02° and the room temperature controlled, the same rotor will sometimes sediment molecules as small as purified egg albumin (molecular weight about 35,000).

More remains to be done before the instrument is uniformly reliable for the smallest molecules. The authors are confident that once the exact relations between the temperatures recorded by the thermocouples and the temperatures of the cell walls have been determined, the problem will have been solved completely, for it is comparatively easy to maintain any desired temperature gradient between the air above and below the cell. Devices are contemplated which promise to make the temperature of the air above, within and below the rotor, wholly independent of the room temperature.[18]

Summary

1. The air-driven spinning top has been developed as a transparent convectionless ultracentrifuge.
2. The three types of instability of the air-driven rotor are described, with their causes and remedies.
3. Means are given for measuring, increasing and controlling the speed of the top, with a discussion of the best materials of construction.
4. Spinning top centrifuges are described in which it is possible to photograph the cell by transmitted light of any monochromatic wave length, visible or ultraviolet.
5. Two different types of cells are described.
6. Means are discussed for measuring and controlling the temperature gradient existing between the top and bottom of the cell.
7. The present stage of the development of the instrument is described.

---

[17] The best average value we have obtained for this protein (uncorrected for viscosity and density) is $s = 61.8 \times 10^{-13}$. The value of 72×10^{-13} published by us in THIS JOURNAL, **57**, 780 (1935), proved to be exceptionally high.

[18] Mr. H. J. Fouts in this Laboratory has since found that in order fully to equalize the temperature inside the rotor with the temperature of the slip stream from the driving air (on account of the friction caused by the periscope upon the air within the rotor) it is advisable to draw the air entering the periscope, as well as the air playing upon the top of the rotor, through a much colder thermostat, instead of taking it from the guard ring as described above.

The Photochemical Decomposition of Nitric Oxide[1]

BY PAUL J. FLORY AND HERRICK L. JOHNSTON

Berthelot[2] observed that nitric oxide decomposed when irradiated with light from the quartz mercury arc and concluded that nitrogen and oxygen are the final products of the decomposition. Macdonald,[3] as part of his investigation of the nitrous oxide decomposition, made a brief study of the decomposition of nitric oxide under irradiation from the aluminum spark, between pressures of 50 and 650 mm. He observed that the rate seemed to depend entirely upon the amount of light absorbed and reported a quantum yield of 0.75. He interpreted his data in terms of a primary mechanism of activation. Noyes[4] found good evidence for the decomposition of nitric oxide through the agency of excited mercury atoms. Under the conditions of his experiments he observed no appreciable amount of direct photochemical reaction.

We have investigated the photochemical decomposition of nitric oxide both with the mercury arc and with sparks between various metal elec-

trodes, as sources of radiation, and over a pressure range from 0.02 to 7 mm. We have been successful in correlating the primary process, which proves to be an act of predissociation, with the absorption spectrum of the gas. This interpretation appears, also, to provide a better explanation than that given by Macdonald for the decomposition at the higher pressures.

Experimental

Reaction System.—The reaction system consisted of a cylindrical quartz cell, 75 mm. long by 25 mm. in diameter, with plane end windows. The cell was connected through a graded quartz to Pyrex seal, to a calibrated McLeod gage and to mercury cut-offs which communicated to a high vacuum system and to a preparation line. No stopcocks were contained in the reaction system.

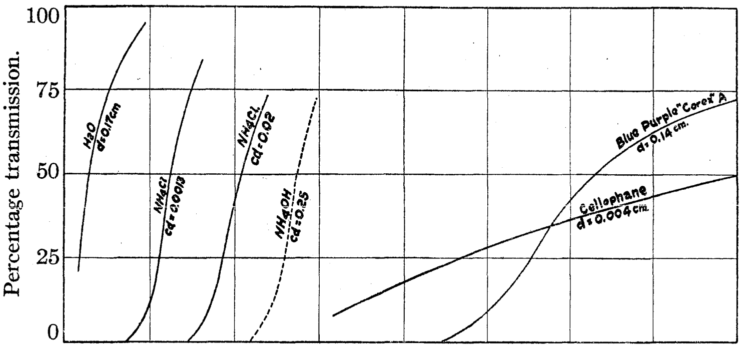

Fig. 1.—Absorption curves of filters (*d*, in centimeters; *c*, in moles per liter).

The reaction system was evacuated to a pressure of 10^{-6} mm. prior to each run, and was usually baked out during evacuation. Nitric oxide, prepared and purified by the method employed by Johnston and Giauque[5] was introduced to the desired pressure and the reaction followed by means of pressure measurements.

In some of the experiments a condenser-diaphragm manometer, similar to the one described by Olson and Hirst[6] was used.

Sources of Illumination.—Most of the experiments were done with a quartz mercury arc which was relatively weak in unreversed λ 2537 resonance radiation. A number of experiments were also made with condensed spark discharges between suitable metal electrodes. It was found necessary to electrically shield the cell, with a tin foil covering, to prevent decomposition under the influence of an induced field set up within the cell.

Filters.—Filters were used to locate the active regions of the spectrum. The absorption characteristics of these filters are shown in Fig. 1. The curves for water and for aqueous ammonium chloride and the solid portion of the curve for ammonium hydroxide are constructed from the absorption data of Ley and Arends.[7] The dotted portion of the ammonium hydroxide curve was constructed from visual estimates obtained with a small ultraviolet fluorescing spectroscope, and is considered reliable to within 25 Å. The curves for cellophane[8] and for the Corex glass were determined by means of a Bausch and Lomb spectrograph equipped with a rotating sector comparator. An under-water spark was the source of continuous radiation.

To prevent photolysis the filter liquids were made to flow through a thin filter cell (one or two mm. liquid thickness) cemented to the reaction cell in such a way that the window of the latter formed one window of the filter cell.

Preliminary Observations

The Gage Reaction.—From considerations of stoichiometry alone nitrogen dioxide, nitrous oxide, nitrogen and oxygen are possibilities as ultimate products of the dissociation.[9] However, Macdonald[3] has shown that nitrous oxide is photochemically decomposed ten times as rapidly as nitric oxide while Norrish[10] has found that nitrogen dioxide is decomposed rapidly into nitric oxide and oxygen at wave lengths shorter than 4000 Å. The reverse thermal reaction is third order and it can be shown from the data of Bodenstein[11] that the rate of recombination of nitric oxide and oxygen is negligible at the pressures of our experiments.

From these considerations it would appear that nitrogen and oxygen should be the final products of the dissociation, regardless of the primary mechanism, and that the final and initial pressures should be equal. Contrary to this expectation preliminary experiments showed that the pressure decreased rapidly to less than one-half of the initial pressure (and went through a minimum at about $^1/_4P_0$).[12] Furthermore, the pressure in the reaction system rose slowly when the arc was shut off but dropped rapidly again, for a short period, when the cell was re-illuminated. As the result of several such alternate periods of light and of dark (*cf.* Fig. 2) the pressure eventually approaches a value which is very near to one-half of the initial pressure.

[8] The cellophane was placed between two pieces of quartz plate to protect it from the action of ozone. Although the cellophane did show some solarization the effect was not great.

[9] Nitrogen tetroxide and nitrogen trioxide may be excluded since at the low pressures of our experiments these molecules would, themselves, dissociate into the simpler oxides.

[12] The position of the minimum is based on subsequently more careful measurements with the technique finally adopted (*cf. seq.*) for removing the accumulation of oxygen.

A clue to this behavior was found in the observation that a film was deposited on the mercury surface in the stem of the McLeod gage, which indicated that something was being removed from the reaction system during compressions in the gage. This indication was confirmed in a series of runs in which the McLeod gage was replaced by the diaphragm manometer. The results are shown graphically in Fig. 3, for several initial pressures. The broken curve, plotted to the same scale, is from data obtained with the McLeod gage and shows the true course of the decomposition. It is clear that our expectations regarding the constancy of pressure during the early course of the photochemical decomposition[13] are verified.

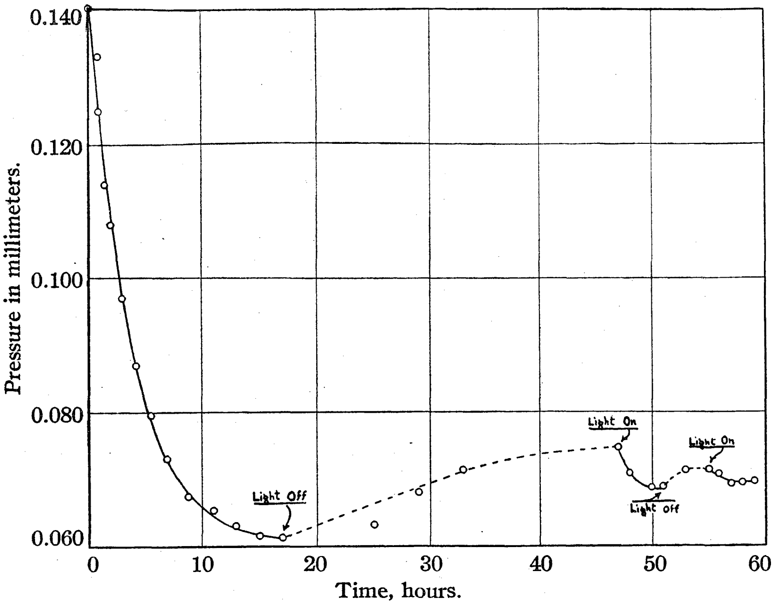

Fig. 2.—Anomalous behavior following the initial period of illumination.

Additional confirmation was obtained in later experiments with the McLeod gage, in which the reaction was allowed to continue for five or six hours without running up the gage. Pressures measured at the end of this period were about $^5/_6$ of the initial pressure, in good accord with the diaphragm gage curves.

The presence of liquid mercury, either on the walls of the connecting tubing or in the reaction cell itself, did not affect the results in either of these experiments.

We interpret this as evidence for the following series of reactions[14]

$$NO + h\nu = {}^1/_2N_2 + {}^1/_2O_2 \qquad (1)$$

$$NO + {}^1/_2O_2 = NO_2 \qquad (2)$$

$$Hg + NO_2 = HgNO_2 \qquad (3)$$

of which (2) and (3) occur only in the gage.

The increase in pressure after the illumination is shut off results from the slow, dark reaction

$$HgNO_2 = HgO + NO \qquad (4)$$

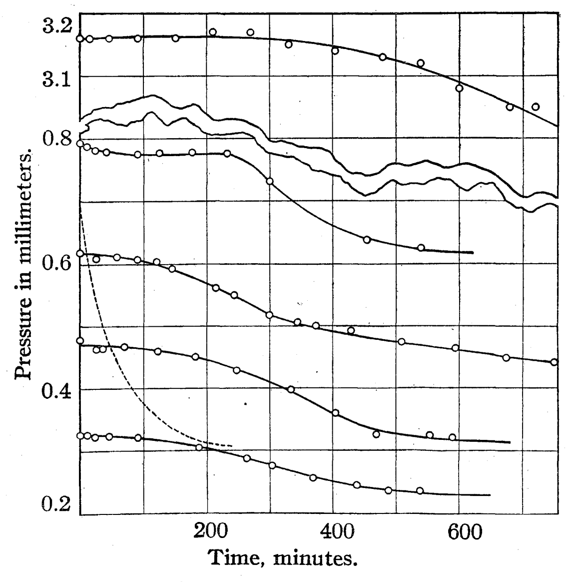

Fig. 3.—Experiments with the membrane manometer; – – – – –, decomposition curve measured with the McLeod gage.

---

(13) The marked pressure drop which comes two hours or more after the reaction is initiated is interesting although it appears to be irrelevant to the subject of our investigation since it comes *after* the decomposition of the nitric oxide is ended (comparison with the broken curve). This fact itself is significant since it seems to indicate that the change which produces the decrease in pressure is either prevented, or compensated, through the agency of nitric oxide. It also appears that the change is produced through the action of light, or of excited mercury, on oxygen since we were able to duplicate the pressure decrease, to the correct order of magnitude, with the cell filled with *oxygen alone*. In this experiment the oxygen pressure decreased to about $^3/_4\ P_0$ in seven and one-half hours and was still falling.

Experiments in which a Blue Purple Corex A filter, which prevented decomposition of the nitric oxide, was placed in the path of the radiant energy prevented the appearance of this delayed pressure drop.

The presence of a yellowish-brown deposit (probably mercuric oxide) on the cell window and on the walls for a few millimeters back from the window provided evidence for some reaction, either of oxygen or of ozone, with excited mercury. There is probably some relation between these results and those observed by Neujmin and Popov [*Z. physik. Chem.*, **B27**, 15 (1934)] for illumination of oxygen with light of wave length shorter than λ 1750 but we did not investigate the reaction further.

(14) We refer here only to the stoichiometrical equations for the successive steps. The arguments advanced against the nonoccurrence of (2) in the reaction cell do not apply to the gage, where the pressure reaches 200 millimeters during the compression. Our data do not permit us to assign the formula $HgNO_2$ with certainty although (*cf. seq.*) they do indicate that the nitrogen/oxygen ratio in the compound is very close to $^1/_2$.

This proves to be a first order reaction, as shown in Fig. 5, with a rate constant of 1.5 × 10^{-2} per hour. This figure is based on data obtained in a run, illustrated in Fig. 4, which was taken primarily to study this phase of the process. P_∞ represents the limiting pressure to which the curve of Fig. 4 (dark reaction) extrapolates asymptotically and is indicated in that figure.

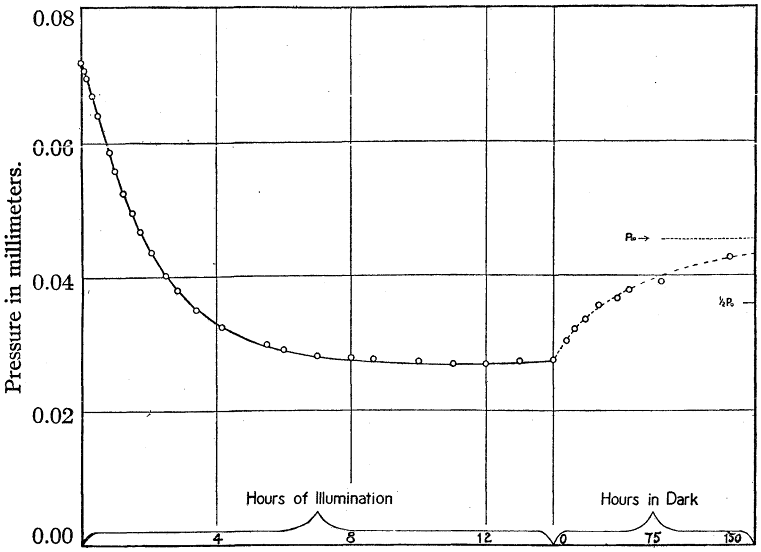

Fig. 4.—Course of a single run, showing the final dark reaction.

Although the reactions which occur in the McLeod gage may appear to be an encumbrance to the study of the photochemical reaction, they actually are an aid since it becomes possible to follow the reaction by measurements of pressure. The expedient was adopted, in all of our later, more careful, quantitative work, of compressing the gas in the gage to a pressure of 200 mm. or more every five minutes, whether pressure readings were wanted or not. Since the gage constituted about 75% of the total volume of the reaction system three-fourths of the accumulated oxygen was thus removed every five minutes. Preliminary trials showed that compression for a period of thirty seconds was more than ample time to remove the oxygen from the gas, and also that the rate of diffusion was sufficient to accomplish removal of the accumulated oxygen by this procedure.

Elimination of Photosensitization as a Mechanism for the Decomposition.—The absence of a mercury sensitized step in the decomposition, under the conditions which pertained to our experiments, was proved by three independent tests.

(1) A mercury vapor filter formed by placing a drop of mercury in the side-arm of an evacuated and baked quartz cell 4.5 cm. long, did not reduce the reaction rate by more than was to be expected for the introduction of two quartz windows into the light path.

(2) The use of a Blue Purple Corex A filter which cuts off the radiation completely below λ 2300 but shows 70% transmission of λ 2537 (*cf.* Fig. 1) reduced the rate to 1.3% of its value without the filter. A similar experiment with a cellophane filter, which cuts out radiation below about λ 2200 but is 45% transparent to λ 2537, reduced the rate to about 1% of its value without the filter.

(3) Insertion of a U-tube cooled with a dry ice–chloroform–carbon tetrachloride bath between the quartz cell (previously baked out thoroughly) and the rest of the reaction system, to keep the cell free of mercury vapor, had no effect on the rate of reaction.

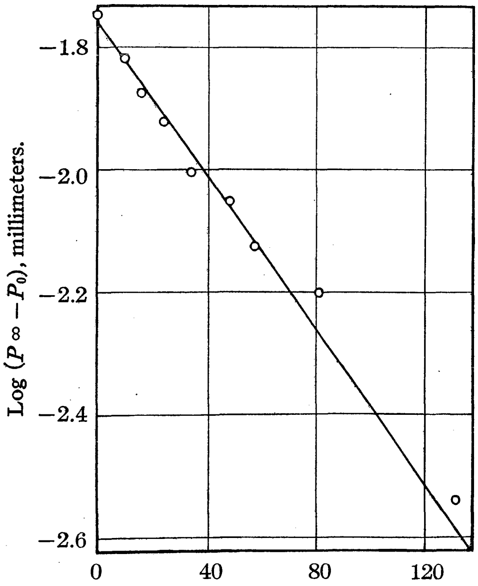

Fig. 5.—The first order gage reaction.

We conclude that the reactions, in our experiments, are at least 98% non-sensitized.[15]

---

[15] Our results in no wise contradict those of Noyes (Ref. 4) who reported a mercury sensitized reaction with negligible photochemical reaction. Noyes used a water-cooled arc which doubtless gave a high intensity of λ 2537 while the cooling water, if tap water were used, must have removed almost all of the radiation which we find to be effective for the photochemical process. Our own air-cooled arc

Dependence on Light Intensity.—The influence of the light intensity on the rate of nitric oxide decomposition was determined by the use of calibrated wire screens[16] placed in the light path.

The results of these experiments, with three different screens, are shown in Table I. These runs were all made at about 0.12 mm. initial pressure, which falls in the region (*cf. seq.*) where, for a given light intensity, the percentage decomposition is a function of time and almost independent of the pressure. "t" and "t_0" refer to the times required for the recorded percentage changes in pressure, with and without the screens in the light path, respectively. The last column in the table is obtained from the screen calibrations.

TABLE I

DEPENDENCE OF REACTION RATE ON LIGHT INTENSITY

Screen no.	Change in pressure, %	t, min.	t (min.	t_0/t	I/I_0
1	11.1	30	19.8	0.66	0.681
	16.9	50	31.6	.63	
2	8.9	40	15.6	.39	.361
	12.7	60	22.8	.38	
	19.1	100	36.4	.364	
3	7.5	150	15	.10	.13

The Primary Process

Influence of Pressure on the Rate of Reaction.—In order to obtain information as to the general character of the primary process the dependence of reaction velocity on the pressure of nitric oxide was determined for a series of pressures varying between 0.02 and about 7 mm. So as to minimize the possible influence of the decomposition products on the reaction velocity, the comparisons were made between the *initial* rates of decomposition. The values of $(dP/dt)_0$ for the several individual runs are recorded in Table II, in which the third column gives the probable error in the several determinations, as deduced from a consideration of the accuracy of the McLeod gage, the completeness of oxygen removal, etc.

TABLE II

VARIATION OF REACTION RATE WITH PRESSURE

Initial pressure P_0, mm.	$(dP/dT)_0$, mm./min.	% Error	$\left(\frac{d \ln P}{dt}\right)_0$ Obsd.	Calcd.
0.0215	1.12×10^{-4}	6	5.2×10^{-3}	5.22×10^{-3}
.0428	2.40	4	5.6	5.16
.0677	3.58	2.5	5.28	5.06
.0907	4.54	2	5.00	4.98

2.24	36.8	3	1.64	1.58
4.37	39	4	0.90	0.84
7.12	44	4	.62	.51

The table indicates that, for very low pressures, $(dP/dt)_0$ is about linear with the pressure and, at high pressures, approaches a constant value. This behavior, together with the linear relationship between rate and light intensity (Table I), suggests at once that the main factor in determining the rate may be the amount of light absorbed. This suggestion is confirmed by the agreement of the experimental values for $(d \ln P/dt)_0$ in column four with those, in column five, which are calculated from the relationship

$$\left(\frac{d \ln P}{dt}\right)_0 = -3/2\, k a I_0 \left(\frac{1 - e^{-aP_0}}{a P_0}\right) \qquad (8)$$

which is derived[17] on the assumption that the decomposition rate is directly proportional to the rate of light absorption and that the absorption of effective radiation obeys Beer's law. The fit is

---

gave out very little unreversed radiation of λ 2537, due largely to self reversal in the arc, and accounts for our low mercury sensitized yield. Subsequent experiments with the same arc operated under conditions that very greatly increased the output of λ 2537 resonance radiation gave evidence of a very considerable mercury sensitized reaction.

(16) Forbes, *J. Phys. Chem.*, **32**, 482 (1928).

(17) Here, k is a constant in which is incorporated the quantum yield and the relation of the pressure decrease to the number of molecules which disappear in unit time; I_0 is the intensity of the incident light of effective wave length and a is its absorption coefficient which includes the fixed length of light path applicable to our experiment. P_0 is the initial pressure.

The derivation is as follows.

$$dP/dt = dP_{NO}/dt + dP_{N_2}/dt \qquad (5)$$
$$= -3/2\, kI_{abs} + k_4A \qquad (6)$$

by the stoichiometry of equations 1–3. Here A represents the pressure equivalent of the NO withdrawn by equation (3) and k_4 is the first order velocity constant of reaction (4).

Introduction of Beer's law gives

$$dP/dt = -\,3/2\, kI_0\,(1 - e^{-aP_{NO}}) + k_4A \qquad (7)$$

which reduces, in the limit of $(t = 0)$, to equation (8) above.

The several factors $3/2kaI_0$ were constant under the experimental conditions which we employed and were evaluated collectively, by extrapolation of the experimental values of $(d \ln P/dt)_0$ (*cf.* Fig. 6) to zero pressure. In this limit the quantity in parenthesis, on the right of equation (8), becomes unity.

The values in the fifth column of Table II were then computed through the choice of an arbitrary "best fit" for the absorption coefficient a which proved to be, for these experiments, 1.44 in reciprocal millimeters of pressure. Justification for regarding this fit as a confirmation of the dependence of initial rate on the amount of absorbed light is provided in the excellent agreement with the experimental results over a thirty-five fold change in the initial pressure, obtained with only this one arbitrary constant.

shown graphically in Fig. 6 where the smooth curve is calculated by equation (8) and the circles represent experimental points.

Influence of Nitrogen on the Rate of Reaction.—We find that nitrogen has no effect on the rate of reaction. This was tested both by studying the influence of an excess of nitrogen added at the beginning of an experiment and by studying the effect of nitrogen accumulation on the progress of a full reaction. The latter study also provides additional confirmation of the dependence of rate on the light absorption.

Table III shows the results obtained in two experiments which were run to test the effect of an initial excess of nitrogen. Within the limits of experimental error the rates of nitric oxide decomposition are the same.

TABLE III

COMPARISON OF THE DECOMPOSITION RATES WITH AND WITHOUT NITROGEN AS A DILUENT

$P_0(N_2)$, mm.	$P_0(NO)$, mm.	$(dP/dt)_0$, mm./min.	$(d \ln P_{NO}/dt)_0$,

0.360	.0916	4.0×10^{-4}	$4.3\ (\pm 0.4) \times 10^{-3}$ min^{-1}

Figure 7 shows the course of a complete run (carried out under the more careful conditions of our later experiments) in which the experimental pressures are shown in their relation to a curve calculated from the same basic assumptions that were employed in the preceding section and with the same value of the absorption coefficient which was derived from the initial rates (namely, 1.44 mm.$^{-1}$).[18]

As the graph shows, the experimental values are a little high in the final period of the reaction. Although the discrepancy is definitely greater than the probable error of the rate measurements themselves,[19] the results are, nevertheless, in sufficiently good agreement with the general shape of the calculated curve to show that the rate-controlling factor throughout the decomposition is the absorption of light and that the accumulated nitrogen has no marked influence on the reaction.

Dissociation as the Primary Step.—It is possible from the above results to deduce the general character of the primary process. At 0.1 mm. pressure of nitric oxide the average time between collisions is about 10^{-6} seconds. If the photoreaction involves the collision of an excited and a normal molecule, then at low pressures where only a small fraction of the active radiation is absorbed and where most of the excited molecules would lose their energy by fluorescence, the rate should be proportional to the square of the nitric oxide pressure. The experimental observation (Table II and Fig. 6) that the rate becomes linear with pressure at low pressures therefore rules out the collision process. A primary dissociation of the molecule is the only alternative. Failure of nitrogen, either as an accumulation product or as an initial diluent, to modify the rate also indicates the absence of primary activation.

We may also conclude that any secondary processes which occur subsequent to the dissociation are little influenced by variation in the pressure either of nitric oxide or of nitrogen.

The Active Region of the Spectrum

Effective Mercury Arc Radiation.—It is difficult to be quite certain of the lower limit of the

---

(18) This curve was calculated from the equation

$$(P_0 - P) + \frac{3}{4a} \ln \left[\frac{1 - e^{-aP_0}}{1 - e^{-a(4P-P_0)/3}}\right] + \frac{k_4}{2a}\left[\frac{(e^{2akI_0t} - 1)}{2a\,kI_0} - t\right] = 3/2\,kI_0t \qquad (14)$$

This equation is derived from (7) as follows. As a first approximation reaction (4) is neglected so far as it influences either the total absorption of light or the amount of $HgNO_2$ remaining at time t. Then, it follows from the stoichiometry of reactions 1–3 that we may rewrite (7) in the form

$$dP/dt = -3/2\,kI_0(1 - e^{-a(4P-P_0)/3}) + 2/3\,k_4(P_0 - P) \qquad (9)$$

which rearranges to give

$$dP + (3a/4)\,d\ln(1 - e^{-a(4P-P_0)/3}) - \frac{2k_4(P_0 - P)dt}{3(1 - e^{-a(4P-P_0)/3})} + 3/2\,kI_0\,dt = 0 \qquad (10)$$

Expansion of (9) by MacLaurin's theorem with disregard of higher powers of $(P - P_0)$ and of the term in k_4 yields, on integration, the following approximate relationships

$$4P - P_0 = 3\,P_0e^{-2aI_0kt} \qquad (11)$$

and

$$P_0 - P = 3/4\,P_0(1 - e^{-2aI_0kt}) \qquad (12)$$

These values are then substituted in the *third term only* (which is a small correction term) of equation (10) and the denominator of this term is then expanded by MacLaurin's theorem, and powers of the exponent higher than the first are neglected. This treatment yields the equation

$$dP + \frac{3a}{4}\,d\ln(1 - e^{-a(4P-P_0)/3}) - \frac{k_4}{2a}(e^{2aktI_0} - 1)\,dt + 3/2\,kI_0\,dt = 0 \qquad (13)$$

which integrates to give (14) above.

The several approximations introduced in this derivation are exact in the limit of $t = 0$ and remain good throughout the greater portion of the reaction. We cannot expect this equation to reproduce accurately the experimental data in the immediate neighborhood of the pressure minimum (shown in Fig. 4), where reaction (4) plays a relatively great influence.

(19) The formation of a little mercurous nitrate (or other compound with an O to N ratio greater than 2), in the gage may be the cause of the discrepancy.

wave lengths which may have entered our reaction cell but in view of the intense continuous absorption which sets in with air below λ 1750 we are safe in concluding that no radiation below λ 1750 need be considered in seeking the details of the photochemical process. In order to determine what line, or lines, may be responsible for the photochemical decomposition with the mercury arc a number of runs were carried out with the filters whose absorption characteristics are shown in Fig. 1. Reference has already been made to the results obtained with the Corex and the cellophane filters which showed that radiation below λ 2300 is responsible for at least 98% of the reaction, under the conditions which pertained to our experiments. The results obtained with the other filters are given in Table IV, which also includes comparative rates which show the influence of filters on the reaction promoted by radiation from aluminum and zinc sparks. The influence of the ammonium chloride and ammonium hydroxide filters places the effective radiation below λ 1900.[20] The effect of water in reducing the reaction rate by about 50% corresponds to the absorption of water for wave lengths in the neighborhood of λ 1830.

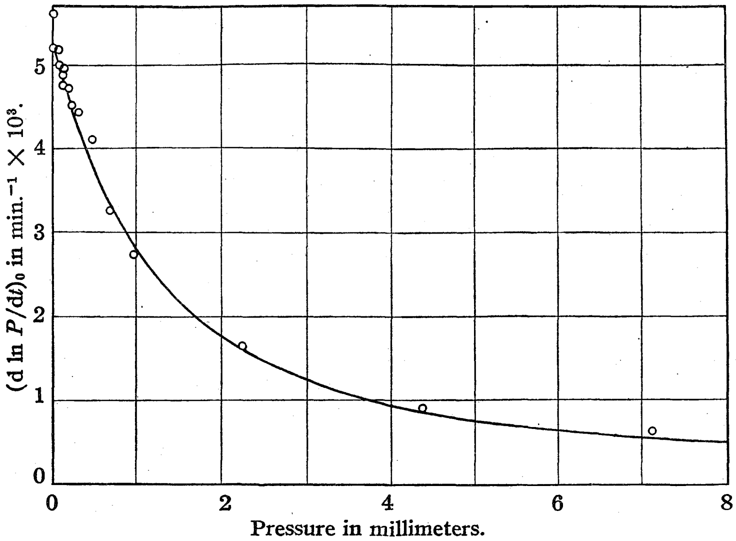

Fig. 6.—Dependence of the initial decomposition rate on the pressure: o, observed: ————, calculated.

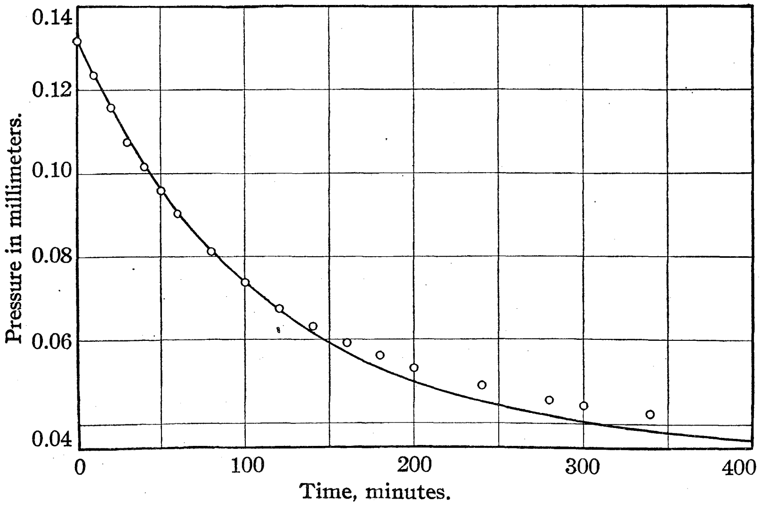

Fig. 7.—Course of a complete run: o, observed; ————, calculated.

The only mercury lines which fall within this active region are those at λλλ 1775, 1832 and 1849, respectively (*cf*. Fig. 8). Hg 1775 falls in a region which is free of nitric oxide absorption. Furthermore, it should be removed completely by the water filter. The results of the several experiments with the mercury arc suggest therefore that the primary process is either the absorption of unreversed radiation from the strong line at λ 1849 in the (9,0) band of the β-system or the absorption of the weak line at λ 1832 (together with continuous radiation surrounding λ 1849) in the (1,0) band of the δ-system. To gain further information on this point an approximate measurement of the absorption coefficient of λ 1849 was carried out spectrographically. An absorption cell 5 cm. long (approximately the mean light path of the divergent light which passed through the 7.5-cm. reaction cell) was placed in front of the spectrograph slit and several exposures of different time lengths were made, both for the evacuated cell and for different pressures of nitric oxide. By visual estimate of the line intensities (all taken on the same plate which was sensitized with Eastman ultraviolet sensitizing solution) the absorption of the λ 1849 line was determined. Application of Beer's Law, which Lambrey[21] has

---

(20) Quantitatively, the 3% residual rates with these filters agree, within limits of error, with the 1% rates obtained with the cellophane and Corex filters and indicate: (1) that none of the mercury arc radiation between λ 1900 and λ 2300 is effective in promoting the decomposition and (2) that the small effect due to radiation of longer wave length is due to unreversed radiation of the λ 2537 line.

Zn spark	..	.35	.06	..

shown to be applicable to β-band absorption, yielded 1.9 (±0.3) × 10^{-2} mm.$^{-1}$ for el (equivalent to a in equation (8)). The rate dependence on pressure, considered in an earlier section of this paper, yielded 1.4 for the mean absorption coefficient, a, of the active radiation. The absorption of λ 1849 is thus much too weak to account for the observed reaction. No reliable quantitative measurement of the absorption of λ 1832 was possible, due to the low intensity of the line. However, it was found that nitric oxide at only 3 mm. pressure caused almost complete removal of the line. This result is not incompatible with an absorption coefficient of 1.4.

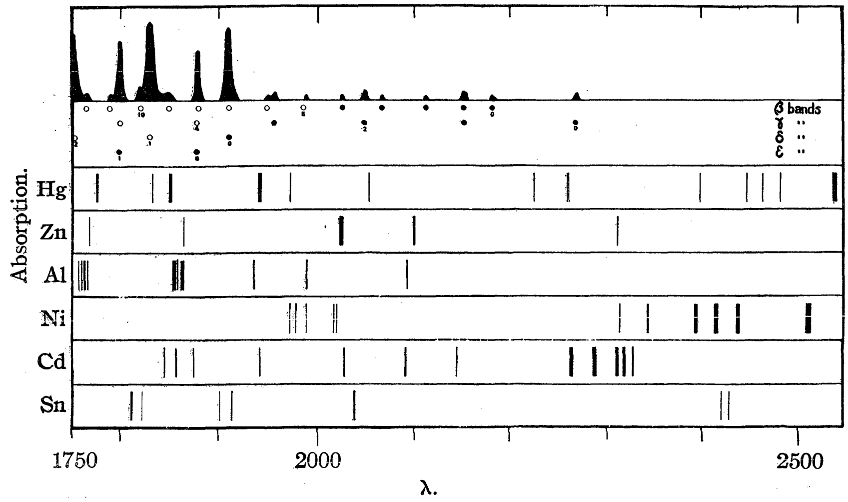

Fig. 8.—Absorption spectrum of nitric oxide in relation to the chief lines of the mercury arc, and of the spark sources employed in this investigation. (The positions and relative intensities of the absorption bands are constructed from the data of Liefson [*Astrophys. J.*, **63**, 73 (1926)] and that of Lambrey [*Ann. phys.*, **14**, 95 (1930)]. The positions and relative intensities of the emission lines are taken from the tabulations in Kayser's "Hauptlinien der Linienspektra aller Elemente." The mercury arc spectrum below λ 1900 is based on the work of Lyman [*Astrophys J.*, **38**, 282 (1913)], who used a mercury arc operated under conditions similar to those we employed except that Lyman's arc was constructed with a fluorite window. Lyman observed that the strong resonance line at λ 1849 was accompanied by continuous radiation extending over more than 40 Å. We confirmed this, for our own arc, by observations taken with a small Gaertner quartz spectrograph. In addition to the broad continuum adjacent to λ 1849 the 1832 line showed up faintly.

The numbers below the circles, which mark the positions of the several absorption bands, represent vibrational quantum numbers of the upper states. White circles mark bands which are absent in emission. Frl. Guillery (*Z. Physik*, **42**, 1212 (1927)) reports emission from the 4′ and 5′ levels of the γ bands but a consideration by one of us (P. J. F.) makes it appear probable that these are, in reality, 0′ and 1′ levels of the ϵ system.

From this we conclude that most, if not all, of the reaction is due to absorption in the δ (1,0) band. Absorption of λ 1849 in the β (9,0) band may have a lesser effect which becomes significant at higher pressures in agreement with the observed rates above 3 mm. pressure (Table II).

Photochemical Effect of Spark Sources.—Results obtained with sparks between metal electrodes confirm the conclusions of the previous section and also indicate some photochemical influence of β-band absorption. The influence of water and ammonium chloride filters on reactions promoted by the aluminum and zinc sparks is included in Table IV. Comparative results obtained with six different spark sources with a 2-mm. water filter are shown in Table V.[22]

The most general observation that we can draw from Table V is that all of the sparks are effective to the same order of magnitude, from which we conclude that their activity is primarily due, not to absorption of their specific lines,[23] but to absorption in the rather considerable continuous background which all of these sources possess.

Removal of the water filter resulted in a two- to four-fold increase in the rates given in Table V. This indicates that most of the active radiation lies below λ 1850. We conclude, therefore, that the same absorption is responsible for dissociation with the several sparks, as with

---

[22] The figures in Table V cannot be compared with those in IV since the nature of the power supply, which produced the sparks, was different in the two cases.

[23] The somewhat lesser influence of the ammonium chloride filter in reducing the activity of the zinc spark, than with either mercury or aluminum, may be due to weak absorption of the strong λ 2025 line of zinc in the β (4,0) absorption band of nitric oxide. The low intensity of emission bands with v' = 4 constitutes evidence for some predissociation from this level.

TABLE V

COMPARATIVE RATES OF DECOMPOSITION WITH DIFFERENT SPARKS

Al	0.30
Zn	.23
Cd	.21
Ni	.19
Cu	.11
Sn	.25

the mercury arc—namely, absorption in the δ (1,0) band of nitric oxide, together with some absorption in the hands of the β-system, of which weak absorption of Hg 1849 (and perhaps of Zn 2025) constitute special examples.

The nature of the dependence of the reaction rate on nitric oxide pressure and its independence of nitrogen pressure indicated that the primary step is dissociation. The fact that the active radiation falls in a banded region of the spectrum proves that the dissociation process is one of predissociation.

This conclusion receives support in the emission spectrum of nitric oxide. Thus Kaplan[24] attributes the absence of bands with v' greater than 4 (and the unexpected weakness of ($v' = 4$) bands) to predissociation to a repulsive level which must intersect the upper $^2\Pi$ potential energy curve (*cf.* Fig. 9) somewhere in the neighborhood of $v' = 4$. A similar explanation may be offered to explain the fact that no δ emission bands have been observed[25] with v' greater than zero, although strong emission bands would be expected for higher vibration states, both on the basis of the Franck–Condon principle and of the distribution in absorption.

We expect that radiation absorbed by any of the bands which are marked with open circles in Fig. 8 would be photochemically active while radiation absorbed by bands marked with black circles would be inactive (except for some activity in the β (4,0) band).

Secondary Processes

Nature of the Dissociation Products.—The dissociation energy of nitrogen now seems to be pretty definitely fixed in the neighborhood of 7.34 volts.[26] Combining this value (equivalent to 169,350 calories per mole) with that of the heat of dissociation of oxygen[27] and with the heat of formation of nitric oxide at the absolute zero,[28] we obtain 121,950 calories as the molal heat of dissociation of nitric oxide into atoms, at zero degrees Kelvin. The energy associated with radiation of wave length 1830 Å. exceeds this dissociation energy of nitric oxide by approximately 33,600 calories. Since this is less than the energy necessary to put either atom into an excited electronic state the dissociation products must be the normal atoms. And since momentum, as well as energy, must be conserved in the dissociation, it is a simple matter to compute the kinetic energies given to the respective atoms in the process. These prove to be: for nitrogen, 17,630 calories per gram atom; for oxygen 15,690 calories per gram atom.

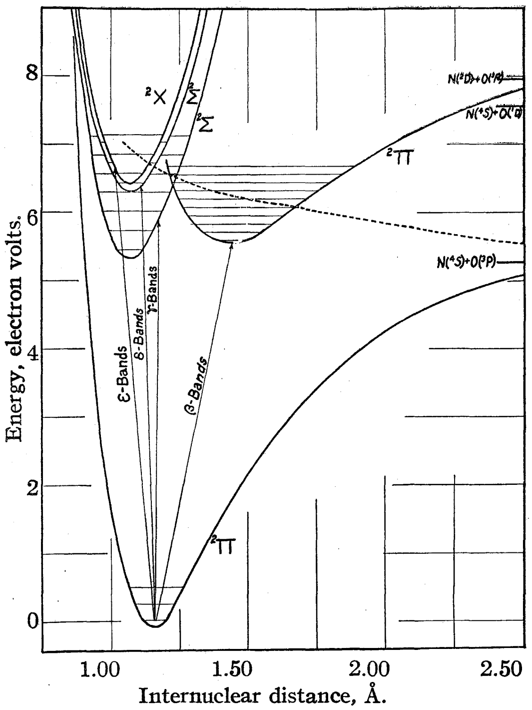

Fig. 9.—Potential energy curves for the known states of nitric oxide: – – – –, estimated position of the $^2\Sigma$ repulsive level responsible for predissociation in the region λ 1800–2000.

Atomic Reactions.—Stoichiometrically possible secondary processes are:

$$N + NO = N_2 + O \qquad + 47{,}400 \tag{15}$$

$$O + NO = O_2 + N \qquad - 4{,}600 \tag{16}$$

$$2N + W = N_2 \qquad +169{,}350 \tag{17}$$

$$2O + W = O_2 \qquad +117{,}350 \tag{18}$$

$O + NO + W = NO_2$ + 48,650 (25)

where W represents reaction with an adsorbed layer of atoms (or molecules) on the walls.

Of these, (20) and (21) are ruled out completely, and (16) reduced to an improbable occurrence, from energy considerations alone.[29]

A simple calculation, based on the measured rate constants, indicates that the accumulation of oxygen in the reaction system rarely exceeded 1×10^{-3} mm., and was, as a rule, considerably lower than this. This eliminates reaction (22), in comparison with (17) or (19), as a contender for the removal of nitrogen atoms.

At the lowest pressures (0.02 mm.) at which the photodecomposition was studied wall recombination of atoms by reactions (17), (18) and (19) should become a competing process with any gas phase reaction, such as (15). If this latter reaction should occur to an appreciable extent the rate would fall off, at these low pressures, more rapidly than with the first power of the pressure, which is contrary to the experimental results (Fig. 6). Furthermore, the quantum yield at high pressures, where bimolecular gas phase reactions would be favored, is less than unity while reaction (15) would, itself, lead to a quantum yield of two. Therefore we conclude that the recombinations of atoms on the walls, by reactions (17), (18) and (19), constitute nearly the entire secondary process. If the specific velocity constants of (17), (18) and (19) are numerically equal there should be a quantum yield of 0.5, but values from 0 to 1 are possible depending on the ratio of the mean of the rates of (17) and (18) to that of (19).[30]

Correlation with the Decomposition at Higher Pressures

Macdonald,[3] who made a brief study of the decomposition for the pressure range 50 to 650 millimeters, found an extinction coefficient for the active radiation which is only 2% of that we have computed for the active radiation at low pressures and about double that which we have measured for the absorption of λ 1849. From this we conclude that β-band absorption, followed by predissociation, is the primary mechanism of the high pressure decomposition. This is reasonable since, through this range of pressures, absorption in the β-bands must increase in almost direct proportion to the pressure while δ-absorption, already substantially complete even at four or five millimeters, can show little gain.

This conclusion differs from that of Macdonald, who pictured the primary mechanism as one of activation, followed by independent bimolecular reactions between activated and normal molecules. However, we find nothing in Macdonald's work (which was restricted almost entirely to the measurement of quantum yield and to the relation between reaction rate and light absorption) which precludes the predissociation mechanism.

Although the details of the secondary processes appear less certain, most of the arguments advanced in favor of atomic recombinations at the walls, for the low pressure decomposition, appear applicable also at the higher pressures. The one objection to this conclusion is Macdonald's purported observation of appreciable nitrous oxide among the reaction products. This may be accounted for in terms of reaction (24) although to produce 10% nitrous oxide among the products would require a very considerable amount of this reaction since nitrous oxide itself decomposes much faster than nitric oxide. This would require a quantum yield approaching 1.5, which is contrary to the facts. On the basis of what de-

---

(29) In collision of a fast oxygen atom, with either nitrogen or nitric oxide in the gas phase, conservation of linear momentum exacts a minimum toll of 35% of the kinetic energy of the oxygen. This leaves only 10,000 calories, as a maximum, for activation. In only a small fraction of the collisions will this maximum energy be available. The great majority of collisions will be elastic due to steric and statistical factors and will dissipate the high energy of the oxygen in successive small losses. A further argument against (16) is the fact that nitrogen as a diluent did not affect the rate.

(30) Reactions (23), (24) and (25) are not excluded on any of the grounds advanced above, although wall reactions of this character appear considerably less probable than (17), (18) or (19). In any case (23), (24) or (25) must be considered in connection with the ultimate products which result from the photodecomposition of the NO_2 or N_2O, which are more rapidly decomposed than the NO. Norrish (ref. 10) has shown that NO_2 decomposes photochemically, by a bimolecular process, to yield NO and O_2. The net effect of (23) would thus be the complete reversal of the initial photodecomposition of nitric oxide, and a consequent quantum yield of zero if this process represented the normal method of removing the nitrogen atoms. It is clearly not of much relative importance in the actual decomposition. The net influence of (25) would be the substitution of a more complex process than (18) for the formation of molecular oxygen. Reactions (17) or (19) would still be required to account for the removal of atomic nitrogen. Macdonald (ref. 3) finds that the photodecomposition of N_2O yields N_2, NO and O_2 in the proportions of 3, 2 and 1. Thus the net effect of (24) is the substitution of a more complex process than (17) or (19) for the removal of nitrogen atoms and would lead to a quantum yield of 1.5, which is double the value observed by Macdonald. Any of these mechanisms (23, 24 or 25) require that one or more of the simple reactions (17, 18 or 19) be operative for the removal of one species of atom. It appears reasonable to credit the entire secondary process, in the main, to the simpler set of reactions.

scription Macdonald gives of his analytical procedure we feel that the presence of nitrous oxide in the reaction products may not be fully established.

Summary

The photochemical decomposition of nitric oxide has been studied, as a function of the pressure, over the pressure range 0.02 to 7 mm. with irradiation both from the mercury arc and from sparks between electrodes of aluminum, zinc, cadmium, nickel, copper and tin, respectively.

The final products of the reaction are nitrogen and oxygen although the latter is removed by a reaction which takes place during compression of the gas in the McLeod gage. This reaction produces a solid product, probably mercurous nitrite, which decomposes to liberate nitric oxide by a first order process which has a velocity constant of 1.5×10^{-2} hr.$^{-1}$.

The rate of decomposition proves to be directly proportional to the rate of light absorption for light of the effective wave length and is, at very low pressures, directly proportional to the pressure. The absorption of effective radiation follows Beer's law and has, for the reaction with the mercury arc, an extinction coefficient of about 2.9×10^{-2} per millimeter light path per millimeter of pressure. Nitrogen as a diluent does not appreciably influence the rate of decomposition. These results, alone, indicate primary dissociation as the first step in the process.

The use of filters containing solutions of ammonium chloride and of ammonium hydroxide places the effective mercury arc radiation below λ 1900. The use of a water filter indicates that the effective region is in the neighborhood of λ 1830. The strong resonance line at λ 1849 is ruled out, except for a relatively small influence at the higher pressures, by measurement of its absorption coefficient which proves to be one hundred times too small for the observed reaction. The alternative is the weak λ 1832 line of mercury which is strongly absorbed by the $(1',0'')$ band of the δ-system of nitric oxide. The essential features of this interpretation are confirmed by the measurement of the decomposition under the influence of both filtered and unfiltered radiation from sparks between metal electrodes. The latter owe the greater portion of their effectiveness to a background of continuous radiation below λ 1900.

This interpretation of the primary process, which must be a predissociation since it occurs in a banded region of the spectrum, agrees well with the evidence for predissociation provided by the emission spectrum of nitric oxide.

Possible secondary processes are considered. All are believed ruled out on theoretical or experimental grounds, in comparison with combination of nitrogen and oxygen atoms on the walls.

Macdonald's work with high pressures of nitric oxide has been considered and it is concluded that the mechanism determined for the low pressure decomposition may also be applied to the results at higher pressures. However, predissociation from the upper levels of the β-bands, rather than the δ-bands, provides the primary step at these higher pressures.

Reduction Studies in the Morphine Series. VII. Pseudocodeinone[1]

BY ROBERT E. LUTZ AND LYNDON SMALL

Pharmacological studies which have been carried out at the University of Michigan coördinate with the chemical investigations at this Laboratory have shown that as regards general physiological action, the four codeine isomers may be grouped in pairs, codeine with allopseudocodeine, and isocodeine with pseudocodeine.[2] This pairing is based primarily upon the relative degree of convulsive and depressant actions exhibited by each of the drugs, upon their toxicity and upon their effective ratios in other respects when toxicity is taken into account. The same relationship holds for the four corresponding isomeric morphines, and suggests that the spatial arrangement of the alcoholic hydroxyl group may be of

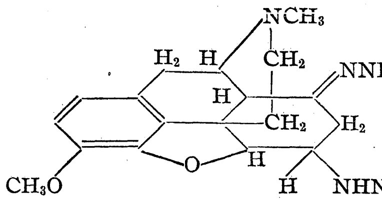
[1] The work reported in this paper is part of a unification of effort by a number of agencies having responsibility for the solution of the problem of drug addiction. The organizations taking part are: The Rockefeller Foundation, the National Research Council, the U. S. Public Health Service, the U. S. Bureau of Narcotics, the University of Virginia and the University of Michigan.

[2] Eddy, *J. Pharmacol.*, **45**, 361 (1932).

more importance for physiological effect than its position (at −6 or −8) on the nucleus.[3] Information on the relative importance of the C-6 and C-8 positions may be expected from the study of derivatives in which the asymmetry at C-6 and C-8 has been destroyed, *i. e.*, compounds whose difference in action must be due to the difference in ring position of the characteristic group present. The present communication deals with the preparation of dihydropseudocodeinone (the "pseudo" analog of Dicodid) and dihydroisomorphinone (the "pseudo"[4] analog of Dilaudid), substances which differ from the well-known drugs cited only in having the keto group at C-8 instead of at C-6. Aside from the practical aspect of the problem, the reduction of pseudocodeinone is of theoretical interest because of the conjugated system involved.

Pseudocodeinone (II) is prepared by oxidation of either pseudocodeine or allopseudocodeine, whereby the secondary alcoholic group at C-8 in these isomers is converted to a carbonyl group, and the stereoisomerism disappears. The location of the carbonyl group at C-8 depends upon the degradation of pseudocodeinone to 3,4,8-trimethoxyphenanthrene.[5] The earlier formulas for pseudocodeine[6] (and hence for pseudocodeinone) placed the alicyclic double linkage at C-13, C-14, whereas the Gulland and Robinson formula[7] locates the unsaturation at C-6, C-7 (formula II). The latter conception is substantiated by the reactions described in the present paper. We have verified the important reaction upon which the Pschorr formula was based, the condensation of pseudocodeinone with benzaldehyde,[8] believed to indicate a methylene group adjacent to the carbonyl. This point of evidence for the Pschorr formula loses most of its weight, however, through our observation that codeine likewise condenses with benzaldehyde under the same conditions.[9]

In favor of the 6,7-position for the pseudocodeinone unsaturation, the reaction with semicarbazide may be advanced. Pseudocodeinone is known to react with semicarbazide to give a monosemicarbazone;[5a] we find that on standing with a large excess of the reagent it reacts with a second molecule in a manner characteristic of α,β-unsaturated ketones[10] to yield a semicarbazino-semicarbazone to which we assign the structure I.



I. Pseudocodeinone semicarbazino-semicarbazone

Hydrogenation of pseudocodeinone in ethanol with a platinum catalyst results largely in formation of the phenolic tetrahydropseudocodeinone,[11] (V), a reaction to be expected from the pseudocodeine type (II) under these conditions. Tetrahydropseudocodeinone still contains the carbonyl group, as is shown by oxime formation.[11] By further reduction, with sodium and alcohol, we obtained only tetrahydropseudocodeine (VI). The diastereomeric tetrahydroallopseudocodeine, whose formation might be anticipated, was not found.

Hydrogenation of pseudocodeinone hydrochloride in glacial acetic acid favors normal saturation of the double linkage, and suppresses reduction of the cyclic ether group. The product consists of nearly equal amounts of the above mentioned tetrahydropseudocodeinone and of the new dihydropseudocodeinone (III).[12] The latter is the desired 8-keto isomer of the 6-keto compound, dihydrocodeinone (Dicodid). In dihydropseudocodeinone the ether bridge is intact, as is shown not only by the lack of phenolic characteristics but also by the reduction (sodium and alcohol) to our previously described non-phenolic dihydropseudocodeine (VII). Through this reduction reaction, as well as by oxime formation, the presence of the carbonyl group in dihydropseudocodeinone is demonstrated. It is notable that the reductions of tetrahydropseudocodeinone and dihydropseudocodeinone are consistent stereochemically in yielding exclusively the reduction product having the pseudocodeine configuration.

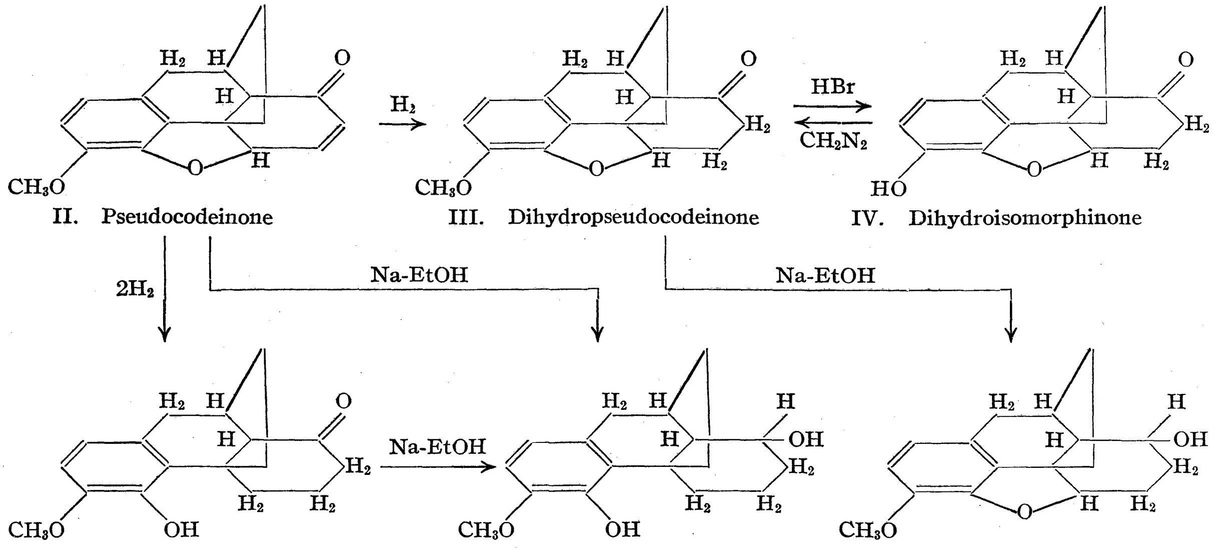
(12) Speyer and Rosenfeld, *Ber.*, **58**, 1117 (1925), obtained from treatment of bromocodeinone with sodium hydrosulfite a compound of formula $C_{18}H_{21}O_3N$, for which they suggested a dihydropseudocodeinone structure. No evidence was advanced to support this suggestion, and the properties of their compound differ from those of our dihydropseudocodeinone.

Sodium and alcohol reduction of pseudocodeinone yields tetrahydropseudocodeine directly, the keto group again being reduced to the favored pseudocodeine configuration as noted above.

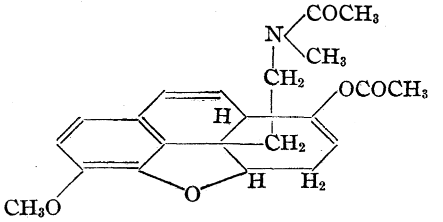


II. Pseudocodeinone III. Dihydropseudocodeinone IV. Dihydroisomorphinone

V. Tetrahydropseudocodeinone VI. Tetrahydropseudocodeine VII. Dihydropseudocodeine

Demethylation of dihydropseudocodeinone gives in good yield dihydroisomorphinone (IV), the 8-keto analog of the 6-keto compound, dihydromorphinone. Dihydroisomorphinone is a strongly phenolic base whose structure is sufficiently demonstrated by the reconversion to dihydropseudocodeinone through the action of diazomethane. The synthesis of dihydroisomorphinone here realized is at present not a practicable one on account of the difficulty involved in the preparation of dihydropseudocodeinone.

An attempt to prepare an 8-enol-acetate analog of the drug "Acedicon" (acetyldemethylodihydrothebaine, or dihydrocodeinone enol acetate) failed because of the lability of the nitrogen-containing ring in dihydropseudocodeinone. The action of acetic anhydride and sodium acetate on dihydropseudocodeinone results in a substance, $C_{22}H_{25}O_5N$, which contains two acetyl groups and which is no longer basic. These facts are best explained by a des-N-acetyldihydropseudocodeinone enol acetate formula, (VIII). This ring opening of dihydropseudocodeinone on acetylation recalls the behavior of apomorphine[13] and morphothebaine,[14] where the driving force of the reaction appears to be the possibility of forming a completely aromatic nucleus.



VIII. Des-N-acetyldihydropseudocodeinone enol acetate

It has long been known that the carbonyl group in codeinone does not react with the Grignard reagent under ordinary conditions[15] or even at temperatures up to 170°, where decomposition occurs.[16] Dihydrocodeinone is attacked only in small degree, yielding traces of a *phenolic* product, and dihydropseudocodeinone is recovered unchanged after treatment with methylmagnesium iodide. Pseudocodeinone, on the other hand, reacts readily with this reagent to yield a substance provisionally named methyldihydropseudocodeinone, which is of interest because of its peculiar properties. It is a strongly phenolic base, whose empirical formula shows that the elements of methane have been added to the starting material. Accordingly, the ether bridge must be open, and the carbonyl group and a double bond still be present. Nevertheless, the new compound resists all attempts at reduction, whether by catalytic methods, sodium in alcohol or cyclohexanol, or the Clemmensen method. None of the other unsaturated or saturated ketones of the morphine series has been found to offer such resist-

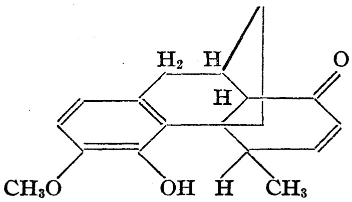
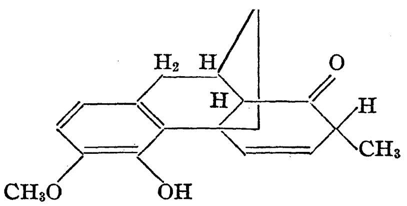
ance to reduction at the double linkage or carbonyl group.[17] Furthermore, repeated attempts to prepare an oxime or a semicarbazone failed. We were unable to find any evidence of the presence of either alicyclic double linkage or carbonyl group, although one or both must be present, whatever may be the mechanism by which *one mole* of alkylmagnesium halide adds. We believe that the best interpretation of the reaction is the 1,2- or 1,4-addition of methylmagnesium iodide to the system consisting of an ether linkage and the 6,7-double bond, such as we postulate in the case of desoxycodeine-C and other pseudocodeine types.[18] That the carbonyl group is not involved is not remarkable in view of the indifference of this group in the examples cited above. The structure of methyldihydropseudocodeinone might be expressed by formula IX or X (or a rearranged form of X), of which the α,β-unsaturated ketone formula IX seems the less probable on account of the extraordinary resistance to reduction with sodium and alcohol.



IX. 5-Methyldihydropseudocodeinone



X. 7-Methyldihydropseudocodeinone

In the cases of phenyldihydrothebaine[19] and the methyldihydrothebaines[20] we have a reluctance toward catalytic hydrogenation similar to that here observed, but it should be noted that methyl, ethyl and cyclohexyl dihydro derivatives of desoxycodeine-C, presumably of structure analogous to that of methyldihydropseudocodeinone, can be hydrogenated without difficulty.[18]

Dihydropseudocodeinone is about one-half as toxic as Dicodid, and shows less convulsant action. Its analgesic effect is much less than that of Dicodid, but in effective doses it causes no emesis and almost no excitement. Its activity in general is about one-tenth that of Dicodid. Dihydroisomorphinone presents a similar picture. In respect to analgesia and respiration it is only one-tenth as effective as the 6-keto isomer, Dilaudid; like dihydropseudocodeinone, it has no emetic and but little exciting action. Convulsions occur only with fatal doses. As far as conclusions are justified by the evidence available, it appears that a functional group in the 6-position exerts much more influence on physiological action than one in the 8-position. Pseudocodeine and γ-isomorphine, because of a favorable configuration of the alcoholic hydroxyl, are effective drugs in spite of the disadvantageous ring position of the group; allopseudocodeine and β-isomorphine, the least active of the isomers, have the hydroxyl unfavorably located both in space and in position. In codeine and morphine, the location of the hydroxyl in the active 6-position is of more importance than the unfavorable spatial arrangement, and in the most effective of the isomers, isocodeine and α-isomorphine, both position and configuration intensify physiological action. These conclusions, although drawn from few examples, are offered as a tentative explanation of the consistent relations (in respect to physiological action) of the codeine and morphine isomers and most of their dihydro derivatives.

Experimental

Pseudocodeinone (II) was prepared by chromic acid oxidation of pseudocodeine according to the method of Knorr and Hörlein.[5a] The product was best isolated by cooling the oxidation mixture through addition of ice, making strongly alkaline with sodium hydroxide, and extracting several times with ether. The yield of pure product seldom exceeded 10 to 15%. The important fact reported by Knorr that allopseudocodeine gives the same ketone on oxidation was verified, the yield in one experiment being 30% of that required by theory. The pseudocodeinone base was purified from butanone; occasionally some unchanged pseudocodeine was found, and was removed by utilizing its very slight solubility in ether.

II-Hydrochloride crystallizes from ethanol or from dilute hydrochloric acid; m. p. 201–203° (corr. with dec.); $[\alpha]^{25}_D$ −24° (water, c = 1.0).

Anal. Calcd. for $C_{18}H_{20}O_3NCl + H_2O$: H_2O, 5.1. Found: H_2O, 4.6. Calcd. for $C_{18}H_{20}O_3NCl$: Cl, 10.63. Found (dried at 120° *in vacuo*): Cl, 10.24.

Pseudocodeinone Semicarbazino-semicarbazone (I).—Two grams of pseudocodeinone with 25 cc. of water, 4 cc. of ethanol and 3 g. of semicarbazide hydrochloride went largely into solution on stirring, and a hydrochloride crystallized out; this showed the constants given by Knorr for pseudocodeinone semicarbazone hydrochloride. When allowed to stand for about three hours with occasional shaking in the presence of the excess semicarbazide, the pre-

cipitate dissolved. After sixty hours the semicarbazinosemicarbazone was thrown out crystalline by ammonia; yield 1.85 g. It is very slightly soluble in most organic solvents, and was purified from 70% alcohol; m. p. 225–227° (unsharp, dec.).

Anal. Calcd. for $C_{20}H_{27}O_4N_7 + H_2O$: H_2O, 4.0. Found: H_2O, 4.1. Calcd. for $C_{20}H_{27}O_4N_7$: C, 55.91; H, 6.34. Found: C, 55.61; H, 6.46.

Dihydropseudocodeinone (III).—A suspension of 13.8 g. of pseudocodeinone hydrochloride in 50 cc. of glacial acetic acid with 0.1 g. of platinum oxide absorbed 1270 cc. (corr.) of hydrogen, or 1.4 moles. The filtered solution was diluted with ice water, made ammoniacal under ether and extracted several times. The oily base thus obtained was dissolved in acetone, from which nearly pure tetrahydropseudocodeinone separated on cooling. Dilution of the filtrate with a little water yielded a second crop of the same product; yield 34%. The acetone solution, partially evaporated in an air blast, gave dihydropseudocodeinone as an oily precipitate, which slowly solidified, m. p. 93–100°, yield 46%. Reduction of pseudocodeinone in alcohol with platinum gave tetrahydropseudocodeinone with only traces of dihydropseudocodeinone.

Dihydropseudocodeinone crystallizes from ethyl acetate or ethyl acetate–ligroin mixtures as balls of rectangular prisms or plates, m. p. 113° (corr.). It may also be purified through the hydriodide. In high vacuum it distils as a colorless glass; $[\alpha]^{25}_D$ +37° (ethanol, c = 0.62).

Anal. Calcd. for $C_{18}H_{21}O_3N$: C, 72.20; H, 7.07. Found: C, 72.19; H, 7.15.

Dihydropseudocodeinone hydrochloride was prepared in acetone with alcoholic hydrogen chloride, and purified from acetone–alcohol mixture. It melts at 172–173° (corr.), and has $[\alpha]^{26}_D$ +13° (water, c = 0.65).

Anal. Calcd. for $C_{18}H_{22}O_3NCl + H_2O$: H_2O, 5.1. Found: H_2O, 4.9. Calcd. for $C_{18}H_{22}O_3NCl$: Cl, 10.57. Found (dried *in vacuo* 120°): Cl, 10.09.

Dihydropseudocodeinone hydriodide crystallizes from water, melts at 250–255° (corr., with dec.), and shows $[\alpha]^{25}_D$ +8.1° (water, c = 0.56).

Anal. Calcd. for $C_{18}H_{22}O_3NI$: I, 29.72. Found (dried *in vacuo* 120°): I, 29.98.

Dihydropseudocodeinone forms a well-crystallized tartrate (from water), m. p. 199–200°, $[\alpha]^{25}_D$ +20° (water, c = 0.91) which gave on analysis values approximating the formula of the acid tartrate.

Dihydropseudocodeinone oxime was prepared by boiling 0.2 g. of base in 2 cc. of water with 1 g. of hydroxylamine hydrochloride; yield nearly quantitative. It was purified from ethanol, and melted at 244–245° (corr.).

Anal. Calcd. for $C_{18}H_{22}O_3N_2$: C, 68.75; H, 7.06. Found: C, 68.69; H, 6.98.

Reduction of dihydropseudocodeinone with sodium in alcohol gave 78% yield of dihydropseudocodeine-A (VII).[21]

Des - N - acetyldihydropseudocodeinone Enol Acetate (VIII).—A solution of 0.5 g. of III in 5 cc. of acetic anhydride with 0.5 g. of sodium acetate, heated for three hours at 100°, gave a nearly quantitative yield of the non-basic product VIII. This crystallized from ethanol as thin six-sided scales of m. p. 191.5–192° (corr.).

Anal. Calcd. for $C_{22}H_{25}O_5N$: C, 68.90; H, 6.57. Found: C, 68.83; H, 6.58.

Tetrahydropseudocodeinone (V).—The physical properties of this compound differ considerably from Hill's description.[11] It behaves like a cryptophenol; it is not readily soluble in dilute sodium hydroxide, and is largely extracted by ether from its solution in alkali. Crystallized from ethanol or acetone it separates as the hemihydrate m. p. 137–138.5° (unsharp, corr.). It sublimes in a high vacuum, yielding the anhydrous form, m. p. 170–171° (corr.); $[\alpha]^{30}_D$ +8.0° (ethanol, c = 0.55).

Anal. Calcd. for $C_{18}H_{23}O_3N + 0.5H_2O$: C, 69.63; H, 7.80. Found: C, 69.64; H, 7.88. Calcd. for $C_{18}H_{23}O_3N$: C, 71.72; H, 7.70. Found (sublimed sample): C, 71.68; H, 8.01.

The base does not react with diazomethane. With acetic anhydride in pyridine (100° for thirty minutes) it forms a monoacetyl derivative which distils as a colorless glass in a high vacuum.

Anal. Calcd. for $C_{18}H_{22}O_3N(COCH_3)$: $COCH_3$, 12.5. Found: $COCH_3$, 12.3.

V-Oxime, crystallized from ethanol, melts at 218–219° (corr.). *Cf.* Hill, m. p. 137° (dec.).

Anal. Calcd. for $C_{18}H_{24}O_3N_2$: C, 68.31; H, 7.65; N, 8.86. Found: C, 68.26; H, 7.81; N, 8.98.

V-Hydrochloride crystallizes hydrated from ethanol, m. p. 165–166° (corr.) with frothing; $[\alpha]^{25}_D$ −6.2° (water, c = 1.29).

Anal. Calcd. for $C_{18}H_{24}O_3NCl + 2H_2O$: H_2O, 9.6; Cl, 9.54. Found: H_2O, 9.7; Cl, 9.36. Calcd. for $C_{18}H_{24}O_3NCl$: Cl, 10.50. Found: Cl, 10.09.

V-Hydriodide crystallizes hydrated from water, m. p. 154–155° (corr.), $[\alpha]^{25}_D$ −5.9° (water, c = 0.85).

Anal. Calcd. for $C_{18}H_{24}O_3NI + H_2O$: H_2O 4.0. Found: H_2O, 3.8. Calcd. for $C_{18}H_{24}O_3NI$: I, 29.58. Found: I, 29.41.

Tetrahydropseudocodeine (VI).—Reduction of either pseudocodeinone or tetrahydropseudocodeinone (0.5 g.) in 50 cc. of absolute alcohol with 5 g. of sodium (nitrogen atmosphere) gave 62% yield of tetrahydropseudocodeine, identified by its two melting points and the melting point of its characteristic methine derivative. Sodium amalgam in dilute acetic acid gave the same product.

Dihydroisomorphinone (IV).—Demethylation of dihydropseudocodeinone with hydriodic acid was unsatisfactory. A solution of 4.5 g. of III in 20 cc. of 48% hydrobromic acid was refluxed for fifteen minutes. An oily base was obtained from ether, and crystallized when digested with ethyl acetate; yield 2.45 g., m. p. 198° (corr.), $[\alpha]^{26}_D$ +46° (ethanol, c = 0.44). The base is soluble in sodium hydroxide, and precipitates on addition of ammonium chloride. The ferric chloride test is intense cobalt blue. IV-Perchlorate crystallizes in rectangular plates; the hydrochloride, hydriodide and tartrate are not crystalline. The base sublimes in a high vacuum at 200°.

Anal. Calcd. for $C_{17}H_{19}O_3N$: C, 71.54; H, 6.72. Found: C, 71.22; H, 6.98.

Methyldihydropseudocodeinone.—Treatment of 12 g. of pseudocodeinone in 1000 cc. of absolute ether with 100 cc. of 1.9 molar methylmagnesium iodide gave an oily base

---

[21] Lutz and Small, THIS JOURNAL, **54**, 4715 (1932).

which partly crystallized from ethanol; yield, 3.3 g. It was purified from isopropyl alcohol, m. p. 213.5–214.5° (corr.).

Anal. Calcd. for $C_{19}H_{23}O_3N$: C, 72.82; H, 7.40. Found: C, 72.96, 72.48; H, 7.62, 7.49.

Methyldihydropseudocodeinone was unaffected by treatment with sodium in alcohol or in boiling cyclohexanol, by catalytic hydrogenation in alcohol, acidified alcohol or glacial acetic acid, by zinc and hydrochloric acid (seven hours under reflux), or by hydroxylamine or semicarbazide under various conditions.

The use of ethylmagnesium iodide in the above reaction gave non-crystalline products.

Summary

1. Pseudocodeinone can be reduced under proper conditions to a non-phenolic dihydropseudocodeinone. The relationship of this to dihydropseudocodeine-A establishes its structure.
2. Demethylation of dihydropseudocodeinone results in dihydroisomorphinone, the 8-keto analog of Dilaudid.
3. Dihydropseudocodeinone is indifferent to methylmagnesium iodide, but pseudocodeinone reacts to give a phenolic dihydromethylpseudocodeinone. This product is remarkable in the complete passivity of its carbonyl group and double linkage toward the usual reagents affecting such structures.
4. Comparison of the physiological action of dihydropseudocodeinone and dihydroisomorphinone with that of Dicodid and Dilaudid, and that of the codeine and morphine isomers indicates that morphine derivatives with the functional group at C-6 are more effective than those with the same group at C-8, but that spatial relationships are also very important.

Vinyldiazomethane

BY CHARLES D. HURD AND S. C. LUI

Recently, Adamson and Kenner[1] described vinyldiazomethane as if it were new. Nirdlinger and Acree,[2] however, prepared it in 1910. They synthesized it from allylnitrosourethan whereas Kenner employed allyl (acetyl-*t*-butyl)-nitrosamine. In the present work, done in 1933–1934, it was studied to learn whether allyl, cyclopropyl or propenyl esters would be formed during reaction with acids. Actually, it was the ally ester which resulted: $C_6H_5COOH + CH_2{=}CHCHN_2 \longrightarrow N_2 + C_6H_5COOCH_2CH{=}CH_2$. The isomerization of vinyldiazomethane to pyrazole, reported by Adamson and Kenner, was observed. In fact, it was found to isomerize appreciably even during the distillation of the diazo compound.

Vinyldiazomethane was prepared by Nirdlinger and Acree's method, namely, by adding a solution (20%) of potassium hydroxide in methanol to a solution of the nitroso compound (A) in ether (B). When a 1:15 or 1:20 ratio of A:B was maintained, a 22–25% yield of vinyldiazomethane resulted. With a 1:9 ratio, the yield dropped to 13%.

Allylurethan and allylnitrosourethan were prepared by methods closely adapted from those given for methylurethan and methylnitrosourethan in "Organic Syntheses" [Vol. XII, p. 38; XIII. p. 84], the difference being that allylamine was taken instead of methylamine. The yields, respectively, were 81 and 94%. This preparation of allylnitrosourethan is new. Nirdlinger and Acree, who made it from nitrogen trioxide and allylurethan, mentioned no yield and gave no analysis. In the present work, the nitroso compound was analyzed after being thoroughly washed, dried and freed from solvent ether: d^{15}_{15} 1.051 d^{20}_{20} 1.047, d^{25}_{25} 1.044. Decomposition attended efforts to distil it (a red oil) at 3 mm.

Anal. Calcd. for $C_6H_{10}O_3N_2$: N, 17.7. Found: N, 17.4.

To estimate the yields, 10.00 cc. of the ether solution of vinyldiazomethane was mixed in a stoppered flask with a solution of 0.500 g. of *p*-nitrobenzoic acid in 25 cc. of dry ether. When the solution became colorless in 15–25 minutes it was back-titrated with 0.1 *N* barium hydroxide. When the reaction period was extended to twenty-four hours the results were but slightly higher; *e. g.*, a 22.3% value changed to 23.1%. With 2,4,6-trinitrobenzoic acid decolorization occurred immediately and gave quantitative values (23.0% in the case cited) if back-titrated at once.

For comparison of *p*-nitrobenzoic acid and benzoic acid, duplicate experiments were performed with reaction times of one-half, one and twenty-four hours. The yields, respectively, from *p*-nitrobenzoic acid were 22.3, 22.8, 23.1%; from benzoic acid, 12.1, 15.2, 16.2%.

Allyl Benzoate.—Vinyldiazomethane (1.855 g.) and benzoic acid (10 g.) were mixed in 360 cc. of dry ether and left for two days. Then the ether and excess acid were removed. The ester which remained distilled at 228°; yield, 2.90 g. or 65.7%. Two grams of this ester was hy-

drolyzed by sodium hydroxide, the alcohol portion ether extracted and a part of it treated with α-naphthyl isocyanate. The allyl α-naphthylcarbamate[3] thus obtained, after two recrystallizations from ligroin, melted at 108°.

Pyrazole.—A vinyldiazomethane solution (0.53 g. in 100 cc. of ether) was set aside for two days, then evaporated. The crystalline residue of pyrazole weighed 0.72 g. This indicates that an appreciable isomerization of the vinyldiazomethane occurs during synthesis in the distillation process. After being twice recrystallized from ether, it melted at 68°. It was identified as pyrazole by converting 0.1 g. of it to pyrazole picrate, m. p. 160°.

Summary

The synthesis and some of the properties of allylnitrosourethan and vinyldiazomethane are discussed.

The Constitution of Liquid Zinc Amalgams

BY HERMAN A. LIEBHAFSKY

Cells in which the electrodes are zinc amalgams of different concentrations, and the electrolyte is an aqueous solution of a zinc salt, have been investigated frequently during the past fifty years.[1] In three of these investigations,[1,2,3] exceptional care has been employed and the accuracy consequently attained has been so great that the problem of determining the electromotive forces of such cells near room temperature appears to be closed, with these two experimental results definitely established. First, dilute zinc amalgams, even in the absence of oxygen, tend increasingly to lose zinc as they become more dilute,[2a] so that the resulting uncertainties in composition constitute the chief stumbling blocks in obtaining the electromotive forces of zinc amalgam cells to within, say, 0.001 millivolt. And, second, these electromotive forces are actually smaller than the ideal values corresponding to the Nernst equation, so that[4]

$$E_{\text{act}} + \Delta E = E_{\text{id}} = 0.09922T\log[\Sigma(\text{Zn})_1/\Sigma(\text{Zn})_2] \quad (1)$$

ΔE, the departure from ideality, is positive and decreases with the concentration of the more concentrated amalgam in the cell. Richards and Forbes[1] pointed out that this departure from ideality qualitatively indicated a partial polymerization of the zinc. Hildebrand[5] contributed greatly to the problem from the experimental side[5b] when he proved that the vapor pressures of zinc amalgams at 300° exhibit deviations from ideality corresponding to ΔE; and from the theoretical side when he showed, in accord with the ideas of Dolezalek,[6] that both types of deviations could, within certain limits, be *quantitatively* explained on the assumption that

$$\text{Zn}_2 \xrightleftharpoons{K_2} 2\text{Zn};\ K_2 = (\text{Zn})^2/(\text{Zn}_2) \qquad (2)$$

was the only equilibrium existing in these amalgams. More recently the *activities* of zinc amalgams have been calculated from the electromotive force data[2b,3] and the interpretation of ΔE in terms of molecular species (a *concentration* treatment) has lost ground—a state of affairs easy to comprehend if, as Crenshaw[2b] states, the best experimental results for these amalgams agree better with each other than they do with Hildebrand's equation

$$E = 0.19834\,\frac{T}{n}\log\frac{1 + N_2 + \sqrt{N_2^2 + 2AN_2 + A}}{1 + N_1 + \sqrt{N_1^2 + 2AN_1 + A}} \quad (4)$$

where $n = 2$, the N's are the number of moles of mercury for one mole of zinc in amalgams 1 and 2, and $A = 4/(K_2^N + 1)$(see Footnote 4).

It is our purpose here to show that the positive values of ΔE for the zinc amalgams can be quantitatively accounted for without recourse to an activity treatment if we assume the equilibrium

---

(3) Pearce and Eversole, *ibid.*, **32**, 209 (1928). For a complete historical summary and additional references, see Ref. 1.

(4) The summation sign, Σ, prefixed to a concentration term indicates that all the zinc in an amalgam is meant; thus, $\Sigma(\text{Zn}) = (\text{Zn}) + (\text{Zn}_2) + (\text{Zn}_3) + \ldots$. Four concentration units have been employed in the investigations referred to above: *viz.*, (1) g. Zn/100 g. Hg, here denoted (as it has just been) by ( ); (2) g. Zn/100 g. amalgam; (3) the units of Richards and Forbes, which we shall designate by $(\text{Zn})^v$—namely, g. Zn/100 g. amalgam for the most concentrated amalgam only; for any other amalgam, this unit with the density change compensated which occurs when the amalgam is prepared by dilution from the most concentrated; (4) the mole fraction of zinc, equal to $1/(1 + N)$, where N is the number of moles of mercury for one mole of zinc; equilibrium constants expressed in this unit will be distinguished by a superscript; thus K_2^N. Electromotive forces will usually be expressed in *millivolts*.

(5) Hildebrand, (a) THIS JOURNAL, **35**, 501 (1913); (b) *Trans. Am. Electrochem. Soc.*, **22**, 335 (1913).

(6) Dolezalek, *Z. physik. Chem.*, (a) **64**, 727 (1908); (b) **71**, 191 (1910).

$$Zn_3 \xrightleftharpoons{K_3} 3Zn;\ K_3 = (Zn)^3/(Zn_3) \qquad (3)$$

to exist in addition to Reaction 2. This means in effect that we assume solutions of Zn, Zn_2, and Zn_3 in mercury at room temperature to be ideal over the entire range of composition.

The Experimental Data

Before proceeding with our interpretation of the experimental data, however, we shall have to re-examine these carefully for the following two reasons. First, all the finally accepted data of Richards and Forbes have never yet been compared with the other accurate experimental results; and, second, although several comparisons have been made, the results thereof are by no means in agreement.[7]

Richards and Forbes measured many combinations of cells at a number of temperatures in the neighborhood of 23° and thus proved beyond doubt that all their final results are concordant; but they did not, as was done in the subsequent investigations, actually measure the electromotive force of every other amalgam against the most concentrated. They did conveniently summarize all their final results, however, when they gave for each value of $(Zn)^{\nu}$ the deviation from ideality (analogous to ΔE, but for which we shall retain their symbols $D\pi$) that they would have obtained had they measured each of the other amalgams against No. 3, the most concentrated. Now, $D\pi$ will not be significantly affected by small changes either in the temperatures of the cells or in the concentrations of the amalgams, and the calculations of E_{act} and ΔE for the data of Richards were based on this fact.[8]

The most serious inaccuracies in these electromotive force investigations are encountered with dilute amalgams since these exhibit the greatest tendency to lose zinc. Crenshaw, and Pearce and Eversole measured all their other amalgams at 25° against the saturated amalgam, for which $\Sigma(Zn) = 2.2200$, as a common reference electrode. We are therefore doubly justified in adopting a method of comparison which places the greatest weight, not upon an arbitrarily chosen dilute amalgam, but upon the most concentrated one in each series. To do this, we modify the procedure of Richards and Forbes slightly by plotting ΔE(Eq. 1) against log $[2.2200/\Sigma(Zn)]$, as in Fig. 1. Their data are for 23.09° (296.2°K.), and have been brought to the same scale as the others (which are for 25°) by adding 2.600 to the ordinate and log 2.2200/0.9173 to the abscissa; this procedure arbitrarily places the point for their No. 1 amalgam on the curve; but it does not similarly constrain the results for their other amalgams, so that the points for these will not agree with the curve unless the corresponding measurements are also in agreement.

An examination of Fig. 1, in which the circles have diameters corresponding to only 0.05 millivolt, immediately reveals that the agreement among all three sets of results is excellent at the higher, and good at the lower, concentrations. The downward deviations for the two most dilute amalgams (Crenshaw's) are undoubtedly caused by loss of zinc,[9] and thus do not indicate a real departure from the horizontal line which ΔE reaches in dilute solution; most of the downward deviations for the other points probably also have their origin in a loss of zinc, so that the actual values of $\Sigma(Zn)$ are less than those employed in

---

[7] Hildebrand, and Pearce and Eversole have concluded that Crenshaw's measurements, made over the largest possible concentration range, do not agree with those made by Richards and Forbes over the smaller range (Zn) = 0.9 to 0.05; such disagreement does exist if the most dilute amalgam considered in each set is taken as reference electrode; as Crenshaw[2b] has pointed out, a comparison on this basis is not trustworthy if (as is likely to be the case) the result for either dilute amalgam is in error.

Pearce and Eversole consider that their recent measurements confirm those of Richards and Forbes, but disagree with those of Crenshaw.

Crenshaw[2b] has recently been able to bring all three sets of results into agreement by the following procedure: $[-E/0.00009922T - \log 1/(N+1)]$ is calculated for each value of the mole fraction of zinc in each set of data. To the values of this activity function thus obtained from the data of Pearce and Eversole, 2.0085 is added; a correction of 2.6775 is similarly applied to the values derived from the data of Richards and Forbes. The corrected values corresponding to all three sets of results are then plotted against $1/(N+1)$, the mole fraction of zinc; at the higher mole fractions, a straight line is obtained which, by a somewhat uncertain extrapolation, is extended to infinite dilution. This method of comparing the results necessarily lacks directness and simplicity; although it is perhaps preferable to employing an uncertain dilute reference electrode, it seems definitely less convincing than the straightforward method employed in the text (*cf.* Fig. 1).

[8] π_{id}, the ideal electromotive force for the cells of Richards and Forbes, and E_{id} differ because they involve different concentration units, and slightly different values for the fundamental constants.

E_{act} and ΔE at 23.09° for the *n*th amalgam of Richards and Forbes were calculated as follows. Since

$$\pi_{id} = 29.361 \log [\Sigma(Zn)_3^{\nu}/\Sigma(Zn)_n^{\nu}]$$

and the logarithms of the concentration quotients for all their amalgams are given by these authors, π_{id} was easily obtained. Also,

$$\pi_{id} - D\pi = \pi_{act} = E_{act} = E_{id} - \Delta E$$

so that E_{act} and ΔE are readily calculable by use of the $D\pi$ values, which are also listed in Reference 1.

[9] Crenshaw's detailed experimental results show how rapidly his dilute amalgams were losing zinc; while the electromotive forces of the more concentrated amalgams remained unchanged for weeks, a cell containing a dilute amalgam and the two-phase reference amalgam usually maintained a constant electromotive force for a matter of minutes only; after that the electromotive force increased, indicating loss of zinc from the dilute amalgam.

calculating ΔE. Figure 1 demonstrates convincingly and for the first time that all the final results of the three accurate investigations are in good agreement. Crenshaw[2b] has already reached a similar conclusion, but in a less straightforward manner, by extrapolating an activity function to infinite dilution.[7] Hildebrand has stated[5a] (p. 506) that his equation will not fit Crenshaw's results; since these agree with the others, we must conclude that assuming the existence of Reaction 2 does not suffice to explain the deviations of the electromotive measurements from ideality if the zinc amalgams are in fact ideal solutions. Since Fig. 1 shows them to be ideal solutions within the relatively large concentration range where $\Delta E = 0$ (the range, that is, within which the electromotive forces—losses of zinc neglected—conform to the limiting horizontal line), we assume provisionally that they remain ideal over the entire range of composition; and that the equilibria, Reactions 2 and 3, are wholly responsible for the apparent deviations from ideality encountered at the higher concentrations.

Interpretation of the Experimental Data

Our polymerization hypothesis, which assumes the simultaneous existence of Zn_2 and Zn_3 in rapid equilibrium with monatomic zinc will receive quantitative support if we can show that reasonably constant values of K_2 and K_3 can be calculated from the experimental data. The complex Eq. 4 obviously cannot furnish the point of departure for a simple method of performing these calculations. A simple method, employing Crenshaw's concentration units, has been devised, however, and will now be outlined.

If the zinc amalgams are ideal solutions, Eq. 1 may be written

$$E_{id} = E_{act} = 0.09922T \log [(Zn)_1/(Zn)_2] \quad (5)$$

the concentration of total zinc, $\Sigma(Zn)$, in Eq. 1 being replaced by the concentration of monatomic zinc. Figure 1 shows that $(Zn) = \Sigma(Zn)$ for the more dilute amalgams; if any such dilute amalgam is chosen as common reference electrode, the evaluation of (Zn) for each of the more concentrated amalgams presents no difficulty. These evaluations were accordingly carried out for each set of measurements, and the corresponding values for the "equilibrium quotient," K'', defined by

$$(Zn)^2/[\Sigma(Zn) - (Zn)] = K'' \quad (6)$$

were calculated. K'' would obviously be identical with K_2, the equilibrium constant of Reaction 2, if only this reaction were of importance; under these conditions it should therefore be reasonably constant. Instead, these K'' values showed a pronounced trend in the direction pointing to the existence of a higher polymer, say Zn_3.

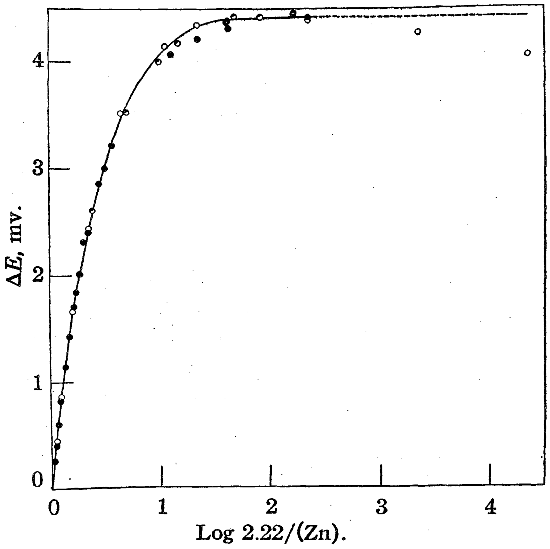

Fig. 1.—Deviations of the electromotive force for zinc amalgams near room temperature. The reference amalgam, for which $\Delta E = 0$, contains 2.220 g. Zn/100 g. Hg. ○, Crenshaw; ●, Pearce and Eversole; ◐, Richards and Forbes.

If Zn_2 and Zn_3 are the only polymers co-existing, then $\Sigma(Zn) = (Zn) + (Zn_2) + (Zn_3)$, and therefore by Eq. 6

$$K'' = (Zn)^2/[(Zn_2) + (Zn_3)] = (Zn)^2/[(Zn)^2/K_2 + (Zn)^3/K_3] \quad (7)$$

the expression on the right being obtained by introducing the equilibrium constants of Reactions 2 and 3. The K'' values for any pair of amalgams, a and b, fix a pair of equilibrium constant values (one for K_2 and one for K_3) because

$$(1/K'')_a = 1/K_2 + (Zn)_a/K_3 \text{ and}$$
$$(1/K'')_b = 1/K_2 + (Zn)_b/K_3 \quad (8)$$
$$\text{whence, } K_3 = \Delta(Zn)/[\Delta(1/K'')] \quad (9)$$

Calculations of K_3 were carried out by reckoning both increments for each of the more dilute amalgams from the most concentrated amalgam in the series; this procedure corresponds to the "long interval" method of evaluating specific rates and also to the experimental method of measuring each of the more dilute amalgams against the most concentrated. Since Fig. 1 shows the data from the three sets of accurate measurements to

be in good agreement, it follows that our hypothesis cannot conflict with any of these data if it agrees well with the data from the set of measurements best adapted to testing it, namely, those of Pearce and Eversole. Accordingly, the results of the other calculations will not be given; those corresponding to the data of Pearce and Eversole are summarized in Table I.

The K'' values in Table I clearly show a trend so marked and so consistent that it can scarcely be attributed to experimental errors; this trend, which indicates qualitatively the presence of a polymer higher than Zn_2, might have been predicted from the failure of Eq. 4 in conforming to Crenshaw's results.[10] There is no *trend* in the K_3 values, and the following analysis will show that their constancy is sufficiently good to establish our polymerization hypothesis as highly plausible. We observe first that, in accord with Eqs. 8, a K_3 result higher than the average means that the K_2 value paired with it will be correspondingly lower; the deviations from constancy for these two quantities are thus simply related. Next we notice that slight uncertainties in composition, which appear to be the most serious sources of error in these investigations, will have the greatest effect on K'' (and hence on K_2 and K_3) at the highest concentrations, where the increments in Eq. 9 are very small, and at the lowest, where the differences Σ(Zn)–(Zn) are not much larger than the uncertainties themselves. (To illustrate: if (Zn) for Nos. 2, 10 and 18 were assumed to be only 0.1% higher than in Table I, K_3 would be changed, respectively, to 6.9, 10.4 and 12.3.) The most convincing way to test our polymerization hypothesis is by using the finally selected K_2 and K_3 values to calculate Σ(Zn) for comparison with the amount of zinc used in making each amalgam; these calculations have been performed, with—as Table I shows— excellent results; only in three cases (Nos. 5, 15 and 16) is there an appreciable discrepancy (slightly larger than 0.5%) between the calculated and the experimental values.

Figure 1 indicates that this discrepancy in the last two cases is due to loss of zinc, so that the calculated Σ(Zn) values may well furnish a more reliable estimate of the actual composition of these amalgams than do the amounts of zinc used in preparing them. Since no "smoothing out" of the results has been done, the close agreement of

---

(10) To show that assuming the existence of Reaction 2 alone fails to explain the experimental results, we need only attempt to calculate Σ(Zn) for, say, No. 1 on this basis. If only Reaction 2 were of importance, K'' would equal $(Zn)^2/(Zn)_2$; employing $K'' = 4.7$, the arithmetical mean of the first 15 Table I values, we obtain $(Zn_2) = 0.5266$; whence $\Sigma(Zn) = 2.0999$, a value that is unacceptable because it is 6% too low.

the two Σ(Zn) columns is gratifying—not often is it possible to find solutions that can be regarded as ideal over the entire range of composition and described so accurately by the assumption of two simple equilibria. The constitution of the liquid zinc amalgams at room temperature thus seems to be reasonably well established; our polymerization hypothesis, when applied to the results of Pearce and Eversole, gives for the composition of the saturated amalgam at 25°: (Zn) = 1.5733, (Zn_2) = 0.2723 and (Zn_3) = 0.3744.

An examination of the calculations based on the other accurate experimental results does not significantly alter these conclusions. For Crenshaw's data, three series of such calculations—employing as reference electrode the amalgam for which Σ(Zn) was, respectively, 0.1, 0.01 and 0.001—have been carried out; the results of all three sets are substantially in accord. The resulting individual K_3 values do not vary significantly more than those in Table I, but the average thereof is some 10 or 15% *lower* than the value selected from Table I; K_2 is correspondingly higher. The K_3 values from the results of Richards and Forbes are more erratic, and show a trend such that K_3 decreases with Σ(Zn). The average of these would be appreciably *higher* than 10.4, the Table I result; but the concentration range of Richards and Forbes' measurements is restricted, so that this average cannot be given serious weight. Since Pearce and Eversole have by far the greatest number of results extant for the concentration range where K_2 and K_3 can be most accurately determined, we shall adopt the values selected from Table I as final.

Summary and Conclusion

The electromotive force data for zinc amalgams have been re-examined, and it has been shown for the first time that all the final experimental results of the three accurate investigations made near room temperature agree excellently for the more concentrated amalgams and well for the dilute, whose investigation is complicated by their tendency to lose zinc. The deviations of these electromotive forces have been explained on a polymerization hypothesis that assumes the simultaneous existence of Zn_2 and Zn_3 in rapid equilibrium with monatomic zinc. A simple method for calculating the dissociation constants for these polymers has been devised and successfully applied to the electromotive force data; the constants thus obtained are satisfactory, so that the polymerization hypothesis and consequently the constitution of the liquid zinc amalgam at room temperature seem reasonably well established. If the validity of the polymerization hypothesis is granted, then it follows that the zinc amalgams at 25° behave as ideal solutions over the entire range of composition and that the fundamental laws underlying the Nernst equation govern them to within the precision of the measurements. The existing experimental work for other temperatures has permitted only these qualitative conclusions: the heats of dissociation of both polymers are small, that of Zn_3 being the greater.

Since the polymers have heats of dissociation not greatly exceeding RT, they cannot be very stable compounds. We must remember, therefore, that the evidence we have adduced for their existence, although as convincing as evidence of its kind can be, is after all indirect in nature; for we have shown only that zinc amalgams at 25° deviate from the laws of ideal solutions *almost exactly as though* Zn_2 and Zn_3 existed in rapid equilibrium with monatomic zinc. Here, as in the cases of many other solutions, it is difficult to decide whether such deviations, by whatever thermodynamic method they are established, should be attributed to compound formation or to a less definite interaction among the molecules composing the solution; a final decision becomes possible only when more direct experimental methods have "proved" the presence or absence of the compounds in question. Where aqueous solutions are concerned, their Raman spectra are often of service; but corresponding evidence for amalgams does not yet seem to be available.[11] Until it does appear, our indirect evidence would seem sufficiently strong to warrant regarding our polymerization hypothesis as provisionally established: for (1), this hypothesis involves only two equilibria (a much larger number would militate against it); (2), the corresponding equilibrium constants are accurately established (say, to within 5 or 10%); (3), no other set of two equilibria can be formulated that will fit the experimental data so well; and (4), any satisfactory alternative explanation of the deviations in question will have to yield ΔE values practically in-

---

[11] In connection with our polymerization hypothesis, it is interesting to observe that many metallic vapors, probably including those of zinc, show band spectra indicating the presence of dimers. See Shawhan, *Phys. Rev.*, **48**, 343 (1935), and Robertson, *Nature*, **135**, 308 (1935), where other references are given.

distinguishable from those given by our polymerization hypothesis; whether any explanation based on intermolecular forces, but not assuming compound formation, will do this becomes doubtful when we remember (see Fig. 1) that ΔE becomes constant long before "infinite dilution" is reached.

It is not claimed, finally, that a *concentration* treatment of amalgams is generally preferable to a treatment in terms of *activities*. The latter quantities are always valuable since they stand, by definition, in simple relation to the free energies of the amalgams, and thus bridge the gap between the thermodynamic functions for an amalgam and its stoichiometric composition. But when amalgams become experimentally indistinguishable from ideal solutions in the manner of Fig. 1, then it seems desirable to try a concentration treatment also, in order to determine whether the deviations from ideality at the higher concentration cannot be quantitatively accounted for by assuming polymerization of the solute; for we may discover in this way what molecular species actually exist in these amalgams.

The Energies and Entropies of Activation of the Reaction between Bromoacetate and Thiosulfate Ions[1]

BY VICTOR K. LA MER AND MILDRED E. KAMNER

In the theory of chemical kinetics there are two important quantities which determine the specific rate constant k, namely, the energy of activation E_{act}, defined through the differential form of the well-known Arrhenius equation

$$d \log k/dT = E_{\text{act}}/2.3RT^2 \qquad (1)$$

and the action constant $B = \log \alpha$ in the integrated form, namely

$$k = \alpha\, e^{-E_{\text{act}}/RT} \qquad (2)$$

$$\log k = B - E_{\text{act}}/2.3RT \qquad (3)$$

E_{act} represents the average energy of those molecules which react minus the average energy of all the molecules in the system, all quantities being defined per mole. La Mer[2] has shown as a consequence of this definition of E_{act}, due to Tolman, that

$$B = \log \alpha = \frac{1}{2.3R}\int_0^T \left(\frac{\partial E_{\text{act}}}{\partial T}\right)\frac{dT}{T} + \text{constant} \qquad (4)$$

determines the frequency with which the activated molecules react. In the special case where E_{act} remains independent of T at all temperatures, the integration constant in (4) equals log Z^0. In the case of unimolecular reactions Z^0 is the frequency of breaking the reactive bond in the activated molecule, whereas in a true bimolecular reaction Z° equals the collision frequency at unit concentrations. The dimension of B is time^{-1}.

The first term of B represents the increase in entropy due to the temperature dependence of E_{act} for the process, inactive molecules ⟶ active molecules, and hence has been called[2] the entropy of activation. Further experimental evidence for the temperature dependence of B and E_{act} for a zero type reaction will appear in another paper.[3]

The present paper will deal primarily with the temperature dependence of the kinetic salt effect in a reaction between ions of the same sign to ascertain in how far interionic attraction influences E_{act} and B. The bromoacetate–thiosulfate ion reaction $BrCH_2COO^- + S_2O_3^= \longrightarrow S_2O_3CH_2COO^= + Br^-$ was selected for the experimental study since it is almost unique among ionic reactions for the absence of side reactions and the high precision with which the velocity constant can be determined.[4]

Accordingly, the experiments were designed to test the behavior of E and B for (a) change of temperature at constant concentration of reactants; (b) change of ionic strength (Brönsted–Debye effect) for the same temperature interval; (c) the effect of substituting high valence cations like La^{+++} for the lower valence ions Ba^{++} and Na^+ at the same ionic strength, and (d) the influence of dielectric constant produced by the addition of non-electrolytes.[5]

The Limiting Law for E_{act} and B.—Equation

---

[1] A preliminary report of these data was given in THIS JOURNAL, **55**, 1739 (1933). A more complete report was read at the St. Petersburg, Florida, meeting of the Society in March, 1934.

(1) and the Brönsted equation $\log k = \log k^0 + \log f_A f_B/f_X$ yields

$$E_{\text{act}} = E^0_{\text{act}} + [\bar{L}_X - (\bar{L}_A + \bar{L}_B)] \qquad (5)$$
$$= E^0_{\text{act}} + \Delta\bar{L}_{\text{act}}$$

when we recall that $\bar{L} = -RT^2\,\partial \ln f/\partial T$.

The superscript zero refers to the standard state of infinite dilution. $\bar{L} = H - H^0$ is the *relative* partial molal heat content, so that $\Delta\bar{L}_{\text{act}}$ may be called the heat of dilution for the activation process $A + B \rightleftarrows X$.

Similarly by using eq. (4), B can be decomposed into the components.

$$B = B^0 + [\bar{S}_X - (\bar{S}_A + \bar{S}_B)] \qquad (6)$$
$$= \log Z^0 + S^0_{\text{act}}/2.3R + \Delta\bar{S}_{\text{act}}/2.3R$$

$\Delta\bar{S}/2.3R$ is the increase in entropy of activation arising from interionic attraction.

When the thermodynamic operators $\bar{S} = -\partial\bar{F}/\partial T$ and $\bar{H} = \partial(\bar{F}/T)/\partial(1/T)$ are applied to the Debye–Hückel limiting law

$$\bar{F}_i = -N(\epsilon Z)^2\kappa/2D \qquad (7)$$
$$\kappa = C(DTV)^{-1/2}$$

one obtains on substituting Wyman's values[6] of $\partial \ln D/\partial \ln T = -1.371$ for water at 25°, that

$$\bar{L}_i = \bar{F}_i\left[3/2\frac{\partial \ln D}{\partial \ln T} + \frac{1}{2}\frac{\partial \ln V}{\partial \ln T} + 3/2\right] \qquad (8)$$
$$= \bar{F}_i\,[-0.51]$$
$$\bar{S}_i = \bar{F}_i/T\left[3/2\,\partial\ln D/\partial\ln T + \frac{1}{2}\partial \ln V/\partial \ln T + \frac{1}{2}\right] \qquad (9)$$
$$= \bar{F}_i/T[-1.52]$$

It is important to emphasize that in the limit for high dilutions, the *reversible* heat of dilution ($-T\bar{S}_i$) is almost exactly three times greater, *but opposite in sign* to the *irreversible* heat of dilution ($\bar{H}_i$). Now

$$\bar{F}_i/2.3RT = \log f_i = -0.506 Z_i^2\sqrt{\mu} \qquad (10)$$

and $Z_x^2 = (Z_A + Z_B)^2$, hence

$$\Delta\bar{L}_{\text{act}}/2.3RT = 0.51 Z_A Z_B\sqrt{\mu} \qquad (11)$$
$$\Delta\bar{S}_{\text{act}}/2.3R = 1.52\, Z_A Z_B\sqrt{\mu} \qquad (12)$$

The Brönsted–Debye equation, accordingly, can be written

$$\log k = [\log Z^0 + S^0_{\text{act}}/2.3R + 1.52\, Z_A Z_B\sqrt{\mu}]$$
$$- [E^0_{\text{act}}/2.3RT + 0.51 Z_A Z_B]\sqrt{\mu} \qquad (13)$$

The limiting slope of the experimental quantities $\log k$, B, and $E_{\text{act}}/2.3RT$ when plotted against $Z_A Z_B\sqrt{\mu}$ should be, respectively, 1.01, 1.52 and 0.51. Equation (11) thus predicts that in the limit of high dilutions the energy barrier, E_{act}, should increase by 684 $Z_A Z_B\sqrt{\mu}$ calories/mole as a result of interionic attraction.

On the prevailing view[7] that the function of a catalyst is to provide a lower by-pass in the energy barrier, one would be forced to conclude that the addition of a neutral salt should *decrease* the rate of a reaction between ions of the same sign—a conclusion which is contrary to abundant experimental evidence. The explanation is that the action constant B increases concomitantly in the limit about three times as rapidly as E_{act}, and hence B plays the predominant role in determining the magnitude of the neutral salt catalysis.

Preparation of Materials

Bromoacetic acid was redistilled at reduced pressure, sodium thiosulfate was recrystallized and solutions of sodium hydroxide and of potato starch were prepared as in earlier experiments.[8] Iodine was sublimed from a potassium iodide–iodine mixture, resublimed and stored over calcium chloride in a desiccator until used in the preparation of standard iodine solutions. The latter always contained 4% of Mallinckrodt neutral potassium iodide, Analytical Quality, the iodate content of which is not over three parts per million. Sodium chloride and barium chloride were recrystallized once and dried at a temperature exceeding 100°. Lanthanum chloride, precipitated from aqueous solution by hydrogen chloride, was washed with alcohol, air dried and stored over phosphorus pentoxide or calcium chloride. This sample yielded values for velocity constants which checked with those for solutions containing a Welsbach cerium-free lanthanum chloride purified several years earlier.[9]

Experimental Procedure

Two types of technique were employed for the bromoacetate–thiosulfate reactions.

1. For experiments in which the time error in starting and stopping the reaction is negligible, equal volumes of equimolar solutions of the reactants were mixed and the reaction was stopped by iodine titration as described by La Mer and Fessenden.[4]

2. A special type of flask, shown in Fig. 1, was devised to reduce errors in timing the more rapid reactions. The flasks were immersed in the thermostat, 50 cc. of sodium bromoacetate

solution was pipetted into (a) and 50 cc. of sodium thiosulfate solution of equal molarity was pipetted into (b). After temperature equilibrium had been reached the reaction was started by tipping the flask sidewise and prompt mixing was achieved by pouring the solution back and forth in the two compartments of the flask. To stop the reaction, iodine just insufficient to neutralize the remaining thiosulfate was pipetted into (a), then poured into (b) at a recorded time. The flask was placed in an ice-bath; the stopper and sides were washed down with about 50 cc. of cold distilled water; starch was added and the titration with iodine solution was completed as quickly as possible. The addition of 0.1 cc. of 0.1 *M* acetic acid to the solution before completion of the titration eliminated any possible error due to presence of hypoiodite. With this technique the error in starting and stopping the reaction was reduced to two to three seconds so that reactions involving times ranging from fifteen minutes to an hour yielded velocity constants as reproducible as those of slower reactions.

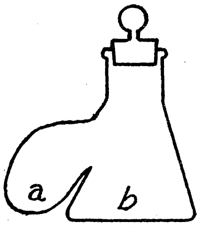

Fig. 1.

Corrections to be made to the end-point of iodine titrations were determined as the volume of the given iodine solution required to produce the same blue color in an equal volume of water containing starch and potassium iodide at the temperature of titration. The use of a daylight lamp improved the precision of the end-point in artificial light.

The fluctuations in the temperature of the thermostat rarely exceeded 0.01° during any of the experiments, except at 50° where the precision of the time average was ±0.01°. Any errors entering into the absolute temperatures, which were determined by the use of the ice-point and of a thermometer calibrated by the Bureau of Standards, cannot be of sufficient magnitude to make any significant difference in the data. For a temperature interval of 25° the uncertainty in E_{act} arising from the uncertainty in temperature is estimated as 0.16% and for a 12.5° interval 0.32%; that is, the order of 24 or 48 calories, respectively.

At 50° eight carefully conducted experiments (no added neutral salts) exhibited a small but reproducible decrease in the velocity constant with the progress of the reaction. The reaction is very rapid at 50° but the drift at this temperature does not appear to be due to errors in timing. We attribute the difficulty to intrusion of the spontaneous water reaction $H_2O + CH_2BrCOO^- \longrightarrow CH_2OHCOO^- + H^+ + Br^-$. This reaction is of entirely negligible velocity at 25 and 37.5° ($k_{25} = 2.8 \times 10^{-6}$) but assumes sufficient importance to vitiate highly precise results at 50°. No data or conclusions are submitted in this paper for temperatures higher than 37.5°.[10]

Recently, Kiss and Vass[11] have reported temperature coefficient data for this reaction over the range 5 to 55°.[12]

The results for the water reaction at 25 and 50° are recorded also in Table I. The method employed consisted in bringing the aqueous solution of sodium bromoacetate to temperature as quickly as possible. The hydrogen ion formed by the hydrolytic reaction was neutralized with sodium hydroxide to a *p*H of 7 at frequent intervals to prevent acid catalysis, using bromthymol blue as indicator. Minor sources of error are incomplete temperature equilibrium at the beginning of the reaction, and the influence of carbon dioxide upon the titration values. To increase the precision, a large number of measurements was made, and the early readings which were burdened with time and temperature errors discarded. The velocity constants for the progressive time intervals were compared with those calculated from the initial time. The $E_{(25-50)}$ for the bromoacetate–water reaction was reproducible to about 0.7% (175 cal.). For typical experiments illustrating the high precision and constancy of the individual velocity constants of the thiosulfate reaction, the reader is referred to the following paper.

---

[10] A. N. Kappanna [*J. Indian Chem. Soc.*, **6**, 45 (1929)] reports velocity constants for the thiosulfate reaction at 30, 40 and 50° at eleven concentrations ranging from $\mu = 0.0025$ to 0.085. He states "The *temperature coefficient* of reaction velocity constant on either side of 40° and at different ionic strengths has *almost* the same value, within *narrow* limits 2.2 to 2.3 for a rise in temperature of 10° C." (Italics ours.) Our calculations of his data show that E_{30-40} is 15,320 ± 500 calories an average deviation from the mean which is about ten times as great as ours. *Cf.* Moelwyn-Hughes, "Kinetics of Reactions in Solutions," p. 201, for a similar calculation.

[11] Kiss and Vass, *Z. anorg. allgem. Chem.*, **217**, 305–320 (1934).

[12] They claim that log *k* varies linearly with $1/T$ in all cases. An examination of their Table 8, however, shows that their E_{act} values for 10-degree intervals fluctuate so irregularly and so violently with temperature (800 calories for the interval 5–15° and 15–25°) that one can only conclude that their experimental errors are too large to establish deviations from a temperature independent E_{act}. On the other hand, the data in their Tables 1 and 4 are sufficiently consistent to support our conclusion that the salt catalysis is primarily the result of an increase in the entropy of activation, and certainly does not result from any decrease in the energy of activation.

Calculations

The bimolecular velocity constants were calculated from the formula, $k = \frac{1}{t} \times \frac{1}{a} \times \frac{x}{(a - x)}$ applicable when $a = b$ = moles of reactants per liter of solution. The time, t, is expressed in minutes. All solutions were standardized at room temperature. However, the correct molarity to be substituted in the bimolecular equation at other temperatures differs slightly from the molarity at 25°, because of the expansion or contraction of the solution. To obtain k in moles per liter at the temperature of reaction, the velocity constant at $t°$ was multiplied by the factor

$$\frac{(\text{volume of 1 g. of water at } t°)}{(\text{volume of 1 g. of water at } 25°)}$$

The values of k used in calculation of the energy of activation are the values of k for the molarity at the temperature indicated. This introduces a very small further correction. $\Delta \log k$ must be obtained as the difference of the logarithms of two velocity constants at different temperatures but for identical volume–molar concentrations. Hence, a correction of $\left[\frac{\mathrm{d} \log k}{\mathrm{d}\sqrt{\mu}} (\sqrt{\mu_{t0}} - \sqrt{\mu_{25}})\right]$ has been subtracted from $\log k_{\text{obsd.}}$ at $t°$. It does not exceed 0.0003.

Method of Calculating Precision of E Values

The error in average $\log k$ is estimated so as to take account not only of the error in the mean k in each of one or more experiments, but also the difference between two mean k values for two separate experiments, whenever these were performed. Thus, it is a measure of precision within a given experiment and of the reproducibility of the value. The error in $\Delta \log k$ is evaluated as the square root of the sum of the squares of the errors in the two average $\log k$ values from which it is derived. An error of 25 calories in the determination of E produces an uncertainty of 0.02 units in B in eq. (3).[13]

Discussion of Results

Table I contains the data for $\log k$ for the bromoacetate–thiosulfate ion reaction for various temperatures and additions of neutral salts. These data are plotted in part in Fig. 2 for 0 and 25° to illustrate the specific character of the positive salt catalysis in the presence of Ba^{++} and La^{+++} ions, and the parallelism of the curves at the two temperatures in the absence of these high valence ions.

The values E_{act} are given in the next to the last column. They indicate that $E(0–25°)$ increases by 127 ± 60 calories (15,881 to 16,008) on passing from $\sqrt{\mu} = 0.0895$ to 0.141, and decreases slowly to 15,941 calories at $\sqrt{\mu} = 0.447$. The initial rise in E_{act} appears to be greater than the demands of the limiting law but the probable experimental error is too large for the short interval to warrant a definite conclusion. An examination of the calorimetrically determined values of $\overline{H}$ for salts shows that the individual deviations[14] from the limiting law persist to much lower concentrations than is the case for the function $\overline{F}$. In fact $\overline{H}$ for sodium iodate, potassium nitrate and barium nitrate passes through a maximum in the neighborhood of $\sqrt{\mu} = 0.10$ quite similar to the behavior of E_{act}. The action constant B rises sharply from 11.19 ($\sqrt{\mu} = 0.0895$) to 11.35 ($\sqrt{\mu} = 0.141$) at a rate which is slightly greater than the limiting law prediction. For further increases of μ, B rises less rapidly but steadily to 11.55 at $\sqrt{\mu} = 0.477$. See Figs. 3 and 4. It will be noted that in this case where the ionic strength increase results solely from an increase in concentration of the reactants in the form of their sodium salts, the increase in $\log k$ is due primarily to an increase in B and only secondarily if at all to a variation in E_{act}. In the following paper the rate of this reaction in

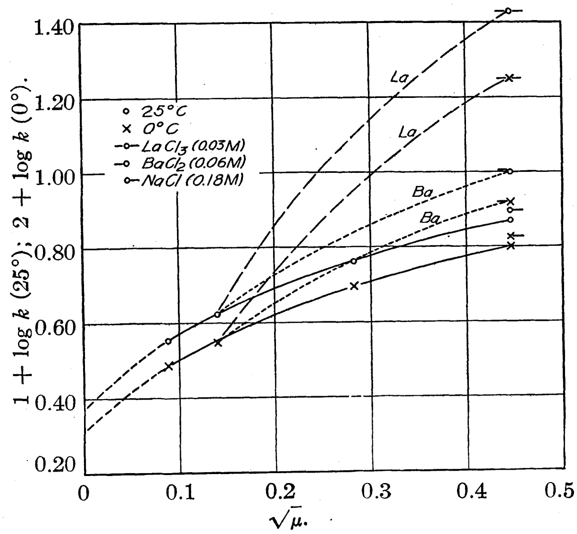

Fig. 2.

---

(13) The correction to the energy of activation arising from the dependence of the collision number upon $\sqrt{T}$ amounts to −278 calories for the (0–12.5°) range and to −303 calories for the (25–37.5) range. This correction would magnify the decrease of E with T from 0 to 37.5° by 25 calories and thus strengthens slightly the conclusion that E_{act} is a function of T.

Log *k*, *E* and *B* Data for the Reaction Sodium Bromoacetate and Water

Concn. moles/liter	*t*, ° C.	Detns.	Conversion range %	6 + log *k* corr.	Δ log *k*	*E*	*B*
0.05	25	7	10–45	0.4440 ± 0.003	1.4121 ± 0.004	24,915 ± 70	12.69
.05	50	10	18–74	1.8561 ± .0024			
.1	25	7	8–42	0.5276 ± .010	1.4013 ± 0.01	24,725 ± 175	12.64
.1	50	11	9–66	1.9289 ± .001			

the presence of 32.4% sucrose is reported. In this solvent we find that *B* increases from 11.02 to 11.49 or 0.47 units for the same range of concentration of reactants, while E_{act} rises slowly but at a lower level than for water.

The addition of 0.18 *M* sodium chloride to $a = b = 0.005$ *M* to produce $\sqrt{\mu} = 0.447$ yields *E* (0–25) = 15,947 and *B*(0–25) = 11.59. These values do not differ very significantly from those for $a = b = 0.05$ *M* ($\sqrt{\mu} = 0.447$) and we may conclude that chloride ions exercise no specific effect on either *E* or *B*.

On the other hand, the presence of 0.06 *M* barium chloride and particularly 0.03 *M* lanthanum chloride to produce the same $\sqrt{\mu} = 0.447$ produces a marked increase in both *B* and *E*. In the presence of 0.03 *M* lanthanum chloride *E* increases by 1780 cal and *B* increases from 11.55 to 13.46 or almost two logarithmic units.

The substitution of La^{+++} for Na^{+} (and to a less degree Ba^{++} for Na^{+}) creates a situation in which the reactant anions must cluster about the La^{+++} ion. By referring to the Fig. 2 of La Mer and Fessenden, where log *k* (25°) is plotted against $\sqrt{\mu}$, it will be noted that log *k* increases rapidly for small additions of La^{+++} but reaches at low concentrations what appears to be a constant saturation value. This behavior can be explained qualitatively on the basis of the higher terms of the Gronwall–La Mer equation, or when $(Z_1Z_2\epsilon^2/DakT)$ becomes too large for rapid convergence, by the more pictorial but essentially equivalent concept of ion-association as defined by Bjerrum. Thus, the later theory predicts[15] that in the presence of La^{+++} most of the reactants will exist as ion-associated pairs of the type $(LaS_2O_3)^+$ colliding with $BrAc^-$ or as $(LaBrAc)^{++}$ colliding with $S_2O_3^=$ for reaction. The ternary complex $(LaBrAcS_2O_3)^\circ$ may also have a finite life-time. We consider it significant that B increases to a value (13.3) in the presence of La^{+++} which is substantially identical with B for the uncharged methyl ester–thiosulfate-ion reaction. In the next paper we direct attention to a similar state of affairs produced by lowering the dielectric constant to a point where ion-association becomes predominant in the absence of high valence ions. The reaction then behaves substantially as one between uncharged reactants.

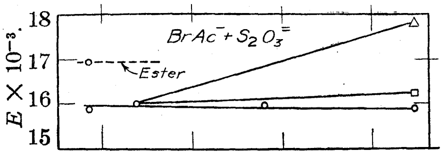

Fig. 3.—○, Sodium salts; □, $BaCl_2$ added; △, $LaCl_3$ added.

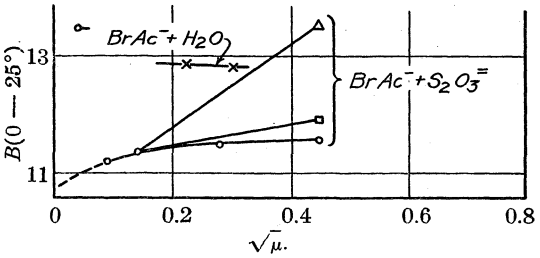

Fig. 4.—-○-, Methyl ester–thiosulfate reaction; ○, reactants present as sodium salts; □, $BaCl_2$ added; △, $LaCl_3$ added.

In any case the highly abnormal local accumulation of reactant anions around a La^{+++} ion will operate to increase $\Delta\bar{L}_{act}$ well above the demands of the limiting law so that E_{act} will be increased. On the theory that the height of the energy barrier is the sole regulator of the rate of reaction, one would be tempted to predict that the rate should be decreased.

The clustering of the reactant anions about a central La^{+++} ion, however, provides a greatly enhanced opportunity for collisions between the bromoacetate and thiosulfate ions. This increase in total number of collisions will be reflected in $\Delta\bar{S}_{act}$, the increase in entropy of activation due to interionic attraction. In Section 2 it was shown that the limiting form of the Debye theory predicts that $\Delta\bar{S}_{act}/2.3R$ increases three times as rapidly as $\Delta\bar{L}_{act}/2.3RT$; it is reasonable to assume that a similar qualitative relation will hold in the high valence mixtures, even though an exact calculation cannot be made.[16]

Hence the increase in B is of sufficient magnitude to more than counterbalance the rate-depressing effect of an increase in E_{act}. The temperature dependence of these marked catalytic effects of high valence ions of sign opposite to the reacting ions furnishes convincing evidence of the importance of taking into account the variations in the entropy of activation as well as the energy of activation in developing a satisfactory theory of catalytic behavior. The previous theories appear to have neglected the most important factor.

Influence of Concentration and Temperature

A closer examination of the data reveals for $a = b = 0.005\ M$ where the reaction has been studied at 12.5° intervals that E_{act} decreases (see Fig. 5) by a small but significant amount (216 cal.), which of course is exactly paralleled by the decrease in B from 11.41 to 11.24. The parallel decrease in B[17] is a result of the relation $\partial E_{act}/\partial B = 2.3RT$ which holds when the solvent is constant. This decrease of E_{act} and B values with rising temperature is more definite in the data for

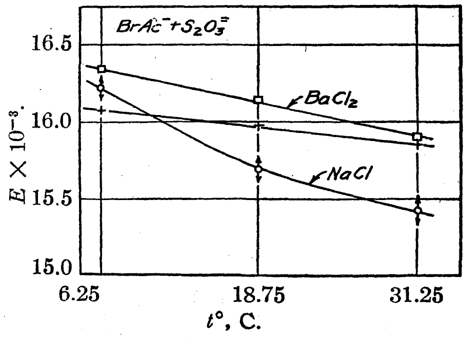

Fig. 5.—+ No added salt.

0.18 *M* sodium chloride additions, where the heat capacity of activation is of the order of -12 cal./deg./mole (see Fig. 5).

In Eyring's theory,[18] which appeared after this work was completed, the activated complex is defined in terms of the partition function (sum of state) of the activated complex. In this theory the attempt is made to dispense completely with the concept of collisions and steric factors in reaction kinetics. Any changes in collision frequency, therefore, will be reflected entirely in terms of an entropy of activation. While this view has the advantage of being independent of any molecular picture, and may prove fruitful in the present case, we incline to the view supported by O. K. Rice and Gershinowitz that the collision mechanism has pictorial merit and should not be entirely discarded.[19]

Rodebush[20] has also pointed out that the collisional mechanism and Eyring's treatment are different but essentially equivalent ways of describing the same phenomenon, a conclusion which is evident from our eq. (4).

One may say, depending upon the point of view, that the reaction proceeds more rapidly as a result of an increase in the number of effective collisions, produced in the present data by an increase in the concentration of positive ions, or that the rate increases because of an increase in the entropy of activation,[21] which means that the number of systems crossing the energy barrier per unit of time is increased as a result of the increased number of reactive complexes per unit of volume of phase space.

Summary

1. An equation has been derived, based upon the limiting form of the Debye–Hückel theory, which predicts that E_{act}, the energy of activation of a reaction, and the entropy of activation (action constant B), will vary for water at 25° with the square root of ionic strength according to the law $E_{\text{act}}/2.3RT = E^0_{\text{act}}/2.3RT + 0.51\ Z_AZ_B\ \sqrt{\mu}$ and $B = B^0 + 1.52\ Z_AZ_B\ \sqrt{\mu}$.

2. The temperature coefficients of the reaction bromoacetate ion plus thiosulfate ion have been studied precisely over a range of temperature and concentration to obtain significant data for the effect of temperature and ionic environment upon E_{act} and B. For the sodium salts at $a = b = 0.005\ M$, $\partial E_{\text{act}}/\partial T = C_{\text{act}} \cong -8.6$ for the range 0–37.5°, in the presence of 0.18 *M* NaCl $C_{\text{act}} \cong -12$ cal./deg. mole.

3. The increase in log *k* produced by the addition of low valence ions (Na^+) is closely correlated with an increase in *B*.

4. In the presence of high valence ions (Ba^{++} and La^{+++}) of sign opposite to the reacting anions, E_{act} is considerably increased, but this retarding effect of an increase of height of the energy barrier is more than compensated for by an increase in the entropy of activation.

This example represents an interesting exception to the theory of catalytic action as usually stated and is discussed in the terms of the picture of ion-association.

The Influence of Non-Electrolytes upon the Kinetics of the Reaction between Bromoacetate and Thiosulfate Ions[1,2]

BY VICTOR K. LA MER AND MILDRED E. KAMNER[3]

Introduction

The literature contains few precise values of the energy of activation for non-ionic reactions and still fewer values in the case of ionic reactions. The problem of solvent influence upon the kinetics of ionic reactions has been approached only through the change in velocity constant and with one exception[4] the data are limited to a single temperature and usually to one concentration of reactants.[5] In this investigation, both the energy and the entropy of activation calculated from experimental data for reaction velocity constants are utilized as a means of approach to the problem of solvent effect upon reaction velocity. The purpose of this investigation was to compare the data in terms of E_{act} and B for the bromoacetate–thiosulfate reaction after addition of urea, sucrose, glycerol or dioxane with the corresponding data for aqueous solution.

Materials

The purification of reacting materials has been described previously.[6]

Urea.—Pure carbamide was recrystallized from distilled water. The solution was not warmed above room temperature as Wyman[7] found that urea solutions allowed to stand for several hours at a temperature of 30 or 35° undergo a change associated with a change in conductivity. The urea was thoroughly air-dried and kept in a calcium chloride desiccator overnight before use.

Sucrose.—Commercial packaged cane sugar was used.

Glycerol.—Kahlbaum twice-distilled glycerol, density 1.26, was employed.

Dioxane.—The commercial product was purified as described by Kraus and Fuoss.[8]

Experimental

The reacting solutions were prepared as follows.

After a solution of bromoacetic acid had been neutralized with sodium hydroxide solution, a weighed quantity of non-electrolyte was added and the solution was made up to volume and weighed. Sodium thiosulfate solution was prepared so as to contain the same weight per cent. of non-electrolyte as the bromoacetate solution and its molarity was determined by titration against a primary iodine standard and adjusted to that of bromoacetate solution.

For the velocity measurements, the two types of technique described in the previous paper were employed. Analytical errors are not greater than one part per thousand.

Experiments were carried out at 25.00 ± 0.01° and at 0.00 ± 0.02°. The 25.00° point was determined on two Beckmann thermometers by means of a platinum resistance thermometer (kindness of Dr. Shedlovsky of The Rockefeller Institute for Medical Research); the readings agreed throughout the work. For zero degrees, two Beckmann thermometers were set at the ice-point of water and the settings were checked frequently. A refrigeration unit maintained the temperature of a water–ethylene glycol bath at zero degrees. Two or more hours were allowed for temperature equilibrium at 25° and at least three hours at 0° before mixing the reactants.

Concentrations of reactants are expressed in moles per liter of solution at 25°. Concentrations of non-electrolytes are in grams of non-electrolyte per 100 g. of solution.

Analytical Precision and Controls

Sodium thiosulfate solutions were freshly prepared for each experiment. Much has been written about the instability of dilute solutions of sodium thiosulfate but the possibility of decomposition in the solid state seems to have been disregarded. A sample of $Na_2S_2O_3 \cdot 5H_2O$ which had been recrystallized several years before and yielded excellent results at that time, gave drifting velocity constants. The cause may have been a slight decomposition to form sulfur and sulfite ion; then, in solution, thiosulfate ions and sulfite ions reacted with bromoacetate simultaneously during the early part of the reaction, accounting for the drift in velocity constants. This source of error does not enter into any of the data presented here.

Commercial dioxane gave an acid solution with water and contained an impurity which oxidized iodide to iodine. After treatment with sodium hydroxide, drying with barium oxide and refluxing over sodium, a non-oxidizing sample was obtained. From an aqueous solution of this dioxane, thiosulfate measured by iodine titration gave 100.2% recovery after twenty-four hours and 100.6% recovery after two weeks. However, the iodine end-point is yellow in the presence of starch and dioxane! Whether dioxane samples remained free of oxidizing impurity and for what period of time was unpredictable and seemingly without relation to their having been protected from light or stored with or without water. It appeared to be not merely a matter of sufficiently long treatment with sodium.

Malone and Ferguson[9] reported that different samples of dioxane showed different dielectric constants depending upon the length of time the dioxane was allowed to stand over sodium. The data for the experiment with a dioxane–water mixture are presented as being only semi-quantitative; the reaction mixture was of *p*H about 5.5 to 6, assuming the same indicator colors for dioxane–water as for water.

The starch–iodine end-point was more easily detected by placing the solutions in an ice-bath. Blanks were usually from 0.01 to 0.04 cc. of iodine solution. If the total blank were due to the added non-electrolyte or an impurity in it, a mole of urea, sucrose or glycerol would react with 10^{-5} to 10^{-6} equivalents of iodine.

Thiosulfate ion does not react with urea, sucrose or glycerol in aqueous solution as shown by iodine titration values which agreed to within less than a part per thousand with the values in the absence of non-electrolyte. The following data show no indication of appreciable side reactions of bromoacetate ion in the presence of these non-electrolytes either with them or with water.

TABLE I

[a] Calculated on basis of initial quantities of reactants.

Calculations

The precision of *k* is expressed as the average deviation of a single value from the mean. The reliability of E_{act} was calculated using the maximum k_{25} value and minimum k_0 value as indicated by the individual precisions of *k* less the E_{act} using the average *k* values. This estimate of the deviations of E_{act} is thus a maximum for this pair of experiments. $\Delta E_{\text{act}} = (E_{\text{act}}$, non-electrolyte $- E_{\text{act}}$, water). The precision measure of ΔE_{act}, $=$ [(precision in E_{act}, water)^2 + (precision in E_{act}, non-electrolyte)^2]$^{1/2}$. An error of 25 calories in E_{act} produces an error of about 0.02 logarithmic unit in *B*.

The detailed data for the velocity constants of four representative experiments are in Table II; the solvent in each case is water and the non-electrolyte indicated. Table III contains values of E_{act} and *B* for the reaction in aqueous solution quoted from the previous paper.[10] The values of E_{act} and *B* for the reaction in solutions containing non-electrolytes and the deviations of E_{act}, *B* and *k* from the values for aqueous solutions appear in Table IV.

Discussion

The addition of urea, sucrose, glycerol or dioxane increased the rate of the bromoacetate–thiosulfate reaction in water at 25 and 0°, the only exception being the 2% decrease in *k* at 25° when a 0.002 *M* solution of reactants is 1.08 *M* in sucrose. These results are shown in Fig. 1. The change in velocity constant is not determined by the ratio of sucrose to reactants.

An interpretation of the changes in velocity constant can be obtained through consideration

[a] k = 0.896 with 21.0% urea ≈ 0.897 with 21.2% urea.

of other properties of the reaction system; namely, the energy of activation and its change with temperature. If the Arrhenius equation, $d \ln k = (E_{\text{act}}/RT^2)dT$ is integrated by assuming that E_{act} is a function of temperature, *i. e.*, $E_{\text{act}} = E^0_{\text{act}} + \int_0^T (\partial E_{\text{act}}/(\partial T)dT$, then

$$\int_0^T (E_{\text{act}}/RT^2)dT = \frac{-E^0_{\text{act}} + \int_0^T (\partial E_{\text{act}}/\partial T)dT}{RT} + \frac{1}{R}\int_0^T \left(\frac{\partial E_{\text{act}}}{\partial T}\right) d \ln T \quad (1)$$

La Mer[11] has defined the change in energy of activation with temperature as the heat capacity of activation and by analogy with thermodynamic heat capacities has designated the last term as the entropy of activation divided by R. Thus

$$\ln k = -E_{\text{act}}/RT + (S_{\text{act}} - S_{0\,\text{act}})/RT + \ln \text{const.} \quad (2)$$

the constant having the dimensions of a frequency (time^{-1}). If the reactants require no activation for reaction, E_{act} becomes zero, and every collision results in reaction. If the reactants are ideal gases the constant becomes the gas kinetic collision frequency at unit concentrations designated as Z^0

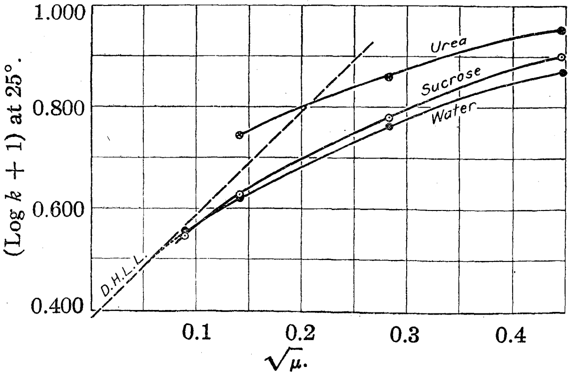

Fig. 1.

$$\log k = -E_{\text{act}}/2.3RT + \underbrace{(S_{\text{act}} - S_{0\,\text{act}})/2.3R + \log Z^0}_{B} \quad (3$$

---

(11) V. K. La Mer, *J. Chem. Phys.*, **1**, No. 5, 289 (1933).

B thus consists of two terms, one involving entropy of activation and the other a collision frequency. A change in the value of B may be attributed, in general, to a change in one or both of the quantities which determine its numerical magnitude, the collision frequency and the derivative of E_{act} with respect to temperature integrated with respect to ln T.

The experimental data show that when urea is added to the aqueous solvent for the bromoacetate–thiosulfate reaction, B is increased, E_{act} is unchanged and k is increased. The addition of sucrose, glycerol or dioxane to the aqueous solvent for the reaction causes a decrease in B, but this decrease in B in the cases of glycerol, dioxane and sucrose (at higher concentrations of reactants) is more than compensated for by the decrease in E_{act} and thus k is increased.

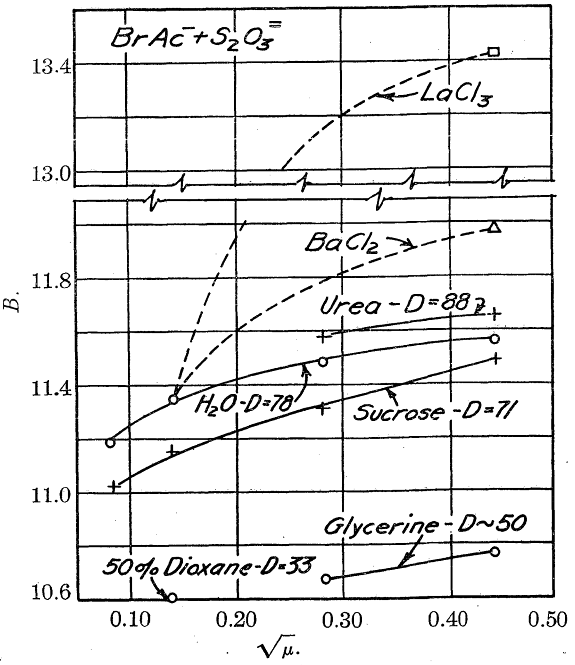

Fig. 2.

In the sucrose solutions as in the case of water (Table III and Fig. 2) B decreases significantly in passing from 0.05 to 0.002 M in reactants. The decrease in E_{act} over this same range may or may not be real; it exceeds but slightly the amount which can be accounted for by experimental errors. One cannot do more than suggest the possibility that the presence of 540 long chain sucrose molecules for a molecule of each reactant diminishes the velocity constant at $a = b = 0.002$ M by having decreased the number of collisions between reactants.

Kappanna[4] has studied the effect of sucrose addition to the bromoacetate–thiosulfate reaction; his data agree with those presented here in respect to the fact that sucrose increases the velocity constant at high concentrations of reactants and decreases it at low concentrations. Calculations made from his velocity constant data show that the addition of alcohol to the aqueous solvent decreases both E_{act} and B.

Influence of Dielectric Constant

For the case of reactions between an ion and a neutral molecule, Harned and Samaras[12] have shown that log k is frequently but not always proportional to D. For the reaction $NH_4^+ + CNO^- \longrightarrow$ urea which involves the collision of ions of opposite sign, Warner and Warrick[13] found that log k is roughly proportional to $1/D$ when the dielectric is decreased by addition of various alcohols or of dioxane to water.

However, no simple relation is revealed by plotting log k against D or $1/D$ either for our data or for those of Kappanna for the bromoacetate–thiosulfate reaction in aqueous alcohol solutions. Kappanna's data show a minimum k value at 40% ethyl alcohol for low concentrations of reactants. The minimum is displaced to lower alcohol concentrations as the ionic strength of the reactants is increased.

Although the dielectric constants of the solvents employed in this research range from urea, D = 98.1 (0°) = 88.4 (25°); water, D = 88.2 (0°) = 78.5 (25°); sucrose (32.4%) D = 78.4 (0°) = 70 (25°); glycerol D = 63.2 (0°) = 55.7 (25°); to dioxane $D \doteq 33$ (25°), the velocity constants in the presence of non-electrolytes exceed those for water. Scatchard's theory[14] of the effect of D obviously does not hold for the present data. Straup-Cope and Cohn[15] report that amino acids which increase the dielectric constant increase the velocity of this reaction.

Since the magnitude of k is determined by the quantities E and B it is appropriate to attempt to correlate E and B rather than k with the dielectric constant of the solvent. In Fig. 3 (E_{act} − 16,000) and B are plotted against $1/D$. B decreases with decreasing dielectric constant of the

solvent to a value of $D \simeq 55$; the lowering of D from 55 to $\simeq 33$ produces no further decrease. Except for the urea solutions, the E curve follows a parallel course to B but is distinctly less sensitive to changes in the concentration of reactants. The increasing value of B with increasing concentration of reactants in sucrose solutions would be interpreted as a result of the increased number of collisions arising from the interionic attraction effect. Our analysis thus supports the Christiansen[16] interpretation of the Brönsted–Debye effect. We suggest that the decrease in B values with decreasing values of D results from a decrease in the number of effective collisions as a result of the increased electrostatic repulsion between reacting ions of the same sign. Finally, with decrease of dielectric a point must be reached in which the reacting ions are no longer dissociated from the sodium ions. When the dielectric constant falls below about 50 the phenomenon of ion association of the sodium ions with the bromoacetate and the thiosulfate ions becomes very important. Fuoss and Kraus[17] claim that for uni-univalent electrolytes in solvents where D is less than 43.6 the behavior of ions of opposite sign is most easily accounted for in terms of a mass action dissociation constant of the salt. In the case of 50% dioxane–water where $D = 33$ the reactants will exist principally in the form of their neutral salt pairs. Somewhere in the neighborhood of $D = 50$, the repulsive effect of lowering the dielectric is exhausted and consequently no further decrease in B can be expected. The reaction now behaves substantially as a reaction between two uncharged molecules, though of course a considerable dipole interaction will still persist at close distances.

In solvents of extremely low dielectric constant the ternary and higher order ion-pairs become stable. It is conceivable that under such conditions the order of the reaction may change. In fact Brönsted and Bell[18] found that the diazoacetic ethyl ester reaction proceeds in benzene at a rate which is proportional to the square of the concentration of the catalyzing acid, whereas in water it is proportional to the first power of the hydrogen-ion concentration.

The kinetic data for the bromoacetate–thiosulfate reaction furnish examples of an increase in velocity constant with (1) an increase in E_{act}, (2) a decrease in E_{act}, (3) E_{act} remaining unchanged.

(1) The increase in E_{act} resulting from the addition of barium chloride or lanthanum chloride was more than compensated for by an increase in B, and k was increased.[10]

(2) In the present work, the addition of sucrose, glycerol or dioxane lowered E_{act} by such an amount that although B was also lowered, k was increased.

(3) E_{act} is unaffected by the addition of urea and the increase in velocity constant results entirely from an increase in B.

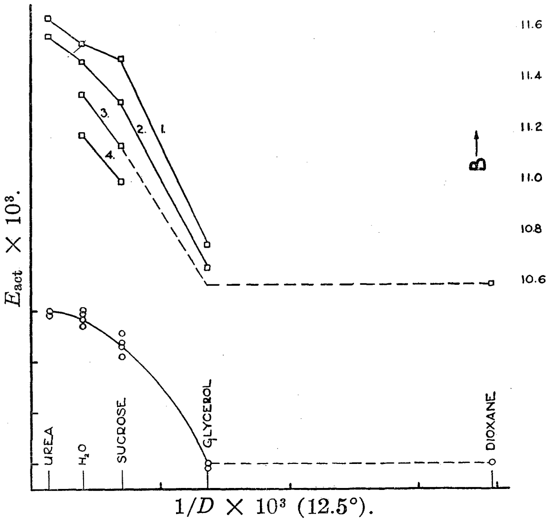

Fig. 3.—1, 0.05 *M;* 2, 0.02 *M;* 3, 0.005 *M;* 4, 0.002 *M.*

Summary

1. The kinetics of the reaction between bromoacetate ions and thiosulfate ions have been studied at 0 and at 25° in the presence of non-electrolytes; the precision of the experimental data is ±0.5%. The velocity constant is increased by addition of urea, sucrose, glycerol or dioxane to the aqueous solvent, in spite of the fact that urea raises the dielectric constant while the others lower it.

2. The energy of activation remains the same in the case of urea but is decreased by addition of each of the other non-electrolytes. The action constant B decreases almost linearly as a function of $1/D$ from $D = 88$ to 55.7.

3. In 32% sucrose solutions ($D = 70$ at 25°), as in water, the positive salt catalysis arises from an increase in the entropy of activation which more than compensates for the retarding influence of an increase in the energy of activation.

Temperature Dependence of the Energy of Activation in the Dealdolization of Diacetone Alcohol

BY VICTOR K. LA MER AND MARY L. MILLER[1]

Introduction

For many reactions the temperature dependence of the velocity constant can be satisfactorily described by the Arrhenius equation

$$d \ln k/dT = E_{act}/RT^2 \qquad (1)$$

by considering the energy of activation E_{act} to be a constant independent of temperature. Under this assumption equation (1) becomes, on integration

$$\ln k = (-E_{act}/RT) + 2.3B \qquad (2)$$

$2.3B$ is the constant of integration, which likewise should be independent of temperature. If we accept, however, the statistical interpretation of E_{act} as exemplified in Tolman's treatment,[2] namely, that E_{act} is the difference between the average energy of those molecules *which react* and the average energy of all the molecules, then as La Mer[3] has pointed out, E_{act} and B must necessarily be functions of the temperature,[4] and for consistency with thermodynamics B must involve a quantity which he called the entropy of activation. The slope of the $E_{act} - T$ curve will give

$$dE_{act}/dT = (\bar{c}_{j,\,act} - \bar{c}_i) \qquad (3)$$

where $\bar{c}_i$ is the partial molal heat capacity of all the molecules and $\bar{c}_j$ is the partial molal heat capacity of all the molecules *which react.* $\bar{c}_j$ includes the k_j factors or specific reactivity rates for different reacting levels involved in the process of statistical averaging. Whether the temperature dependence will be of significant magnitude is a question which must be decided for each reaction by experiments covering as wide a temperature range as possible. This was the primary purpose of the research. The prevailing view as epitomized in the statement of Moelwyn-Hughes[5] "*As a general rule examples which appear to contradict the Arrhenius law may also be omitted for experience has shown that such seeming deviations can usually be attributed to the presence of impurities or inadequate control of temperature,*" is primarily a result of the difficulties inherent in precise temperature coefficient measurement and an unwarranted faith in the constancy of E_{act}. Since the temperature variation of E_{act} is frequently within the limits of experimental error, it is usually detectable only in those cases where the analytical method can be considerably refined as in the case of solution reactions, or where the temperature interval can be made comparatively large. Furthermore, it is recognized that relatively small errors in the temperature scale can produce a trend in E_{act}, which is without significance.

Although the literature contains a number of carefully investigated reactions,[3,6] which yield values for E_{act} which certainly are not independent of temperature, yet in most instances the authors have either ignored the effect or have drawn unduly conservative conclusions.[7] An important exception is to be noted in the recent papers of Semerano,[8] of Liebhafsky and Mohammed, and of Harned and Seltz.[9]

On recalculating the data of G. M. Murphy[10] on the dealdolization of diacetone alcohol $(CH_3)_2COHCH_2COCH_3 + OH^- = 2CH_3COCH_3 + OH^-$, carried out at 20, 25, 30 and 35°, one of us

noted that they required a value for $C_{act} \cong 200$ cal. mol.$^{-1}$ deg.$^{-1}$. Since a heat capacity of activation of this magnitude is astonishingly large, and could arise from an error in measurement at a single temperature, we have reinvestigated the kinetics of this reaction at 5-degree intervals from 0 to 50°.

The dealdolization reaction has been investigated extensively by Koelichen, Åkerlöf, French, John Miller and Kilpatrick at 25°. It is free from complicating side reactions and is pseudo unimolecular for constant concentrations of bases. The absolute velocity can be varied over wide limits by varying the concentration of the base used as catalyst; hence the reaction is well suited for investigation over a wide range of temperature.

II. Experimental Method

The velocity was measured by the dilatometric method. A solution prepared by diluting an appropriate volume of 0.25 *N* sodium hydroxide to about 250 cc. was evacuated and kept in a thermostat regulated to 0.01° (at 0.0 and 5 to 0.02°) for at least two and one-half hours. The reaction was initiated by adding 2%[11] by volume of diacetone alcohol. After boiling under vacuum, the mixture was transferred by pressure to the dilatometer. Vacuum was reapplied until no bubbles were visible. Pressure was again applied momentarily, about 8 cm. of mercury was introduced into the capillary, and after a predetermined time readings were begun. The equilibrium value was taken at a time appropriate to the given velocity and about an hour thereafter. The capillary was water-jacketed and kept within one or two degrees of the surrounding bath.

An important innovation in the present work was the determination of the concentration of alkali after completion of the reaction by titration of an aliquot with standard acid. The customary procedure is open to the objection that the concentrations calculated from the weight of water, alkali and substrate used in preparing the mixture, may be altered during the degassing process. After the equilibrium value had been obtained the solution was brought to room temperature in the dilatometer. The first aliquot was removed for density determination and a second withdrawn in an atmosphere of carbon dioxide-free air directly into the weight buret. For the slower reactions measurements were taken at equal time intervals. Thus it was not always necessary to obtain an equilibrium value since the Guggenheim method for calculating the constant[12] could then be used. Our procedure differs from that of Åkerlöf principally in the determination of the concentrations and in the filling of the dilatometer. Åkerlöf filled his dilatometer by suction, a method which involves considerable foaming. We minimized foaming by transferring the mixture using pressure as did John Miller and Kilpatrick.[13] Since these measurements are to be interpreted from the point of view of the collision theory, concentrations are expressed in terms of normality of the final solution rather than molality of the initial solution. Time is in minutes.

The results of some preliminary experiments involving distinct variations in the experimental procedure are given in Table I. Although of lower precision than the subsequent data, they serve to indicate that the factors investigated are relatively unimportant.

TABLE I

PRELIMINARY RUNS TO INVESTIGATE THE EFFECT OF MISCELLANEOUS FACTORS AT 25.00°

Factor investigated	Concn. NaOH	$k/c \times 10^3$
Darkened reaction tube	0.02993	226
Darkened reaction tube	.03971	221
Darkened reaction tube and light protection during distn.	.03381	228
	.04382	222
Previous sun exposure (9 hrs.) of diacetone alcohol	.02909	240
Sun exposure as above (94 hrs.)	.03033	225
In the presence of 0.0002 *M* Ba^{++}	.02474	228
In the presence of 0.002 *M* Ba^{++}	.03145	222
With excess acetone (2% by vol.)	.07724	225
Measurements using cathetometer	.05720	223
Three months later	.05622	223
Foaming method	.03666	219
Foaming method	.03321	219

The velocity constants *k* were calculated by the well-known equation for first order reactions, or at low temperatures, 0 and 5°, by the Guggenheim method; in many cases by both. Typical experiments illustrating the character of the results at 50° for high and low concentrations of sodium hydroxide are to be found in the Dissertation.

Preparation and Purity of Materials

Sodium Hydroxide.—An approximately 0.25 *N* stock solution was prepared with Kahlbaum "sodium hydroxide from sodium." This was freed from carbonate with barium hydroxide[14] and stored in a paraffin lined bottle.

Water.—The water was redistilled and freed from carbon dioxide by boiling.

Hydrochloric Acid.—0.05 *N* HCl was made up by weight from constant boiling acid[15] and standardized gravimetrically as chloride.

Methyl Alcohol.—An analyzed product from Eimer and Amend was distilled from sodium hydroxide and iodine[16] and fractionated with a 38-cm. Hempel column; sp. gr.$^{25}_{0}$ 0.800. The alcohol was not dried.

Diacetone Alcohol.—Diacetone alcohol, Eastman No. 1084, was distilled under about 20 mm. pressure (b. p.

One distillation, one crystn.	.07895	176.0
One distillation and one crystn.	.08328	176.0

Precision

Temperature.—A 24-junction copper–constantan thermocouple[17] which had previously been calibrated by Dr. Eichelberger in terms of the platinum resistance thermometer at Rockefeller Institute for Medical Research, was used for the temperature standard. During the course of these experiments it was recalibrated against the freezing point of benzene[18] 5.83°, the transition point of sodium sulfate[19] 32.384°, and against Baudin Thermometer No. 18537 at 25.00 and 40.15°. Temperatures so obtained are believed to be accurate to 0.01°.

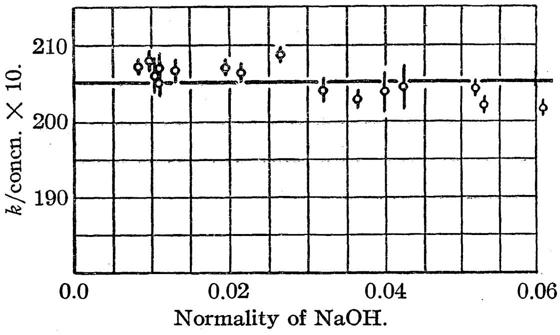

Fig. 1.—Concentration dependence of k/c values at 49.97°.

Concentration.—A precision of 0.1% was easily obtained in the titration of the sodium hydroxide content of the final solution, using weight burets and brom cresol purple as indicator.

Velocity.—The dilatometers[20] differed from those of Åkerlöf only in being equipped with a smaller water-jacket, graduated in millimeters. The reaction tube contained about 90 cc. and the capillary was usually 70 cm. long and 0.7 mm. in diameter. The height of the mercury was read to 0.1 mm. All dilatometers were calibrated to correct for irregularities in scale and bore. The readings were precise to 0.1% when at least 10 cm. from the initial and final values, which is the optimum precision to be expected in the k values.

Concentration Dependence.—From his measurements at 25° French[21] concludes that the ratio of velocity constant to molality is independent of sodium hydroxide concentration from 0.01 to 0.10 *M*, a conclusion which Murphy states that he has confirmed. From the point of view of temperature coefficient measurements it is important to ascertain whether this concentration independence of k/c obtains at the extremes of temperature to be examined. At 0.0° the relationship holds for the concentrations in Table II. Although runs at lower concentrations are undoubtedly possible, they were not made since the range already investigated covers a region readily measurable at 25°.

TABLE III

DEPENDENCE OF k/c ON NaOH CONCENTRATION AT 49.97°

Concn. of NaOH	$k/c \times 10^2$	Concn. of NaOH	$k/c \times 10^2$
0.008275	207.3 ± 1.0	0.02647	208.6 ± 0.8
.009849	208.0 ± 1.5	.03230	203.8 ± 1.4
.01052	205.8 ± 2.7	.03662	202.7 ± 1.1
.01073	205.1 ± 2.0	.03976	203.9 ± 2.8
.01091	207.1 ± 3.2	.04228	204.5 ± 3.3
.01354	206.9 ± 1.5	.05190	204.2 ± 0.6
.01963	207.1 ± 0.8	.05323	202.0 ± 1.0
.02153	206.6 ± 1.3	.06087	201.4 ± 1.0

The data of Table III for k/c at 49.97° (see Fig. 1) reveal a decrease with rising concentration which is barely outside the experimental error.

Above 0.06 *N* sodium hydroxide the method of measurement becomes inapplicable, the constants being no longer reproducible and the solutions becoming slightly yellow. Åkerlöf,[22] while studying the effect of higher concentrations of sodium hydroxide, over 2 *m*, at 25°, found that at a velocity constant about equal to 0.1 (at 50° $k = 0.1$ when $c = 0.05$ *N*) the simple method broke down. He attributes this behavior to failure to maintain temperature equilibrium during the course of the reaction. Therefore for higher velocities he used a dilatometer containing a spiral through which the bath water was circulated.

In Fig. 2 we plot our data (Table IV) for k/c at 25° (circles) as a function of the concentration of sodium hydroxide, along with Koelichen's values[23]

DEPENDENCE OF k/c ON NaOH CONCENTRATION AT 25.00°

Concn. NaOH	$k/c \times 10^3$
0.02052	221.9 ± 0.3
.02920	223.3 ± 1.2
.05180	224.3 ± 0.6
.06160	221.8 ± 0.2
.07099	222.2 ± 0.8
.08637	219.4 ± 0.1
.1045	221.0 ± 0.8
	221.9 ± 1.0

(crosses) for k/c obtained by averaging his closely agreeing values for sodium hydroxide and barium hydroxide at 25.2° and reducing by 2% for comparison at 25°. Both sets of data are in excellent agreement and amply verify the linear dependence of k upon the concentration of sodium hydroxide.

On the other hand, the k/m values of French,[24] of Murphy,[25] and of Åkerlöf,[22] although agreeing fairly well among themselves are distinctly lower (6% at 0.1 N and 10% at 0.01 N) than ours, and furthermore exhibit a concentration dependence. The discrepancy persists even after we correct our k/c values to the k/m concentration scale as indicated by the dashed line in Fig. 2.

Incomplete removal of bubbles or leakage at the stopcock is not the explanation although in individual cases these factors may contribute to the scattering of the k/c values. We suspect that the discrepancy arises in the determination of the concentration of alkali. Our method of direct determination by titration at the conclusion of the reaction eliminates any possibility of reporting incorrect values for the concentration due to absorption of carbon dioxide during the process of filling the dilatometer and to the presence of acid impurities in the diacetone alcohol.

None of the previous investigators, except Koelichen, gives the method of preparation or the characteristics of the diacetone alcohol used. We find that 20 g. of the Eastman product contains 1.2×10^{-4} mole of acid, whereas the preparation Diacetone (Commercial Solvents) contains 2×10^{-3} mole of acid. The presence of acid impurities would lead to a decrease in k/m values with decreasing molality of sodium hydroxide, and is consistent with the hypothesis that these errors enter in the data of French, Murphy and Åkerlöf.

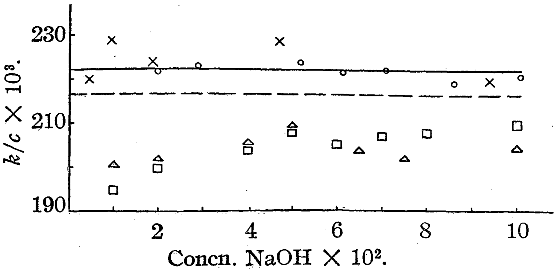

Fig. 2.—Concentration dependence of k/c at 25.00°: ○, this investigation, Table IV; ×, Koelichen k/c; △, French k/m; □, Murphy k/m; ——, mean of Table IV; ----, Table IV corrected to k/m scale.

Methyl Alcohol Effect

Since the recalculation of Murphy's data indicated a change in C_{act} with addition of methyl alcohol to the solvent, it seemed desirable to obtain a few points on the energy of activation–temperature curve for a water–methyl alcohol mixture, with a view, not only of affording a check on the general character of the water curve but possibly of shedding light on the mechanism of the reaction.

Tests showed that the final titration was unaffected by the quantity of alcohol used. Since the procedure of boiling by vacuum would remove slightly different amounts of alcohol at different temperatures, it was necessary to measure the methyl alcohol concentration in the final solution. This was accomplished by constructing density–alcohol concentration curves at each temperature, using a fixed quantity of diacetone alcohol in the mixture and allowing the sodium hydroxide concentration to vary only over narrow limits.

Experimental Results

A summary of the velocity constants obtained at eleven different temperatures is given in Table V.

TABLE V

VELOCITY CONSTANTS WITH AQUEOUS SODIUM HYDROXIDE

T., °C.	No. of expts. in average	Average k for 0.1 N NaOH
0.00	7	$(176.7 \pm 0.5) \times 10^{-5}$
5.86	2	$(322.1 \pm 2.2) \times 10^{-5}$
9.79	2	$(484.9 \pm 2.3) \times 10^{-5}$
14.98	2	$(825.7 \pm 3.7) \times 10^{-5}$
19.92	2	$(134.7 \pm 0.8) \times 10^{-4}$

by volume of methyl alcohol in the final solution, are given in Table VI.

TABLE VI

VELOCITY CONSTANTS USING 18.5% OF METHYL ALCOHOL

T., °C.	No. of expt. in average	Average k for 0.1 N NaOH
0.00	2	$(93.14 \pm 0.64) \times 10^{-5}$
11.22	2	$(339.7 \pm 0.9) \times 10^{-5}$
14.84	2	$(507.7 \pm 2.8) \times 10^{-5}$
25.04	2	$(152.6 \pm 1.0) \times 10^{-4}$
29.98	1	256.1×10^{-4}
34.99	1	428.0×10^{-4}
49.95	2	$(183.2 \pm 0.1) \times 10^{-3}$

For comparison with the collision theory, the values of E_{act} and the integration constant B are given in Tables VII and VIII. The nature of the temperature dependence is strikingly exhibited by plotting these E_{act} and B values against temperature as in Figs. 3 and 4. From these curves the following points are observed. (1) E_{act} increases by nearly 1400 calories from 5 to 32.5° and then decreases by 500 calories (over five times the probable error) to 45°. (2) In the presence of 18.5% methyl alcohol E_{act} follows a similar course to 32.5°. (3) E_{act} increases by 1500 calories at 20° on the addition of 18.5% methyl alcohol. (4) Addition of 18.5% methyl alcohol produces an increase of one logarithmic unit in B. (5) The B values parallel the E_{act} values very closely.

[a] The precision of E is estimated at 90 cal. and that of B at 0.07 unit in B, the estimate being obtained as follows. The "average error" of the mean is averaged for all temperatures and used to obtain the ∂k_1. The $\partial E)_{\text{k}_1\text{k}_2\text{T}\Delta\text{T}} \cong 0$ and $\Delta T = 10°$ $\partial(\Delta T) = 0.02°$. Numerical values are taken at 25°.

$$\partial E)_{\text{k}_1\text{k}_2\text{T}_1\text{T}_2} = \frac{-RT_1T_2 \ln k_1/k_2 \, \partial(\Delta T)}{(\Delta T)^2} = 34 \text{ cal.}$$

$$\partial B)_{\text{kT}} = \frac{\partial E}{2.3RT} = 0.067$$

$$\partial E)_{\text{k}_2(\Delta\text{T})\text{T}_1\text{T}_2} = \frac{-RT_1T_2 \, \partial k_1}{\Delta T k_1} = 60 \text{ cal.}$$

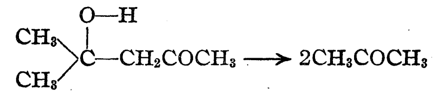
$$\partial B)_{\text{ET}} = 2.3\partial k/k = 0.008$$

$$\partial B)_{\text{Ek}} \cong 0$$

$$\partial E)_{\text{k}_1(\Delta\text{T})\text{T}_1\text{T}_2} = 60 \text{ cal.}$$

$$\Delta E = 90 \text{ cal.} \qquad \Delta B = 0.07 \text{ unit of } B$$

A survey of the literatures shows that reactions which have so far demonstrated a marked temperature dependence of E_{act} fall roughly into two classes; namely, those involving a halogen compound and those which are either a hydrolysis or a proton change.[26] The present reaction is of the latter type being the reversal of an aldol process.



$$(CH_3)_2C(OH){-}CH_2COCH_3 \longrightarrow 2CH_3COCH_3$$

It was pointed out in the previous theoretical paper[27] that when E_{act} is strictly independent of temperature B reduces to log Z^0, where Z^0 is the gas kinetic collision number, since in the expression

$$B = \log Z^0 + \frac{1}{2.3R}\int_0^T \left(\frac{\partial E_{\text{act}}}{\partial T}\right)\frac{\mathrm{d}T}{T} \tag{4}$$

the last term to the right involving the change in energy of activation with temperature vanishes. It should be remarked that although B for this reaction is not far from the order of magnitude predicted for a pure collision number,[28] however, its behavior with temperature is not at all the $T^{1/2}$ effect which would be demanded and the constant increment on the addition of methyl alcohol indicates its complex nature. Obviously the increase of one logarithmic unit in B can hardly be interpreted as arising solely from a ten-fold increase in the number of collisions.

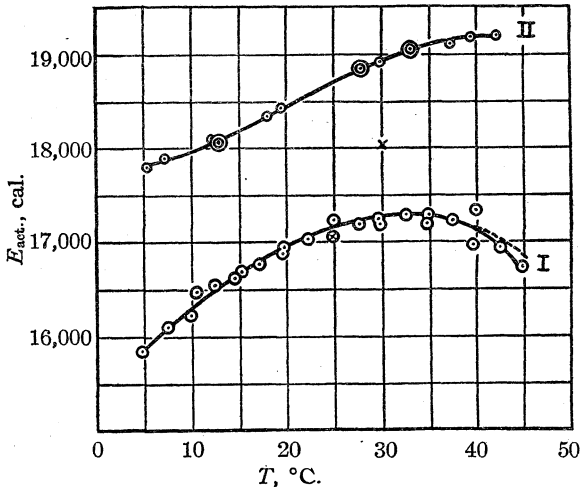

Fig. 3.—Temperature dependence of the Arrhenius E: I, water solution; II, 18.5% methyl alcohol; ×, Murphy's data; ◉, very small temperature interval.

The presence of such difficulties is recognized even by the proponents of the extreme form of the collision theory. Since the linear extrapolation of the log k − $1/T$ curve to infinite temperature, by which the collision number, Z, is obtained, cannot be made unless E_{act} is independent of temperature, some authors have attempted to correct E_{act} and others to correct B to justify this procedure. Moelwyn-Hughes' theory[29] would obtain the "true" E_{act} for reactions of this type (*i. e.*, involving a neutral molecule and an ion), which exhibit a marked discrepancy between the calculated and observed collision frequency by using for the calculation, not k, but k divided by the viscosity coefficient. Such a procedure implies that if the corrected E_{act} is to be independent of temperature the measured E_{act} was not. It may be recalled that the reactions which required this interpretation include the acid hydrolysis of esters and amides, the decomposition of nitrosotriacetoneamine, hydrolysis of sugars and the hydrolysis of γ stearolactone. A like treatment, applied to the present reaction,[30] gives E^*_{act} = 21,300 cal. and B^* = 13.9, a good correlation. However, in methyl alcohol solution E^*_{act} = 23,800 cal. and B^* = 14.9, making the former agreement seem purely fortuitous.

The parallel behavior of E_{act} and B previously pointed out is not surprising in the special case where T is the independent variable, but is a consequence of equation (4) relating B to the entropy of activation.

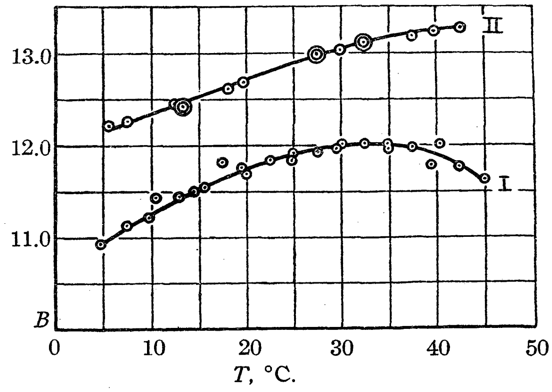

Fig. 4.—Diacetone alcohol: I, solvent water; II, solvent 18.5% methyl alcohol.

Thus, by differentiating the expressions for E_{act} and 2.3 B in respect to temperature and forming the ratio, we get

$$2.3\,\frac{\mathrm{d}B}{\mathrm{d}E} = 2.3\,\frac{\mathrm{d}B}{\mathrm{d}T}\bigg/\frac{\mathrm{d}E_{\text{act}}}{\mathrm{d}T} = \frac{1}{RT}$$

The above considerations apply solely to the dB/dE resulting from a change in temperature and are not to be confused with the rough parallelisms between E_{act} and B[31] observed when either the solvent or one of the reactants is changed.

---

(27) V. K. La Mer, (a) *J. Chem. Phys.*, **1**, 289 (1933); (b) THIS JOURNAL, **55**, 1739 (1933).

(28) The fortuitous nature of such agreement has been emphasized by Polissar, and by D. T. Lewis and Hudleston: M. J. Polissar, *ibid.*, **54**, 3105 (1932); D. T. Lewis and L. J. Hudleston, *Trans. Chem. Soc.*, 1398 (1932).

(29) E. A. Moelwyn-Hughes, *Phil. Mag.*, **14**, 112 (1932).

(30) Since the following approximations were made in order to use the viscosity data ("I. C. T."), a constancy of E^*_{act} of better than ±300 cal. can hardly be expected: (1) graphical interpolation for concentration and temperature; (2) additivity of η for acetone and methyl alcohol solutions; (3) negligible change in η due to the small amount of sodium hydroxide present.

(31) W. A. Holzschmidt, *Z. anorg. allgem. Chem.*, **200**, 82 (1931); S. Roginsky and L. Rosenkewitsch, *Z. physik. Chem.*, **10B**, 47 (1930); J. K. Syrkin, *Z. anorg. allgem. Chem.*, **199**, 28 (1931).

Summary

1. The velocity constant for the diacetone alcohol decomposition in the presence of dilute sodium hydroxide has been measured at 5° intervals from 0 to 50°.

2. The constancy of ratio of velocity constant to sodium hydroxide concentration has been confirmed over a limited concentration range at 25°.

3. The energy of activation, calculated from the Arrhenius equation for a series of temperature intervals, has been shown to be a function of temperature well outside the limits of error. E_{act} increases consistently from a value of 15,850 cal. at 5° to 17,250 at 32.5 and then decreases by about 400 cal. at 45°.

4. On the addition of 18.5% of methyl alcohol E_{act} increases by over 1700 cal. but the general character of the E_{act}–T curve remains little changed to 30°.

5. The corresponding B values from the integrated Arrhenius equation, $\ln k = 2.3\,B - (E_{\text{act}}/RT)$, both in water and the methyl alcohol solution parallel these E_{act} values and furnish experimental evidence for abandoning the unfortunate term "temperature independent constant" for this quantity.

6. The data show that the collision theory is inadequate and that the entropy of activation is an important quantity in considering solution reactions.

The Structure and Entropy of Ice and of Other Crystals with Some Randomness of Atomic Arrangement

BY LINUS PAULING

Investigations of the entropy of substances at low temperatures have produced very important information regarding the structure of crystals, the work of Giauque and his collaborators being particularly noteworthy. For example, the observed entropy of crystalline hydrogen shows that even at very low temperatures the molecules of orthohydrogen in the crystal are rotating about as freely as in the gas;[1] subsequent to this discovery the phenomenon of rotation of molecules in crystals was found to be not uncommon. Also the entropy values of carbon monoxide[2] and nitrous oxide[3] show that in crystals of these substances the molecules are not uniquely oriented, but have instead a choice between two orientations, presumably the opposed orientations CO and OC or NNO and ONN along fixed axes. It is pointed out in this note that the observed entropy of ice at low temperatures provides strong support for a particular structure of ice, and thus gives an answer to a question which has been extensively discussed during the past few years.

It has been generally recognized since the discovery of the hydrogen bond[4] that the unusual properties of water and ice (high melting and boiling points, low density, association, high dielectric constants, etc.) owe their existence to hydrogen bonds between water molecules. The arrangement of oxygen atoms (but not of hydrogen atoms) in crystals of ice is known from x-ray studies;[5] it is not a close-packed arrangement (as of sulfur atoms in the high-temperature form of hydrogen sulfide), but a very open one, like that of the silicon atoms in high-tridymite. Each oxygen atom in ice is tetrahedrally surrounded by four other oxygen atoms at the distance 2.76 Å., and it has been assumed that it is bonded to these atoms by hydrogen bonds, the number of hydrogen atoms being just that required to place one hydrogen atom between each pair of oxygen atoms. (Similarly in high-tridymite there is an oxygen atom between each pair of silicon atoms; we might say that each silicon atom is attached to four others by oxygen bonds.)

The question now arises as to whether a given hydrogen atom is midway between the two oxygen

atoms it connects or closer to one than to the other. The answer to this is that it is closer to one than to the other. In the gas molecule the O–H distance is 0.95 Å., and the magnitudes of the changes in properties from steam to ice are not sufficiently great to permit us to assume that this distance is increased to 1.38 Å. In ice each hydrogen atom is about 0.95 Å. from one oxygen atom and 1.81 Å. from another.

We now ask whether each hydrogen atom (or rather hydrogen nucleus) has a choice of two positions along its oxygen–oxygen axis, independent of the positions of the other hydrogen nuclei. The answer is in the negative; for we know that the concentration of $(OH)^-$ and $(H_3O)^+$ ions in water is very small, and we expect the situation to be essentially unchanged in ice. Hence the hydrogen nuclei will assume positions such that each oxygen atom (with at most very few exceptions) will have two hydrogen atoms attached to it.

Let us now make the following assumptions (to be supported later by a discussion of the entropy) regarding the structure of ice.

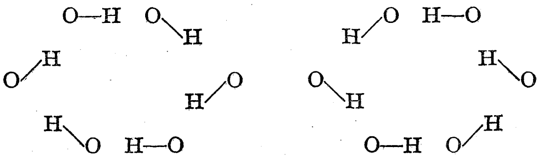
(1) In ice each oxygen atom has two hydrogen atoms attached to it at distances of about 0.95 Å., forming a water molecule, the HOH angle being about 105° as in the gas molecule.

(2) Each water molecule is oriented so that its two hydrogen atoms are directed approximately toward two of the four oxygen atoms which surround it tetrahedrally, forming hydrogen bonds.

(3) The orientations of adjacent water molecules are such that only one hydrogen atom lies approximately along each oxygen–oxygen axis.

(4) Under ordinary conditions the interaction of non-adjacent molecules is not such as to appreciably stabilize any one of the many configurations satisfying the preceding conditions with reference to the others.

Thus we assume that an ice crystal can exist in any one of a large number of configurations,[6] each corresponding to certain orientations of the water molecules. The crystal can change from one configuration to another by rotation of some of the molecules or by the motion of some of the hydrogen nuclei, each moving a distance of about 0.86 Å. from a potential minimum 0.95 Å. from one oxygen atom to another one 0.95 Å. from an adjacent oxygen atom. It is probable that both processes occur. As an example of a change from one to another configuration, we may consider one of the puckered rings of six oxygen atoms occurring in ice



Change from one of the two cyclic arrangements of hydrogen nuclei to the other is permitted by our postulates. The fact that at temperatures above about 200Å. the dielectric constant of ice is of the order of magnitude of that of water shows that the molecules can orient themselves with considerable freedom, the crystal changing under the influence of the electric field from unpolarized to polarized configurations satisfying the above conditions. On cooling the crystal to low temperatures it freezes into some one of the possible configurations; but it does not go over (in a reasonable period of time) to a perfect crystal with no randomness of molecular orientation. It will have at very low temperatures the entropy $k \ln W$, in which W is the number of configurations accessible to the crystal.

Let us now calculate W, using two different methods.

There are N molecules in a mole of ice. A given molecule can orient itself in six ways satisfying condition 2. However, the chance that the adjacent molecules will permit a given orientation is $^1/_4$; inasmuch as each adjacent molecule has two hydrogen-occupied and two unoccupied tetrahedral directions, making the chance that a given direction is available for each hydrogen of the original molecule $^1/_2$, and the chance that both can be located in accordance with the given orientation $^1/_4$. The total number of configurations for N molecules is thus $W = (^6/_4)^N = (^3/_2)^N$.

The same result is given by the following equivalent argument. Ignoring condition 1, there are 2^{2N} configurations with hydrogen bonds between adjacent oxygen atoms, each hydrogen nucleus having the choice of two positions, one near one oxygen atom and the other near the other. Some of these are ruled out by condition 1. Let us now consider a given oxygen atom and the four surrounding hydrogen atoms. There are sixteen arrangements of the four hydrogen nuclei. Of

---

(6) One of the large number of configurations is represented by the structure of ice suggested by J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, 1, 515 (1933); these authors also suggested that at temperatures just below the melting point (but not at lower temperatures) the molecular arrangement might be partially or largely irregular.

these ten are ruled out by condition 1—one gives $(H_4O)^{++}$, four give $(H_3O)^+$, four $(OH)^-$ and one O^{--}. This condition for each oxygen atom thus permits only $^6/_{16} = {}^3/_8$ of the configurations, the total number of permitted configurations being accordingly $W = 2^{2N}(^3/_8)^N = (^3/_2)^N$.

The contribution of this lack of regularity to the entropy of ice is thus R ln $^3/_2 = 0.805$ E. U. The observed entropy discrepancy of ice at low temperatures is 0.87 E. U., obtained by subtracting the entropy difference of ice at very low temperatures and water vapor at standard conditions, for which the value 44.23 E. U. has been calculated from thermal data by Giauque and Ashley,[7] from the spectroscopic value 45.101 E. U. for the entropy of water vapor given by Gordon.[8] The agreement in the experimental and theoretical entropy values provides strong support of the postulated structure of ice.[9]

The structure of ice is seen to be of a type intermediate between that of carbon monoxide and nitrous oxide, in which each molecule can assume either one of two orientations essentially independently of the orientations of the other molecules in the crystal, and that of a perfect molecular crystal, in which the position and orientation of each molecule are uniquely determined by the other molecules. In ice the orientation of a given molecule is dependent on the orientations of its four immediate neighbors, but not directly on the orientations of the more distant molecules.

It should be pointed out that a finite residual entropy calculated for a substance from experimental data obtained at temperatures extending down to a certain temperature, with extrapolation below that point, may arise either from failure of the experimenter to obtain thermodynamic equilibrium in his calorimetric measurements or from error in the extrapolation. Measurements made under ideal conditions and extended to sufficiently low temperatures would presumably lead to zero entropy for any system.

Other Crystals with Residual Entropy

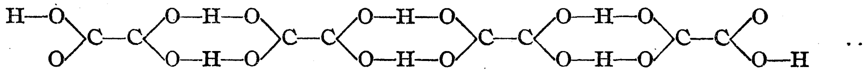
Our knowledge of the structure of crystals permits the prediction to be made that many other crystals will be found to have residual entropy at very low temperatures as a result of some randomness of atomic arrangement. It is probable, however, that experimental verification of the residual entropy would be difficult for most of the cases mentioned below.

Diaspore, $AlHO_2$, contains groups OHO with hydrogen bonds.[10] As in water, we expect the hydrogen nucleus to be closer to one oxygen atom than to the other. Inasmuch as there is no restriction on the choice of the two positions, each oxygen atom forming only one hydrogen bond, this would lead to a residual entropy of R ln 2 per mole of $AlHO_2$. The same residual entropy is expected per HO_2 group for other crystals containing this group (staurolite).

Hydrogen bonds may not always lead to residual entropy. For example, the crystal lepidocrocite,[11] FeOOH, contains infinite strings of oxygen atoms joined by hydrogen bonds, $^{\rm O}{\rm H}_{\rm O}{\rm H}^{\rm O}{\rm H}_{\rm O}{\rm H}^{\rm O}{\rm H}$. If we assume that the choice of two positions by a hydrogen nucleus is restricted by the requirement that each oxygen have one and only one attached hydrogen, then there are two accessible configurations per string. This lack of definiteness does not lead to an appreciable residual entropy for a large crystal.

In the double molecules of formic acid, with the structure[12]  and in other monocarboxylic acids forming double molecules, we expect that the interaction within a carboxyl group is strong enough to permit only the two configurations in which one hydrogen nucleus is attached to each carboxyl group to be stable at low temperatures. This would lead to a residual entropy of $^1/_2$ R ln 2 per RCOOH.

By a similar argument we calculate for β-oxalic acid (anhydrous), which contain finite strings[13] of molecules



the residual entropy R ln 2 per mole of $(COOH)_2$, whereas α-oxalic acid, containing layers with the dealized structure[13] in which there are infinite sequences of carboxyl groups attached by hydrogen bonds, would have no appreciable residual

[8] A. R. Gordon, *J. Chem. Phys.*, **2**, 65 (1934).

[9] The existence of this residual entropy of ice at very low temperatures was discovered by Giauque and Ashley (ref. 7), who preliminarily ascribed it to the persistance of rotation of ortho-water molecules (comprising $^3/_4$ of the total) about their electric-moment axes, giving an entropy of $^3/_4$ R ln $2 = 1.03$ E. U.

entropy. The experimental verification of this prediction by heat capacity measurements and the study of the equilibrium between the two forms might be practicable.

At present it is not possible to predict with confidence whether the hydrogen nucleus between two fluorine atoms connected by a hydrogen bond has the choice of two positions (as for oxygen atoms) or not. The FHF distance of 2.35 Å. is somewhat greater than twice the H–F distance in HF, 0.91 Å., although the difference (29%) is not so great as for OHO and H–O (45%). The question would be answered by a determination of the residual entropy of potassium hydrogen fluoride, KHF_2, or of some other crystal containing the HF_2 group; the residual entropy would be $R \ln 2$ if the potential function for the hydrogen nucleus has two minima rather than one. The same residual entropy would also be shown by KH_2F_3, KH_3F_4, etc. If crystalline hydrofluoric acid contains cyclic molecules $(HF)_6$, with the structure  $\begin{matrix} & {}_{\mathrm{H}}{}^{\mathrm{FHF}}{}_{\mathrm{H}} & \\ \mathrm{F} & & \mathrm{F} \\ & {}^{\mathrm{H}}{}_{\mathrm{FHF}}{}^{\mathrm{H}} & \end{matrix}$, the two-minimum function and the restriction that one hydrogen is attached to each fluorine would lead to a residual entropy of $^1/_6\, R \ln 2$ per mole of HF.

Hydrogen bonds between unlike atoms, as in NH_4F, would not lead to residual entropy.

Residual entropy may also result from the multiplicity of stable positions for atoms other than hydrogen. In γ-Al_2O_3 and γ-Fe_2O_3 the oxygen ions are arranged in a close-packed framework, which provides nine positions for every eight cations. The x-ray data[14] indicate that the cations are distributed essentially at random among these positions, leading to a residual entropy of $^3/_2\, R \ln {}^{27}/_{16} = 1.558$ E. U. per mole of R_2O_3. In pyrrhotite,[15] $Fe_{1-\delta}S$, the sulfur atoms have a hexagonal arrangement, the iron atoms being distributed apparently at random among the positions provided, of which they occupy the fraction $1 - \delta$. In the cubic tungsten bronzes,[16] Na_xWO_3, the sodium ions occupy the fraction x of the available positions. These crystals would presumably show residual entropy of mixing of the ions W^{5+} and W^{6+} as well as the entropy of random distribution of the sodium ions. A somewhat similar case is provided by the hexagonal form of silver iodide,[17] in which at room temperature each silver atom has the choice of four or five positions a few tenths of an Ångström apart. At liquid air temperatures, however, most of the atoms settle into one position, so that no residual entropy would be shown.

Many crystals show an uncertainty in structure similar to that of CO and NNO or of solid solutions. For potassium cyanate the x-ray data[18] indicate that each cyanate ion has the choice of two orientations, NCO and OCN, which would lead to the residual entropy $R \ln 2$. In spinel, $MgAl_2O_4$, and other crystals with the spinel structure, the bivalent and trivalent cations are distributed with considerable randomness among the available positions,[19] leading to a residual entropy corresponding to a crystalline solution. In muscovite,[20] $KAl_2(AlSi_3)O_{10}(OH)_2$, one aluminum and three silicon atoms per formula are distributed, presumably with considerable randomness, among the available tetrahedral positions. The same phenomenon, leading to residual entropy, without doubt occurs in many aluminosilicates.

Crystals of cadmium bromide[21] and nickel bromide[22] prepared in certain ways show a type of randomness which does not lead to any appreciable residual entropy, provided that the crystals are not extremely small. This randomness of structure ("Wechselstruktur," alternating layer structure) consists in a choice between two positions for each layer of a layer structure, leading to an entropy of $k \ln 2$ for each layer, which remains

inappreciable, inasmuch as the number of layers in a crystal (other than an extremely small crystal) is very small compared with the number of atoms.

In this connection it might be mentioned that there exists the possibility that ice may crystallize with such an alternating layer structure. The oxygen-atom arrangement assigned to ice corresponds to superimposing double oxygen layers in the sequence ABAB—(A at 00, B at $^1/_3\ ^2/_3$, C at $^2/_3\ ^1/_3$ of a hexagonal net). The sequence ABCABCABC— would also lead to an arrangement (diamond) such that each oxygen atom is surrounded by four others arranged tetrahedrally, which is indeed, so far as I can see, just as satisfactory as the reported arrangement. There is no good evidence that such a cubic modification of ice has been observed. However, the arbitrariness of orientation which we have found to exist for the water molecules in ice suggests that there may also be an arbitrariness in the sequence of double oxygen layers, with configurations such as ABABABCBCB— occurring. Such an alternating layer structure would have hexagonal symmetry, might develop faces at angles corresponding to the axial ratio $c/a = 1.63$, and would not be distinguishable so far as residual entropy is concerned from a crystal with fixed oxygen atom arrangement. The x-ray data show that the sequence of layers is not completely random, the structure being essentially ABABAB—; it is possible, however, that a change in the sequence, corresponding to twinning on the basal plane, occurs occasionally.

I am indebted to Professor W. F. Giauque for discussing the question of the structure and entropy of ice, as well as related questions, with me.

Summary

It is suggested that ice consists of water molecules arranged so that each is surrounded by four others, each molecule being oriented in such a way as to direct its two hydrogen atoms toward two of the four neighbors, forming hydrogen bonds. The orientations are further restricted by the requirement that only one hydrogen atom lie near each O–O axis. There are $(^3/_2)^N$ such configurations for N molecules, leading to a residual entropy of $R \ln {}^3/_2 = 0.805$ E. U., in good agreement with the experimental value 0.87 E. U.

The structure and entropy of other crystals showing randomness of atom arrangement are discussed.

The Radial Distribution Method of Interpretation of Electron Diffraction Photographs of Gas Molecules

BY LINUS PAULING AND L. O. BROCKWAY

Introduction

The only method of interpretation of electron diffraction photographs of gas molecules which has been used to any great extent is the so-called *visual method*, involving the correlation of apparent maxima and minima on the photographs with maxima and minima on simplified theoretical curves calculated for various models of the molecule under consideration. This method of interpretation, originally developed by Wierl,[1] has been thoroughly tested by Pauling and Brockway[2] who have shown it to yield values of interatomic distances accurate to within about 1% (estimated probable error). The main disadvantage of the method is that it does not involve a straightforward process of determining the structure of a molecule from the analysis of experimental results, but consists instead in the testing (and rejection or acceptance) of any structures which may be formulated, a tedious calculation being required for each structure.

We have developed a new method of interpretation of the photographs which does not suffer from this disadvantage. This *radial distribution method*, which is closely related to the method of interpretation of x-ray diffraction data developed by Zernike and Prins[3] for the study of the structure of liquids and applied by Warren and Gingrich[4] to crystals, consists in the calculation (from

data provided by the electron diffraction photograph) of a distribution function for scattering power, representing the product of the scattering powers in volume elements the distance l apart as a function of l. Since the scattering power of an atom for fast electrons is large only in the neighborhood of the nucleus, a maximum in this distribution function indicates that the internuclear distance for two atoms in the molecule is given by the corresponding value of l. The radial distribution method thus leads directly to values of the internuclear distances and hence to the structure of the molecule.

Because of the difficulty of obtaining satisfactory photometer records of electron diffraction photographs of gas molecules, we have adapted and extended the visual method to the calculation of radial distribution curves, by making use of the values of $(4\pi \sin \vartheta/2)/\lambda$ obtained by the measurement of ring diameters (as in the usual visual method) in conjunction with visually estimated intensities of the rings, as described below. Various tests of the method indicate that the important interatomic distances can be determined in this way to within 1 or 2% (probable error).

The radial distribution method, while thus not completely independent of the usual visual method, is sufficiently different from it to lead in some cases to somewhat different values for interatomic distances. We feel that these values carry some weight, and we have accordingly discussed by the new method a number of molecules whose structures as determined by the usual visual method have been reported in earlier publications, and have then combined the results of the two methods in presenting a revised set of values of interatomic distances for these molecules.

The radial distribution method is especially satisfying in that it leads directly to the values of the principal interatomic distances, and so immediately rules out all structures for the molecule except those compatible with these values. Moreover, the method can be applied unchanged to those molecules for which the investigator is unable to formulate a reasonable structure (such as S_2Cl_2, in which the rotation about the S–S bond may be restricted to some extent, leading to difficultly predictable variation in the Cl–Cl distance), yielding a distribution curve which reveals the information provided by the photograph regarding the structure of the molecule.

We are greatly indebted to Dr. S. Weinbaum, Dr. J. Sherman, and Mr. J. Y. Beach for assistance in the preparation of this paper.

Description of the Method

The intensity of the coherent electron scattering at the angle ϑ by gas molecules is usually represented by the expression

$$I(\vartheta) = K \sum_i \sum_j \psi_i \psi_j \frac{\sin x_{ij}}{x_{ij}} \qquad (1)$$

in which K is a constant, and

$$x_{ij} = \frac{4\pi \sin \vartheta/2}{\lambda} l_{ij} \qquad (2)$$

with l_{ij} the distance between atoms i and j in the molecule, λ the wave length of the electrons, and ψ_i the scattering function for the ith atom. A more general expression is

$$s^4 I(s) = K' \int_0^\infty l^2 D(l) \frac{\sin sl}{sl} \, dl \qquad (3)$$

in which we have introduced the new angle variable

$$s = (4\pi \sin \vartheta/2)/\lambda \qquad (4)$$

and have replaced the double sum by an integral, writing in place of the product of atomic scattering powers $\psi_i\psi_j$ the function $l^2 D(l)/s^4$, representing, aside from the factor $1/s^4$ (the scattering factor for electrons by a unit charge), the product of scattering powers in all volume elements the distance l apart. This expression is a Fourier integral for $s^5 I(s)$, the coefficients of the Fourier terms being $lD(l)$. On inverting the Fourier integral we obtain the following expression for $D(l)$ in terms of $I(s)$

$$D(l) = K'' \int_0^\infty s^6 I(s) \frac{\sin sl}{sl} \, ds \qquad (5)$$

Instead of attempting to apply the expression in this form, we simplify it radically in a way suggested by the appearance of the electron diffraction photographs, which to the eye show a succession of rings; namely, by replacing the integral by a finite sum of terms, including one term for each ring. We accordingly write, ignoring the constant K''

$$D(l) = \sum_{k=1}^{n} I_k \frac{\sin s_k l}{s_k l} \qquad (6)$$

in which

$$s_k = (4\pi \sin \vartheta_k/2)/\lambda$$

ϑ_k being the scattering angle for the kth ring as measured in the usual way,[2] and I_k an estimated value[5] for the integrated intensity of the kth ring

---

(5) It is our experience that the intensities as estimated visually (the change from ring to ring being small, as seen in the tables) are satisfactory, despite neglect of the factor s^6. This may be due in part to the comparison by the eye of each ring with the adjacent background, which falls off in intensity approximately with $1/s^4$.

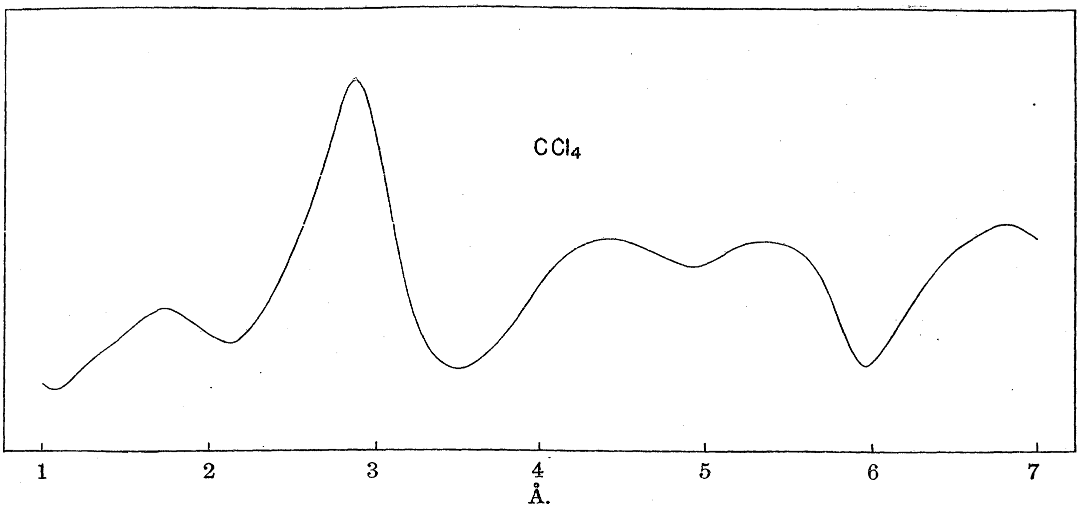

Fig. 1.—Radial distribution function for carbon tetrachloride. The part of the curve beyond 4 Å. is without significance.

(the factor s^6 being included in I_k). This simplification, which at first seems extreme, is seen on analysis not to be unreasonable; each section of the integral, corresponding to the range of angles between successive apparent minima, is replaced by a single Fourier term, whose frequency is in the middle of the frequencies for the range replaced, the coefficient of the single term being an integrated coefficient over the range. For values of l in the region of importance (corresponding to interatomic distances in the molecule) this simplification will not change the form of $D(l)$ very much; at smaller and larger values of l, however, it will introduce false maxima, instead of falling asymptotically to zero.

It is seen that the calculation of a radial distribution curve is closely similar to the calculation of a simplified theoretical intensity curve for the usual visual method, the summation being over the rings seen on the photograph instead of over the interatomic distances in the assumed model; but whereas in the usual treatment the calculation may need to be repeated for many models, a single curve only is required for the new method.

In the usual treatment the apparent intensities of the rings play only a minor part, in that some use is made of them in the decision among models by qualitative comparison of photograph and curves. Numerical values of estimated intensities are needed for the new method; it is found empirically, however, that the positions of the principal maxima are not very sensitive to changes in the estimated intensities, as long as the rings are kept in correct qualitative relation to one another. It is sometimes necessary to introduce a term in the series to represent a shelf on one side of a ring, or some similar feature of the photograph.[6]

In the calculations reported in this paper the curves were evaluated at intervals of 0.1 Å. except in the neighborhood of the principal maxima, where smaller intervals (usually 0.02 Å.) were used. The values of (sin sl)/sl were obtained from tables prepared by Dr. P. C. Cross with the aid of Sherman's (sin x)/x tables.[7]

Tests of the Method

Carbon Tetrachloride.—By the usual visual method and by other methods involving microphotometer records, we have assigned[8] to the carbon tetrachloride molecule the value 1.760 ± 0.005 Å. for the C–Cl distance, a value supported by other recent work.[9] The radial distribution function for this molecule calculated by Equation 6, using the ten terms for which data are given in Table I, is shown in Fig. 1.

It is seen that the six Cl–Cl terms are shown by a very sharp peak, the four C–Cl terms appearing

---

(6) Dr. Simon Bauer has suggested that it may sometimes be convenient to introduce terms corresponding to the apparent minima between rings, using negative coefficients.

(7) J. Sherman, *Z. Krist.*, **85**, 404 (1933). The tables prepared by Dr. Cross give values of (sin sl)/sl for $0.80 \leqslant s \leqslant 4.00$ at intervals of 0.01, for values of l up to 40, and $4.02 \leqslant s \leqslant 8.00$ at intervals of 0.02, for values of l up to 20. the intervals for l being 0.2.

10	1	22.34

as a small peak at a smaller value of l; in addition some broad peaks occur at larger values of l. The complete Fourier integral representing the radial distribution would, of course, fall asymptotically to zero after the Cl–Cl maximum. Because of the crudity of our approximation to the integral by a series of ten terms we can expect our function to continue to vary appreciably in this region, the maxima there having no significance.

The l value given by the small C–Cl peak, about 1.74 Å., is unreliable, inasmuch as it is rather sensitive to change in the number of rings considered. That given by the Cl–Cl hump, however, is reliable. It is Cl–Cl = 2.856 Å., which corresponds to C–Cl = 1.749 Å., in good agreement with the earlier value, the deviation being in the direction of the values of Cosslett and de Laszlo.

The effect of including successive rings is shown in Fig. 2, the first curve including only one term (ring 1), the second two (rings 1 and 2), and so on. It is seen that the principal peak assumes its position and shape very quickly, the Cl–Cl distance being given to within 2% (2.81 Å.) by two terms alone, and quickly rising to a constant value (2.85 Å. for five terms, 2.86 Å. for six and more terms). The small C–Cl peak, on the other hand, fluctuates considerably, the l value varying between 1.72 and 1.78 Å. for curves 5 to 10.

Bromine and Chlorine.—Accurate values of the internuclear distances in the molecules Br_2 and Cl_2 are known from band spectral studies, namely, Br–Br = 2.281 Å. and Cl–Cl = 1.988 Å. The visual method led to results (2.289 Å. and 2.009 Å., respectively) in satisfactory agreement with these.[8] Radial distribution curves for these substances are shown in Fig. 3, the data used being given in Tables II and III. For bromine, with seven rings, three different estimates of intensities lead to the same Br–Br distance, 2.270 Å., less than 0.5% from the band spectral value. The Cl–Cl distance, given by the curve, 1.995 Å., is still closer to that found from band spectra. The agreement for these two molecules indicates that there is no large error inherent in the radial distribution method.

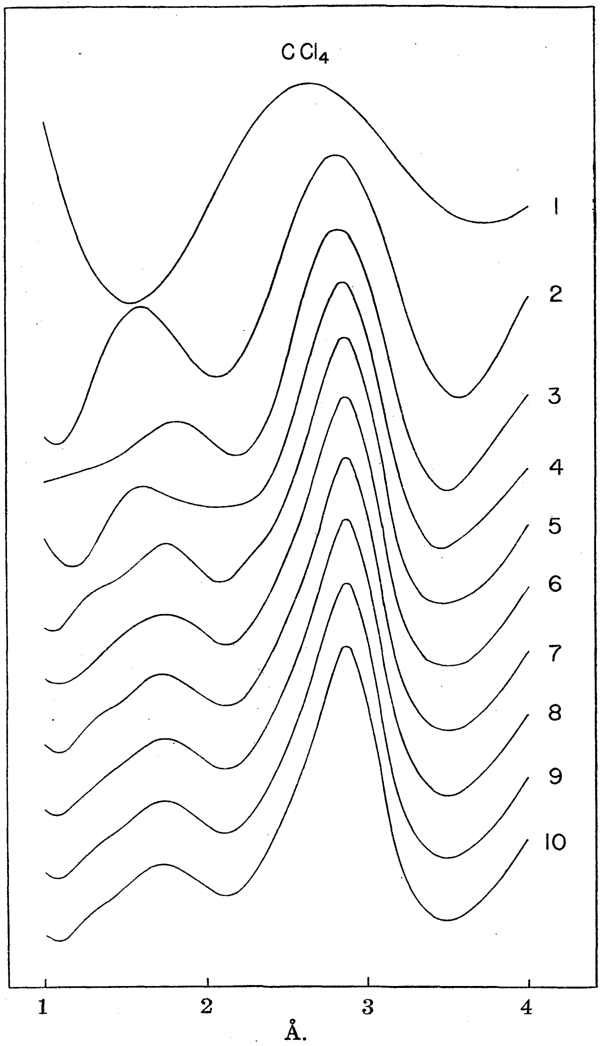

Fig. 2.—Radial distribution curves for carbon tetrachloride, calculated with one term (1), two terms (2) and so on.

Benzene.—A careful study of photographs of benzene both by the visual method and by the analysis of microphotometer records[8] has led to the value C–C = 1.390 ± 0.005 Å. for the edge of the plane hexagon formed by the carbon atoms, in agreement with the values 1.39 ± 0.03 Å. and 1.40 ± 0.03 Å. reported by Wierl.[1] The accuracy of this determination and the fact that the various carbon–carbon distances are geometrically related

make benzene a suitable substance for testing the new method.

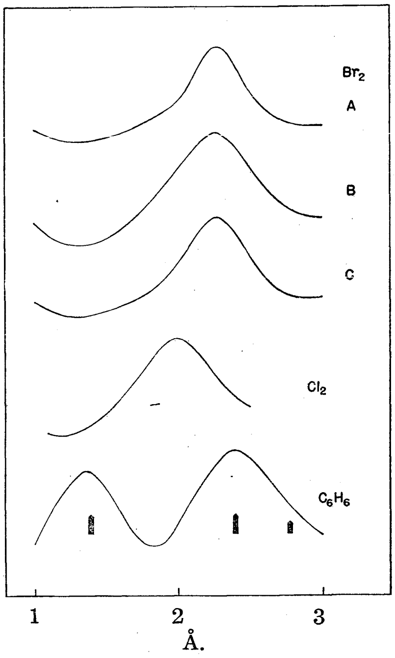

Fig. 3.—Radial distribution curves for bromine, chlorine and benzene.

The radial distribution curve calculated with the inclusion of seven terms, for which data are given in Table IV (the fourth and sixth terms corresponding to apparent shelves rather than well-defined rings), is shown in Fig. 3.

Only the two principal distances, corresponding to the six ortho C–C interactions and the six meta C–C interactions, are represented by maxima, the three para C–C interactions (which should yield a hump about one-half as pronounced as the others at the position indicated by the smallest arrow) and the various C–H interactions not being indicated on the curve. This is in agreement with our experience in general with the radial distribution method, which usually can be relied on (in the form in which we are using it) to provide information regarding only the two or three most important interactions, the peaks for which must also be separated by at least about 0.5 Å. in order to be resolved.

TABLE IV

BENZENE

k	I_k	s_k
1	50	3.35
2	160	5.805
3	20	9.55
4	5	11.50
5	15	13.83
6	3	16.23
7	8	18.66

The two maxima occur at the distances 1.381 and 2.390 Å., their ratio being 1:1.731. The close approximation of this ratio to the value $1:\sqrt{3}$ required by the hexagonal configuration of the molecule provides an interesting check on the method.

The value 1.381 Å. is 0.009 Å. less than that found in the earlier treatment. We believe that in this case the earlier treatment, involving the analysis of microphotometer records as well as the application of the usual visual method, is the more reliable, and we prefer not to change from the value 1.390 ± 0.005 Å. Indeed, we think that the usual visual method is itself somewhat more reliable than the radial distribution method in the case of benzene, inasmuch as the photographs show some precisely measurable features (very sharp fourth minimum and fourth maximum) as well as some rather diffuse rings which can be measured only with less precision; in the usual visual method great weight can be given to the results calculated from the precisely measured features, whereas in the radial distribution method the weighting is determined by the intensities of the rings, the result being dependent on the diffuse as well as the sharp ones.

Tetrahedral Molecules.—The tetrahedral molecules MX_4 permit an interesting test of the radial distribution method in that the ratio of the two distances X–X and M–X should be $2\sqrt{2}/\sqrt{3} = 1.633$. We have seen that in carbon tetrachloride this ratio is given by the curve to within about 1%. The compounds CF_4, SiF_4,

$SiCl_4$, $GeCl_4$ and $SnCl_4$ provide better tests, inasmuch as the two maxima arise from more nearly equal interactions. The curves for these five molecules, calculated for the constants[10] given in Table V, are shown in Fig. 4. It is seen that each curve shows two well-defined peaks, that for X–X being stronger than that for M–X in CF_4 and $SiCl_4$, and weaker in the other three. The lack of symmetry of the peaks (particularly pronounced for $GeCl_4$) could presumably be remedied by changing the estimated values of I_k; though such a procedure might be justified, we have not adopted it, retaining instead the original estimates in every case.

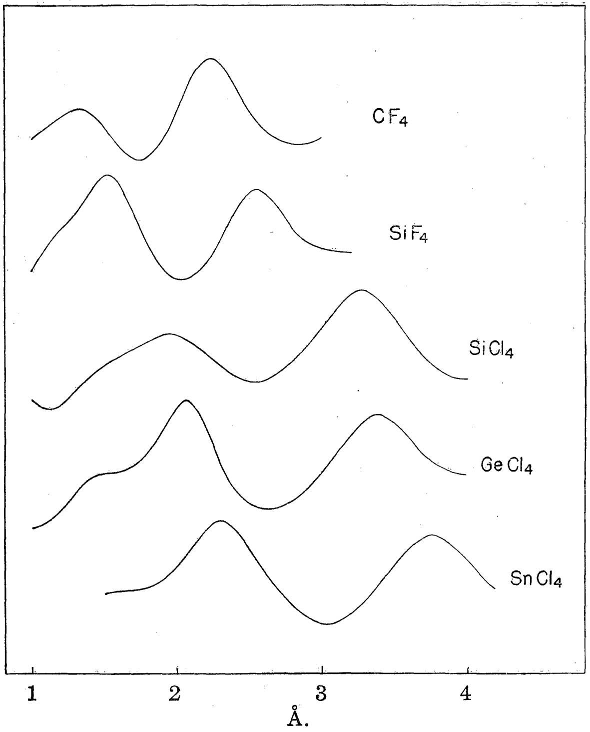

Fig. 4.—Radial distribution curves for carbon and silicon tetrafluorides and silicon, germanium and tin tetrachloride.

The values of l for the X–X and M–X peaks are given in Table VI, together with their ratios. It is seen that the ratio is in every case slightly higher than the correct value 1.633. The deviations of 0.3 to 2.7% provide some indication as to the reliability of the method; there seems to be some tendency for the maxima of the two peaks to be displaced away from one another.

Carbon Disulfide and Carbon Oxysulfide.—Radial distribution curves for carbon disulfide and carbon oxysulfide (treated by the usual method by Cross and Brockway[11]) are shown in Fig. 5. For carbon disulfide the maxima of the two peaks occur at 1.60 and 3.07 Å. In this symmetrical linear molecule the C–S distance is just one-half the S–S distance; the values found deviate from this ratio by 4%. Similarly in carbon oxysulfide the sum of two interatomic distances equals the third. The values C–S = 1.60 Å. and O–S = 2.70 Å. given by the two maxima differ by 1.10 Å. The C–O distance is not given by the curve (being indicated only by a hump at the point indicated by the arrow); there is little doubt that the value 1.16 ± 0.02 Å. found by Cross and Brockway is

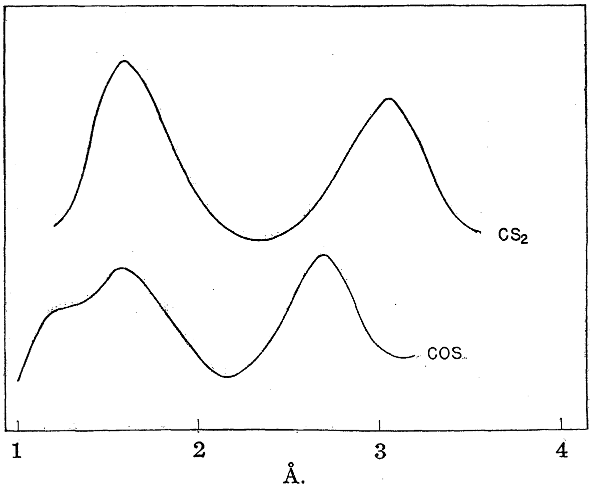

Fig. 5.—Radial distribution curves for carbon disulfide and carbon oxysulfide.

(10) The s_k values are in the main taken from (a) L. O. Brockway and F. T. Wall, THIS JOURNAL, **56**, 2373 (1934), and (b) L. O. Brockway, *ibid.*, **57**, 958 (1935), with values for shelves (not given in these papers) obtained by measurement of the original photographs.

(11) P. C. Cross and L. O. Brockway, *J. Chem. Phys.*, **3**, December (1935).

reliable, however, showing that there is an error of about 3% in the values given by the maxima. It is interesting to note that the two peaks for these curves are displaced toward one another, rather than away from one another as for the tetrahalides.

The comparison with the interatomic distance values reported by Cross and Brockway, C–S = 1.54 ± 0.03 Å. and S–S = 3.08 ± 0.06 Å. in CS_2, C–O = 1.16 ± 0.02 Å., C–S = 1.56 ± 0.03 Å., and O–S = 2.72 ± 0.05 Å. in COS, indicates that of the two peaks of these radial distribution curves the outer one is somewhat more reliable than the inner one.

Discussion of the Method

From the examples given we see that the radial distribution method in the simplified form which we have developed for the treatment of electron diffraction photographs of gas molecules is reasonably reliable and accurate, usually providing values of the two or three most important interatomic distances in the molecule (that is, those which contribute most to the diffraction pattern) with an accuracy of 1 or 2%. Probably the principal advantage of the method is that its application is straightforward; no previous information or hypothesis regarding the structure of the molecule (or, in fact, regarding even the chemical composition of the scattering gas) is needed. The information provided by a radial distribution curve usually eliminates all models of the molecule under consideration except those defined by a narrow range of values of the structural parameters; these models can then be considered in detail by the usual method, this consideration usually leading to a further restriction in the parameter values. The calculation of a radial distribution curve is thus the logical first step in the analysis of an electron diffraction photograph. Examples showing the use of these curves are included in the following paper.

We recommend that in general values of interatomic distances given by the two methods be averaged, with about equal weights unless it is felt that in a special case one method is more satisfactory than the other. The usual visual method is superior to the radial distribution method under circumstances such as the following: (1) when there are geometrical relations among interatomic distances (CS_2, C_3O_2, benzene, etc.); (2) when the photographs show some especially precisely measurable features, such as some very sharp rings (benzene); (3) when knowledge regarding certain structural parameters is available and it is desired to vary only the others; (4) when the molecule contains two or more important interatomic distances with values so close to one another that the corresponding peaks are not resolved on the radial distribution curves. On the other hand, the radial distribution method is superior in cases such as the following: (1) when the molecule contains rotating groups or some other structural feature making the detailed formulation of a model difficult (S_2Cl_2, etc.); (2) when the decision as to the model depends on quantitative intensity estimates and small changes in ring diameters (ClO_2, SO_2, etc.).

Revised Values of Structural Parameters of Molecules

On calculating radial distribution curves for molecules for which structures have been previously reported from this Laboratory on the basis of the usual method of interpretation, we have in some cases obtained interatomic distance values agreeing exactly with the earlier values and in some cases values which deviate by a small amount (rarely more than 3%). For a few molecules the new method has provided information (bond angles in ClO_2 and SO_2) not before available. We feel that it is worth while to present a table of revised values of structural parameters for these molecules, giving weight to the results of both methods. The revision includes most of the substances which have been studied in this Laboratory; some (methyl azide, diacetylene, carbon suboxide, dioxane, etc.) are omitted because of the small number of rings shown on the photographs or the unsuitability of the radial distribution method (for reasons such as those mentioned above).

Benzene.—We recommend no change in the value C–C = 1.390 ± 0.005 Å. in benzene.

Tetrahalides.—Values of M–X and (X–X)/1.633 given by the maxima on the radial distribution curves (Figs. 1 and 4) for six tetrahalides are shown in the second and third columns of Table XI, with the values obtained by the usual visual method[10a] in the fourth column. In averaging these we have assigned weights to the two radial distribution peaks as indicated by their prominence, and have given the two distinct methods about equal weight. It is seen that in no case is the change made greater than 1%.

Trihalides of Phosphorus and Arsenic.—Radial distribution curves for PF_3, AsF_3, PCl_3 and $AsCl_3$, calculated with the data given in Table VIII, are shown in Fig. 6. Each curve shows two peaks, corresponding to M–X and X–X; values for their maxima (except for X–X in AsF_3, this peak being so broad as to make its maximum unreliable) are given in Table XII, together with the values obtained by the usual visual method in an earlier investigation.[10a] The weighted averages for M–X, X–X and the X–M–X angle are given in the last three columns.

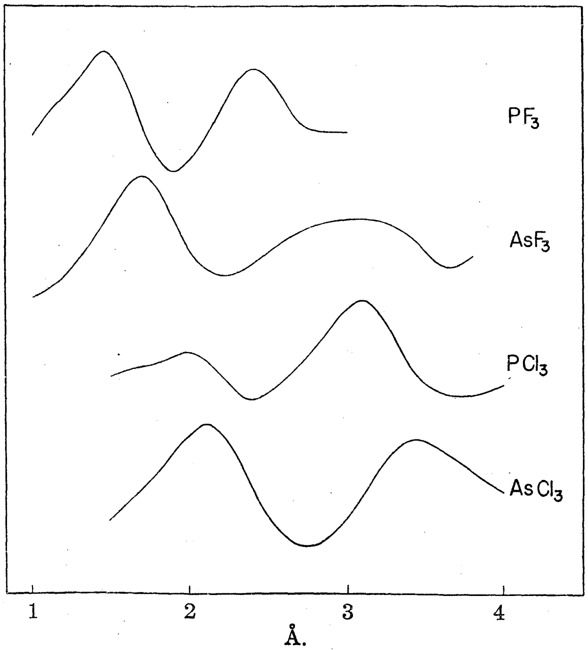

Fig. 6.—Radial distribution curves for triflourides and trichlorides of phosphorus and arsenic.

Methylene Chloride and Chloroform.—Curves for CH_3Cl, CH_2Cl_2 and $CHCl_3$ (Table IX) are shown in Fig. 7. The maximum for methyl chloride lies at 1.80 Å.; we do not consider this value sufficiently reliable to warrant a change from the value C–Cl = 1.77 ± 0.02 Å. previously reported.[12] The M–X and X–X values given by the maxima for methylene chloride and chloroform (Table XII) are in excellent agreement with those found by the usual method.

Chlorine Monoxide, Dimethyl Ether, Chlorine Dioxide and Sulfur Dioxide.—The radial distribution curves for Cl_2O, $(CH_3)_2O$, ClO_2 and SO_2 (Fig. 8) show two peaks, the positions of the

---

[12] Sutton and Brockway, THIS JOURNAL, **57**, 473 (1935).

maxima being recorded in Table XII. For chlorine monoxide we have averaged the results of the two methods with equal weights (the agreement being less satisfactory than usual). In the case of dimethyl ether smaller weight is given to the results of the radial distribution method because of the lack of symmetry of the first peak, which may cause the maximum to be displaced. It is interesting to note that the radial distribution method provides values of the angles in ClO_2 and SO_2, whereas the usual method of interpretation failed in this respect, presumably because the qualitative comparisons must be supplemented by quantitative considerations in order to obtain this information.

Summary

It is shown by empirical tests that the radial distribution function given by a sum of Fourier terms corresponding to the rings observed on an electron diffraction photograph of gas molecules (using visually measured ring diameters and estimated intensities) provides values of the important interatomic distances accurate to one or two per cent. (probable error). The substances used in the tests include carbon tetrachloride and other tetrahalides, bromine, chlorine, benzene, carbon disulfide and carbon oxysulfide.

The radial distribution method of interpretation is applied to a number of molecules previously investigated, and revised values of interatomic distances and bond angles, obtained by considering the results of this method as well as of the usual visual method, are presented (Tables XI and XII).

It is pointed out that the radial distribution method is particularly satisfying in that it leads directly to the values of the important interatomic distances in the molecule, thus eliminating many possible models and usually limiting the molecule to the structures represented by small ranges of values of the structural parameters.

The Electron Diffraction Investigation of Phosgene, the Six Chloroethylenes, Thiophosgene, α-Methylhydroxylamine and Nitromethane[1]

BY L. O. BROCKWAY, J. Y. BEACH AND LINUS PAULING

Introduction

The importance of the use of interatomic distances as a test for resonance of molecules among several valence-bond structures has been mentioned in earlier papers,[2] in which it was pointed out that the interatomic distance for two bonded atoms in a resonating molecule is determined mainly by the strongest of the bonds between the two atoms provided by the resonating structures. We have now obtained evidence regarding the quantitative dependence of interatomic distance on bond type for resonance between a single bond and a double bond, and have made use of this relation in the discussion of the electronic structure of a number of molecules involving single bond–double bond resonance. The investigation is based largely on the determination of the atomic configuration of molecules by the diffraction of electrons; the description of this work is given in this paper, and the interpretation and discussion of results in the following one.

Electron diffraction photographs of the gas molecules investigated were prepared in the usual way,[3] with film distances of about 12, 20 or 30 cm., the electron wave lengths being about 0.06 Å. The photographs were measured on a comparator and interpreted both by the radial distribution method[4] and the usual visual method.[5] The results are given below; in each case the interatomic distances and bond angles are provided with estimated probable errors, which indicate the extent to which we consider them to be reliable.

We are indebted to Dr. S. Weinbaum and Dr. J. Sherman for aid in connection with the extensive calculations involved in the interpretation of the photographs.

Phosgene.—The phosgene used was prepared by the action of fuming sulfuric acid on carbon tetrachloride in the presence of a catalyst (infusorial earth), and was purified by distillation.

The photographs show eight rings, with values of $s = (4\pi \sin \Theta/2)/\lambda$ (averages for eleven photographs measured by two observers) and estimated intensities given in Table I.

The eight-term radial distribution function (Fig. 1) shows two peaks, the first, with maximum at 1.79 Å., representing C–Cl, and the second, a broad peak with maximum at 2.74 Å., representing Cl–Cl and Cl–O (unresolved).

In applying the usual visual method we calculated curves for sixteen plane symmetric models. Three parameters are involved, the Cl–C–Cl angle, the C–O distance, and the C–Cl distance, the qualitative appearance of the curves being dependent on the angle and the ratio of the distances. The angle was varied from 110 to 125° and the ratio C–Cl/C–O from 1.23 to 1.60. Most of the models are eliminated at once by qualitative comparisons. The model corresponding to the valence bond structure  $\mathrm{Cl_2C{=}O}$, with C–Cl = 1.76, C–O = 1.28, and the angle Cl–C–Cl = 110°, leads to curve A of Fig. 2, which is unsatisfactory in regard to the fourth and sixth rings, each of which is observed to be close to the preceding one. Curve B of Fig. 2 represents the model (with C–O = 1.12, C–Cl = 1.80, angle Cl–C–Cl = 110°) reported by Dornte[6] as the result of the study of electron diffraction photographs showing only four rings; it is seen that this curve is unsatisfactory, showing no maximum corresponding to our observed fourth ring.

It was found that models with the Cl–C–Cl angle equal to about 117° and the ratio of distances C–O/C–Cl equal to about 1.28/1.66 lead to curves in reasonably good qualitative agreement with experiment, all other models tried being unsatisfactory. Thus in Fig. 3 the curve for α = 117° (C) is reasonably satisfactory, the fourth and sixth rings being represented by humps rather than maxima; the curve for α = 115° (D) shows no sign of the sixth ring, and that for 120° (B) is unsatisfactory with regard to the clearly ob-

						Average	1.687 Å.	1.681 Å.	1.683 Å.

Model C: Cl–C–Cl = 117° C–O = 1.28 Å. C–Cl = 1.64 Å
D: Cl–C–Cl = 117° 1.28 1.68
F: Cl–C–Cl = 118° 1.28 1.66

Results: C–Cl = 1.68 ± 0.02 Å.
Cl–Cl = 2.87 ± .02 Å.
C–O = 1.28 ± .03 Å.
Angle Cl–C–Cl = 117 ± 2°
Angle Cl–C–O = 121°30′ ± 1°

[a] This ring or shelf does not appear as a maximum on the simplified theoretical curves for these models.

served fourth ring. The effect of changing the C–O/C–Cl ratio is shown by the lower four curves in Fig. 2. Of these the curves for 117°, 1.28/1.64, and 117°, 1.28/1.68, agree very well with the photographs in qualitative appearance except that the sixth ring is not quite so well represented as expected, appearing only as a shelf on the curves.

In the figures of this paper showing intensity curves the observed values of *s* for apparent maxima and minima are indicated by small vertical lines. In comparing these with the calculated intensity curves it must be borne in mind that a linear change of scale may be made; the indicated *s* values are shown in each case for the *x*/*s* ratio determined by quantitative comparison for the model finally accepted.

The results of the quantitative comparison of the photographs with the curves for three models are given in Table I. Bearing in mind the qualitative comparison, we write as the probable configuration of the phosgene molecule $\alpha = 117 \pm 2°$ (angle Cl–C–Cl), C–Cl = 1.68 ± 0.02 Å., C–O = 1.28 ± 0.03 Å., and Cl–Cl = 2.87 ± 0.02 Å.

The values of Dornte (whose work has been referred to above), $\alpha = 110 \pm 5°$, C–Cl = 1.80 ± 0.04 Å., and C–O = 1.12 ± 0.02 Å., we believe to be less accurate than the errors assigned to them indicate.

Vinyl Chloride.—Photographs of vinyl chloride (from the Carbide and Carbon Chemical Company) were taken with a film distance of 12.19 cm. (the same distance being used also for the other chloroethylenes). The photographs show about six rings: the first very weak, the second strong, the third and fourth medium, the fifth weak and the sixth very weak. In addition there is apparent a very weak ring or shelf be-

Results: C–C = 1.38 Å. (assumed)
C_1–Cl = 1.69 ± 0.02 Å.
C_2–Cl = 2.70 ± .02 Å.
α = 122 ± 2°

tween the third and fourth rings, somewhat closer to the third than to the fourth. Measured values of *s* obtained by two observers from nine photographs are given in the fourth column of Table II and estimated intensities for the rings in the third column.

The six-term radial distribution curve is given in Fig. 1. It shows two pronounced peaks, with maxima at 1.695 and 2.69 Å., with indication of a subsidiary peak at 1.35 or 1.40 Å. The first two we associate with the two carbon–chlorine interactions, and the last with carbon–carbon. If we accept the value 1.38 Å. for C–C, the distances 1.695 and 2.69 Å. lead to the value 121° for the C–C–Cl bond angle α.

In applying the usual visual method, we have found that the photographs do not provide enough information to permit us to evaluate simultaneously the two distances C–Cl and C–C and the angle Cl–C–C with much accuracy. Accordingly we have assumed the C–C distance to have the double bond value 1.38 Å., and have calculated curves for C–Cl = 1.68, C–C = 1.38 and the angle α = 130, 125, 122.5 and 120°. These are shown as B, C, D and E in Fig. 4. Of these B and C are qualitatively unsatisfactory in that the hump corresponding to the faint ring or shelf observed between the third and fourth rings is too large, and E in that the hump is too small. Comparison of measured values of *s* with the *x* values for model D (Table II) leads to the carbon–chlorine distances 1.683 and 2.70 Å.

Combining the results of the two methods, we write C–C = 1.38 Å. (assumed), C_1–Cl = 1.69 ± 0.02 Å., C_2–Cl = 2.70 ± 0.02 Å., α = 122 ± 2°. No earlier electron diffraction work on this substance has been reported.

It is of interest to consider also the model with C_1–Cl = 1.76, C–C = 1.38 and α = 125°, corresponding to the non-resonating structure  $\mathrm{ClHC{=}CH_2}$. This gives the curve A of Fig. 4, which is in satisfactory qualitative agreement with the photographs. The quantitative comparison leads to the distances C–Cl = 1.68 Å. and C–C = 1.32 Å., however, and since the latter distance should not fall below 1.38 Å., the experimentally established value for the carbon–carbon double bond, the non-resonating structure is unsatisfactory.

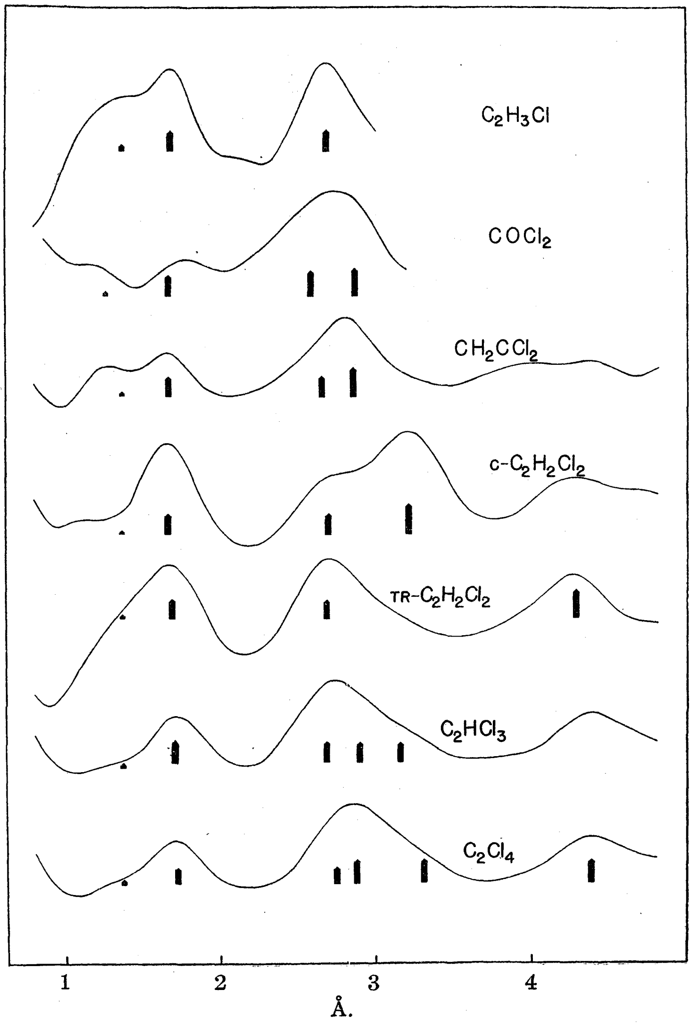

Fig. 1.—Radial distribution curves for phosgene and the six chloroethylenes.

1,1-Dichloroethylene.—The substance was prepared by treating 1,1,2-trichloroethane (made by passing vinyl chloride into antimony pentachloride) with alcoholic potassium hydroxide, and was purified by fractional distillation.

The photographs, showing seven well-defined rings, have the following qualitative appearance: the first medium, the second strong, the third medium, the fourth weak and the fifth medium weak, these five being about equally spaced; then a wide minimum and a weak ring, and another wide minimum and weak ring. Measured values of *s* (averages for four photographs) and estimates of *I* are given in Table III.

Table III

1,1-Dichloroethylene

Max.	Min.	I	s	x for Model C	D	C–Cl for Model C	D

6		10	15.55	15.75	15.56	1.722	1.701
					Average C–Cl =	1.695 Å.	1.680 Å.
					Cl–Cl =	2.858 Å.	2.870 Å.

Model C: C–Cl/C–C = 1.70/1.38, β = 115°
Model D: C–Cl/C–C = 1.70/1.38, β = 117.5°
Results: C–C = 1.38 Å. (assumed)
C–Cl = 1.69 ± 0.02 Å.
Cl–Cl = 2.86 ± 0.02 Å.
Angle Cl–C–Cl = 116 ± 2°
Angle Cl–C–C = 122 ± 1°

The six-term radial distribution function (Fig. 1) shows a C–Cl peak with maximum at 1.67 Å., and a large peak due to both Cl–Cl and C–Cl interactions. The lack of resolution of this peak (maximum at 2.81 Å.) makes its interpretation difficult.

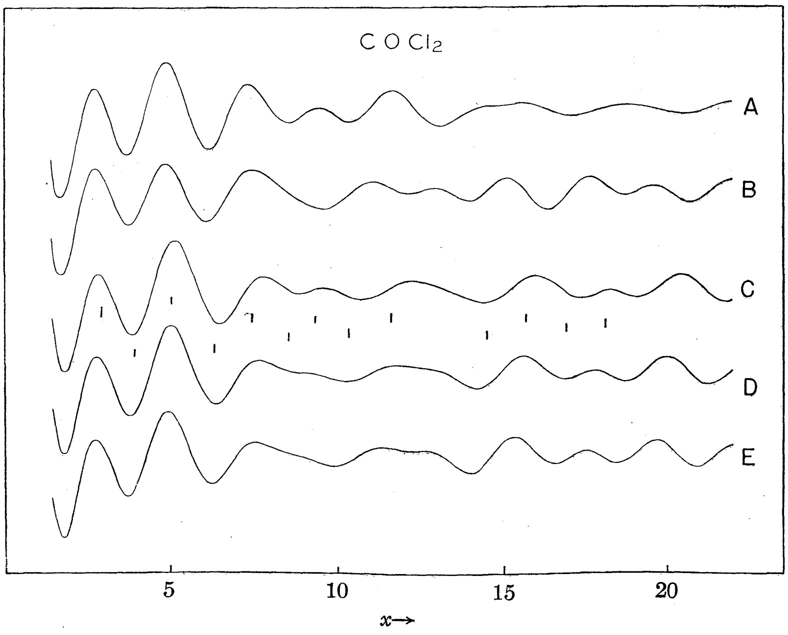

Fig. 2.—Simplified intensity curves for phosgene. A, α (angle Cl–C–Cl) = 110°, r (ratio C–O/C–Cl) = 1.28/1.76; B, α = 110°, r = 1.12/1.80; C, α = 117°, r = 1.28/1.64; D, α = 117°, r = 1.28/1.68; E, α = 117°, r = 1.28/1.72.

We have calculated intensity curves for twelve models, with the Cl–C–Cl angle β varied between 110 and 125° and the C–Cl/C–C ratio varied between 1.76/1.38 and 1.64/1.38. It was not found possible to evaluate the C–Cl/C–C ratio as well as the angle β with much accuracy; accordingly we have assumed the C–C distance to have the double bond value 1.38 Å. Of the models tried, only those with β equal to about 115° agree qualitatively with the photographs. For example, the model with C–Cl = 1.76 Å., C–C = 1.38 Å., and β = 110°, corresponding to the valence-bond structure , is unsatisfactory in that the fourth maximum on the curve (curve A of Fig. 5) is higher than the third, whereas the fourth ring is observed to be much weaker than the third and fifth. Quantitative comparison with this and other curves shows the C–Cl distance to be about 1.70 Å. Curves B, C, D and E of Fig. 5 are calculated for C–Cl = 1.70, C–C = 1.38, and the angle β = 112.5, 115, 117.5 and 120°, respectively. Of these curve B is unsatisfactory in that it shows an additional maximum between those corresponding to the fifth and sixth rings, and curve E in that the fourth maximum is too high. Curves C and D are satisfactory, and we accordingly accept for the Cl–C–Cl angle the value $\beta = 116 \pm 2°$.

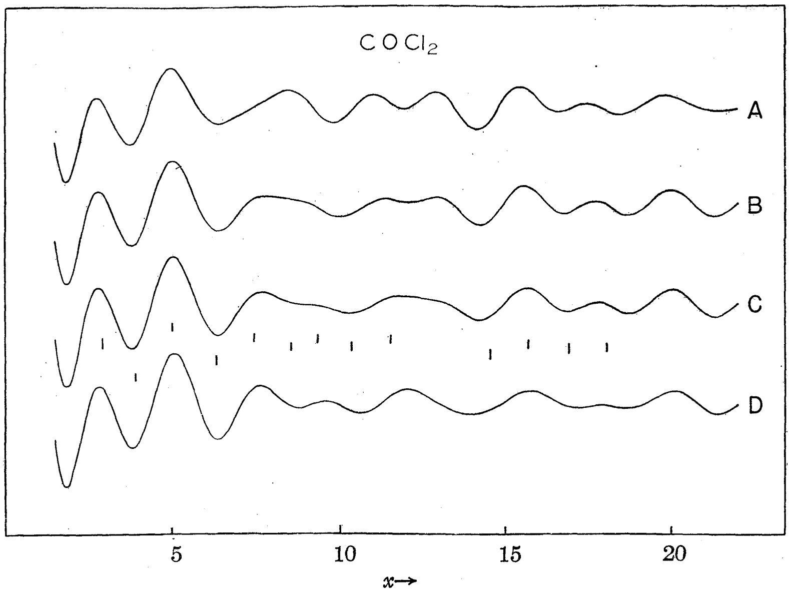

Fig. 3.—Intensity curves for phosgene, with $r = 1.28/1.68$, and $\alpha = 125$, 120, 117 and 115° for A, B, C and D, respectively.

The quantitative comparison of the measured values of s and the x values for models C and D, given in Table III, leads to the interatomic distances C–Cl = 1.69 ± 0.02 Å., Cl–Cl = 2.86 ± 0.02 A., with the angle Cl–C–Cl = 116 ± 2° and C–C = 1.38 Å. (assumed).

The only previous investigation of this substance, that of Wierl[7] by electron diffraction, gave the value Cl–Cl = 2.9 ± 0.3 Å.

cis-Dichloroethylene.—The sample of *cis*-dichloroethylene used was obtained from a mixture of the *cis* and *trans* compounds by fractional distillation with a 90-cm. column.

The photographs show five well-defined rings, with the following qualitative appearance: the first ring medium; the second strong, with an outer shelf; the third medium; the fourth weak, and somewhat closer to the third than to the fifth; the fifth medium weak. Observed values of s (averages for nine photographs) and estimated intensities are given in Table IV.

The six-term radial distribution function is shown in Fig. 1. It shows two well-defined peaks, with maxima at 1.67 Å. (C–Cl) and 3.21 Å. (Cl–Cl). These correspond to the value 123°15′ for the angle Cl–C–C, and to another C–Cl distance of 2.69 Å., some indication of which is visible in the curve.

On calculation of theoretical intensity curves it was found that all models giving rough qualitative agreement with the photographs lead to a Cl–Cl distance close to 3.23 Å. In order to determine the C–Cl distance, curves were calculated for a series of models with C–C = 1.38 and Cl–Cl = 3.23, the value of C–Cl being varied. It was found that the shelf beyond the second ring changes rapidly in this series; only for C–Cl = 1.68 (curve C in Fig. 6) does the shelf correspond to its appearance on the photograph (about one-fourth as pronounced as the second ring). Decrease by 3% wipes it out entirely. We accordingly accept model C. The comparison of observed s values and x values for this model, given in Table IV, leads to C–Cl = 1.671 Å., Cl–Cl = 3.223 Å.

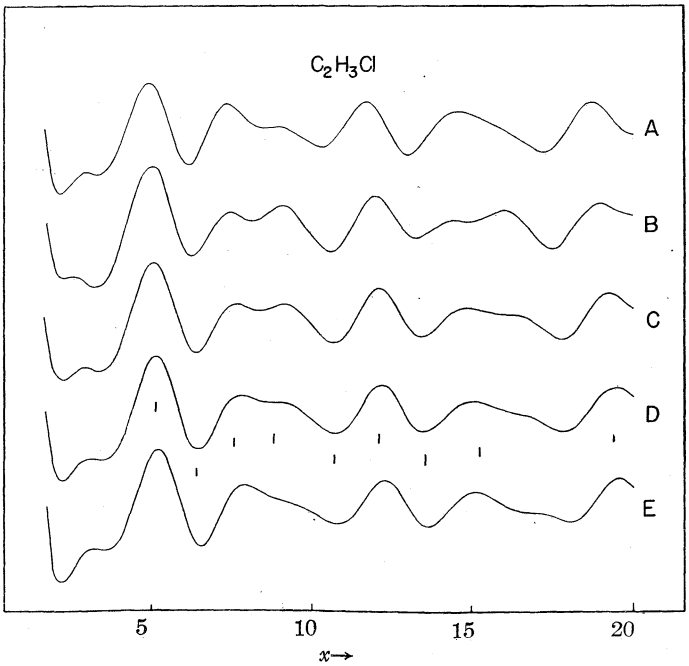

Fig. 4.—Intensity curves for five models of vinyl chloride.

Curve A, calculated for the non-resonating

4		3	10.10	9.62	10.01	1.677	1.665
	5		11.16	10.54	10.98	1.664	1.653
5		10	12.17	11.63	12.15	1.682	1.677
					Average	1.674 Å.	1.671 Å.

Model A: C–C = 1.38, C–Cl = 1.76, β = 125°
Model C: C–C = 1.38, C–Cl = 1.68, β = 123.7°
Results: C–C = 1.38 Å. (assumed)
C–Cl = 1.67 ± 0.03 Å.
Cl–Cl = 3.22 ± 0.02 Å.
Angle Cl–C–C = 123.5 ± 1°

model with the Cl–C–C angle β = 125°, C–C = 1.38, and C–Cl = 1.76, is in satisfactory qualitative agreement with the photographs, quantitative comparison, however, giving C–Cl = 1.674 Å. and Cl–Cl = 3.233 Å. (Table IV), the only essential difference from the results for model C being in the C–C distance, for which the low value 1.30 Å. is obtained. Curve D, calculated for β = 130°, C–Cl = 1.72, and C–C = 1.38, shows the extreme qualitative disagreement caused by a relatively small change in model.

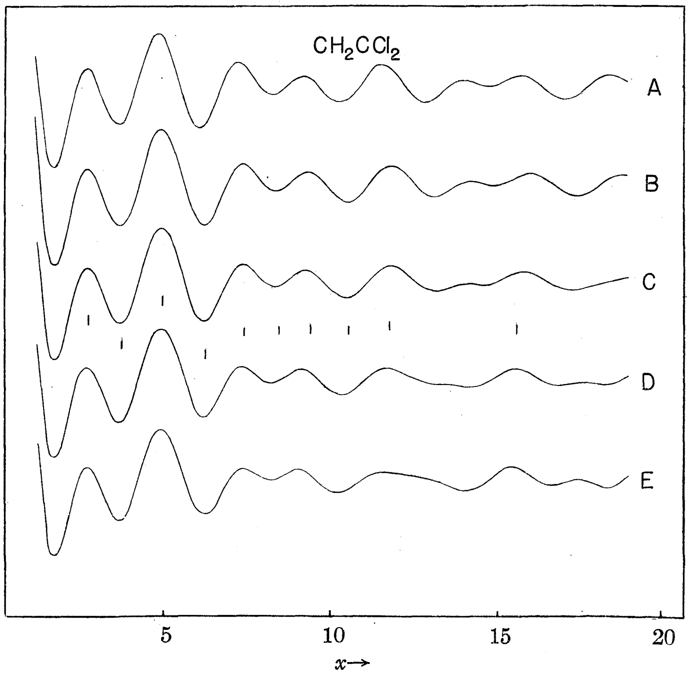

Fig. 5.—Intensity curves for 1,1-dichloroethylene.

Combining the results of the two methods, we accept for the structural constants the values C–C = 1.38 Å. (assumed), C–Cl = 1.67 ± 0.03 Å., Cl–Cl = 3.22 ± 0.02 Å., β (angle Cl–C–C) = 123.5 ± 1°. Previous investigations have given the less accurate values Cl–Cl = 3.30 ± 0.1 Å. (Wierl,[7] electron diffraction) and Cl–Cl = 3.6 Å. (Debye,[8] x-ray diffraction).

trans-Dichloroethylene.—The sample of *trans*-dichloroethylene was separated from a mixture with the *cis* compound by fractional distillation.

The photographs show seven measurable rings, with apparent intensities as given in Table V (the second ring showing an outer shelf). Values of *s* (averages for ten photographs) are also given in the table for the features which could be measured with accuracy.

The eight-term radial distribution function, given in Fig. 1, shows three well-defined peaks, with maxima at 1.675, 2.70 and 4.27 Å. These we correlate with the two C–Cl interactions and the Cl–Cl interaction, the three interactions being of about equal importance. The distances correspond to the values C–C = 1.38 Å., β (angle Cl–C–C) = 123°.

In applying the usual visual method we observed that the quantitative comparison with the photographs of all the models tried gave values close to 4.27 Å. for the Cl–Cl distance. We then

4		1	9.18	9.17	9.18	1.698	1.720
5		1	10.59	10.63	10.62	1.706	1.724
6		5	12.11	12.10	12.11	1.699	1.720
7		2	14.97	15.05	15.02	1.709	1.725
					Average C–Cl	1.697 Å.	1.719 Å.
					Cl–Cl	4.272 Å.	4.277 Å.

Results:

C–C = 1.38 Å. (assumed)

C–Cl = 1.69 ± 0.02 Å.

Cl–Cl = 4.27 ± 0.02 Å.

Angle Cl–C–C = 122.5 ± 1°

calculated curves for models with Cl–Cl = 4.28, C–C = 1.38, and C–Cl = 1.68, 1.70, 1.72 and 1.76 (curves B, C, D and E, respectively, of Fig. 7). All of these agree qualitatively with the photographs except in so far as the weak fourth and fifth rings are concerned; the approximate equality of these rings is best represented by curve D. The results of the quantitative comparison for C and D are given in Table V; it is seen that the value of the Cl–Cl distance is essentially independent of the model.

Averaging the results of the two methods, with about equal weights, we assign to the structural parameters the values C–C = 1.38 Å. (assumed), C–Cl = 1.69 ± 0.02 Å., Cl–Cl = 4.27 ± 0.02 Å., β (angle Cl–C–C) = 122.5 ± 1°. Previous studies gave the values Cl–Cl = 4.33 ± 0.1 Å. (Wierl,[7] electron diffraction) and Cl–Cl = 4.1 Å. (Debye,[8] x-ray diffraction). In addition a note has been published by de Laszlo[9] in which the C–Cl distance in this molecule is given as 1.74 Å.

Trichloroethylene.—The photographs of trichloroethylene (Eastman) show six rings, with intensities weak, strong, medium, weak, medium weak, weak. Characteristic features are that there is some indication of a small shelf between the second and third rings (closer to the second than to the third) and that the weak fourth ring is closer to the third than to the fifth. The measured values of *s* (average for three photographs, two observers) are given in Table VI.

The five-term radial distribution function (Fig. 1) shows three peaks, with maxima at 1.73, 2.85 and 4.37 Å., the first corresponding to the small C–Cl distances, the second to the larger C–Cl distances and to two Cl–Cl distances, and the third to the *trans* Cl–Cl distance. The lack of resolution of the second peak makes it of little value.

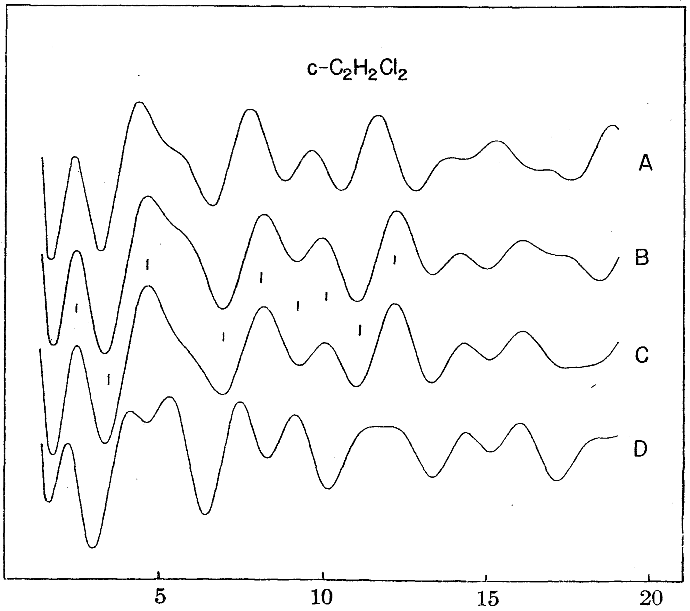

Fig. 6.—Intensity curves for *cis*-dichloroethylene.

In discussing the possible molecular models we have restricted ourselves mainly to those in which

---

(9) H. de Laszlo, *Nature*, **135**, 474 (1935).

the three Cl–C–C angles are equal. Curve A (Fig. 8) is calculated for C–C = 1.38, C–Cl = 1.76 and the angles Cl–C–C = 125° for the CCl_2 group and 123° for the CHCl group. This curve agrees with the photographs qualitatively, and leads on quantitative comparison to the value 1.69 Å. for C–Cl (and hence 1.32 Å. for C–C).

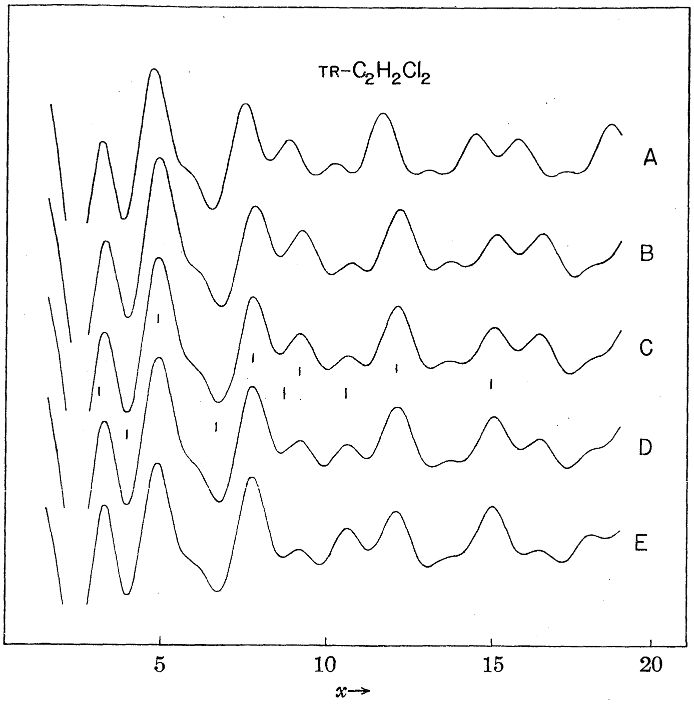

Fig. 7.—Intensity curves for *trans*-dichloroethylene.

Other models lead to about the same C–Cl value. Curves B, C, D and E of Fig. 8 are calculated for C–C = 1.38, C–Cl = 1.70 and the angles Cl–C–C = 125, 122.5, 121.5 and 120°, respectively. Of these curves C alone is in satisfactory qualitative agreement with the photographs. Quantitative comparison (Table VI) leads to the values C–Cl = 1.69 Å., Cl–Cl = 2.85, 3.19 and 4.27 Å. Giving somewhat more weight to these than to the radial distribution values, we accept as representing the configuration of the molecule the values C–C = 1.38 Å. (assumed), C–Cl = 1.71 ± 0.03 Å., Cl–Cl = 2.72 ± 0.04 Å. (in the CCl_2 group), and Cl–Cl = 3.23 ± 0.05 Å. and 4.33 ± 0.05 Å. (between CCl_2 and CHCl), with the angles Cl–C–C = 123 ± 2°.

Table VI

Trichloroethylene

				Average	1.690 Å.

Results: C–C = 1.38 Å. (assumed)
C–Cl = 1.71 ± 0.03 Å.
Cl–Cl = 2.72 ± 0.04 Å.
3.23 ± 0.05 Å.
4.33 ± 0.05 Å.
Angles Cl–C–C = 123 ± 2°

Trichloroethylene previously has been studied by this method by Dornte,[10] who reported the values C–C = 1.32 ± 0.08 Å., C–Cl = 1.82 ± 0.08 Å., Cl–Cl = 3.41 ± 0.08 Å., and Cl–Cl = 4.52 ± 0.08 Å., in approximate agreement with our values.

Tetrachloroethylene.—The rather weak photographs of tetrachloroethylene (Eastman) obtained at room temperature show six rings, the first medium, the second strong, the third medium, the fourth weak, the fifth medium weak and the sixth weak. Averaged values of *s* (for four photographs) and estimated intensities are given in Table VII.

The six-term radial distribution function (Fig. 9) shows three peaks, with maxima at 1.72, 2.86 and 4.37 Å., the first representing a C–Cl distance, the third the *trans* Cl–Cl distance, and the large second peak representing three distances.

Curves A, B, C and D of Fig. 9 are calculated

[10] R. W. Dornte, *J. Chem. Phys.*, **1**, 566 (1933).

for models with C–C = 1.38, C–Cl = 1.74 and the angles Cl–C–C = 125°, 123°45′, 122°30′ and 121°15′, respectively. It is seen that the curves change very rapidly with change in angle. The appearance of the photograph is closely reproduced by curve B, and not so well by C or A; the latter is unsatisfactory only in that the fourth peak is not sufficiently displaced toward the third. We accordingly accept for the Cl–C–C angle the value 123°45′ ± 1°.

TABLE VIII

THIOPHOSGENE

Max.	Min.	*I*	*s*	*x* for model B	C–Cl
1		10	2.84	2.67	(1.598 Å.)
	2		3.75	3.67	(1.664)
2		25	5.00	4.84	(1.646)
	3		6.08	6.04	1.689
3		12	7.16	7.13	1.693
	4		8.10	8.06	1.692
4		12	9.17	9.09	1.685
	5		10.25	10.29	1.707
5		6	11.40	11.49	1.713
	6		12.43	12.51	1.711
6		3	13.41	13.48	1.709
	7		14.51	14.56	1.706
7		3	15.56	15.75	1.721
	8		16.78	16.88	1.710
8		1	17.79	17.90	1.711
	9		18.90	18.87	1.697
9		1	19.90	19.97	1.706
				Average	1.704 Å.

Results: C–S = 1.63 Å. (assumed)
Angle Cl–C–Cl = 116 ± 2° (assumed)
C–Cl = 1.70 ± 0.02 Å.
Cl–Cl = 2.88 ± 0.04 Å.
Cl–S = 2.90 ± 0.04 Å.

The quantitative comparison leads to C–Cl = 1.732 Å. and Cl–Cl (*trans*) = 4.38 Å., in essential agreement with the results of the radial distribution treatment. We accordingly accept for the structural parameters of the molecule the values C–C = 1.38 Å. (assumed), C–Cl = 1.73 ± 0.02 Å., Cl–Cl = 2.87 ± 0.03 Å. (in the same CCl_2 group), and Cl–Cl = 3.30 ± 0.03 Å. and 4.28 ± 0.03 Å. (between CCl_2 groups), with the angle Cl–C–C = 123°45′ ± 1°.

A previous electron diffraction investigation by Dornte[10] gave the values C–C = 1.32 ± 0.08 Å., C–Cl = 1.82 ± 0.08 Å., and Cl–Cl = 3.41 ± 0.08 Å. and 4.52 ± 0.08 Å., in approximate agreement with our results. De Laszlo has also reported the value C–Cl = 1.74 Å. in a preliminary note.[9]

Thiophosgene.—The thiophosgene used was prepared by the chlorination of carbon disulfide and subsequent reduction, and purified by fractional distillation.[11]

The photographs show nine rings, for which measured *s* values and estimated intensities are given in Table VIII (averages for four photo-

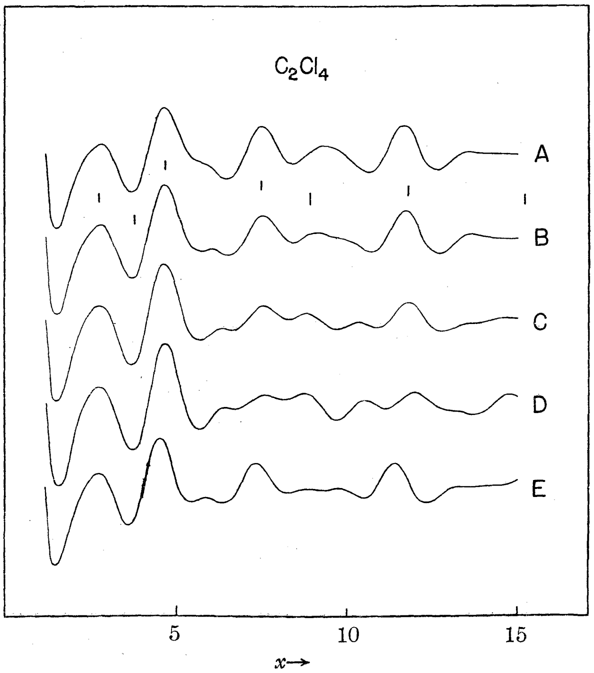

Fig. 9.—Intensity curves for tetrachloroethylene.

---

[11] "Organic Syntheses," John Wiley and Sons, Inc., New York City Coll., Vol. I, p. 493.

graphs[12]). The nine-term radial distribution curve (Fig. 10) shows two well-defined peaks, the first, with maximum at 1.59 Å., corresponding to the C–S and C–Cl distances, and the second, with maximum at 2.87 Å., to the Cl–Cl and Cl–S distances. The sharpness of the second peak (which closely resembles the Cl–Cl peak for carbon tetrachloride) indicates strongly that the Cl–Cl and Cl–S distances are nearly equal. The position of the first maximum is unreliable, being strongly dependent on the estimated intensity values.

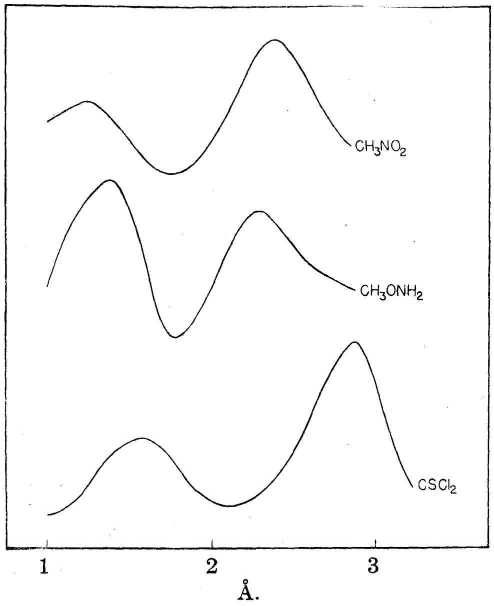

Fig. 10.—Radial distribution curves for nitromethane, α-methylhydroxylamine and thiophosgene.

On calculating simplified intensity curves for eight models it was found that all of the parameters determining the structure of the molecule could not be evaluated. The curves out to the tenth ring are affected very little by small changes in the Cl–Cl/Cl–S ratio, no perceptible differences existing between those calculated for C–S = 1.63, C–Cl = 1.70, and the angle Cl–C–Cl = 114, 116, 118 and 120°, respectively, the Cl–Cl/Cl–S ratio changing from 0.97 to 1.02. All of these curves agree satisfactorily with the photographs in qualitative appearance; the 116° curve is shown as A in Fig. 11. The curves are also not very sensitive to small changes in the position of the light carbon atom; however, the curve for C–Cl = 1.76, C–S = 1.44 and the angle Cl–C–Cl = 110° (B of Fig. 11) is qualitatively unsatisfactory in regard to the fourth ring, which is observed to be as strong as the third.

We have assumed for the C–S distance the double bond value 1.63 Å., as given by the table of covalent radii (and verified by the value 1.64 Å. reported for crystals of thiourea),[13] and for the angle Cl–C–Cl the value 116 ± 2°, as in phosgene and 1,1-dichloroethylene. The observed size of the Cl–Cl–S triangle then requires that C–Cl be close to 1.70 Å. The quantitative comparison with curve A leads to C–Cl = 1.704 Å.; taking some cognizance of the 2.87 Å. peak on the radial distribution curve, we accept for the structural parameters the values C–S = 1.63 Å. (assumed), angle Cl–C–Cl = 116 ± 2° (assumed), C–Cl = 1.70 ± 0.02 Å., Cl–Cl = 2.88 ± 0.04 Å., and Cl–S = 2.90 ± 0.04 Å.

α-Methylhydroxylamine.—The photographs of α-methylhydroxylamine (Eastman) show three well-defined rings, with *s* values (average for four films) and estimated intensities given in Table IX. The three-term radial distribution function (Fig. 10) shows peaks with maxima at 1.39 and 2.31 Å. The first we interpret as showing the C–O and O–N distances, unresolved, the table of covalent radii giving for them the values 1.43 and 1.36 Å., respectively. The C–N distance 2.31 Å. then leads to the value 112° for the C–O–N angle.

Intensity curves were calculated for the following values of the angle: 114, 110 and 106°. In these the ratio of the O–N and C–O distances was taken as 1.36/1.43. The curves for the first two are shown in Fig. 12 and the *x* values in Table IX. Model A (110° angle) is superior to Model B (114° angle) as indicated by the poor agreement between the *x* and *s* values for the second maxi-

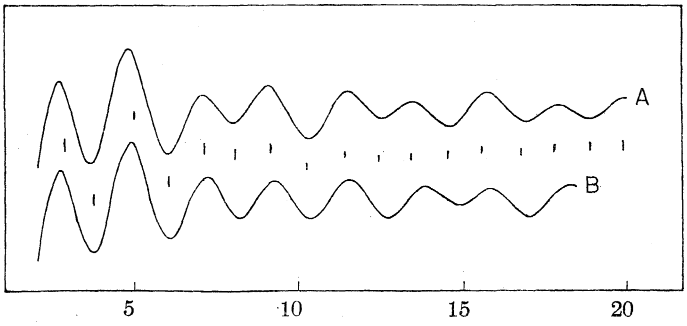

Fig. 11.—Intensity curves for thiophosgene.

---

[12] Some measurements made on five rings of very weak photographs, disagreeing with those in the table by about 2%, were discarded.

TABLE IX

α-METHYLHYDROXYLAMINE

				Model A		Model B	
Max.	Min.	*I*	*s*	*x*	N–O	*x*	N–O
1		5	6.00	6.10	1.383 Å.	6.04	1.369 Å.
	2		7.95	7.93	1.357	7.88	1.349
2		2	9.49	9.93	1.418	10.20	(1.461)
	3		12.13	12.20	1.367	12.17	1.362
3		1	13.94	14.30	1.393	14.18	1.381
				Average	1.384 Å.		1.365 Å.

Results: N–O = 1.37 ± 0.02 Å.
C–O = 1.44 ± 0.02 Å.
C–N = 2.31 ± 0.03 Å.
Angle C–O–N = 111 ± 3°

mum in Model B. The 106° model was rejected because it leads to widely fluctuating values for the size of the molecule as calculated from the various maxima and minima. The quantitative comparison for Model A leads to N–O = 1.38 Å., C–O = 1.45 Å. and C–N = 2.31 Å.

Combining the results of the two methods we obtain the values N–O = 1.37 ± 0.02 Å., C–O = 1.44 ± 0.02 Å., angle C–O–N = 111 ± 3°, C–N = 2.31 ± 0.03 Å.

Nitromethane.—The photographs of nitromethane (Eastman) show four well-defined rings followed by a very wide minimum and two more very faint maxima. The *s* values averaged from six photographs and the estimated intensities are given in Table X. The six-term radial distribution function (Fig. 10) shows two peaks with maxima at 1.19 and 2.18 Å., the first corresponding to the N–O distance with the N–C distance unresolved and the second to the O–O and C–O distances.

TABLE X

NITROMETHANE

Max.	Min.	*I*	*s*	*x*	$N–O_{125°}$
1		10	3.65	3.27	(1.09 Å.)
	2		5.04	4.43	(1.07)
2		30	6.50	6.26	1.175
	3		7.96	8.00	1.226
3		12	9.29	9.28	1.219
	4		10.54	10.17	1.178
4		12	11.75	11.83	1.228
	5		13.47	13.61	1.231
5		3	17.77	17.21	1.181
	6		19.37	19.50	1.227
6		2	21.02		
				Average	1.208 Å.

Results: N–O = 1.21 ± 0.02 Å.
C–N = 1.46 ± 0.02 Å.
Angle O–N–O = 127 ± 3°

The photographs do not permit the evaluation of all the structural parameters. We expect, however, that the C–N distance has the single bond value 1.47 Å. and the N–O distances approximately the double bond value 1.22 Å. The three curves in Fig. 13 correspond to models having the relative dimensions determined by the above distances and the three values of the O–N–O angle, 120, 125 and 130°, respectively. The qualitative features of the photographs fix the angle at about 127°. Thus, the prominence of the third maximum relative to the fourth and the position and character of the fifth minimum as observed on the photograph eliminate the 120° model. In the 130° curve the position of the seventh maximum is a little better than in the one for 125° but the hump following the fifth minimum is too pronounced. The quantitative comparison (Table X) leads to the values C–N = 1.46 ± 0.02 Å. and N–O = 1.21 ± 0.02 Å., with the angle O–N–O = 127 ± 3°.

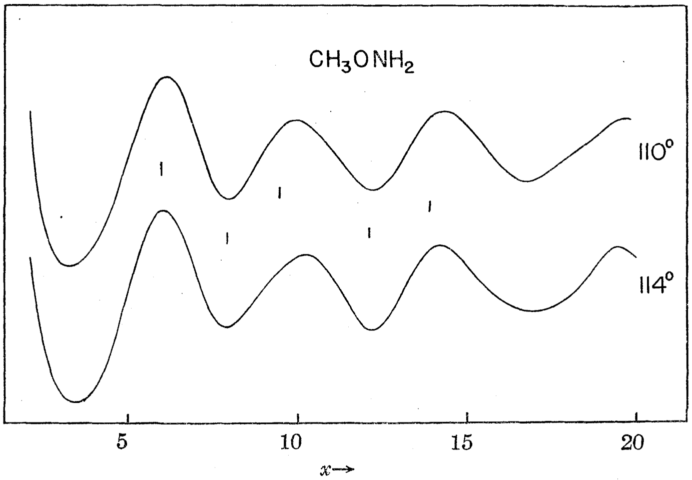

Fig. 12.—Intensity curves for α-methylhydroxylamine.

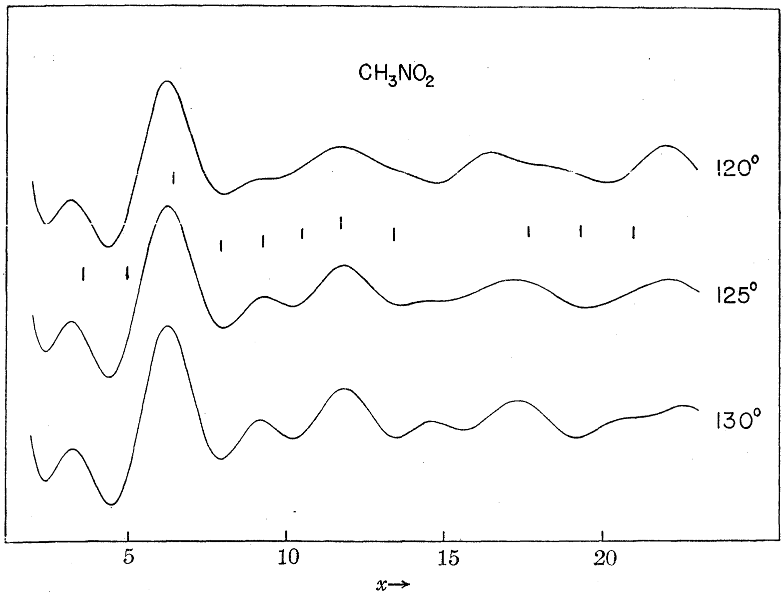

Fig. 13.—Intensity curves for nitromethane.

Discussion of Results

In phosgene, thiophosgene and the six chloroethylenes the carbon–chlorine distances vary between 1.67 and 1.73 Å., being between 5 and 2% less than the normal single bond value 1.76 Å. This decrease is due to the partial double bond character caused by resonance resulting from the conjugation of an unshared pair of electrons on the chlorine atom with the adjacent double bond. The values found for the angle Cl–C–X are somewhat smaller than the tetrahedral value 125°16′ for the angle between a single bond and a double bond, as a result of the same phenomenon. A detailed discussion of these effects is given in the following paper.

For the other interatomic distances the values found are in good agreement with the table of covalent radii. In phosgene the carbon–oxygen distance has the double bond value 1.28 ± 0.02 Å. (1.28 Å. from the table), and for thiophosgene the double bond value 1.63 Å. for the carbon–sulfur distance leads to a satisfactory interpretation of the photographs. The N–O distance 1.21 ± 0.02 Å. for the nitro group in nitromethane is close to the double bond value 1.22 Å. The distances N–O = 1.37 ± 0.02 Å. and C–O = 1.44 ± 0.02 Å. in α-methylhydroxylamine and C–N = 1.46 ± 0.02 Å. in nitromethane agree well with the single bond values 1.36, 1.43 and 1.47 Å., respectively, given by the table of radii.

Summary

The arrangements of atoms in molecules of phosgene, the six chloroethylenes, thiophosgene, α-methylhydroxylamine and nitromethane have been determined by the use of electron diffraction photographs, interpreted both by the radial distribution method and the usual visual method, with the following results. (Values given without attached probable errors were assumed to be correct in the investigation.)

Phosgene: C–Cl = 1.68 ± 0.02 Å.; C–O = 1.28 ± 0.02 Å.; angle Cl–C–O = 121.5 ± 1°.

	C—C	C—Cl	Angle Cl—C—C
Vinyl chloride	1.38 Å.	1.69 ± 0.02 Å.	122 ± 2°
1,1-Dichloroethylene	1.38	1.69 ± 0.02	122 ± 1°
cis-Dichloroethylene	1.38	1.67 ± 0.03	123.5 ± 1°
trans-Dichloroethylene	1.38	1.69 ± 0.02	122.5 ± 1°
Trichloroethylene	1.38	1.71 ± 0.03	123 ± 2°
Tetrachloroethylene	1.38	1.73 ± 0.02	123.75 ± 1°

Thiophosgene: C–Cl = 1.70 ± 0.02 Å.; C–S = 1.63 Å.; angle Cl–C–S = 122°.
α-Methylhydroxylamine: N–O = 1.37 ± 0.02 Å.; O—C = 1.44 ± 0.02 Å.; angle C–O–N = 111 ± 3°.
Nitromethane: N–O = 1.21 ± 0.02 Å.; C–N = 1.46 ± 0.02 Å.; angle O–N–O = 127 ± 3°.

The discussion and interpretation of these results are given in the following paper.

The Dependence of Interatomic Distance on Single Bond–Double Bond Resonance[1]

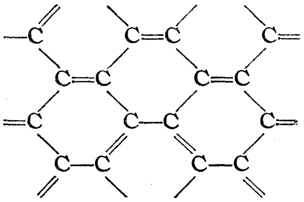
BY LINUS PAULING, L. O. BROCKWAY AND J. Y. BEACH

Introduction

Three years ago it was pointed out[2] that observed values of interatomic distances provide useful information regarding the electronic structures of molecules, and especially regarding resonance between two or more valence bond structures. On the basis of the available information it was concluded that resonance between two or more structures leads to interatomic distances nearly as small as the smallest of those for the individual structures.[3] For example, in benzene each carbon–carbon bond resonates about equally between a single bond and a double bond (as given by the two Kekulé structures); the observed carbon–carbon distance, 1.39 Å., is much closer to the carbon–carbon double bond distance, 1.38 Å., than to the single bond distance, 1.54 Å.

In benzene the two Kekulé structures contribute equally. In general, however, the coefficients of the functions corresponding to different structures in the approximate wave function of a molecule may have arbitrary values, and a bond between two atoms may have any intermediate character between the extremes of a pure single bond and a pure double bond. For a series of bonds covering the range between a pure single bond and a pure double bond we expect the interatomic distance to change continuously from the single bond value to the double bond value. In this paper we present evidence regarding the nature of the function expressing the dependence of interatomic distance on single bond–double bond resonance, and then make use of the function in order to obtain information regarding the electronic structures of resonating molecules for which experimental interatomic distance values are available. The effect of resonance on bond angles is also discussed.

The Interatomic Distance Function for Single Bond–Double Bond Resonance.—The carbon–carbon single bond distance is 1.54 Å. (diamond, aliphatic compounds). For the carbon–carbon double bond distance we shall use the value 1.38 Å. given by the table of covalent radii;[4] some support for this is given by Badger's value[5] 1.37 Å. for ethylene. These give the two extreme points of the interatomic distance function for single bond–double bond resonance. The midway point, for fifty per cent. double bond character, is provided by the value 1.39 Å. for benzene;[6] the electronic structure of benzene is represented in the main by resonance between the two Kekulé structures (the contribution of excited structures being small[7]), and this makes each bond resonate equally between a double and a single bond. Another point on the curve is provided by graphite (C–C = 1.42 Å.), in which each bond has one-third double bond character, corresponding to resonance among many structures such as



Through these four points we draw a smooth curve, as shown in Fig. 1, which we accept as representing the dependence of carbon–carbon interatomic distance on double-bond character for single bond–double bond resonance. We believe that by a suitable translation and a change of vertical scale (to give the correct end-points) the same function can be used for bonds between other atoms, and probably also for double bond–triple bond resonance. This use of the curve will be illustrated below.

---

[1] Part of the material in this paper was presented at the meeting of the A. A. A. S. in Berkeley, June, 1934.

[2] L. Pauling, *Proc. Nat. Acad. Sci.*, **18**, 293 (1932).

[3] The following argument, suggested by Professor P. M. Morse, shows that this conclusion is reasonable. Of two potential functions corresponding to two structures, the one with the smaller value of the equilibrium internuclear distance will have the greater curvature in the neighborhood of the minimum [see for example, R. M. Badger, *J. Chem. Phys.*, **2**, 128 (1934)]. Hence the more stable of the two resultant potential functions corresponding to resonance between these two structures will tend to have its minimum in the position determined by the original curve of greater curvature, that is, near the smaller value of the internuclear distance.

[5] R. M. Badger, *Phys. Rev.*, **45**, 648 (1934).

[6] L. Pauling and L. O. Brockway, *J. Chem. Phys.*, **2**, 867 (1934).

[7] A possibly more accurate value for the double bond character of the bonds in benzene (0.46) is obtained by considering all five canonical structures with weights equal to the squares of their coefficients in the wave function. There is some uncertainty as to the significance of this, however, because of the non-orthogonality of the wave functions for the canonical structures, and for chemical purposes it is sufficiently accurate to follow the simple procedure adopted above.

It is seen that a small amount of double bond character causes a large decrease in interatomic distance below the single bond value, whereas only a small change from the double bond value is caused by even as much as fifty per cent. single bond character.[8] In consequence, the interatomic distance criterion for resonance provides quantitative information only through about one-half of the bond character region.

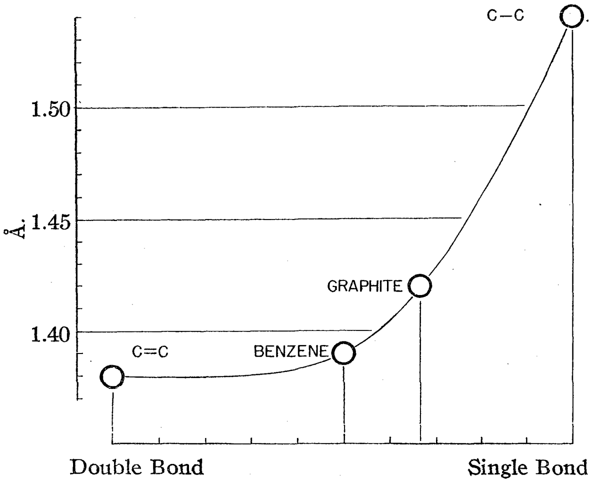

Fig. 1.—The empirical function expressing the dependence of carbon–carbon interatomic distance on bond character for single bond–double bond resonance.

The applicability of the curve to bonds other than carbon–carbon can be tested with the data for carbon–oxygen and nitrogen–oxygen bonds given in Table I, the predicted distances being obtained from the table of covalent radii for pure single and double bonds, and from the curve (with end-points determined by the table) for bonds of intermediate type. The carbonate and nitrate ions resemble graphite in that the double bond resonates among three positions, whereas in the carboxyl and nitro groups, as in benzene, the double bond resonates between two positions. It is seen that there is approximate agreement between predicted and observed values.

TABLE I

COMPARISON OF PREDICTED AND OBSERVED INTERATOMIC DISTANCES

Amount of double bond character	Predicted distance	Observed distance
Carbon–Oxygen Bonds		
0	1.43 Å.	1.42 Å. in $(CH_3)_2O$[a]
		1.44 in CH_3ONH_2[a]
$^1/_3$	1.32	1.31 (1.26) in $(CO_3)^{=b}$
$^1/_2$	1.29	1.29 in $(HCOOH)_2$[c]
1	1.28	
Nitrogen–Oxygen Bonds		
0	1.36 Å.	1.37 Å. in CH_3ONH_2[a]
$^1/_3$	1.26	1.22 (1.26) in $(NO_3)^{-b}$
$^1/_2$	1.23	1.21 in CH_3NO_2[a]
1	1.22	

[a] Preceding papers. [b] Preliminary values obtained through redetermination of parameters in crystals (calcite and sodium nitrate) by Mr. Norman Elliot. The values in parentheses are based on older parameter determinations. [c] L. Pauling and L. O. Brockway, *Proc. Nat. Acad. Sci.*, **20**, 336 (1934). The value 1.25 Å. reported in crystals of oxalic acids and oxalates is probably less reliable.

The Use of the Interatomic Distance Function in Discussing the Electronic Structure of Molecules.—The observed interatomic distances listed in Table II are interpreted with the aid of the curve of Fig. 1 to lead to the assignment of fractional double bond character as given in the last column. It is seen that a single bond between conjugated double bonds (cyclopentadiene) or conjugated benzene rings (biphenyl) *p*-diphenylbenzene, has about 15 or 20% double bond character,[9] whereas a single bond between conjugated

TABLE II

INTERATOMIC DISTANCES AND BOND TYPE

Molecule	Bond	Observed distance	Amount of double bond character
Cyclopentadiene	C—C	1.46 Å.[a]	0.20
p-Diphenylbenzene	C—C	1.48[b]	.14
Biphenyl	C—C	1.48[c]	.14

---

[8] Verification of the shape of the curve has been obtained with the collaboration of Dr. J. Sherman by the theoretical treatment of a somewhat similar problem (the effect of *s-p* hybridization of bond orbitals on interatomic distance).

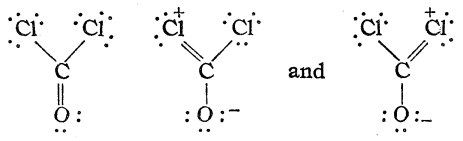
[9] The comparison of these results with the simple theory of conjugated systems [Pauling and Sherman, *J. Chem. Phys.*, **1**, 679 (1933)] is not straightforward because of non-orthogonality of the canonical structures. If we assume that the double bond character is given by the square of the coefficient of the structure — = — in the normalized wave function for a system of two conjugated double bonds the simple theory leads to the value 0.25, in approximate agreement with the experimental result.

triple bonds (cyanogen, diacetylene) has about 30% double bond character. In cyanuric triazide the reported distance for the bond linking an azide group to the cyanuric ring corresponds to about 25% double bond character.

In urea and thiourea the ionic structures such as  are of sufficient importance to give each C–N bond about 28% double bond character. In case these structures were equivalent to the structure  giving complete resonance, each bond would have one-third double bond character, as in the carbonate, nitrate, and guanidonium ions. The experimental result shows that resonance is nearly complete.

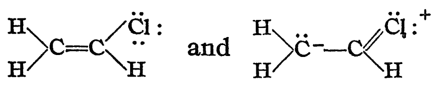
In carbon suboxide, for which the structure $:\ddot{O}=C=C=C=\ddot{O}:$ is most important, structures such as $^{-}:\underset{\cdot\cdot}{\ddot{O}}-C\equiv C-C\equiv O:^{+}$ contribute about 20% triple bond character to each bond.

Resonance of a Carbon–Chlorine Bond and an Adjacent Double Bond.—We expect the phosgene molecule to resonate among the structures



of which the first is the most important, the second and third making only small contributions to the normal state of the molecule. The value 1.68 ± 0.02 Å. for the C–Cl distance, reported in the preceding paper,(10) corresponds to 17% double bond character for the carbon–chlorine bonds, calculated with the curve of Fig. 1, with end points C–Cl = 1.76 Å. and C=Cl = 1.58 Å. The value C–Cl = 1.70 ± 0.02 Å. in thiophosgene leads to 12% double bond character, indicating that the ionic structures make a smaller contribution for this molecule than for phosgene.

We might predict that of the six chloroethylenes the C–Cl distance would be smallest in vinyl chloride, which resonates between the structures



and largest in tetrachloroethylene, in which the effect of the double bond is divided among four carbon–chlorine bonds. This is found experimentally (Table III), except that the distance reported for *cis*-dichloroethylene is about 0.02 Å. smaller and that for vinyl chloride somewhat larger than expected. The amounts of double bond character shown in the table are reasonable—about 15% for mono- and dichloroethylenes, 10% for trichloroethylene, and 6% for tetrachloroethylene.

TABLE III

INTERATOMIC DISTANCES AND BOND TYPE FOR CARBON–CHLORINE BONDS

Molecule	C–Cl distance	Double bond character
Phosgene	1.68 ± 0.02 Å.	0.17
Thiophosgene	1.70 ± .02	.12
CH_2CHCl	1.69 ± .02	.14
CH_2CCl_2	1.69 ± .02	.14
cis-CHClCHCl	1.67 ± .03	.20
trans-CHClCHCl	1.69 ± .02	.14
$CHClCCl_2$	1.71 ± .03	.10
C_2Cl_4	1.73 ± .02	.06

The effect of this partial double bond character on the chemical properties of chlorine atoms conjugated to double bonds is well known; it corresponds in the main to a diminution in reactivity. The correlation with bond angles is discussed in a later section of this paper.

Inasmuch as the conjugation properties of a double bond and a benzene ring are closely similar,(11) we expect for the halogen substituted benzenes interatomic distances similar to those for the halogen ethylenes. De Laszlo(12) has reported the values C–Cl = 1.69 Å., C–Br = 1.88 Å., and C–I = 2.05 Å., corresponding to 14, 6, and 10% double bond character, respectively.(13)

The Dependence of Bond Angles on Single Bond–Double Bond Resonance.—In a molecule such as phosgene or 1,1-dichloroethylene the value 125°16′ for the angle Cl–C–O (β) is predicted by the theory of the tetrahedral carbon atom in case that the C–Cl bonds have no double bond character. If the double bond resonates equally among all three positions, giving the Cl–C bond one-third double bond character, we expect from symmetry

(11) L. Pauling and J. Sherman, *J. Chem. Phys.*, **1**, 679 (1933).

(12) H. de Laszlo, *Proc. Roy. Soc.* (London), **A146**, 690 (1934).

(13) The interatomic distance values given are stated to hold for hexahalogen, *sym*-trihalogen and *p*-dihalogen benzenes. We expect the distances in these different compounds to be different, however; and investigation of these and other halogen compounds is under way in this Laboratory. De Laszlo has also reported values of C–Br and C–I distances in ethylenic and acetylenic compounds in a letter to *Nature*, **135**, 474 (1935).

the value 120° for β. Between these limits the dependence of β on the amount of double bond character of the C–Cl bonds may be postulated to be given by a curve similar in shape to the interatomic distance curve of Fig. 1. If this is so, there would be a linear relation connecting the angle β and the C–Cl distance, between the points β = 125°16′, C–Cl = 1.76 Å. and β = 120°, C–Cl = 1.64 Å. (as given by the curve for one-third double bond character). From a similar discussion, the other chloroethylenes (except vinyl chloride) would be expected to fall roughly on the same line.

A test of this relation is shown in Fig. 2, the seven points being those determined experimentally for phosgene and the six chloroethylenes.

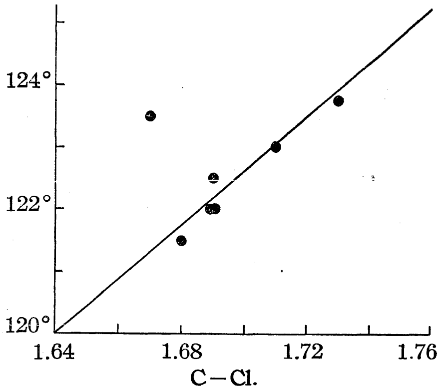

Fig. 2.—The relation between bond angle and carbon-chlorine distance for phosgene and the chloroethylenes.

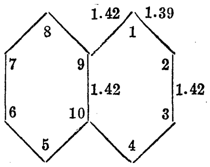
It is seen that, with one exception, the points lie very close to the straight line drawn according to our assumptions, the displacements being much less than the probable errors of the experimental values. The exceptional point is that for *cis*-dichloroethylene, the discrepancy confirms the suggestion made in the preceding section that our results for this substance are slightly in error.[14] It is surprising that vinyl chloride obeys the same relation, as there is no apparent reason for the angle to be much different from 125°16′.

Interatomic Distances in Polynuclear Aromatic Hydrocarbons.—As a further example of the use of the interatomic distance function we shall discuss the polynuclear aromatic hydrocarbons.

For naphthalene there are three unexcited structures   and 
Giving these equal weights, we obtain the result that the 1–2 bonds have $^2/_3$ double bond character and all others $^1/_3$. These correspond to the values 1.39 Å. for the 1–2 interatomic distances (including 3–4, 5–6 and 7–8), and 1.42 Å. for all others, giving the configuration



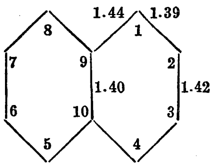
A possibly more reliable prediction can be made on the basis of Sherman's wave function for naphthalene,[15] by considering all 42 canonical structures. The fractional double bond character of a bond can be considered to be given approximately (neglecting non-orthogonality of the canonical wave functions) by the expression

$$\sum_i' a_i^2 \Big/ \sum_i a_i^2$$

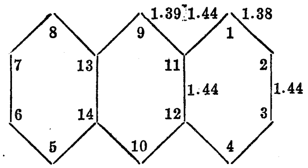
in which a_i represents the coefficient for the *i*th structure; the unprimed sum includes all structures of the set of 42, and the primed sum those for which the bond in question is a double bond. The results of this calculation are the following:[16]

Bond	1–2	2–3	9–1	9–10
Double bond character	0.60	0.33	0.26	0.43
C–C distance	1.39 Å.	1.42 Å.	1.44 Å.	1.40 Å.

corresponding to the configuration



The four unexcited structures for anthracene, given equal weights, lead to $^3/_4$ double bond character for the 1–2 bonds, $^1/_2$ for the 9–11 bonds and $^1/_4$ for others, the predicted configuration being



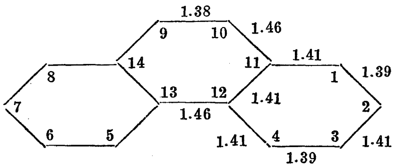
---

[14] The discrepancies are removed by increasing the C–Cl distance by 0.02 Å., to 1.69 Å., and decreasing the angle by 1°, to 122°30′. These changes are within the estimated probable errors of our determination, ±0.03 Å. and ±1°, respectively.

[15] J. Sherman, *J. Chem. Phys.*, **2**, 488 (1934).

[16] It may be pointed out that the changes from the simple calculation given above result mainly from the fact that the coefficient for the structure  is larger than that for the other unexcited structures.

For phenanthrene the five unexcited structures lead to $^4/_5$ double bond character for the 9–10 bonds, $^3/_5$ for the 1–2 bonds, $^2/_5$ for the 1–11, 11–12 and 4–12 bonds, and $^1/_5$ for the 10–11 and 12–13 bonds, and the predicted configuration is



Similar prediction can be made for larger molecules. It must be pointed out that the contributions of excited structures become important for bonds with small double bond character, inasmuch as in conjugated systems excited structures alone may lead to as much as 20% double bond character; it is probable that the maximum carbon–carbon bond distance in aromatic hydrocarbons is about 1.46 Å., the minimum being the double bond distance 1.38 Å.

The predicted average interatomic distance is 1.41 Å. in naphthalene, anthracene and phenanthrene, this value being somewhat larger than the benzene value (1.39 Å.). With increase in size of the hydrocarbon the carbon–carbon distances should all approach the graphite value 1.42 Å.

The only experimental values of sufficient accuracy to permit a test of the predicted values are those obtained by Robertson in his careful and thorough x-ray investigations of the structure of crystals of naphthalene[17] and anthracene.[18] In each of these molecules Robertson reports the value 1.41 Å. for the average carbon–carbon bond distance, in complete agreement with the predicted value.[19] He does not discuss individual variations from the average; however, measurements made on his reproduced electron distribution projections (Fig. 2 for naphthalene, Fig. 2 for anthracene) show differences of 2 or 3% in the predicted directions.[20]

Summary

Using experimental values for carbon–carbon bonds, a function is plotted showing the dependence of interatomic distance on bond character for single bond–double bond resonance. This function is tested with data for other bonds, and used in the discussion of the electronic structure of molecules containing conjugated double or triple bonds or aromatic nuclei and of molecules containing carbon–chlorine bonds adjacent to double bonds. The dependence of bond angles on single bond–double bond resonance is discussed. Values of carbon–carbon bond distances in polynuclear aromatic hydrocarbons are predicted and compared with the existent experimental data.

[17] J. M. Robertson, *Proc. Roy. Soc.* (London), **A142**, 674 (1933).

[18] J. M. Robertson, *ibid.*, **A140**, 79 (1933).

[19] The data for chrysene [J. Iball, *ibid.*, **A146**, 140 (1934)] are also compatible with this value.

[20] The value 1.41 Å. has also been reported for the carbon–carbon distance in benzene derivatives. We think it probable that this is 0.02 Å. too large.

Vapor Pressures of Certain Glycols

BY O. J. SCHIERHOLTZ AND M. L. STAPLES

In connection with other current research work, the authors have had occasion to determine the vapor pressure curves for the following glycols: ethylene, 1,2-propylene, 1,3-propylene, 1,3-butylene and 2,3-butylene.

A search of the literature for physical constants of these compounds revealed the fact that comparatively little has been published. With the exception of ethylene glycol, no vapor pressure data could be found, and many of the physical constants which are recorded are not at all concordant. The densities and refractive indices have been determined for all the above glycols, and are tabulated below.

All the compounds used in the determinations were purified by distillation, suitable neutralizing agents being used to obtain completely neutral, colorless, odorless products. The purities were such that the refractive index of successive fractions did not differ by more than 0.00038, and in most cases the difference was considerably less.

The starting materials for those glycols not synthesized in this laboratory were as follows: ethylene glycol and 1,2-propylene glycol, Carbide and Carbon Chemicals Corporation; 1,3-propylene glycol, Eastman Kodak Company.

Preparation of 2,3-Butylene Glycol.—This compound was prepared by the hydrolysis of 2,3-dibromobutylene, $CH_3CHBrCHBrCH_3$ (Eastman, b. p. 155–157°) in the presence of lead oxide. A similar method has been used by Dr. Harold Hibbert of McGill University, in the synthesis of a number of polyhydroxy compounds.

The following procedure was used: 30 cc. of 2,3-dibromobutylene and 300 g. of finely ground lead oxide were agitated in 2 liters of water for twenty-four hours at room temperature, with a high-speed stirrer. The precipitated lead bromide and excess lead oxide were then filtered off and the liquid concentrated under vacuum to about 500 cc. By chilling with ice, as much as possible of the lead bromide still in solution was precipitated and removed by filtration. To remove any lead remaining in solution, the filtrate was treated with hydrogen sulfide. After filtering, the liquid was further concentrated in the presence of a small amount of silver carbonate, to eliminate the last traces of halogen. The yield of glycol obtained was 50% of the theoretical. Prompt reaction of any liberated hydrogen bromide with the lead oxide seems to be essential to obtain good yields. Efficient agitation is an aid to this end. With the same point in view, the use of freshly precipitated lead hydroxide has been advocated.

Preparation of 1,3-Butylene Glycol.—The synthesis of this compound was carried out by using a slight modification of the method described by Halpern.[1] The procedure consisted of the reduction of acetaldol with aluminum amalgam. In the present case, 200 cc. of acetaldol (Eastman, Tech.) was distilled at 20 mm. pressure into 2 liters of water, in order to avoid the usual strongly exothermic reaction which is noted in the receiver when aldol is distilled alone. The solution was further diluted to 3.5 liters and cooled to 18°. Aluminum amalgam was then added at intervals to avoid rise in temperature, and the mixture allowed to stand for three days in order to complete the reaction. A yield of 75% of the theoretical amount of glycol was finally obtained.

Method of Determining Vapor Pressures.—The vapor pressures were studied by boiling the liquid under different pressures. The apparatus consisted of a Claisen distilling flask with a specially wide side-arm bent down at right angles and attached, by means of an adapter, to a receiver which was packed in ice. A cone-type electrical heater was placed under the distilling flask, and the whole assembly mounted on a shaking machine of the reciprocating type.

With the use of agitation, practically all superheating was overcome, as indicated by the difference between the liquid and vapor temperatures which was found to be of the order of about 0.5°. The vapor temperatures were determined by a short-range type precision thermometer. With this type of thermometer, the mercury column was surrounded completely by vapor, and stem corrections were avoided. The usual practice of bleeding a fine stream of air into the boiling liquid, in order to overcome bumping, could not be used, for this was shown to produce a considerable effect on the boiling point. Constant pressures were obtained by including a 10-liter chamber in the apparatus train, and using a pressure regulator.[10] The temperatures were determined to an accuracy of 0.1°, while the pressures could be read to 0.3 mm. All pressures are recorded in mm. of mercury at 0°.

Experimental Results

In the case of each compound, determinations were made at from twelve to fifteen different pressures over the range 10–760 mm. By plotting the logarithm of the vapor pressure against the reciprocal of the absolute temperature, an almost straight line relationship was obtained. The constants for the conventional equation

$$\log_{10} p_{\text{mm.}} = -(A/T) + B$$

were evaluated, and are recorded in Table II. Vapor pressures calculated by means of this equation fall within the limit of error of the experimental results.

Summary

1. The vapor pressure curves over the range 10–760 mm. have been determined for the following glycols: ethylene, 1,2-propylene, 1,3-propylene, 1,3-butylene and 2,3-butylene. With the exception of ethylene glycol, these data are here reported for the first time.

2. The densities and refractive indices are given for all the above compounds.

3. The methods used for the preparation of 1,3-butylene and 2,3-butylene glycols are also described.

The Mercury–Mercuric Oxide–Saturated Barium Hydroxide and Calcium Hydroxide Electrodes

BY G. J. SAMUELSON AND D. J. BROWN

It was the purpose of this research to study the mercury, mercuric oxide, barium hydroxide electrode with a view to its being used as a reference electrode. A saturated solution of the base was used to avoid troublesome preparation of standard solutions, thus permitting of easier preparation than is possible with the unsaturated type. Brown and Andrews[1] used Ming Chow's[2] electrode, containing sodium hydroxide, as a standard in their work and found its use very satisfactory.

The cell studied was, according to the common convention in designating it, as follows

$$\text{Hg}/(\text{HgO(s)}, \text{Ba(OH)}_2\text{(s)}/m\ \text{KCl}/\text{KCl(s)}, \text{Hg}_2\text{Cl}_2\text{(s)}/\text{Hg}$$

In the spontaneous reaction within the cell, an electron current flows in the external circuit from left to right, the complete reaction being

$$\text{Hg} + \text{Ba(OH)}_2 + \text{Hg}_2\text{Cl}_2 \rightleftharpoons 2\text{Hg} + \text{BaCl}_2 + \text{HgO} + \text{H}_2\text{O}$$

Mercuric Oxide.—Mercuric oxide was prepared by decomposing pure mercuric nitrate. However, electrodes containing this oxide gave potentials not differing sensibly from those obtained with half-cells containing "chemically pure" commercial mercuric oxide.

Barium Hydroxide.—The best available grade of barium hydroxide was recrystallized from distilled water.

Potassium Chloride.—This was prepared by recrystallization of "chemically pure" potassium chloride from distilled water.

Mercurous Chloride.—Calomel was prepared electrolytically by the method of Lipscomb and Hulett.[3]

Agar-Agar.—This was an ordinary commercial form of the substance.

Water.—The water used was twice distilled, once from alkaline permanganate, Pyrex containers and a block-tin condenser being employed.

Electrode Vessels.—Electrode vessels similar to type to those of Lewis, Brighton and Sebastian.[4]

Reference Half-Cell.—A layer of mercury in the chamber was covered with a layer of electrolytically prepared calomel containing crystals of potassium chloride. Over this was poured a saturated solution of potassium chloride to within a few centimeters of the top of the chamber.

Experimental Half-Cells.—A flask containing water and excess barium hydroxide and mercuric oxide was shaken frequently, the contents of the flask being kept near the temperature at which measurements were to be made. This mixture was poured into the electrode chamber in which were a layer of mercury and additional barium hydroxide and mercuric oxide.

Half-Cell Chamber.—A glass jar, 6 cm. in diameter and similar to a hydrometer jar, was nearly filled with a saturated solution the same as that used in the electrode, excess of the solute being added. The jar was fitted with a large rubber stopper. The lower part of the long straight arm of an h-shaped glass tube passed through the large rubber stopper and dipped into the solution within the jar. The bent side-arm of the tube passed through a one-holed rubber stopper which was inserted into the mouth of the electrode vessel, the tube dipping beneath the surface of the solution in the vessel. The arrangement was such that the small stopper and h-tube suspended the electrode vessel in a position parallel to the jar, and on about the same

---

[1] Brown and Andrews, THIS JOURNAL, **42**, 488 (1920).

[2] Ming Chow, *ibid.*, **56**, 388 (1934); **57**, 254 (1935).

[3] Lipscomb and Hulett, *ibid.*, **38**, 22 (1916).

[4] Lewis, Brighton and Sebastian, *ibid.*, **39**, 2245 (1917).

level, so that when the apparatus was immersed in the water-bath, the level of the water just reached the top of the jar and of the electrode vessel. The upper end of the longer straight arm of the h-shaped tube was closed with a short piece of rubber tubing containing a glass bead as a valve. Connection between the solution in the electrode vessel and that in the jar was effected whenever desired by sucking on the rubber tube at the upper end of the h-tube, the glass bead preventing the return of air and so making the solutions continuous.

Several such nests of four to eight electrodes each were made for both experimental and reference electrodes. Thus the electrodes could be checked against each other simply by connecting any pair of them to the potentiometer.

Baths.—Measurements on the electrodes were made at temperatures of 0, 15, 25 and 35 ± 0.02°.

Standard Cell.—A Weston standard cell recently calibrated by the Bureau of Standards.

Potentiometer.—All potential measurements were made with a Leeds and Northrup Type K potentiometer calibrated by the Bureau of Standards and equipped with a Type R reflecting galvanometer.

Salt Bridge.—Several methods of effecting contact between the saturated solutions of barium hydroxide in the one electrode and of potassium chloride in the reference electrode were tried.[5] Finally the gel–salt bridge method was adopted. The bridge used in this work consisted of a gel of 2.5% agar–agar in molar potassium chloride solution.

Several bridges were tried in every set of measurements to establish the reproducibility and constancy of the agar–salt bridge. Table I gives representative data for the cell

$Hg/HgO(s),\ Ba(OH)_2(s)/bridge/KCl(s),\ Hg_2Cl_2(s)/Hg$

at 25° with four changes of the agar–salt bridge, the time elapsed from insertion of the bridge being also indicated in hours and electromotive force in volts. The same combination of half-cells was used with all of these bridges, the different bridges being used successively.

TABLE I

AGAR BRIDGES WITH SAME CELL

Bridge 1 Time	Bridge 1 E. m. f.	Bridge 2 Time	Bridge 2 E. m. f.
0	0.0965	0	0.0972
2½	.0975	5	.0979
15	.0982	21	.0981
23	.0982	95	.0980
64	.0981		
Bridge 3		**Bridge 4**	
0	0.0984	0	0.0982
4	.0985	1	.0984
18	.0985	7	.0985
30	.0985	23	.0984

From these data it appears that the whole cell, which includes the reference and experimental electrodes and the agar–salt bridge, becomes relatively constant within a short time after insertion of the bridge, and for an indefinite period of time.

Before comparison of the experimental half-cell with the reference electrode was made, it was customary to check the latter against the other members of the reference nest (consisting of four saturated calomel electrodes, an occasional exchange of one of these for a freshly prepared one being made). At all times the maximum variation between the various calomel half-cells used was within 0.1 millivolt. These were found also to be very nearly constant and reproducible if made of highly purified materials exactly as directed.

The usual procedure with the experimental electrodes was to compare the several ones with one another, Table II, and to compare only one of these with the reference half-cell.

TABLE II

E. M. F. COMPARISON OF BARIUM HYDROXIDE HALF-CELLS

Cell	Hours 1	18	42	87
2–6	0.00018	0.00019	0.00019	0.00019
3–6	.00007	.00010	.00007	.00007
4–6	.00004	.00004	.00005	.00005
5–6	.00013	.00011	.00011	.00011
3–4	.00005	.00004	.00004	.00004

The first column indicates the half-cell combination read, the electrodes being numbered, the one on the left being negative to the one on the right. The potential differences in volts are given at the indicated time elapsed from the insertion of the nest of electrodes in the bath.

These half-cells, when measured against the reference electrode, gave values, from the beginning of the period of measurement to the end, which were more nearly constant than the bridge itself. From Table II it may be seen that the barium hydroxide half-cells reached almost at once, and maintained for indefinite periods of time, steady relationship with each other. Moreover, the greatest difference between any pair of the freshly prepared half-cells containing purified substances is less than 0.2 millivolt. A summary of data for representative determinations on electrodes of the type mercury-mercuric oxide-saturated barium hydroxide, where the material used were of the highest quality available, is given in Table III.

This electrode is negative to the saturated calomel electrode, according to convention, and since the latter has been established as ±0.2446 volt

TABLE III

CELLS, $Hg/HgO(s)$, $Ba(OH)_2(s)//KCl(s)$, $Hg_2Cl_2/(s)Hg$

T., °C.	Electrodes	Period of meas. days	Max. deviation, v.	Av. e. m. f. as read, v.	Av. e. m. f. *vs.* cal. at 25°	Temp. coefficient volts deg.
0	6	5	0.0004	0.0794	0.0844	−0.00052
15	6	5	.0002	.0902	.0922	− .00062
25	6	16	.0003	.0984	.0984	− .00062
35	5	18	.0002	.1066	.1046	

at 25° in comparison with the normal hydrogen electrode,[6] the former may be seen from Table III to have a value of +0.1562 volt at 25° against the hydrogen electrode. With an increase in temperature, the mercuric oxide–saturated barium hydroxide electrode becomes more negative to the calomel electrode and so less positive to the hydrogen electrode by 0.00060 volt per degree. Hence, the true potential of the electrode against the normal hydrogen electrode is given by the expression

$$E_t = 0.1462 - 0.00060(t - 25°)$$

A number of rapid exchanges from one bath to another were tried on this electrode to establish the effect of a sudden change of temperature on its potential. In all of these, whether the temperature change was positive or negative, the electrode assumed potentials within an hour which varied not more than 0.0003 volt from those of the ones already in the bath.

It has been seen from the data in Table II, which are representative of those obtained for various determinations, that the experimental electrode under investigation attained equilibrium very rapidly and then was almost constant in potential for an indefinite period of time. This was found to be the case whether chemically pure or further purified materials were employed in its preparation. The electrode was very easily prepared. A mixture of the oxide, barium hydroxide and water, shaken for a few minutes to ensure saturation, and then poured over a layer of mercury in the half-cell chamber constituted an electrode the potential of which, within an hour after it was placed in the bath, was not sensibly different from that of another prepared by mechanically shaking the mixture for several hours, or by occasionally agitating it for several days.

The electrode was readily reproducible in potential value when made of the purest materials. However, with the less pure materials the potentials, though constant to within 0.0002 volt for any half-cell were noticeably different for various half-cells from those obtained when the purest materials were used. In all the electrodes of ordinary "chemically pure" barium hydroxide and mercuric oxide, red and yellow, secured from various sources, and once-distilled water that were studied, the potentials were within a maximum variation of ±0.001 volt of those attained by electrodes of repurified materials.

The Mercury, Mercuric Oxide, Saturated Calcium Hydroxide Electrode

Other factors influencing the electromotive forces of the half-cells being constant, the mercury–mercuric oxide electrode containing saturated calcium hydroxide should have a temperature coefficient less negative than that of the one containing saturated barium hydroxide.

The study of the mercury, mercuric oxide, calcium hydroxide electrode was carried out, in general, in the same manner as that of the barium hydroxide electrode. The calcium hydroxide was prepared from pure calcium carbonate. Pure sodium carbonate and calcium chloride were allowed to react and the carbonate was filtered, washed free of chlorides and calcined until no carbonate remained. The resulting oxide was then used in the half-cell. The $Hg/HgO(s)$ $Ca(OH)(s)$ electrode is negative to the saturated calomel electrode. From the table the electromotive force of the mercury–mercuric oxide–saturated calcium electrode at 25° is −0.0523 volt against the saturated calomel at 25°. Accordingly, it should have a value of +0.1923 volt against the normal hydrogen electrode at that temperature. With an increase in temperature the electrode becomes less negative to the saturated calomel electrode at 25° by 0.00010 volt per degree.

CELLS, $Hg//HgO(s)$, $Ca(OH)_2(s)//KCl(s)$, $Hg_2Cl_2/(s)Hg$

T., °C.	Electrodes	Period of meas. days	Max. dev., v.	Av. e. m. f. as read v.	Av. e. m. f. *vs.* cal. at 25°	Temp. coefficient volts/deg.
0	8	2	0.0022	0.0497	0.0547	+0.00010

25	12	7	.0018	.0523	.0523	+ .00010
35	10	7	.0016	.0533	.0513	

In the most extreme cases the agar–salt bridge showed a reproducibility, with the calcium hydroxide electrodes, which was within ±0.0010 volt—not as good as with the barium hydroxide

---

[6] Ewing, THIS JOURNAL, **47**, 301 (1925).

electrodes. However, the mercury, mercuric oxide, calcium hydroxide electrodes compared very favorably in speed of reaching equilibrium and in constancy with those containing barium hydroxide. It may be seen from the table that the maximum deviations between the electrodes read at the various temperatures is considerably greater than with the barium hydroxide half-cells, reaching a maximum of about two millivolts. This was the usual situation with these half-cells. A number of electrodes were made up using ordinary materials, "technical" calcium oxide, ordinary C. P. red and yellow mercuric oxide, etc., and these were found to give potentials usually well within ±0.002 volt of the above value.

Summary

1. The electrode $Hg/HgO(s)$, $Ba(OH)_2(s)$ has been studied from the standpoints of ease of preparation, constancy, reproducibility and effect of temperature change.

2. The potential of the electrode including a liquid junction, compared to the hydrogen electrode at zero is $+0.1462 - 0.00060(t - 25°) \pm 0.0002$ volt.

3. Likewise the potential of the electrode using ordinary materials is $\pm 0.1462 - 0.00060 (t - 25°) \pm 0.001$ volt.

4. The electrode using ordinary materials is very satisfactory for ordinary work.

5. The electrode $Hg/HgO(s)$, $Ca(OH)_2(s)$ has been studied from the standpoint of ease of preparation, constancy, reproducibility and temperature coefficient.

6. The potential of the electrode against the normal hydrogen electrode is $+0.1923 + 0.00010 (t - 25°) \pm 0.0010$ volt.

The Diffusion of Helium through Fused Silica

BY E. O. BRAATEN AND G. F. CLARK

Introduction

It has been established by many observers[1] that the lighter gases can diffuse readily through fused silica. Over a wide range of temperatures and pressures it has been found that the rate of diffusion is proportional to the pressure, and that the diffusion process has a temperature coefficient expressed by an exponential relation (equation 1). Most of the results have been obtained at high temperatures where rates of diffusion are larger and experimental procedure less tedious. Sufficient data are not yet available at the lower temperatures to permit of construction of a theory valid over the whole temperature range where diffusion occurs.

Theory

It has been shown that when the Lennard-Jones[2] theory for diffusion is applied to systems of inert gases in silica the resulting equations do not fit experimental results. It appears, therefore, that the diffusion of monatomic gases through silica does not involve the mechanism of surface adsorption followed by subsequent diffusion. An extension of the theory was made by Alty,[3] who postulated that the gas enters the solid directly from the gas phase after which it penetrates the solid in the manner described by Lennard-Jones. Before the gas can enter the cracks in the solid it must have an energy, W_0, sufficient to overcome a potential barrier composed of two overlapping fields at the entrance to each pore, a comparatively small energy E_0 being also required for the atom to diffuse along the cracks.

The diffusion equation which Alty derived is

$$M = Bp\, e^{-(W_0 + E_0)/kT} \qquad (1)$$

where $E_0 \ll kT$, p is the pressure, M is the mass flowing through the solid per unit time, k is Boltzmann's constant, B is a constant, and T the absolute temperature. Equation (1) is found to be valid for temperatures above 200°, but below this temperature the rates are higher than would be expected according to the equation. Barrer[4]

has shown that one may expect a decrease in energy of activation E_0 below 200°, this decrease being attributed to the formation of a new surface phase removable by treatment of the surface with hydrofluoric acid.

Experimental

Two different types of apparatus were used. The first arrangement, Fig. 1a, consisted of two tubes, the inner one of fused silica and the outer of soft glass, held together by means of a waxed ground joint. The capillary neck between the silica bulb and the ground joint prevented any appreciable error in the measurements if the top part of the system should be at a slightly lower temperature than the bulb itself. (This error would, in any case, be small between the temperatures 25 and 130°.) The second apparatus, Fig. 1b, was designed to work over all ranges of temperature. It consisted of a silica bulb attached to a Pyrex bulb by means of a graded seal which permitted the complete submersion of the bulb in the heating bath.

In the first apparatus bulbs of thicknesses 1.8, 1.0 and 0.5 mm. were used. They were made from the same sample of clear fused silica of good quality.[5] A further silica bulb 20 cm. long, 2 cm. diam. and 0.19 mm. thick was used in the second apparatus. An estimate of the average thickness of a bulb was made both by averaging the measured wall thicknesses, and by calculation from the weight of the bulb. The gas used was helium (99.9% pure).

The systems were heated by an electric furnace and the temperature, measured on a mercury thermometer, was kept constant to about 1° by means of a brass–invar thermostat. The pressure measurements were made on a sensitive McLeod gage and the mass of gas diffusing through the bulbs was calculated from the volumes of the different parts of the system and the densities of the gas in those parts. A small amount of gas diffuses through the Pyrex–silica graded seal connecting the silica bulb to the McLeod gage. This has been calculated to be less than 0.1% of the mass of gas diffusing through the silica bulb. Calculations show that no corrections were necessary for thermomolecular flow. It may be noted that in Fig. 1a the gas diffuses from the inside out while in Fig. 1b the diffusion is from outside the fused silica to the inside.

Results

Tables I to V show the values obtained for the mass of helium in grams diffusing through 1 sq. cm. of silica surface per hour for different pressures, sets of values being given for several temperatures and thicknesses of silica.

These values have been plotted in Fig. 2 and show that the rate of diffusion varies linearly with pressure, in agreement with earlier work. Fig. 3 shows that the rate of diffusion is inversely proportional to the thickness, the graph being linear within the limits of experimental error.

Table VI shows the values for the mass diffusing through 1 sq. cm. at a fixed pressure of 76 cm. for different temperatures. A set of values has been obtained for each thickness of silica. In Fig. 4 it will be observed that when the logarithm of the mass of gas diffusing is plotted against $1/T$ a

straight line is obtained in every case over the whole temperature range, namely, from 0 to 135°. Curves A, B, C and D are all parallel which suggests that the energies of activation are the same for samples of fused silica with the same silicate content. The energy of activation determined from the graph is 4800 cal./gram atom. The data for curve E obtained previously[5] lead to an activation energy of 4120 cal. E was not from the same melt as the other samples; Barrer[4] has already reported that the activation energy depends on the sample.

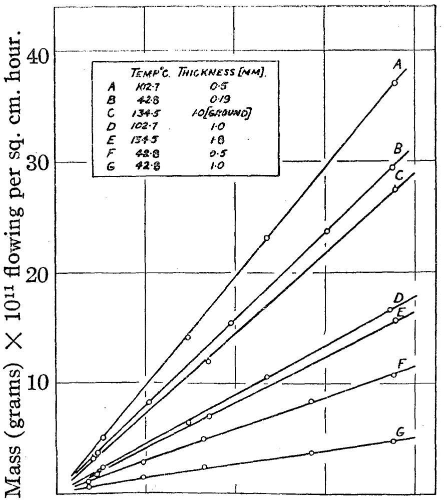

Fig. 2.

After measurements had been completed on the tube of thickness 1.0 mm., its outer surface was ground with fine carborundum and the measurements repeated. The rates were very slightly higher but the same value of $W_0 + E_0$ was obtained. (These results are not in the graph.)

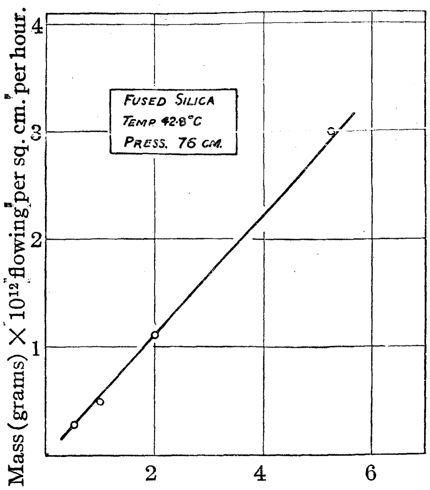

Fig. 3.

Table VII shows the values obtained for the 0.19-mm. bulb at a constant pressure and a wide range of temperatures.

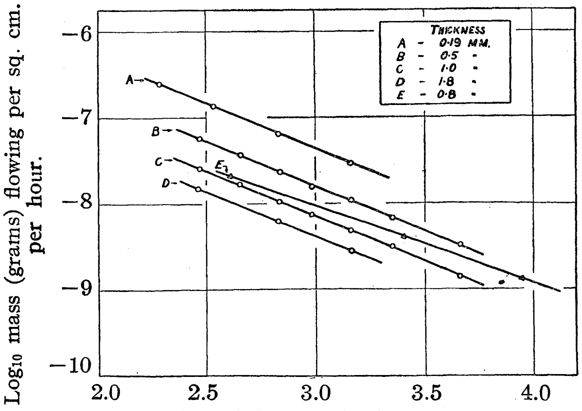

Fig. 4.

Theory[3] predicts that, at least at higher temperatures, the graph showing the relation between the logarithm of the mass and $1/T$ should be a straight line. These results have been plotted in Fig. 5 and certainly a straight line is indicated above 180°. At this temperature there seems to be a change of slope, the points corresponding to lower temperatures apparently fitting a second straight line. The value for the activation energy as calculated for the region between 180 and 562° is 5390 cal., in fair agreement with the results of other observers who worked in this temperature range, while the magnitude of $W_0 + E_0$ for the region 180 to −78° is 4800 cal. per gram atom. It should be noted that no decrease of activation energy is found below −20°. Previous results suggesting a decrease[6] were not corroborated, and it appears that the discrepancy is due to the use of a bulb which could not be kept at sufficiently uniform temperature.

The change in the slope for the graph in Fig. 5 has also been obtained by Van Voorhis[7] and T'sai and Hogness[8] for the passage of helium through fused silica, although no values were obtained by them for temperatures below 180°. It is generally agreed upon that the activation energy remains constant for temperatures from 250 to 1000°.

The heat treatment which the thin bulb received did not appear to affect its properties for diffusion.[4] In obtaining the results for the thin-walled tube the initial temperature 42.9° was gradually increased to 562°. The rates of diffusion were measured again while changing from high to low temperature. The appearance of the tube remained unchanged during the work.

It is a pleasure to thank Professor E. F. Burton for his valuable advice and encouragement throughout this work, and Mr. Chappell for his assistance in constructing the apparatus.

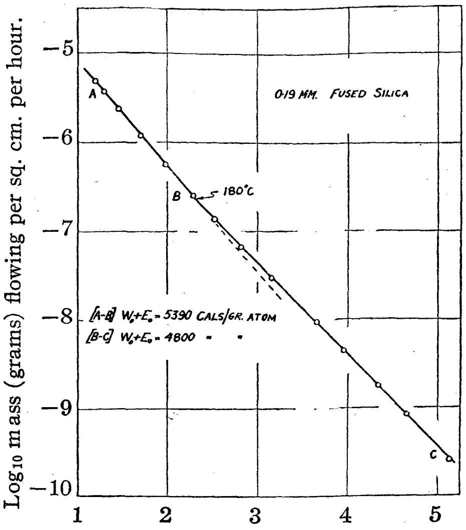

Fig. 5.

Summary

It has been found for the diffusion of helium through fused silica that (a) the gas passing through is proportional to the pressure, (b) increasing the emergent surface many times only slightly increases the rate of diffusion and (c) the rate of diffusion is inversely proportional to the thickness, which is in accord with Fick's law of diffusion.

Two values for the activation energy have been obtained depending on the temperature region for which the experiments were carried out. The magnitude for $W_0 + E_0$ was found to be independent of the thickness of the sample and to depend on the silicate content.

Catalysis by Fusions

BY I. E. ADADUROW AND P. D. DIDENKO

The problem of the part played by solid surfaces in the catalytic process has been repeatedly the object of many discussions. Owing to the work of Schwab and Pietsch,[1] it has been more often repeated recently that not all places on the surface of the catalyzer possess an equal catalytic activity and that the latter is particularly inherent to places possessed of an elevated energy. Nevertheless, in a recent paper, Steacie and Elkin[2] attempted to demonstrate, on the example of the decomposition of methanol by solid and liquid zinc, that these places of elevated energy, active centers, etc., do not play any substantial part in the catalytic process. In their investigation these authors proceed from the conjecture that, if the activity of the catalyzer is essentially based on irregularities and disturbances of the crystalline surface (active places, edges and angles of crystals, etc.), it must fall abruptly if the catalyzer becomes fused. To verify this conjecture, Steacie and Elkin measured the dependence of the speed of decomposition of methyl alcohol vapors by zinc from the change of temperature between 360 and 440°, the size of the surface of the zinc remaining constant (for example, 0.5 sq. cm.). The time of increase of total pressure for a determined percentage rate was used by the authors as a standard of catalytic activity. An uninterrupted increase of activity with the rise of temperature was thus obtained, without interruption of this increase at the fusion point, *i. e.*, at 420°. The authors conclude from this that the surface of zinc is regularly active and that in general the activity of a solid substance cannot be attributed to a limited part of its surface.

We have repeatedly expressed[3] the idea that the nature of the catalytic action of a solid on the molecules of the catalyzed components of the reaction represents an influence of the field of the surface that deforms the molecules, which results in the obtaining of an active reacting condition by the molecules. But, for such a deformation to take place, two basic conditions are required. The first consists in a sufficient deforming power of the field to bring the molecule in an active condition. The second consists merely in the correspondence of the field of pertinent active places (edges, angles of disturbances, etc.) or centers (active points, points of the network) to the fields of the molecules that are being catalyzed, *i. e.*, in their possessing a necessary and definite texture and shape.[4]

From this point of view it is possible to agree with Steacie and Elkin only in the case if the form of the field that is necessary for the activation be maintained not only when approximating the fusing point, 420°, but also in the fused zinc; the power of the field yet retaining a value sufficient for the necessary deformation of the molecule that is being catalyzed.

Recently, in 1933, Randall and Rooksby[5] undertook an x-ray investigation of a whole series of liquid metals near their fusing points with the result that sodium, potassium, rubidium and cesium show in the Röntgenogram maxima at the points where intensive lines of these metals in solid condition are situated. Otherwise, near the fusing point fused metals can keep or obtain the reciprocal disposition of molecules which the metal possesses in the solid phase. It is clear that such a disposition of molecules can be fixed only by the field that is prevalent in the fusion. If not by the value of its tension, the field must in any case correspond in shape and texture to the shape and texture of the field of the crystalline network. Thus it is only necessary that its value be sufficient for the deformation of the molecule called forth by it to be able to produce in it the proper reacting power, and then the cata-

lytic process by the fusion will result, in the same way that it had been secured by the solid body.

As a subject for investigation of catalysis by fusion we selected the catalytic oxidation of ammonia by fusions of metallic tin and silver, which melt at 231.8 and 960°, respectively. The oxidation was carried out in the apparatus schematically shown in Fig. 1. The apparatus consists of a test-tube (a), in whose neck a quartz tube (b), soldered at one end, for the thermocouple used in measuring the temperature of the fusion, is inserted through a stopper consisting of an acid-proof and thermally resistant plaster. Another quartz tube (c) is reserved for the introduction of the air–ammonia mixture that bubbles through the fused liquid metal or passes through the solid metal. To make it possible for the gas to pass through the solid metal (silver), it is first fused and then allowed to cool very slowly without interrupting the flow of the air–ammonia mixture, which thus works a series of thin channels through the hardening metal, through which the gas mixture passes afterward when the metal has completely solidified. Besides these two tubes, a quartz tube (d) for discharging the gases is also soldered into the stopper. The whole apparatus is put into an electric furnace and heated to the temperature required. In the lower part of the test-tube (c) is introduced the catalyzing metal. The analysis of the air–ammonia mixture and of the gases leaving the conversion apparatus was made by the usual method.

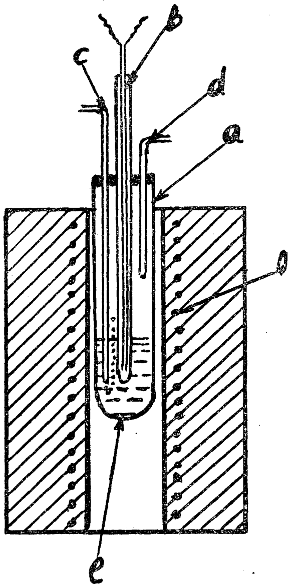

Fig. 1.

The experiments with tin gave the following results at about 300° and at a rate of 0.03 liter per minute of ammonia and 0.30 liter per minute of air: at a ratio of 10% ammonia to 90% air, a white vapor of the nitrite appears. With the increase of the velocity of the gas current to 0.05 liter/minute for ammonia and 0.50 liter/minute for the air, the development of ammonium nitrite increases. Only at about 650° the contacting action begins to be evident and the nitrite vapor disappears. But it is to be noted that simultaneously with the appearance of nitrite a grayish-white deposit forms on the tube discharging the converted gases, which upon investigation proved to be a mixture of tin oxide and tin dioxide ($SnO + SnO_2$). The results of the investigation are shown in Table I.

After opening the contact tube, it was found that nearly all the metal had been transformed to a grayish-white-green mixture of particles of metal that did not have time to oxidize with tin oxide and tin dioxide.

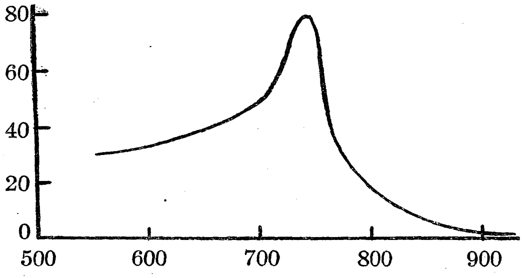

Fig. 2.

Thus the catalyzing effect here is obtained not by metallic tin, but by tin oxide, which has been used already by Wortmann[6] as a contact mass for the oxidation of ammonia. The appearance of tin oxide here is also not unexpected, because tin that is resistant to the oxidizing action of atmospheric oxygen at an ordinary temperature goes over to oxides easily enough at temperatures above the fusing point.

Thus a metal should be selected which would not form compounds with oxygen at elevated temperatures approximating the melting point or

---

(6) Oskar Kausch, "Catalyzers for the Production of Sulfuric and Nitric Acids and Synthetic Ammonia," NTWU, 1934, p. 140; also An., p. 79049.

above and at the same time would catalyze the reaction of oxidation of ammonia nitrogen compounds. Such a substance is silver, which, as has been said by D. I. Mendelejew, "is a metal that does not oxidize in the heat."[7] The silver is not oxidized by atmospheric oxygen at any temperature and its oxide, Ag_2O, decomposes when heated. According to Le Chatelier, the dissociation pressure of oxygen isolated by silver oxide at 300° is a trifle over 10 atm.; silver peroxide decomposes when being dried and heated to 150°, giving off oxygen.

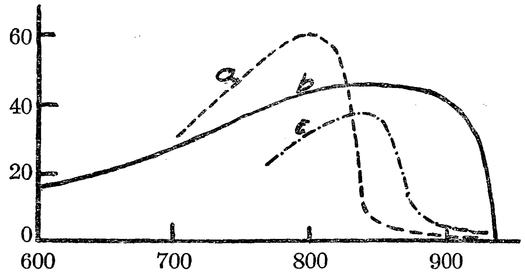

Fig. 3.

Because of the catalytic properties of silver W. Manchot and I. Haas[8] proposed to use it for the oxidation of ammonia, indicating that an active catalyst is obtained by reducing dry silver oxide at a temperature under 100°. The results of the experiments are shown in Table II.

Curve C

These data form in certain temperature limits curves (a, b, c, Fig. 3) that are very like the conversion curves obtained by Andrusow[9] for the influence of velocity.

They differ, however, from the curves of Andrusow in that there is an abrupt fall in the rate of conversion in certain temperature intervals and that near the fusing point of silver the pyrometer always indicates an abrupt rise of temperature to 1000 or more degrees. This points to the fact that the reaction of oxidation of ammonia to nitric oxide is here substituted at the moment when the network dissociates owing to the transformation of the metal from the solid to liquid state by the reaction of dissociation of ammonia to elementary nitrogen and hydrogen, which oxidizes afterward to water. As can be seen from the equations, the latter reaction goes on with a much greater evolution of heat as compared with the first.

$$4NH_3 + 5O_2 = 4NO + 6H_2O + 215 \text{ cal.} \quad (1)$$
$$4NH_3 + 3O_2 = 2N_2 + 6H_2O + 315 \text{ cal.} \quad (2)$$

In the present case, therefore, an oxidation of ammonia by liquid fused metals cannot be brought about. In the case of tin the oxidation begins at the start of the oxidation of the fused metal and of the forming of a slow-fusing mixture of tin oxide and dioxide.

By making tests with such a metal as silver, for which the forming of slow-fusing oxides is excluded owing to the natural properties of this metal, we see that at temperatures below the melting point the reaction of oxidation of ammonia goes on with a greater or lower percentage of conversion, but near the fusing point the rate of oxidation falls abruptly, what is most clearly seen from Curve C, Fig. 3, for the velocity 2340. At the fusing point the reaction changes its character, being substituted by the reaction of decomposition of ammonia to elementary nitrogen with an abrupt change in the rise of the temperature of the reaction.

This fact, independently or not of our admitting a catalytic inhomogeneity of the surface, is con-

---

[7] D. I. Mendelejew, "Principles of Chemistry," Vol. II, 1932, p. 228.

[8] M. Manchot and I. Haas, German Patent 30,065.

[9] Z. Andrusow, *Z. angew. Chem.*, **39**, 321 (1926); **40**, 166 (1926); **59**, 458 (1927); **60**, 536 (1927).

nected with an abrupt change of the field of the elements of the network under the influence of temperature at the fusing point, when the energy of the structure has fallen to naught and when further on the attractive power between the elements of the network is substituted by a repulsing power. It is quite clear that at this moment the potential of the outer field ceases to be adequate not only to the intramolecular field of the molecule that is being catalyzed, but it changes not only by size, but also by form and therefore it is difficult to admit that the catalytic process that takes place when a solid catalyzer is being used takes place also if it is substituted by a liquid fusion.

Therefore the work of Steacie and Elkin appears to us as not irreproachable. The dissociation of methyl alcohol takes place according to Bone and Davies[10] by the equation $CH_3OH = CH_4 + O$, and it is quite certain that the cause of the uninterrupted growth of activity in the limits of 360 to 440°, with no exception for the fusing point of zinc at 420°, does not lie in the equal activity of the surface of zinc; similarly to the case of the attempt with the catalytic oxidation of ammonia by fused tin, where the catalysis takes place not on the surface of the fused metal, but on the oxide, in the case of zinc the catalysis takes place not on the fused metal, but on the surface of the solid zinc oxide that forms in proportion to the atomic oxygen that separates the moment the dissociation of methyl alcohol takes place.

The higher the temperature, the more zinc oxide is being formed, and it is plain why the work of Steacie and Elkin demonstrates here an uninterrupted growth of activity with the increase of temperature. A check test made of the dissociation of methyl alcohol by zinc chips demonstrated quite clearly that at 360–400° the zinc chips are transformed first from the surface and then nearly completely (depending on the quantity of the vapor passed), to zinc oxide when methyl alcohol vapors are passed through them. Furthermore with the growth of the quantity of zinc oxide that is being formed the speed of the reaction of the dissociation of methyl alcohol increases. The fact that finely ground zinc or zinc dust acts as a reducing agent even on water, which is easily decomposed at low temperatures (100°) with simultaneous formation of zinc oxide being known, it was easy to foresee this result. What concerns the catalytic action of the zinc oxide that is being formed on the decomposition of methyl alcohol, it has been investigated by Adkins and Perkins,[11] who indicated that zinc oxide, under 350°, possesses a nearly imperceptible catalytic faculty for the decomposition of methyl alcohol. If the temperature is being raised, an increasing amount of gaseous products is being formed such as methane, hydrogen, ethane, carbon monoxide and carbon dioxide, which are being obtained also when the decomposition over aluminum oxide (Al_2O_3) is carried out.

Messrs. Deutsh and Prozorowsky, scientific laborers of the laboratory, took part in the experimental part of the work.

Conclusions

1. The work of Steacie and Elkin is subject to no objections as to its principal points, if it will be taken into consideration that x-ray investigations demonstrate that the orientation of the elements of the network is retained by some metals near the fusing point and in fused condition, which indicates that the shape of the field is being retained in any case. And if its potential is sufficient for the needed deformation of the catalyzed molecule, there is no impossibility of catalysis by fusions near the fusing point.

2. But in the special case of decomposition by Steacie and Elkin of methyl alcohol in the temperature range of 360 to 440° attention is attracted by the too great interval of temperature and the growing activity with the increase of temperature inherent to the solid as to the fused catalyzer, which does not take place in usual catalytic processes and calls forth a doubt as to the correctness of the explanation of the causes given by the authors.

3. The oxidation of ammonia by fused tin as carried out by us demonstrates the same increasing activity of the liquid catalyst at high temperatures (up to 840°), where nothing similar to an orientation of the crystalline network can last. The growth of the catalytic activity with time as with the increase of temperature clearly indicates the necessity of searching for other causes of its growth.

4. In the course of the investigation it has been quite clearly demonstrated that the oxidation of ammonia begins only from the moment of the formation of tin oxide and dioxide, which

---

[10] W. A. Bone and H. Davies, *J. Chem. Soc.*, **105**, 1691 (1914).

[11] H. Adkins and P. D. Perkins, *J. Phys. Chem.*, **32**, 221 (1929).

has been recommended as a catalyzer for the oxidation of ammonia by Wortmann.

5. The example of silver taken as a catalyzer which does not form oxides and does not change its metallic individuality with rise of temperature demonstrated that near the fusing point the catalytic activity falls abruptly simultaneously with a change of the type of the reaction itself at the fusing point.

6. From this it becomes likely that in the process of decomposition of methyl alcohol by zinc the nature of the increasing activity may be explained by the formation of zinc oxide similarly to what had been demonstrated by us in the case of oxidation of ammonia by fused tin, where the increasing activity is related to the formation of tin oxide.

7. The formation of tin oxide in the process of decomposition of methyl alcohol is very probable, as Bone and Davies have demonstrated that its thermal decomposition takes place according to the equation $CH_3OH \longrightarrow CH_4 + O$, and the reaction takes place according to the equation $2CH_3OH \longrightarrow CH_3OCH_3 + H_2O$.

The formation of zinc oxide in proportion to water vapor is also quite evident, as in the case of $CH_3OCH_3 \longrightarrow C_2H_6 + O$; the formation of zinc oxide is inevitable.

8. The attempted decomposition of methyl alcohol vapor by zinc chips at 360–400° undertaken by us showed experimentally that zinc chips either are partially covered by zinc oxide on their surface or go over to it completely, depending on the quantity of methyl alcohol that has been passed and the time this has taken.

9. From the aforesaid, it is to be acknowledged that the conclusion of Steacie and Elkin that the surface of zinc is equally active and that in general the catalytic activity of a solid matter cannot be ascribed to a limited part of its surface, is baseless and results from an insufficient cleanness of the experiment.

Thermocouples from 2 to 90° Absolute

BY J. ELSTON AHLBERG AND WALTER O. LUNDBERG

In the establishment of temperature scales, several methods are being employed. Due to the necessity of setting up an accurate temperature scale between 20 and 70°K. it was thought desirable to test mathematical equations relating the electromotive force of thermocouples to temperature. The general trend of the data given by Giauque and associates[1,2] for a copper–constantan thermocouple (ice reference junction) between 13 and 90° K. made it apparent that the following simple equation might accurately represent the results

$$E = A + BT^2 + CT^3 + DT^4$$

E is the thermocouple voltage in microvolts, T is the absolute temperature, A, B, C and D are constants. The third law of thermodynamics requires that the term associated with the first power of temperature be equal to zero. Terms associated with powers of temperature higher than the fourth are assumed negligible.

Using the values by Giauque and associates[1,2] at 15, 20, 70 and 90°K. we find $A = 6681.26$, $B = -1.6547 \times 10^{-1}$, $C = 5.5460 \times 10^{-4}$ and $D = -9.878 \times 10^{-7}$. The agreement between the data of Giauque and associates and the above equation is as follows: from 13 to 23°K. better than 0.008°; from 24 to 35°K. better than 0.05°; and from 40 to 90°K. better than 0.03°. The agreements are well within the limits of accuracy claimed by them. The agreements additionally indicate the validity of the temperature scale at the University of California and of the data used in its establishment.[3] Moreover, the average deviation of the temperature coefficients of voltage from the calculated values is but 0.3%.

At the Johns Hopkins University we have experimentally compared a copper–constantan ther-

[2] Giauque, Johnston and Kelley, *ibid.*, **49**, 2367 (1927).

[3] Onnes, Keesom and Associates, *Comm. Phys. Lab. Univ. Leiden*; Simon and Lange, *Z. Physik*, **15**, 312 (1923).

mocouple (ice reference junction) with a helium gas thermometer between 2 and 20°K. and with oxygen vapor pressures between 70 and 90°K. The average deviation of the thermocouple voltages from the above equation is less than 0.01%. The constants determined are $A = 6039.9$, $B = -1.5475 \times 10^{-1}$, $C = 6.2064 \times 10^{-4}$ and $D = -1.5652 \times 10^{-6}$.

Comparisons of the above sets of experimental data, and of other thermocouples, show, to a first approximation, that the differences in voltages of two different thermocouples are proportional to their average voltage. The limitations of this last rule can be estimated from the two sets of constants given in this report.

The data discussed suggest that only four isolated comparisons of voltage and temperature are necessary in the calibration of thermocouples for use below 90°K.[4] However, when time and equipment are available, direct experimental calibration of thermocouples is to be preferred to the method suggested in this report.

---

(4) At temperatures lower than 20°K. the temperature coefficient of voltage of thermocouples becomes very small making it advisable to resort to other methods for temperature measurement.

The Thermal Reaction between Gaseous Iodine Monochloride and Hydrogen

BY W. D. BONNER, W. L. GORE AND DON M. YOST

It has been found that at about 200° and above, gaseous iodine monochloride and hydrogen react slowly to form hydrogen chloride and iodine. That no hydrogen iodide is present in the reacting mixture is shown by the results of some unpublished experiments made by the late Prof. H. P. Ramsperger, who found that iodine monochloride and hydrogen iodide react very rapidly to form iodine and hydrogen chloride. A simple free energy calculation shows that this reaction goes practically to completion. The main reaction between iodine monochloride and hydrogen is then

$$2\mathrm{ICl(g)} + \mathrm{H_2(g)} = \mathrm{I_2(g)} + 2\mathrm{HCl(g)}$$

Inasmuch as no pressure change accompanies the reaction, the compositions of the reacting mixtures were determined iodimetrically. Weighed quantities of best quality liquid chlorine and solid iodine in small breakable capsules were placed in 100-cc. bulbs. The bulbs were evacuated and then filled to the desired pressure with hydrogen which had been carefully freed from oxygen and water vapor. After sealing off, the bulbs were shaken to break the capsules and were then immersed in a thermostat filled with molten Crisco. At suitable time intervals a bulb was removed from the thermostat, and the reaction was stopped by cooling the bulb rapidly in an air blast. Independent experiments had shown that no detectable reaction takes place below 100°. The cooled bulbs were opened under a solution of potassium iodide and the resulting iodine titrated with 0.1 N thiosulfate.

The best constants were obtained when the rate equation was assumed to be

$$-d(\mathrm{ICl})/dt = k(\mathrm{H_2})(\mathrm{ICl})$$

$$k = \frac{2 \times 2.303}{t(c_1 - 2c_2)} \log \frac{2c_2(1 - B)}{2c_2 - c_1B}$$

where c_1 and c_2 are the initial concentrations of ICl(g) and H_2(g), respectively, and B is the fraction of ICl consumed in time t. At 205°, $k = 0.031 \pm 0.006$; at 230°, $k = 0.17 \pm 0.06$; and at 240°, $k = 0.35 \pm 0.06$. The concentrations of ICl and H_2 are here expressed in moles per liter, and the time is given in minutes. Experiments in which the bulbs were filled with powdered Pyrex glass yielded, within the errors indicated, the same values for the specific rate constants. Representative results of the experiments are presented in Table I.

TABLE I

RESULTS OF REACTION RATE EXPERIMENTS

Temp., °C.	t, min.	Moles per liter $c_1 \times 10^2$	$c_2 \times 10^2$	Fraction ICl reacted B	k
205	360	3.12	3.19	0.329	0.033
	360	4.43	3.19	.199	.021
	60	2.20	3.15	.0674	.038
230	120	3.09	3.42	.402	.139
	60	2.53	3.43	.376	.248
	60	2.04	3.43	.202	.113
	31	1.49	3.43	.131	.138
	31	2.66	3.45	.113	.116
	30	2.68	3.13	.155	.180
	15	2.24	3.43	.098	.208
240	85	2.41	3.44	.466	.322
	50	1.38	1.94	.241	.298
	48	2.13	2.73	.375	.414
	39	1.68	1.94	.188	.284
	31	1.62	3.44	.350	.420

The mechanism suggested by these results is the following, which is put forward as a purely tentative one

$$\mathrm{H_2} + \mathrm{ICl} = \mathrm{HI} + \mathrm{HCl} \qquad \text{(slow)}$$
$$\mathrm{HI} + \mathrm{ICl} = \mathrm{HCl} + \mathrm{I_2} \qquad \text{(rapid)}$$

The deviation of the values of individual rate constants from the mean is appreciably greater than is usually found where a single mixture can be followed with time, yet no correlation between the deviations and the concentrations of reactants or products is evident.

It must be pointed out that iodine monochloride dissociates[1] somewhat (3% at 210°) into iodine and chlorine, and that a mechanism involving the possible reaction of hydrogen with chlorine must be considered. Inasmuch as the dissociation is greatly repressed as soon as some free iodine is formed, and since mixtures initially containing excess iodine gave sensibly the same results, such a mechanism does not seem likely. The direct reaction between hydrogen and iodine is very slow at 240° and below.[2]

When the average values of the specific reaction rate constants are plotted against $1/T$ a straight line results. The energy of activation for the assumed slow reaction is 33,900 cal.

Specific Heat and Binding Conditions of Adsorbed Argon on Charcoal

BY HANS M. CASSEL

When a monoatomic gas is adsorbed at the surface of an elementary solid, the first adsorption layer represents a more or less perfect continuation of the crystal lattice. Accordingly, the "adatoms"[1] behave as being bound by certain centers of attraction around which they move similarly as the atoms of the adsorbent. But, due to the anisotropy of the situation, the oscillation perpendicular to the surface freezes in, if the temperature is enough decreased, whereas the degrees of freedom parallel to the surface, corresponding to weaker binding forces, remain still excited at much lower temperatures.

It depends on the size and shape of the potential box in which the adatom may be regarded as contained,[2] whether the movement is a two-dimensional translation or a two-dimensional harmonic oscillation. Accordingly, the specific heat of the adatoms, in the first case, has the value, R, remaining constant except at extremely low temperatures, and, in the second case, the value, $2R$, decreasing with decreasing temperature in analogy to the Debye function of the three-dimensional oscillator.

F. Simon and R. C. Swain[3] recently having measured the heat capacity of argon adsorbed on charcoal observed the rather constant value, R, between 80 and 60°K., but, at lower temperatures, a decrease leading to an almost imperceptible amount below 20°K. Thus, the experimental result agrees neither with the first nor with the second possibility explained above. Instead, the appearance of the sloping-down perfectly resembles the Debye function of a one-dimensional oscillator.

This view, indeed, is justified, since it is much more probable that an argon atom is adsorbed in the hollow edges or steps of the very cleavable material than on the smooth surfaces of the netplanes. Adatoms bound by two vicinal crystal planes, at low temperatures, are capable of only one-dimensional vibrations parallel to both surfaces. The specific heat measurements, therefore, back the suggestion that the majority of the argon atoms is adsorbed in this way.

Areametric Analysis. A Useful Technique in Estimating Small Amounts of Heavy Precipitates

BY V. R. DAMERELL AND M. AXELROD

In attempting to measure small amounts (0.01 to 5 mg.) of lead sulfate in contact with sulfuric acid, the authors were able to develop a simple technique whereby compact circular (or square) piles of precipitate could be obtained, of reproducible dimensions, in the center of the flask bottom (see Fig. 1). The apparent areas of these "spots" (as viewed from above, and assuming them to be flat circles or squares) could be readily measured and compared to the areas produced by known amounts of precipitate. This method of analysis is new, according to the authors' best knowledge, and since it involves the measurement of an area, the term areametric analysis is proposed.

The method is generally applicable to heavy precipitates of the lead sulfate type, such as barium sulfate, lead arsenate, lead chromate, etc. The determination is made right in the precipitation beaker or flask, and the procedure is of such simplicity that the authors feel the method may be of considerable use in the estimation of small amounts of many substances.

The technique used in the formation of these "spots" was as follows. The liquid in the flask was first swirled twenty or thirty times, to loosen the precipitate and cause part of it to go to the center. Then after allowing the precipitate to settle for a minute or two, the flask was tipped so that the line made by the edge of the liquid crept nearly to the center of the flask bottom. Sufficient liquid was present in the flask so that the flask bottom made a maximum angle of about 60° with the desk top. This was done ten times to the left, ten times to the right, and ten times each backward and forward. The precipitate was brought to the center of the flask bottom by this procedure.

Finally the flask was held by the thumb and finger of the right hand near the bottom and the thumb and finger of the left hand near the top, over a black surface. The right hand now made a series of short backward and forward movements (about ten to a series, at the rate of three or four a second). During these movements the flask did not move more than a millimeter or two, and the force was applied by the whole forearm, the wrist being held practically stiff. After each series of shakes the flask was rotated 30 or 40°. These vibrational movements caused the precipitate to be swept into a compact circular pile. Photographs of spots obtained are given in Fig. 1.

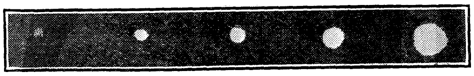

Fig. 1.—Lead sulfate "spots."

After a few minutes of such shaking the spot reached an essentially constant, minimum size. The flask was then placed on the "standard spot" card (Fig. 2) and moved along until a spot was reached which matched the unknown spot in size. This card was simply a reduced copy of a contact photograph of a twist drill and steel wire gage. It was calibrated with known amounts of precipitate. A sheet of millimeter graph paper can be substituted for occasional determinations.

This vibration method was used to obtain circles having an apparent area up to about twenty square millimeters. For larger amounts than this the minimum area of the square was obtained by the tipping process described above. The dimensions of the square could be rapidly obtained by placing the flask on millimeter graph paper.

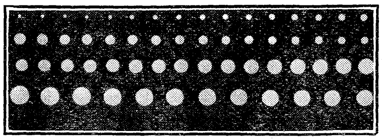

Fig. 2.

Quantitative results are given in Table I for lead sulfate in contact with 10 cc. of 40% sulfuric acid, measured in a 50-cc. Pyrex Erlenmeyer flask.

The Catalytic Oxidation of Carbon

BY JESSE E. DAY,[1] RICHARD F. ROBEY AND HYP J. DAUBEN

A few years ago, Taylor[2] reported a means of demonstrating the peculiar catalytic effect of sodium chloride on the oxidation of soot carbon, a phenomenon well known to the layman in its practical application.

We have successfully performed the demonstration of Taylor many times; it was discovered, however, that not only sodium chloride is effec-

---

(2) R. K. Taylor, THIS JOURNAL, 52, 3025 (1930).

tive, but other salts apparently equally as well. This seemed so striking that we immediately endeavored to verify this observation in a somewhat more exact manner.

A small tube (2.4 cm. in diameter) was rotated (3 r. p. m.) on its long axis inside a split type laboratory combustion furnace. A short (4 cm.) length of the tube, in the center of the furnace, and having a negligible temperature gradient, was coated completely with the salt in question. Thus the concentration of the salt was assumed to be constant at the carbon–salt interface. The temperature of the furnace was then increased to and maintained at a predetermined convenient value (±3°). Carbon film deposition, mirror reflected observation, and air admittance were made through a narrow longitudinal slot (2 cm. wide) in the under portion of the surrounding furnace. The apparatus was entirely enclosed in a small glass-fronted cabinet to protect it from drafts.

Carbon deposition was carried out by means of a wide flame of enriched natural gas from a Pyrex glass burner which moved mechanically along the slot in the furnace at a uniform rate (0.02 cm./sec.). The flame deposited the carbon film uniformly, as evidenced by the manner in which it disappeared on oxidation, and at a rate of 3.5 micromoles/sec., reproducible within 10%.

The lengths of time required for the disappearance of the carbon film from the 4 cm. sector were determined when deposited on bare glass as well as on the following c. p. salts: lithium, sodium, potassium, calcium, strontium and barium chlorides, calcium and barium hydroxides, sodium and potassium sulfates.

At 575° the carbon burned off the bare glass in about 180 sec. This was cut down by all of the salts to between 20 and 30 sec., as far as could be discerned by the method of observation. At 550° the oxidation of the carbon from the bare surface required 280 sec. It was reduced by the presence of the salts to 130–150 sec. At 515°, the oxidation from the bare surface required 630 sec. This was cut down by the barium and strontium salts to about 300, by the calcium salts and sodium chloride to about 230, and by the potassium and lithium chlorides, and sodium and potassium sulfates to about 170 sec. The values given are the averages of two or more observations usually agreeing within 10% or less. This agreement evidences a fair reproducibility of oxidizable surface area.

The most ready explanation of the effect of salts in the oxidation of carbon is that offered by Taylor and Neville.[3] They pointed out that the probable function of salts in the reaction of steam on carbon is in hastening the decomposition of the C_xO_y surface complex. With this barrier removed, a carbon surface is more readily attacked by oxidizing gases.

The Isolation and Identification of a Paraffin Hydrocarbon from Urine of Pregnancy

By William Forris Hart and M. Allen Northup

Marrian[1] has mentioned that a paraffin hydrocarbon which is physiologically inactive, occurs in urine of pregnancy. Schwenk[2] also states that he has encountered a physiologically inactive hydrocarbon in urine of pregnancy.

We have isolated and identified one hydrocarbon, heptacosane, from urine of pregnancy, and have evidence of the presence of another, pentacosane, in the same material.

Experimental.—Twelve liters of urine were aged for several months and acidified to Congo red with concentrated hydrochloric acid, the acidified urine was then treated with 28 g. of fuller's earth per liter, agitated thoroughly, and allowed to stand overnight. The fuller's earth was then filtered off, and a second absorption on 14 g. per liter was applied. The combined fuller's earth fractions were air dried and extracted seven times with convenient volumes of low boiling petroleum ether (below 70°). The combined petroleum ether residue was taken up in 50 cc. of ethyl acetate. This solution, on chilling, deposited 1.4 g. of white plate-like crystals. It was found on recrystallizing from methanol that this material could be separated into two fractions, one soluble, and the other insoluble, in warm methanol.

The fraction insoluble in warm methanol was recrystallized repeatedly from ethyl acetate. The final melting point was 58–59° (uncorrected). Analysis gave: C, 85.83 and 84.56, H, 14.62 and 14.62; molecular weight (micro Rast), 391, 391. Calcd. for heptacosane ($C_{27}H_{56}$): C, 85.16,

---

[1] Marrian, *Physiol. Rev.*, **13**, 185 (1933).

[2] E. Schwenk, private communication.

H, 14.83; molecular weight, 380; melting point, 59°.[3]

The fraction soluble in warm methanol was recrystallized repeatedly from ethyl acetate. The final melting point was 52–54° (uncorrected). Analysis gave: C, 85.07; H, 15.08%. Calcd. for pentacosane ($C_{25}H_{52}$): C, 85.37; H, 14.63; melting point, 54°.[3]

It is not certain whether this fraction consists of a pure hydrocarbon, or a mixture of two or more hydrocarbons. On crystallizing from ethyl acetate on a microscope slide it has the form of homogeneous hexagonal plates.

Besides the solubilities mentioned above, these fractions are very soluble in chloroform and benzene, soluble in hot and insoluble in cold acetone and ethanol, and insoluble in water and alkali.

They contain no nitrogen or phosphorus, have no acid or saponification number, do not reduce Fehling's solution, and do not absorb bromine from chloroform solution. They have been found to have no oestrogenic activity.

The procedure outlined above was applied to eight liters of non-pregnant female urine which had been aged for two weeks. From the petroleum ether was obtained 3.8 mg. of an impure waxy substance from which it was not possible to isolate any crystalline material melting below 120°.

The same procedure was also applied to two samples of male urine of eight liters each. One of these was a year old; the other had been aged two weeks. Like the non-pregnant female urine each yielded a few milligrams of impure waxy substance from which no crystalline material melting below 120° could be isolated. If these hydrocarbons occur in non-pregnant female, and male, urine they must do so in an amount far less than in urine of pregnancy. The physiological source of these hydrocarbons during pregnancy raises many interesting speculations.

The authors regret that factors beyond their control have prevented an extension of this investigation. They wish to thank Dr. F. R. Eldred, Director of Research, of Reed and Carnrick, for his kind permission to publish this work, and Dr. J. B. Niederl of Washington Square College, New York University, for the micro analyses and molecular weight determinations.

Preparation of Alpha-Naphthoic Acid

BY D. J. LODER[1] AND F. C. WHITMORE

During some work which demanded the preparation of a considerable amount of pure alpha-naphthoic acid, all of the regular methods of preparing this substance were tried with only mediocre success. At the same time some studies were being carried out on the preparation of tertiary alcohols by the action of the Grignard reagent with diethyl carbonate and it had been observed that when the Grignard reagent was "sterically hindered" the reaction could be stopped at the ketone stage or even at the ester stage. Consequently, alpha-naphthylmagnesium bromide (5 moles in 2.5 liters of absolute ether) was added slowly to a solution of ethyl carbonate (7.5 moles in 500 cc. of dry ether). Treatment of the mixture with a slight excess of 30% sulfuric acid, separation of the ether layer and isolation in the usual way gave a 70% yield of redistilled ethyl alpha-naphthoate boiling at 143–144.5° at 3 mm. Hydrolysis of the ester gave over a 90% yield of pure alpha-naphthoic acid.

The Mechanism of the Addition of Halogens to Ethylenic Linkages

BY RICHARD A. OGG, JR.

The addition in solution of halogens to an ethylenic linkage is assumed by Ingold[1] to proceed through the formation of an intermediate positive carbonium ion, as RCHBr—C^+HR, which subsequently adds a halide ion. Experiment indicates positive carbonium ions to be configuratively unstable,[2,3] and hence this mechanism would lead one to expect identical products (*i. e.*, a mixture of meso and *dl* dihalides) from *cis–trans* isomers, in contradiction to experimental fact.

Carothers[4] has proposed that addition reactions of ethylenic linkages are initiated by an internal ionization of the double bond, followed by addition of the reagent molecule at the positive end,

[4] W. H. Carothers, THIS JOURNAL, **46**, 2227 (1924).

and subsequent rearrangement to the stable addition product. Such an internal ionization of double linkages, in view of the rapid racemization of positive carbonium ions, would cause a rapid *cis–trans* isomerization of ethylene derivatives even in the absence of reagents. Hence this mechanism is open to the same objection as that of Ingold, *i. e.*, in leading to identical addition products from *cis–trans* isomers. Both mechanisms infer the addition reactions in question to be uncatalyzed.

The following mechanism is suggested as more plausible. Using bromine, for example, the consecutive reactions are

(1) $Br^- + RCH{=}CHR \longrightarrow RCHBr{-}C^-HR$
(2) $RCHBr{-}C^-HR + Br{-}Br \longrightarrow RCHBr{-}CBrHR + Br^-$

That is, the addition is catalyzed by halide ion, and the intermediate is a carbanion. Carbanions have been shown[2] to have stable configurations, and hence stereochemically different products should result from *cis–trans* isomers. Further, explanation is afforded of the generally observed *trans* addition of halogens to ethylenic linkages. Reaction (1) is to be regarded as a substitution reaction of the halide ion with one of the electron pair bonds of the ethylenic linkage, and hence as attended by *optical inversion* of the intermediate carbon atom.[5] The carbanion thus has a *trans* configuration, and since no configuration change attends reaction (2), the final addition product should be *trans*.

Experimental evidence for the proposed mechanism is found in a number of cases in which addition or removal of halogens from an ethylenic linkage is catalyzed by halide ions. Thus Slator[6] found the decomposition of ethylene diiodide to be catalyzed by iodide ions in alcoholic solution. Obviously the addition of iodine to ethylene must be similarly catalyzed. Reaction of a 1,2-dibromo compound with iodide ions to yield the corresponding unsaturated compound is a well-known typical reaction. Halogen addition to simple ethylenic hydrocarbons in solution is ordinarily exceedingly rapid. However, the marked slowness of the addition of bromine to ethylene in rigorously purified and dried solvents[7] indicates the ordinary reaction to be catalyzed by impurities, of which halide ions appear most likely. The otherwise immeasurably slow addition of bromine to maleic and fumaric esters was found by Hanson and Williams[8] to be catalyzed by a trace of hydrogen bromide. Finally, the author has observed, using glacial acetic acid as a solvent, that the normally slow addition of bromine to maleic and fumaric acids, stilbene, cinnamic acid and tetrachloroethylene is markedly catalyzed by dissolved lithium and potassium bromides.

A very similar mechanism to the above probably obtains for addition of hydrogen halides to ethylenic linkages, step (2) being replaced by addition of a hydrogen ion to the carbanion. *Trans* addition should also occur in this case. Likewise the addition of halogens and hydrogen halides to acetylenic linkages should proceed in analogous fashion, giving *trans* addition products, as is actually observed.

It is to be emphasized that the above mechanism applies to reactions in solution, and in the dark. Gas phase addition of halogens to double bonds cannot of course be caused by ionic catalysis, and it is significant that no homogeneous reaction of gaseous ethylene with bromine or chlorine[9,10] is observed at low temperatures. In the photochemical reaction the chains are carried by free halogen atoms and the radicals RCHBr—CHR. The rapid racemization of the latter, followed by loss of halogen atoms, explains the well-known halogen-sensitized *cis–trans* isomerization of ethylene derivatives. Likewise, the photochemical reaction is to be expected to lead to a mixture of *cis* and *trans* addition products.

Cases in which marked *cis* addition of halogens occurs practically all involve the *ions* of maleic and fumaric acids.[11] Due to the Coulomb repulsion between the negative charges of the halide ion and of the acid ions, the above mechanism could hardly be expected to obtain. It is much more probable that intermediate lactone formation occurs, in which case the *cis* addition is readily explicable.

The recent communication of Anantakrishnan and Ingold[12] substantiates the above suggestion that halogen addition to ethylenic hydrocarbons is catalyzed by halide ions.

Catalysis in Organic Chemistry. V. Decompositions of Esters and Acids by Anhydrous Zinc Chloride[1]

BY H. W. UNDERWOOD, JR., AND O. L. BARIL

The catalytic decomposition of esters and acids by anhydrous zinc chloride has been described in previous papers.[2] The transformations observed were represented by three different types of decomposition which involved the elimination of an aliphatic unsaturated hydrocarbon or carbon dioxide or both. In order to substantiate these results, additional experiments of a similar nature were performed, from which the following regularities and generalities may be concluded.

The methyl, ethyl, propyl and butyl esters of monobasic aliphatic acids were not affected by the catalyst under the conditions of the experiment. The esters derived from amyl alcohol and from a monobasic aliphatic acid decomposed very slowly into an unsaturated hydrocarbon and the aliphatic acid. The rate of decomposition increases with a rise in the number of carbon atoms in the alcohol group. The aliphatic monobasic acids themselves are not affected by the catalyst. Esters of aliphatic dibasic acids are all decomposed, the dibasic acid reacting with the zinc chloride to form the zinc salt of the dibasic acid with evolution of hydrogen chloride. The hydrogen chloride in turn forms the alkyl halide with the liberated unsaturated hydrocarbon.

Esters of aromatic acids decompose into an unsaturated hydrocarbon and the aromatic acid, which in turn decomposes into carbon dioxide and a saturated aromatic hydrocarbon, providing the aromatic acid is monobasic. If the aromatic acid is a dibasic acid, the anhydride of the acid is formed. Benzyl esters decompose into the acid, and the benzyl groups polymerize, forming a dark tarry residue. All unsaturated hydrocarbons evolved, whether aliphatic or aromatic, polymerize, the polymerization increasing with the rise in the number of carbon atoms in the hydrocarbon.

Esters and acids readily decomposed by heat were not used. Those which were used could be distilled or fused without decomposition. In every case, decomposition of the ester or acid was effected, in the presence of anhydrous zinc chloride, at a much lower temperature than if heated alone. Zinc chloride dissolved in the ester or acid before any evidence of decomposition appeared. Esters and acids which did not dissolve the zinc chloride on heating were not themselves decomposed. This peculiar phenomenon was also noted in the experiments described in previous papers. During the decomposition, there was always a color change from colorless to yellow to orange to red to brown and finally black. The temperature in every case was raised until the ester or acid dropped freely from the end of the reflux condenser. There was often evidence of decomposition in the reaction flask before this temperature was reached. The tests described by Mulliken ["Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, 1916, 1922, Vols. I, II and IV] were used for the identification of all the products of decomposition.

Experimental

No evidence of decomposition was found in experiments with ethyl chloroacetate, dichloroethyl acetate, trichloroethyl acetate, ethyl isovalerate, *n*-butyl formate, *n*-propyl acetate, propyl formate, isopropyl formate and methyl *m*-nitrobenzoate.

Esters Decomposing with Evolution of Carbon Dioxide.—Methyl cinnamate yielded styrene and its polymers; ethyl cyanoacetate gave ethylene and methyl cyanide; amyl chlorocarbonate decomposed into amylene and its polymers, amyl chloride and hydrogen chloride; amyl chloroacetate into amylene and its polymers, chloroacetic acid and hydrogen chloride; ethyl anisate into ethylene, anisic acid, anisole and *p*-ethyl cresyl ether; ethyl phenylacetate into ethylene, phenylacetic acid, propylbenzene and acetic acid; isoamyl valerate into valeric acid, isopropylethylene and its dimer; *n*-amyl acetate into acetic acid, amylene and its polymers; isoamyl propionate into propionic acid, isopropyl ethylene and its dimer; ethyl *m*-aminobenzoate into ethylene and aniline; and ethyl *p*-nitrobenzoate into ethylene and *p*-nitrobenzoic acid.

Ethyl acetoacetate yielded acetone, ethyl acetate and propyl methyl ketone; and isobutyl acetoacetate gave isobutylene, acetone, isobutyl acetate and methyl isoamyl ketone. Ethyl diethylmalonate gave ethylene and ethyl diethylacetate; while ethyl dipropylmalonate gave ethylene and ethyl dipropylacetate. Methyl carbonate yielded methyl alcohol; cyclohexyl acetate gave cyclohexane and acetic anhydride; while ethyl orthoformate decomposed into ethyl ether and ethyl formate when distilled over anhydrous zinc chloride, but on refluxing the mixture for one hour at 60°, ethyl alcohol and paraldehyde were obtained.

Acetal and ethylal gave ethyl alcohol and paraform, whereas dimethyl acetal yielded methyl alcohol and par-

[2] Underwood and Baril, THIS JOURNAL, **52**, 395 (1930); **53**, 2200 (1931).

aldehyde. Benzene was obtained from both the iso- and terephthalic acids. Anisic acid gave anisole; *p*-toluic acid yielded toluene and the zinc salt of *p*-toluic acid; and diphenylacetic acid decomposed into diphenylmethane.

Esters Decomposing without Evolution of Carbon Dioxide.—Benzyl benzoate and benzyl butyrate decomposed into their respective acids, benzoic and butyric. The benzyl groups polymerized, forming a dark colored and tarry residue. Dimethyl phthalate gave phthalic anhydride, and *n*-amyl phthalate gave phthalic anhydride, amylene and its polymers. Phenyl acetate yielded phenol; and phenyl salicylate gave phenol at a temperature of 177° in presence of the catalyst, although a temperature of 280° is required to decompose it without a catalyst. Phenylacetic acid yielded acetic acid; *m*- and *p*-nitrobenzoic acid reacted with the catalyst to form the zinc salt of the acid with evolution of hydrogen chloride. The *p*-nitrobenzoic acid mixture blew up after fifteen minutes of heating, leaving a deposit of soot over the entire apparatus.

A new type of decomposition has been observed with the elimination of carbon monoxide instead of carbon dioxide from halogenated aliphatic acids. Monochloroacetic acid decomposed into carbon monoxide, formaldehyde and hydrogen chloride; and the trichloroacetic acid decomposed into carbon monoxide, carbonyl chloride and hydrogen chloride.

The authors wish to express their thanks for a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences which partly defrayed the cost of this work.

Reduction of Nitroguanidine. III. Synthesis of Aminoguanidine[1]

BY G. B. L. SMITH AND EDWARD ANZELMI

Aminoguanidine has been prepared by the reduction of nitroguanidine with zinc in a solution of acetic acid,[2] by the interaction of hydrazine hydrochloride and cyanamide,[3] and by the electrolytic reduction of nitroguanidine.[4] We have prepared aminoguanidine in high purity and excellent yield by the hydrazinolysis of methyl isothiourea sulfate. To 139 g. of methyl isothiourea sulfate in 200 ml. of water at 10° is added 119 ml. of a 42% solution of hydrazine hydrate[5] diluted with an equal volume of water. The methyl mercaptan liberated can be absorbed in a solution of sodium hydroxide.[6] Finally the aminoguanidine sulfate is precipitated by addition of an equal volume of 95% ethanol to the solution concentrated to 200 ml. A second crop of crystals separates on concentration of the filtered solution. The water of crystallization (1 molecule) may be removed by drying *in vacuo* or at 105°; yield 90%; m. p. 206° with decomposition (Thiele, 207–208°). Aminoguanidine sulfate was identified through conversion to the picrate and bicarbonate, by liberation in alkaline solution of one-half of the nitrogen as ammonia and by hydrolysis to hydrazine.[7] *Anal.* calcd. for $(CH_6N_4)_2H_2SO_4$: SO_4, 39.83; NH_3, 27.67; N_2H_4, 26.02. Found: SO_4, 39.3, 39.7; NH_3, 27.2, 27.5, 27.7; N_2H_4, 26.03, 25.93. The fact that aminoguanidine bicarbonate has the composition $CN_4H_6H_2CO_3$ has been established by analysis. A solution of aminoguanidine is a strong base K_B estimated as 1.1×10^{-3}. Further work on aminoguanidine and alkylaminoguanidines is in progress.

COMMUNICATIONS TO THE EDITOR

THE RELATIVE ATOMIC WEIGHT OF OXYGEN IN WATER AND IN AIR

Sir:

Washburn, Smith and Smith [*Bur. Standards J. Res.*, **13,** 599 (1934)] burned oxygen and hydrogen from an electrolytic cell separately with "normal" hydrogen and oxygen, respectively, obtaining in the first fraction a difference of density in p. p. m., γ, between these waters and normal water -13.2 for the cell oxygen plus "normal" hydrogen and -7.8 for the cell hydrogen plus atmospheric oxygen. The cell hydrogen and oxygen burned together gave water of γ value, -20.5, approximately the sum of the first two data. A little reflection will show that if this work is correct, there is no difference between the atomic weight of oxygen in air and in water. Unfortunately it now appears that due to an unlucky compensation of effects this agreement is merely a coincidence and that there is a significant difference in the atomic weight of oxygen from the two sources.

I have electrolyzed water made from tank hydrogen and Linde oxygen (whose atomic weight in reference to atmospheric oxygen was corrected for) and burned the oxygen with tank hydrogen. Two electrolyses gave γ equal to -6.9 for this water. Two electrolyses of normal water, followed by combustion of the oxygen with the same tank hydrogen gave water having a γ value of -11.5; the difference between the results is 4.6, from which the atomic weight of oxygen in the air can be calculated to be 16.00008 if the atomic weight of oxygen in Lake Michigan water is 16.00000.

Understanding this fact makes easy the explanation of several anomalous and unexplained results of other workers. In the work of Washburn mentioned above neither his tank hydrogen nor his oxygen was "normal," *i. e.*, had the same atomic weight as the two elements in water, the hydrogen being too light and the oxygen too heavy. It is also clear why Washburn, Smith and Smith's conclusion that the oxygen isotopes fractionate more rapidly than those of hydrogen on electrolysis is erroneous. Greene and Voskuyl's [This Journal 56, 1649 (1934)] anomalous finding that tank hydrogen burned with air resulted in water denser than normal is explained, and the results of W. Heinlen Hall and Johnston [This Journal, **57,** 1515 (1935)] indicating that the isotopes of hydrogen fractionate on combustion will now have to be largely modified. The increase in density of water obtained by myself and many others in the combustion of organic substances will have to be reinterpreted.

Incidentally the data reported here confirm the prediction of Urey and Greiff [This Journal, **57,** 321 (1935)] that when water and oxygen are brought into equilibrium, the O^{18} concentrates in the oxygen, and the conclusion that it is meaningless to express the atomic weight of oxygen to more than four decimal places.

It is hoped to repeat more accurately the experimental work described in this paper.

THE PREPARATION OF 9,10-DIHYDROPHENANTHRENE AND ITS DERIVATIVES

Sir:

The selective activity of copper–chromium–barium oxide catalyst permits the expectation that in phenanthrene only, or chiefly the 9,10-double bond, which in some respects exhibits a decidedly olefinic character, would be saturated by hydrogenation in the presence of this catalyst.

Phenanthrene, purified according to Cohen and Cormier [This Journal, **52,** 4363 (1930)] and treated with, and distilled over sodium, was dissolved in 2 to 3 parts of absolute alcohol and mixed with about 10% (by weight) of catalyst 37 KAF [Connor, Folkers and Adkins, *ibid.*, **54,** 1138 (1932)]. The hydrogenation was carried out at pressures from 2000 to 4000 lb./sq. in., maintaining a temperature of 220° for twenty-four to thirty-six hours. After separating from the reaction mixture 10 to 20% of unchanged phenanthrene (as the picrate), 60 to 80% of crude 9,10-dihydrophenanthrene was obtained (after distillation *in vacuo*). No tetrahydro- or octahydrophenanthrene could be detected. The

Substance	M. p., °C.	Formula	C, % Calcd.	C, % Found	H, % Calcd.	H, % Found
2-Acetyl-9,10-dihydrophenanthrene	51–52	$C_{16}H_{14}O$	86.44	86.77	6.35	6.64
-Oxime	146–147.5	$C_{16}H_{15}NO$	80.97	80.61	6.38	6.43
-Semicarbazone	236–237	$C_{17}H_{17}N_3O$	73.07	73.05	6.14	6.14
9,10-Dihydro-2-bromoacetylphenanthrene	93.5–95	$C_{16}H_{13}BrO$	63.78	63.71	4.35	4.49
9,10-Dihydrophenanthrene-2-carboxylic acid	211.5–212.5	$C_{15}H_{12}O_2$	80.32	80.34	5.39	5.42
-Methyl ester	Oil	$C_{16}H_{14}O_2$	80.63	80.50	5.93	5.66
2-Acetyl-9,10-phenanthrenequinone	223–224	$C_{16}H_{10}O_3$	76.78	76.67	4.03	4.36

compound thus obtained is sufficiently pure for the reactions described below. After further purification, the 9,10-dihydrophenanthrene melted at 31–32° and showed $n^{25}{}_D$ 1.6464 [*cf.* Schroeter, *Ber.*, **62**, 645 (1929)].

In the Friedel–Crafts reaction, which proceeds equally well in carbon disulfide or nitrobenzene, only one acetyl compound is formed (purified through the semicarbazone, yield, about 90%). The acetyl group enters the 2-position of the dihydrophenanthrene, which resembles in respect to this reaction diphenyl rather than phenanthrene. Structural proof: (A) acetyldihydrophenanthrene $\xrightarrow{CrO_3}$ 2-acetyl-9,10-phenanthrene quinone; (B) acetyldihydrophenanthrene $\xrightarrow{NaOCl}$ dihydrophenanthrene carboxylic acid $\longrightarrow$ methyl ester $\xrightarrow[20\text{ hrs., }300°]{Se}$ phenanthrene-2-carboxylic acid.

We intend to study substitution products of 9,10-dihydrophenanthrene prepared either by introducing substituents into dihydrophenanthrene or by partial hydrogenation of substituted phenanthrenes. We are interested in particular in the synthesis of compounds with nitrogen-containing side chains and rings similar to the phenanthrene and dibenzofuran derivatives previously described from this Laboratory. The preference shown by the acetyl group for position 2 (and this will undoubtedly hold true for similar substituents) makes starting materials for the synthesis of substances related to sterols and sex hormones easily accessible.

Anthracene, submitted to high pressure hydrogenation with copper chromite, is reduced nearly quantitatively to 9,10-dihydroanthracene. In this case the reduction is completed at a considerably lower temperature (160°) within a few hours. This demonstrates again the marked difference between the reactivities of the meso-positions in anthracene and phenanthrene, respectively.

THE APPLICATION OF POLANYI'S POTENTIAL THEORY TO THE VAN DER WAALS ADSORPTION OF GASES ON IRON SYNTHETIC AMMONIA CATALYSTS

Sir:

Polanyi's "potential theory" of gas adsorption by solids [*Verhandl. deut. phys. Ges.*, **18,** 55 (1916)] in its original form was interpreted in terms of a postulated thick film of compressed or liquefied gas on the surface of the solid. In 1928 Polanyi and Goldman [*Z. physik. Chem.*, **132,** 321 (1928)] pointed out that the theory can be applied to adsorption in monomolecular layers. Thus far the theory has been applied exclusively to the adsorption of organic vapors, carbon dioxide and sulfur dioxide on amorphous adsorbents like charcoal and silica gel. The present communication shows the applicability of the theory to some low temperature isotherms that we have been obtaining on iron catalysts.

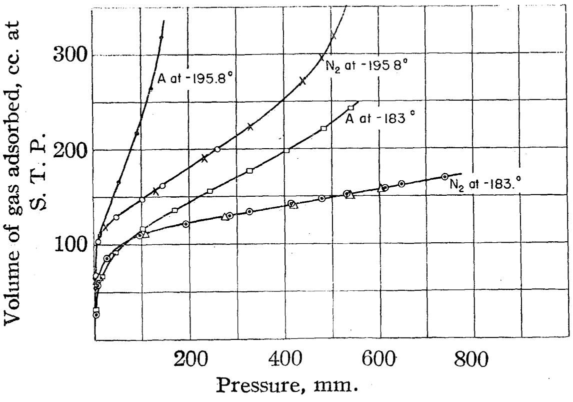

Fig. 1.

Figure 1 shows isotherms obtained for argon and nitrogen on a 25-cc. sample (43.6 g. of iron) of a singly promoted (10.2% Al_2O_3) iron synthetic ammonia catalyst at −183° and −195.8°. These adsorption data plotted according to Polanyi's theory are shown in Fig. 2. As abscissas are plotted $RT\log_{10}P_s/P$; these abscissa values when multiplied by 2.303 give the free energy of compression of the gas from the pressure P, at which a particular adsorption point is obtained, to the liquefaction pressure P_s of the gas at temperature T. Nitrogen isotherms for the above two temperatures have also been obtained for a pure iron and a doubly promoted iron catalyst. In all of these cases the adsorption of a given gas on a particular catalyst at two or more temperatures could be represented by a single potential curve of the type shown in Fig. 2.

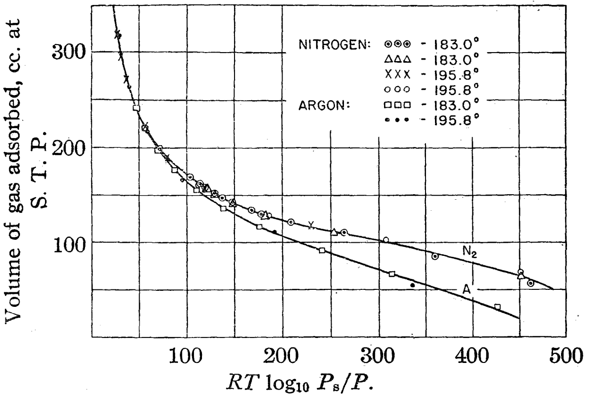

Fig. 2.—Potential–volume curves for the adsorption of nitrogen and argon on a single promoted iron synthetic ammonia catalyst.

The potential plots seem to represent the isotherms very closely throughout the entire pressure range covered, including: (a) the region concave to the pressure axis where probably less than a molecular layer of gas exists, (b) the linear portion which we have postulated represents the building up of a second layer of gas on the catalyst surface [THIS JOURNAL, **57,** 1754 (1935)], and (c) the higher pressure portion which is convex to the pressure axis and which, it is generally believed, represents the condensation of the gas to liquid in the capillaries of the adsorbent. The inclusion of this last region in the portions represented by the potential theory is rather unexpected since the theory was not intended to include such capillary condensations.

One other characteristic of the potential curves is worth noting. Polanyi and Goldman found that for their data the adsorbed mass-potential plots did not coincide at different temperatures, the higher temperature curves being slightly below the lower temperature curves in every case. They explained this displacement by postulating constancy of adsorption volume and thermal expansion of the adsorbed gas, so that less gas was required to fill the adsorption volume at higher temperatures than at lower. As shown in Fig. 2 our potential curves exhibit no such variation with temperature, the −183 and −195.8° points falling on the same curve. The significance of this result is not certain as yet.

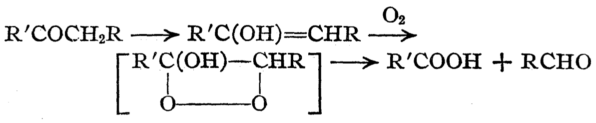
THE AUTO-OXIDATION OF KETONES

Sir:

Several ketones of the type $R'COCH_2R$ (R = phenyl) on standing in the presence of light and air for varying periods of time were observed to acquire an aldehyde-like odor. On further investigation it was found that an acid $R'COOH$ and an aldehyde $RCHO$ could be isolated.

Benzyl-2-chlorophenyl ketone, which is a liquid [Jenkins and Richardson, THIS JOURNAL, **55,** 1618 (1933)] on standing slowly solidifies and acquires a strong odor of benzaldehyde. The solid is shaken up with dilute sodium carbonate solution and extracted with ether. The aqueous layer is acidified with hydrochloric acid and 2-chlorobenzoic acid is obtained. The ether is distilled and the oil which remains is steam distilled. The distillate is treated with phenylhydrazine acetate and benzalphenylhydrazone is obtained. The solid gives a strong peroxide reaction using the test of Kharasch [Kharasch, McNab and Mayo, *ibid.*, **55,** 2523 (1933)].

The course of the reaction may be illustrated as



$$R'COCH_2R \longrightarrow R'C(OH){=}CHR \xrightarrow{O_2} \left[\begin{array}{c} R'C(OH){-}CHR \\ |\qquad\quad | \\ O{-\!-\!-\!-}O \end{array}\right] \longrightarrow R'COOH + RCHO$$

These reactions are being fully investigated and the results will be reported later.

CHEMICAL STUDIES ON TOAD POISONS. VIII. THE DEHYDROGENATION OF CINOBUFAGIN

Sir:

In our investigation of the chemical relationship of the bufagins (cardiac principles present in toad secretions) to the cardiac plant aglucones, possessing similar pharmacological and chemical properties, and to the sterols, it seemed of interest to ascertain whether the bufagins, on dehydrogenation with selenium, would yield methylcyclopentenophenanthrene. The formation of this hydrocarbon, $C_{18}H_{16}$, is generally considered a characteristic of the sterol ring system. Cinobufagin, $C_{25}H_{32}O_6$ [Jensen and Evans, *J. Biol. Chem.*, **104**, 307 (1934)] (the analytical data obtained for cinobufagin and certain of its derivatives would also agree with $C_{26}H_{34}O_6$ [Crowfoot, *Chem. and Ind.*, **54**, 568 (1935)]), was therefore subjected to dehydrogenation by the procedure of Diels [Diels, Gaedke and Koerding, *Ann.*, **459**, 1 (1927)]. As only a limited amount of material was available for this study, and losses were involved in the separation of compounds closely related chemically, the quantity of the hydrocarbon finally obtained was so small that a complete characterization was impossible. From the mixture of the reaction products about 10 mg. of a hydrocarbon fraction was secured which melted at 120–121°. This hydrocarbon is believed to be identical with methylcyclopentenophenanthrene. Its analytical data agree with the formula $C_{18}H_{16}$, and on mixing it with methylcyclopentenophenanthrene obtained by Elderfield and Jacobs [*J. Biol. Chem.*, **107**, 143 (1934)] by dehydrogenation of strophanthidin, no melting point depression was observed. It appears, therefore, that cinobufagin and probably also the various other bufagins contain the same ring system as the cardiac plant aglucones and the sterols. After completing this work, a paper by Ikawa [*J. Pharm. Soc. Japan*, **55**, 144 (German abstract), 748 (original Japanese) (1935)] appeared, in which he reports the isolation of the Diels hydrocarbon $C_{18}H_{16}$ from the dehydrogenation mixture of ψ-bufotaline. In this connection it might be mentioned that Wieland and Hesse [*Ann.*, **517** 22 (1935)] recently have obtained a hydrocarbon from the dehydrogenation mixture of bufotaline which they believe to be identical with chrysene. Investigations are now in progress to determine, in the bufagins, the exact nature of the side chain which contains the lactone ring.

Five grams of cinobufagin, dried at 110° *in vacuo*, was mixed with 6 g. of selenium and heated in a flask with a glass joint ascending tube for thirty-five hours at 310–320° and then for ten hours at 320–340°. The reaction mass was extracted with ether and the residue from evaporation of the solvent was subjected to fractional distillation at 12 mm. The fraction distilling at 200–230° was semi-crystalline and was fractionally recrystallized from alcohol according to the triangle scheme. After numerous crystallizations a hydrocarbon fraction was secured which melted at 120–121° and showed a m. p. of 121–122° when mixed with methylcyclopentenophenanthrene (m. p. 123–124°) prepared from strophanthidin (Elderfield and Jacobs). *Anal.* (by Dr. Ing. A. Schoeller, Berlin-Schmargendorf, Germany). Calcd. for $C_{18}H_{16}$: C, 93.05; H, 6.95. Found: C, 92.81; H, 6.82.

The author is greatly indebted to Dr. W. A. Jacobs, of the Rockefeller Institute for Medical Research, New York, for a sample of methylcyclopentenophenanthrene, and would like also to express his thanks to Dr. K. K. Chen, Lilly Research Laboratories, Indianapolis, for a supply of an extract of Ch'an Su.

THE COLLAPSE OF MONOMOLECULAR FILMS OF PALMITIC ACID UPON ACID SOLUTIONS

Sir:

When monomolecular films of palmitic acid were compressed on very pure hydrochloric acid or phosphate buffer solutions contained in a Langmuir film-pressure trough, in the range 15–20°, it was noticed that after each increment of weight had been placed in the balance pan, and the barrier advanced to establish equilibrium, a slow shrinkage followed, the area, however, finally attaining a value which was reproducible to a high degree. When the compression was carried out in this manner, with an attempt to obtain "equilibrium areas" at every point of the force–area curve, the films collapsed at a pressure apparently connected with the hydrogen-ion concentration (*i. e.*, the films could be compressed without limit when a definite pressure was reached, the value of which has been called the "collapse pressure" in the literature). When the collapse pressure values were plotted against *p*H values of the substrate (which varied from *p*H 1 to *p*H 6) an S-shaped curve resulted, similar to the percentage neutralization curve in the case of a weak organic acid in water solution. However, the mid-point of this curve was about *p*H 3, as compared to *p*H 5, the mid-point of neutralization curves of fatty acids. Since the variation of collapse pressure with *p*H may be considered as related to neutralization, this appears to be evidence of increased activity of palmitic acid when oriented on a water surface.

The collapse pressure was specific for hydrogen ions alone, although increased spread at low pressures was noticed when calcium or magnesium ions were present in the hydrochloric acid solution. A specific effect, in causing what may be either collapse or solution of the film at room temperatures, has been noticed in the case of neutral potassium permanganate solutions. This was not noticed with hydrogen peroxide, potassium ferricyanide or potassium dichromate solutions.

In view of the work of Cary and Rideal [*Proc. Roy. Soc.* (London), **A109,** 301 (1925)] on the spreading of fatty acid crystals on acid solutions, which indicates that many of the films should be thermodynamically unstable above 8 dynes, in the neighborhood of 20°, work is now in progress on a repetition of the above studies, using mixtures of higher hydrocarbons, such as tetradecane, with palmitic and other acids, to determine whether this relation between collapse pressure and hydrogen-ion concentration holds for an interface where the acid film may collapse in a reversible manner. It is planned further to apply thermodynamic interpretation, such as Harkins' spreading coefficient to the collapse phenomena. The results with the monomolecular films alone will be reported more fully in the near future, together with those obtained with mixed films.

THE ACTIVATION OF SPECIFIC BONDS IN COMPLEX MOLECULES AT CATALYTIC SURFACES

Sir:

It has now become possible to examine the activation of specific bonds in complex molecules at catalytic surfaces, a fundamental problem in surface catalysis, that of specificity. We shall illustrate a method capable of quite general applicability by a specific example, that of the molecule ethane. In this we are concerned with two types of bond, the C–C and the C–H bond. We have followed the activation of these bonds on an active nickel surface by the study of the two reactions (a) the exchange reaction $C_2H_6 + mD_2 \longrightarrow C_2H_xD_y$ where $x + y = 6$ and m may be varied arbitrarily; (b) $C_2H_6 + H_2 = 2CH_4$. The former involves only the C–H, the latter the C–C bond, the other reactant in each case being hydrogen (or deuterium) adsorbed on the surface in the activated form. We find that, on this catalyst, the exchange reaction proceeds quantitatively at 138° under conditions in which reaction (b) is quite negligible. The production of methane sets in, under our conditions about 150° and is sensibly complete around 200°. We thus define the temperature, catalyst and reactant concentration conditions necessary to activated adsorption of ethane molecules producing either the C–H or the C–C bond split or both. By extension of these studies to other catalyst surfaces, to molecules which contain a wide variety of other bonds, *e. g.*, O–H, N–H, C–O, C–N, etc., and to varied operating conditions we plan to determine in detail the factors which produce specific activity of catalysts in general.

SYNTHESIS OF DEUTERO-ACETALDEHYDE

Sir:

By absorbing deutero-acetylene in an acid solution of mercury salts in deuterium oxide we have succeeded in synthesizing deutero-acetaldehyde. About 25 cc. have been prepared so far. The aldehyde freed from deuterium oxide by repeated distillations at low temperatures is a colorless mobile liquid. Preliminary determinations indicate a vapor pressure of 327 mm. at 0°. It shows the usual aldehyde reactions: reducing ammoniacal silver solutions, forming a white crystalline compound with ammonia and a phenylhydrazone with phenylhydrazine.

The D_2O used in generating the acetylene and in the absorbing solution was 99.6% pure. The burning of about 2 cc. of the aldehyde over copper oxide in a current of oxygen gave D_2O of 99.2% purity, both values determined by the interferometer method.

The determination of the physical constants of this compound as well as its chemical properties is proceeding in this Laboratory.

NEW BOOKS

The Chemistry of Solids. By CECIL H. DESCH. The George Fisher Baker Non-Resident Lectureship in Chemistry at Cornell University. Cornell University Press, 124 Roberts Place, Ithaca, N. Y., 1934. 196 pages. 15 × 22 cm. Price, $2.50.

This volume, which contains the substance of lectures delivered by the author as George Fisher Baker non-resident lecturer in Chemistry at Cornell University, comprises seventeen chapters, of which about one half deal with topics more familiar to metallographers than to chemists, the other half with views less unfamiliar to chemists than to metallographers. It brings together and examines, from a single viewpoint, a great deal of diverse information; its style is clear and simple, as would be expected by those familiar with the author's publications; and altogether it is to be recommended as a very interesting readable book which deserves to be widely read and pondered. For this general subject of the make-up and behavior of solids touches every one interested in physical science, pure or applied; far less is known about it than is commonly supposed, and much remains to be ascertained before we can claim to have even a passable knowledge and command of the behavior of solids. Perusal of this book should stimulate a more widespread interest in these important questions.

JOHN JOHNSTON

Life and Experiences of a Bengali Chemist. Vol. II. By PRAFULLA CHANDRA RÂY. Chuckervertty, Chatterjee and Company, Ltd., 15 College Square, Calcutta, India, 1935. viii + 469 pp. 15 × 22.5 cm. Price, 6s.

A review of the first Volume of this autobiography of Rây has already appeared in THIS JOURNAL (**55**, 1298 (1933)). This second and concluding Volume contains a collection of the author's essays on diverse educational, political, social and economic problems of Hindu civilization.

In the Introduction the author assures us that . . . "throughout my active career, now extending over half-a-century, I have served Chemistry as the Goddess of my idolatry; to her I have been a whole-hearted devotee . . . ." In spite of this, it is evident that the author has also been an active participant in the public life of his country.

These essays are written in a spirited and lucid style, and like the more connected contents of the previous Volume, disclose a keen and courageous personality, passionately devoted to the welfare of India.

ADDITIONS AND CORRECTIONS

Notice to Readers.—For the convenience of those who may wish to cut out the corrections and attach them to the margins of the articles corrected, they have been printed only upon one side of the page.

1932, Vol. 54

Aliphatic Tertiary Alcohols and Chlorides Containing the Normal Amyl Group and the Related Olefins and their Ozonolysis. By Frank C. Whitmore and F. E. Williams.

Page 408. "The density reported for tri-*n*-amylcarbinol, d^{25}_{4} 0.8293, was abnormally low when compared with those recorded for other di-*n*-amylcarbinols. The refractive index, n^{20}_{D} 1.4470, was recorded for the same carbinol.

"A more recent preparation of tri-*n*-amylcarbinol showed d^{25}_{4} 0.8349, which is in complete accord with the densities of the homologs. The refractive index obtained on the present sample, n^{20}_{D} 1.4484, indicates that the first sample of carbinol contained olefin."—Frank C. Whitmore, F. E. Williams and A. H. Popkin.

The Photolysis of Hydrogen Peroxide in Aqueous Solution. By Lawrence Joseph Heidt.

Page 2842. Table I, col. 5, "I/I_0" should read: 100 I/I_0.

Line 19 of the text, $\epsilon(1/cd \log I/I_0$. . . should read $\epsilon = (1/cd)$ [log (I_0/I)].

Line 20, cm.), should read: cm., .

Line 23, "Using the method of Forbes, Heidt and Boissonannas[10]" should read: Using the method described in later work by the author.[10]. . ."—Lawrence Joseph Heidt.

1933, Vol. 55

The Desoxymorphines. By Lyndon F. Small and David E. Morris.

Page 2885. In the seventh line from the top $[\alpha]_{\mathrm{D}}$ $-118.8°$ should read $[\alpha]_{\mathrm{D}}$ $+118.8°$.—Lyndon F. Small.

1934, Vol. 56

Low Pressure Data of State of Nitric Oxide and of Nitrous Oxide between their Boiling Points and Room Temperature. By Herrick L. Johnston and Harry R. Weimer.

Page 628. A misplaced decimal point occurs in the second term of Equation (6). The coefficient of this term should be 56115.0.—H. L. Johnston.

The Interaction of the Acid Chloride of 2-Benzoylbenzoic Acid with Phenols. II. Diarylphthalides. By F. F. Blicke and R. D. Swisher.

Page 924. The third phthalide in Table I should be named 2′-hydroxy-5′-bromodiphenyl instead of 2′-hydroxy-4′-bromodiphenyl.—F. F. Blicke.

The Vapor Pressure of Certain Ketones. By M. Glenn Mayberry and John G. Aston.

Page 2682. ". . . The range of the measurements was not given due to an oversight in revision. This was approximately the same for all ketones and extended from room temperature to the boiling point except in the case of the ketones of lower vapor pressure, when the range was from 10 or 20 mm. to 735 mm. In one exceptional case, namely, that of diisopropyl ketone, the range was 49–123°."—J. G. Aston.

1935, Vol. 57

Preparation of Deuterium Free Water. Deuterium Content of Ordinary Water and the Atomic Weight of Hydrogen. Electrolytic Separation of the Oxygen Isotopes. By Herrick L. Johnston.

Page 485. "Dr. Malcolm Dole has kindly called our attention to the significance of a small correction for thermal expansion of the Pyrex float, which we did not apply in our original computations. With this correction applied, which amounts to 11 p. p. m. in density for each full degree of temperature (or 4.0% on the uncorrected density increments), our figure 19.1 ± 1 p. p. m. should be replaced by 18.3 ± 1 p. p. m.

"There was also a small computation error in the H/D ratio, 5750 ± 250. The correct H/D ratio, computed for the density difference of 18.3 ± 1 p. p. m., is 5815 ± 250, based on Taylor and Selwood's value, 1.1079, for the density of pure D_2O or 5790 ± 250, based on the value 1.1074 recently published by Tronstad, Nordhagen and Brun [*Nature*, **136**, 515 (1935)]. Obviously 5800 ± 250 is the best representation of our results. These computations take account of the slight non-additivity of D_2O and H_2O volumes found by Luten [*Phys. Rev.*, **45**, 161 (1934)].

"These slight changes are without significance in the further computations in our paper."—H. L. Johnston.

Heat Capacities and Dissociation Equilibria of Gases. By Bernard Lewis and Guenther von Elbe.

Page 612. "Due to several typographical errors and also to the recent exact determination of the $'\Delta$ level of the oxygen molecule by spectroscopic methods as 0.97 volt [Herzberg, *Nature*, **133**, 759 (1934); Ellis and Kneser, *Phys. Rev.*, **45**, 133 (1934)] we wish to make corrections to Table I of this paper. The new oxygen values are obtained by adding $^3/_2$ RT to the numbers given in Table II of Johnston and Walker's paper [This Journal, **57**, 682 (1935)]. We have improved the values for other molecules by a more precise method of interpolation for temperatures intermediate between published values. In the revised table given herewith the values of NO, O_3, Br_2 and HBr are omitted because they could not be improved upon.

"Log K of oxygen at 5000°K. in Table II should read 1.715."—Bernard Lewis.
